

Springer
Handbook *of*
**Engineering
Statistics**

Pham
Editor

2nd Edition

Springer Handbooks

Springer Handbooks maintain the highest standards of references in key areas of the physical and applied sciences for practitioners in industry and academia, as well as graduate students. Designed to be useful and readable desk reference books, but also prepared in various electronic formats, these titles allow fast yet comprehensive review and easy retrieval of essential reliable key information. Springer Handbooks cover methods, general principles, functional relationships and fundamental data and review established applications.

All Springer Handbooks are edited and prepared with great care by editors committed to harmonizing the content. All chapters are written by international experts in their field.

Indexed by SCOPUS. The books of the series are submitted for indexing to Web of Science.

To My Mother on Her 90th Birthday!

Preface

In recent years modern techniques of statistics have been applied to a wide variety of fields and applications especially in big data in health informatics, machine learning, and signal processing. Statistical techniques are finding increased use in the fields of engineering, data science, artificial intelligence (AI), and Industry 4.0 technologies and will continue even more so in the coming decades.

In response to such technological trends along with much feedback that we have received from users of the first edition of the *Springer Handbook of Engineering Statistics* (published in 2006), we have made substantial changes in this new edition by

- Adding 35 completely new contributions revolving around current trends related to modern statistical computing and its applications ranging from data science to electronic packaging, from high-dimensional data to AI, and from fusion data to optimal decision-making
- Updating more than 20 selected chapters from the first edition thoroughly to reflect the current state of the art where all the topics from the previous edition have integrated into all the chapters in this new edition

The *Springer Handbook of Engineering Statistics*, altogether 56 chapters, provides a comprehensive state-of-the-art reference volume that covers both fundamental and theoretical work in the areas of engineering statistics including: adaptive progressive censoring, AI, accelerated life testing, adversarial learning, artificial neural network, Bayesian inferences and prediction, Bootstrap and boosting methods, censored survival data, competing risk models, change-point detection, correlated failures, counting processes, copula methods, data mining, deep learning, dynamic robust design, difference of convex functions (DC), detecting outliers in high-dimensional data, dimension reduction and nonparametric methods, distributional inference, electronic packaging, fatigue life prediction, functional dependence measure, fusion learning, genetic algorithms, exponentially weighted moving average, gradient method, high-dimension time series, importance measures, indecisive weighted voting system, logistic regression, machine learning, multi-agent support systems, majorization-minimization, Monte Carlo simulation, influential observations, Markov decision process, model selection, multivariate distributions, multiple stresses designs, multivariate time series, multi-criteria decisions, nonparametric empirical Bayesian, inspection-maintenance, order statistics, product reliability, repairable system reliability, renewal processes, process control and improvement, proportional hazards regression and sampling, random forests for censoring data, recursive partitioning algorithm, software reliability, semi-parametric for survival data, step-stress life testing, statistical process control, six sigma design and methodology, stationary causal process, stochastic dependences, statistical design and diagnostics, stochastic expectation maximization algorithm, stress-strength models, unsupervised learning, variable importance in high-dimensional, voltage, and vibration acceleration models, among others.

The contents of the handbook are organized in six parts:

- PART I. Fundamental Statistics and Its Applications
- PART II. Process Monitoring and Improvement
- PART III. Reliability Models and Survival Analysis
- PART IV. Advanced Statistical Methods and Modeling
- PART V. Statistical Computing and Data Mining
- PART VI. Applications in Engineering Statistics

The chapters are written by more than 110 leading experts in statistics, biostatistics, engineering statistics, reliability engineering, computer science, applied statistics, machine learning, management, and related areas.

Practitioners will certainly find this *Springer Handbook* useful when looking for solutions to practical problems. Researchers, statisticians, scientists, engineers, teachers, and students can use it for quick access to the background, recent research and trends, and most important references regarding certain topics, if not all, in engineering statistics.

Acknowledgments I am deeply indebted to our authors from 20 different countries for the hard work, time, and effort that they put into their contributions, especially during the COVID-19 pandemic.

My grateful appreciation goes to the international advisory board members who have provided excellent help for this book. I would also like to express my thanks to the editorial board members who have reviewed and offered a variety of constructive criticisms on the chapters in the handbook.

I wish to thank our editors from Springer: Dr. Judith Hinterberg, Anthony Doyle, and Ursula Barth for their support and guidance. It has been a pleasure working with them, and I thank Springer for their commitment to publish this new edition.

I am indebted to my wife and children for permanent support and patience.

Piscataway, New Jersey
July 2022

Contents

Part I Fundamental Statistics and Its Applications	1
1 Basic Statistics	3
Hoang Pham	
2 Generalized Statistical Distributions	43
Gauss M. Cordeiro and Artur Lemonte	
3 Statistics for Reliability Modeling	53
Paul Kvam and Jye-Chyi Lu	
4 Functional Data Analysis	67
Yuhang Xu	
5 Symmetric Geometric Skew Normal Regression Model	87
Debasis Kundu and Deepak Prajapati	
6 Statistical Analysis of Modern Reliability Data	105
Yueyao Wang, I-Chen Lee, Lu Lu, and Yili Hong	
7 Mathematical Reliability Aspects of Multivariate Probability Distributions	129
Lidia Z. Filus and Jerzy K. Filus	
8 Introduction to Stochastic Processes	137
Hoang Pham	
9 Progressive Censoring Methodology	153
Narayanaswamy Balakrishnan and Erhard Cramer	
10 Warranty Policies: Analysis and Perspectives	185
Hoang Pham and Jun Bai	
Part II Process Monitoring and Improvement	197
11 Statistical Methods for Quality and Productivity Improvement	199
Wei Jiang, Terrence E. Murphy, Kwok-Leung Tsui, and Yang Zhao	
12 Chain Sampling	221
Govindaraju Kondaswamy	
13 Six Sigma	239
Fugee Tsung and Kai Wang	
14 Statistical Models for Monitoring the High-Quality Processes	261
Min Xie, Thong Ngee Goh, and Tahir Mahmood	
15 Statistical Management and Modeling for Demand Spare Parts	275
Emilio Ferrari, Arrigo Pareschi, Alberto Regattieri, and Alessandro Persona	

16	D-Efficient Mixed-Level Foldover Designs for Screening Experiments	305
	Nam-Ky Nguyen, Ron S. Kenett, Tung-Dinh Pham, and Mai Phuong Vuong	
17	Censored Data Prediction Based on Model Selection Approaches	315
	Tzong-Ru Tsai, Jyun-You Chiang, Shuai Wang, and Yan Qin	
18	Monitoring Coefficient of Variation Using CUSUM Control Charts	333
	Phuong Hanh Tran, Huu Du Nguyen, Cédric Heuchenne, and Kim Phuc Tran	
19	Change-Point-Based Statistical Process Controls	361
	Partha Sarathi Mukherjee	
Part III Reliability Models and Survival Analysis		383
20	Reliability Characteristics and Optimization of Warm Standby Systems	385
	Suprasad V. Amari and Hoang Pham	
21	Importance and Sensitivity Analysis on Complex Repairable Systems and Imprecise System Reliability	403
	Geng Feng	
22	Hardware and Software Reliability, Verification, and Testing	415
	Ashis Kumar Chakraborty, E. V. Gijo, Anisha Das, and Moutushi Chatterjee	
23	OSS Reliability Analysis and Project Effort Estimation Based on Computational Intelligence	443
	Shigeru Yamada, Yoshinobu Tamura, and Kodai Sugisaki	
24	Vulnerability Discovery Analysis in Software Reliability and Related Optimization Problems	457
	P. K. Kapur and Saurabh Panwar	
25	Software Reliability Modeling and Prediction	481
	Hoang Pham and Xiaolin Teng	
26	Statistical Maintenance Modeling	495
	Hoang Pham and Wenjian Li	
27	Continuous-Time Predictive Maintenance Modeling with Dynamic Decision Framework	521
	Antoine Grall and Elham Mosayebi Omshi	
28	Stochastic Redundant Replacement Maintenance Models	543
	Toshio Nakagawa, Satoshi Mizutani, and Xufeng Zhao	
Part IV Advanced Statistical Methods and Modeling		573
29	Confidence Distribution and Distribution Estimation for Modern Statistical Inference	575
	Yifan Cui and Min-ge Xie	
30	Logistic Regression Tree Analysis	593
	Wei-Yin Loh	
31	Detecting Outliers and Influential and Sensitive Observations in Linear Regression	605
	Daniel Peña	
32	Statistical Methodologies for Analyzing Genomic Data	621
	Fenghai Duan and Heping Zhang	

33 Genetic Algorithms and Their Applications	635
Mitsuo Gen and Lin Lin	
34 Deterministic and Stochastic DCA for DC Programming	675
Hoai An Le Thi, Tao Pham Dinh, Hoang Phuc Hau Luu, and Hoai Minh Le	
35 Inference for Coherent Systems with Weibull Components Under a Simple Step-Stress Model	703
Narayanaswamy Balakrishnan, Debanjan Mitra, and Xiaojun Zhu	
36 Bivariate Distributions with Singular Components	733
Debasis Kundu	
37 Bayesian Models	763
Ashis Kumar Chakraborty, Soumen Dey, Poulami Chakraborty, and Aleena Chanda	
Part V Statistical Computing and Data Mining	795
38 Data Mining Methods and Applications	797
Kwok-Leung Tsui, Victoria Chen, Wei Jiang, Fangfang Yang, and Chen Kan	
39 Statistical Methods for Tensor Data Analysis	817
Qing Mai and Xin Zhang	
40 Random Forests for Survival Analysis and High-Dimensional Data	831
Sarah E. Formentini, Yifan Cui, and Ruoqing Zhu	
41 Probability Inequalities for High-Dimensional Time Series Under a Triangular Array Framework	849
Fang Han and Wei Biao Wu	
42 Statistical Machine Learning	865
Maryam Arabzadeh Jamali and Hoang Pham	
43 Covariance Estimation via the Modified Cholesky Decomposition	887
Xiaoning Kang, Zhiyang Zhang, and Xinwei Deng	
44 Statistical Learning	901
Qingyi Gao and Xiao Wang	
45 Bayesian Survival Analysis in the Presence of Monotone Likelihoods	921
Jing Wu, Mário de Castro, and Ming-Hui Chen	
46 Multivariate Modeling with Copulas and Engineering Applications	931
Jun Yan	
Part VI Applications in Engineering Statistics	947
47 Environmental Risks Analysis Using Satellite Data	949
Yuriy V. Kostyuchenko	
48 Probabilistic Models for Reliability Analysis Using Safe-Life and Damage Tolerance Methods	965
Xuefei Guan and Jingjing He	
49 Application of Cognitive Architecture in Multi-Agent Financial Decision Support Systems	981
Marcin Hernes and Ngoc Thanh Nguyen	
50 Reliability of Electronic Packaging	1003
Wen-Fang Wu and Yi-An Lu	

51 Accelerated Life Testing	1025
Qingchuan He, Wen-Hua Chen, and Jun Pan	
52 Accelerated Life Testing Data Analyses for One-Shot Devices	1039
Narayanaswamy Balakrishnan and Man Ho Ling	
53 Tangent Space Approximation in Geometric Statistics	1059
Ted Chang	
54 Statistical Modeling of Discrete Choices for Human Behaviors	1075
Xi Zhu and Shuai Huang	
55 Weighted Voting Systems	1089
Hainan Zhang	
56 Image Registration, Rigid Bodies, and Unknown Coordinate Systems	1109
Ted Chang	
Correction to: Monitoring Coefficient of Variation Using CUSUM Control Charts	C1
Phuong Hanh Tran, Huu Du Nguyen, Cédric Heuchenne, and Kim Phuc Tran	
Index	1129

About the Editor

Hoang Pham is a distinguished professor and former chairman (2007–2013) of the Department of Industrial and Systems Engineering at Rutgers University. Before joining Rutgers in 1993, he was a senior engineering specialist with the Idaho National Engineering Laboratory, Idaho Falls, Idaho, and Boeing Company in Seattle, Washington. His research areas include reliability modeling and prediction, software reliability, and statistical inference. He is editor-in-chief of the *International Journal of Reliability, Quality and Safety Engineering* and editor of Springer Series in Reliability Engineering and has been conference chair and program chair of over 40 international conferences and workshops. Dr. Pham is the author or coauthor of 7 books and has published over 200 journal articles, 100 conference papers, and edited 20 books including *Springer Handbook of Engineering Statistics* and *Handbook of Reliability Engineering*. He has delivered over 40 invited keynote and plenary speeches at many international conferences and institutions. His numerous awards include the 2009 IEEE Reliability Society Engineer of the Year Award. He is a fellow of the IEEE, AAIA, and IISE.

International Advisory Board

Narayanaswamy Balakrishnan

Department of Mathematics and Statistics
McMaster University
Hamilton, ON, Canada

Dr. Narayanaswamy Balakrishnan is a distinguished university professor in the Department of Mathematics and Statistics at McMaster University, Hamilton, Ontario, Canada. He received his B.Sc. and M.Sc. in Statistics from the University of Madras, India, in 1976 and 1978, respectively, and then his Ph.D. from the Indian Institute of Technology, Kanpur, India, in 1981. He has very wide research interests spanning univariate and multivariate distribution theory, reliability analysis, ordered data analysis, biostatistics and survival analysis, statistical inference, applied probability, nonparametric statistics, and statistical methods and applications to different fields in science and engineering, and has published many journal articles in all these areas. He has coauthored numerous books including the well-known four volumes on distribution theory published by John Wiley & Sons and has also coedited the Second Edition of 16-Volume *Encyclopedia of Statistical Sciences* published by John Wiley & Sons. He is the editor-in-chief of *Communications in Statistics* and *Mathematical Methods of Statistics* and is an associate editor of numerous journals such as *Journal of Multivariate Analysis*, *Statistical Methods in Medical Research*, *International Statistical Review*, *Probability in the Engineering and Informational Sciences*, and *Applied Stochastic Models in Business and Industry*.

He has received many honors and accolades including fellow of the Royal Society of Canada, fellow of the American Statistical Association, and fellow of the Institute of Mathematical Statistics and an honorary doctorate degree from the National and Kapodistrian University of Athens, Greece.

**Toshio Nakagawa**

Department of Business Administration
Aichi Institute of Technology
Toyota, Japan

Dr. Toshio Nakagawa received B.S.E. and M.S. degrees from Nagoya Institute of Technology in 1965 and 1967, respectively, and Doctor of Engineering degree from Kyoto University in 1977. He worked as a research associate at Syracuse University for 2 years from 1972 to 1973. He is now a honorary professor at Aichi Institute of Technology in Toyota City. He has published 7 books with Springer, 20 book chapters, and about 200 journal papers. His research interests are optimization problems in operations research and management science and analysis for stochastic and computer systems in reliability and maintenance theory.

**Min-ge Xie**

Rutgers University
Piscataway, NJ, USA

Dr. Min-ge Xie is a distinguished professor and director of the Office of Statistical Consulting, Department of Statistics, Rutgers University, the State University of New Jersey. His main research interest is in the foundation of statistical inference, fusion learning, and data science. His other expertise includes estimating equations, robust statistics, hierarchical models, asymptotic theories, and applications in biostatistics and industry. Dr. Xie received his B.S. degree in mathematics from the University of Science and Technology (USTC) with the highest honor and Ph.D. degree in statistics from the University of Illinois at Urbana-Champaign (UIUC). He is a fellow of the American Statistical Association, a fellow of the Institute of Mathematical Statistics, and an elected member of the International Statistical Institute. He has served on numerous scientific review panels and editorial boards. He is a co-founder of the BFF research community. His research has been supported in part by grants from NSF, NIH, DHS, NSA, and FAA.

International Editorial Board

Mingxiao Jiang

Medtronic, PLC.
Minneapolis, MN, USA

Dr. Mingxiao Jiang received his B.S. in Engineering Mechanics from Zhejiang University, M.S. in Reliability Engineering from the University of Arizona, and Ph.D. in Mechanics of Materials from Georgia Institute of Technology. He is currently a technical fellow and a distinguished engineer at Medtronic. He is a CRE and a senior member of ASQ and IEEE. He has 3 US patents and 50 publications in refereed journals and conference proceedings. He has been active in reliability societies as a vice chair for the organization RAMS® (2009–2013) and committee member for several international reliability conferences. He has been serving on the Editorial Review Boards for Reliability Review and Quality Engineering.

Yi-Kuei Lin

National Yang Ming Chiao Tung University
Hsinchu, Taiwan

Dr. Yi-Kuei Lin is currently a chair professor of the Industrial Engineering and Management Department, National Yang Ming Chiao Tung University, Taiwan. He was the president of the Operations Research Society of Taiwan in 2018 and 2019. He received a bachelor degree from the Applied Mathematics Department at National Chiao Tung University, Taiwan. He obtained his master degree and Ph.D. degree from the Department of Industrial Engineering and Engineering Management at National Tsing Hua University, Taiwan, Republic of China. He had the honor of receiving the Outstanding Research Awards from the Ministry of Science and Technology of Taiwan in 2008, 2010, and 2013, respectively. He served as dean, College of Management at Vanung University from 2003 to 2007, and chairman, Department of Industrial Management at National Taiwan University of Science and Technology from 2012 to 2014. He is now serving as associate editor of *IEEE Transactions on Reliability*, *Annals of Operations Research*, and *Quality Technology & Quantitative Management*. His research interest includes performance evaluation, network reliability, operations research, and telecommunication management. He has published more than 200 papers in refereed international journals

Hon Keung Tony Ng
Southern Methodist University
Dallas, TX, USA

Dr. Hon Keung Tony Ng received his Ph.D. in Mathematics from McMaster University, Hamilton, ON, Canada, in 2002. He is currently a professor with the Department of Statistical Science, Southern Methodist University, Dallas, TX, USA. His research interests include reliability, censoring methodology, ordered data analysis, nonparametric methods, and statistical inference. Dr. Ng is an associate editor of *Communications in Statistics*, *Computational Statistics*, *IEEE Transactions on Reliability*, *Journal of Statistical Computation and Simulation*, *Naval Research Logistics*, *Sequential Analysis*, and *Statistics & Probability Letters*. He is the coeditor of the books *Ordered Data Analysis*, *Modeling and Health Research Methods*, *Statistical Modeling for Degradation Data*, *Statistical Quality Technologies: Theory and Practice*, and *Advances in Statistics: Theory and Applications* published by Springer. He is a fellow of the American Statistical Association and an elected member of the International Statistical Institute.

Peihua Qiu
University of Florida
Gainesville, FL, USA

Dr. Peihua Qiu received his Ph.D. in Statistics from the Department of Statistics at the University of Wisconsin at Madison in 1996. He worked as a senior research consulting statistician of the Biostatistics Center at the Ohio State University during 1996–1998. He then worked as an assistant professor (1998–2002), an associate professor (2002–2007), and a full professor (2007–2013) at the School of Statistics at the University of Minnesota. He is an elected fellow of the American Statistical Association, an elected fellow of the Institute of Mathematical Statistics, and an elected member of the International Statistical Institute. He served as associate editor for some top statistical journals, including *Journal of the American Statistical Association*, *Biometrics*, and *Technometrics*. He was the editor (2014–2016) of *Technometrics*. Since 2013, he has been a professor and the founding chair of the Department of Biostatistics at the University of Florida. Qiu has made substantial contributions in the areas of jump regression analysis, image processing, statistical process control, survival analysis, disease screening, and disease surveillance. So far, he has published over 140 research papers in refereed journals, many of which appeared in top journals, such as *Technometrics*, *Journal of the American Statistical Association*, and *IEEE Transactions on Pattern Analysis and Machine Intelligence*. His research monograph titled *Image Processing and Jump Regression Analysis* (2005, Wiley) won the inaugural Ziegel prize in 2007. His second book titled *Introduction to Statistical Process Control* was published in 2014 by Chapman & Hall/CRC.

**Mengmeng Zhu**

North Carolina State University
Raleigh, NC, USA

Dr. Mengmeng Zhu is an assistant professor in the Department of Textile Engineering, Chemistry and Science, and an associate faculty member of the Operations Research Graduate Program, North Carolina State University, Raleigh, North Carolina, USA. She received the Ph.D. degree in Industrial and Systems Engineering and the M.S. degrees in Statistics and Industrial and Systems Engineering from Rutgers University, New Brunswick, New Jersey, USA, in 2018, 2016, and 2015, respectively. Her research interests lie at system reliability and resilience engineering, applied operations research, prognostics and health management, and computational data analytics. Dr. Zhu is the recipient of the Best Paper Award of the 24th ISSAT International Conference on Reliability and Quality in Design, 2018, and the Best Student Paper Award of the 23rd ISSAT International Conference on Reliability and Quality in Design, 2017.

Abstract

This chapter presents some fundamental elements of engineering probability and statistics with which some readers are probably already familiar, but others may not be. Statistics is the study of how best one can describe and analyze the data and then draw conclusions or inferences

based on the data available. The first section of this chapter begins with some basic definitions, including probability axioms, basic statistics, and reliability measures.

The second section describes the most common distribution functions such as the binomial, Poisson, geometric, exponential, normal, log normal, Student's t , gamma, Pareto, beta, Rayleigh, Cauchy, Weibull, Pham, and Vtub-shaped failure rate distributions, their applications, and their use in engineering and applied statistics.

The third section describes statistical inference, including parameter estimation and confidence intervals. Statistical inference is the process by which information from sample data is used to draw conclusions about the population from which the sample was selected that hopefully represents the whole population. This discussion also introduces the maximum likelihood estimation (MLE) method, the method of moments, MLE with censored data, the statistical change-point estimation method, nonparametric tolerance limits, sequential sampling, and Bayesian methods.

Finally, the last section provides a short list of books and articles for readers who are interested in advanced engineering and applied statistics.

Keywords

Failure rate · Parameter estimation · Distribution function · Interarrival time · Reliability function · Mean time to failure

1.1 Basic Probability Measures

We start off this chapter by defining several useful terms:

1. Outcome: A result or observation from an experiment, which cannot be predicted with certainty.
2. Event: Subset of a set of all possible outcomes.

H. Pham (✉)

University, Piscataway, NJ, USA
e-mail: hopham@soe.rutgers.edu

3. Probability: The relative frequency at which an event occurs in a large number of identical experiments.
4. Random variable: A function which assigns real numbers to the outcomes of an experiment.
5. Statistics: A function (itself a random variable) of one or more random variables that does not depend upon any unknown parameters.

1.1.1 Probability Axioms

Now let C be a subset of the sample space ($C \subset \Omega$). A probability set function, denoted by $P(C)$, has the following properties:

1. $P(\Omega) = 1, P(C) \geq 0$
2. $P(C_1 \cup C_2 \cup \dots) = P(C_1) + P(C_2) + \dots$

where the subsets C_i have no elements in common (i.e., they are mutually exclusive).

Let C_1 and C_2 be two subsets of the sample space Ω . The conditional probability of getting an outcome in C_2 given that an outcome from C_1 is given by

$$P(C_2|C_1) = \frac{P(C_2 \cap C_1)}{P(C_1)}.$$

Let C_1, C_2, \dots, C_n be n mutually disjoint subsets of the sample space Ω . Let C be a subset of the union of the C_i s, that is

$$C \subset \bigcup_{i=1}^n C_i.$$

Then

$$P(C) = \sum_{i=1}^n P(C|C_i)P(C_i) \quad (1.1)$$

and

$$P(C_i|C) = \frac{P(C|C_i)P(C_i)}{\sum_{i=1}^n P(C|C_i)P(C_i)}.$$

Equation (1.1) is known as the law of total probability or Bayes' rule.

Example 1.1 Suppose the total inventory of a company is a collection of lots from four different suppliers, A, B, C, and D, as indicated below:

Supplier	Percent of inventory
A	60
B	20
C	5
D	15

Furthermore, suppose that past records indicate that lots from suppliers A, B, C, and D are 5, 3, 2, and 8% defective, respectively. Using the Bayes' rule, the probability that a defective item selected as random is from supplier B can be calculated as follows:

$$P(B|\text{defective}) = \frac{(0.2)(0.03)}{(0.6)(0.05) + (0.2)(0.03) + (0.05)(0.02) + (0.15)(0.08)} = 0.122$$

1.1.2 Basic Statistics

The cumulative distribution function (cdf) F is a unique function which gives the probability that a random variable X takes on values less than or equal to some value x . In other word, $F(x) = P(X \leq x)$.

The probability density function (pdf) f is the probability that X takes on the value x ; that is, $f(x) = P(X = x)$.

The pdf satisfies the following two relations for discrete and continuous random variables, respectively:

$$\sum_{\text{all } x} f(x) = 1$$

and

$$\int_{-\infty}^{\infty} f(x)dx = 1.$$

In the continuous case, the pdf is the derivative of the cdf:

$$f(x) = \frac{\partial F(x)}{\partial x}.$$

The expected value of a random variable X is given by

$$E(X) = \sum_{\text{all } x} xf(x)$$

in the discrete case, and by

$$E(X) = \int_{-\infty}^{\infty} xf(x)dx$$

in the continuous case. Similarly, the variance of a random variable X , denoted by σ^2 , is a measure of how the values of X are spread about the mean value. It is defined as

$$\sigma^2 = E(X - \mu)^2.$$

It is calculated for discrete and continuous random variables, respectively, by

$$\sigma^2 = \sum_{\text{all } x} (x - \mu)^2 f(x)$$

and

$$\sigma^2 = \int_{-\infty}^{\infty} (x - \mu)^2 f(x) dx.$$

The standard deviation of X , denoted by σ , is the square root of the variance.

The skewness coefficient of a random variable X is a measure of the symmetry of the distribution of X about its mean value μ , and is defined as

$$S_c = \frac{E(X - \mu)^3}{\sigma^3}.$$

The skewness is zero for a symmetric distribution, negative for a left-tailed distribution, and positive for a right-tailed distribution.

Similarly, the kurtosis coefficient of a random variable X is a measure of how much of the mass of the distribution is contained in the tails, and is defined as

$$K_c = \frac{E(X - \mu)^4}{\sigma^4}.$$

Obviously, kurtosis is always positive; however, larger values represent distributions with heavier tails. The measure of kurtosis serves to differentiate between a flat distribution curve and a sharply peaked curve.

Given a random sample of size n from a distribution, the sample mean and sample variance are defined as, respectively,

$$\bar{X} = \frac{1}{n} \sum_{i=1}^n X_i \quad \text{and} \quad S^2 = \frac{1}{n-1} \sum_{i=1}^n (X_i - \bar{X})^2. \quad (1.2)$$

If the data are arranged in order of magnitude, the median is the central point of the series, i.e., there are equal numbers of observations greater than and less than the medians. In case if n (the total number of observations) is even, it is usual to take the mean of the two central values as the median.

Suppose that n values of a variable X are ordered in increasing order of magnitude, i.e., we have x_1, x_2, \dots, x_n such that $x_{(1)} \leq x_{(2)} \leq \dots \leq x_{(n)}$ then the median of a set of values is equal to $x_{(\frac{n+1}{2})}$ if n is odd and $\frac{1}{2} (x_{(\frac{n}{2})} + x_{(\frac{n}{2}+1)})$ if n is even.

The median of a random variable X is the value m such that the cdf $F(m) = \frac{1}{2}$. The median always exists if the random variable is continuous, whereas it may not always exist if the random variable is discrete.

Example 1.2 The probability density function of a random variable X is

$$f(x) = \begin{cases} 2x & 0 \leq x \leq 1 \\ 0 & \text{otherwise.} \end{cases}$$

The cdf of X is given by

$$F(x) = \begin{cases} 0 & x < 0 \\ x^2 & 0 \leq x \leq 1 \\ 1 & x > 1. \end{cases}$$

Set $F(m) = 1/2$, then the median of X is $\frac{\sqrt{2}}{2}$.

The mode is the value of the variate which occurs most frequently for which the frequency is a maximum. In other words, the mode of a set of values of a variable is the most frequently occurring value in the set. The use of the mode is most often associated with discrete distributions where it is simple to count which value of the variate occurs most often.

Example 1.3 The density function of X is given by

$$f(x) = \begin{cases} \frac{2}{3}x & 0 \leq x \leq 1 \\ \frac{1}{3} & 1 < x \leq 3. \end{cases}$$

The cdf of X is

$$F(x) = \begin{cases} 0 & x < 0 \\ \frac{x^2}{3} & 0 \leq x \leq 1 \\ \frac{x}{3} & 1 < x \leq 3 \\ 1 & x > 3. \end{cases}$$

Since $F(\frac{3}{2}) = \frac{1}{2}$, so the median of X is equal to $\frac{3}{2}$. Similarly, the mode is equal to 1 since $f(x)$ is a maximum when $x = 1$.

Which measure to choose? The mode should be used when calculating measure of center for the qualitative variable. When the variable is quantitative with symmetric distribution, then the mean is proper measure of center. In a case of quantitative variable with skewed distribution, the median is good choice for the measure of center. This is related to the fact that the mean can be highly influenced by an observation that falls far from the rest of the data, called an outlier.

Moment Inequalities

The following moment inequalities are commonly used in applied engineering statistics.

Theorem 1.1 (Jensen's Inequality) For any random variable X and a convex function $g(x)$,

$$g(E(X)) \leq E[g(X)]. \quad (1.3)$$

Example 1.4 Since the function $g(x) = x^2$ is a convex function, using Jensen's inequality we obtain

$$g[E(X)] \leq E(g(X))$$

or

$$[E(X)]^2 \leq E(X^2)$$

In other words, since $\text{var}(X) = E(X^2) - [E(X)]^2 \geq 0$ this implies that $E(X^2) \geq [E(X)]^2$.

Theorem 1.2 (Cauchy-Schwarz Inequality) For any two random variables X and Y ,

$$E|XY| \leq \sqrt{E(X^2)E(Y^2)}. \quad (1.4)$$

Theorem 1.3 (Holder's Inequality) For any two random variables X and Y and two positive real values a and b such that $a + b = 1$,

$$E|XY| \leq \sqrt{\left(E(|X|^{1/a})\right)^a \left(E(|Y|^{1/b})\right)^b}.$$

The conditional distribution of a random variable Y given that another random variable X takes on a value x is given by:

$$f(y|X=x) = \frac{f(x,y)}{f_1(x)},$$

where

$$f_1(x) = \int_{-\infty}^{\infty} f(x,y) dy.$$

Let X and Y be two independent lifetimes with pdf $f_1(x)$ and $f_2(y)$, respectively. Let $Z = X + Y$ be the total lifetime having the pdf $g(z)$ and cdf $G(z)$. Using a convolution approach, the pdf of z can be obtained as

$$\begin{aligned} g(z) &= \int_0^z f_1(x)f_2(z-x) dx = \int_0^z f_1(z-y)f_2(y)dy \\ &= f_1(z) * f_2(z) \end{aligned}$$

where $*$ denotes the convolutions of the distributions. Similarly, the distribution function of Z , $G(z)$, is given by

$$G(z) = P[Z \leq z] = \int_0^z f_1(x)dx \int_0^{z-x} f_2(y)dy.$$

Note that the two random variables X and Y are said to be independent if knowledge of one of the variables has no effect on the distribution of probability for the other.

1.1.3 Order Statistics

Let X_1, X_2, \dots, X_n be a random sample of size n , each with cdf $F(x)$ and pdf $f(x)$. Let $X_{(i)}$ be the i th order statistic of the sample where such characteristic values of a sample of observations have been sorted from smallest to largest. The r th order statistic is the r th smallest value in the sample, say $X_{(r)}$. That is,

$$X_{(1)} \leq X_{(2)} \leq \dots \leq X_{(r-1)} \leq X_{(r)} \leq \dots \leq X_{(n)}$$

are called the *order statistics*. Imagine we are building an elevator, for example, and our random variables are the weight on the elevator of various times during the day. We would want to know how much weight it can bear. In this case, we will care about the distribution of the maximum.

Let $F_{(r)}(x)$ denote the cdf of the r th order statistic $X_{(r)}$. Note that the order statistics $X_{(1)}, X_{(2)}, \dots, X_{(n)}$ are neither independent nor identically distributed. Let $X_{(r)}$ be the r th order statistic. Then the cdf of $X_{(r)}$ is given by

$$\begin{aligned} F_{(r)}(x) &= P(X_{(r)} \leq x) \\ &= P(\text{at least } r \text{ of } X_1, X_2, \dots, X_n \text{ are } \leq x) \\ &= \sum_{i=r}^n P(\text{exactly } i \text{ of } X_1, X_2, \dots, X_n \text{ are } \leq x) \\ &= \sum_{i=r}^n \binom{n}{i} F^i(x)[1-F(x)]^{n-i} \\ &= F^r(x) \sum_{j=0}^{n-r} \binom{r+j-1}{r-1} [1-F(x)]^j \\ &= r \binom{n}{r} \int_0^{F(x)} t^{r-1} (1-t)^{n-r} dt \end{aligned}$$

The probability density function (pdf) of the r th order statistic $X_{(r)}$ is given by

$$f_{X_{(r)}}(x) = \frac{n!}{(r-1)!(n-r)!} f(x) F^{r-1}(x) [1-F(x)]^{n-r}$$

The pdf of the largest, i.e., n st order statistic $X_{(n)}$, value is given by

$$F_{X_{(n)}}(x) = nf(x)[F(x)]^{n-1}$$

Similarly, the pdf of the smallest, i.e., first-order statistic $X_{(1)}$, value of n independent random variables, is given by

$$F_{X_{(1)}}(x) = nf(x)[1 - F(x)]^{n-1}$$

Assume there are n random variables X_1, X_2, \dots, X_n which may or may not be mutually independent. The joint cdf, if it exists, is given by

$$P(X_1 \leq x_1, X_2 \leq x_2, \dots, X_n \leq x_n) = \int_{-\infty}^{x_n} \int_{-\infty}^{x_{n-1}} \dots \int_{-\infty}^{x_1} f(t_1, t_2, \dots, t_n) dt_1 dt_2 \dots dt_n \tag{1.5}$$

If the n random variables are mutually statistically independent, then the joint pdf can be rewritten as:

$$f(x_1, x_2, \dots, x_n) = \prod_{i=1}^n f(x_i).$$

1.2 Reliability Measures

1.2.1 Coherent Systems

In reliability theory, both the system and its components are commonly allowed to take only two possible states or binary states: either working or failed. In a multistate system, both the system and its components are allowed to experience more than two possible states, e.g., fully working, partially or degraded working, or failed. A multistate system reliability model provides more flexibility for modeling of system's conditions. The reliability can be defined for a more general coherent structure. A coherent system with binary states can be simply described as follows. Consider that a system consists of n components and define

$$x_i = \begin{cases} 1 & \text{if component } i \text{ is functioning} \\ 0 & \text{if component } i \text{ is failed} \end{cases} \quad \text{for } i = 1, 2, \dots, n$$

and

$$\phi(\mathbf{x}) = \begin{cases} 1 & \text{if the system is functioning} \\ 0 & \text{if the system is failed} \end{cases}$$

where $\mathbf{x} = (x_1, x_2, \dots, x_n)$. Binary indicators x_i and $\phi(\mathbf{x})$ indicate the state of component i and the state of the system, respectively. The function $\phi(\mathbf{x})$ is referred to as the structure function of the system. Define

$$\begin{aligned} (0_i, \mathbf{x}) &= (x_1, x_2, \dots, x_{i-1}, 0, x_{i+1}, \dots, x_n) \\ (1, \mathbf{x}) &= (x_1, x_2, \dots, x_{i-1}, 1, x_{i+1}, \dots, x_n). \end{aligned}$$

The *structure function* of the system indicates that the state of the system is completely determined by the states of all components. A component is relevant if its state does affect the state of the system.

Definition 1.1 A binary system with n components is said to be coherent if:

- The structure function ϕ is nondecreasing in each argument $x_i, i = 1, 2, \dots, n$
- Each component is relevant, i.e., there exists at least one vector \mathbf{x} such that $\phi(1_i, \mathbf{x}) = 1$ and $\phi(0_i, \mathbf{x}) = 0$
- $\phi(\mathbf{0}) = 0$ and $\phi(\mathbf{1}) = 1$

For coherent systems, when $\mathbf{x} < \mathbf{y}$ then $\phi(\mathbf{x}) \leq \phi(\mathbf{y})$.

Example 1.4 For a series system consisting of n components to function, all its components must function. Then structure function of the series system is given by

$$\phi(\mathbf{x}) = \prod_{i=1}^n x_i = \min(x_1, x_2, \dots, x_n)$$

For the parallel system consisting of n components to work there is at least one component to work. Then structure function of the parallel system is given by

$$\phi(\mathbf{x}) = 1 - \prod_{i=1}^n (1 - x_i) = \max(x_1, x_2, \dots, x_n)$$

Similarly, the k out of n system is functioning if and only if there is at least k component to function. Then structure function of the k out of n system is given by

$$\phi(\mathbf{x}) = \begin{cases} 1 & \text{if } \sum_{i=1}^n x_i \geq k \\ 0 & \text{if } \sum_{i=1}^n x_i < k \end{cases}$$

We now discuss the minimal path and minimal cut sets. Let A_1, A_2, \dots, A_s denote the minimal path sets of a given system.

Definition 1.2 A state vector \mathbf{x} is called a *path vector* (or link vector) if $\phi(\mathbf{x}) = 1$.

A path set is a set of components whose functioning ensures the functioning of the system.

Definition 1.3 A *minimal path vector* is a path vector for which the failure of any functioning components results in system failure.

Definition 1.4 A *minimal path set* is a minimal set of components whose functioning ensures the functioning of the system.

In other words, a *minimal path vector* is a path vector \mathbf{x} such that $\phi(\mathbf{y}) = 0$ for any $\mathbf{y} < \mathbf{x}$ and its corresponding path set is *minimal path set*. Let

$$\alpha_j(\mathbf{x}) = \begin{cases} 1 & \text{iff all the components of } A_j \text{ are functioning} \\ 0 & \text{otherwise} \end{cases}$$

then

$$\alpha_j(\mathbf{x}) = \prod_{i \in A_j} X_i$$

A system will function if and only if all the components of at least one minimal path sets are functioning. That is,

$$\begin{aligned} \phi(\mathbf{x}) &= \max_j \alpha_j(\mathbf{x}) \\ &= 1 - \prod_{j=1}^s (1 - \alpha_j(\mathbf{x})) \\ &= 1 - \prod_{j=1}^s \left(1 - \prod_{i \in A_j} X_i \right). \end{aligned} \quad (1.6)$$

Similarly, let C_1, C_2, \dots, C_k denote the minimal cut sets of a given system.

Definition 1.5 A state vector \mathbf{x} is called a *cut vector* if $\phi(\mathbf{x}) = 0$. A cut set is a set of components whose failure ensures the failure of the system.

Definition 1.6 A *minimal cut vector* is a cut vector for which the repair of any failed component results in a functioning system.

Definition 1.7 A *minimal cut set* is a minimal set of components whose failure ensures the failure of the system.

In other words, a *minimal cut vector* is a cut vector \mathbf{x} such that $\phi(\mathbf{y}) = 1$ for any $\mathbf{y} > \mathbf{x}$ and its corresponding cut set is *minimal cut set*.

Note that for a minimal path set to work, each component in the set must work. For a minimal cut set to fail, all components in the set must fail.

Let

$$\beta_j(\mathbf{x}) = \begin{cases} 1 & \text{if at least one component in} \\ & \text{the } j\text{th minimal cut set is functioning} \\ 0 & \text{otherwise for } j = 1, 2, \dots, k \end{cases}$$

then

$$\beta_j(\mathbf{x}) = \max_{i \in C_j} X_i$$

A system is not functioning (or system unreliability) if and only if all the components of at least one minimal cut set are not functioning. In other words, a system is functioning if and only if at least one component in each minimal cut sets is functioning. Thus, the structure function based on the minimal cut sets is given by

$$\begin{aligned} \phi(\mathbf{x}) &= \prod_{j=1}^k \beta_j(\mathbf{x}) \\ &= \prod_{j=1}^k \max_{i \in C_j} X_i \\ &= \prod_{j=1}^k \left(\prod_{i \in C_j} X_i \right) \\ &= \prod_{j=1}^k \left(1 - \prod_{i \in C_j} (1 - X_i) \right). \end{aligned}$$

Let p_i is the component i reliability. That is,

$$p_i = P(X_i = 1) = E[X_i].$$

The system reliability function can be defined as

$$r(p) = P(\phi(\mathbf{x}) = 1) = E[\phi(\mathbf{x})].$$

Theorem 1.4 If ϕ is a coherent system of independent components with minimal path set A_1, A_2, \dots, A_s and minimal cut sets C_1, C_2, \dots, C_k then

$$\prod_{j=1}^k \left(1 - \prod_{i \in C_j} (1 - p_i) \right) \leq r(p) \leq 1 - \prod_{j=1}^s \left(1 - \prod_{i \in A_j} p_i \right). \quad (1.7)$$

Example 1.5 A k -out-of- n system works if and only if at least k of the n components work. In a k -out-of- n system, there are $\binom{n}{k}$ minimal path sets and $\binom{n}{n-k+1}$ minimal cut sets. Each minimal path set contains exactly k different components and each minimal cut set contains exactly $n - k + 1$ components. Thus, all minimal path sets and minimal cut sets are known. One can easily obtain the reliability of a k -out-of- n system either in terms of the minimal path sets or minimal cut sets.

Definitions of reliability given in the literature vary according to the practitioner or researcher. The generally accepted definition is as follows:

Definition 1.8 *Reliability* is the probability that the system will perform its intended function under specified design limits.

More specifically, reliability is the probability that a product or system will operate properly for a specified period of time (design life) under the design operating conditions (such as temperature, voltage, etc.) without failure. In other words, reliability can be used as a measure of the system's success at providing its function properly. Reliability is one of the quality characteristics that consumers require from manufacturers.

Mathematically, reliability $R(t)$ is the probability that a system will be successful in the interval from time 0 to time t :

$$R(t) = P(T > t), \quad t \geq 0, \quad (1.8)$$

where T is a random variable denoting the time to failure or failure time.

Unreliability, or the cdf $F(t)$, a measure of failure, is defined as the probability that the system will fail by time t .

$$F(t) = P(T \leq t), \quad t \geq 0.$$

In other words, $F(t)$ is the failure distribution function. If the time-to-failure random variable T has a density function $f(t)$, then

$$R(t) = \int_t^{\infty} f(s) ds$$

or, equivalently,

$$f(t) = -\frac{d}{dt} [R(t)].$$

The density function can be mathematically described in terms of T :

$$\lim_{\Delta t \rightarrow 0} P(t < T \leq t + \Delta t).$$

This can be interpreted as the probability that the failure time T will occur between the operating time t and the next interval of operation $t + \Delta t$.

Consider a new and successfully tested system that operates well when put into service at time $t = 0$. The system becomes less likely to remain successful as the time interval increases. The probability of success for an infinite time interval is, of course, zero. Thus, the system starts to function at a probability of one and eventually decreases to a probability of zero. Clearly, reliability is a function of mission time. For example, one can say that the reliability of the system is 0.995 for a mission time of 24 h.

Example 1.6 A computer system has an exponential failure time density function

$$f(t) = \frac{1}{9000} e^{-\frac{t}{9000}}, \quad t \geq 0.$$

The probability that the system will fail after the warranty (six months or 4380 h) and before the end of the first year (one year or 8760 h) is given by

$$\begin{aligned} P(4380 < T \leq 8760) &= \int_{4380}^{8760} \frac{1}{9000} e^{-\frac{t}{9000}} dt \\ &= 0.237. \end{aligned}$$

This indicates that the probability of failure during the interval from 6 months to 1 year is 23.7%.

Consider the Weibull distribution, where the failure time density function is given by

$$f(t) = \frac{\beta t^{\beta-1}}{\theta^{\beta}} e^{-(\frac{t}{\theta})^{\beta}}, \quad t \geq 0, \theta > 0, \beta > 0.$$

Then the reliability function is

$$R(t) = e^{-(\frac{t}{\theta})^{\beta}}, \quad t \geq 0.$$

Thus, given a particular failure time density function or failure time distribution function, the reliability function can be obtained directly. Section 1.2 provides further insight for specific distributions.

Definition 1.9 *Conditional reliability* is the probability of surviving a mission of length h under specified design limits given that the system has been survived up to time t .

In other words, conditional reliability $R(h|t)$ is the probability that a system will be successful in the interval $(t, t + h)$ given that it already survived more than t . Mathematically,

$$R(h|t) = P(T > t + h | T > t) = \frac{R(t+h)}{R(t)} \quad t \geq 0, h > 0$$

It is obvious that the probability of prolongation by additional mission length h decreases with increasing h . Indeed, the longer prolongation of life time required, the smaller is the probability of such an event.

1.2.2 System Mean Time to Failure

Suppose that the reliability function for a system is given by $R(t)$. The expected failure time during which a component is expected to perform successfully, or the system mean time to failure (MTTF), is given by

$$\text{MTTF} = \int_0^{\infty} tf(t)dt$$

or, equivalently, that

$$\text{MTTF} = \int_0^{\infty} R(t)dt. \quad (1.9)$$

Thus, MTTF is the definite integral evaluation of the reliability function. In general, if $\lambda(t)$ is defined as the failure rate function, then, by definition, MTTF is not equal to $1/\lambda(t)$.

The MTTF should be used when the failure time distribution function is specified because the reliability level implied by the MTTF depends on the underlying failure time distribution. Although the MTTF measure is one of the most widely used reliability calculations, it is also one of the most misused calculations. It has been misinterpreted as a “guaranteed minimum lifetime.” Consider the results given in Table 1.1 for a 12-component life duration test.

A component MTTF of 3660 h was estimated using a basic averaging technique. However, one of the components failed after 920 h. Therefore, it is important to note that the system MTTF denotes the average time to failure. It is neither the failure time that could be expected 50% of the time nor is it the guaranteed minimum time of system failure, but mostly depends on the failure distribution.

A careful examination of Eq. (1.4) will show that two failure distributions can have the same MTTF and yet produce different reliability levels.

Example 1.7 Assume that the failure rate for a hydraulic component is given by

$$h(t) = \frac{t}{t+1} \quad t > 0$$

Table 1.1 Results from a 12-component life duration test

Component	Time to failure (h)
1	4510
2	3690
3	3550
4	5280
5	2595
6	3690
7	920
8	3890
9	4320
10	4770
11	3955
12	2750

where t is in years. Note that the reliability function $R(t)$ can be written as follows:

$$R(t) = e^{-\int_0^t h(x)dx}.$$

Then we obtain

$$R(t) = e^{-\int_0^t \frac{x}{x+1} dx} = (t+1)e^{-t}$$

From Eq. (1.9), the MTTF of the component is given by

$$\text{MTTF} = \int_0^{\infty} R(t)dt = \int_0^{\infty} (t+1)e^{-t} dt = 2$$

1.2.3 Failure Rate Function

The probability of a system failure in a given time interval $[t_1, t_2]$ can be expressed in terms of the reliability function as

$$\begin{aligned} \int_{t_1}^{t_2} f(t)dt &= \int_{t_1}^{\infty} f(t)dt - \int_{t_2}^{\infty} f(t)dt \\ &= R(t_1) - R(t_2) \end{aligned}$$

or in terms of the failure distribution function (or the unreliability function) as

$$\begin{aligned} \int_{t_1}^{t_2} f(t)dt &= \int_{-\infty}^{t_2} f(t)dt - \int_{-\infty}^{t_1} f(t)dt \\ &= F(t_2) - F(t_1). \end{aligned}$$

The rate at which failures occur in a certain time interval $[t_1, t_2]$ is called the *failure rate*. It is defined as the probability that a failure per unit time occurs in the interval, given that a failure has not occurred prior to t_1 , the beginning of the interval. Thus, the failure rate is

$$\frac{R(t_1) - R(t_2)}{(t_2 - t_1)R(t_1)}.$$

Note that the failure rate is a function of time. If we redefine the interval as $[t, t + \Delta t]$, the above expression becomes

$$\frac{R(t) - R(t + \Delta t)}{\Delta t R(t)}.$$

The rate in the above definition is expressed in failures per unit time, but in reality the time units might instead correspond to miles, hours, trials, etc. The *hazard function* is defined as the limit of the failure rate as the interval

approaches zero. Thus, the hazard function $h(t)$ is the instantaneous failure rate, and is defined by

$$\begin{aligned} h(t) &= \lim_{\Delta t \rightarrow 0} \frac{R(t) - R(t + \Delta t)}{\Delta t R(t)} \\ &= \frac{1}{R(t)} \left[-\frac{d}{dt} R(t) \right] \\ &= \frac{f(t)}{R(t)}. \end{aligned} \quad (1.10)$$

The quantity $h(t)dt$ represents the probability that a device of age t will fail in the small interval of time t to $(t + dt)$. The importance of the hazard function is that it indicates the change in the failure rate over the life of a population of components by plotting their hazard functions on a single axis. For example, two designs may provide the same reliability at a specific point in time, but the failure rates up to this point in time can differ.

The death rate, in statistical theory, is analogous to the failure rate, as the nature of mortality is analogous to the hazard function. Therefore, the hazard function, hazard rate, or failure rate function is the ratio of the pdf to the reliability function.

Example 1.8 Consider the lifetime of a communication device, having a pdf

$$f(t) = \begin{cases} 0 & t \leq t_0 \\ \frac{4(t-t_0)}{(t_1-t_0)^2} & t_0 \leq t \leq \frac{t_0+t_1}{2} \\ \frac{4(t_1-t)}{(t_1-t_0)^2} & \frac{t_0+t_1}{2} \leq t \leq t_1 \\ 0 & t_1 \leq t \end{cases}$$

Then the cdf is

$$F(t) = \begin{cases} 0 & t \leq t_0 \\ \frac{2(t-t_0)^2}{(t_1-t_0)^2} & t_0 \leq t \leq \frac{t_0+t_1}{2} \\ 1 - \frac{2(t_1-t)^2}{(t_1-t_0)^2} & \frac{t_0+t_1}{2} \leq t \leq t_1 \\ 1 & t_1 \leq t \end{cases}$$

Mean Residual Life Function

Another important measure of reliability is the mean residual life $\mu(t)$, which is the expected remaining life beyond the present age t . Mathematically, the mean residual life can be defined as

$$\mu(t) = E[T - t | T \geq t] = \frac{\int_t^\infty R(s) ds}{R(t)}. \quad (1.11)$$

In other words, the mean residual life (MRL) is the expected remaining life, $T - t$, given that the item has survived to time t . When $t = 0$, the MRL function becomes the MTTF.

1.3 Common Probability Distribution Functions

In some situations, particularly when evaluating reliability of a product in the field, exact information on the failure times is not possible to obtain, but the information on the number of failures during the time interval $[a, b]$ perhaps is available. The difference between the actual time til failure, T , and the number of failures, N , is that T is a continuous random variable while N is a discrete random variable. Random variables can be discrete or continuous.

This section presents some of the common discrete and continuous distribution functions and several hazard models that are applied in engineering statistics [1].

1.3.1 Discrete Random Variable Distributions

Binomial Distribution

The binomial distribution is one of the most widely used discrete random variable distributions in reliability and quality inspection. It has applications in reliability engineering, for example, when one is dealing with a situation in which an event is either a success or a failure.

The binomial distribution can be used to model a random variable X which represents the number of successes (or failures) in n independent trials (these are referred to as Bernoulli trials), with the probability of success (or failure) being p in each trial. The pdf of the distribution is given by

$$P(X = x) = \binom{n}{x} p^x (1-p)^{n-x}, \quad x = 0, 1, 2, \dots, n,$$

$$\binom{n}{x} = \frac{n!}{x!(n-x)!},$$

where n = number of trials, x = number of successes, and p = single trial probability of success.

The mean of the binomial distribution is np and the variance is $np(1-p)$. The coefficient of skewness is given by

$$S_c = \frac{1-2p}{\sqrt{np(1-p)}}$$

and the coefficient of kurtosis is

$$K_c = 3 - \frac{6}{n} + \frac{1}{np(1-p)}.$$

The reliability function $R(k)$ (i.e., at least k out of n items are good) is given by

$$R(k) = \sum_{x=k}^n \binom{n}{x} p^x (1-p)^{n-x}.$$

Example 1.9 Suppose that, during the production of lightbulbs, 90% are found to be good. In a random sample of 20 lightbulbs, the probability of obtaining at least 18 good lightbulbs is given by

$$\begin{aligned} R(18) &= \sum_{x=18}^{20} \binom{20}{x} (0.9)^x (0.1)^{20-x} \\ &= 0.667. \end{aligned}$$

Poisson Distribution

Although the Poisson distribution can be used in a manner similar to the binomial distribution, it is used to deal with events in which the sample size is unknown. A Poisson random variable is a discrete random variable distribution with a probability density function given by

$$P(X = x) = \frac{\lambda^x e^{-\lambda}}{x!} \quad \text{for } x = 0, 1, 2, \dots \quad (1.12)$$

where $\lambda =$ constant failure rate and $x =$ the number of events. In other words, $P(X = x)$ is the probability that exactly x failures occur.

A Poisson distribution is used to model a Poisson process. A Poisson random variable has a mean and a variance both equal to λ where λ is called the parameter of the distribution. The skewness coefficient is

$$S_c = \frac{1}{\sqrt{\lambda}}$$

and the kurtosis coefficient is

$$K_c = 3 + \frac{1}{\lambda}.$$

The Poisson distribution reliability up to time t , $R(k)$ (the probability of k or fewer failures), can be defined as follows:

$$R(k) = \sum_{x=0}^k \frac{(\lambda t)^x e^{-\lambda t}}{x!}.$$

This distribution can be used to determine the number of spares required for a system during a given mission.

Example 1.10 A nuclear plant is located in an area susceptible to both high winds and earthquakes. From historical data, the mean frequency of large earthquakes capable of damaging important plant structures is one every 50 years. The corresponding frequency of damaging high winds is

once in 25 years. During a strong earthquake, the probability of structure damage is 0.1. During high winds, the damage probability is 0.05. Assume that earthquakes and high winds can be described by independent Poisson random variables and that the damage caused by these events are independent. Let us answer the following questions:

1. What is the probability of having strong winds but not large earthquakes during a ten-year period?
2. What is the probability of having strong winds and large earthquakes in the ten-year period?
3. What is the probability of building damage during the ten-year period?

Considering the first question, let the random variables X and Y represent the number of earthquakes and the number of occurrences of high winds, respectively. We assume that the two random variables are statistically independent. The means of X and Y are, respectively, given by

$$\lambda_X = \frac{1}{50 \text{ y}} (10 \text{ y}) = 0.2$$

and

$$\lambda_Y = \frac{1}{25 \text{ y}} (10 \text{ y}) = 0.4.$$

The conditional damage probabilities are given as follows:

$$P(\text{damage/earthquake}) = 0.1$$

and

$$P(\text{damage/wind}) = 0.05.$$

Let event

- $A = \{\text{strong winds and no earthquakes}\}$
- $B = \{\text{strong winds and large earthquakes}\}$
- $C = \{\text{building damage}\}$

Assuming that the winds and earthquakes are independent of each other, the probability of having strong winds but not earthquakes during the ten-year period can be written as:

$$\begin{aligned} P(A) &= P(\text{winds}) P(\text{no earthquakes}) \\ &= [1 - P(\text{no winds})] P(\text{no earthquakes}) \end{aligned}$$

Therefore, we obtain

$$P(A) = (1 - e^{-0.4}) (e^{-0.2}) = 0.27$$

For the second question, the probability of having strong winds and earthquakes during the ten-year period can be obtained from

$$\begin{aligned} P(B) &= P(\text{winds}) P(\text{earthquakes}) \\ &= [1 - P(\text{no winds})] [1 - P(\text{no earthquakes})] \\ &= (1 - e^{-0.4}) (1 - e^{-0.2}) = 0.06. \end{aligned}$$

Finally, for the third question, we assume that multiple occurrences of earthquakes and high winds do not occur during the ten-year period. Therefore, the probability of building damage can be written as

$$\begin{aligned} P(C) &= P(\text{damage/earthquakes}) P(\text{earthquakes}) \\ &\quad + P(\text{damage/wind}) P(\text{wind}) \\ &\quad - P(\text{damage/earthquakes and wind}) \\ &\quad P(\text{earthquake and wind}) \\ &= P(\text{damage/earthquakes}) P(\text{earthquakes}) \\ &\quad + P(\text{damage/wind}) P(\text{wind}) \\ &\quad - P(\text{damage/earthquakes}) P(\text{damage/wind}) \\ &\quad P(\text{earthquake and wind}) \\ &= (1 - e^{-0.2}) (0.1) + (1 - e^{-0.4}) (0.05) \\ &\quad - (0.05)(0.1)(0.06) \\ &= 0.0343. \end{aligned}$$

Geometric Distribution

Consider a sequence of independent trials where each trial has the same probability of success, p . Let N be a random variable representing the number of trials until the first success. This distribution is called the geometric distribution. It has a pdf given by

$$P(N = n) = p(1 - p)^{n-1}, \quad n = 1, 2, \dots$$

The corresponding cdf is

$$F(n) = 1 - (1 - p)^n, \quad n = 1, 2, \dots$$

The expected value and the variance are, respectively,

$$E(N) = \frac{1}{p}$$

and

$$V(N) = \frac{1 - p}{p^2}.$$

It should be noted that the geometric distribution is the only discrete distribution having the *memoryless property*. In other words, mathematically, it is

$$P(N \geq (n + s) | N > s) = P(N \geq n) \quad n = 1, 2, \dots$$

This memoryless property can be shown as follows. We know that

$$P(N > n) = P(N \geq n + 1) = (1 - p)^n$$

Thus,

$$\begin{aligned} P(N \geq (n + s) | N > s) &= \frac{P(N \geq n + s)}{P(N > s)} \\ &= \frac{(1 - p)^{n+s-1}}{(1 - p)^s} \\ &= (1 - p)^{n-1} \\ &= P(N \geq n). \end{aligned}$$

The Pascal Distribution

The random variable X for the Pascal distribution represents the number of trials until the r th success where p is the probability of success of each trial. The Pascal distribution of X is given by

$$P(X = n) = \binom{n-1}{r-1} p^r (1-p)^{n-r} \quad n = r, r+1, r+2, \dots \quad (1.13)$$

The Pascal distribution is the probability distribution of a certain number of successes and failures in a series of independent and identically distributed Bernoulli trials. For n Bernoulli trials with success probability p , the Pascal distribution gives the probability of r successes and $(n - r)$ failures, with a success on the last trial. The mean and the variance of the Pascal distribution are

$$E(X) = \frac{r}{p}$$

and

$$V(X) = \frac{r(1-p)}{p^2}$$

respectively. When $r = 1$ the Pascal distribution becomes geometric distribution.

Hypergeometric Distribution

The hypergeometric distribution is a discrete distribution that arises in sampling, for example. It has a pdf given by

$$f(x) = \frac{\binom{k}{x} \binom{N-k}{n-x}}{\binom{N}{n}} \quad x = 0, 1, 2, \dots, n. \quad (1.14)$$

Typically, N will be the number of units in a finite population; n will be the number of samples drawn without replacement from N ; k will be the number of failures in the population; and x will be the number of failures in the sample.

The expected value and variance of the hypergeometric random variable X are, respectively

$$E(X) = \frac{nk}{N}$$

and

$$V(X) = \frac{k(N-k)n(N-n)}{N^2(N-1)}.$$

1.3.2 Continuous Distributions

Exponential Distribution

The exponential distribution plays an essential role in reliability engineering because it has a constant failure rate. It has been used to model the lifetimes of electronic and electrical components and systems. This distribution is applicable to the case where a used component that has not failed is as good as a new component – a rather restrictive assumption. It should therefore be used carefully, since there are numerous situations where this assumption (known as the “memoryless property” of the distribution) is not valid.

If the time to failure is described by an exponential failure time density function, then

$$f(t) = \frac{1}{\theta} e^{-\frac{t}{\theta}}, \quad t \geq 0, \theta > 0 \quad (1.15)$$

and this will lead to the reliability function

$$R(t) = \int_t^{\infty} \frac{1}{\theta} e^{-\frac{s}{\theta}} ds = e^{-\frac{t}{\theta}}, \quad t \geq 0,$$

where $\theta = 1/\lambda > 0$ is an MTTF's parameter and $\lambda \geq 0$ is a constant failure rate. Figure 1.1 shows the exponential pdf for various values of λ .

The hazard function or failure rate for the exponential density function is constant, i.e.,

$$h(t) = \frac{f(t)}{R(t)} = \frac{\frac{1}{\theta} e^{-\frac{t}{\theta}}}{e^{-\frac{t}{\theta}}} = \frac{1}{\theta} = \lambda.$$

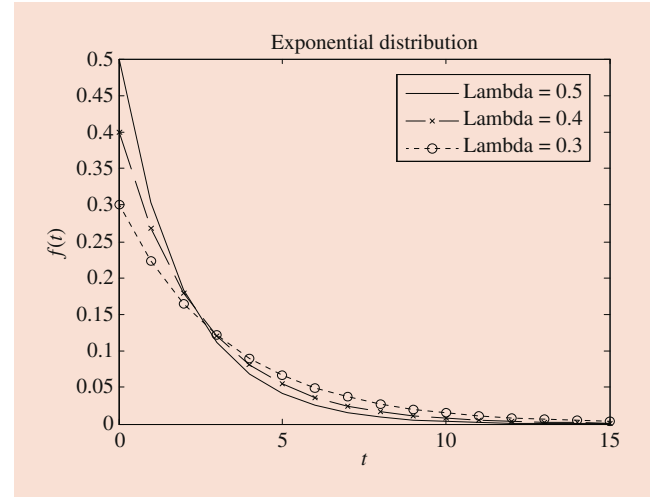

Fig. 1.1 Exponential density function for various values of λ

The failure rate for this distribution is λ , a constant, which is the main reason for this widely used distribution. Because of its constant failure rate, the exponential is an excellent model for the long flat “intrinsic failure” portion of the bathtub curve. Since most parts and systems spend most of their lifetimes in this portion of the bathtub curve, this justifies frequent use of the exponential distribution (when early failures or wearout is not a concern). The exponential model works well for interarrival times. When these events trigger failures, the exponential lifetime model can be used.

We will now discuss some properties of the exponential distribution that can be used to understand its characteristics and when and where it can be applied.

Property 1.1 (*Memoryless property*). The exponential distribution is the only continuous distribution that satisfies

$$P\{T \geq t\} = P\{T \geq t + s | T \geq s\} \quad \text{for } t > 0, s > 0.$$

This result indicates that the conditional reliability function for the lifetime of a component that has survived to time s is identical to that of a new component. This term is the so-called “used as good as new” assumption.

Property 1.2 If T_1, T_2, \dots, T_n are independently and identically distributed exponential random variables (r.v.'s) with a constant failure rate λ , then

$$2\lambda \sum_{i=1}^n T_i \sim \chi^2(2n), \quad (1.16)$$

where $\chi^2(2n)$ is a chi-squared distribution with $2n$ degrees of freedom. This result is useful for establishing a confidence interval for λ .

Lower-Bound Truncated Exponential Distribution

The lower-bound truncated exponential distribution is an exponential distribution starting at t_0 . The model can be used when no unit fails before the time t_0 . The pdf of a lower-bound truncated exponential function can be defined as follows:

$$f(t) = \begin{cases} 0 & t < t_0 \\ \frac{1}{\theta} e^{-\frac{t-t_0}{\theta}} & t \geq t_0 \end{cases}$$

The parameters θ and t_0 are the scale parameter and location parameter. Note that the failure rate of this lower-bound truncated exponential distribution is a constant for all $t \geq t_0$. This can be easily obtained as follows. The reliability function is given by

$$R(t) = \int_t^{\infty} \frac{1}{\theta} e^{-\frac{x-t_0}{\theta}} dx = e^{-\frac{t-t_0}{\theta}}$$

Thus, the failure rate of truncated exponential distribution is

$$h(t) = \frac{f(t)}{R(t)} = \frac{1}{\theta}.$$

Upper-Bound Truncated Exponential Distribution

For many applications, it is desired to consider to truncate a distribution on an upper tail. Let us assume that the exponential density be truncated at time T . The pdf of an upper-bound truncated exponential distribution function is defined as

$$f(t) = \begin{cases} 0 & t > T \\ \frac{\lambda e^{-\lambda t}}{1 - e^{-\lambda T}} & 0 < t \leq T \end{cases}$$

The reliability function is

$$R(t) = \int_t^T f(x) dx = \int_t^T \frac{\lambda e^{-\lambda x}}{1 - e^{-\lambda T}} dx = \frac{e^{-\lambda t} - e^{-\lambda T}}{1 - e^{-\lambda T}}.$$

Obviously as for the upper-bound truncated exponential distribution, the failure rate is not a constant for all $t > T$. To see this, the failure rate of this upper-bound truncated exponential distribution is

$$h(t) = \frac{f(t)}{R(t)} = \frac{\lambda}{1 - e^{-\lambda(T-t)}}.$$

and is a function of t .

Uniform Distribution

Let X be a random variable with a uniform distribution over the interval (a, b) where $a < b$. The pdf is given by

$$f(x) = \begin{cases} \frac{1}{b-a} & a \leq x \leq b \\ 0 & \text{otherwise} \end{cases}.$$

The expected value and variance are, respectively,

$$E(X) = \frac{a+b}{2}$$

and

$$V(X) = \frac{(b-a)^2}{12}.$$

Normal Distribution

The normal distribution plays an important role in classical statistics due to the *central limit theorem*. In production engineering, the normal distribution primarily applies to measurements of product susceptibility and external stress. This two-parameter distribution is used to describe mechanical systems in which a failure results from some wearout effect. The normal distribution takes the well-known bell shape. This distribution is symmetrical about the mean and the spread is measured by the variance. The larger the value, the flatter the distribution. The pdf is given by

$$f(t) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{t-\mu}{\sigma}\right)^2}, \quad -\infty < t < \infty,$$

where μ is the mean value and σ is the standard deviation. The cumulative distribution function (cdf) is

$$F(t) = \int_{-\infty}^t \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{s-\mu}{\sigma}\right)^2} ds.$$

The reliability function is

$$R(t) = \int_t^{\infty} \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{s-\mu}{\sigma}\right)^2} ds.$$

There is no closed-form solution for the above equation. However, tables for the standard normal density function are readily available (see Table 1.8 in Appendix A) and can be used to find probabilities for any normal distribution. If

$$Z = \frac{T - \mu}{\sigma}$$

is substituted into the normal pdf, we obtain

$$f(z) = \frac{1}{\sqrt{2\pi}} e^{-\frac{z^2}{2}}, \quad -\infty < Z < \infty.$$

This is a so-called standard normal pdf, with a mean value of 0 and a standard deviation of 1. The standardized cdf is given by

$$\Phi(t) = \int_{-\infty}^t \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}s^2} ds, \quad (1.17)$$

where Φ is a standard normal distribution function. Thus, for a normal random variable T , with mean μ and standard deviation σ ,

$$P(T \leq t) = P\left(Z \leq \frac{t - \mu}{\sigma}\right) = \Phi\left(\frac{t - \mu}{\sigma}\right),$$

where Φ yields the relationship required if standard normal tables are to be used.

It should be noted that the coefficient of kurtosis in the normal distribution is 3. The hazard function for a normal distribution is a monotonically increasing function of t . This is easily shown by proving that $h'(t) \geq 0$ for all t . Since

$$h(t) = \frac{f(t)}{R(t)}$$

then

$$h'(t) = \frac{R(t)f'(t) + f^2(t)}{R^2(t)} \geq 0.$$

One can attempt this proof by using the basic definition of a normal density function f .

Example 1.11 A component has a normal distribution of failure times with $\mu = 2000$ h and $\sigma = 100$ h. The reliability of the component at 1900 h is required.

Note that the reliability function is related to the standard normal deviate z by

$$R(t) = P\left(Z > \frac{t - \mu}{\sigma}\right),$$

where the distribution function for Z is given by (1.17). For this particular application,

$$\begin{aligned} R(1900) &= P\left(Z > \frac{1900 - 2000}{100}\right) \\ &= P(z > -1). \end{aligned}$$

From the standard normal table in Table 1.8 in Appendix A, we obtain

$$R(1,900) = 1 - \Phi(-1) = 0.8413.$$

The value of the hazard function is found from the relationship

$$h(t) = \frac{f(t)}{R(t)} = \frac{\Phi\left(\frac{t - \mu}{\sigma}\right)}{\sigma R(t)},$$

where Φ is the pdf of the standard normal density. Here

$$\begin{aligned} h(1900) &= \frac{\Phi(-1.0)}{\sigma R(t)} = \frac{0.1587}{100(0.8413)} \\ &= 0.0019 \text{ failures/cycle.} \end{aligned}$$

The normal distribution is flexible enough to make it a very useful empirical model. It can be theoretical derived under assumptions matching many failure mechanisms. Some of these are: corrosion, migration, crack growth, and failures resulting from chemical reactions or processes in general. That does not mean that the normal distribution is always the correct model for these mechanisms, but it does perhaps explain why it has been empirically successful in so many of these cases.

Log Normal Distribution

The log normal lifetime distribution is a very flexible model that can empirically fit many types of failure data. This distribution, when applied in mechanical reliability engineering, is able to model failure probabilities of repairable systems, the compressive strength of concrete cubes, the tensile strength of fibers, and the uncertainty in failure rate information. The log normal density function is given by

$$f(t) = \frac{1}{\sigma t \sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\ln t - \mu}{\sigma}\right)^2}, \quad t \geq 0, \quad (1.18)$$

where μ and σ are parameters such that $-\infty < \mu < \infty$, and $\sigma > 0$. Note that μ and σ are not the mean and standard deviations of the distribution.

Its relationship to the normal (just take natural logarithms of all of the data and time points and you have “normal” data) makes it easy to work with many good software analysis programs used to treat normal data.

Mathematically, if a random variable X is defined as $X = \ln T$, then X is normally distributed with a mean of μ and a variance of σ^2 . That is,

$$E(X) = E(\ln T) = \mu$$

and

$$V(X) = V(\ln T) = \sigma^2.$$

Since $T = e^X$, the mean of the log normal distribution can be found via the normal distribution. Consider that

$$E(T) = E(e^X) = \int_{-\infty}^{\infty} \frac{1}{\sigma \sqrt{2\pi}} e^{[x - \frac{1}{2}\left(\frac{x - \mu}{\sigma}\right)^2]} dx.$$

By rearranging the exponent, this integral becomes

$$E(T) = e^{\mu + \frac{\sigma^2}{2}} \int_{-\infty}^{\infty} \frac{1}{\sigma \sqrt{2\pi}} e^{-\frac{1}{2\sigma^2} [x - (\mu + \sigma^2)]^2} dx.$$

Thus, the mean of the log normal distribution is

$$E(T) = e^{\mu + \frac{\sigma^2}{2}}.$$

Proceeding in a similar manner,

$$E(T^2) = E(e^{2X}) = e^{2(\mu + \sigma^2)}$$

so the variance for the log normal is

$$V(T) = e^{2\mu + 2\sigma^2} (e^{\sigma^2} - 1).$$

The coefficient of skewness of this distribution is

$$S_c = \frac{e^{3\sigma^2} - 3e^{\sigma^2} + 2}{(e^{\sigma^2} - 1)^{\frac{3}{2}}}.$$

It is interesting that the skewness coefficient does not depend on μ and grows rapidly as the variance σ^2 increases.

The cumulative distribution function for the log normal is

$$F(t) = \int_0^t \frac{1}{\sigma s \sqrt{2\pi}} e^{-\frac{1}{2} \left(\frac{\ln s - \mu}{\sigma} \right)^2} ds$$

and this can be related to the standard normal deviate Z by

$$\begin{aligned} F(t) &= P(T \leq t) = P(\ln T \leq \ln t) \\ &= P\left(Z \leq \frac{\ln t - \mu}{\sigma}\right). \end{aligned}$$

Therefore, the reliability function is given by

$$R(t) = P\left(Z > \frac{\ln t - \mu}{\sigma}\right)$$

and the hazard function would be

$$h(t) = \frac{f(t)}{R(t)} = \frac{\Phi\left(\frac{\ln t - \mu}{\sigma}\right)}{\sigma t R(t)}$$

where Φ is the cdf of standard normal density.

The log normal lifetime model, like the normal, is flexible enough to make it a very useful empirical model. It can be theoretically derived under assumptions matching many failure mechanisms, including corrosion, migration, crack growth, and failures resulting from chemical reactions or processes in general. As with the normal distribution, this

does not mean that the log normal is always the correct model for these mechanisms, but it suggests why it has been empirically successful in so many of these cases.

Student's T Distribution

Student's t probability density function of a random variable T is given by:

$$f(t) = \frac{\Gamma\left(\frac{r+1}{2}\right)}{\sqrt{\pi} \Gamma\left(\frac{r}{2}\right) \left(1 + \frac{t^2}{r}\right)^{\frac{r+1}{2}}} \quad \text{for } -\infty < t < \infty.$$

In other words, if a random variable T is defined as

$$T = \frac{W}{\sqrt{\frac{V}{r}}},$$

where W is a standard normal random variable and V has a chi-square distribution with r degrees of freedom, and W and V are statistically independent, then T is Student's t -distributed, and parameter r is referred to as the degrees of freedom (see Table 1.9 in Appendix A).

The F Distribution

Let us define the random variable F is as follows:

$$F = \frac{U/r_1}{V/r_2},$$

where U has a chi-square distribution with r_1 degrees of freedom, V is also chi-square-distributed, with r_2 degrees of freedom, and U and V are statistically independent, then the probability density function of F is given by

$$f(t) = \frac{\Gamma\left(\frac{r_1+r_2}{2}\right) \left(\frac{r_1}{r_2}\right)^{\frac{r_1}{2}} t^{\frac{r_1}{2}-1}}{\Gamma\left(\frac{r_1}{2}\right) \Gamma\left(\frac{r_2}{2}\right) \left(1 + \frac{r_1 t}{r_2}\right)^{\frac{r_1+r_2}{2}}} \quad \text{for } t > 0.$$

The F distribution is a two-parameter r_1 and r_2 - distribution where the parameters are the degrees of freedom of the underlying chi-square random variables (see Table 1.10 in Appendix A).

It is worth noting that if T is a random variable with a t distribution and r degrees of freedom, then the random variable T^2 has an F distribution with parameters $r_1 = 1$ and $r_2 = r$. Similarly, if F is F -distributed with r_1 and r_2 degrees of freedom, then the random variable Y , defined as

$$Y = \frac{r_1 F}{r_2 + r_1 F}$$

has a beta distribution with parameters $r_1/2$ and $r_2/2$.

Weibull Distribution

The exponential distribution is often limited in applicability owing to its memoryless property. The Weibull distribution [2] is a generalization of the exponential distribution and is commonly used to represent fatigue life, ball-bearing life, and vacuum tube life. The Weibull distribution is extremely flexible and appropriate for modeling component lifetimes with fluctuating hazard rate functions and is used to represent various types of engineering applications. The three-parameter Weibull probability density function is

$$f(t) = \frac{\beta(t - \gamma)^{\beta-1}}{\theta^\beta} e^{-\left(\frac{t-\gamma}{\theta}\right)^\beta}, \quad t \geq \gamma \geq 0, \quad (1.19)$$

where θ and β are known as the scale and shape parameters, respectively, and γ is known as the location parameter. These parameters are always positive. By using different parameters, this distribution can follow the exponential distribution, the normal distribution, etc. It is clear that, for $t \geq \gamma$, the reliability function $R(t)$ is

$$R(t) = e^{-\left(\frac{t-\gamma}{\theta}\right)^\beta} \quad \text{for } t > \gamma > 0, \quad \beta > 0, \theta > 0 \quad (1.20)$$

hence,

$$h(t) = \frac{\beta(t - \gamma)^{\beta-1}}{\theta^\beta}, \quad t > \gamma > 0, \quad \beta > 0, \quad \theta > 0. \quad (1.21)$$

It can be shown that the hazard function decreases for $\beta < 1$, increases for $\beta > 1$, and is constant when $\beta = 1$.

Note that the Rayleigh and exponential distributions are special cases of the Weibull distribution at $\beta = 2$, $\gamma = 0$, and $\beta = 1$, $\gamma = 0$, respectively. For example, when $\beta = 1$ and $\gamma = 0$, the reliability of the Weibull distribution function in (1.20) reduces to

$$R(t) = e^{-\frac{t}{\theta}}$$

and the hazard function given in (1.21) reduces to $1/\theta$, a constant. Thus, the exponential is a special case of the Weibull distribution. Similarly, when $\gamma = 0$ and $\beta = 2$, the Weibull probability density function becomes the Rayleigh density function. That is,

$$f(t) = \frac{2}{\theta} t e^{-\frac{t^2}{\theta}} \quad \text{for } \theta > 0, \quad t \geq 0.$$

Other Forms of Weibull Distributions

The Weibull distribution is widely used in engineering applications. It was originally proposed in order to represent breaking strength distributions of materials. The Weibull model is very flexible and has also been applied in many applications as a purely empirical model, with theoretical justifi-

fication. Other forms of Weibull probability density function include, for example,

$$f(x) = \lambda \gamma x^{\gamma-1} e^{-\lambda x^\gamma}. \quad (1.22)$$

When $\gamma = 2$, the density function becomes a Rayleigh distribution.

It is easy to show that the mean, variance, and reliability of the above Weibull distribution are, respectively:

$$\text{Mean} = \lambda^{\frac{1}{\gamma}} \Gamma\left(1 + \frac{1}{\gamma}\right);$$

$$\text{Variance} = \lambda^{\frac{2}{\gamma}} \left\{ \Gamma\left(1 + \frac{2}{\gamma}\right) - \left[\Gamma\left(1 + \frac{1}{\gamma}\right) \right]^2 \right\};$$

$$\text{Reliability} = e^{-\lambda t^\gamma}.$$

Example 1.12 The time to failure of a part has a Weibull distribution with $1/\lambda = 250$ (measured in 10^5 cycles) and $\gamma = 2$. The part reliability at 10^6 cycles is given by:

$$R(10^6) = e^{-(10^6)^2/250} = 0.6703.$$

The resulting reliability function is shown in Fig. 1.2.

Gamma Distribution

The gamma distribution can be used as a failure probability function for components whose distribution is skewed. The failure density function for a gamma distribution is

$$f(t) = \frac{t^{\alpha-1}}{\beta^\alpha \Gamma(\alpha)} e^{-\frac{t}{\beta}}, \quad t \geq 0, \quad \alpha, \beta > 0, \quad (1.23)$$

where α is the shape parameter and β is the scale parameter. In this expression, $\Gamma(\alpha)$ is the gamma function, which is defined as

Fig. 1.2 Weibull reliability function versus time

$$\Gamma(\alpha) = \int_0^\infty t^{\alpha-1} e^{-t} dt \quad \text{for } \alpha > 0.$$

Hence,

$$R(t) = \int_t^\infty \frac{1}{\beta^\alpha \Gamma(\alpha)} s^{\alpha-1} e^{-\frac{s}{\beta}} ds.$$

If α is an integer, it can be shown by successive integration by parts that

$$R(t) = e - \frac{t}{\beta} \sum_{i=0}^{\alpha-1} \frac{\left(\frac{t}{\beta}\right)^i}{i!} \quad (1.24)$$

and

$$h(t) = \frac{f(t)}{R(t)} = \frac{\frac{1}{\beta^\alpha \Gamma(\alpha)} t^{\alpha-1} e^{-\frac{t}{\beta}}}{e^{-\frac{t}{\beta}} \sum_{i=0}^{\alpha-1} \frac{\left(\frac{t}{\beta}\right)^i}{i!}}. \quad (1.25)$$

The gamma density function has shapes that are very similar to the Weibull distribution. At $\alpha = 1$, the gamma distribution becomes the exponential distribution with a constant failure rate $1/\beta$. The gamma distribution can also be used to model the time to the n th failure of a system if the underlying failure distribution is exponential. Thus, if X_i is exponentially distributed with parameter $\theta = 1/\beta$, then $T = X_1 + X_2 + \dots + X_n$ is gamma-distributed with parameters β and n .

Example 1.13 The time to failure of a component has a gamma distribution with $\alpha = 3$ and $\beta = 5$. Obtain the reliability of the component and the hazard rate at 10 time units.

Using Eq. (1.24), we compute

$$R(10) = e^{-\frac{10}{5}} \sum_{i=0}^2 \frac{\left(\frac{10}{5}\right)^i}{i!} = 0.6767.$$

The hazard rate is given by

$$h(10) = \frac{f(10)}{R(10)} = \frac{0.054}{0.6767} = 0.798 \text{ failures/unit time.}$$

The other form of the gamma probability density function can be written as follows:

$$f(x) = \frac{\beta^\alpha t^{\alpha-1}}{\Gamma(\alpha)} e^{-t\beta}, \quad t > 0.$$

This pdf is characterized by two parameters: the shape parameter α and the scale parameter β . When $0 < \alpha < 1$, the

failure rate monotonically decreases; when $\alpha > 1$, the failure rate monotonically increases; when $\alpha = 1$ the failure rate is constant.

The mean, variance, and reliability of the gamma random variable are:

$$\text{Mean (MTTF)} = \frac{\alpha}{\beta};$$

$$\text{Variance} = \frac{\alpha}{\beta^2};$$

$$\text{Reliability} = \int_t^\infty \frac{\beta^\alpha x^{\alpha-1}}{\Gamma(\alpha)} e^{-x\beta} dx.$$

Example 1.14 A mechanical system time to failure is gamma-distributed with $\alpha = 3$ and $1/\beta = 120$. The system reliability at 280 h is given by

$$R(280) = e^{-\frac{280}{120}} \sum_{k=0}^2 \frac{\left(\frac{280}{120}\right)^k}{k!} = 0.85119$$

and the resulting reliability plot is shown in Fig. 1.3.

The gamma model is a flexible lifetime model that may offer a good fit to some sets of failure data. Although it is not widely used as a lifetime distribution model for common failure mechanisms, the gamma lifetime model is commonly used in Bayesian reliability applications.

Beta Distribution

The two-parameter beta density function $f(t)$ is given by

$$f(t) = \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha) \Gamma(\beta)} t^{\alpha-1} (1-t)^{\beta-1}, \quad (1.26)$$

$$0 < t < 1, \alpha > 0, \beta > 0,$$

Fig. 1.3 Gamma reliability function versus time

where α and β are the distribution parameters. This two-parameter beta distribution is commonly used in many reliability engineering applications and also plays an important role in the theory of statistics. Note that the beta-distributed random variable takes on values in the interval $(0, 1)$, so the beta distribution is a natural model when the random variable represents a probability. Likewise, when $\alpha = \beta = 1$, the beta distribution reduces to a uniform distribution.

The mean and variance of the beta random variable are, respectively,

$$E(T) = \frac{\alpha}{\alpha + \beta}$$

and

$$V(T) = \frac{\alpha\beta}{(\alpha + \beta + 1)(\alpha + \beta)^2}.$$

Pareto Distribution

The Pareto distribution was originally developed to model income in a population. Phenomena such as city population size, stock price fluctuations, and personal incomes have distributions with very long right tails. The probability density function of the Pareto distribution is given by

$$f(t) = \frac{\alpha k^\alpha}{t^{\alpha+1}}, \quad k \leq t < \infty. \quad (1.27)$$

The mean, variance, and reliability of the Pareto distribution are:

$$\text{Mean} = k/(\alpha - 1) \quad \text{for } \alpha > 1;$$

$$\text{Variance} = \alpha k^2 / [(\alpha - 1)^2 (\alpha - 2)] \quad \text{for } \alpha > 2;$$

$$\text{Reliability} = \left(\frac{k}{t}\right)^\alpha.$$

The Pareto and log normal distributions are commonly used to model population size and economical incomes. The Pareto is used to fit the tail of the distribution, and the log normal is used to fit the rest of the distribution.

Rayleigh Distribution

The Rayleigh model is a flexible lifetime model that can apply to many degradation process failure modes. The Rayleigh probability density function is

$$f(t) = \frac{t}{\sigma^2} \exp\left(-\frac{t^2}{2\sigma^2}\right). \quad (1.28)$$

The mean, variance, and reliability of the Rayleigh function are:

$$\text{Mean} = \sigma \left(\frac{\pi}{2}\right)^{\frac{1}{2}};$$

$$\text{Variance} = \left(2 - \frac{\pi}{2}\right) \sigma^2;$$

$$\text{Reliability} = e^{-\frac{\sigma^2}{2t}}.$$

Example 1.15 Rolling resistance is a measure of the energy lost by a tire under load when it resists the force opposing its direction of travel. In a typical car traveling at 60 miles per hour, about 20% of the engine power is used to overcome the rolling resistance of the tires. A tire manufacturer introduces a new material that, when added to the tire rubber compound, significantly improves the tire rolling resistance but increases the wear rate of the tire tread. Analysis of a laboratory test of 150 tires shows that the failure rate of the new tire increases linearly with time (h). This is expressed as

$$h(t) = 0.5 \times 10^{-8} t.$$

The reliability of the tire after one year (8760 h) of use is

$$R(1 \text{ y}) = e^{-\frac{0.5}{2} \times 10^{-8} \times (8760)^2} = 0.8254.$$

Figure 1.4 shows the resulting reliability function.

Pham Distribution

A two-parameter distribution with a Vtub-shaped hazard rate curve was developed by Pham [3], known as *loglog distribution* or *Pham distribution* [3, 15]. Note that the loglog distribution with a Vtub-shaped hazard rate and the Weibull distribution with bathtub-shaped failure rates are not the same. For the bathtub-shaped failure rate, after an initial “infant mortality period,” the useful life of the system begins. During its useful life, the system fails at a constant rate. This period is then followed by a wearout period during which

Fig. 1.4 Rayleigh reliability function versus time

Fig. 1.5 Pham probability density function for various values of α with $a = 2$

Fig. 1.6 Pham probability density function for various values of a with $\alpha = 1.5$

the system failure rate slowly increases with the onset of wearout. For the Vtub-shaped hazard rate, after the infant mortality period, the system experiences a relatively low but increasing failure rate. The failure rate increases due to aging.

The Pham probability density function is defined as [3]:

$$f(t) = \alpha t^{\alpha-1} a^{t^\alpha} e^{1-a^{t^\alpha}} \ln(a) \quad \text{for } t > 0, a > 1, \alpha > 0. \quad (1.29)$$

The corresponding Pham cdf and reliability function are given by

$$F(t) = \int_0^t f(x)dx = 1 - e^{1-a^{t^\alpha}}$$

and

$$R(t) = e^{1-a^{t^\alpha}}, \quad (1.30)$$

respectively. The corresponding failure rate of the Pham distribution is given by

$$h(t) = \alpha \ln a t^{\alpha-1} a^{t^\alpha}. \quad (1.31)$$

Figures 1.5 and 1.6 describe the density functions and failure rate functions for various values of a and α .

Two-Parameter Hazard Rate Function

This is a two-parameter function that can have increasing and decreasing hazard rates. The hazard rate $h(t)$, the reliability function $R(t)$, and the pdf are, respectively, given as follows:

$$h(t) = \frac{n\lambda t^{n-1}}{\lambda t^n + 1} \quad \text{for } n \geq 1, \lambda > 0, t \geq 0, \quad (1.32)$$

$$R(t) = e^{-\ln(\lambda t^n + 1)}$$

and

$$f(t) = \frac{n\lambda t^{n-1}}{\lambda t^n + 1} e^{-\ln(\lambda t^n + 1)}, \quad n \geq 1, \lambda > 0, t \geq 0,$$

where n = shape parameter and λ = scale parameter.

Three-Parameter Hazard Rate Function

This is a three-parameter distribution that can have increasing and decreasing hazard rates. The hazard rate $h(t)$ is given as

$$h(t) = \frac{\lambda(b+1)[\ln(\lambda t + \alpha)]^b}{(\lambda t + \alpha)}, \quad (1.33)$$

$$b \geq 0, \lambda > 0, \alpha \geq 0, t \geq 0.$$

The reliability function $R(t)$ for $\alpha = 1$ is

$$R(t) = e^{-[\ln(\lambda t + \alpha)]^{b+1}}.$$

The probability density function $f(t)$ is

$$f(t) = e^{-[\ln(\lambda t + \alpha)]^{b+1}} \frac{\lambda(b+1)[\ln(\lambda t + \alpha)]^b}{(\lambda t + \alpha)},$$

where b = shape parameter, λ = scale parameter, and α = location parameter.

Extreme-Value Distribution

The extreme-value distribution can be used to model external events such as floods, tornadoes, hurricanes, and high winds in risk applications. The cdf of this distribution is given by

$$F(t) = e^{-e^y} \quad \text{for } -\infty < t < \infty. \quad (1.34)$$

Cauchy Distribution

The Cauchy distribution can be applied when analyzing communication systems where two signals are received and one is interested in modeling the ratio of the two signals. The Cauchy probability density function is given by

$$f(t) = \frac{1}{\pi(1+t^2)} \quad \text{for } -\infty < t < \infty. \quad (1.35)$$

It is worth noting that the ratio of two standard normal random variables is a random variable with a Cauchy distribution.

Vtub-Shaped Failure Rate

Pham [14] recently presents a distribution function that characterizes a Vtub-shaped failure rate function. Note that, for the bathtub-shaped failure rate, during its useful life period the failure rate is constant. For the Vtub-shaped failure rate, after the infant mortality period the system will begin to experience a rather low increasing failure rate but never be at a constant rate due to aging. The Vtub-shaped failure rate function $h(t)$ is defined as

$$h(t) = at \ln(bt) + \frac{a}{b} \quad \text{for } t > 0, \quad a > 0, \quad b > 0 \quad (1.36)$$

Figure 1.7 shows the Vtub-shaped failure rate $h(t)$ for $a = 0.75$ and various values of b (i.e., 0.35, 0.45, and 0.55). The corresponding probability density function $f(t)$ and reliability function $R(t)$ are as follows:

$$f(t) = \left(at \ln(bt) + \frac{a}{b} \right) e^{-\left\{ at \left[\frac{t}{2} \ln(bt) - \frac{t}{4} + \frac{1}{b} \right] \right\}} \quad (1.37)$$

for $t > 0, a > 0, b > 0$

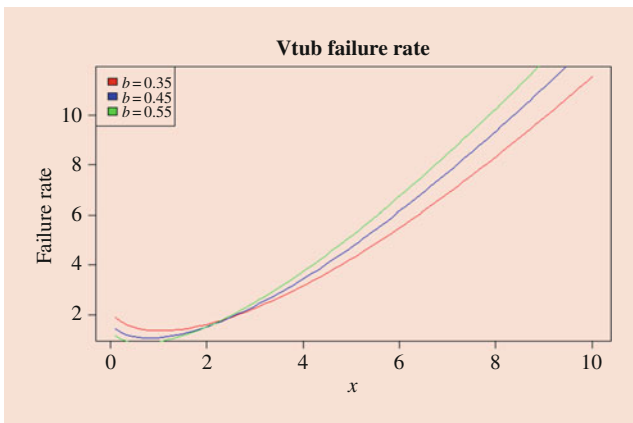

Fig. 1.7 A Vtub-shaped failure rate for $a = 0.75$ and various values of b (i.e. 0.35, 0.45, and 0.55)

and

$$R(t) = e^{-at \left[\frac{t}{2} \ln(bt) - \frac{t}{4} + \frac{1}{b} \right]} \quad \text{for } t > 0, \quad a > 0, \quad b > 0 \quad (1.38)$$

respectively.

Triangular Distribution

A triangular distribution (sometime called a triangle distribution) is a continuous probability distribution shaped like a triangle. It is defined by

a : the minimum value

c : the peak value (the height of the triangle)

b : the maximum value, where $a \leq c \leq b$.

The triangular probability density function is given by

$$f(t) = \begin{cases} 0 & t < a \\ \frac{2(t-a)}{(b-a)(c-a)} & a \leq t \leq c \\ \frac{2(b-t)}{(b-a)(b-c)} & c \leq t \leq b \\ 0 & t > b \end{cases} \quad (1.39)$$

The three parameters a , b , and c change the shape of the triangle. The mean and the variance for this distribution, respectively, are:

$$\text{mean} = \frac{1}{3}(a + b + c)$$

and

$$\text{variance} = \frac{1}{18}(a^2 + b^2 + c^2 - ab - ac - bc).$$

1.4 Statistical Inference and Estimation

Inference about the values of parameters involved in statistical distributions is known as estimation. The engineer might be interested in estimating the mean life of an electronic device based on the failure times of a random sample placed on life test. An interesting question that commonly is asked from many practitioners is how close this estimator would be to the true value of the parameter being estimated from a known distribution.

The problem of “point estimation” is that of estimating the parameters of a population, such as λ or θ from an exponential, μ and σ^2 from a normal, etc. It is assumed that the type of population distribution involved is known, but the distribution parameters are unknown and they must be estimated using collected failure data. This section is devoted to the theory of estimation and discusses several common estimation techniques, such as maximum likelihood, method

of moments, least squared estimation, and Bayesian methods. We also discuss confidence interval and tolerance limit estimation. For example, assume that n independent samples are drawn from the exponential density function $f(x; \lambda) = \lambda e^{-\lambda x}$ for $x > 0$ and $\lambda > 0$. Then the joint probability density function (pdf) or sample density (for short) is given by

$$f(x_1, \lambda) \cdot f(x_2, \lambda) \cdots f(x_n, \lambda) = \lambda^n e^{-\lambda \sum_{i=1}^n x_i}. \quad (1.40)$$

The problem here is to find a “good” point estimate of λ , which is denoted by $\hat{\lambda}$. In other words, we want to find a function $h(X_1, X_2, \dots, X_n)$ such that, if x_1, x_2, \dots, x_n are the observed experimental values of X_1, X_2, \dots, X_n , the value $h(x_1, x_2, \dots, x_n)$ will be a good point estimate of λ . By “good,” we mean that it possesses the following properties:

- unbiasedness
- consistency
- efficiency (minimum variance)
- sufficiency

In other words, if $\hat{\lambda}$ is a good point estimate of λ , then one can select a function $h(X_1, X_2, \dots, X_n)$ where $h(X_1, X_2, \dots, X_n)$ is an unbiased estimator of λ and the variance of $h(X_1, X_2, \dots, X_n)$ is a minimum. We will now present the following definitions.

Unbiasedness

For a given positive integer n , the statistic $Y = h(X_1, X_2, \dots, X_n)$ is called an unbiased estimator of the parameter θ if the expectation of Y is equal to a parameter θ ; that is,

$$E(Y) = \theta.$$

Consistency

The statistic Y is called a consistent estimator of the parameter θ if Y converges stochastically to a parameter θ as n approaches infinity. If ε is an arbitrarily small positive number when Y is consistent, then

$$\lim_{n \rightarrow \infty} P(|Y - \theta| \leq \varepsilon) = 1.$$

Minimum Variance

The statistic Y is called the minimum variance unbiased estimator of the parameter θ if Y is unbiased and the variance of Y is less than or equal to the variance of every other unbiased estimator of θ . An estimator that has the property of minimum variance in large samples is said to be efficient.

Sufficiency

The statistic Y is said to be sufficient for θ if the conditional distribution of X , given that $Y = y$, is independent of θ .

This is useful when determining a lower bound on the variance of all unbiased estimators. We now establish a lower-bound inequality known as the *Cramér–Rao inequality*.

Cramér–Rao Inequality

Let X_1, X_2, \dots, X_n denote a random sample from a distribution with pdf $f(x; \theta)$ for $\theta_1 < \theta < \theta_2$, where θ_1 and θ_2 are known. Let $Y = h(X_1, X_2, \dots, X_n)$ be an unbiased estimator of θ . The lower-bound inequality on the variance of Y , $\text{Var}(Y)$, is given by

$$\text{Var}(Y) \geq \frac{1}{nE \left[\left(\frac{\partial \ln f(x; \theta)}{\partial \theta} \right)^2 \right]} = \frac{1}{-nE \left(\frac{\partial^2 \ln f(x; \theta)}{\partial \theta^2} \right)}. \quad (1.41)$$

Theorem 1.5 An estimator $\hat{\theta}$ is said to be asymptotically efficient if $\sqrt{n}\hat{\theta}$ has a variance that approaches the Cramér–Rao lower bound for large n ; that is,

$$\lim_{n \rightarrow \infty} \text{Var}(\sqrt{n}\hat{\theta}) = \frac{1}{-nE \left(\frac{\partial^2 \ln f(x; \theta)}{\partial \theta^2} \right)}. \quad (1.42)$$

1.4.1 Parameter Estimation

We now discuss some basic methods of parameter estimation, including the method of maximum likelihood estimation (MLE) and the method of moments. The assumption that the sample is representative of the population will be made both in the example and in later discussions.

Maximum Likelihood Estimation Method

In general, one deals with a sample density

$$f(x_1, x_2, \dots, x_n) = f(x_1; \theta) f(x_2; \theta) \cdots f(x_n; \theta),$$

where x_1, x_2, \dots, x_n are random, independent observations of a population with density function $f(x)$.

For the general case, we would like to find an estimate or estimates, $\hat{\theta}_1, \hat{\theta}_2, \dots, \hat{\theta}_m$ (if such exist), where

$$\begin{aligned} f(x_1, x_2, \dots, x_n; \theta_1, \theta_2, \dots, \theta_m) > \\ f(x_1, x_2, \dots, x_n; \theta'_1, \theta'_2, \dots, \theta'_m). \end{aligned}$$

The notation $\theta'_1, \theta'_2, \dots, \theta'_m$ refers to any other estimates different to $\hat{\theta}_1, \hat{\theta}_2, \dots, \hat{\theta}_m$.

Consider a random sample X_1, X_2, \dots, X_n from a distribution with a pdf $f(x; \theta)$. This distribution has a vector $\theta = (\theta_1, \theta_2, \dots, \theta_m)'$ of unknown parameters associated with it, where m is the number of unknown parameters. Assuming that the random variables are independent, then the likelihood function, $L(X; \theta)$, is the product of the probability density function evaluated at each sample point

$$L(X, \theta) = \prod_{i=1}^n f(X_i; \theta), \quad (1.43)$$

where $\mathbf{X} = (X_1, X_2, \dots, X_n)$. The maximum likelihood estimator $\hat{\theta}$ is found by maximizing $L(\mathbf{X}; \theta)$ with respect to θ . In practice, it is often easier to maximize $\ln [L(\mathbf{X}; \theta)]$ in order to find the vector of MLEs, which is valid because the logarithmic function is monotonic. The log likelihood function is given by

$$\ln L(X, \theta) = \prod_{i=1}^n \ln f(X_i; \theta) \quad (1.44)$$

and is asymptotically normally distributed since it consists of the sum of n independent variables and the central limit theorem is implied. Since $L(X; \theta)$ is a joint probability density function for X_1, X_2, \dots, X_n , its integral must be 1; that is,

$$\int_0^\infty \int_0^\infty \cdots \int_0^\infty L(X; \theta) dX = 1.$$

Assuming that the likelihood is continuous, the partial derivative of the left-hand side with respect to one of the parameters, θ_i , yields

$$\begin{aligned} & \frac{\partial}{\partial \theta_i} \int_0^\infty \int_0^\infty \cdots \int_0^\infty L(X; \theta) dX \\ &= \int_0^\infty \int_0^\infty \cdots \int_0^\infty \frac{\partial}{\partial \theta_i} L(X; \theta) dX \\ &= \int_0^\infty \int_0^\infty \cdots \int_0^\infty \frac{\partial \log L(X; \theta)}{\partial \theta_i} L(X; \theta) dX \\ &= E \left(\frac{\partial \log L(X; \theta)}{\partial \theta_i} \right) \\ &= E [U_i(\theta)] \quad \text{for } i = 1, 2, \dots, m, \end{aligned}$$

where $\mathbf{U}(\theta) = [U_1(\theta), U_2(\theta), \dots, U_m(\theta)]'$ is often called the score vector, and the vector $\mathbf{U}(\theta)$ has components

$$U_i(\theta) = \frac{\partial [\log L(X; \theta)]}{\partial \theta_i} \quad \text{for } i = 1, 2, \dots, m \quad (1.45)$$

which, when equated to zero and solved, yields the MLE vector $\hat{\theta}$.

Suppose that we can obtain a nontrivial function of X_1, X_2, \dots, X_n , say $h(X_1, X_2, \dots, X_n)$, such that, when θ is replaced by $h(X_1, X_2, \dots, X_n)$, the likelihood function L will achieve a maximum. In other words,

$$L[X, h(X)] \geq L(X, \theta)$$

for every θ . The statistic $h(X_1, X_2, \dots, X_n)$ is called a maximum likelihood estimator of θ and will be denoted as

$$\hat{\theta} = h(x_1, x_2, \dots, x_n). \quad (1.46)$$

The observed value of $\hat{\theta}$ is called the MLE of θ . In general, the mechanics for obtaining the MLE can be obtained as follows:

Step 1.	Find the joint density function $L(X, \theta)$
Step 2.	Take the natural log of the density $\ln L$
Step 3.	Find the partial derivatives of $\ln L$ with respect to each parameter
Step 4.	Set these partial derivatives to “zero”
Step 5.	Solve for parameter(s)

Example 1.16 Let X_1, X_2, \dots, X_n , denote a random sample from the normal distribution $N(\mu, \sigma^2)$. Then the likelihood function is given by

$$L(X, \mu, \sigma^2) = \left(\frac{1}{2\pi} \right)^{\frac{n}{2}} \frac{1}{\sigma^n} e^{-\frac{1}{2\sigma^2} \sum_{i=1}^n (x_i - \mu)^2}$$

and

$$\ln L = -\frac{n}{2} \log(2\pi) - \frac{n}{2} \log \sigma^2 - \frac{1}{2\sigma^2} \sum_{i=1}^n (x_i - \mu)^2.$$

Thus, we have

$$\begin{aligned} \frac{\partial \ln L}{\partial \mu} &= \frac{1}{\sigma^2} \sum_{i=1}^n (x_i - \mu) = 0, \\ \frac{\partial \ln L}{\partial \sigma^2} &= -\frac{n}{2\sigma^2} - \frac{1}{2\sigma^4} \sum_{i=1}^n (x_i - \mu)^2 = 0. \end{aligned}$$

Solving the two equations simultaneously, we obtain

$$\begin{aligned} \hat{\mu} &= \frac{\sum_{i=1}^n x_i}{n}, \\ \hat{\sigma}^2 &= \frac{1}{n} \sum_{i=1}^n (x_i - \bar{x})^2. \end{aligned}$$

Note that the MLEs, if they exist, are both sufficient and efficient estimates. They also have an additional property called invariance – in other words, for an MLE of θ , $\mu(\theta)$ is the MLE of $\mu(\theta)$. However, they are not necessarily unbiased (i.e., $E(\hat{\theta}) = \theta$). In fact, the point is that

$$E(\hat{\sigma}^2) = \left(\frac{n-1}{n} \right) \sigma^2 \neq \sigma^2.$$

Therefore, for small n , σ^2 is usually adjusted to account for this bias, and the best estimate of σ^2 is

$$\hat{\sigma}^2 = \left(\frac{1}{n-1} \right) \sum_{i=1}^n (x_i - \bar{x})^2.$$

Sometimes it is difficult to directly obtain maximum likelihood estimators by taking the partial derivatives of the log of likelihood function as mentioned in Step 3 but need to consider another appropriate step, which now leads to a given example below.

Example 1.17 Let X_1, X_2, \dots, X_n represent a random sample from the distribution with pdf

$$f(x; \theta) = e^{-(x-\theta)} \quad \text{for } \theta \leq x \leq \infty \text{ and } -\infty < \theta < \infty$$

The likelihood function is given by

$$\begin{aligned} L(\theta; X) &= \prod_{i=1}^n f(x_i; \theta) \quad \text{for } \theta \leq x_i \leq \infty \text{ all } i \\ &= \prod_{i=1}^n e^{-(x_i-\theta)} = e^{-\sum_{i=1}^n x_i + n\theta} \end{aligned}$$

For fixed values of x_1, x_2, \dots, x_n , we wish to find the value of θ which maximizes $L(\theta; X)$. Here we cannot use the techniques of calculus to maximize $L(\theta; X)$. Note that $L(\theta; X)$ is largest when θ is as large as possible. However, the largest value of θ is equal to the smallest value of X_i in the sample. Thus,

$$\hat{\theta} = \min \{X_i\} \quad 1 \leq i \leq n.$$

Sometimes it is difficult, if not impossible, to obtain maximum likelihood estimators in a closed form, and therefore numerical methods must be used to maximize the likelihood function as we now discuss the following example.

Example 1.18 Suppose that X_1, X_2, \dots, X_n is a random sample from the Weibull distribution with pdf

$$f(x, \alpha, \lambda) = \alpha \lambda x^{\alpha-1} e^{-\lambda x^\alpha}.$$

The likelihood function is

$$L(X, \alpha, \lambda) = \alpha^n \lambda^n \prod_{i=1}^n x_i^{\alpha-1} e^{-\lambda \sum_{i=1}^n x_i^\alpha}.$$

Then

$$\ln L = n \log \alpha + n \log \lambda + (\alpha - 1) \sum_{i=1}^n \log x_i - \lambda \sum_{i=1}^n x_i^\alpha,$$

$$\frac{\partial \ln L}{\partial \alpha} = \frac{n}{\alpha} + \sum_{i=1}^n \log x_i - \lambda \sum_{i=1}^n x_i^\alpha \log x_i = 0,$$

$$\frac{\partial \ln L}{\partial \lambda} = \frac{n}{\lambda} - \sum_{i=1}^n x_i^\alpha = 0.$$

As noted, solutions of the above two equations for α and λ are extremely difficult to obtain and require the application of either graphical or numerical methods. It is sometimes desirable to use a quick method of estimation, which leads to a discussion of the method of moments.

Method of Moments

Here one simply sets the sample moments equal to the corresponding population moments. For example, for the gamma distribution, the mean and the variance of the distribution are, respectively, $\frac{\alpha}{\beta}$ and $\frac{\alpha}{\beta^2}$. Therefore, one has the following two equations in two unknowns:

$$\begin{aligned} \bar{X} &= \frac{\alpha}{\beta}, \\ S^2 &= \frac{\alpha}{\beta^2}. \end{aligned}$$

Solving these two equations simultaneously, we obtain

$$\begin{aligned} \alpha &= \frac{\bar{X}^2}{S^2}, \\ \beta &= \frac{\bar{X}}{S^2}. \end{aligned}$$

1.4.2 Maximum Likelihood Estimation with Censored Data

Censored data arises when we monitor for a random variable of interest – unit failure, for example – but the monitoring is stopped before measurements are complete (i.e., before the unit fails). In other words, censored observation contains only partial information about the random variable of interest. In this section, we consider two types of censoring. The first type of censoring is called Type I censoring, where the event is only observed if it occurs prior to some prespecified time. The second type of censoring is Type II censoring, in which the study continues until the failure of the first r units (or components), where r is some predetermined integer ($r < n$).

Examples of Type II censoring are often used when testing equipment life. Here our items are tested at the same time, and the test is terminated when r of the n items have failed. These approaches may save time and resources because it may take a very long time for all of the items to fail. Both Type I and Type II censoring arise in many reliability applications.

For example, let us say that we have a batch of transistors or tubes. We begin to test them all at $t = 0$, and record their times to failure. Some transistors may take a long time to burn out, and we will not want to wait that long to end the experiment. We might stop the experiment at a prespecified

time t_c , in which case we have Type I censoring. On the other hand, we might not know what fixed value to use for the censoring time beforehand, so we decide to wait until a prespecified number of units have failed, r , in which case we have Type II censoring.

Censoring times may vary from individual to individual or from application to application. We now discuss a general case known as multiple censored data.

Parameter Estimate with Multiple Censored Data

The likelihood function for multiple censored data is given by

$$\begin{aligned} L &= f(t_{1,f}, \dots, t_{r,f}, t_{1,s}, \dots, t_{m,s}) \\ &= C \prod_{i=1}^r f(t_{i,f}) \prod_{j=1}^m [1 - F(t_{j,s})], \end{aligned} \quad (1.47)$$

where C is a constant, $f(\cdot)$ is the density function, and $F(\cdot)$ is the distribution function. There are r failures at times $t_{1,f}, \dots, t_{r,f}$ and m units with censoring times $t_{1,s}, \dots, t_{m,s}$.

Note that we obtain Type I censoring by simply setting $t_{i,f} = t_{i,n}$ and $t_{j,s} = t_0$ in the likelihood function in (1.47). The likelihood function for Type II censoring is similar to Type I censoring except $t_{j,s} = t_r$ in (1.47). In other words, the likelihood function for the first r observations from a sample of size n drawn from the model in both Type I and Type II censoring is given by

$$L = f(t_{1,n}, \dots, t_{r,n}) = C \prod_{i=1}^r f(t_{i,n}) [1 - F(t_*)]^{n-r}, \quad (1.48)$$

where $t_* = t_0$, the time of cessation of the test for Type I censoring, and $t_* = t_r$, the time of the r th failure for Type II censoring.

Example 1.19 Consider a two-parameter probability density distribution with multiple censored data and a distribution function with bathtub-shaped failure rate, as given by [4]:

$$f(t) = \lambda \beta t^{\beta-1} \exp \left[t^\beta + \lambda (1 - e^{t^\beta}) \right], \quad t, \lambda, \beta > 0 \quad (1.49)$$

and

$$F(t) = 1 - \exp \left[\lambda (1 - e^{t^\beta}) \right], \quad t, \lambda, \beta > 0, \quad (1.50)$$

respectively.

Substituting the functions $f(t)$ and $F(t)$ into (1.49) and (1.50) into (1.48), we obtain the logarithm of the likelihood function:

$$\begin{aligned} \ln L &= \ln C + r \ln \lambda + r \ln \beta + \sum_{i=1}^r (\beta - 1) \ln t_i \\ &+ (m + r) \lambda + \sum_{i=1}^r t_i^\beta - \left[\sum_{i=1}^r \lambda e^{t_i^\beta} + \sum_{j=1}^m \lambda e^{t_j^\beta} \right]. \end{aligned}$$

The function $\ln L$ can be maximized by setting the partial derivative of $\ln L$ with respect to λ and β equal to zero, and solving the resulting equations simultaneously for λ and β . Therefore, we obtain

$$\frac{\partial \ln L}{\partial \lambda} = \frac{r}{\lambda} + (m + r) - \sum_{i=1}^r e^{t_i^\beta} - \sum_{j=1}^m e^{t_j^\beta} \equiv 0,$$

$$\begin{aligned} \frac{\partial \ln L}{\partial \beta} &= \frac{r}{\beta} + \sum_{i=1}^r \ln t_i + \sum_{i=1}^r t_i^\beta \ln t_i \\ &- \lambda \left(\sum_{i=1}^r e^{t_i^\beta} t_i^\beta \ln t_i + \sum_{j=1}^m e^{t_j^\beta} t_j^\beta \ln t_j \right) \equiv 0. \end{aligned}$$

This implies that

$$\hat{\lambda} = \frac{r}{\left(\sum_{i=1}^r e^{t_i^{\hat{\beta}}} + \sum_{j=1}^m e^{t_j^{\hat{\beta}}} \right) - m - r} \quad (1.51)$$

and that $\hat{\beta}$ is the solution of

$$\begin{aligned} \frac{r}{\hat{\beta}} + \sum_{i=1}^r \ln t_i + \sum_{i=1}^r t_i^{\hat{\beta}} \ln t_i \\ &= \frac{r}{\left(\sum_{i=1}^r e^{t_i^{\hat{\beta}}} + \sum_{j=1}^m e^{t_j^{\hat{\beta}}} \right) - m - r} \\ &\left(\sum_{i=1}^r e^{t_i^{\hat{\beta}}} t_i^{\hat{\beta}} \ln t_i + \sum_{j=1}^m e^{t_j^{\hat{\beta}}} t_j^{\hat{\beta}} \ln t_j \right). \end{aligned} \quad (1.52)$$

We now discuss two special cases.

Case 1: Type I or Type II Censored Data

From Eq. (1.48), the likelihood function for the first r observations from a sample of size n drawn from the model in both Type I and Type II censoring is

$$L = f(t_{1,n}, \dots, t_{r,n}) = C \prod_{i=1}^r f(t_{i,n}) [1 - F(t_*)]^{n-r},$$

where $t_* = t_0$, the test cessation time for Type I censoring, and $t_* = t_r$, the time of the r th failure for Type II censoring. Equations (1.51) and (1.52) become

$$\begin{aligned}\hat{\lambda} &= \frac{r}{\sum_{i=1}^r e^{t_i^{\hat{\beta}}} + (n-r)e^{t_*^{\hat{\beta}}} - n}, \\ \frac{r}{\hat{\beta}} + \sum_{i=1}^r \ln t_i + \sum_{i=1}^r t_i^{\hat{\beta}} \ln t_i \\ &= \frac{r}{\sum_{i=1}^r e^{t_i^{\hat{\beta}}} + (n-r)e^{t_*^{\hat{\beta}}} - n} \\ &\quad \times \left(\sum_{i=1}^r e^{t_i^{\hat{\beta}}} t_i^{\hat{\beta}} \ln t_i + \sum_{j=1}^m e^{t_j^{\hat{\beta}}} t_j^{\hat{\beta}} \ln t_j \right)\end{aligned}$$

Case 2: Complete Censored Data

Simply replace r with n in (1.51) and (1.52) and ignore the t_j portions. The maximum likelihood equations for the λ and β are given by

$$\begin{aligned}\hat{\lambda} &= \frac{n}{\sum_{i=1}^n e^{t_i^{\hat{\beta}}} - n}, \\ \frac{n}{\hat{\beta}} + \sum_{i=1}^n \ln t_i + \sum_{i=1}^n t_i^{\hat{\beta}} \ln t_i \\ &= \frac{n}{\sum_{i=1}^n e^{t_i^{\hat{\beta}}} - n} \times \sum_{i=1}^n e^{t_i^{\hat{\beta}}} t_i^{\hat{\beta}} \ln t_i.\end{aligned}$$

Confidence Intervals of Estimates

The asymptotic variance–covariance matrix for the parameters (λ and β) is obtained by inverting the Fisher information matrix

$$I_{ij} = E \left(-\frac{\partial^2 L}{\partial \theta_i \partial \theta_j} \right), \quad i, j = 1, 2, \quad (1.53)$$

where $\theta_1, \theta_2 = \lambda$ or β [5]. This leads to

$$\begin{aligned}&\begin{pmatrix} \text{Var}(\hat{\lambda}) & \text{Cov}(\hat{\lambda}, \hat{\beta}) \\ \text{Cov}(\hat{\lambda}, \hat{\beta}) & \text{Var}(\hat{\beta}) \end{pmatrix} \\ &= \begin{pmatrix} E \left(-\frac{\partial^2 \ln L}{\partial^2 \lambda} \Big|_{\hat{\lambda}, \hat{\beta}} \right) & E \left(-\frac{\partial^2 \ln L}{\partial \lambda \partial \beta} \Big|_{\hat{\lambda}, \hat{\beta}} \right) \\ E \left(-\frac{\partial^2 \ln L}{\partial \beta \partial \lambda} \Big|_{\hat{\lambda}, \hat{\beta}} \right) & E \left(-\frac{\partial^2 \ln L}{\partial^2 \beta} \Big|_{\hat{\lambda}, \hat{\beta}} \right) \end{pmatrix}. \quad (1.54)\end{aligned}$$

We can obtain approximate $(1 - \alpha)100\%$ confidence intervals for the parameters λ and β based on the asymptotic normality of the MLEs [5] as:

$$\hat{\lambda} \pm Z_{\alpha/2} \sqrt{\text{Var}(\hat{\lambda})} \quad \text{and} \quad \hat{\beta} \pm Z_{\alpha/2} \sqrt{\text{Var}(\hat{\beta})}, \quad (1.55)$$

where $Z_{\alpha/2}$ is the upper percentile of the standard normal distribution.

Application 1

Consider the lifetime of a part from a helicopter's main rotor blade. Data on lifetime of the part taken a system database collected from October 1995 to September 1999 [3] are shown in Table 1.2. In this application, we consider several distribution functions for this data, including Weibull, log normal, normal, and loglog distribution functions.

The Pham pdf with parameters a and α is

$$f(t) = \alpha (\ln a) t^{\alpha-1} a^\alpha e^{1-a^\alpha} \quad \text{for } t > 0, \alpha > 0, a > 1$$

and its corresponding log likelihood function (1.44) is

$$\begin{aligned}\log L(a, \alpha) &= n \log \alpha + n \ln(\ln a) \\ &\quad + (\alpha - 1) \left(\sum_{i=1}^n \ln t_i \right) \\ &\quad + \ln a \cdot \sum_{i=1}^n t_i^\alpha + n - \sum_{i=1}^n a^{t_i^\alpha}.\end{aligned}$$

We then determine the confidence intervals for parameter estimates a and α . From the above log likelihood function, we can obtain the Fisher information matrix \mathbf{H} as $\mathbf{H} = \begin{pmatrix} h_{11} & h_{12} \\ h_{21} & h_{22} \end{pmatrix}$, where

$$h_{11} = E \left(-\frac{\partial^2 \log L}{\partial a^2} \right),$$

$$h_{12} = h_{21} = E \left(-\frac{\partial^2 \log L}{\partial a \partial \alpha} \right),$$

$$h_{22} = E \left(-\frac{\partial^2 \log L}{\partial \alpha^2} \right),$$

The variance matrix \mathbf{V} can be obtained as follows:

$$\mathbf{V} = (\mathbf{H})^{-1} \begin{pmatrix} v_{11} & v_{12} \\ v_{21} & v_{22} \end{pmatrix}. \quad (1.56)$$

The variances of a and α are

$$\text{Var}(a) = v_{11} \quad \text{Var}(\alpha) = v_{22}.$$

One can approximately obtain the $(1 - \beta)100\%$ confidence intervals for a and α based on the normal distribution as $\left[\hat{a} - z_{\frac{\beta}{2}}\sqrt{v_{11}}, \hat{a} + z_{\frac{\beta}{2}}\sqrt{v_{11}}\right]$ and $\left[\hat{\alpha} - z_{\frac{\beta}{2}}\sqrt{v_{22}}, \hat{\alpha} + z_{\frac{\beta}{2}}\sqrt{v_{22}}\right]$, respectively, where v_{ij} is given in (1.56) and z_{β} is $\left(1 - \frac{\beta}{2}\right)100\%$ of the standard normal distribution. Having obtained \hat{a} and $\hat{\alpha}$, the MLE of the reliability function can be computed as:

$$\hat{R}(t) = e^{1-\hat{a}t^{\hat{\alpha}}}. \quad (1.57)$$

Let us define a partial derivative vector for reliability $R(t)$ as:

$$v[R(t)] = \left(\frac{\partial R(t)}{\partial a} \quad \frac{\partial R(t)}{\partial \alpha} \right)$$

Then the variance of $R(t)$ can be obtained as:

$$\text{Var}[R(t)] = v[R(t)]V(v[R(t)])^T,$$

where V is given in (1.56).

One can approximately obtain the $(1 - \beta)100\%$ confidence interval for $R(t)$ as

$$\left[\hat{R}(t) - z_{\beta}\sqrt{\text{Var}[R(t)]}, \hat{R}(t) + z_{\beta}\sqrt{\text{Var}[R(t)]} \right].$$

The MLE parameter estimations for the loglog distribution and its corresponding parameters, based on the dataset shown in Table 1.2, are:

$$\begin{aligned} \hat{\alpha} &= 1.1075, \quad \text{Var}(\hat{\alpha}) = 0.0162, \\ 95\% \text{CI for } \hat{\alpha} &: [0.8577, 1.3573]; \\ \hat{a} &= 1.0002, \quad \text{Var}(\hat{a}) = 2.782e^{-08}, \\ 95\% \text{CI for } a &: [0.9998, 1.0005]. \end{aligned}$$

Similarly, the C.I. for $R(t)$ can be obtained directly using (1.53).

1.4.3 Statistical Change-Point Estimation Methods

The change-point problem has been widely studied in reliability applications in areas such as biological sciences, survival analysis, and environmental statistics.

Assume that there is a sequence of random variables X_1, X_2, \dots, X_n , that represent the inter-failure times, and that an index change-point τ exists, such that $X_1, X_2, \dots, X_{\tau}$

have a common distribution F with a density function $f(t)$ and $X_{\tau+1}, X_{\tau+2}, \dots, X_n$ have a distribution G with a density function $g(t)$, where $F \neq G$. Consider the following assumptions:

1. There is a finite but unknown number of units N to be tested.
2. At the beginning, all of the units have the same lifetime distribution F . After τ failures are observed, the remaining $(N - \tau)$ items have the distribution G . The change-point τ is assumed unknown.
3. The sequence $\{X_1, X_2, \dots, X_\tau\}$ is statistically independent of the sequence $\{X_{\tau+1}, X_{\tau+2}, \dots, X_n\}$.
4. The lifetime test is performed according to the Type II censoring approach, in which the number of failures n is predetermined.

Note that the total number of units to put up for testing N can be determined in advance in hardware reliability testing. However, in software reliability testing, the parameter N can be defined as the initial number of faults in the software, and it can be considered to be an unknown parameter. Let T_1, T_2, \dots, T_n be the arrival times for sequential failures. Then

$$\begin{aligned} T_1 &= X_1, \\ T_2 &= X_1 + X_2, \\ &\vdots \\ T_n &= X_1 + X_2 + \dots + X_n. \end{aligned} \quad (1.58)$$

The failure times T_1, T_2, \dots, T_τ are the first τ order statistics of a sample of size N from the distribution F . The failure times $T_{\tau+1}, T_{\tau+2}, \dots, T_n$ are the first $(n - \tau)$ order statistics of a sample of size $(N - \tau)$ from the distribution G .

Example 1.20 The Weibull change-point model of the lifetime distributions F and G with parameters (λ_1, β_1) and (λ_2, β_2) , respectively, can be expressed as:

$$F(t) = 1 - \exp(-\lambda_1 t^{\beta_1}), \quad (1.59)$$

$$G(t) = 1 - \exp(-\lambda_2 t^{\beta_2}). \quad (1.60)$$

Assume that the distributions belong to parametric families $\{F(t|\theta_1), \theta_1 \in \Theta_1\}$ and $\{G(t|\theta_2), \theta_2 \in \Theta_2\}$. Assume that T_1, T_2, \dots, T_τ are the first τ order statistics of a sample of size N from the distribution $\{F(t|\theta_1), \theta_1 \in \Theta_1\}$ and that $T_{\tau+1}, T_{\tau+2}, \dots, T_n$ are the first $(n - \tau)$ order statistics of a sample of size $(N - \tau)$ from the distribution $\{G(t|\theta_2), \theta_2 \in \Theta_2\}$, where N is unknown. The log likelihood function can be expressed as follows [6]:

$$\begin{aligned} L(\tau, N, \theta_1, \theta_2 | T_1, T_2, \dots, T_n) &= \sum_{i=1}^{\tau} (N - i + 1) + \sum_{i=1}^{\tau} f(T_i | \theta_1) \\ &+ \sum_{i=\tau+1}^n g(T_i | \theta_2) + (N - \tau) \log [1 - F(T_\tau | \theta_1)] \\ &+ (N - n) \log [1 - G(T_n | \theta_2)]. \end{aligned} \quad (1.61)$$

If the parameter N is known in which where hardware reliability is commonly considered, for example, then the likelihood function is given by

$$\begin{aligned} L(\tau, N, \theta_1, \theta_2 | T_1, T_2, \dots, T_n) &+ \sum_{i=1}^{\tau} f(T_i | \theta_1) + \sum_{i=\tau+1}^n g(T_i | \theta_2) \\ &+ (N - \tau) \log [1 - F(T_\tau | \theta_1)] + (N - n) \\ &\log [1 - G(T_n | \theta_2)]. \end{aligned}$$

The maximum likelihood estimator (MLE) of the change-point value $\hat{\tau}$ and $(\hat{N}, \hat{\theta}_1, \hat{\theta}_2)$ can be obtained by taking partial derivatives of the log likelihood function in (1.61) with respect to the unknown parameters that maximize the function. It should be noted that there is no closed form for $\hat{\tau}$, but it can be obtained by calculating the log likelihood for each possible value of τ , $1 \leq \tau \leq (n - 1)$, and selecting the value that maximizes the log likelihood function.

Application 2: A Software Model with a Change Point

In this application, we examine the case where the sample size N is unknown. Consider a software reliability model developed by *Jelinski* and *Moranda* in 1972, often called the Jelinski–Moranda model. The assumptions of the model are as follows:

1. There are N initial faults in the program.
2. A detected fault is removed instantaneously and no new fault is introduced.
3. Each failure caused by a fault occurs independently and randomly in time according to an exponential distribution.
4. The functions F and G are exponential distributions with failure rate parameters λ_1 and λ_2 , respectively.

Based on these assumptions, the inter-failure times X_1, X_2, \dots, X_n are independently exponentially distributed. Specifically, $X_i = T_i - T_{i-1}$, $i = 1, 2, \dots, \tau$, are exponentially distributed with parameter $\lambda_1(N - i + 1)$, where λ_1 is the initial fault detection rate of the first τ failures, and $X_j = T_j - T_{j-1}$, $j = \tau + 1, \tau + 2, \dots, n$ are exponentially distributed with parameter $\lambda_2(N - \tau - j + 1)$, where λ_2 is the fault detection rate of the first $n - \tau$ failures. If $\lambda_1 = \lambda_2$,

it means that each fault removal is the same and that the change-point model becomes the Jelinski–Moranda software reliability model [7].

The MLEs of the parameters $(\tau, N, \lambda_1, \lambda_2)$ can be obtained by solving the following equations simultaneously:

$$\hat{\lambda}_1 = \frac{\tau}{\sum_{i=1}^{\tau} (\hat{N} - i + 1) x_i}, \quad (1.62)$$

$$\hat{\lambda}_2 = \frac{(n - \tau)}{\sum_{i=\tau+1}^n (\hat{N} - i + 1) x_i}, \quad (1.63)$$

$$\sum_{i=1}^n \frac{1}{(\hat{N} - i + 1)} = \hat{\lambda}_1 \sum_{i=1}^{\tau} x_i + \hat{\lambda}_2 \sum_{i=\tau+1}^n x_i. \quad (1.64)$$

To illustrate the model, we use the dataset shown in Table 1.3 to obtain the unknown parameters $(\tau, N, \lambda_1, \lambda_2)$ using (1.62)–(1.64). The data in Table 1.3 [8] shows the successive inter-failure times for a real-time command and control system. The table reads from left to right in rows, and the recorded times are execution times, in seconds. There are 136 failures in total. Figure 1.8 plots the log-likelihood function versus the number of failures. The MLEs of the parameters $(\tau, N, \lambda_1, \lambda_2)$ with one change point are given by

$$\hat{\tau} = 16, \hat{N} = 145, \hat{\lambda}_1 = 1.1 \times 10^{-4}, \\ \hat{\lambda}_2 = 0.31 \times 10^{-4}.$$

If we do not consider a change point in the model, the MLEs of the parameters N and λ , can be given as

$$\hat{N} = 142, \hat{\lambda} = 0.35 \times 10^{-4}.$$

From Fig. 1.8, it is clear that it is worth considering change points in reliability functions.

Table 1.3 Successive inter-failure times (in s) for a real-time command system

1.4.4 Goodness-of-Fit Techniques

The problem discussed here is one of comparing an observed sample distribution with a theoretical distribution. Practitioners often wonder how to test some hypothesis about the distribution of a population. If the test is concerned with the agreement between the distribution of a set of observed sample values and a theoretical distribution, we call it a test of “goodness of fit.”

The basic question in validating distribution models is whether the shape of the fitted model corresponds to that of the data. To do that, we may just simply make a direct comparison of the observed data with what we expect to see from the fitted distribution model. Two common techniques that will be discussed are the χ^2 goodness-of-fit test and the Kolmogorov–Smirnov “ d ” test.

Chi-Squared Test

The chi-square test often requires large samples and is applied by comparing the observed frequency distribution of the sample to the expected value under the assumption of the distribution. More specifically, consider a large sample of size N . Let $a_0 < a_1 < \dots < a_k$ be the upper points of k subintervals of the frequency distribution. The following statistic

$$\chi^2 = \sum_{i=1}^k \left(\frac{x_i - \mu_i}{\sigma_i} \right)^2 \quad (1.65)$$

has a chi-squared (χ^2) distribution with k degrees of freedom. The procedure used for the chi-squared test is as follows:

1. Divide the sample data into mutually exclusive cells (normally 8–12) such that the range of the random variable is covered.
2. Determine the frequency, f_i , of sample observations in each cell.

3. Determine the theoretical frequency, F_i , for each cell (the area under density function between cell boundaries X_n – total sample size). Note that the theoretical frequency for each cell should be greater than 1. This step normally requires estimates for the population parameters, which can be obtained from the sample data.
4. Form the statistic

$$A = \sum_{i=1}^k \frac{(f_i - F_i)^2}{F_i} \tag{1.66}$$

5. From the χ^2 tables, choose a value of χ^2 with the desired significance level and degrees of freedom ($= k - 1 - r$, where r is the number of population parameters estimated).
6. Reject the hypothesis that the sample distribution is the same as the theoretical distribution if

$$A > \chi^2_{1-\alpha, k-1-r}$$

where α is called the significance level.

Example 1.21 Given the data in Table 1.4, can the data be represented by the exponential distribution with a significance level of α ?

From the above calculation, $\hat{\lambda} = 0.00263$, $R_i = e^{-\lambda t_i}$ and $Q_i = 1 - R_i$. Given that the significance level α is 0.1, from (1.66) we obtain

$$A = \sum_{i=1}^{11} \frac{(f_i - F_i)^2}{F_i} = 6.165.$$

From Table 1.11 in Appendix A, the value of χ^2 with nine degrees of freedom and $\alpha = 0.1$ is 14.68; that is,

$$\chi^2_{9,0.1} = 14.68.$$

Since $S = 6.165 < 14.68$, we would not reject the hypothesis of an exponential with $\lambda = 0.00263$.

Table 1.4 Sample observations for each cell boundary

Cell boundaries	f_i	$Q_i = (1 - R_i) 60$	$F_i = Q_i - Q_{i-1}$
0–100	10	13.86	13.86
100–200	9	24.52	10.66
200–300	8	32.71	8.19
300–400	8	39.01	6.30
400–500	7	43.86	4.85
500–600	6	47.59	3.73
600–700	4	50.45	2.86
700–800	4	52.66	2.21
800–900	2	54.35	1.69
900–1000	1	55.66	1.31
>1000	1	58.83	2.17

If in the statistic

$$A = \sum_{i=1}^k \left(\frac{f_i - F_i}{\sqrt{F_i}} \right)^2, \quad \left(\frac{f_i - F_i}{\sqrt{F_i}} \right)$$

is approximately normal for large samples, then A also has a χ^2 distribution. This is the basis for the goodness-of-fit test.

Kolmogorov–Smirnov (KS) Test

Both the χ^2 and “KS” tests are nonparametric tests. However, the χ^2 test largely assumes sample normality of the observed frequency about its mean, while “KS” assumes only a continuous distribution. Let $X_1 \leq X_2 \leq X_3 \leq \dots \leq X_n$ denote the ordered sample values. Define the observed distribution function, $F_n(x)$, as:

$$F_n(X) = \begin{cases} 0 & \text{for } x \leq x_1 \\ \frac{i}{n} & \text{for } x_i < x \leq x_{i+1} \\ 1 & \text{for } x > x_n \end{cases}$$

Assume the testing hypothesis

$$H_0 : F(x) = F_0(x),$$

where $F_0(x)$ is a given continuous distribution and $F(x)$ is an unknown distribution. Let

$$d_n = \sup_{-\infty < x < \infty} |F_n(x) - F_0(x)| \tag{1.67}$$

Since $F_0(x)$ is a continuous increasing function, we can evaluate $|F_n(x) - F_0(x)|$ for each n . If $d_n \leq d_{n,\alpha}$, then we will not reject the hypothesis H_0 ; otherwise, we will reject it when $d_n > d_{n,\alpha}$. The value of $d_{n,\alpha}$ can be found in Table 1.7 in Appendix A, where n is the sample size and α is the level of significance.

Example 1.22 Determine whether the following failure data (in days) of a system:

10.50, 1.75, 6.10, 1.30, 15.00, 8.20, 0.50, 20.50, 11.05, 4.60

be represented as a sample from an exponential population distribution with constant rate $\lambda = 0.20$ failures per day at the ($\alpha =$) 5% level of the significance using KS test.

Under the hypothesis that failure times are exponential distribution, so the theoretical pdf and cdf are given by:

$$f(x) = 0.2e^{-0.2x} \quad \text{for } x > 0$$

and

$$F(x) = 1 - e^{-0.2x}$$

Table 1.5 The observed and theoretical cdf values

Failure time x	$F_n(x)$	$F_0(x)$	$ F_n(x) - F_0(x) $
0.50	0.10	0.0952	0.0048
1.30	0.20	0.2289	0.0289
1.75	0.30	0.2953	0.0047
4.60	0.40	0.6015	0.2015
6.10	0.50	0.7048	0.2048
8.20	0.60	0.8061	0.2061
10.50	0.70	0.8776	0.1776
11.05	0.80	0.8903	0.0903
15.00	0.90	0.9503	0.0503
20.50	1.00	0.9835	0.0165

respectively. From Table 1.5, the maximum difference D_n is 0.2061.

From Table 1.7 in Appendix A, here $n = 10$ and $\alpha = 5\%$, then we obtain the critical value $d_{n,\alpha} = 0.409$. Since $D_n \leq d_{n,\alpha}$, therefore the null hypothesis, that failure times are exponentially distributed with constant rate $\lambda = 0.20$, cannot be rejected at the 5% level of significance.

1.4.5 Least Squares Estimation

One common approach to curve fitting, which is unrelated to normal regression theory and MLE estimates of coefficients but uses identical formulae, is called the method of least squares. This method is based on minimizing the sum of the squared distances from the best fit line to the actual data points. It just so happens that finding the MLEs for the coefficients of the regression line also involves this sum of squared distances.

Normal Linear Regression

Regression considers the distribution of one variable as a function of another when the other variable is fixed at each of several levels. In the normal bivariate case, consider the distribution of X as a function of given values of Z where $X = \alpha + \beta Z$. Consider a sample of n observations (x_i, z_i) . We can obtain the likelihood and its natural log for the normal distribution as follows:

$$\begin{aligned}
 f(x_1, x_2, \dots, x_n) &= \frac{1}{2\pi^{n/2}} \left(\frac{1}{\sigma^2} \right)^{n/2} e^{-\frac{1}{2\sigma^2} \sum_{i=1}^n (x_i - \alpha - \beta z_i)^2} \\
 \ln L &= -\frac{n}{2} \log 2\pi - \frac{n}{2} \log \sigma^2 \\
 &\quad - \frac{1}{2\sigma^2} \sum_{i=1}^n (x_i - \alpha - \beta z_i)^2.
 \end{aligned}$$

Taking the partial derivatives of $\ln L$ with respect to α and β , we have

$$\begin{aligned}
 \frac{\partial \ln L}{\partial \alpha} &= \sum_{i=1}^n (x_i - \alpha - \beta z_i) = 0, \\
 \frac{\partial \ln L}{\partial \beta} &= \sum_{i=1}^n z_i (x_i - \alpha - \beta z_i) = 0.
 \end{aligned}$$

The solutions to the simultaneous equations are

$$\begin{aligned}
 \hat{\alpha} &= \bar{X} - \beta \bar{Z}, \\
 \hat{\beta} &= \frac{\sum_{i=1}^n (X_i - \bar{X})(Z_i - \bar{Z})}{\sum_{i=1}^n (Z_i - \bar{Z})^2}. \tag{1.68}
 \end{aligned}$$

Least Squared Straight Line Fit

Assume that there is a linear relationship between X and $E(Y | x)$; that is, that $E(Y | x) = a + bx$. Given a set of data, we want to estimate the coefficients a and b that minimize the sum of the squares. Suppose that the desired polynomial, $p(x)$, is written as

$$\sum_{i=0}^m a_i x^i,$$

where a_0, a_1, \dots, a_m are to be determined. The method of least squares chooses as ‘‘solutions’’ those coefficients that minimize the sum of the squares of the vertical (y) distances from the data points to the presumed polynomial. This means that the ‘‘best’’ polynomial is the one whose coefficients minimize the function L , where

$$L = \sum_{i=1}^n [y_i - p(x_i)]^2.$$

Here, we will only treat the linear case, where $X = \alpha + \beta Z$. The procedure for higher-order polynomials is identical, although the computations become much more tedious. Assume a straight line of the form $X = \alpha + \beta Z$. For each observation (x_i, z_i) : $X_i = \alpha + \beta Z_i$, let

$$Q = \sum_{i=1}^n (x_i - \alpha - \beta z_i)^2.$$

We wish to find estimates for α and β that minimize Q . Taking partial differentials, we obtain

$$\begin{aligned}
 \frac{\partial Q}{\partial \alpha} &= -2 \sum_{i=1}^n (x_i - \alpha - \beta z_i) = 0, \\
 \frac{\partial Q}{\partial \beta} &= -2 \sum_{i=1}^n z_i (x_i - \alpha - \beta z_i) = 0.
 \end{aligned}$$

Note that the above are the same as the MLE equations for normal linear regression. Therefore, we obtain the following results:

$$\hat{\alpha} = \bar{x} - \beta \bar{z},$$

$$\hat{\beta} = \frac{\sum_{i=1}^n (x_i - \bar{x})(z_i - \bar{z})}{\sum_{i=1}^n (z_i - \bar{z})^2}. \quad (1.69)$$

The above gives an example of least squares applied to a linear case. The same pattern applies for higher-order curves with 3, 4, and so on solutions.

1.4.6 Interval Estimation

A point estimate is sometimes inadequate at providing an estimate for an unknown parameter, since it rarely coincides with the true value of the parameter. An alternative way is to obtain a confidence interval estimation of the form $[\theta_L, \theta_U]$ where θ_L is the lower bound and θ_U is the upper bound.

Point estimates can become more useful if some measure of their error is given; in other words, if some kind of tolerance for their high and low values is given. Thus, if an interval estimator is $[\theta_L, \theta_U]$ with a given probability $(1 - \alpha)$, then θ_L and θ_U are called the 100 $(1 - \alpha)\%$ confidence limits for the given parameter θ , and the interval between them is a 100 $(1 - \alpha)\%$ confidence interval, while $(1 - \alpha)$ is called the confidence coefficient.

Confidence Intervals for Normal Parameters

The one-dimensional normal distribution has two parameters: mean μ and variance σ^2 . The simultaneous employment of both parameters in a confidence statement concerning percentages of the population will be discussed in the next section on tolerance limits. Hence, individual confidence statements about μ and σ^2 will be discussed here.

Confidence Limits for a Mean μ with a Known σ^2

It is easy to show that the statistic

$$Z = \frac{\bar{X} - \mu}{\sigma/\sqrt{n}}$$

is a standard normal distribution, where

$$\bar{X} = \frac{1}{n} \sum_{i=1}^n X_i.$$

Hence, a 100 $(1 - \alpha)\%$ confidence interval for the mean μ is given by

$$P \left[\bar{X} - Z_{\frac{\alpha}{2}} \frac{\sigma}{\sqrt{n}} < \mu < \bar{X} + Z_{\frac{\alpha}{2}} \frac{\sigma}{\sqrt{n}} \right] = 1 - \alpha. \quad (1.70)$$

In other words,

$$\mu_L = \bar{X} - Z_{\frac{\alpha}{2}} \frac{\sigma}{\sqrt{n}} \quad \text{and} \quad \mu_U = \bar{X} + Z_{\frac{\alpha}{2}} \frac{\sigma}{\sqrt{n}}.$$

Example 1.23 Draw a sample of size 4 from a normal distribution with a known variance = 9, say $x_1 = 2$, $x_2 = 3$, $x_3 = 5$, and $x_4 = 2$. Determine the location of the true mean (μ). The sample mean can be calculated as

$$\bar{x} = \frac{\sum_{i=1}^n x_i}{n} = \frac{2 + 3 + 5 + 2}{4} = 3.$$

Assuming that $\alpha = 0.05$ and, from the standard normal distribution (Table 1.8 in Appendix A), $Z_{0.025} = 1.96$, then we obtain

$$P \left[3 - 1.96 \frac{3}{\sqrt{4}} < \mu < 3 + 1.96 \frac{3}{\sqrt{4}} \right] = 0.95,$$

$$P [0.06 < \mu < 5.94] = 0.95.$$

This example shows that there is a 95% probability that the true mean is somewhere between 0.06 and 5.94. Now, μ is a fixed parameter and does not vary, so how do we interpret the probability? If samples of size 4 were to be repeatedly drawn, a different set of limits would be constructed each time. If this is the case, the interval becomes the random variable and the interpretation is that, for 95% of the time, the interval constructed in this way will contain the true (fixed) parameter.

Confidence Limits for a Mean μ with an Unknown σ^2

Let

$$S = \sqrt{\frac{1}{n-1} \sum_{i=1}^n (X_i - \bar{X})^2}. \quad (1.71)$$

It can be shown that the statistic

$$T = \frac{\bar{X} - \mu}{\frac{S}{\sqrt{n}}}$$

has a t distribution with $(n - 1)$ degrees of freedom (see Table 1.9 in Appendix A). Thus, for a given sample mean and sample standard deviation, we obtain

$$P [|T| < t_{\frac{\alpha}{2}, n-1}] = 1 - \alpha.$$

Hence, a 100 $(1 - \alpha)\%$ confidence interval for the mean μ is given by

$$P \left[\bar{X} - t_{\frac{\alpha}{2}, n-1} \frac{S}{\sqrt{n}} < \mu < \bar{X} + t_{\frac{\alpha}{2}, n-1} \frac{S}{\sqrt{n}} \right] = 1 - \alpha. \quad (1.72)$$

Example 1.24 The variability of a new product was investigated. An experiment was run using a sample of size $n = 25$; the sample mean was found to be $\bar{X} = 50$ and the sample variance $S^2 = 16$. From Table 1.9 in Appendix A, $t_{\frac{\alpha}{2}, n-1} = t_{0.025, 24} = 2.064$. The 95% confidence limit for μ is given by

$$P \left[50 - 2.064 \sqrt{\frac{16}{25}} < \mu < 50 + 2.064 \sqrt{\frac{16}{25}} \right] = 0.95, \\ P [48.349 < \mu < 51.651] = 0.95.$$

Note that, for one-sided limits, one should choose t_α , or $t_{1-\alpha}$.

Confidence Limits on σ^2

Note that $n\hat{\sigma}^2/\sigma^2$ has a χ^2 distribution with $(n-1)$ degrees of freedom. Correcting for the bias in $\hat{\sigma}^2$, it is clear that $(n-1)\hat{\sigma}^2/\sigma^2$ has this same distribution. Hence,

$$P \left[\chi_{\frac{\alpha}{2}, n-1}^2 < \frac{(n-1)S^2}{\sigma^2} < \chi_{1-\frac{\alpha}{2}, n-1}^2 \right] = 1 - \alpha$$

or

$$P \left[\frac{\sum (x_i - \bar{x})^2}{\chi_{1-\frac{\alpha}{2}, n-1}^2} < \sigma^2 < \frac{\sum (x_i - \bar{x})^2}{\chi_{\frac{\alpha}{2}, n-1}^2} \right] = 1 - \alpha. \quad (1.73)$$

Again, for one-sided limits, one should choose $\chi^2(\alpha)$ or $\chi^2(1-\alpha)$.

Confidence Intervals for Exponential Parameters

The pdf and cdf for the exponential distribution are

$$f(x) = \lambda e^{-\lambda x}, \quad x > 0, \lambda > 0$$

and

$$F(x) = 1 - e^{-\lambda x},$$

respectively. It was shown that the distribution of a function of the estimate

$$\hat{\lambda} = \frac{r}{\sum_{i=1}^n x_i + (n-r)x_r} \quad (1.74)$$

derived from a test of n identical components with common exponential failure density (failure rate λ), whose testing was stopped after the r th failure, was chi-squared (χ^2), i.e.,

$$2r \frac{\lambda}{\hat{\lambda}} = 2\lambda T \quad (\chi^2 \text{ distribution with } 2r \text{ degrees of freedom}),$$

where T is the total time accrued by all units. Knowing the distribution of $2\lambda T$ allows us to obtain the confidence limits on the parameter as:

$$P \left[\chi_{1-\frac{\alpha}{2}, 2r}^2 < 2\lambda T < \chi_{\frac{\alpha}{2}, 2r}^2 \right] = 1 - \alpha$$

or, equivalently, that

$$P \left[\frac{\chi_{1-\frac{\alpha}{2}, 2r}^2}{2T} < \lambda < \frac{\chi_{\frac{\alpha}{2}, 2r}^2}{2T} \right] = 1 - \alpha.$$

This means that in $(1-\alpha)\%$ of the samples of a given size n , the random interval

$$\left(\frac{\chi_{1-\frac{\alpha}{2}, 2r}^2}{2T}, \frac{\chi_{\frac{\alpha}{2}, 2r}^2}{2T} \right)$$

will contain a population of constant failure rate. For $\theta = 1/\lambda$ or the MTBF, the above confidence limits change to

$$P \left[\frac{2T}{\chi_{\frac{\alpha}{2}, 2r}^2} < \theta < \frac{2T}{\chi_{1-\frac{\alpha}{2}, 2r}^2} \right] = 1 - \alpha.$$

If testing is stopped at a fixed time rather than a fixed number of failures, the number of degrees of freedom in the lower limit increases by two. Table 1.6 shows the confidence limits for θ , the mean of the exponential density.

Confidence Intervals for Binomial Parameters

Consider a sequence of n Bernoulli trials with k successes and $(n-k)$ failures. We now determine one-sided upper and lower and two-sided limits on the parameter p , the probability of success. For the lower limit, the binomial sum is set up such that the probability of k or more successes with a true p as low as p_L is only $\alpha/2$. This means that the probability of k or more successes with a true p higher than p_L is $(1 - \frac{\alpha}{2})$, such that

Table 1.6 Confidence limits for θ

Confidence limits	Fixed number of failures	Fixed time
One-sided lower limit	$\frac{2T}{\chi_{\alpha, 2r}^2}$	$\frac{2T}{\chi_{\alpha, 2r+2}^2}$
One-sided upper limit	$\frac{2T}{\chi_{1-\alpha, 2r}^2}$	$\frac{2T}{\chi_{1-\alpha, 2r}^2}$
Two-sided limits	$\frac{2T}{\chi_{\alpha/2, 2r}^2}, \frac{2T}{\chi_{1-\alpha/2, 2r}^2}$	$\frac{2T}{\chi_{\alpha/2, 2r+2}^2}, \frac{2T}{\chi_{1-\alpha/2, 2r}^2}$

$$\sum_{i=k}^n \binom{n}{i} p_L^i (1-p_L)^{n-i} = \frac{\alpha}{2}.$$

Similarly, the binomial sum for the upper limit is

$$\sum_{i=k}^n \binom{n}{i} p_U^i (1-p_U)^{n-i} = \frac{\alpha}{2}$$

or, equivalently,

$$\sum_{i=0}^{k-1} \binom{n}{i} p_U^i (1-p_U)^{n-i} = \frac{\alpha}{2}.$$

Solving for p_L and p_U in the above equations,

$$P[p_L < p < p_U] = 1 - \alpha.$$

For one-sided limits, merely change $\alpha/2$ to α .

Example 1.25 Given $n = 100$ with 25 successes, and 75 failures, an 80% two-sided confidence limit on p can be obtained as follows:

$$\begin{aligned} \sum_{i=25}^{100} \binom{100}{i} p_L^i (1-p_L)^{100-i} &= 0.10, \\ \sum_{i=0}^{24} \binom{100}{i} p_U^i (1-p_U)^{100-i} &= 0.10. \end{aligned}$$

Solving the above two equations simultaneously, we obtain

$$\begin{aligned} p_L &\approx 0.194 \text{ and } p_U \approx 0.313, \\ P[0.194 < p < 0.313] &= 0.80. \end{aligned}$$

Continuing with Example 1.25 above, we now find an 80% one-sided confidence limit on p .

We start by setting the top equation to 0.20 and solving for p_L . It is then easy to obtain $p_L = 0.211$ and $P[p > 0.211] = 0.80$.

Let us now define $\bar{p} = k/n$, the number of successes divided by the number of trials. For large values of n and if $np > 5$ and $n(1-p) > 5$, and from the central limit theorem [9], the statistic

$$Z = \frac{(\bar{p} - p)}{\sqrt{\frac{\bar{p}(1-\bar{p})}{n}}}$$

approximates to the standard normal distribution. Hence

$$P[-z_{\frac{\alpha}{2}} < Z < z_{\frac{\alpha}{2}}] = 1 - \alpha.$$

Then

$$\begin{aligned} P\left[\bar{p} - z_{\frac{\alpha}{2}} \sqrt{\frac{\bar{p}(1-\bar{p})}{n}} < p \right. \\ \left. < \bar{p} + z_{\frac{\alpha}{2}} \sqrt{\frac{\bar{p}(1-\bar{p})}{n}}\right] = 1 - \alpha. \end{aligned}$$

Example 1.26 Find the two-sided confidence limit for $n = 900$, $k = 180$, and $\alpha = 0.05$. Then we obtain $p = 180/900 = 0.2$ and

$$\begin{aligned} P\left[0.2 - 1.96 \sqrt{\frac{0.2(0.8)}{900}} < p \right. \\ \left. < 0.2 + 1.96 \sqrt{\frac{0.2(0.8)}{900}}\right] = 0.95, \\ P[0.174 < p < 0.226] &= 0.95. \end{aligned}$$

Confidence Intervals for Poisson Parameters

Limits for the Poisson parameters are completely analogous to those for the binomial distribution except that the sample space is denumerable instead of finite. The lower and upper limits can be solved simultaneously in the following equations:

$$\begin{aligned} \sum_{i=k}^{\infty} \frac{\lambda_L^i e^{-\lambda_L}}{i!} &= \frac{\alpha}{2}, \\ \sum_{i=k}^{\infty} \frac{\lambda_U^i e^{-\lambda_U}}{i!} &= 1 - \frac{\alpha}{2}, \end{aligned}$$

or, equivalently,

$$\begin{aligned} \sum_{i=k}^{\infty} \frac{\lambda_L^i e^{-\lambda_L}}{i!} &= \frac{\alpha}{2}, \\ \sum_{i=0}^{k-1} \frac{\lambda_U^i e^{-\lambda_U}}{i!} &= \frac{\alpha}{2}. \end{aligned}$$

The one-sided limits are constructed in the same way as for binomial limits.

1.4.7 Nonparametric Tolerance Limits

Nonparametric tolerance limits are based on the smallest and largest observation in the sample, designated X_S and X_L , respectively. Due to their nonparametric nature, these limits are quite insensitive, and obtaining precisions similar to the parametric methods necessitates much larger samples. An interesting question here is to determine the sample size required to include at least 100 $(l - \alpha)\%$ of the population between X_S and X_L with a given probability y .

For two-sided tolerance limits, if $(1 - \alpha)$ is the minimum proportion of the population contained between the largest

observation X_L and the smallest observation X_S with a confidence $(1 - \gamma)$, then it can be shown that

$$n(1 - \alpha)^{n-1} - (n - 1)(1 - \alpha)^n = \gamma.$$

Therefore, the number of observations required is given by

$$n = \left(\frac{(2 - \alpha)}{4\alpha} \chi_{1-\gamma,4}^2 + \frac{1}{2} \right) + 1, \quad (1.75)$$

where a value of $\chi_{1-\gamma,4}^2$ is given in Table 1.11 in Appendix A.

Example 1.27 Determine the tolerance limits that include at least 90% of the population with probability 0.95. Here,

$$\alpha = 0.1, \quad \gamma = 0.95 \quad \text{and} \quad \chi_{0.05,4}^2 = 9.488.$$

Therefore, a sample of size

$$n = \left[\frac{(2 - 0.1)}{4(0.1)} (9.488) + \frac{1}{2} \right] + 1 = 46$$

is required. For a one-sided tolerance limit, the number of observations required is given by

$$n = \left(\frac{\log(1 - \gamma)}{\log(1 - \alpha)} \right) + 1.$$

Example 1.28 As in Example 1.27, we wish to find a lower tolerance limit; that is, the number of observations required such that the probability is 0.95 that at least 90% of the population will exceed X_S . This is given by

$$n = \left(\frac{\log(1 - 0.95)}{\log(1 - 0.1)} \right) + 1 = 30.$$

One can easily generate a table containing the sample size required to include a given percentage of the population between X_S and X_L with a given confidence, or the sample size required to include a given percentage of the population above or below X_S or X_L , respectively.

1.4.8 Sequential Sampling

A sequential sampling scheme is one in which items are drawn one at a time and the results at any stage determine whether sampling or testing should stop. Thus, any sampling procedure for which the number of observations is a random variable can be regarded as sequential sampling. Sequential tests derive their name from the fact that the sample size is not determined in advance, but allowed to “float” with a decision (accept, reject, or continue test) after each trial or data point.

In general, let us consider the hypothesis

$$H_0 : f(x) = f_0(x) \quad \text{versus} \quad H_1 : f(x) = f_1(x).$$

For an observational test, say X_1 , if $X_1 \leq A$, then we will accept the testing hypothesis [$H_0: f(x) = f_0(x)$]; if $X_1 \geq A$ we will reject H_0 and accept $H_1: f(x) = f_1(x)$. Otherwise, we will continue to perform at least one more test. The interval $X_1 \leq A$ is called the acceptance region. The interval $X_1 \geq A$ is called the rejection or critical region.

A “good” test is one that makes the α and β errors as small as possible where

$$P \{\text{Type I error}\} = P \{\text{Reject } H_0 | H_0 \text{ is True}\} = \alpha$$

$$P \{\text{Type II error}\} = P \{\text{Accept } H_0 | H_0 \text{ is False}\} = \beta$$

However, there is not much freedom to do this without increasing the sample size. A common procedure is to fix the β error and then choose a critical region to minimize the error or to maximize the “power” (power = $1 - \beta$) of the test, or to choose the critical region so as to equalize the α and β errors to reasonable levels.

One criterion (similar to the MLE) used to construct tests is called the “probability ratio,” which is the ratio of the sample densities under H_1/H_0 . Consider the ratio of probabilities

$$\lambda_m = \frac{\prod_{i=1}^n f_1(x_i)}{\prod_{i=1}^n f_0(x_i)} > k. \quad (1.76)$$

Here, x_1, x_2, \dots, x_n are n independent random observations and k is chosen to give the desired a error.

Recall from the MLE discussion in Sect. 1.4.1 that $f_1(x_1), f_1(x_2), \dots, f_1(x_n)$ are maximized under H_1 when the parameter(s), e.g., $\theta = \theta_1$ and similarly $f_0(x_1), f_0(x_2), \dots, f_0(x_n)$ are maximized when $\theta = \theta_0$. Thus, the ratio will become large if the sample favors H_1 and will become small if the sample favors H_0 . Therefore, the test will be called a sequential probability ratio test if we

1. Stop sampling and reject H_0 as soon as $\lambda_m \geq A$
2. Stop sampling and accept H_0 as soon as $\lambda_m \leq B$
3. Continue sampling as long as $B < \lambda_m < A$, where $A > B$

The selection of A and B using the above test, as suggested by Wald (see [9]), can be determined as follows:

$$B = \frac{\beta}{1 - \alpha} \quad \text{and} \quad A = \frac{1 - \beta}{\alpha}$$

The bases for α and β are therefore:

$$P[\lambda_m > A | H_0] = \alpha$$

$$P[\lambda_m < A | H_1] = \beta$$

1.4.9 Bayesian Methods

The Bayesian approach to statistical inference is based on a theorem first presented by Thomas Bayes. To demonstrate the approach, let X have a pdf $f(x)$, which is dependent on θ . In the traditional statistical inference approach, θ is an unknown parameter, and hence is a constant. We now describe our prior supposition for the value of θ by a pdf of $h(\theta)$. This amounts to quantitatively assessing subjective judgment and should not be confused with the so-called objective probability assessment derived from the long-term frequency approach. Thus, θ will now essentially be treated as a random variable θ with a pdf of $h(\theta)$.

Consider a random sample X_1, X_2, \dots, X_n from $f(x)$ and define a statistic Y as a function of this random sample. Then there exists a conditional pdf $g(y | \theta)$ of Y for a given θ . The joint pdf for y and θ is

$$f(\theta, y) = h(\theta)g(y|\theta).$$

If θ is continuous, then

$$f_1(y) = \int_{\theta} h(\theta)g(y|\theta)d\theta$$

is the marginal pdf for the statistic y . Given the information y , the conditional pdf for θ is

$$k(\theta|y) = \frac{h(\theta)g(y|\theta)}{f_1(y)} \quad \text{for } f_1(y) > 0$$

$$= \frac{h(\theta)g(y|\theta)}{\int_{\theta} h(\theta)g(y|\theta)d\theta}$$

If θ is discrete, then

$$f_1(y) = \sum_k P(\theta_k)P(y|\theta_k)$$

and

$$P(\theta_i|y_i) = \frac{P(\theta_k)P(y_i|\theta_i)}{\sum_k P(\theta_k)P(y_j|\theta_k)}$$

where $P(\theta_j)$ is the prior probability of event θ_i and $P(\theta_j | y_j)$ is the posterior probability of event y_j given θ_i . This is simply a form of Bayes' theorem. Here, $h(\theta)$ is the prior pdf that expresses our belief about the value of θ before the data ($Y = y$) became available. Then $k(\theta | y)$ is the posterior pdf, given the data ($Y = y$).

Note that the difference in the shape of the prior pdf $h(\theta)$ compared to the posterior pdf $k(\theta | y)$ due to the information

is a result of the product of $g(y | \theta)$ and $h(\theta)$, because $f_1(y)$ is simply a normalization constant for a fixed y . The idea of reliability is to take "prior" data and combine it with current data to gain a better estimate or confidence interval or test than would be possible with either on their own. As more current data is acquired, the prior data is "washed out" [1].

1.5 Further Reading

The reader interested in a deeper understanding of advanced probability theory and stochastic processes should note the following citations, which refer to highly recommended books: [9–13].

Abstract

There has been an increased interest in developing generalized families of distributions by introducing additional shape parameters to a baseline cumulative distribution. This mechanism has proved to be useful to make the generated distributions more flexible especially for studying tail properties than existing distributions and for improving their goodness-of-fit statistics to the data under study. Let $G(x)$ be the cumulative distribution function (CDF) of a baseline distribution and $g(x) = dG(x)/dx$ be the associated probability density function (PDF). We present generalized families with one and two additional shape parameters by transforming the CDF $G(x)$ according to four

important generators. These families are important for modeling data in several engineering areas. Many special distributions in these families are discussed by Tahir and Nadarajah (An Acad Bras Cienc 87(2):539–568, 2015).

Keywords

Distribution theory · Extended distributions · Failure rate function · Repaired systems · Reliability studies · Survival analysis

2.1 Beta-G Family

Eugene et al. [6] defined the CDF of the beta-G family with two additional shape parameters $a > 0$ and $b > 0$ by

$$F_{\text{beta-G}}(x) = I_{G(x)}(a, b) = \frac{1}{B(a, b)} \int_0^{G(x)} w^{a-1} (1-w)^{b-1} dw, \quad x \in \mathbb{R}, \quad (2.1)$$

where $B(a, b) = \Gamma(a + b)/[\Gamma(a)\Gamma(b)]$ is the beta function, $\Gamma(\alpha) = \int_0^\infty w^{\alpha-1} e^{-w} dw$ is the gamma function, and $I_y(a, b) = B(a, b)^{-1} \int_0^y w^{a-1} (1-w)^{b-1} dw$ is the incomplete beta function ratio. The PDF corresponding to (2.1) has a very simple form

$$f_{\text{beta-G}}(x) = \frac{g(x)}{B(a, b)} G(x)^{a-1} \{1 - G(x)\}^{b-1}, \quad x \in \mathbb{R}. \quad (2.2)$$

The beta-G family has been receiving increased attention over the last years. More than 50 distributions were published in this family, the majority of them cited by Tahir and Nadarajah [22, Table 3].

The PDF $f_{\text{beta-G}}(x)$ will be most tractable when the functions $G(x)$ and $g(x)$ have simple analytic expressions. Except for some special choices for $G(x)$ in (2.1), the PDF (2.2) will be difficult to deal with in generality. If $g(x)$ is a symmetric distribution around zero, then $f_{\text{beta-G}}(x)$ will also be a

symmetric distribution when $a = b$. We can generate observations from the beta-G family using beta random variables and the quantile function (QF) of the baseline G distribution, say, $Q_G(u) = G^{-1}(u)$. In fact, if V has a beta distribution with parameters $a > 0$ and $b > 0$, then $X = Q_G(V)$ follows the PDF (2.2).

The CDF of the beta-Weibull (beta-W) distribution (with four positive parameters) is defined by taking the Weibull CDF $G_{\lambda,c}(x) = 1 - \exp\{-(\lambda x)^c\}$ with shape parameter $c > 0$ and scale parameter $\lambda > 0$ in Eq. (2.1). The PDF and the hazard rate function (HRF) of the beta-W distribution are (using $I_x(a, b) = I_{1-x}(b, a)$)

$$f_{\text{beta-W}}(x) = \frac{c\lambda^c}{B(a, b)} x^{c-1} \exp\{-b(\lambda x)^c\} \times [1 - \exp\{-(\lambda x)^c\}]^{a-1}, \quad x > 0,$$

and

$$\tau_{\text{beta-W}}(x) = \frac{c\lambda^c x^{c-1} \exp\{-b(\lambda x)^c\} [1 - \exp\{-(\lambda x)^c\}]^{a-1}}{B(a, b) I_{\exp\{-(\lambda x)^c\}}(b, a)}, \quad x > 0,$$

respectively.

Birnbaum and Saunders [3] introduced a probability distribution which is commonly used in reliability studies. The CDF of the beta-Birnbaum-Saunders (beta-BS) distribution is given by $F(x) = I_{\Phi(v)}(a, b)$, for $x > 0$, where $v = v(x; \alpha, \beta) = \alpha^{-1} \rho(x/\beta)$, $\rho(z) = z^{1/2} - z^{-1/2}$, $\Phi(\cdot)$ is the standard normal CDF, and $\alpha > 0$ and $\beta > 0$. The corresponding PDF is

$$f_{\text{beta-BS}}(x) = \frac{\kappa(\alpha, \beta) x^{-3/2} (x + \beta) \exp\{-\tau(x/\beta)/(2\alpha^2)\}}{B(a, b) \Phi(v)^{1-a} [1 - \Phi(v)]^{1-b}}, \quad x > 0,$$

where $\kappa(\alpha, \beta) = \exp(\alpha^{-2})/(2\alpha\sqrt{2\pi\beta})$ and $\tau(z) = z + z^{-1}$. For $a = b = 1$, the beta-BS becomes equal to the BS distribution.

Finally, another example is the beta-log-logistic (beta-LL) distribution (see, e.g., Lemonte [9]), whose PDF with positive parameters a, b, α , and β is given by

$$f(x) = \frac{(\beta/\alpha)}{B(a, b)} \frac{(x/\alpha)^{a\beta-1}}{[1 + (x/\alpha)^\beta]^{a+b}}, \quad x > 0. \quad (2.3)$$

Evidently, the beta-LL density function does not involve any complicated function and can be easily computed from Eq. (2.3). The beta-LL distribution can be applied in survival analysis, hydrology, and economics, among others, as the LLog distribution and can be used to model reliability

problems. The beta-LL distribution allows for greater flexibility of its tails and can be widely applied in many areas.

The study of the PDF (2.3) is important since it also includes some special sub-models. The log-logistic (LLog) distribution arises as the basic exemplar when $a = b = 1$. The exponentiated LLog (ELLog) distribution corresponds to $b = 1$. Other special sub-model arises for $a = 1$ as the new Lehmann type II LLog (LeLLog) distribution. For a and b positive integers, the beta-LL density function becomes the density function of the a th order statistic from the LLog distribution in a sample of size $a + b - 1$. However, Eq. (2.3) can also alternatively be extended, when a and b are real non-integers, to define fractional LLog order statistics distributions.

2.2 Kumaraswamy-G Family

Cordeiro and de Castro [5] introduced the Kumaraswamy-G (“Kw-G” for short) family with CDF and PDF

$$F_{\text{Kw-G}}(x) = 1 - \{1 - G(x)^a\}^b, \quad x \in \mathbb{R}, \quad (2.4)$$

and

$$f_{\text{Kw-G}}(x) = a b g(x) G(x)^{a-1} \{1 - G(x)^a\}^{b-1}, \quad x \in \mathbb{R}, \quad (2.5)$$

respectively. The Kw-G family has the same parameters of the baseline G distribution plus two extra shape parameters $a > 0$ and $b > 0$. Each new Kw-G distribution can be constructed from a specified G distribution. For $a = b = 1$, the G distribution is a special model of the Kw-G family with a continuous crossover toward cases with different shapes (e.g., a particular combination of skewness and kurtosis). One major benefit of the Kw-G PDF (2.5) is its ability of fitting skewed data that cannot be properly fitted by existing distributions. Further, this family allows for greater flexibility of its tails and can be widely applied in many areas of engineering. Tahir and Nadarajah [22, Table 5] described almost 25 published distributions belonging to the Kw-G family.

The simulation from the Kw-G distribution is very easy. The QF corresponding to (2.4) is directly obtained from the QF associated with $G(x)$ by

$$Q_{\text{Kw-G}}(u) = F_{\text{Kw-G}}^{-1}(u) = Q_G \left\{ \left[1 - (1 - u)^{1/b} \right]^{1/a} \right\}, \quad u \in (0, 1). \quad (2.6)$$

Then, we can generate Kw-G variates by

$$X = Q_G \left\{ \left[1 - (1 - U)^{1/b} \right]^{1/a} \right\},$$

where U is a uniform variate on the unit interval $(0, 1)$.

We provide two examples of the Kw-G distributions. First, the Kw-Weibull PDF (for $x > 0$) follows from the Weibull CDF (with parameters $\lambda > 0$ and $c > 0$) introduced in Sect. 2.1. It has the form

$$f_{\text{Kw-W}}(x) = \frac{abc\beta^c x^{c-1} \exp\{-(\lambda x)^c\} [1 - \exp\{-(\lambda x)^c\}]^{a-1}}{1 - [1 - \exp\{-(\lambda x)^c\}]^a}^{1-b}, \quad x > 0.$$

For $c = 1$, we obtain as a special model the Kw-exponential distribution. The exponentiated Weibull (EW), which is well suited for modeling bathtub failure rate lifetime data, is also a special case when $b = 1$.

Second, the Gumbel distribution is frequently used to model the distribution of the maximum (or the minimum) of a number of samples of various distributions. The Kw-Gumbel density function is defined from the Gumbel CDF $G(x) = 1 - \exp\{-\exp(-\frac{x-\mu}{\sigma})\}$ (for $x \in \mathbb{R}$) with location parameter $\mu > 0$ and scale parameter $\sigma > 0$, whose mean and variance are equal to $\mu - \gamma\sigma$ and $\pi^2\sigma^2/6$, respectively, and γ is Euler's constant ($\gamma \approx 0.57722$). It is given by

$$f_{\text{Kw-Gu}}(x) = \frac{ab \exp\{z - \exp(z)\} [1 - \exp\{-\exp(-z)\}]^{a-1}}{\sigma \{1 - [1 - \exp\{-\exp(-z)\}]^a\}^{1-b}},$$

where $z = (y - \mu)/\sigma$.

2.3 Gamma-G Family

Zografos and Balakrishnan [23] and Ristić and Balakrishnan [20] defined the gamma-G (Γ -G) family with an extra shape parameter $a > 0$ by the CDF (for $x \in \mathbb{R}$)

$$F_{\Gamma\text{-G}}(x) = \frac{\gamma(a, -\log[1 - G(x)])}{\Gamma(a)} = \frac{1}{\Gamma(a)} \int_0^{-\log[1 - G(x)]} t^{a-1} e^{-t} dt,$$

where $\gamma(a, z) = \int_0^z t^{a-1} e^{-t} dt$ is the incomplete gamma function. The PDF of the Γ -G family has the form

$$f_{\Gamma\text{-G}}(x) = \frac{1}{\Gamma(a)} \{-\log[1 - G(x)]\}^{a-1} g(x), \quad x \in \mathbb{R}. \quad (2.7)$$

Each new Γ -G distribution can be determined from a given baseline distribution. For $a = 1$, the G distribution is a basic exemplar of the Γ -G family.

Zografos and Balakrishnan [23] and Ristić and Balakrishnan [20] presented a physical motivation for the Γ -G family: if $X_{L(1)}, \dots, X_{L(n)}$ are lower record values from a sequence of independent random variables with common PDF $g(\cdot)$, then the PDF of the n th lower record value has the form (2.7). If Z is a gamma random variable with unit scale parameter and shape parameter $a > 0$, then $X = Q_G(1 - e^{-Z})$ has density (2.7). So, the Γ -G distribution is easily generated from the gamma distribution and the QF of G.

Let $G_{\lambda,c}(x)$ be the Weibull CDF (with scale parameter $\lambda > 0$ and shape parameter $c > 0$) given in Sect. 2.1. The Γ -Weibull (Γ -W) density function (for $x > 0$) can be expressed as

$$f_{\Gamma\text{-W}}(x) = \frac{c\lambda^{ca}}{\Gamma(a)} x^{ac-1} \exp\{-(\lambda x)^c\}. \quad (2.8)$$

Equation (2.8) extends some distributions previously discussed in the literature. In fact, it is identical to the generalized gamma distribution [21]. The Weibull distribution is a basic exemplar when $a = 1$, whereas the gamma distribution follows when $c = 1$. The half-normal distribution is obtained for $a = 3$ and $c = 2$. In addition, the log-normal distribution is a limiting special case when a tends to infinity.

The Γ -normal distribution is defined from (2.7) by taking $G(x)$ and $g(x)$ to be the CDF and PDF of the normal $N(\mu, \sigma^2)$ distribution. Its density function (for $x \in \mathbb{R}$) has the form

$$f_{\Gamma\text{-N}}(x) = \frac{1}{\Gamma(a)} \left\{ -\log \left[1 - \Phi\left(\frac{x-\mu}{\sigma}\right) \right] \right\}^{a-1} \phi\left(\frac{x-\mu}{\sigma}\right), \quad (2.9)$$

where $\mu \in \mathbb{R}$ is a location parameter, $\sigma > 0$ is a scale parameter, and $\phi(\cdot)$ is the standard normal density. For $\mu = 0$ and $\sigma = 1$, we obtain the standard Γ -normal distribution. Further, it coincides with the normal distribution when $a = 1$.

Consider the Gumbel distribution with location parameter $\mu \in \mathbb{R}$ and scale parameter $\sigma > 0$ as defined in Sect. 2.2. The Gumbel PDF is

$$g(x) = \frac{1}{\sigma} \exp \left\{ \left(\frac{x-\mu}{\sigma} \right) - \exp \left(\frac{x-\mu}{\sigma} \right) \right\}, \quad x \in \mathbb{R},$$

where $\mu \in \mathbb{R}$ and $\sigma > 0$. The Γ -Gumbel (Γ -Gu) PDF can be expressed as

$$f_{\Gamma\text{-Gu}}(x) = \frac{1}{\sigma\Gamma(a)} \exp \left\{ (a-1) \left(\frac{x-\mu}{\sigma} \right) + \left(\frac{x-\mu}{\sigma} \right) - \exp \left(\frac{x-\mu}{\sigma} \right) \right\}.$$

Clearly, the Gumbel distribution corresponds to $a = 1$.

2.4 Marshall and Olkin-G Family

Marshall and Olkin [11] pioneered a general method to expand a distribution by adding an extra shape parameter. The CDF of their family (for $\theta > 0$) is

$$\begin{aligned} F_{\text{MO-G}}(x) &= \frac{G(x)}{\theta + (1 - \theta)G(x)} \\ &= \frac{G(x)}{1 - (1 - \theta)[1 - G(x)]}, \quad x \in \mathbb{R}. \end{aligned} \quad (2.10)$$

The density function corresponding to (2.10) is

$$f_{\text{MO-G}}(x) = \frac{\theta g(x)}{[\theta + (1 - \theta)G(x)]^2}, \quad x \in \mathbb{R}. \quad (2.11)$$

For $\theta = 1$, $f_{\text{MO-G}}(x)$ is equal to $g(x)$, and, for different values of θ , $f_{\text{MO-G}}(x)$ can be more flexible than $g(x)$. The extra parameter θ is called ‘‘tilt parameter,’’ since the HRF of the MO-G family is shifted below ($\theta > 1$) or above ($0 < \theta < 1$) of the baseline HRF. Equation (2.11) provides a useful mechanism to generate new distributions from existing ones. The advantage of this approach for constructing new distributions lies in its flexibility to model both monotonic and non-monotonic HRFs even when the baseline HRF may be monotonic. Tahir and Nadarajah [22, Table 2] presented 30 distributions belonging to the MO-G family. Further, this family is easily generated from the baseline QF by $Q_{\text{MO-G}}(u) = Q_G(\theta u / [\theta u + 1 - u])$ for $u \in (0, 1)$.

Marshall and Olkin considered the exponential and Weibull distributions for the baseline G and derived some structural properties of the generated distributions. The special case that G is an exponential distribution refers to a two-parameter competitive model to the Weibull and gamma distributions. A simple interpretation of (2.10) can be given as follows. Let T_1, \dots, T_N be a sequence of independent and identically distributed (i.i.d.) random variables with survival function (SF) $\bar{G}(x) = 1 - G(x)$, and let N be a positive integer random variable independent of the T_i 's defined by the probability generating function (PGF) of a geometric distribution with parameter θ , say, $\tau(z; \theta) = \theta z [1 - (1 - \theta)z]^{-1}$. Then, the inverse of $\tau(z; \theta)$ becomes $\tau^{-1}(z; \theta) = \tau(z; \theta^{-1})$. We can verify that Eq. (2.10) comes from $1 - F_{\text{MO-G}}(x) = \tau(\bar{G}(x); \theta)$ for $0 < \theta < 1$ and $1 - F_{\text{MO-G}}(x) = \tau(\bar{G}(x); \theta^{-1})$ for $\theta > 1$. For both cases, $1 - F_{\text{MO-G}}(x)$ represents the SF of $\min\{T_1, \dots, T_N\}$, where N has PGF $\tau(z; \cdot)$ with probability parameters θ or θ^{-1} .

Nadarajah and Haghghi [14] introduced a two-parameter generalization of the exponential distribution as an alternative to the gamma and Weibull distributions with CDF (NH stands for the authors) $G_{\text{NH}}(x) = 1 - \exp[1 - (1 + \lambda x)^\alpha]$, $x \geq 0$, where $\lambda > 0$ is the scale parameter and $\alpha > 0$ is the shape parameter. The associated density is $g_{\text{NH}}(x) = \alpha \lambda (1 +$

$\lambda x)^{\alpha-1} \exp[1 - (1 + \lambda x)^\alpha]$, $x \geq 0$. The function $g_{\text{NH}}(x)$ is always monotonically decreasing with $g_{\text{NH}}(0) = \alpha \lambda$. These authors pointed out that $g_{\text{NH}}(x)$ has the attractive feature of always having the zero mode. They also showed that larger values of α will lead to faster decay of the upper tails. The SF and HRF are $S_{\text{NH}}(x) = \exp[1 - (1 + \lambda x)^\alpha]$ and $\tau_{\text{NH}}(x) = \alpha \lambda (1 + \lambda x)^{\alpha-1}$, respectively. Like the Weibull distribution, the SF and HRF of the NH distribution have closed-form expressions. Additionally, the HRF can be monotonically increasing for $\alpha > 1$ and monotonically decreasing for $\alpha < 1$. For $\alpha = 1$, the HRF is constant. So, the major weakness of the NH distribution is its inability to accommodate non-monotone HRFs (i.e., bathtub and unimodal shapes).

The MO-NH distribution was defined by Lemonte et al. [10] by combining the MO generator and the NH distribution. Its CDF is

$$F_{\text{MO-NH}}(x) = \frac{1 - \exp[1 - (1 + \lambda x)^\alpha]}{1 - (1 - \theta) \exp[1 - (1 + \lambda x)^\alpha]}, \quad x \geq 0, \quad (2.12)$$

where the parameters $\alpha > 0$ and $\beta > 0$ control the shapes of the distribution and the parameter $\lambda > 0$ is the scale parameter. Clearly, the MO-NH distribution is equal to the NH distribution when $\theta = 1$. For $\alpha = 1$, we obtain the MO-exponential (MO-E) distribution. The exponential distribution follows as a special model when $\alpha = \theta = 1$.

The MO-NH PDF follows by differentiating (2.12) as

$$f_{\text{MO-NH}}(x) = \alpha \theta \lambda \frac{(1 + \lambda x)^{\alpha-1} \exp[1 - (1 + \lambda x)^\alpha]}{[1 - (1 - \theta) \exp[1 - (1 + \lambda x)^\alpha]]^2}, \quad x \geq 0. \quad (2.13)$$

Equation (2.13) can take various forms depending on the values of the shape parameters α and θ . In particular, it can be a decreasing function, or it can be a skewed unimodal density. Additionally, the MO-NH density function can present some other interesting forms. In fact, this distribution is very versatile since the additional parameter θ has substantial effects on its skewness and kurtosis.

The MO-NH HRF can be constant, decreasing, increasing, unimodal, and bathtub-shaped. Further, it can also be decreasing-increasing-decreasing. The MO-NH distribution is a good alternative to many existing lifetime distributions in modeling real data due to the great flexibility of its HRF.

2.5 Linear Representations

Linear representations for the PDFs of the four families defined previously can be derived using the concept of exponentiated distributions. For an arbitrary baseline CDF $G(x)$, the exponentiated-G (exp-G) distribution with parameter $a > 0$ has CDF and PDF in the forms

$$\Pi_a(x) = G(x)^a \quad \text{and} \quad \pi_a(x) = a g(x) G(x)^{a-1},$$

respectively. The properties of exponentiated distributions have been studied by many authors in recent years; see [12] for exponentiated Weibull, [8] for exponentiated Pareto, [7] for exponentiated exponential, and [13] for exponentiated gamma distribution. Tahir and Nadarajah [22] cited almost 30s exponentiated distributions in their Table 2.1.

Linear representations for the four PDFs in terms of exp-G densities are important to determine their mathematical properties from those of the exp-G distributions. They can follow from the papers described below. For the beta-G density (2.2), [16] demonstrated that

$$f_{\text{beta-G}}(x) = \sum_{i=0}^{\infty} w_i^{\text{beta-G}} \pi_{a+i}(x),$$

where

$$w_i^{\text{beta-G}} = w_i^{\text{beta-G}}(a, b) = \frac{(-1)^i}{(a+i)B(a, b)} \binom{b-1}{i}.$$

Nadarajah et al. [17] determined a linear combination for the Kw-G density (2.5), namely,

$$f_{\text{Kw-G}}(x) = \sum_{i=0}^{\infty} w_i^{\text{Kw-G}} \pi_{(i+1)a}(x), \quad (2.14)$$

where

$$w_i^{\text{Kw-G}} = w_i^{\text{Kw-G}}(b) = \frac{(-1)^i b}{(i+1)} \binom{b-1}{i}.$$

The linear combination for the Γ -G density (2.7) was derived by Castellares and Lemonte [4] as

$$f_{\Gamma\text{-G}}(x) = \sum_{i=0}^{\infty} w_i^{\Gamma\text{-G}} \pi_{a+i}(x),$$

where

$$w_i^{\Gamma\text{-G}} = w_i^{\Gamma\text{-G}}(a) = \frac{\varphi_i(a)}{(a+i)},$$

$$\varphi_0(a) = \frac{1}{\Gamma(a)}, \quad \varphi_i(a) = \frac{(a-1)}{\Gamma(a)} \psi_{i-1}(i+a-2), \quad i \geq 1,$$

and $\psi_{i-1}(\cdot)$ are the Stirling polynomials defined by

$$\begin{aligned} \psi_{n-1}(x) &= \frac{(-1)^{n-1}}{(n+1)!} \left[H_n^{n-1} - \frac{x+2}{n+2} H_n^{n-2} + \frac{(x+2)(x+3)}{(n+2)(n+3)} H_n^{n-3} \right. \\ &\quad \left. - \dots + (-1)^{n-1} \frac{(x+2)(x+3) \dots (x+n)}{(n+2)(n+3) \dots (2n)} H_n^0 \right], \end{aligned}$$

where H_n^m are positive integers given recursively by $H_{n+1}^m = (2n+1-m)H_n^m + (n-m+1)H_n^{m-1}$, with $H_0^0 = 1, H_{n+1}^0 = 1 \times 3 \times 5 \times \dots \times (2n+1), H_{n+1}^n = 1$.

Following Barreto-Souza et al. [2], the MO-G density (2.11) admits the linear combination

$$f_{\text{MO-G}}(x) = \sum_{i=0}^{\infty} w_i^{\text{MO-G}} \pi_{i+1}(x),$$

where the coefficients are (for $i = 0, 1, \dots$)

$$\begin{aligned} w_i^{\text{MO-G}} &= w_i^{\text{MO-G}}(\theta) \\ &= \begin{cases} \frac{(-1)^i \theta}{(i+1)} \sum_{j=i}^{\infty} \binom{j}{i} (j+1) \bar{\theta}^j, & \theta \in (0, 1), \\ \theta^{-1} (1-\theta^{-1})^i, & \theta > 1, \end{cases} \end{aligned}$$

and $\bar{\theta} = 1 - \theta$.

2.6 Mathematical Properties

In this section, we present only some mathematical properties for the Kw-G family from Eq. (2.14). The properties for the beta-G, Γ -G, and MO-G families can be obtained from their linear representations in a similar manner. Henceforth, let $X \sim \text{Kw-G}(a, b)$ and $Y_i \sim \text{exp-G}((i+1)a)$ for $i \geq 0$.

2.6.1 Moments

Nadarajah et al. [17] derived explicit expressions for the moments of X as linear functions of probability weighted moments (PWMs) of the baseline G. A first representation for the n th moment of X follows from (2.14) as

$$\mu'_n = E(X^n) = \sum_{i=0}^{\infty} w_i^{\text{Kw-G}} E(Y_i^n). \quad (2.15)$$

Equation (2.15) holds for $b > 0$ real non-integer. If b is a positive integer, the index i in this expansion stops at $b - 1$. Explicit expressions for moments of several exponentiated distributions are reported by Nadarajah and Kotz [15] which can be used to calculate μ'_n .

A second representation for μ'_n can be determined from (2.14) as

$$\mu'_n = a \sum_{i=0}^{\infty} (i+1) w_i^{\text{Kw-G}} \tau_n((i+1)a-1), \quad (2.16)$$

where the integral $\tau_n(a) = \int_{-\infty}^{\infty} y^n G(y)^a g(y) dy$ can be expressed in terms of the baseline QF as

$$\tau_n(a) = \int_0^1 Q_G(u)^n u^a du. \quad (2.17)$$

The central moments (μ_n) and cumulants (κ_n) of X can be calculated recursively as

$$\mu_n = \sum_{k=0}^n (-1)^k \binom{n}{k} \mu_1^k \mu'_{n-k} \quad \text{and}$$

$$\kappa_n = \mu'_n - \sum_{k=1}^{n-1} \binom{n-1}{k-1} \kappa_k \mu'_{n-k},$$

respectively, where $\kappa_1 = \mu'_1$. The skewness $\gamma_1 = \kappa_3/\kappa_2^{3/2}$ and kurtosis $\gamma_2 = \kappa_4/\kappa_2^2$ are obtained from the second, third, and fourth cumulants.

The ordinary moments of several Kw-G distributions can be determined directly from (2.16) and (2.17). For example, the moments of the Kw-exponential (with parameter $\lambda > 0$) and Kw-Pareto, where $G(x) = 1 - (1+x)^{-\nu}$ and $\nu > 0$, are given by

$$\mu'_n = a n! \lambda^n \sum_{i,j=0}^{\infty} \frac{(-1)^{n+j} (i+1) \binom{(i+1)a-1}{j} w_i^{\text{Kw-G}}}{(j+1)^{n+1}},$$

and

$$\mu'_n = a \sum_{i,j=0}^{\infty} (-1)^{n+j} (i+1) w_i^{\text{Kw-G}} \binom{n}{j} B((i+1)a, 1 - j\nu^{-1}),$$

respectively. For the Kw-standard logistic, where $G(x) = \{1 + \exp(-x)\}^{-1}$, we obtain

$$\mu'_n = a \sum_{i=0}^{\infty} (i+1) w_i^{\text{Kw-G}} \left(\frac{\partial}{\partial t} \right)^n B(t + (i+1)a, 1-t) \Big|_{t=0}.$$

The shape of many distributions can be usefully described by what we call the incomplete moments. These types of moments, and more importantly the first moment, play the main role for measuring inequality such as the mean deviations, income quantiles, and Lorenz and Bonferroni curves. The n th incomplete moment of X , say, $m_n(y) = E(X^n | X < w)$, can be expressed as

$$m_n(y) = a \sum_{i=0}^{\infty} (i+1) w_i^{\text{Kw-G}} \int_0^{G(w)} Q_G(u)^n u^{(i+1)a-1} du. \quad (2.18)$$

Equation (2.18) can be computed (at least numerically) for most baseline G distributions.

2.6.2 Other Measures

The mean deviations of X about the mean ($\delta_1(X)$) and about the median ($\delta_2(X)$) are given by

$$\delta_1(X) = E(|X - \mu'_1|) = 2\mu'_1 F_{\text{Kw-G}}(\mu'_1) - 2m_1(\mu'_1),$$

and

$$\delta_2(X) = E(|X - M|) = \mu'_1 - 2m_1(M),$$

respectively. Here, $\mu'_1 = E(X)$, $M = Q_G\{[1 - 2^{-1/b}]^{1/a}\}$ is the median, $F_{\text{Kw-G}}(\mu'_1)$ comes from (2.4), and $m_1(z)$ (the first incomplete moment) follows from (2.18) as

$$m_1(z) = a \sum_{i=0}^{\infty} (i+1) w_i^{\text{Kw-G}} T_i(z),$$

where

$$T_i(z) = \int_0^{G(z)} Q_G(u) u^{(i+1)a-1} du.$$

The mean deviations of any Kw-G distribution can be computed using the last equation and the baseline QF. Taking the generalized binomial expansion, the mean deviations of the Kw-exponential (with parameter λ), Kw-standard logistic, and Kw-Pareto (with parameter $\nu > 0$) are given by

$$T_i(z) = \lambda^{-1} \Gamma((i+1)a + 1) \sum_{j=0}^{\infty} \frac{(-1)^j \{1 - \exp(-j\lambda z)\}}{\Gamma((i+1)a + 1 - j)(j+1)!},$$

$$T_i(z) = \frac{1}{\Gamma(k)} \sum_{j=0}^{\infty} \frac{(-1)^j \Gamma((i+1)a + j) \{1 - \exp(-jz)\}}{(j+1)!},$$

and

$$T_i(z) = \sum_{j=0}^{\infty} \sum_{r=0}^j \frac{(-1)^j \binom{(i+1)a}{j} \binom{j}{r} z^{1-r\nu}}{(1-r\nu)},$$

respectively.

An alternative representation for $m_1(z)$ follows from (2.14) as

$$m_1(z) = \sum_{i=0}^{\infty} w_i^{\text{Kw-G}} J_i(z), \quad (2.19)$$

where

$$J_i(z) = \int_{-\infty}^z x \pi_{(i+1)a}(x) dx. \quad (2.20)$$

Equation (2.20) is the basic quantity to compute the mean deviations of the exp-G distributions. Hence, the Kw-G mean

deviations depend only on the mean deviations of the exp-G distribution. A simple application is provided by the Kw-Weibull distribution. The PDF (for $x > 0$) of the EW distribution with power parameter $(i + 1)a$ is

$$\pi_{(i+1)a}(x) = a(i + 1)c\lambda^c x^{c-1} \exp\{-(\lambda x)^c\} \times [1 - \exp\{-(\lambda x)^c\}]^{(i+1)a-1},$$

and then

$$J_i(z) = (i + 1)a c \lambda^c \sum_{r=0}^{\infty} (-1)^r \binom{(i + 1)a - 1}{r} \times \int_0^z x^c \exp\{-(r + 1)(\lambda x)^c\} dx.$$

We can write $J_i(z)$ in terms of the incomplete gamma function

$$J_i(z) = (i + 1)a \lambda^{-1} \sum_{r=0}^{\infty} \frac{(-1)^r \binom{(i+1)a-1}{r}}{(r + 1)^{1+c^{-1}}} \gamma(1 + c^{-1}, (r + 1)(\lambda z)^c).$$

Equations (2.19) and (2.20) can be used to find Bonferroni and Lorenz curves defined, for a given probability p , by $B(p) = m_1(q)/(p\mu'_1)$ and $L(p) = m_1(q)/\mu'_1$, respectively, where $\mu'_1 = E(X)$ and $q = Q_G\{[1 - (1 - p)^{1/b}]^{1/a}\}$.

2.6.3 Generating Function

We now provide three representations of the moment generating function (MGF) $M(t) = E(e^{tX})$ of X . The first one comes from (2.14) as

$$M(t) = a \sum_{i=0}^{\infty} (i + 1) w_i^{\text{Kw-G}} E[e^{tX} U^{(i+1)a+1}],$$

where U is a uniform random variable on the unit interval. Note that X and U are not independent.

A second representation for $M(t)$ can be written from (2.14) as

$$M(t) = \sum_{i=0}^{\infty} w_i^{\text{Kw-G}} M_i(t),$$

where $M_i(t)$ is the MGF of Y_i . Hence, for several Kw-G distributions, $M(t)$ can be determined from the exp-G generating function.

A third representation for $M(t)$ can be derived from (2.14) as

$$M(t) = a \sum_{i=0}^{\infty} (i + 1) w_i^{\text{Kw-G}} \rho(t, a(i + 1) - 1), \quad (2.21)$$

where the function $\rho(t, a) = \int_{-\infty}^{\infty} e^{tx} G(x)^a g(x) dx$ can be calculated from the baseline QF as

$$\rho(t, a) = \int_0^1 \exp\{tQ_G(u)\} u^a du. \quad (2.22)$$

We can obtain the MGFs of several Kw-G distributions from (2.21) and (2.22). For example, the MGFs of the Kw-exponential (with parameter λ), Kw-standard logistic, and Kw-Pareto (with parameter $\nu > 0$) are

$$M(t) = a \sum_{i=0}^{\infty} (i + 1) w_i^{\text{Kw-G}} B((i + 1)a, 1 - \lambda t),$$

$$M(t) = a \sum_{i=0}^{\infty} (i + 1) w_i^{\text{Kw-G}} B(t + (i + 1)a, 1 - t),$$

and

$$M(t) = a e^{-t} \sum_{i,r=0}^{\infty} \frac{(i + 1) w_i^{\text{Kw-G}} B((i + 1)a, 1 - r\nu^{-1})}{r!} t^r,$$

respectively.

2.7 T-X Family

Alzaatreh et al. [1] proposed the T-X family of distributions as follows. Let $r(t)$ be the PDF and $R(t)$ be the CDF of a random variable $(rv) T \in [a, b]$ for $-\infty < a < b < \infty$, and let $W[G(x)]$ be a function of the CDF $G(x)$ of some rv X defined on a standard probability space such that $W[G(x)]$ satisfies the following conditions:

- (i) $W[G(x)] \in [a, b]$.
- (ii) $W[G(x)]$ is differentiable and monotonically nondecreasing.
- (iii) $\lim_{x \rightarrow -\infty} W[G(x)] = a$ and $\lim_{x \rightarrow \infty} W[G(x)] = b$.

The T - X family is defined by

$$F(x) = \int_a^{W[G(x)]} r(t) dt = R(W[G(x)]), \quad (2.23)$$

where $W[G(x)]$ satisfies the conditions (i)–(iii). The PDF related to (2.23) turns out to be

$$f(x) = r(W[G(x)]) \frac{dW[G(x)]}{dx}. \quad (2.24)$$

Equation (2.23) can be used to define several families such as the beta-G, Kw-G, and Γ -G introduced before. The beta-G and Kw-G families are obtained from (2.23) by choosing the identity function for $W[G(x)]$ and the beta and Kumaraswamy PDFs (with support in $(0, 1)$) for $r(t)$, respectively. The Γ -G family is just defined by $G[W(x)] = -\log[1 - G(x)]$ and taking the gamma PDF with unity scale parameter and shape parameter $a > 0$ for $r(t)$.

We can generate thousands of distributions from Eq.(2.24) by choosing the density $r(t)$ and the function $W[G(x)]$ appropriately. Some of the basic motivations for selecting the density (2.24) in practice are as follows: (i) construct heavy-tailed distributions that are not longer-tailed for modeling real data; (ii) make the kurtosis more flexible compared to the baseline model; (iii) produce a skewness for symmetrical distributions; (iv) generate distributions with symmetric, left-skewed, right-skewed, and reversed J-shaped; (v) provide consistently better fits than other generated models under the same baseline distribution; and (vi) define special models with all types of the HRF.

Let $G(x)$, $g(x)$, $\bar{G}(x) = 1 - G(x)$, and $Q_G(p) = G^{-1}(p)$ be the CDF, PDF, SF, and QF of any rv X . We can define the odds (O), log-odds (LO), and log-odds ratio (LOR) functions by $O(x) = [G(x)/\bar{G}(x)]$, $LO(x) = \log [G(x)/\bar{G}(x)]$, and $LOR(x) = g(x)/[G(x)\bar{G}(x)]$, respectively. The use of the odds ratio is becoming very popular and has applications in the fields of reliability and survival analysis, large sample theory, and discriminant analysis, among others. The LOR is also a useful measure for modeling data that exhibits non-monotone failure rate. The distributions being non-monotone in terms of failure rate are monotone in terms of LOR.

Some generalized classes have been proposed using the O-function in the statistical literature. For each baseline G , the CDF of the odd log-logistic-G (OLL-G) class follows from (2.23) by integrating the log-logistic PDF

$$F(x) = \int_0^{\frac{G(x)}{1-G(x)}} \frac{\alpha t^{\alpha-1}}{(1+t^\alpha)^2} dt = \frac{G(x)^\alpha}{G(x)^\alpha + [1-G(x)]^\alpha}, \quad (2.25)$$

where $\alpha > 0$ is an extra shape parameter to the G distribution. The PDF corresponding to (2.25) is given by

$$f(x) = \frac{\alpha g(x) G(x)^{\alpha-1} [1-G(x)]^{\alpha-1}}{\{G(x)^\alpha + [1-G(x)]^\alpha\}^2}, \quad (2.26)$$

where $g(x)$ is the baseline PDF. This PDF allows greater flexibility of its tails and can be useful in applications in several areas. It will be most tractable when $G(x)$ and $g(x)$ have closed-forms.

We now present a wide distribution in the OLL-G family. The three-parameter generalized gamma distribution (GG) pioneered by Stacy [21] includes as special models the exponential, Weibull, gamma, and Rayleigh distributions, among others. The GG distribution has been used in several research areas such as engineering, hydrology, and survival analysis. It is suitable for modeling data with different forms of HRF: increasing, decreasing, in the form of bathtub, and unimodal. The CDF and PDF of the $GG(\rho, \tau, p)$ distribution is

$$G(x; \rho, \tau, p) = \gamma_1 \left(p, \left(\frac{x}{\rho} \right)^\tau \right) = \frac{\gamma(p, (x/\rho)^\tau)}{\Gamma(p)}, \quad x > 0,$$

$$g(x; \rho, \tau, p) = \frac{\tau}{\rho \Gamma(p)} \left(\frac{x}{\rho} \right)^{\tau p - 1} \exp \left[- \left(\frac{x}{\rho} \right)^\tau \right],$$

where $\rho > 0$, $\tau > 0$, $p > 0$, and $\gamma_1(p, x) = \gamma(p, x)/\Gamma(p)$ is the incomplete gamma function ratio.

The OLLGG density (for $x > 0$) with four positive parameters is defined by substituting $G(x; \rho, \tau, p)$ and $g(x; \rho, \tau, p)$ into Eq. (2.26)

$$f(x) = \frac{\alpha \tau (x/\rho)^{\tau p - 1} \exp[-(x/\rho)^\tau] \{\gamma_1(p, (x/\rho)^\tau) [1 - \gamma_1(p, (x/\rho)^\tau)]\}^{\alpha-1}}{\rho \Gamma(p) \{\gamma_1(p, (x/\rho)^\tau)^\alpha + [1 - \gamma_1(p, (x/\rho)^\tau)]^\alpha\}^2},$$

where ρ is a scale parameter and τ , p , and α are shape parameters.

Some sub-models can be immediately defined from this equation: OLL-gamma ($\tau = 1$), OLL-Weibull ($p = 1$), OLL-exponential ($\tau = p = 1$), OLL-Rayleigh ($\tau = 2$ and $p = 1$), OLL-Maxwell ($\tau = 2$ and $p = 3/2$), and OLL-folded normal ($\tau = \sqrt{2}$ and $p = 1/2$).

One major benefit of the OLLGG density is its ability of fitting skewed data that cannot be properly fitted by existing distributions. It also allows for greater flexibility of its tails and can be widely applied in many areas of engineering and biology.

Finally, we provide an example of (2.23). Let T be a logistic rv with CDF $R(t) = (1 + e^{-\alpha t})^{-1}$ and PDF $r(t) = \alpha e^{-\alpha t} (1 + e^{-\alpha t})^{-2}$ with support in \mathbb{R} , where $\alpha > 0$. By setting $W[G(x)] = \log\{-\log[G(x)]\}$, a monotonically nonincreasing function in $G(x)$, the CDF of the logistic-G family is defined from (2.23) as

$$F(x) = 1 - [1 + \{-\log[G(x)]\}^{-\alpha}]^{-1}, \quad x \in \mathbb{R}.$$

The corresponding PDF takes the form

$$f(x) = \frac{\alpha g(x) \{-\log[G(x)]\}^{-\alpha-1}}{G(x) [1 + \{-\log[G(x)]\}^{-\alpha}]^2}, \quad x \in \mathbb{R}.$$

2.8 Fitting Distributions

All distributions in the families mentioned previously can be fitted to real data sets using the *AdequacyModel* package for the R statistical computing environment (<https://www.r-project.org/>). An important advantage of this package is that it is not necessary to define the log-likelihood function and that it computes the maximum likelihood (ML) estimates, their standard errors, and the formal statistics presented in the next section. We only need to provide the PDF and CDF of the distribution to be fitted to a data set. This *AdequacyModel* package uses the PSO (particle swarm optimization) method obtained by traditional global search approaches such as the quasi-Newton BFGS, Nelder-Mead, and simulated annealing methods to maximize the log-likelihood function. This method does not require initial values. More details are available at <https://rdrr.io/cran/AdequacyModel/>.

2.9 Real Data Illustrations

In this section, we shall illustrate the use of some generalized distributions in practice, specifically the beta-BS and Γ -W distributions. First, we consider an uncensored data set from Nichols and Padgett [18] on breaking stress of carbon fibers (in Gba). Table 2.1 lists the ML estimates of the parameters (standard errors between parentheses), and the values of AIC (Akaike Information Criterion), BIC (Bayesian Information Criterion), and CAIC (Consistent Akaike Information Criterion) are given in Table 2.2. From the values of these statistics, we conclude that the beta-BS model provides a better fit to these data than the BS model. The LR statistic to test the hypothesis H_0 : BS against H_1 : beta-BS is 17.6679 (p -value < 0.01). Thus, using any usual significance level, we reject the null hypothesis in favor of the beta-BS distribution, i.e., the beta-BS distribution is significantly better than the BS distribution. We can also perform formal goodness-of-fit tests in order to verify which distribution fits better to these data. We apply the Cramér-von Mises (CM) and Anderson-Darling (AD) tests. In general, the smaller the values of CM and AD, the better the fit to the data. For the first data set, we have $CM = 0.4601$ and $AD = 2.5896$ for the BS distribution and $CM = 0.2108$ and $AD = 1.2010$ for the beta-BS distribution. Thus, according to these statistics, the second distribution fits these data better than the first distribution.

As a second application, we analyze a real data set on the strengths of 1.5 cm glass fibers, measured at the National Physical Laboratory, England. Unfortunately, the units of measurement are not given in the paper. Table 2.3 lists the ML estimates of the parameters (standard errors between parentheses), and the values of AIC, BIC, and CAIC are given in Table 2.4. Again, from the values of these statistics,

Table 2.1 ML estimates (standard errors in parentheses); first data set

Distribution	Estimates			
	α	β	a	b
Beta-BS	1.0445 (0.0036)	57.6001 (0.3313)	0.1930 (0.0259)	1876.7324 (605.05)
BS	0.4371 (0.0381)	2.5154 (0.1321)		

Table 2.2 AIC, BIC, and CAIC; first data set

Distribution	Statistic		
	AIC	BIC	CAIC
Beta-BS	190.71	199.47	191.36
BS	204.38	208.75	204.57

Table 2.3 ML estimates (standard errors in parentheses); second data set

Distribution	Estimates			
	α	β	a	b
Beta-BS	1.0505 (0.0101)	30.4783 (0.5085)	0.3638 (0.0709)	7857.5658 (3602.2)
BS	0.2699 (0.0267)	1.3909 (0.0521)		

Table 2.4 AIC, BIC, and CAIC; second data set

Distribution	Statistic		
	AIC	BIC	CAIC
Beta-BS	37.552	45.280	38.422
BS	48.378	52.242	48.628

we conclude that the beta-BS model provides a better fit to these data than the BS model. The LR statistic to test the hypothesis H_0 : BS against H_1 : beta-BS is 14.8258 (p -value < 0.01). Thus, the beta-BS distribution is significantly better than the BS distribution. Additionally, we have $CM = 0.6395$ and $AD = 3.3894$ for the BS distribution and $CM = 0.3651$ and $AD = 1.9728$ for the beta-BS distribution. Again, the wider distribution fits the data set better than the baseline distribution.

Finally, we consider the data set consisting of the number of successive failures for the air-conditioning system of each member in a fleet of 13 Boeing 720 jet airplanes; see [19]. The ML estimates of the parameters (standard errors between parentheses) of the Weibull and Γ -W distributions and the values of the AIC, BIC, and CAIC statistics are reported in Tables 2.5 and 2.6, respectively. The values in Table 2.6 indicate that the Γ -W model is better than the usual Weibull model in terms of fitting to these data. The LR statistic to test the hypothesis H_0 : Weibull against H_1 : Γ -W is 7.42 (p -value < 0.01). Thus, we reject the null hypothesis in favor of the Γ -W distribution using any usual significance level. Therefore, the Γ -Weibull distribution is significantly better than the Weibull distribution based on the LR test. Further, we have $CM = 0.0348$ and $AD = 0.2628$ for the Weibull

Table 2.5 ML estimates (standard errors in parentheses); third data set

Distribution	Estimates		
	λ	c	a
Γ -W	1.0915 (1.7942)	0.3735 (0.1739)	5.1353 (4.5227)
Weibull	0.0170 (0.0044)	0.9109 (0.0503)	

Table 2.6 AIC, BIC, and CAIC; third data set

Distribution	Statistic		
	AIC	BIC	CAIC
Γ -W	2072.1	2081.8	2072.2
Weibull	2077.5	2084.0	2077.6

distribution and $CM = 0.1594$ and $AD = 0.9968$ for the Γ -W distribution. These results also indicate that the Γ -W distribution provides a more adequate fit to these data than the Weibull distribution.

Abstract

This chapter provides a short summary of fundamental ideas in reliability theory and inference. The first part of the chapter accounts for lifetime distributions that are used in engineering reliability analysis, including general properties of reliability distributions that pertain to lifetime for manufactured products. Certain distributions are formulated on the basis of simple physical properties, and other are more or less empirical. The first part of the

chapter ends with a description of graphical and analytical methods to find appropriate lifetime distributions for a set of failure data.

The second part of the chapter describes statistical methods for analyzing reliability data, including maximum likelihood estimation (both parametric and nonparametric) and likelihood ratio testing. Degradation data are more prevalent in experiments in which failure is rare and test time is limited. Special regression techniques for degradation data can be used to draw inference on the underlying lifetime distribution, even if failures are rarely observed.

The last part of the chapter discusses reliability for systems. Along with the components that comprise the system, reliability analysis must take account of the system configuration and (stochastic) component dependencies. System reliability is illustrated with an analysis of logistics systems (e.g., moving goods in a system of product sources and retail outlets). Robust reliability design can be used to construct a supply chain that runs with maximum efficiency or minimum cost.

Keywords

Weibull distribution · System reliability · Empirical likelihood · Residual life · Lifetime data

3.1 Introduction and Literature Review

In everyday use, words like reliability and quality have meanings that vary depending on the context. In engineering, *reliability* is defined as the ability of an item to perform its function, usually measured in terms of probability as a function of time. *Quality* denotes how the item conforms to its specifications, so reliability is a measure of the item's quality over time.

Since the time of *Birnbaum* and *Sanders* [1], when system reliability emerged as its own discipline, research has centered on the operation of simple systems with identical parts working independently of each other. Today's systems do not fit this mold; system representation must include multifaceted components with several component states that can vacillate between perfect operation and terminal failure. Not only do components interact within systems, but many systems are dynamic in that the system configuration can be expected to change during its operation, perhaps due to component failures or external stresses. Computer software, for example, changes its failure structure during the course of design, testing, and implementation.

Statistical methods for reliability analysis grew from this concept of system examination, and system reliability is often gauged through component lifetime testing. This chapter reviews the current framework for statistical reliability and considers some modern needs from experimenters in engineering and the physical sciences.

Statistical analysis of reliability data in engineering applications cannot be summarized comprehensively in a single book chapter such as this. The following books (listed fully in the reference section) serve as an excellent basis for a serious treatment of the subject:

1. *Statistical Theory of Reliability and Life Testing* by Barlow and Proschan [2]
2. *Practical Methods for Reliability Data Analysis* by Ansell and Phillips [3]
3. *Reliability: Probabilistic Models and Statistical Methods* by Leemis [4]
4. *Applied Reliability* by Tobias and Trindade [5]
5. *Engineering Reliability* by Barlow [6]
6. *Reliability for Technology, Engineering, and Management* by Kales [7]
7. *Statistical Methods for Reliability Data* by Meeker and Escobar [8]
8. *Reliability Modeling, Prediction, and Optimization* by Blischke and Murthy [9]
9. *Statistical Methods for the Reliability of Repairable Systems* by Rigdon and Basu [10] and
10. *Bayesian Reliability* by Hamada et al. [11]

Some of the books in this list focus on reliability theory, and others focus exclusively on reliability engineering. From the more inclusive books, [8] provides a complete, high-level guide to reliability inference tools for an engineer, and most examples have an engineering basis (usually in manufacturing). For reliability problems closely associated with materials testing, *Bogdanoff* and *Kozin* [12] connect the physics of degradation to reliability models. *Sobczyk* and *Spencer* [13] also relate fatigue to reliability through probability modeling. For reliability prediction in software

performance, *Lyu* [14] provides a comprehensive guide of engineering procedures for software reliability testing, while a more theoretical alternative by *Singpurwalla* and *Wilson* [15] emphasizes probability modeling for software reliability, including hierarchical Bayesian methods. Closely related to reliability modeling in engineering systems, *Bedford* and *Cooke* [16] covers methods of probabilistic risk assessment, which is an integral part of reliability modeling for large and complex systems.

Other texts emphasize reliability assessment in a particular engineering field of interest. For statistical reliability in geotechnical engineering, *Baecher* and *Christian* [17] is recommended as it details statistical problems with soil variability, autocorrelation (i.e., Kriging), and load/resistance factors. *Ohring* [18] provides a comprehensive guide to reliability assessment for electrical engineering and electronics manufacturing, including reliability pertaining to degradation of contacts (e.g., crack growth in solder), optical fiber reliability, semiconductor degradation, and mass-transport-induced failure. For civil engineering, *Melchers'* [19] reliability text has a focus on reliability of structural systems and loads, time-dependent reliability, and resistance modeling.

3.2 Lifetime Distributions in Reliability

While engineering studies have contributed a great deal of the current methods for reliability life testing, an equally great amount exists in the biological sciences, especially relating to epidemiology and biostatistics. Life testing is a crucial component to both fields, but the bio-related sciences tend to focus on mean lifetimes and numerous risk factors. Engineering methods, on the other hand, are more likely to focus on upper (or lower) percentiles of the lifetime distribution as well as the stochastic dependencies between working components. Another crucial difference between the two application areas is that engineering models are more likely to be based on principles of physics that lead to well-known distributions such as Weibull, log-normal, extreme value, and so on.

The failure time distribution is the most widely used probability tool for modeling product reliability in science and industry. If $f(x)$ represents the probability density function for the product's failure time, then its reliability is $R(x) = \int_x^\infty f(u)du$, and $R(t) = 1 - F(t)$ where F is the cumulative distribution function (CDF) corresponding to f . A *quantile* is the CDF's inverse; the p th quantile of F is the lifetime value t_p such that $F(t_p) = p$. To understand the quality of a manufactured product through these lifetime probability functions, it is often useful to consider the notion of *aging*. For example, the (conditional) reliability of a product that has been working t units of time is

$$R(x|t) = \frac{R(t+x)}{R(t)}, \text{ if } R(t) > 0. \quad (3.1)$$

The rate of change of $R(x|t)$ is an important metric for judging a product's quality, and the conditional *failure rate* function $h(t)$ is defined as

$$h(t) = \lim_{x \rightarrow \infty} x^{-1} \frac{R(t) - R(t+x)}{R(t)} = \frac{f(t)}{R(t)}. \quad (3.2)$$

The *cumulative failure rate* (sometimes called the *hazard function*) is $H(t) = \int_0^t h(u)du$, and has many practical uses in reliability theory because of its monotonicity and the fact that $H(t) = -\log R(t)$.

The failure rate clearly communicates how the product ages during different spans of its lifetime. Many manufactured products have an increasing failure rate, but the rate of increase is rarely stable throughout the product's lifetime. If $r(t)$ remains constant, it is easy to show the lifetime distribution is exponential $f(x) = \theta \exp(-\theta x)$, $x > 0$ and the product exhibits no aging characteristics. Many electronic components and other manufactured items have brief initial period when failure rate is relatively high and decrease toward a steady state, where it stays until aging causes the rate to increase. This is called a bath-tub failure rate. The period in which early failures occur (called *infant mortality*) is called the *burn-in* period, and is often used by manufacturers to age products and filter out defectives (early failures) before being making it available to the consumer.

3.2.1 Alternative Properties to Describe Reliability

The failure rate function, reliability function, cumulative hazard function, and probability density describe different aspects of a lifetime distribution. The expected lifetime, or *mean time to failure* (MTTF), is an important measure for repairable systems. Several alternatives for characterizing properties of the lifetime distribution include:

- *Mean residual life* = $L(t) = E_X(X - t|X \geq t)$ which is the expected residual life of a component that has already lasted t units of time. If $L(t)$ is less than the expected lifetime μ , the product is exhibiting aging by the time t .
- *Reversed hazard rate* = $v(t) = f(x)/F(x)$ that provides a different aspect of reliability: the conditional failure frequency at the time just before t given that the product failed in $(0, t]$ (see Chap. 1 of [20], for example).
- *Percentile residual life* = $Q_\alpha = F^{-1}[1 - (1 - \alpha) \times R(t)] - t$ which is the α quantile of the residual life (the conditional lifetime distribution given that the product has lasted t units of time). The median residual life, where $\alpha = 1/2$ compares closely to $L(t)$.

- *Mill's ratio* = $R(x)/f(x) = 1/h(x)$, used in economics, which is not an ordinary way to characterize reliability, but it is worth noting because of its close connection to failure rate.

3.2.2 Conventional Reliability Lifetime Distributions

So far, only one distribution (exponential) has been mentioned. Rather than presenting a formal review of commonly used reliability distributions, a summary of commonly applied lifetime distributions is presented in Table 3.1, including the exponential, gamma, Weibull, log-normal, logistic, Pareto, and extreme value. In the table, $\Gamma(t) = \int_0^\infty x^{t-1} e^{-x} dx$ is the ordinary gamma function, and $IG(t, x)$ represents the corresponding incomplete gamma function.

For manufacturing centers and research laboratories that conduct lifetime tests on products, lifetime data is an essential element of reliability analysis. However, a great deal of reliability analysis is based on field data, or reliability information sampled from day-to-day usage of the product. In many of these instances, lifetime data is a luxury not afforded to the reliability inference. Instead, historical event data and inspection counts are logged for the data analysis. Consequently, several discrete distributions (e.g., Poisson, binomial, and geometric) are important in reliability applications. Chapter ▶ 4 has a more detailed discussion of these and other statistical distributions applied in engineering problems.

3.2.3 From Physics to Failure Distributions

Many of the distributions in Table 3.1 are derived based on physical principles. For example, *Weibull* [21] derived the distribution that takes his name to represent the breaking strength of materials based on the idea that some components are comparable to a chain that is no stronger than its weakest link. From this premise, the distribution can be derived from properties of minimums, in contrast to the extreme value distribution, which can be derived through the properties of maximums (see [22], for example). In a short time after its introduction, the Weibull distribution was successfully applied to numerous modeling problems in engineering and has become the hallmark distribution in applied reliability. A primary reason for its suitability to lifetime analysis is its flexible failure rate; unlike other distributions listed in Table 3.1, the Weibull failure rate is simple to model, easy to demonstrate, and it can be either increasing or decreasing. A mixture of two Weibull distributions can be used to portray a bath-tub failure rate (as long as only one of the shape parameters is less than one). *Mudholkar* et al. [23] introduce

Table 3.1 Common lifetime distributions used in reliability data analysis

Distribution	$f(t), t > 0$	$h(t)$	μ	σ^2	Parameter space
Exponential	$\theta e^{-\theta t}$	θ	$1/\theta$	$1/\theta^2$	$\theta > 0$
Weibull	$\lambda \kappa t^{\kappa-1} e^{-\lambda t^\kappa}$	$\lambda \kappa t^{\kappa-1}$	$\lambda^{-1/\kappa} \Gamma\left(1 + \frac{1}{\kappa}\right)$	$\lambda^{-2/\kappa} \left[\Gamma\left(1 + \frac{2}{\kappa}\right) - \Gamma^2\left(1 + \frac{1}{\kappa}\right) \right]$	$\kappa > 0, \lambda > 0$
Gamma	$\lambda^r \Gamma^{-1}(r) t^{r-1} e^{-\lambda t}$	$\frac{\lambda^r t^{r-1} e^{-\lambda t}}{\Gamma(r)[1 - \Gamma(r, \lambda t)]}$	r/λ	r/λ^2	$r > 0, \lambda > 0$
Log-normal	$\frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(\log t - \mu)^2}{2\sigma^2}}$	$f(t)/R(t)$	$e^{\mu + \sigma^2/2}$	$e^{2\mu + 2\sigma^2} - e^{2\mu + \sigma^2}$	$-\infty < \mu < \infty, \sigma > 0$
Logistic	$\frac{e^{-(t-\lambda)/\beta}}{\beta(1 + e^{-(t-\lambda)/\beta})^2}$	$[\beta(1 + e^{-(t-\lambda)/\beta})]^{-1}$	λ	$(\beta\pi)^2/3$	$-\infty < \lambda < \infty, \beta > 0$
Pareto	$\frac{m\theta^m}{t^{m+1}}$	$\frac{m}{t}$	$\frac{m\theta}{m-1}$	$\frac{m\theta^2}{(m-1)^2(m-2)}$	$t > \theta, m > 0$
Extreme value	$\frac{\exp[-(t-a)/b]}{b \exp[-\exp(-(t-a)/b)]}$	$\frac{\exp[-(t-a)/b]}{b \exp[-\exp(-(t-a)/b)] - 1}$	$a - b\Gamma'(1)$	$(b\pi)^2/6$	$-\infty < a < \infty, b > 0$

a new shape parameter to a generalized Weibull distribution that allows bath-tub-shaped failure rates as well as a broader class of monotone failure rates.

For materials exposed to constant stress cycles with a given stress range, lifetime is measured in number of cycles until failure (N). The Whöler curve (or S - N curve) relates stress level (S) to N as $NS^b = k$, where b and k are material parameters (see [13] for examples). By taking logarithms of the S - N equation, we can express cycles to failure as a linear function: $Y = \log N = \log k - b \log S$. If N is log-normally distributed, then Y is normally distributed and regular regression models can be applied for predicting cycles to failure (at a given stress level). In many settings, the log-normal distribution is applied as the failure time distribution when the corresponding degradation process is based on rates that combine multiplicatively. Despite having a concave-shaped (or upside-down bath-tub shape) failure rate, the log-normal is especially useful in modeling fatigue crack growth in metals and composites.

Birnbaum and Saunders [1] modeled the damage to a test item after n cycles as $B_n = \zeta_1 + \dots + \zeta_n$, where ζ_i represents the damage amassed in the i th cycle. If failure is determined by B_n exceeding a fixed damage threshold value B^* , and if the ζ_i are identically and independently distributed,

$$P(N \leq n) = P(B_n > B^*) \approx \Phi\left(\frac{B^* - n\mu}{\sigma\sqrt{n}}\right), \quad (3.3)$$

where Φ is the standard normal CDF. This happens because B_n will be approximately normal if n is large enough. The reliability function for the test unit is

$$R(t) \approx \Phi\left(\frac{B^* - n\mu}{\sigma\sqrt{n}}\right) \quad (3.4)$$

which is called the *Birnbaum-Saunders* distribution. It follows that

$$W = \frac{\mu\sqrt{N}}{\sigma} - \frac{B^*}{\sigma\sqrt{N}} \quad (3.5)$$

has a normal distribution, which leads to accessible implementation in lifetime modeling (see [24] or [12] for more properties).

3.2.4 Lifetime Distributions from Degradation Modeling

These examples show how the product's lifetime distribution can be implied by knowledge of how it degrades in time. In general, degradation measurements have great potential to improve lifetime data analysis, but they also introduce new problems to the statistical inference. Lifetime models have been researched and refined for many manufactured products that are put on test. On the other hand, degradation models tend to be empirical (e.g., nonparametric) or based on simple physical properties of the test item and its environment (e.g., the Paris crack law, Arrhenius rule, and power law) which often lead to obscure lifetime models. *Meeker and Escobar* [8] provide a comprehensive guide to degradation modeling, and show that many valid degradation models will not yield lifetime distributions with closed-form solutions. Functions for estimating parameters in reliability models are available in R packages, for example, the "WeibullR" package [25].

In a setting where the lifetime distribution is known, but the degradation distribution is unknown, degradation information does not necessarily complement the available lifetime data. For example, the lifetime data may be distributed as Weibull, but conventional degradation models will contradict the Weibull assumption (actually, the rarely used *reciprocal Weibull* distribution for degradation with a fixed failure threshold leads to Weibull lifetimes).

In selecting a degradation model based on longitudinal measurements of degradation, monotonic models are

typically chosen under the assumption that degradation is a one-way process. In some cases, such as the measured luminosity of light displays (vacuum fluorescent displays and plasma display devices), the degradation is not necessarily monotonic because, during the first phase of product life, impurities inside the light display's vacuum are slowly burned off and luminosity increases. After achieving a peak level, usually before 100 h of use, the light slowly degrades in a generally monotonic fashion. See *Bae and Kvam* [26, 27] for details on the modeling of non-monotonic degradation data. Degradation data analysis is summarized in Sect. 3.3.3.

3.2.5 Censoring

For most products tested in regular use conditions (as opposed to especially harsh conditions), the allotted test time is usually too short to allow the experimenter to witness failure times for the entire set that is on test. When the item is necessarily taken off test after a certain amount of test time, its lifetime is *right censored*. This is also called type I censoring. Type II censoring corresponds to tests that are stopped after a certain number of failures (say k out of n , $1 \leq k \leq n$) occur.

Inspection data are lifetimes only observed at fixed times of inspection. If the inspection reveals a failed test item, it must be *left censored* at that fixed time. Items that are still working at the time of the last inspection are necessarily right censored. This is sometimes called *interval censoring*.

Censoring is a common hindrance in engineering applications. Lifetime data that are eclipsed by censoring cause serious problems in the data analysis, but it must be kept in mind that each observation, censored or not, contributes information and increases precision in the statistical inference, overall.

3.2.6 Probability Plotting

Probability plotting is a practical tool for checking the adequacy of a fitted lifetime distribution to a given set of data. The rationale is to transform the observed data according to a given distribution, so a linear relationship exists if the distribution was specified correctly. In the past, probability plotting paper was employed to construct the transformation, but researchers can find plotting options on many computer packages that feature data analysis (e.g., SAS, S-Plus, Matlab, Minitab, and SPSS) making the special plotting paper nearly obsolete. Despite the applicability of this technique, few engineering texts feature in-depth discussion on probability plotting and statistics texts tend to focus on theory more than implementation. *Rigdon and Basu* [10] provide a thorough discussion of basic probability plotting, and

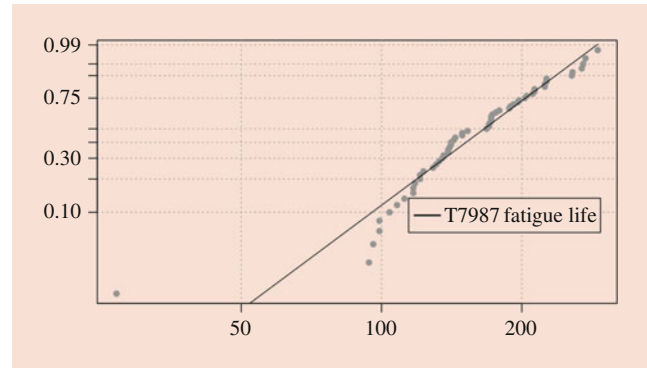

Fig. 3.1 Weibull probability plot for alloy T7987 fatigue life [8]

Atkinson [28] provides a substantial discussion of the subject in the context of regression diagnostics. Advanced plotting techniques even allow for censored observations (see *Waller and Turnbull* [29], for example).

To illustrate how the plot works, we first linearize the CDF of the distribution in question. For example, if we consider the two-parameter Weibull distribution, the *quantile function* is

$$t_p = \left(\frac{-\log p}{\lambda} \right)^{1/\kappa}, \quad (3.6)$$

which implies that the plot of $\log t$ has a linear relationship with the \log - \log function of $p = F(t)$. Hence, Weibull probability plots are graphed on \log - \log probability paper. Figure 3.1 shows a Weibull plot (using Minitab) for the fatigue life of 67 alloy specimens that failed before $n = 300,000$ cycles. This dataset is from *Meeker and Escobar* [8] and the plot also includes 95% confidence bands that identify the uncertainty associated with the plot. In this case, the curvature (especially noticeable on the left side) suggests that the Weibull distribution does not provide an adequate fit.

3.3 Analysis of Reliability Data

Once the lifetime distribution of a test item is determined, the data can be used to estimate important properties of the distribution, including mean, standard deviation, failure rate, reliability (at a fixed time t), and upper or lower quantiles that pertain to early or late failure times.

There are two fundamental methods for approaching the analysis of lifetime data: Bayesian methods and, for the lack of an optimal term, non-Bayesian methods. Although Bayesian methods are accepted widely across many fields of engineering and physical science, non-Bayesian statistics, mostly frequentist and likelihood methods, are still an industry standard. This chapter will not detail how methods of statistical inference are derived in various frameworks of

statistical ideology. Accelerated life testing, an important tool for designing reliability experiments, is discussed in detail in Chap. ▶ 22 and is only mentioned in this chapter. Instead, a summary of important procedures is outlined for statistical estimation, confidence intervals, and hypothesis tests.

3.3.1 Maximum Likelihood

Parametric likelihood methods examine a family of probability distributions and choose the parameter combination that best fits the data. A likelihood function is generally defined by the observed probability model; if the lifetime data X_1, \dots, X_n are independently and identically (IID) distributed with density function $f_X(x; \theta)$, the likelihood function is

$$L(\theta) = \prod_{i=1}^n f_X(x_i; \theta) \quad (3.7)$$

and the *maximum likelihood estimator* (MLE) is the value of θ that maximizes $L(\theta)$. Single-parameter distributions such as the exponential generate easily solved MLEs, but distributions with two or more parameters are not often straightforward. Samples that are not IID lead to complicated likelihood functions and numerical methods are usually employed to solve for MLEs. If an observation x represents a right censoring time, for example, then $P(\text{censor}) = R(x)$ and this information contributes the term $R(x)$ to the likelihood instead of $f(x)$. *Leemis* [4] provides a thorough introduction to the likelihood theory for reliability inference.

For most parametric distributions of interest, the MLE $(\hat{\theta})$ has helpful limit properties. As the sample size $n \rightarrow \infty$, $\sqrt{n}(\hat{\theta} - \theta) \rightarrow N[0, i(\theta)^{-1}]$, where

$$i(\theta) = E \left[\left(\frac{\partial}{\partial \theta} \log f \right)^2 \right] = -E \left(\frac{\partial^2}{\partial \theta^2} \log f \right) \quad (3.8)$$

is the estimator's *Fisher information*. For other parameters of interest, say $\psi(\theta)$, we can construct approximate confidence intervals based on an estimated variance using the Fisher information:

$$\hat{\sigma}^2 [\psi(\hat{\theta})] \approx \frac{1}{\psi(\hat{\theta})^2 i(\hat{\theta})}. \quad (3.9)$$

This allows the analyst to make direct inference for the component reliability $[\psi(\theta; t) = R_\theta(t)$, for example].

Example MLE for failure rate with exponential data (X_1, \dots, X_n) : The likelihood is based on $f(x) = \theta \exp(-\theta x)$ where $\theta > 0$ and is easier to maximize in its natural log form

$$\log L(\theta) = \log \left(\prod_{i=1}^n \theta e^{-\theta x_i} \right) = n \log \theta - \theta \sum_{i=1}^n x_i.$$

The maximum occurs at $\hat{\theta} = 1/\bar{x}$, and the Fisher information $i(\theta) = n/\theta^2$, so an approximate $(1 - \alpha)$ confidence interval is

$$\frac{1}{\bar{x}} \pm z_{\alpha/2} i(\hat{\theta})^{-1/2} = \frac{1}{\bar{x}} \pm z_{\alpha/2} \frac{\hat{\theta}}{\sqrt{n}} = \frac{1}{\bar{x}} \pm z_{\alpha/2} (\bar{x}\sqrt{n})^{-1}. \quad (3.10)$$

In this case, the approximation above is surpassed by an exact interval that can be constructed from the statistic $2\theta(X_1 + \dots + X_n)$ which has a chi-squared distribution with $2n$ degrees of freedom. The confidence statement

$$P[\chi_{2n}^2(1 - \alpha/2) \leq (X_1 + \dots + X_n) \leq \chi_{2n}^2(\alpha/2)] = 1 - \alpha,$$

where $\chi_{2n}^2(\alpha)$ represents the α quantile of the chi-squared distribution with $2n$ degrees of freedom, leads to a $1 - \alpha$ confidence interval for θ of

$$\left(\frac{\chi_{2n}^2(1 - \alpha/2)}{2n\bar{x}}, \frac{\chi_{2n}^2(\alpha/2)}{2n\bar{x}} \right). \quad (3.11)$$

3.3.2 Likelihood Ratio

Uncertainty bounds, especially for multidimensional parameters, are more directly computed using the likelihood ratio (LR) method. Here we consider θ to have p components. Confidence regions are constructed by actual contours (in p -dimensions) of the likelihood function. Define the LR as

$$\Lambda(\theta, \hat{\theta}) = \frac{L(\theta)}{L(\hat{\theta})}, \quad (3.12)$$

where $\hat{\theta}$ is the MLE of L . If θ is the true value of the parameter, then

$$-2 \log \Lambda \sim \chi_p^2,$$

where χ_p^2 is the chi-squared distribution with p degrees of freedom. A $(1 - \alpha)$ confidence region for θ is

$$\left\{ \theta : -2 \log \Lambda(\theta, \hat{\theta}) \leq \chi_p^2(\alpha) \right\}, \quad (3.13)$$

where $\chi_p^2(\alpha)$ represents the $1 - \alpha$ quantile of the χ_p^2 distribution.

Example Confidence region for Weibull parameters: In this case, the MLEs for $\theta = (\lambda, r)$ must be computed using numerical methods. Many statistical software packages

Fig. 3.2 $1 - \alpha = 0.50, 0.90,$ and 0.95 confidence regions for Weibull parameters (λ, r) based on simulated data of size $n = 100$

compute such estimators along with confidence bounds. With $(\hat{\lambda}, \hat{r})$, $L(\hat{\lambda}, \hat{r})$ standardizes the likelihood ratio so that $0 \leq \Lambda(\theta, \hat{\theta}) \leq 1$ and Λ peaks at $(\lambda, r) = (\hat{\lambda}, \hat{r})$. Figure 3.2 shows 50%, 90%, and 95% confidence regions for the Weibull parameters based on a simulated sample of $n = 100$.

Empirical likelihood provides a powerful method for providing confidence bounds on parameters of inference without necessarily making strong assumptions about the lifetime distribution of the product (i.e., it is *nonparametric*). This chapter cannot afford the space needed to provide the reader with an adequate description of its method and theory; *Owen* [30] provides a comprehensive study of empirical likelihood including its application to lifetime data. Rather, we will summarize the fundamentals of nonparametric reliability estimation below.

3.3.3 Kaplan–Meier Estimator

For many modern reliability problems, it is not possible to find a lifetime distribution that adequately fits the available failure data. As a counterpart to parametric maximum likelihood theory, the nonparametric likelihood, as defined by Kiefer and Wolfowitz [31], circumvents the need for continuous densities:

$$L(F) = \prod_{i=1}^n (F(x_i) - F(x_i^-)),$$

where F is the cumulative distribution of the sample X_1, \dots, X_n . Kaplan and Meier [32] developed a nonparametric maximum likelihood estimator for F that allows for censored data in the likelihood. The prevalence of right censoring (when a reliability test is stopped at a time t so the component’s failure time is known only to be greater than t) in reliability studies, along with the increasing computing capabilities provided to reliability analysts, has made nonparametric data analysis more mainstream in reliability studies.

Suppose we have a sample of possibly right-censored lifetimes. The sample is denoted $\{(X_i, \delta_i), i = 1, \dots, n\}$, where X_i is the time measurement, and δ_i indicates whether the time is the observed lifetime ($\delta_i = 1$) or a right censor time $\delta_i = 0$. The likelihood

$$L(F) = \prod_{i=1}^n (1 - F(x_i))^{1-\delta_i} dF(x_i)^{\delta_i}$$

can be shown to be maximized by assigning probability mass only to the observed failure times in the sample according to the rule

$$\hat{F}(t) = 1 - \prod_{x_j \leq t} \left(1 - \frac{d_j}{m_j}\right)$$

where d_j are the number of failures at time x_j and m_j are the number of test items that had survived up to the time x_j^- (i.e., just before the time x_j). A pointwise (approximate) confidence interval can be constructed based on the Kaplan–Meier variance estimate

$$\hat{\sigma}^2(t_i) = \left(1 - \hat{F}(t_i)\right)^2 \sum_{t_i \leq t_j} \frac{d_j}{m_j(m_j - d_j)}.$$

Nair [33] showed that large-sample approximations work well in a variety of settings, but for medium samples, the following serves as an effective $(1 - \alpha)$ -level confidence interval for the survival function $1 - F(t)$:

$$\left(1 - \hat{F}(t)\right) \pm \sqrt{-\frac{\ln(\frac{\alpha}{2})}{2n}} \left(1 - \hat{F}(t)\right)^2 \left(1 + \hat{\sigma}^2(t)\right).$$

We illustrate in Fig. 3.3 the nonparametric estimator with strength measurements (in coded units) for 48 pieces of weathered cord along with 95% pointwise confidence intervals for the cord strength. The data, found in Crowder, et al. [34], include seven measurements that were damaged and yielded strength measurements that are considered right censored.

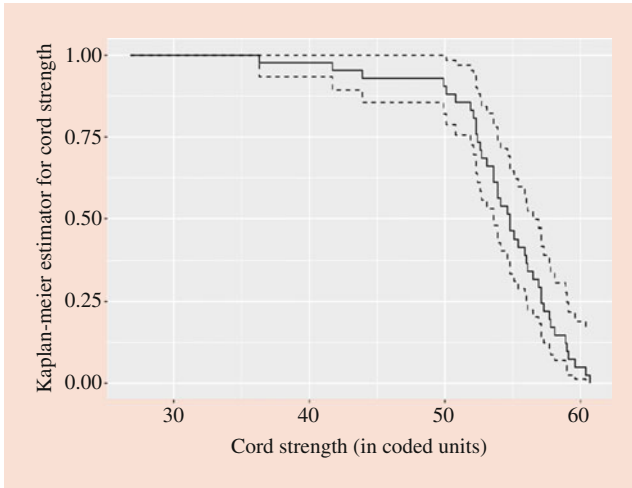

Fig. 3.3 Estimated Kaplan–Meier survival function (1-F) for cord strength data, along with 95% pointwise confidence interval

3.3.4 Degradation Data

As an alternative to traditional life testing, degradation tests can be effective in assessing product reliability when measurements of degradation leading to failure are observable and quantifiable. *Meeker* and *Escobar* [8] provide the most comprehensive discussion on modeling and analyzing degradation data for manufactured items that have either a soft failure threshold (i.e., an arbitrary fixed point at which the device is considered to have failed) or items that degrade before reaching a failed state. In the electronics industry, product lifetimes are far too long to test in a laboratory; some products in the lab will tend to become obsolete long before they actually fail. In such cases, accelerated degradation testing (ADT) is used to hasten product failure. In the manufacture of electronic components, this is often accomplished by increasing voltage or temperature. See Chap. ▶ 22 for a review of recent results in ALT.

If the degradation path is modeled as

$$y_i(t) = \eta_i(t) + \epsilon_i(t), \quad (3.14)$$

where η_i is the path of the i th tested unit ($i = 1, \dots, n$) and ϵ_i represents an error term that has a distribution $H(\epsilon; \Sigma)$ with parameter Σ unknown. Failure would be declared once $y_i(t)$ passes a certain degradation threshold, say y^* . The lifetime distribution can be computed as (assuming degradation is an increasing function)

$$F(t) = P[y(t) > y^*] = P[\epsilon_i(t) > y^* - \eta_i(t)]. \quad (3.15)$$

If η is a deterministic function, the lifetime distribution is driven completely by the error term. This is not altogether realistic. In most cases, item-to-item variability exists and the

function η contains *random coefficients*; that is, $\eta(t) = \eta(t, \lambda, \theta)$, where λ is a vector of unknown parameters (common to all units) and θ is a vector of random coefficients which have a distribution G (with further unknown parameters β) so that realizations of θ change from unit to unit. With an accumulated set of unknown parameters (λ, β, Σ), this makes for a difficult computation of the lifetime distribution. Numerical methods and simulations are typically employed to generate point estimates and confidence statements.

Least squares or maximum likelihood can be used to estimate the unknown parameters in the degradation model. To estimate $F(t_0)$, one can simulate M degradation curves (choosing M to be large) from the estimated regression by generating M random coefficients $\theta_1, \dots, \theta_M$ from the estimated distribution $G(\theta; \hat{\beta})$. Next compute the estimated degradation curve for y_i based on the model with θ_i and $\hat{\lambda}$: $y_i(t) = \eta_i(t; \hat{\lambda}, \theta_i)$. Then $\hat{F}(t_0)$ is the proportion of the M generated curves that have reached the failure threshold y^* by time t_0 .

Meeker and *Escobar* use *bootstrap confidence intervals* for measuring the uncertainty in the lifetime distribution estimate. Their method follows the general algorithm for nonparametric bootstrap confidence intervals described in *Efron* and *Tibshirani* [35]. There are numerous bootstrap sampling methods for various uncertainty problems posed by complex models. This algorithm uses a nonparametric bootstrap sampling procedure which resamples n of the sample degradation curves *with replacement* (i.e., some curves may not be represented in the sample while others may be represented multiple times). This resampled set will be termed the bootstrap sample in the following procedure for constructing confidence intervals.

1. Compute estimates of the parameters β, λ, Σ .
2. Use simulation (as above) to construct $\hat{F}(t_0)$.
3. Generate $N \geq 1000$ bootstrap samples, and for each one, compute estimates $\hat{F}^{(1)}(t_0), \dots, \hat{F}^{(N)}(t_0)$. This is done as before except now the M simulated degradation paths are constructed with an error term generated from $H(\eta; \hat{\Sigma})$ to reflect variability in any single degradation path.
4. With the collection of bootstrap estimates from step 3, compute a $1 - \alpha$ confidence interval for $F(t_0)$ as $[\hat{F}^l(t_0), \hat{F}^u(t_0)]$, where the indexes $1 \leq l \leq u \leq N$ are calculated as $l/N = \Phi[2\Phi^{-1/2}(p_0) + \Phi^{-1/2} \times (\alpha/2)]$ and $u/N = \Phi[2\Phi^{-1/2}(p_0) + \Phi^{-1/2} \times (1 - \alpha/2)]$, and p_0 is the proportion of bootstrap estimates of $F(t_0)$ less than $\hat{F}(t_0)$.

Procedures based on realistic degradation models can obviously grow to be computationally cumbersome, but for important applications the increase in statistical efficiency can be dramatic. In the past, these computations have

impeded degradation analysis from being a feature of reliability problem-solving. Such analyses are easier to implement now, and the reliability analyst need not be coerced into using an overly simplistic model – for instance, a linear model that does not allow for random coefficients.

3.4 System Reliability

A *system* is an arrangement of components that work together for a common goal. So far, the discussion has fixated on the lifetime analysis of a single component, so this represents an extension of single-component reliability study. At the simplest level, a system contains n components of an identical type that are assumed to function independently. The mapping of component outcomes to system outcomes is through the system's structure function. The *reliability function* describes the system reliability as a function of component reliability.

A *series* system is such that the failure of any of the n components in the working group causes the system to fail. If the probability that a single component fails in its mission is p , the probability the system fails is $1 - P(\text{system succeeds}) = 1 - P(\text{all } n \text{ components succeed}) = 1 - (1 - p)^n$. More generally, in terms of component reliabilities (p_1, \dots, p_n) , the system reliability function Ψ is

$$\Psi(p_1, \dots, p_n) = \prod_{i=1}^n (1 - p_i). \quad (3.16)$$

A *parallel* system is just the opposite; it fails only after every one of its n working components fail. The system failure probability is then

$$\Psi(p_1, \dots, p_n) = 1 - \prod_{i=1}^n p_i. \quad (3.17)$$

The parallel system and series system are special cases of a k -out-of- n system, which is a system that works as long as at least k out of its n components work. Assuming $p_i = p$, $i = 1, \dots, n$, the reliability of a k -out-of- n systems is

$$\Psi(p) = \sum_{i=k}^n \binom{n}{i} (1 - p)^i p^{n-i}. \quad (3.18)$$

Of course, most component arrangements are much more complex than a series or parallel system. With just three components, there are five unique ways of arranging the components in a coherent way (that is, so that each component success contributes positively to the system reliability). Figure 3.4 shows the *system structure* of those five arrangements

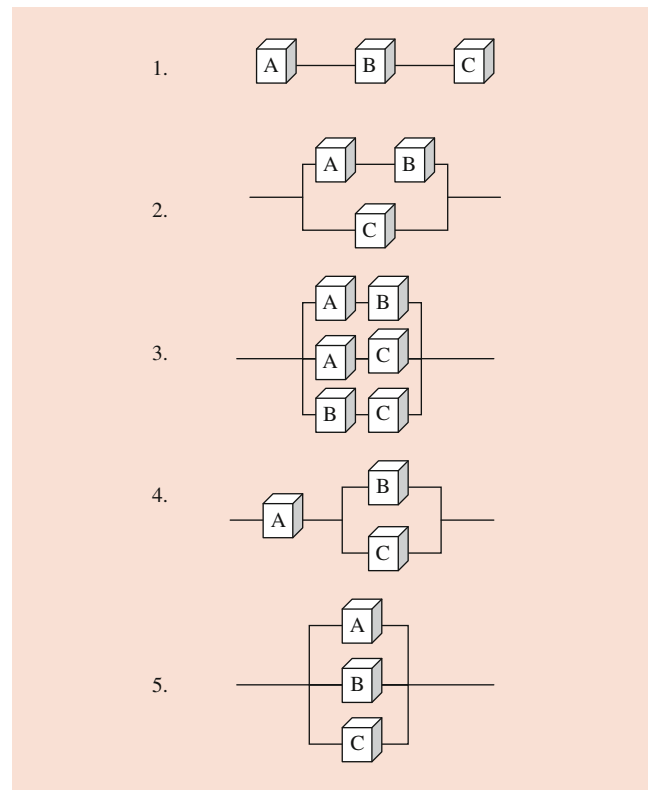

Fig. 3.4 Five unique systems of three components: (1) is series, (3) is 2-out-of-3, and (5) is parallel

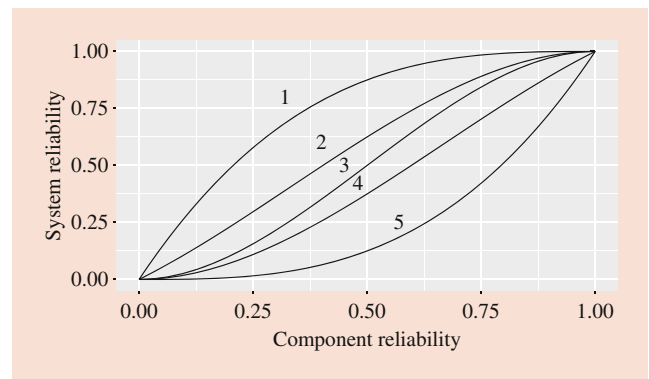

Fig. 3.5 System reliabilities of five system configurations in Fig. 3.4 from the parallel system (1) to the series system (5)

in terms of a *logic diagram* including a series system (1), a 2-out-of-3 system (3), and a parallel system (5). Note that the 2-out-of-3 system cannot be diagrammed with only three components, so each component is represented twice in the logic diagram. Figure 3.5 displays the corresponding reliabilities, as a function of the component reliability $0 \leq p \leq 1$ of those five systems. Fundamental properties of coherent systems are discussed in [2, 4].

3.4.1 Estimating System and Component Reliability

In many complex systems, the reliability of the system can be computed through the reliability of the components along with the system's structure function. If the exact reliability is too difficult to compute explicitly, reliability bounds might be achievable based on *minimum cut sets* (MCS) and *minimum path sets* (MPS). An MPS is the collection of the smallest component sets that are required to work in order to keep the system working. An MCS is the collection of the smallest component sets that are required to fail in order for the system to fail. Table 3.2 shows the minimum cuts sets and path sets for the three-component systems from Fig. 3.4.

In most industrial systems, components have different roles and varying reliabilities, and often the component reliability depends on the working status of other components. System reliability can be simplified through fault-tree analyses (see Chap. 7 of [16], for example), but uncertainty bounds for system reliability are typically determined through simulation.

In laboratory tests, component reliabilities are determined and the system reliability is computed as a function of the statistical inference of component lifetimes. In field studies, the tables are turned. Component manufacturers seeking reliability data outside laboratory tests look to component lifetime data within a working system. For a k -out-of- n system, for example, the system lifetime represents an order statistic of the underlying distribution function. That is, if the ordered lifetimes form a set of independent and identically distributed components ($X_{1:n} \leq X_{2:n} \leq \dots \leq X_{n:n}$), then $X_{n-k+1:n}$ represents the k -out-of- n system lifetime. The density function for $X_{r:n}$ is

$$f_{r:n}(t) = r \binom{n}{r} F(t)^{r-1} [1 - F(t)]^{n-r} f(t), t > 0. \quad (3.19)$$

Kvam and Samaniego [36] derived the nonparametric maximum likelihood estimator for $F(t)$ based on a sample of k -out-of- n system data, and showed that the MLE $\hat{F}(t)$ is consistent. If the i -th system ($i = 1, \dots, m$) observed is a k_i -out-of- n_i system, the likelihood can be represented as

$$L(F) = \prod_{i=1}^m f_{k_i:n_i}(t_i) \quad (3.20)$$

Table 3.2 Minimum cut sets and path sets for the systems in Fig. 3.3

System	Minimum path sets	Minimum cut sets
1	{A,B,C}	{A}, {B}, {C}
2	{A,B}, {C}	{A,C}, {B,C}
3	{A,B}, {A,C}, {B,C}	{A,B}, {A,C}, {B,C}
4	{A,B}, {A,C}	{A}, {B,C}
5	{A}, {B}, {C}	{A,B,C}

and numerical methods are employed to find \hat{F} . Huang [37] investigated the asymptotic properties of this MLE, and Chen [38] provides an ad hoc estimator that examines the effects of censoring.

Compared to individual component tests, observed system lifetimes can be either advantageous or disadvantageous. With an equal number of k -out-of- n systems at each $1 \leq k \leq n$, Takahasi and Wakimoto [39] showed that the estimate of MTTF is superior to that of an equal number of individual component tests. With an unbalanced set of system lifetimes, no such guarantee can be made. If only series systems are observed, Kvam and Samaniego [40] show how the uncertainty in $\hat{F}(t)$ is relatively small in the lower quantiles of F (where system failures are observed) but explodes in the upper quantiles.

3.4.2 Stochastic Dependence Between System Components

Almost all basic reliability theory is based on systems with independently operating components. For realistic modeling of complex systems, this assumption is often impractical; system components typically operate at a level related to the quality and operational state of the other system components.

External events that cause the simultaneous failure of component groups is a serious consideration in reliability analysis of power systems. This can be a crucial point in systems that rely on built-in component redundancy to achieve high target system reliability. Shock models, such as those introduced by Marshall and Olkin [41], can be employed to demonstrate how multiple component failures can occur. An extra failure process is added to the otherwise independent component failure processes, representing the simultaneous failure of one or more components, thus making the component lifetimes positively dependent. This is the basis for most dependent failure models in probabilistic risk assessment, including *common cause failure* models used in the nuclear industry (alpha-factor model, beta-factor model, and binomial failure rate model). See Chapt. 8 of Bedford and Cooke [16] for discussion about how these models are used in risk assessment.

In dynamic systems, where system configurations and component reliability can change after an external event or a failure of one or more of the system components, the shock model approach cannot be applied effectively. In some applications, a load-share model applies. Early applications of the load-share system models were investigated by Daniels [42] for studying the reliability of composite materials in the textile industry. Yarns and cables fail after the last fiber (or wire) in the bundle breaks, thus a bundle of fibers can be considered a parallel system subject to a constant tensile load. An individual fiber fails in time with an individual rate that

depends on how the unbroken fibers within the bundle share the load of this stress. Depending on the physical properties of the fiber composite, this load sharing has different meanings in the failure model. Yarn bundles or untwisted cables tend to spread the stress load uniformly after individual failures which defines an *equal load-share rule*, implying the existence of a constant system load that is distributed equally among the working components.

As expected, a load-sharing structure within a system can increase reliability (if the load distribution saves the system from failing automatically) but reliability inference is hampered even by the simplest model. *Kvam and Pena* [43] show how the efficiency of the load-share system, as a function of component dependence, varies between that of a series system (equivalent to sharing an infinite load) and a parallel system (equivalent to sharing zero load).

3.4.3 Logistics Systems

Numerous studies have examined fundamental problems in network reliability [44], system performance degradation, and workload rerouting for telecommunication, power, and transportation networks [45, 46]. In comparison, the literature on modeling logistics system reliability or performance degradation is scarce. Logistics systems that transport goods, energy (e.g., electricity and gas), water, sewage, money, or information from origins to destinations are critical to every nation's economic prosperity. Unlike the hub in the typical Internet or telecommunication network, where the messages are not mixed together, logistics distribution centers (DCs) tend to mix products from various sources for risk-pooling purposes [47]. Past studies [48] of road network reliability mainly addressed connectivity and travel time reliability. These developments have limited use in providing a first-cut analysis for system-level planning that involves robust logistics network design to meet reliability requirements or supply chain cost and delivery time evaluation for contract decisions [49].

Consider a logistics network consisting of many suppliers providing goods to several DCs, which support store operations to meet customer demands. The reliability of such a network can be evaluated in terms of the probability of delivering goods to stores in a prespecified time limit t_0 . Traveling time in transport routes contains uncertainty, as does the processing time for products shipped through DCs. Random traveling time is a function of routing distances, road and traffic conditions, and possible delays from seaport or security checkpoint inspections. Traveling distance depends on the configuration of logistics networks. Some retail chains use single-layer DCs, but others use multiple-layer

DCs similar to airline hubs (e.g., regional DCs and global DCs) in aggregating various types of goods. Vehicle routing procedures typically involve trucks that carry similar products to several stores in an assigned region. Different products are consolidated in shipment for risk-pooling purposes and to more easily control delivery time and store-docking operations.

When one DC cannot meet the demands from its regional stores (due to demand increase or the DC's limited capability), other DCs provide backup support to maintain the overall network's service reliability. Focusing on the operations between DCs and stores, *Ni et al.* [49] defined the following network reliability as a weighted sum of the individual reliabilities from each DC's operations:

$$r_{\text{system},k}^* = \left[\sum_{i=1, i \neq k}^M d_i P(T_{m,i}^* < t_0) + \sum_{i=1, i \neq k}^M p_i d_k P(T_{m,k,i}^* < t_0) \right] / \sum_{i=1}^M d_i, \quad (3.21)$$

where d_i is the demand aggregated at the i th DC, $T_{m,i}^*$ is the motion time defined as the sum of traveling time from DC $_i$ to its assigned stores (including material processing time at DC $_i$), p_i is the proportion of products rerouted from DC $_k$ through DC $_i$ due to the limited capability in DC $_k$, and $T_{m,j}^*$ is the modified motion time including the rerouted traveling time.

For modeling the aggregated demand d_i and calculating routing distance, *Ni et al.* [49] proposed a multiscale approximation model to quantify demand patterns at spatially located clustered stores. Then, they evaluated product rerouting strategies for maintaining system service reliability, defined in (3.19). Based on the store locations of a major retail chain, several examples show the importance of designing a robust logistics network to limit service reliability degradation when a *contingency* (e.g., multiple DC failure) occurs in the network. Future work includes:

1. Modeling the low-probability but high-impact contingency in the DCs [49] and routes for calculating their relative importance to network reliability.
2. Examining the trade-off between the cost of adding more DCs and the improvement of service reliability.
3. Resolving the *domino effect* when the added workload to DCs after a local DC failure causes further DC failures due to faulty predetermined rules of rerouting to maintain system reliability (e.g., the 2003 electricity blackout in the northeastern region of the USA).

3.4.4 Robust Reliability Design in the Supply Chain

Past studies of robust parameter design [50] focused on product quality issues and assumed that all the controllable variables are under single ownership. Recent outsourcing trends in automobile and electronic manufacturing processes motivate the presentation in this section. In an automobile manufacturing enterprise system, various parts suppliers have control of variables determining quality and reliability. Most of the automobile supply chain systems assemble these parts into a subsystem and then move these systems to other locations owned by different partners for the final system-level assembly and testing. Every segment of the assembly operation controls a subset of variables leading to different levels of system reliability. Because the warranty policy is addressed to all of the part manufacturing and assembly processes in making the final product, it is important to extend the robust parameter design concept to the supply-chain-oriented manufacturing processes.

Supply chain partners have their own operation objectives (e.g., maximize the profit of manufacturing parts to supply several automobile companies). Some of the objectives are aligned to manufacturing a specific type of product, but there are many potential situations with conflicting objectives. When there is no single ownership of all controllable variables in the manufacturing processes, negotiation is needed to resolve potential conflicts. Game theory [51] is commonly used in supply chain contract decisions. Following the framework of *Chen and Lewis* [52], we can decompose the set of controllable variables into a few subsets owned by distinct partners and formulate the objectives of these partners. The supply chain manager can define the product quality and reliability measures and build models to link them to the controllable and uncontrollable variables that are seen in robust parameter design.

Different negotiation situations (e.g., the final product assembly company has more bargaining power than other partners) will lead to distinct levels selected for the controllable variables (see *Charoensiriwath and Lu* [53], for example, in negotiations). As a result, the reliability of the final product can vary. Designing a supply chain system that leads to the most reliable products (with minimum cost) presents an acute challenge, and warranty policies can be designed correspondingly. Because parts and subsystems are made by various partners, warranty responsibilities for certain parts are distributed among partners under the negotiated supply chain contracts.

Paul Kvam is a professor of statistics at the University of Richmond. He joined UR in 2014 after 19 years as professor at Georgia Tech and 4 years as scientific staff at the Los Alamos National Laboratory. Dr. Kvam received his B.S. in mathematics from Iowa State University in 1984, an M.S. in statistics from the University of Florida in 1986, and his Ph.D. in statistics from the University of California, Davis in 1991. His research interests focus on statistical reliability with applications to engineering, nonparametric estimation, and analysis of complex and dependent systems. He is a fellow of the American Statistical Association and an elected member of the International Statistics Institute.

Paul Kvam received his Ph.D. from the University of California, Davis, in 1991. He was a staff scientist at Los Alamos National Laboratory from 1991–1995, and professor at Georgia Tech from 1995–2014 in the School of Industrial and Systems Engineering. Kvam is currently professor of statistics in the Department of Mathematics and Computer Science at the University of Richmond.

Jye-Chyi (JC) Lu is a professor in the School of Industrial and Systems Engineering (ISyE). He received a Ph.D. in statistics from University of Wisconsin at Madison in 1988, and joined the faculty of North Carolina State University where he remained until 1999 when he joined Georgia Institute of Technology. Dr. Jye-Chyi Lu's research areas cover industrial statistics, signal processing, semiconductor and electronic manufacturing, data mining, bioinformatics, supply chain management, logistics planning, and nanotechnology. He has about 93 disciplinary and interdisciplinary publications, which have appeared in both engineering and statistics journals. He has served as an associate editor for *Technometrics*, *IEEE Transactions on Reliability*, and *Journal of Quality Technology*.

His work now includes reliability, human-in-the-loop variable selections for large p small n problems, decision, and data analytics.

Abstract

This chapter introduces functional data analysis (FDA) and selective topics in FDA, including functional principal component analysis (FPCA) and functional linear regression (FLR), with real data applications using a software package, which is publicly available. The methods in this chapter are based on local polynomial regression, a basic and important smoothing technique in nonparametric and semiparametric statistics. The approaches included in this chapter are not limited to the analysis of dense functional data but can also be used for the analysis of sparse functional/longitudinal data.

In Sect. 4.1, we introduce FDA with some interesting examples of functional data and briefly describe FPCA and FLR. Section 4.2 details FPCA, one of the most important topics and tools in FDA. Topics such as the estimation of mean and covariance functions using non-parametric smoothing, choosing the number of principal components (PC) using subjective and objective methods, and prediction of trajectories are included and illustrated using a publicly available bike-sharing data set. Section 4.3 presents FLR based on FPCA described in Sect. 4.2. FLR is a generalization of traditional linear regression to the case of functional data. It is a powerful tool to model the relationship between functional/scalar response and functional predictors. This section is also illustrated using the same bike-sharing data set. We focus on the case when both response and predictor are functions in this section, but we mentioned other types of FLR topics in Sect. 4.4. Section 4.4 presents a short overview of other selected topics and software packages in FDA. These topics are either about functional data with more complex features than the simple and basic ones included in the previous two sections or about other statistical estimation and inference not covered before. The statistical software packages used in this chapter are written in Matlab and may be appropriate for the analysis of some basic types of functional data but not for others. Section 4.4 described other software packages written in different languages, such as R, and those packages have the flexibility to analyze various problems in functional data and different types of functional data.

4.1 Introduction

FDA deals with the analysis of data which are in the form of functions. The functions could be curves, images, or other types of forms, depending on the set on which the functions are recorded. A common type of functional data are curves recorded during a time interval. For example, a well-known example of functional data described in a classic book on FDA [1] is the Canadian weather station data. The data set is about the daily temperature and precipitation data recorded in 35 Canadian weather stations. The daily average temperature data are shown in Fig. 4.1. We notice that, on average, the data look like a parabola; also there are obvious variations among those weather stations, and some patterns of correlation may exist between two time points. In FDA, some of those findings can be described using a univariate mean function and a bivariate correlation function.

FDA has received increasing attention and interests during the past two decades. This is probably due to the development of technology, which enables the collection of functional data in many fields, including medical science, public health, engineering, biological science, environmental science, etc.

For example, in plant breeding and precision agriculture, high-throughput phenotyping technologies have been successfully employed, which enables collecting phenotyping data over time automatically. The characteristics of crops over time are examples of functional data. For example, [2] studied the growth and its dynamics of maize using high-throughput phenotyping data. The sizes of maize plants in the study were observed during a 21-day period of time, and their

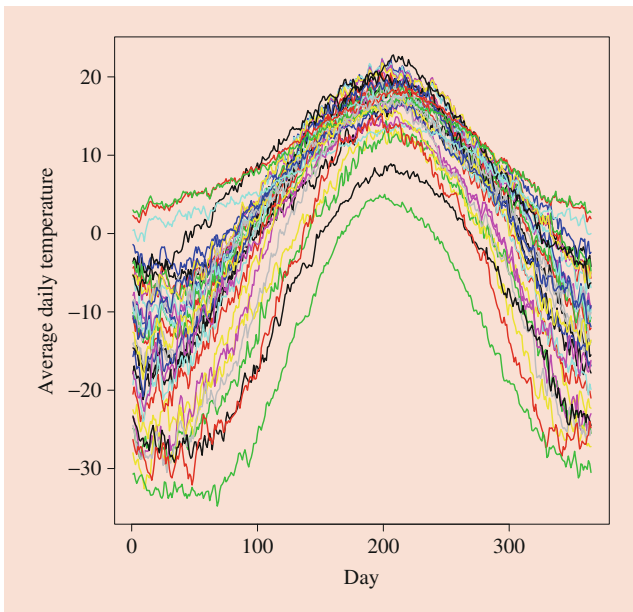

Fig. 4.1 Average daily temperature measured at 35 Canadian weather stations

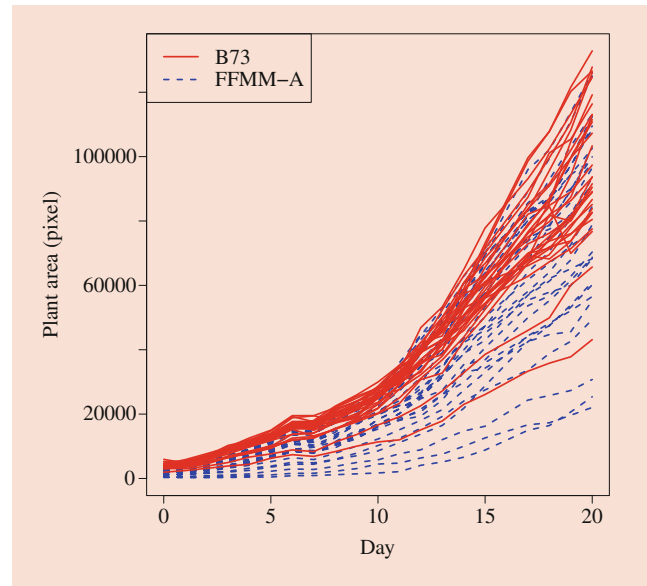

Fig. 4.2 The growth of maize of two genotypes: genotype B73 and genotype FFMM-A

Fig. 4.3 The development of root tip angles of thousands of maize seeds during 3-h experiments

growth curves are shown in Fig. 4.2. In the study of root gravitropism, modern technology also facilitates the collection of gravitropism data automatically using advanced digital cameras. For example, [3] studied the root gravitropism over time using FDA. In particular, the gravitropism data has a multilevel structure, namely, multilevel or hierarchical functional data, which will be discussed in Sect. 4.4.1 (Fig. 4.3).

Functional data are intrinsically infinite-dimensional. They are usually represented by random processes over a fixed time interval. In real-world applications, the processes

are not observed completely but discretely over regular or irregular time points. In classical FDA, e.g., the methods introduced in [1], there are usually abundant observations for each curve, so each curve contains enough information for the trajectory of a subject. For example, in the study of the activities of a brain, data collected using the electro-physiological monitoring method usually have thousands of observations per curve. However, in longitudinal studies, often there are only a few observations per curve, namely, sparse functional data. Yao et al. [4] proposed the idea of pooling information from all curves for the analysis of such type of data. The methods we described in this chapter are mainly based on the idea of [4], but the application of the methods is not limited to sparse functional data.

FPCA, as an important dimension reduction tool, has been used widely in FDA. It captures the majority of the variation in functional data, facilitates the interpretation of the data, and provides outputs which can be used for further statistical analysis. In FPCA, the observed curves are treated as realizations from a random process. The random process is usually decomposed into three parts: an overall fixed mean function, a zero-mean random process, and a zero-mean random variable representing measurement errors. The mean function and the covariance function of the zero-mean process are usually assumed to be smooth. Therefore, non-parametric smoothing methods, such as local polynomial regression and spline-based approaches, become fundamental tools for FPCA. For example, [1] mainly uses spline-based approaches and [4] employs local polynomial regression for smoothing. The main attraction of FPCA is it enables the representation of the zero-mean random process as a finite linear combination of random variables, called functional principal component (PC) scores, and fixed functions, called eigenfunctions.

Probably the most important models in statistics are linear regression models. In a linear regression model, it is assumed that there is a linear relationship between a response and predictors. The counterpart in FDA is called FLR models. In a FLR model, the regression parameter in a classical linear regression model becomes a regression function. The regression function is a one-dimensional function if the response is scalar or a two-dimensional function if the response is also a function. The results of FPCA for the predictor if the response is scalar, or for both the predictor and response if the response is also a function, can be used to obtain the regression function. Similar to classical linear regression models, FLR models can also be used to make a prediction of the unknown response given a new predictor trajectory.

The rest of this chapter is structured as follows. Section 4.2 details the methods used for FPCA based on local polynomial regression with a real data application. FPCA-based FLR is described in Sect. 4.3 with an example when both the response and the predictor are functions. Section 4.4 includes

selective topics in FDA which have applications in engineering and other fields. All the analyses in Sects. 4.2 and 4.3 are implemented using the same public available statistical software package, and the details of the implementation are also provided. Some other statistical software packages for FDA are described in Sect. 4.4.

4.2 Functional Principal Component Analysis

4.2.1 Model for FPCA

In FDA, it is often assumed that data are independent realizations of a smooth stochastic process, $X(t)$, over a compact interval. Without loss of generality, we assume the interval to be $[0, 1]$. In this chapter, we refer t as a time variable, but it could be other index variables, such as locations in image analysis. The random process $X(t)$ is often assumed to belong to a Hilbert space, $L^2([0, 1])$, with finite second moment; that is, $E\{\int_0^1 X^2(t)dt\} < \infty$. The mean function of $X(t)$ is defined as $\mu(t) = E\{X(t)\}$, and the covariance function is denoted by $C(s, t) = \text{Cov}(X(s), X(t))$.

In real-world applications, we never observe the whole process over the time interval. Instead, data are collected discretely. There are roughly two typical types of designs depending on how the data are collected. Assume that there are n subjects. For each subject $i = 1, \dots, n$, the observations are made at time $T_{ij}, j = 1, \dots, N_i$ of the process $X_i(t)$, where $X_i(t)$ are independent realizations of $X(t)$. If the number of observations per subject, N_i , is not bounded and the observations are made on a regular grid, then it is called dense design; if N_i is bounded and observations are made randomly during the time interval, it is called sparse design.

The data set we will use for the illustration of FPCA is a bike-sharing data set. This data set contains hourly count of rental bikes during 2011 and 2012 in the Capital Bikeshare system with weather and seasonal information. After removing an obvious outlier curve, we chose days in 2011 which are neither a weekend nor a holiday. There are 249 days in total. In this section, we are interested in the count of rental bikes observed hourly as shown in Fig. 4.4. As we expected, there are two peaks of those curves: one is in the morning when people go to work, and the other is in the afternoon when people go home after work. We should mention that the design of this data might neither be a dense nor sparse design because for some days there are less than 24 observations. The method we described in the section is based on [4] which is originally proposed to deal with sparse functional data. However, it can still be applied to such types of functional data or dense functional data.

To represent the variation in functional data, FPCA has become one of the most popular methods because

Fig. 4.4 The count of rental bikes measured hourly for 249 days in 2011. Each curve represents observations during a day

it can explain most of the variance in the data with a small number of components. According to Karhunen-Loève theorem, each random curve can be expressed as $X_i(t) = \mu(t) + \sum_{k=1}^{\infty} \xi_{ik} \phi_k(t)$, where ξ_{ik} , called PC scores, are uncorrelated zero-mean random variables with variance λ_k such that $\sum_{k=1}^{\infty} \lambda_k < \infty$. Most of the time, the measurements are contaminated with noise. For example, miscounting could happen in the Capital Bikeshare system. To incorporate possible measurement errors, assume that Y_{ij} , realizations of the process $Y(t) = X(t) + \epsilon$, are the observations we have and can be written as $Y_{ij} = \mu(T_{ij}) + X_i(T_{ij}) + \epsilon_{ij}$, where ϵ_{ij} are zero-mean measurement errors with constant variance σ^2 . The errors ϵ_{ij} are assumed to be independent of PC scores. The whole model can be expressed as

$$Y_{ij} = \mu(T_{ij}) + \sum_{k=1}^{\infty} \xi_{ik} \phi_k(T_{ij}) + \epsilon_{ij}. \quad (4.1)$$

4.2.2 Estimation of Mean Function, Eigenvalues, and Eigenfunctions

We first estimate the mean function $\mu(t)$. In FDA, it is often assumed that the functions in (4.1) are smooth. Therefore, smoothing methods can be applied to estimate unknown functions or surfaces. Yao et al. [4] used local polynomial [5] smoothing method, and [6, 7] employed spline-based approaches. Here, we introduce the local polynomial-based approach described by Yao et al. [4]. At time point t , the value of the mean function can be estimated by minimizing

$$\sum_{i=1}^n \sum_{j=1}^{N_i} \{Y_{ij} - a_0 - a_1(T_{ij} - t)\}^2 K\{(T_{ij} - t)/h_{\mu}\}$$

with respect to (a_0, a_1) , where $K(\cdot)$ is a symmetric density function, called a kernel function, and h_{μ} is a smoothing parameter, called a bandwidth, which controls the smoothness of the resulting function. Explicit solutions can be obtained and are denoted by (\hat{a}_0, \hat{a}_1) . The estimator of the mean function is $\hat{\mu}(t) = \hat{a}_0$. Rice, and Silverman [6] proposed a cross-validation method to choose the bandwidth, h_{μ} .

We now apply the local linear smoother to the bike-sharing data to obtain the mean function estimate. The package we use to implement the data analysis in this chapter is called PACE package. PACE is written in Matlab and provides functions to implement various methods in FDA. Here is the link to PACE: <http://www.stat.ucdavis.edu/PACE/>. The function to perform FPCA is also called FPCA in PACE. We applied this function to the data and obtained the estimated mean function in Fig. 4.5. The estimated curve clearly shows the pattern during a regular working day: the number of sharing bikes increases during an early morning until a smaller peak around 8 AM; then it decreases until noon and increases again; it reaches the second and bigger peak around 6 PM and then decreases again.

Define the residuals as $e_{ij} = Y_{ij} - \hat{\mu}(T_{ij})$. Similarly, the covariance function can also be estimated using local linear regression. At time point (s, t) , the estimated covariance function can be obtained by minimizing

$$\sum_{i=1}^n \sum_{j \neq k} \{e_{ij} e_{ik} - b_0 - b_1(T_{ij} - s) - b_2(T_{ik} - t)\}^2 \times K\{(T_{ij} - s)/h_C\} K\{(T_{ik} - t)/h_C\},$$

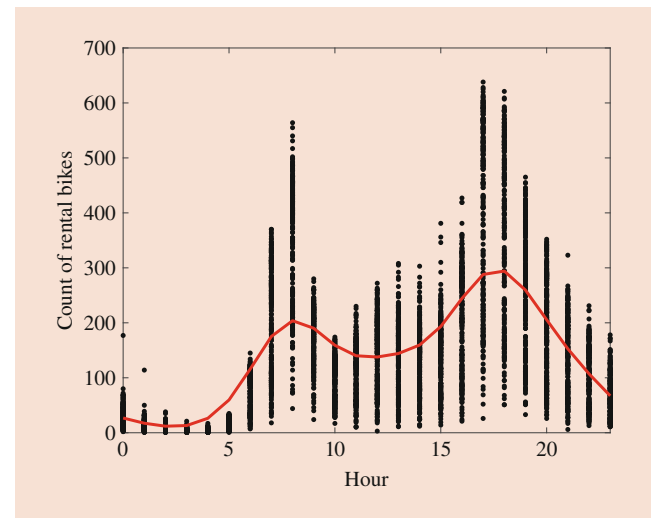

Fig. 4.5 The scatter plot of the count of the bike-sharing data and the estimated mean function using local linear smoothing

Fig. 4.6 The estimated covariance function using a local linear smoother

where h_C is a bandwidth. Denote the solutions as $(\widehat{b}_0, \widehat{b}_1, \widehat{b}_2)$; then the estimate of the covariance function is $\widehat{C}(s, t) = \widehat{b}_0$. We applied the FPCA function of the PACE package to the real data and obtained the estimated covariance function in Fig. 4.6. The main diagonal of the estimated covariance surface has two peaks located around 8 AM and 6 PM, which is consistent with the scatter plot in Fig. 4.5. We also see that the covariance between the two time points of the two peaks is large. One explanation for this phenomenon is that many people using rental bikes to go to work in the morning end up using them to go back home as well.

Let $V(t) = \text{Var}\{Y(t)\} = C(t, t) + \sigma^2$. Similarly, we estimate $V(t)$ using local linear regression and denote the solution as $\widehat{V}(t)$. The error variance σ^2 is estimated by $\widehat{\sigma}^2 = \int_0^1 \{\widehat{V}(t) - \widehat{C}(t, t)\} dt$. For the bike-sharing data, the estimated standard deviation is $\widehat{\sigma} = 53.51$, which indicates a significant amount of measurement errors.

The Karhunen-Loève theorem leads to $C(s, t) = \sum_{k=1}^{\infty} \lambda_k \phi_k(s) \phi_k(t)$. Therefore, the estimated eigenvalues, $\widehat{\lambda}_k$, and eigenfunctions, $\widehat{\phi}_k(t)$, are estimated by the following equations:

$$\int_0^1 \widehat{C}(s, t) \widehat{\phi}_k(s) ds = \widehat{\lambda}_k \widehat{\phi}_k(t), \quad (4.2)$$

where the eigenfunctions are orthonormal which means $\int_0^1 \widehat{\phi}_k(t) \widehat{\phi}_l(t) dt = \mathbf{I}(k = l)$. In practice, the eigenfunctions are often estimated by discretizing the estimated smooth covariance surface [4, 6].

Notice that the Karhunen-Loève theorem leads to an infinite sum. In real data applications, it is often truncated to a relatively large number first, e.g., 25. A criterion can then be used to select first few dominant components. A

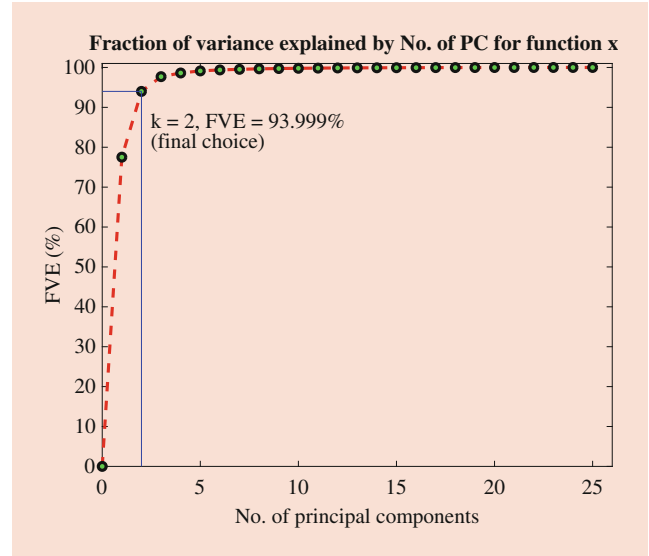

Fig. 4.7 The scree plot for FPCA of the bike-sharing data using 90% as a threshold

simple criterion is the fraction of variance explained (FVE) method. This method needs us to specify a threshold fraction first, such as 90%. If the first K components can explain at least 90% of the total variation, then FVE will choose the first K components. For the application to the bike-sharing data, if we set 90% as the threshold, the FVE method chooses the first two components as shown in the scree plot, Fig. 4.7. FVE method is simple, but a drawback of it is it is a subjective method. Data-driven approaches, such as AIC and BIC proposed in [8], are better approaches to choose the dominant components in FPCA. The first two estimated eigenfunctions are shown in Figs. 4.8 and 4.9. The other way to visualize the effects is to plot components as perturbation of the mean. Ramsay and Silverman [1] suggests to use $\widehat{\mu}(t) \pm 0.2c\widehat{\phi}_k(t)$, where $c = \sqrt{\|\widehat{\mu}(t) - \bar{\mu}\|^2}$ and $\bar{\mu} = \int_0^1 \widehat{\mu}(t) dt$. The perturbation plot for the first component is shown in Fig. 4.10. It shows that the effect of the first PC of variation is approximately adding or subtracting larger values when the value of the estimated mean function is larger. On the other hand, the effect of the second PC of variation, as shown in Fig. 4.11, shows an opposite pattern. It adds or subtracts smaller values when the value of the estimated mean function is larger.

4.2.3 Estimation of PC Scores

The next step is to estimate the PC scores $\xi_{ik} = \int_0^1 \{X_i(t) - \mu(t)\} \phi_k(t) dt$. For dense functional data, numerical integration approximation is suitable. However, for sparse functional data when there are only a few observations per subject,

Fig. 4.8 The first eigenfunction obtained from the FPCA of the bike-sharing data

Fig. 4.9 The second eigenfunction obtained from the FPCA of the bike-sharing data

numerical integration approximation is very inaccurate. One major contribution of [4] is they proposed an algorithm called the Principal Analysis by Conditional Estimation (PACE) to solve the difficulty for sparse functional data. The advantage of PACE is it pool time points from the entire sample to predict the PC scores. Define $\tilde{X}_i = (X_i(T_{i1}), \dots, X_i(T_{iN_i}))'$, $\tilde{Y}_i = (Y_{i1}, \dots, Y_{iN_i})'$, $\mu_i = (\mu(T_{i1}), \dots, \mu(T_{iN_i}))'$, and $\phi_{ik} = (\phi_k(T_{i1}), \dots, \phi_k(T_{iN_i}))'$. Then, model (4.1) becomes a linear mixed model when the infinite sum is truncated to a finite number, K (e.g., for the bike-sharing data, $K = 2$). Assuming that the PC scores and measurement errors are joint normal, best linear unbiased prediction (BLUP) can be used to predict the functional PC scores. Specifically,

Fig. 4.10 The mean curve and the effects of adding (+) and subtracting (*) a multiple of the first eigenfunction

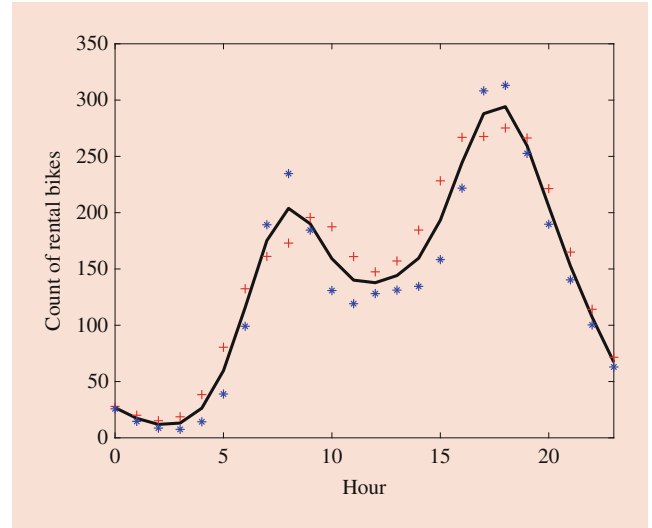

Fig. 4.11 The mean curve and the effects of adding (+) and subtracting (*) a multiple of the second eigenfunction

$$\hat{\xi}_{ik} = \hat{\lambda}_k \hat{\phi}_{ik}' \hat{\Sigma}_{Y_i}^{-1} (\tilde{Y}_i - \hat{\mu}_i), \quad (4.3)$$

where the (l_1, l_2) th element of $\hat{\Sigma}_{Y_i}$ is $\hat{C}(T_{il_1}, T_{il_2}) + \hat{\sigma}^2 \mathbf{I}(l_1 = l_2)$. According to the properties of BLUP, regardless of whether the Gaussian assumption holds or not, $\hat{\xi}_{ik}$ is the best linear prediction of ξ_{ik} .

4.2.4 Prediction of Trajectories and Confidence Bands

Now, the model (4.1) has been fitted and truncated to a suitable number of PC. The fitted model can then be used

Fig. 4.12 The predicted number of rental bikes for the 18th day of the bike-sharing data. The observed values are marked as circles

Fig. 4.13 The predicted number of rental bikes for the 18th day of the bike-sharing data and its 95% point-wise confidence band. The observed values are marked as circles

to predict the trajectory $X_i(t)$ for the i th subject. Naturally, $X_i(t)$ is estimated by

$$\widehat{X}_i(t) = \widehat{\mu}(t) + \sum_{k=1}^K \widehat{\xi}_{ik} \widehat{\phi}_k(t). \quad (4.4)$$

The prediction formula is more attractive in the sparse design in FDA because even if we observe only one or two observations for a certain subject, we can still recover the whole curve for this subject using the above formula because PACE can pool the information from curves of all subjects to make the prediction. For the bike-sharing data, most days there are 23 or 24 observations per curve. For illustration, we found one day there are only eight observations, from the 16th hour to the 23rd hour, as shown in Fig. 4.12. Using the prediction formula (4.4), we are able to recover the whole curve. From the predicted curve, we notice that this is actually a particular day because the first peak in the morning is taller than the second peak in the afternoon.

Further, confidence bands can also be obtained for each individual trajectory. Let $\widehat{\Omega}_K = \widehat{\Lambda} - \widehat{H} \widehat{\Sigma}_Y^{-1} \widehat{H}'$, where $\widehat{\Lambda} = \text{diag}\{\widehat{\lambda}_1, \dots, \widehat{\lambda}_K\}$, and $\widehat{H} = (\widehat{\lambda}_1 \widehat{\phi}_{i1}, \dots, \widehat{\lambda}_K \widehat{\phi}_{iK})'$. The $100(1 - \alpha)\%$ point-wise asymptotic confidence band for $X_i(t)$ is

$$\widehat{X}_i(t) \pm z_{1-\frac{\alpha}{2}} \sqrt{\widehat{\phi}_K' \widehat{\Omega}_K \widehat{\phi}_K}, \quad (4.5)$$

where $z_{1-\frac{\alpha}{2}}$ is the $(1 - \frac{\alpha}{2})$ quantile of the standard normal distribution and $\widehat{\phi}_K = (\widehat{\phi}_1(t), \dots, \widehat{\phi}_K(t))'$. Using the formula (4.5), we constructed the 95% point-wise confidence band for the predicted curve in Fig. 4.12 using the PACE package.

Table 4.1 First ten rows of the bike-sharing data

Hour	Humidity	Wind speed	Count	Day
0	0.44	0.3582	5	1
1	0.44	0.4179	2	1
4	0.47	0.3881	1	1
5	0.47	0.2836	3	1
6	0.50	0.3881	30	1
7	0.50	0.1940	64	1
8	0.50	0.2836	154	1
9	0.43	0.3881	88	1
10	0.43	0.2537	44	1
11	0.40	0.3284	51	1

The confidence band is shown in Fig. 4.13. It also supports the finding that the first peak is higher.

4.2.5 Implementation Details

In this section, we first describe the data we used for the analysis in both Sects. 4.2 and 4.3. The first ten observations of the whole data set are shown in Table 4.1. The first column represents the hour of measurements, ranging from 0 to 23. Humidity and wind speed are shown in the second and third columns. Both variables are normalized with a maximum at 1. The fourth column shows the number of total rental bikes including both casual and registered. The last column is simply a label of the day in the year 2011. More details about this data set can be found at “<https://archive.ics.uci.edu/ml/datasets/bike+sharing+dataset>.”

Below are Matlab codes used to implement the FPCA, predict, and obtain relevant figures in this section.

4.3 Functional Linear Regression

4.3.1 Model for FLR

A common case in FLR is both a response variable and predictors are functions over compact sets. For example, in the bike-sharing data set, one predictor, which might be useful to predict the number of rental bikes, is humidity measurement over time. In this section, we mainly focus on the situation when there is a continuous covariate measured over a compact set. The methodology is proposed in [9] for sparse functional data regression, but it may also be applied to other designs of functional data.

Without loss of generality, we also assume the compact set to be $[0,1]$. Assume that the observed values of the predictor are W_{il} , $i = 1, \dots, n$, $l = 1, \dots, M_i$. Similar to (4.1), we write the model for the predictor as

$$\begin{aligned} W_{il} &= V_i(S_{il}) + \varepsilon_{il} \\ &= \mu_V(S_{il}) + \sum_{k=1}^{\infty} \zeta_{ik} \psi_k(S_{il}) + \varepsilon_{il}, \end{aligned} \quad (4.6)$$

where $\mu_V(s) = E\{V_i(s)\}$ is the mean function, S_{il} are measurement times for V_i , ζ_{ik} are zero-mean functional PC scores with variance ρ_k , $\psi_k(s)$ are eigenfunctions, and ε_{il} are zero-mean measurement errors with variance σ_V^2 . The same FPCA procedure described in Sect. 4.2 can be applied to the predictor trajectory to obtain estimates in model (4.6).

We now apply FPCA to the predictor in the bike-sharing data. To make predictions later, we only use the first 247 days for model fitting, and the remaining last 2 days are used for functional prediction. The humidity variable considered here is normalized by dividing it by the maximum, 100. The trajectories of the normalized humidity and the estimated mean function are shown in Fig. 4.14. Notice that the maximum humidity may appear any time during a day because of rain. The smooth estimate, $\hat{v}(s)$, shows a sinusoidal pattern, reaching a maximum around 5 AM when the temperature is about the lowest during a day and reaching a minimum around 3 PM when the temperature is close to the highest during a day. We set 90% as the threshold, and the FVE method chooses the first three PC. The estimated first three eigenfunctions are shown in Fig. 4.15. The first eigenfunction is close to a constant and reflects an overall level of shift. The second eigenfunction represents a contrast between early and late times during a day, and the third eigenfunction shows a contrast between the middle times and the times of the two tails. In this application, both humidity and the count of rental bikes are measured hourly. However, this is not required in FLR. A covariate function could be measured over a different compact set.

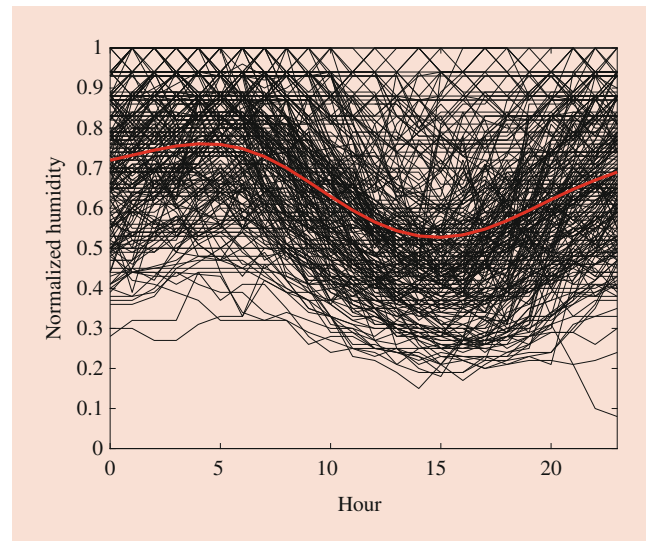

Fig. 4.14 Observed curves of normalized humidity in the bike-sharing data and the estimated mean function using local linear smoothing

Fig. 4.15 Smooth estimates of the first (solid), second (dashed), and third (dash-dot) eigenfunctions for the normalized humidity in the bike-sharing data

A FLR model when both the predictor and response are random functions can be expressed by

$$E[X(t)|V] = \alpha(t) + \int_0^1 \beta(s, t) V(s) ds, \quad (4.7)$$

where $\beta(s, t)$ is a smooth and square integrable bivariate regression function. The above model (4.7) is a natural generalization of the simple linear regression model, $E[X|V] = \alpha + \beta V$. It is well known that for a simple linear regression model, $\beta = \text{Cov}(V, X)/\text{Var}(V)$. For FLR, under certain

regularity conditions, this representation still holds. The regression function is given by

$$\begin{aligned}\beta(s, t) &= \sum_{k=1}^{\infty} \sum_{m=1}^{\infty} \frac{\text{Cov}(\zeta_m \psi_m(s), \xi_k \phi_k(t))}{\|\text{Var}(\zeta_m \psi_m(s))\|^2} \\ &= \sum_{k=1}^{\infty} \sum_{m=1}^{\infty} \frac{\text{E}[\zeta_m \xi_k]}{\text{E}[\zeta_m^2]} \psi_m(s) \phi_k(t).\end{aligned}\quad (4.8)$$

4.3.2 Estimation of Regression Function and R^2

To estimate $\beta(s, t)$ in (4.8), we need to obtain the estimators of the covariance among the PC scores, $\sigma_{km} = \text{E}[\zeta_m \xi_k]$. By the Karhunen-Loève theorem of the predictor and response processes, it follows that the cross-covariance surface between the two processes is

$$\text{Cov}(V(s), X(t)) = \sum_{k=1}^{\infty} \sum_{m=1}^{\infty} \text{E}[\zeta_k \xi_m] \psi_k(s) \phi_m(t).$$

Similarly, the cross-covariance surface can be estimated using local polynomial smoothing by smoothing the ‘‘raw’’ cross-covariances, $\{W_{ij} - \widehat{\mu}_V(S_{ij})\}\{Y_{ij} - \widehat{\mu}(T_{ij})\}$. Let $\widehat{\text{Cov}}(V(s), X(t))$ be the estimated cross-covariance surface; then, $\sigma_{km} = \text{E}[\zeta_m \xi_k]$ is obtained by

$$\int_0^1 \int_0^1 \widehat{\psi}_m(s) \widehat{\text{Cov}}(V(s), X(t)) \widehat{\phi}_k(t) ds dt.$$

Assume that the estimated numbers of PC for the predictor and response process are M and K separately. The estimator for $\beta(s, t)$ becomes

$$\widehat{\beta}(s, t) = \sum_{k=1}^K \sum_{m=1}^M \frac{\widehat{\sigma}_{km}}{\widehat{\rho}_m} \widehat{\psi}_m(s) \widehat{\phi}_k(t).\quad (4.9)$$

We now apply the procedure to the bike-sharing data. The function which performs the above procedure is FPCReg. Previous FPCA for the predictor and the response has shown that $M = 3$ and $K = 2$ (the same as we expected when only the last 2 days are dropped). Using (4.9), we obtained the estimated regression function in Fig. 4.16. The contour plot clearly shows that during the first 5 hours of a day, the humidity does not contribute to the prediction of the number of rental bikes. The regression function seems to have two big peaks, two small peaks, and two valleys. Interestingly, they all located around the time when the time of humidity is around 9 AM and 6 PM.

In regression models, the coefficient of determination is often used to measure how well the observed responses are

predicted by the model. It reflects the proportion of the variance in the dependent variable that is predictable from the predictors. In [9], a functional counterpart of the coefficient of determination is also proposed. A global coefficient of determination, denoted by R^2 , is defined as

$$\begin{aligned}R^2 &= \int_0^1 \frac{\text{Var}(\text{E}[X(t)|V])}{\text{Var}(X(t))} dt \\ &= \int_0^1 \frac{\sum_{m=1}^{\infty} \sum_{k,l=1}^{\infty} \sigma_{km} \sigma_{lm} \phi_k(t) \phi_l(t) / \rho_m}{\sum_{k=1}^{\infty} \lambda_k \phi_k^2(t)} dt.\end{aligned}$$

A natural estimator of R^2 is

$$\widehat{R}^2 = \int_0^1 \frac{\sum_{m=1}^M \sum_{k,l=1}^K \widehat{\sigma}_{km} \widehat{\sigma}_{lm} \widehat{\phi}_k(t) \widehat{\phi}_l(t) / \widehat{\rho}_m}{\sum_{k=1}^K \widehat{\lambda}_k \widehat{\phi}_k^2(t)} dt.\quad (4.10)$$

Applying the formula (4.10) to the real data, we got $\widehat{R}^2 = 0.14$, which indicates that humidity does not contribute very much to the prediction of the number of rental bikes. One may be wondering whether the contribution is significant or not. The Rtest function in PACE allows a bootstrapped sampling-based method to test whether the R-square is zero or not. We set the number of bootstrapped samples to be 500 and obtained a P-value smaller than 0.002, which states that the correlation is significant.

4.3.3 Prediction and Confidence Bands

One of the most important roles of a regression model is it allows us to predict the response for a new subject given a predictor of the subject. In functional regression, this can also be performed similarly. By the properties of conditional expectation, Eq. (4.7) has the following equivalent expression:

$$\text{E}[X(t)|V] = \mu(t) + \int_0^1 \beta(s, t) \{V(s) - \mu_V(s)\} ds.\quad (4.11)$$

Given a predictor process V^* , (4.8), (4.11), and the orthogonality of eigenfunctions leads to

$$\text{E}[X^*(t)|V^*] = \mu(t) + \sum_{k=1}^{\infty} \sum_{m=1}^{\infty} \frac{\sigma_{km}}{\rho_m} \zeta_m^* \phi_k(t),\quad (4.12)$$

where $\zeta_m^* = \int_0^1 \{V^*(s) - \mu_V(s)\} \psi(s) ds$. Except ζ_m^* , all quantities in (4.12) have been obtained in the model fitting. The PC scores of V^* , ζ_m^* , may be estimated easily for dense functional data by the plug-in of V^* , $\widehat{\mu}_V(s)$, and $\widehat{\psi}(s)$. For sparse functional data design, ζ_m^* can be estimated through BLUP (see [9]) for details). After the number of PC has been determined, the predicted trajectory, X^* , is

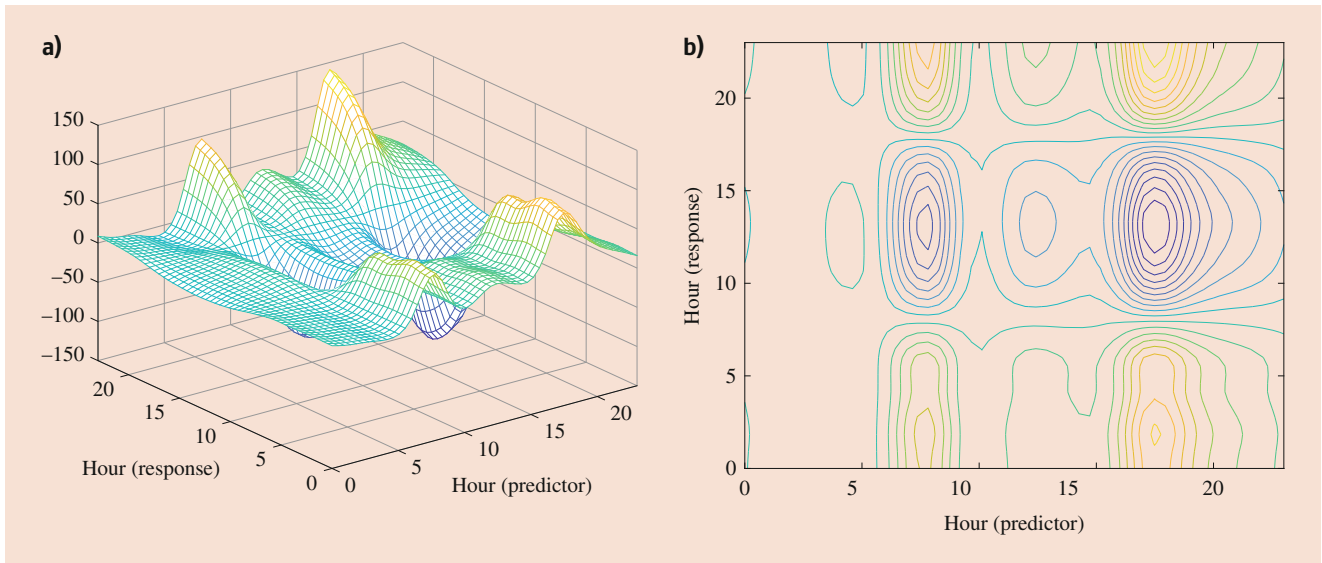

Fig. 4.16 Estimated regression function when the predictor is normalized humidity and the response is number of rental bikes for the bike-sharing data. (a) is the 3-D plot of the estimated regression function; (b) is the corresponding contour plot

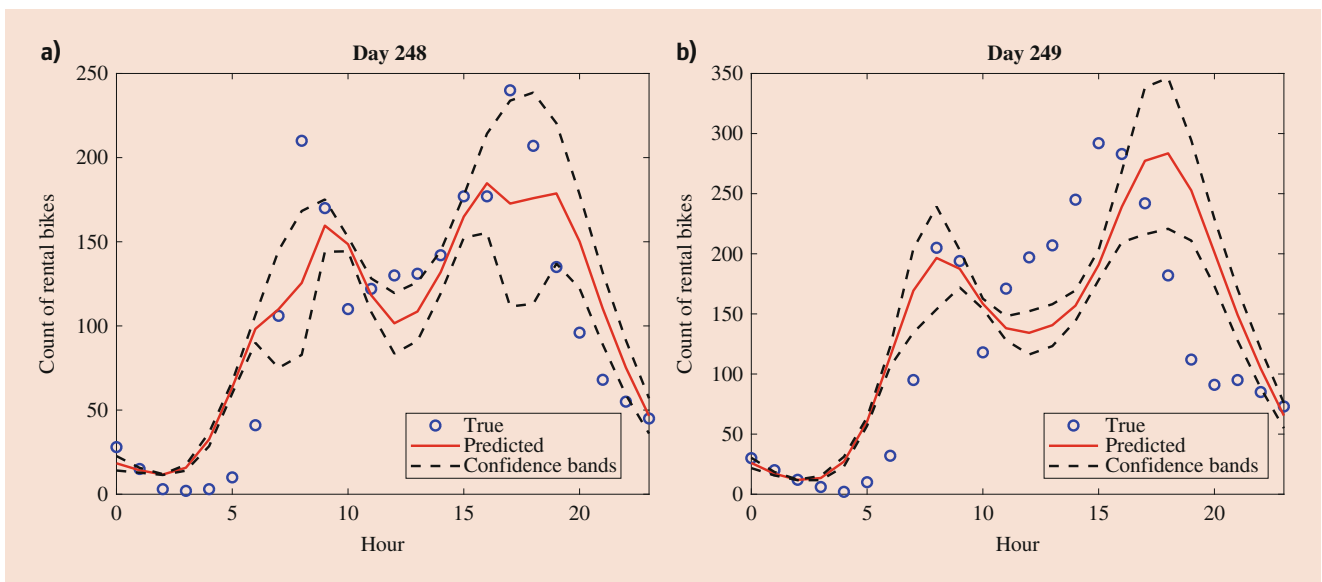

Fig. 4.17 Two days of observed values (circles) of bike-sharing data that are not used for the prediction. The predicted curves (solid) and corresponding 95% point-wise confidence bands (dashed), for the last 2 days in the data. (a) prediction for the 248th day; (b) prediction for the 249th day

$$\widehat{X}^*(t) = \widehat{\mu}(t) + \sum_{k=1}^K \sum_{m=1}^M \frac{\widehat{\sigma}_{km}}{\widehat{\rho}_m} \widehat{\zeta}_m^* \widehat{\phi}_k(t). \quad (4.13)$$

The asymptotic point-wise confidence bands for $X^*(t)$ are also provided in [9].

We applied the procedures to the bike-sharing data to make predictions of the number of rental bike trajectories of the last 2 days using the data of the previous days. The estimated trajectories and their corresponding 95% confidence bands are shown in Fig. 4.17. The prediction is not bad

considering that humidity is not a very important variable to predict the number of rental bikes and only contributes 14% to the explanation of the variance.

4.3.4 Implementation Details

The description of the data is in Sect. 4.2.5. Below are Matlab codes used to implement the functional regression, predict, and obtain relevant figures in this section.

```

% add the toolbox to the working path
addpath(genpath('C:/Program Files/MATLAB/toolbox/release2.17/'))

% Load the data set and create 4 cells to be used
data = csvread('data.csv');      % a 5911 by 5 matrix
ncohort = 249;                    % 249 days in total
t = cell(1,ncohort);
humid = cell(1,ncohort);
wind = cell(1,ncohort);
y = cell(1,ncohort);
for i=1:ncohort
    day_i = data(data(:,5)==i,1:4);
    t{i} = day_i(:,1)';           % hour: 0 to 23
    humid{i} = day_i(:,2)';
    wind{i} = day_i(:,3)';
    y{i} = day_i(:,4)';          % count of bicycles used
end

```

4.4 Other Selected Topics in FDA and Software Packages

In this section, we briefly review some other topics in FDA and software packages developed for FDA. The topics and packages introduced here are not intended to be comprehensive but selective. A review of recent developments in FDA is [10].

4.4.1 Other Selected Topics in FDA

Although [4] provides some asymptotic results, such as consistency of mean and covariance functions, eigenvalues and eigenfunctions, and asymptotic confidence bands, the asymptotic properties are not optimal. Hall et al. [11] further studied the asymptotic properties for the estimators proposed by Yao et al. [4]. Their work shows that the estimation of eigenvalues is a semiparametric problem, with root- n consistent estimators, even if only a few observations are made of each function and if each observation is contaminated with noise. However, the estimation of eigenfunctions becomes a nonparametric problem when observations are sparse. Hall and Vial [12] proposed techniques for assessing the finiteness of dimensionality in FDA. Li and Hsing [13] developed strong uniform convergence rates of the nonparametric estimation of the mean and covariance functions for functional/longitudinal data. Li and Hsing [14] considered regression models with a functional predictor and a scalar response. They assumed that the response depends on the predictor only through a finite number of projections and investigated the dimensionality of the linear subspace spanned by the projections. Recently, [15] provided a comprehensive analysis of the asymptotic properties of nonparametric estimation of mean and covariance functions for various types of sampling plans.

Sometimes it is of interest to recover the underlying derivative from a sample or random functions with a sparse sampling design and measurement errors. Liu and Müller [16] considered the following model for the derivative process $X_i^{(v)}(t)$:

$$X_i^{(v)}(t) = \mu^{(v)}(t) + \sum_{k=1}^{\infty} \xi_{ik} \phi_k^{(v)}(t), \quad (4.14)$$

where $\mu^{(v)}(t)$ and $\phi_k^{(v)}(t)$ denote the v th derivative of mean and eigenfunctions. It is assumed that the observations are made over irregular time points and are contaminated with errors. Liu and Müller [16] then proposed an approach based on estimating derivatives of eigenfunctions and expansions of random functions to obtain a representation for the derivative process. Dai et al. [17] studied similar problems but based on a different approach. They used a direct Karhunen-Loève expansion of the unobserved derivatives and numerically showed that the method recovers the underlying derivatives more accurately.

The FLR we described in Sect. 4.3 is called function-on-function regression, where, for each subject, both response and predictors are trajectories over compact sets. When the response is not functional but scalar, the corresponding regression model is called scalar-on-function regression. For example, for the bike-sharing data, the response could be the total number of rental bikes each day. A FLR model with scalar response can be expressed as

$$E[X|V] = \alpha + \int_0^1 \beta(t)V(t)dt, \quad (4.15)$$

where X is a scalar response, $V(t)$ is a functional covariate, and $\beta(t)$ is the coefficient function. The interpretation of such a linear regression model will be easier than the one in function-on-function regression. For a given time point t , the larger the absolute value of $\beta(t)$, the larger is the impact of V on X . For regular and dense functional data, Chapter 15 of [1] describes classical methods for scalar-on-function regression. The methods are basically estimating $\beta(t)$ by the use of basis functions, such as splines and wavelets. The main methodology of [9] can also be applied to scalar-on-function regression when covariates are sparse functional or longitudinal data. Furthermore, the PACE package also provides functions for such implementation. A review of the developments of functional regression can be found in [18]. The author highlighted the modeling structures that

have been developed in the past 10 years and the various regularization approaches employed in three types of regression models: function-on-function, scalar-on-function, and function-on-scalar, where the response is functional but the predictor is scalar.

In statistics, analysis of variance (ANOVA) is used to analyze the differences among group means in data. In FDA, when the predictor is categorical, such as group factors or treatments, and the response is a trajectory over a compact set, the corresponding model is termed as a functional ANOVA model. For example, one group factor in the bike-sharing data could be the day of a week. For regular and dense functional data, see Chapter 13 of [1] for the classical methods. Xu et al. [2] considered a recent application of functional ANOVA in plant sciences. Let $i = 1, \dots, n$ be the index of maize plant. Define genotype indicator G_i as $G_i = 1$ if the i th maize is of genotype B73 and $G_i = 0$ if the i th maize is of genotype MM. Define the environment indicator W_i as $W_i = 1$ if the i th maize is sufficiently watered and $W_i = 0$ if the i th maize is insufficiently watered. Xu et al. [2] assumed the following functional analysis of variance model for the plant growth:

$$y_i(t) = \mu(t) + G_i g(t) + W_i w(t) + \epsilon_i(t), \quad (4.16)$$

where $\mu(t)$ is the growth function of insufficiently watered MM maize, $g(t)$ is the main effect function of genotype B73, $w(t)$ is the main effect function of sufficient watering, and $\epsilon_i(t)$ is a zero-mean random process representing errors. Zhang [19] includes various major topics in functional ANOVA and some up-to-date hypothesis testing methods for FDA.

The functional data we introduced in the previous sections are actually uni-level functional data, where it is assumed that the processes are independently and identically distributed. In practice, data may have a multilevel structure. For example, [20] studied the impact of national culture on corporate environmental management, where the data have a two-level hierarchical structure because corporations are nested in countries. Di et al. [21] described a sleep heart health study, where there are two visits for each patient with functional measurements, so the data have two levels with visits nested in patients. Xu et al. [3] presented a study of the bending rates of maize roots based on FPCA of functional phenotypes collected from seeds. The data are shown in Fig. 4.3. The data have a three-level nested hierarchical structure, with seeds nested in groups nested in genotypes. Let $Y_i(t)$ be the bending rate of the i th seed at time $t \in [0, 1.5]$, $i = 1, 2, \dots, n$. Denote s_i as the lunar day on which the i th seed was measured, where $s_i \in [1, 30]$. For each seed, a covariate vector X_i is observed depending on the camera setup. Xu et al. [3] modeled the data by the following hierarchical functional data model:

$$Y_i(t) = \mu(s_i, t) + X_i' \alpha + Z_{1,g(i)}(t) + Z_{2,f(i)}(t) + Z_{3,i}(t) + \epsilon_i(t), \quad (4.17)$$

where $\mu(s_i, t)$ is the mean function of the bending rate under a baseline camera setup; α represents fixed effects of cameras; $Z_{1,g(i)}(t)$, $Z_{2,f(i)}(t)$, and $Z_{3,i}(t)$ are random processes representing the functional random effects of genotype $g(i)$, file/group $f(i)$, and seed i , respectively; and $\epsilon_i(t)$ is a white noise measurement error with variance σ^2 .

It is well known in robust statistics that principal component analysis (PCA) has the issue of non-robustness. Similarly, the issue also occurs in FDA using PCA. In FPCA, the estimation of the covariance function and the functional PC are sensible to outliers. Therefore, a robust version of FPCA is needed. Sawant et al. [22] proposed an algorithm for outlier detection and robust FPCA for FDA. The method is motivated by the combination of both projection pursuit and robust covariance estimation using the minimum covariance determinant (MCD) method. She et al. [23] introduced a method called robust orthogonal complement PC analysis. The method they proposed is called orthogonal complement principal component analysis (ROC-PCA). Their framework combines the popular sparsity-enforcing and low-rank regularization techniques together to deal with row-wise outliers and element-wise outliers. This approach can identify outliers and perform robust principal subspace recovery simultaneously.

The confidence band presented in this chapter is called a point-wise confidence band, which means that for each t , the truth is covered by the confidence interval at t with the probability $1 - \alpha$. Specifically, if the mean function to estimate is $\mu(t)$, a point-wise confidence band $\hat{\mu}(t) \pm \hat{\delta}(t)$ with coverage probability $1 - \alpha$ satisfies the following condition separately for each time point t :

$$P\{\hat{\mu}(t) - \hat{\delta}(t) < \mu(t) < \hat{\mu}(t) + \hat{\delta}(t)\} = 1 - \alpha.$$

Simultaneous confidence band, on the other hand, covers the truth for all t with the probability $1 - \alpha$. For the estimation of the mean function, that is,

$$P\{\hat{\mu}(t) - \hat{\delta}(t) < \mu(t) < \hat{\mu}(t) + \hat{\delta}(t) \text{ for all } t\} = 1 - \alpha.$$

Usually, a simultaneous confidence band will be wider than a point-wise confidence band when the coverage probability is the same. In both [4] and [9], the asymptotic confidence bands given are point-wise confidence bands. A simultaneous confidence band for the mean function in the scenario of dense functional data is proposed in [24]. The estimator is a polynomial spline estimator, and the authors showed that the confidence band has an oracle efficiency property. Cao et al. [25] further developed simultaneous confidence envelopes for the covariance function in dense functional data.

In statistics, classification is usually adopted when we want to identify to which group a new observation should be assigned given a training data set. In FDA, the counterpart is called functional classification, in which we want to assign the membership for a new functional object with a classifier. Müller [26] used a functional binary regression model for functional classification. James and Hastie [27] proposed a method to classify functions based on a functional linear discriminant analysis approach. Their technique extends the classical linear discriminant analysis method to the case where the predictor variable is functions.

Multivariate statistics is an important branch of statistics. In FDA, when many characteristics of a subject are measured over time, the data collected is, namely, multivariate functional data. Multivariate FPCA based on a normalization approach was proposed in [28]. Wong et al. [29] investigated the prediction of a scalar response by both parametric effects of a multivariate predictor and nonparametric effects of a multivariate functional predictor. To be specific, [29] model the relationship between scale response y_i , $i = 1, \dots, n$ and a predictor vector z_i and a multivariate functional predictor x_i as

$$y_i = m(z_i, x_i) + \epsilon_i,$$

where $m(\cdot, \cdot)$ is the regression function and ϵ_i are zero-mean errors independent with the predictors. The regression function is assumed to have an additive form, and the effects of predictors are assumed to be linear. Wong et al. [29] proposed an estimation procedure for such models and applied it to a crop yield prediction application.

4.4.2 Selected Software Packages

fdapace is a counterpart of the PACE package, but it is written in R, free software which can be downloaded from <https://www.r-project.org/>. Although they are not exactly the same, the key functions are similar. Both FPCA and FPCReg functions we used for the analysis in this chapter can be used similarly in the *fdapace* package. Most of the methods used in this package are proposed for sparse and irregularly spaced functional data, but they may also be used for the analysis of dense or regularly spaced functional data. The core algorithm in this package allows users to implement the estimation of mean and covariance functions, eigenfunctions and PC scores, and prediction of continuous trajectories with point-wise confidence bands. The main smoothing method used in this package is the local polynomial smoothing.

fd is a package written in R. The functions in this package are aimed to perform the statistical analysis in FDA described in [1]. The classic book in FDA, [1], includes a variety of topics in FDA, such as FPCA, functional canonical correlation and discriminant analysis, functional linear models

with scalar or functional responses, and principal differential analysis. However, the book and its package mainly focus on the modeling and analysis of dense functional data rather than sparse functional data. *fd* mainly used splines and Fourier basis for smoothing and approximation.

refund, short for regression with functional data, is also a package written in R. It provides functions to perform different functional regressions, including function-on-scalar regression, scalar-on-function regression, and function-on-function regression. In particular, some functions in *refund* can be used to analyze image data. *refund* mainly uses splines and Fourier bases for smoothing and approximation, but it also provides wavelet-based functional regression methods with scalar responses and functional predictors. Multilevel FPCA is also available in *refund*.

fd.usc, short for functional data analysis and utilities for statistical computing, is a R package. Except for traditional FPCA and functional regression, it also provides functions for supervised and non-supervised classification for functional data. It also provides an exploratory and descriptive analysis of functional data such as depth measurements and atypical curve detection. This package uses both spline smoothing and local polynomial smoothing.

FRegSigCom, short for functional regression using signal compression approach, is a package written in R. This package is mainly about various function-on-function regression methods, including linear function-on-function model with functional response and both scalar and functional predictors for a small or large number of functional, stepwise selection for function-on-function models with interactions, and some nonlinear function-on-function models. Particularly, their method can handle a large number of functional predictors and spiky functional data (see [30] for details). Splines and Fourier bases are mainly used for smoothing.

normal (MGSN) distribution also has several desirable properties. In this paper, we have proposed a symmetric geometric skew normal (SGSN) distribution as an alternative to a symmetric distribution like normal distribution, log Birnbaum-Saunders (BS) distribution, Student's t distribution, etc. It is a very flexible class of distributions, of which normal distribution is a special case. The proposed model has three unknown parameters, and it is observed that the maximum likelihood (ML) estimators of the unknown parameters cannot be obtained in explicit forms. In this paper, we have proposed a very efficient expectation maximization (EM) algorithm, and it is observed that the proposed EM algorithm works very well. We have further considered a location shift SGSN regression model. It is a more flexible than the standard Gaussian regression model. The ML estimators of the unknown parameters are obtained based on EM algorithm. Extensive simulation experiments and the analyses of two data sets have been presented to show the effectiveness of the proposed model and the estimation techniques.

Abstract

Recently, Kundu (2014, Sankhya, Ser. B, 167–189, 2014) proposed a geometric skew normal (GSN) distribution as an alternative to Azzalini's skew normal (ASN) distribution. The GSN distribution can be a skewed distribution; it can be heavy tailed as well as multimodal also, unlike ASN distribution. It can be easily extended to the multivariate case also. The multivariate geometric skew

5.1 Introduction

Azzalini [3] introduced a skew normal distribution which has received considerable attention in the last three decades. It has three parameters, and it is a skewed distribution of which normal distribution is a special case. From now on we call it as the Azzalini's skew normal (ASN) distribution. A three-parameter ASN distribution has the following probability density function (PDF):

$$f(x) = 2\phi\left(\frac{x-\mu}{\sigma}\right)\Phi\left(\frac{\lambda(x-\mu)}{\sigma}\right).$$

Here $\phi(\cdot)$ is the PDF of a standard normal distribution, the $\Phi(\cdot)$ is the corresponding cumulative distribution function (CDF), $-\infty < \mu < \infty$ is the location parameter, $\sigma > 0$ is the scale parameter, and $-\infty < \lambda < \infty$ is the skewness or tilt parameter. Note that when $\lambda = 0$, it becomes a normal PDF with mean μ and standard deviation σ . It has some interesting physical interpretation also as a hidden truncation model; see, for example, Arnold et al. [2] and Arnold and Beaver [1]. It is a very flexible class of distribution functions, and due to which it has been used to analyze various skewed data sets. Although it has several desirable properties, it has been observed that the maximum likelihood (ML) estimators of the unknown parameters may not always exist; see, for example, Gupta and Gupta [10]. It can be shown that for any sample size if the data come from an ASN distribution, there is a positive probability that the MLEs do not exist. The problem becomes more severe for higher dimension. Moreover, the PDF of an ASN distribution is always unimodal and thin tailed. Due to these limitations, ASN distribution cannot be used for analyzing for a large class of skewed data sets.

To overcome the problem of the ASN distribution, Gupta and Gupta [10] proposed the power normal distribution which has the following CDF:

$$F(x) = \left[\Phi\left(\frac{x-\mu}{\sigma}\right) \right]^\alpha.$$

Here also, $-\infty < \mu < \infty$ is the location parameter, $\sigma > 0$ is the scale parameter, and $\alpha > 0$ is the skewness parameter. When $\alpha = 1$, it becomes a normal distribution function with mean μ and standard deviation σ . Therefore, in this case also the normal distribution can be obtained as a special case. It has been shown by Gupta and Gupta [10] that for $\alpha > 1$ it is positively skewed and, for $\alpha < 1$, it is negatively skewed. They have obtained several other interesting properties of the power normal distribution in the same paper. Kundu and Gupta [18] provided an efficient estimation procedure and also defined bivariate power normal distribution. Although the power normal distribution as proposed by Gupta and Gupta [10] has several desirable properties, and the ML estimators also always exist, it is always unimodal and thin tailed similar to the ASN distribution. Therefore, if the data indicate that the observations are coming from a heavy tailed or multimodal distribution, it can be used to analyze that data set.

Recently, Kundu [14] introduced a three-parameter geometric skew normal (GSN) distribution as an alternative to the popular Azzalini's [3] skew normal (ASN) distribution or the power normal distribution of Gupta and Gupta [10]. The GSN distribution can be defined as follows. Suppose X_1, X_2, \dots , are independent and identically distributed (i.i.d.)

normal random variables with mean μ and variance σ^2 , and N is a geometric random variable with parameter p . Here, a geometric random variable with parameter p will be denoted by $GE(p)$, and it has the following probability mass function:

$$P(N = n) = p(1-p)^{n-1}; \quad n = 1, 2, \dots \quad (5.1)$$

It is assumed that N and X_i 's are independently distributed. The random variable

$$X \stackrel{d}{=} \sum_{i=1}^N X_i,$$

is said to have a GSN distribution with the parameters μ , σ , and p . From now on it will be denoted by $GSN(\mu, \sigma, p)$.

The GSN distribution also has three parameters similar to the ASN or power normal distribution. But the main advantage of the GSN distribution over the ASN or the power normal distribution is that the GSN distribution is more flexible than them in the sense its PDF can have more variety of shapes compared to the ASN distribution. The PDF of the GSN distribution can be symmetric, skewed, unimodal, bimodal, and multimodal shaped also. Moreover, the GSN distribution can be heavy tailed also depending on the parameter values. In case of an ASN distribution, it is observed that the ML estimators may not always exist. In fact it can be shown that the ML estimates will not exist if the all the data points are of the same sign. But in case of the GSN distribution, the ML estimates of the unknown parameters exist, if the sample size is greater than three. If $\mu = 0$, it becomes a symmetric distribution, and it is called a symmetric GSN (SGSN) distribution. From now on a $GSN(\mu, \sigma, p)$ with $\mu = 0$ will be denoted by $SGSN(\sigma, p)$.

As GSN has been introduced, along the same line, multivariate geometric skew normal (MGSN) distribution has been introduced by Kundu [17] as an alternative to Azzalini's multivariate skew normal distribution. In this case, the marginals are GSN distributions, and the joint PDF can be unimodal, bimodal, and multimodal also. Multivariate normal distribution can be obtained as a special case. It has also several interesting properties, and the moments and product moments can be obtained quite conveniently from the joint characteristic function, which can be expressed in explicit form. It has several characterization properties similar to the multivariate normal distribution. A brief review of the MGSN distribution will be provided in Sect. 5.3.

In recent times, the Birnbaum-Saunders (BS) distribution has received a considerable amount of attention in the statistical and some related literature. The BS distribution was originally derived by Birnbaum and Saunders [7] by showing that the fatigue failure is caused by the development and growth of cracks from the cyclic loading. The BS distribution can be defined as follows. Suppose T is a nonnegative random

variable and T is said to have a BS distribution with shape parameter α and scale parameter β ; it will be denoted by $BS(\alpha, \beta)$, if the cumulative distribution function (CDF) of T is given by

$$F_{BS}(t; \alpha, \beta) = \Phi \left\{ \frac{1}{\alpha} \left(\sqrt{\frac{t}{\beta}} - \sqrt{\frac{\beta}{t}} \right) \right\}, \quad t > 0, \quad (5.2)$$

and zero, otherwise. Here $\Phi(\cdot)$ is the CDF of a standard normal distribution. If T follows (\sim) , $BS(\alpha, \beta)$, then $Y = \ln T$ is said to have a log-BS (LBS) distribution. The CDF of Y can be written as

$$F_{LBS}(y; \alpha, \beta) = \Phi \left\{ \frac{2}{\alpha} \sinh \left(\frac{y - \ln \beta}{2} \right) \right\}, \quad -\infty < y < \infty, \quad (5.3)$$

and it will be denoted by $LBS(\alpha, \beta)$. The LBS distribution was originally proposed by Rieck [25]; see also Rieck and Nedelman [26] and Kundu [15, 16] in this respect. It has been observed by Rieck [25] that the LBS distribution is symmetric, it is strongly unimodal for $\alpha < 2$ and for $\alpha \geq 2$, and it is bimodal. It may be mentioned that SGSN distribution is more flexible than the LBS distribution in the sense. SGSN distribution can be heavy tailed also, whereas LBS distribution can never be a heavy tailed. For a comprehensive review on BS distribution, one is referred to the review article by Balakrishnan and Kundu [6]. Although LBS distribution can be bimodal and the ML estimators of the unknown parameters always exist, it cannot be multimodal or heavy tailed.

In this paper, we have introduced a location-shift SGSN (LS-SGSN) distribution. It is observed that due to the presence of three parameters, it is more flexible than a two-parameter normal distribution. Moreover, the normal distribution can be obtained as a special case of the LS-SGSN distribution. We have provided several properties of the LS-SGSN distribution and obtained the characteristic function and different moments. It is interesting to observe that although the PDF of a SGSN distribution can be obtained as an infinite series, the characteristic function can be obtained in explicit form. The LS-SGSN distribution has three parameters. The ML estimators cannot be obtained in explicit forms; they have to be obtained by solving a three-dimensional optimization problem. Some standard numerical methods like Newton-Raphson or Gauss-Newton may be used to compute the ML estimates. But it involves providing efficient initial guesses; otherwise, the algorithm may not converge, and even if it converges it may converge to a local minimum rather than a global minimum. To avoid that, we have treated this problem as a missing value problem, and we have used the EM algorithm to compute the ML estimators. It is observed that at each ‘‘E’’-step, the corresponding ‘‘M’’-step can be performed explicitly. Hence,

no optimization problem needs to be solved numerically at the ‘‘M’’-step, and they are unique. Moreover, at the last step of the EM algorithm, one can easily obtain the observed Fisher information matrix based on the method of Louis [22]. Hence, the confidence intervals of the unknown parameters also can be obtained quite conveniently. We have performed extensive simulation experiments, and the analysis of one data set has been presented for illustrative purposes.

We have further considered the multiple linear regression model in the presence of additive SGSN errors. Note that the analysis of multiple linear regression model in the presence of additive ASN distribution has been well studied in the statistical literature both from the classical and Bayesian viewpoints; see, for example, Sahu et al. [27], Lachos et al. [20], and the references cited therein. Similarly, log-linear BS regression model also has been well studied in the literature; see, for example, Zhang et al. [30] and Balakrishnan and Kundu [6]. It is expected that the proposed multiple regression model will be more flexible than the ASN and LBS multiple regression models.

In this paper, we provide the likelihood inference of the unknown parameters of the proposed SGSN regression model. It is observed that the ML estimators of the unknown parameters cannot be obtained in closed forms. In this case, also we have used a very efficient EM algorithm to avoid solving nonlinear optimization problem. The implementation of the proposed EM algorithm is quite simple in practice. Moreover, using the method of Louis [22] at the last step of the EM algorithm, the observed Fisher information matrix also can be obtained in a standard manner. Hence, the confidence intervals of the unknown parameters based on the observed Fisher information matrix also can be constructed. Simulation experimental results and analysis of a data set have been presented.

The rest of the paper is organized as follows. In Sects. 5.2 and 5.3, we provide a brief review of the GSN distribution and MGSN distribution, respectively. The SGSN and LS-SGSN distributions have been introduced, and the EM algorithm has been discussed in Sect. 5.4. In Sect. 5.5, we have formulated the LS-SGSN regression model and discussed the corresponding EM algorithm. Simulation results have been presented in Sect. 5.6, and the analysis of two data sets has been presented in Sect. 5.7. Finally, we conclude the paper in Sect. 5.8.

5.2 Geometric Skew Normal Distribution

In the previous section, we have provided the definition of a GSN distribution. In this section, we provide a brief review and some properties of a GSN distribution. All the details can be obtained in Kundu [14]. If $X \sim GSN(\mu, \sigma, p)$, then the CDF and PDF of X become

$$F_{GSN}(x; \mu, \sigma, p) = p \sum_{k=1}^{\infty} \Phi\left(\frac{x - k\mu}{\sigma\sqrt{k}}\right) (1-p)^{k-1}, \quad (5.4)$$

and

$$f_{GSN}(x; \mu, \sigma, p) = \sum_{k=1}^{\infty} \frac{p}{\sigma\sqrt{k}} \phi\left(\frac{x - k\mu}{\sigma\sqrt{k}}\right) (1-p)^{k-1}, \quad (5.5)$$

respectively, for $x \in \mathbb{R}$. Here $\phi(\cdot)$ denotes the PDF of a standard normal distribution function.

The PDF of the GSN distribution (5.5) can take a variety of shapes. It can be symmetric, positively skewed, negatively skewed, unimodal, bimodal, multimodal, and heavy tailed also. For different shapes of the PDF of a GSN distribution, see Fig. 5.1 and also Kundu [14]. It is clear that it can be positively skewed, negatively skewed, unimodal, multimodal, and heavy tailed also depending on the parameter values.

If $X \sim \text{GSN}(\mu, \sigma, p)$, then the characteristic function of X is

$$\phi_X(t) = E(e^{itX}) = \frac{pe^{(i\mu t - \frac{\sigma^2 t^2}{2})}}{1 - (1-p)e^{(i\mu t - \frac{\sigma^2 t^2}{2})}}, \quad t \in \mathbb{R}.$$

The mean and variance of X are

$$E(X) = \frac{\mu}{p} \quad \text{and} \quad V(X) = \frac{\mu^2(1-p) + \sigma^2 p}{p^2}.$$

Any higher order moment can be obtained as infinite series as follows:

$$E(X^m) = p \sum_{n=1}^{\infty} (1-p)^{n-1} c_m(n\mu, n\sigma^2).$$

Here, $c_m(n\mu, n\sigma^2) = E(Y^m)$, where $Y \sim N(n\mu, n\sigma^2)$. It may be mentioned that c_m can be obtained using confluent hypergeometric function; see, for example, Johnson, Kotz, and Balakrishnan [13]. The skewness of a GSN(μ, σ, p) can be written as

$$\gamma_1 = \frac{(1-p)(\mu^3(2p^2 - p + 1) + 2\mu^2 p^2 + \mu\sigma^2(3-p)p)}{(\sigma^2 p + \mu^2(1-p))^{3/2}}.$$

Hence, unlike normal distribution, the skewness depends on all the three parameters.

If $\mu = 0$, it becomes symmetric, and the CDF and PDF of a SGSN distribution become

$$F_{SGSN}(x; \sigma, p) = p \sum_{k=1}^{\infty} \Phi\left(\frac{x}{\sigma\sqrt{k}}\right) (1-p)^{k-1}, \quad (5.6)$$

and

$$f_{SGSN}(x; \sigma, p) = \sum_{k=1}^{\infty} \frac{p}{\sigma\sqrt{k}} \phi\left(\frac{x}{\sigma\sqrt{k}}\right) (1-p)^{k-1}, \quad (5.7)$$

respectively, for $x \in \mathbb{R}$. The PDF of SGSN are provided in Fig. 5.2 for different σ and p values.

It is clear from Fig. 5.2 that the tail probabilities of a SGSN distribution increase as p decreases. It behaves like a heavy tailed distribution as p tends to zero. As p tends to one, it behaves like a normal distribution.

If $X \sim \text{SGSN}(\sigma, p)$, then the characteristic function of X can be obtained as

$$\phi_X(t) = E(e^{itX}) = \frac{pe^{(-\frac{\sigma^2 t^2}{2})}}{1 - (1-p)e^{(-\frac{\sigma^2 t^2}{2})}}, \quad t \in \mathbb{R}.$$

Using the characteristic function or otherwise, the mean and variance of X can be expressed as follows:

$$E(X) = 0 \quad \text{and} \quad V(X) = \frac{\sigma^2}{p}.$$

For higher moments, it can be easily observed from the characteristic function that if $X \sim \text{SGSN}(1, p)$, then

$$E(X^m) = pd_m \sum_{n=1}^{\infty} (1-p)^{n-1} n^{m/2},$$

where $d_m = E(Z^m)$, $Z \sim N(0, 1)$, and

$$d_m = \begin{cases} 0 & \text{if } m \text{ is odd} \\ \frac{2^{m/2} \Gamma(\frac{m+1}{2})}{\sqrt{\pi}} & \text{if } m \text{ is even.} \end{cases}$$

In Fig. 5.3, we have plotted the characteristic functions of SGSN for different parameter values. Just to show how different it can be from a normal distribution, we have plotted the characteristic function of the corresponding normal distribution with mean zero and variance σ^2/p . It is clear that the characteristic functions can be quite different particularly for small values of p . But as p approaches one, they become close to each other.

It can be easily seen that the variance diverges as p approaches zero. The GSN distribution is known to be infinitely divisible and geometrically stable. For different other properties and estimation methods, interested readers are referred to the original article of Kundu [14].

The following derivations are needed for further development. These results will be used to develop EM algorithm for SGSN distribution. Suppose $X \sim \text{SGSN}(\sigma, p)$ and N is the associated GE(p) random variable, then for $0 < p < 1$, and $-\infty < x < \infty$, $n = 1, 2, \dots$,

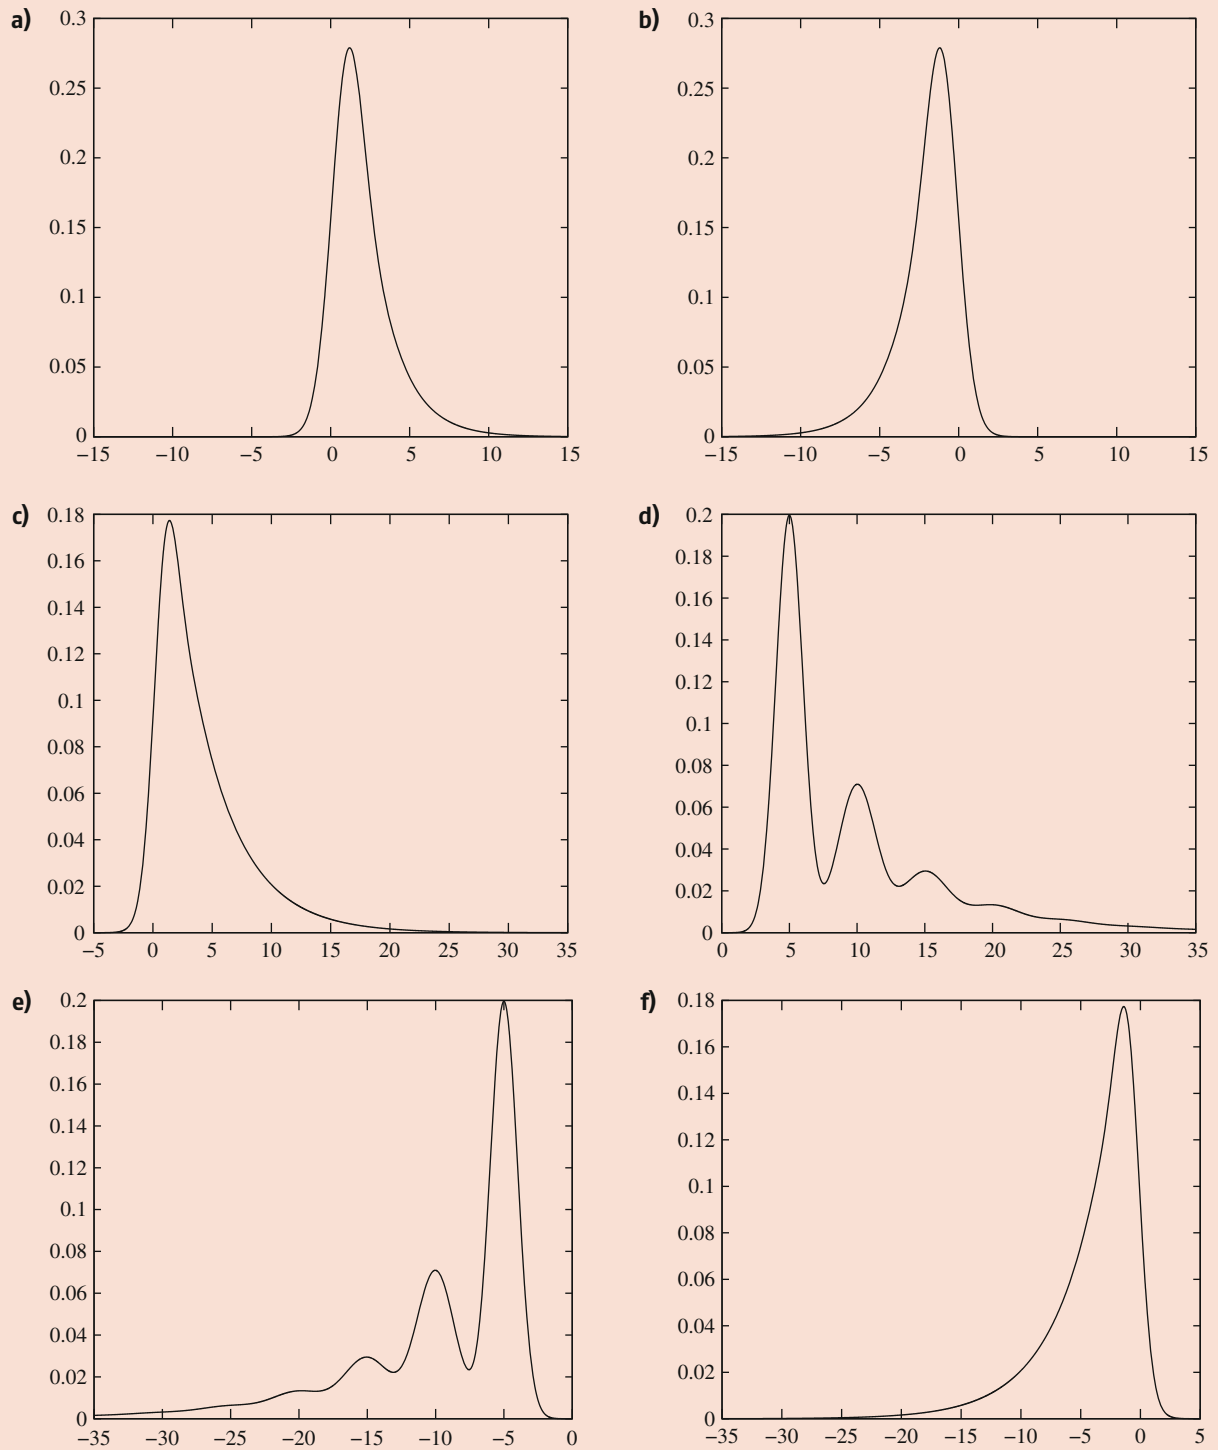

Fig. 5.1 PDF plots of $\text{GSN}(\mu, \sigma, p)$ distribution for different (μ, σ, p) values: (a) $(1.0, 1.0, 0.5)$ (b) $(-1.0, 1.0, 0.5)$ (c) $(1.0, 1.0, 0.25)$ (d) $(5.0, 1.0, 0.5)$ (e) $(-5.0, 1.0, 0.5)$ (f) $(-1.0, 1.0, 0.25)$

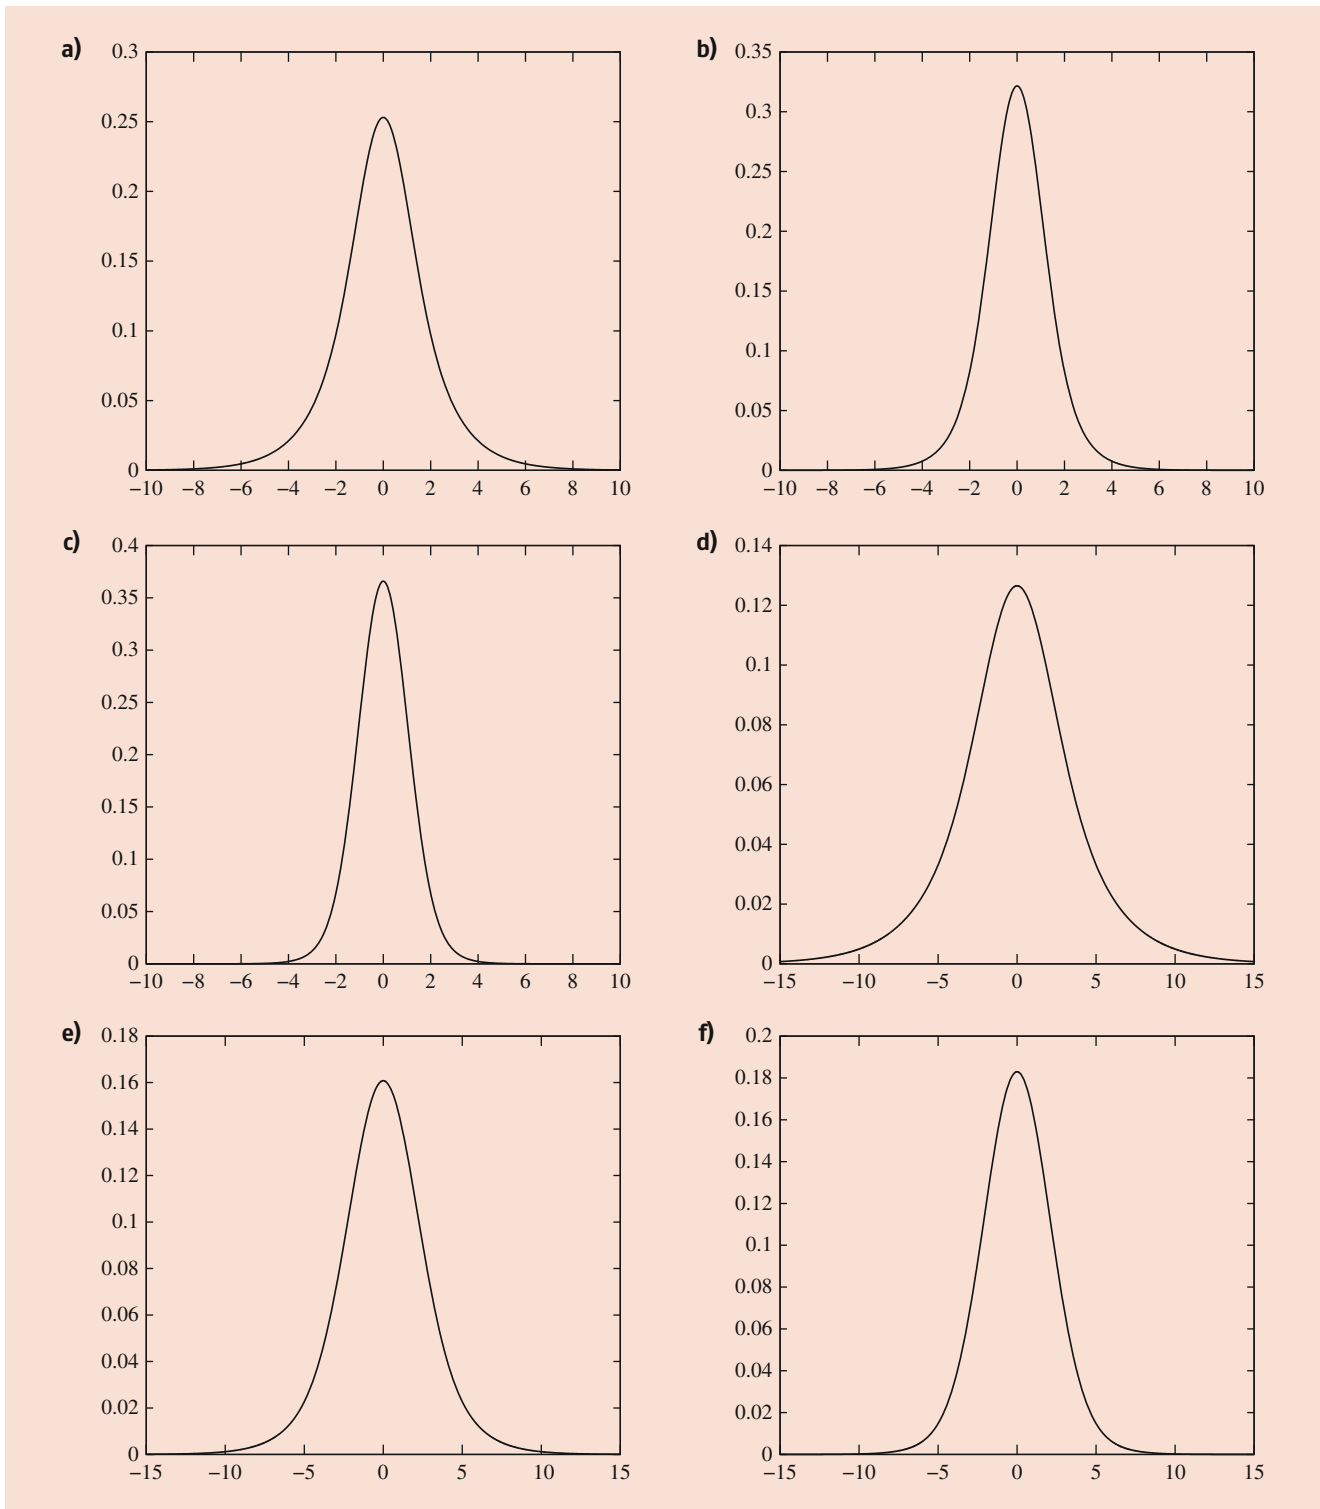

Fig. 5.2 PDF plots of $SGSN(\sigma, p)$ distribution for different (σ, p) values: (a) (1.0,0.25) (b) (1.0,0.50) (c) (1.0,0.75) (d) (2.0,0.25) (e) (2.0,0.50) (f) (2.0,0.75)

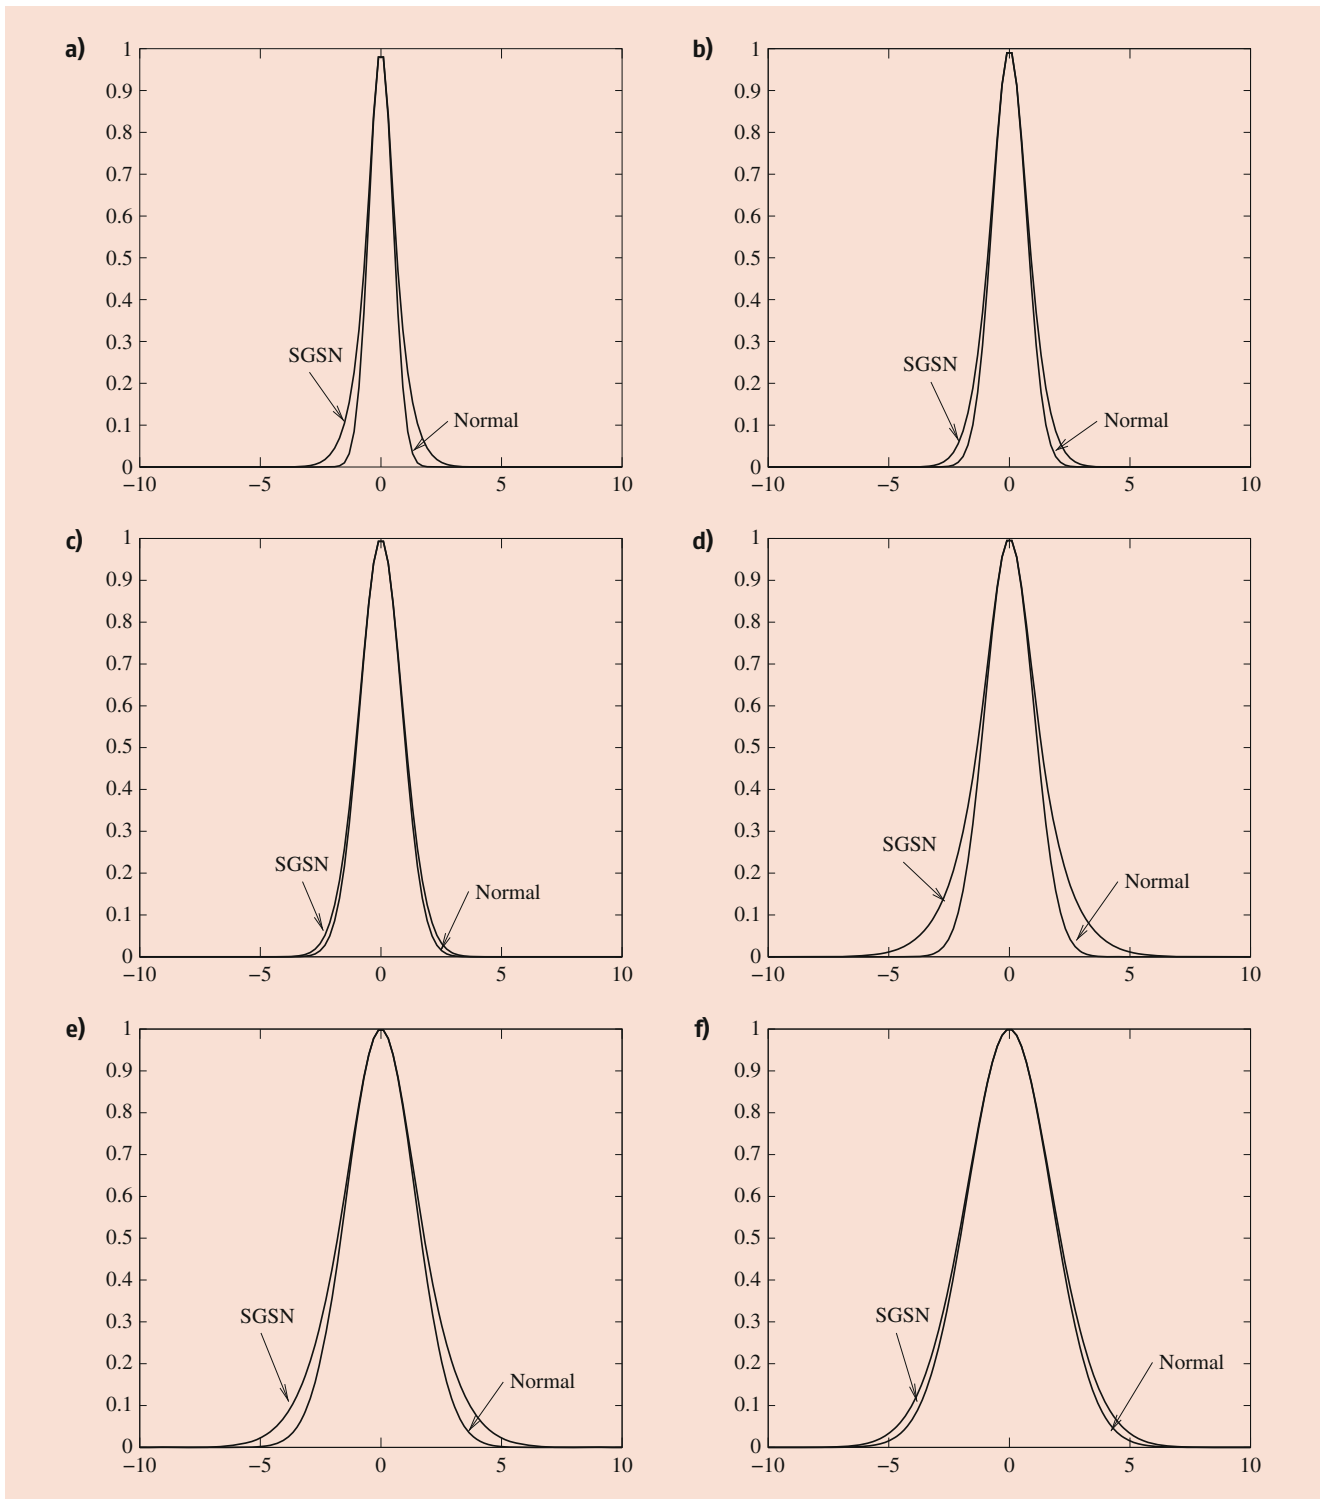

Fig. 5.3 CHF plots of $\text{SGSN}(\sigma, p)$ distribution for different (σ, p) values: (a) (1.0,0.25) (b) (1.0,0.50) (c) (1.0,0.75) (d) (0.5,0.25) (e) (0.5,0.50) (f) (0.5,0.75)

$$\begin{aligned} P(X \leq x, N = n) &= P(X \leq x|N = n)P(N = n) \\ &= p(1-p)^{n-1}\Phi\left(\frac{x}{\sigma\sqrt{n}}\right), \end{aligned} \quad (5.8)$$

for $p = 1$,

$$P(X \leq x, N = n) = \begin{cases} \Phi\left(\frac{x}{\sigma}\right) & \text{if } n = 1 \\ 0 & \text{if } n > 1. \end{cases} \quad (5.9)$$

Hence, the joint PDF, $f_{X,N}(x, n)$, of (X, N) for $0 < p < 1$, $-\infty < x < \infty$, $n = 1, 2, \dots$, becomes

$$f_{X,N}(x, n) = p(1-p)^{n-1} \frac{1}{\sigma\sqrt{2\pi n}} e^{-\frac{x^2}{2n\sigma^2}},$$

and for $p = 1$,

$$f_{X,N}(x, n) = \begin{cases} \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{x^2}{2\sigma^2}} & \text{if } n = 1 \\ 0 & \text{if } n > 1. \end{cases} \quad (5.10)$$

Therefore,

$$P(N = n|X = x) = \frac{(1-p)^{n-1} e^{-\frac{x^2}{2n\sigma^2}} / \sqrt{n}}{\sum_{j=1}^{\infty} (1-p)^{j-1} e^{-\frac{x^2}{2j\sigma^2}} / \sqrt{j}}. \quad (5.11)$$

It can be easily shown that (5.11) is a unimodal function in n . Hence, there exists a unique n_0 such that $P(N = n_0|X = x) > P(N = n|X = x)$, for any $n \neq n_0$. In fact, n_0 can be obtained as the minimum value of $n \geq 1$, such that

$$\frac{P(N = n+1|X = x)}{P(N = n|X = x)} = \frac{\sqrt{n}(1-p)}{\sqrt{n+1}} e^{\frac{x^2}{2\sigma^2} \left(\frac{1}{n} - \frac{1}{n+1} \right)} < 1. \quad (5.12)$$

Moreover, from (5.11) one can easily obtain

$$E(N|X = x) = \frac{\sum_{n=1}^{\infty} \sqrt{n}(1-p)^{n-1} e^{-\frac{x^2}{2n\sigma^2}}}{\sum_{j=1}^{\infty} (1-p)^{j-1} e^{-\frac{x^2}{2j\sigma^2}} / \sqrt{j}}, \quad (5.13)$$

and

$$E(1/N|X = x) = \frac{\sum_{n=1}^{\infty} n^{-3/2}(1-p)^{n-1} e^{-\frac{x^2}{2n\sigma^2}}}{\sum_{j=1}^{\infty} (1-p)^{j-1} e^{-\frac{x^2}{2j\sigma^2}} / \sqrt{j}}. \quad (5.14)$$

5.3 Multivariate Geometric Skew Normal Distribution

Azzalini and Dalla Valle [5] introduced a multivariate distribution with ASN marginals. We call it as multivariate ASN (MASN) distribution, and it can be defined as follows:

A random vector $\mathbf{Z} = (Z_1, \dots, Z_d)^\top$ is a d-variate MASN distribution, if it has the following PDF:

$$g(\mathbf{z}) = 2\phi_d(\mathbf{z}, \mathbf{\Omega})\Phi(\boldsymbol{\alpha}^\top \mathbf{z}), \quad \mathbf{z} \in \mathbb{R}^d,$$

where $\phi_d(\mathbf{z}, \mathbf{\Omega})$ denotes the PDF of a d-variate multivariate normal distribution with standardized marginals and correlation matrix $\mathbf{\Omega}$. Here the parameter vector $\boldsymbol{\alpha}$ is known as the shape vector, and depending on the shape vector, the PDF of a MASN distribution can take a variety of shapes. The PDF is always unimodal, and when $\boldsymbol{\alpha} = \mathbf{0}$, then \mathbf{Z} has the multivariate normal distribution with mean vector $\mathbf{0}$ and correlation matrix $\mathbf{\Omega}$. Although MASN is a very flexible distribution, but if the marginals are heavy tailed or multimodal, it cannot be used; see, for example, the excellent recent monograph by Azzalini and Capitanio [4]. Moreover, if the data come from a MASN distribution, it can be shown that the MLEs do not exist with a positive probability. Due to these reasons, several kernels instead of normal kernel have been used, but they have their own problems.

Kundu [17] proposed MGSN distribution along the same line as the GSN distribution. The MGSN distribution has been defined as follows. Let us use the following notations. A d-variate normal random variable with mean vector $\boldsymbol{\mu}$ and the dispersion matrix $\boldsymbol{\Sigma}$ will be denoted by $N_d(\boldsymbol{\mu}, \boldsymbol{\Sigma})$. The corresponding PDF and CDF will be denoted $\phi_d(x; \boldsymbol{\mu}, \boldsymbol{\Sigma})$ and $\Phi_d(x; \boldsymbol{\mu}, \boldsymbol{\Sigma})$, respectively. Now a d-variate MGSN distribution can be defined as the following. Suppose X_i for $i = 1, 2, 3, \dots$ are i.i.d. $N_d(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ and $N \sim \text{GE}(p)$ and they are independently distributed. Then

$$X = \sum_{i=1}^N X_i$$

is said to have MGSN distribution with parameters $\boldsymbol{\mu}$, $\boldsymbol{\Sigma}$, and p and will be denoted by $\text{MGSN}_d(\boldsymbol{\mu}, \boldsymbol{\Sigma}, p)$.

MGSN is a very flexible multivariate distribution, and its joint PDF can take a variety of shapes. It can be unimodal, bimodal, and multimodal also. Since the marginals are GSN distributions, therefore the marginals can be positively and negatively skewed, and it can be heavy tailed also. If $\mathbf{X} \sim \text{MGSN}_d(\boldsymbol{\mu}, \boldsymbol{\Sigma}, p)$, then the PDF and CDF of X can be written as

$$f_X(x, \boldsymbol{\mu}, \boldsymbol{\Sigma}, p) = \sum_{k=1}^{\infty} \frac{p(1-p)^{k-1}}{(2\pi)^{d/2} |\boldsymbol{\Sigma}|^{1/2} k^{d/2}} e^{-\frac{1}{2k} (x-k\boldsymbol{\mu})^\top \boldsymbol{\Sigma}^{-1} (x-k\boldsymbol{\mu})}$$

and

$$F_X(x, \boldsymbol{\mu}, \boldsymbol{\Sigma}, p) = \sum_{k=1}^{\infty} p(1-p)^{k-1} \Phi_d(x; k\boldsymbol{\mu}, k\boldsymbol{\Sigma}),$$

respectively. When $\boldsymbol{\mu} = \mathbf{0}$, the PDF and CDF of \mathbf{X} can be written as

$$f_{\mathbf{X}}(\mathbf{x}, \mathbf{0}, \boldsymbol{\Sigma}, p) = \sum_{k=1}^{\infty} \frac{p(1-p)^{k-1}}{(2\pi)^{d/2} |\boldsymbol{\Sigma}|^{1/2} k^{d/2}} e^{-\frac{1}{2k} \mathbf{x}^{\top} \boldsymbol{\Sigma}^{-1} \mathbf{x}}$$

and

$$F_{\mathbf{X}}(\mathbf{x}, \boldsymbol{\mu}, \boldsymbol{\Sigma}, p) = \sum_{k=1}^{\infty} p(1-p)^{k-1} \Phi_d(\mathbf{x}; \mathbf{0}, k\boldsymbol{\Sigma}),$$

respectively.

Similar to the GSN distribution, when $p = 1$, MGSN distribution becomes multivariate normal distribution. The PDF of a MGSN distribution can take a variety of shapes. Contour plots of the PDF of a MGSN distribution for different parameter values when $d = 2$ are provided in Fig. 5.4. It is clear that it can be positively and negative skewed, unimodal, bimodal, multimodal, heavy tailed depending on the parameter values. When $\boldsymbol{\mu} = \mathbf{0}$, then it becomes a symmetric distribution.

If $\mathbf{X} \sim \text{MGSN}_d(\boldsymbol{\mu}, \boldsymbol{\Sigma}, p)$, then the characteristic function of \mathbf{X} is

$$\phi_{\mathbf{X}}(\mathbf{t}) = \frac{p e^{i\boldsymbol{\mu}^{\top} \mathbf{t} + \frac{1}{2} \mathbf{t}^{\top} \boldsymbol{\Sigma} \mathbf{t}}}{1 - (1-p) e^{i\boldsymbol{\mu}^{\top} \mathbf{t} + \frac{1}{2} \mathbf{t}^{\top} \boldsymbol{\Sigma} \mathbf{t}}}, \quad \mathbf{t} \in \mathbb{R}^d.$$

Since the characteristic function is in a compact form, many properties can be derived quite conveniently. Different moments, product moments, and multivariate skewness can be obtained using the characteristic function; see Kundu [17] for details.

MGSN distribution has several properties like multivariate normal distribution. For example, if \mathbf{X} is a d -variate MGSN distribution, then if we partition \mathbf{X} as

$$\mathbf{X} = \begin{pmatrix} \mathbf{X}_1 \\ \mathbf{X}_2 \end{pmatrix},$$

where \mathbf{X}_1 and \mathbf{X}_2 are of the orders d_1 and $n - d_1$, respectively, then \mathbf{X}_1 is d_1 -variate MGSN distribution and \mathbf{X}_2 is a $n - d_1$ variate MGSN distribution. Similarly, if \mathbf{X} is d -variate MGSN distribution and \mathbf{D} is a $s \times d$ matrix, with rank $s \leq d$, then $\mathbf{Z} = \mathbf{D}\mathbf{X}$ is a s -variate MGSN distribution. It has been shown that \mathbf{X} is d -variate MGSN distribution if and only if $Y = \mathbf{c}^{\top} \mathbf{X}$ is a GSN distribution, for all $\mathbf{c} \in \mathbb{R}^d \neq \mathbf{0}$. Several other interesting properties including canonical correlation, majorization, and characterization have been provided in Kundu [17]. Estimation of the unknown parameters is an important problem. A d -variate MGSN distribution has $1 + d + d(d + 1)/2$ unknown parameters. The usual ML computation involves solving a $1 + d + d(d + 1)/2$ variate

optimization problem. Therefore, even for $d = 3$, it involves solving a ten-dimensional optimization problem, and clearly it is a nontrivial problem. A very efficient EM algorithm has been proposed by Kundu [17], which does not require solving any optimization problem, i.e., at each ‘‘E’’-step, the corresponding ‘‘M’’-step can be performed explicitly. Due to this reason, MGSN can be used quite efficiently in practice even for large d .

5.4 Location Shift SGSN Distribution

5.4.1 Model Description

Now we will introduce location shift SGSN distribution, which can be used quite effectively for analyzing symmetric data as an alternative to any symmetric distribution such as normal, log-BS, Student’s t distributions, etc. A random variable Y is called a location shift SGSN (LS-SGSN) distribution if

$$Y = \theta + X, \quad (5.15)$$

where $\theta \in \mathbb{R}$ and $X \sim \text{SGSN}(\sigma, p)$. If the random variable Y has the form (5.15), then it will be denoted by LS-SGSN(θ, σ, p). If $Y \sim \text{LS-SGSN}(\theta, \sigma, p)$, then the CDF and PDF of Y become

$$F_Y(y; \theta, \sigma, p) = p \sum_{k=1}^{\infty} \Phi\left(\frac{y - \theta}{\sigma\sqrt{k}}\right) (1-p)^{k-1}, \quad (5.16)$$

and

$$f_Y(y; \theta, \sigma, p) = \sum_{k=1}^{\infty} \frac{p}{\sigma\sqrt{k}} \phi\left(\frac{y - \theta}{\sigma\sqrt{k}}\right) (1-p)^{k-1}, \quad (5.17)$$

respectively. Clearly, LS-SGSN distribution will be a more flexible than a normal distribution due to the presence of an extra parameter. Moreover, normal distribution can be obtained as a special case of the LS-SGSN distribution. We need the following derivations for further development, when $0 < p < 1$, $y \in \mathbb{R}$, and $n = 1, 2, \dots$:

$$\begin{aligned} P(Y \leq y, N = n) &= P(X \leq y - \theta, N = n) \\ &= p(1-p)^{n-1} \Phi\left(\frac{y - \theta}{\sigma\sqrt{n}}\right). \end{aligned}$$

and

$$f_{Y,N}(y, n) = p(1-p)^{n-1} \frac{1}{\sigma\sqrt{2\pi n}} e^{-\frac{(y-\theta)^2}{2\sigma^2 n}}.$$

If $Y \sim \text{LS-SGSN}(\theta, \sigma, p)$, then the characteristic function of Y can be obtained as

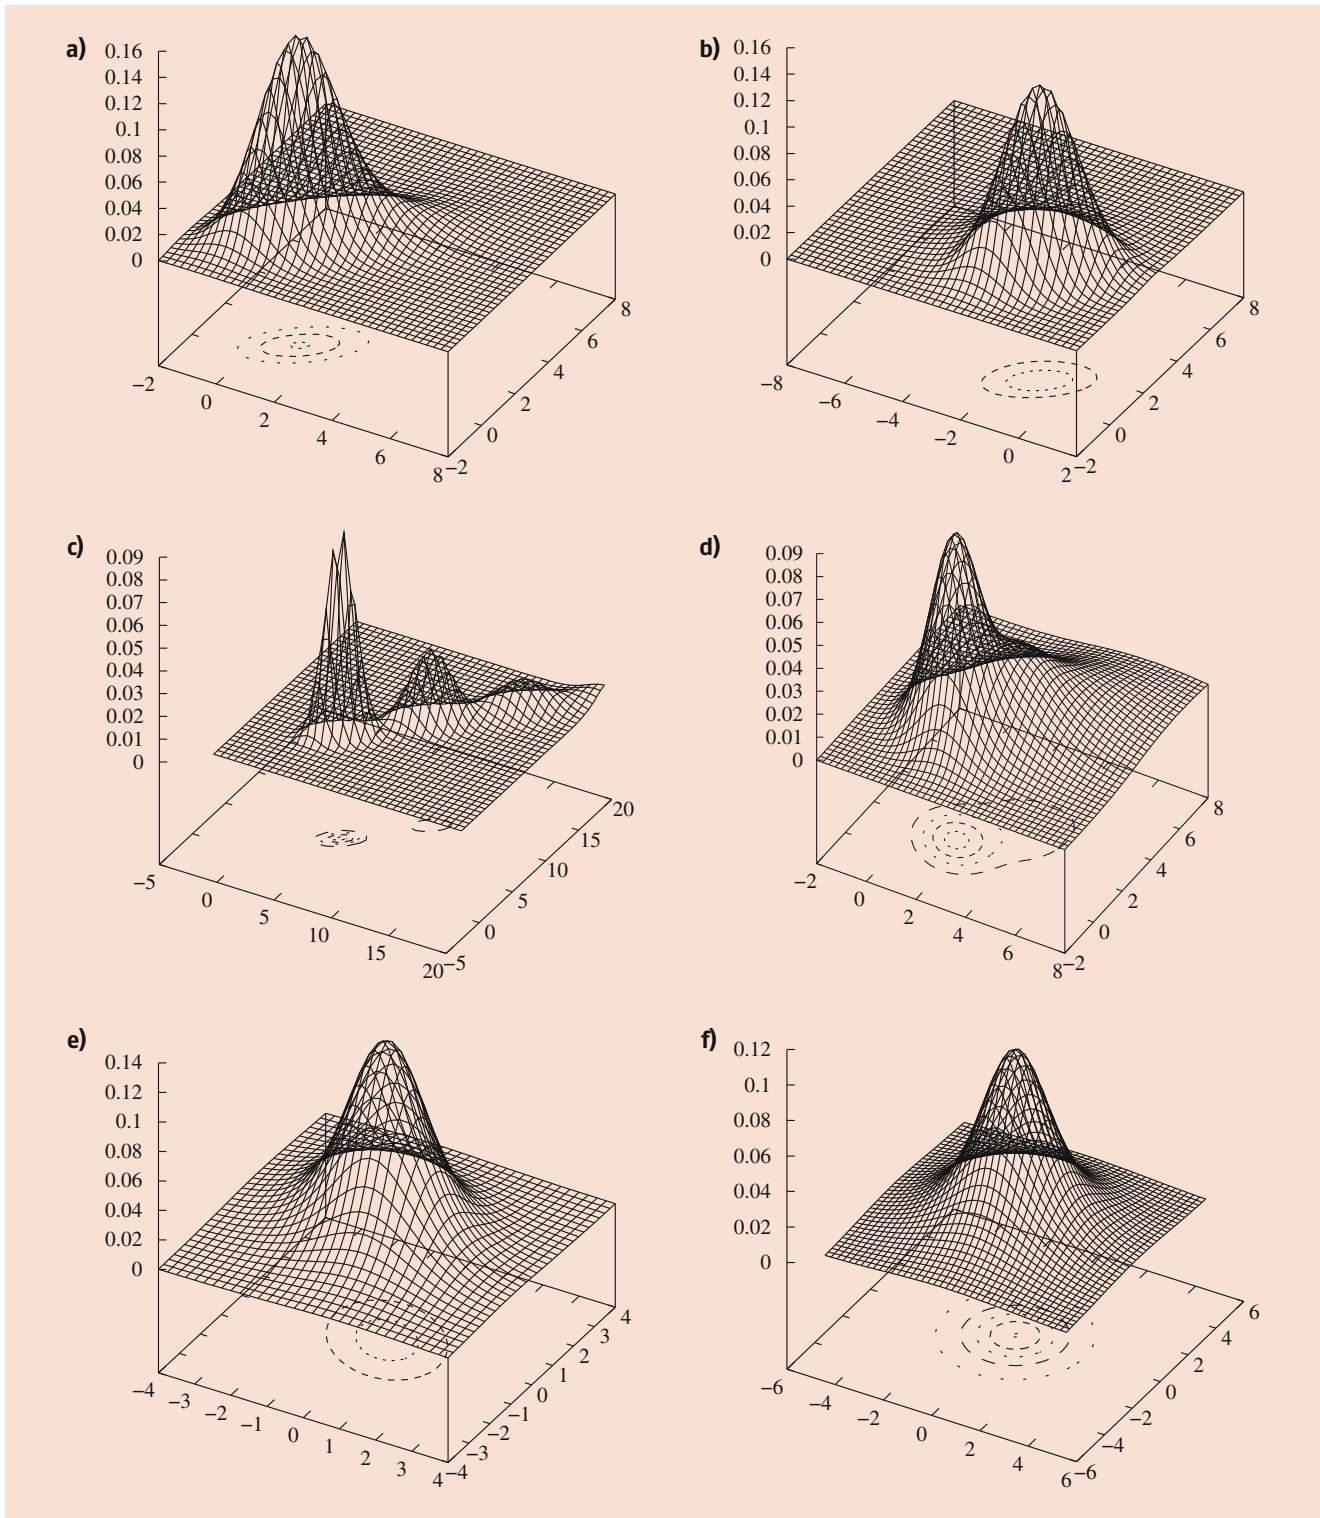

Fig. 5.4 PDF plots of $MGSN_2(\mu, \Sigma, p)$ distribution for different $(\mu_1, \mu_2, \sigma_{11}, \sigma_{22}, \sigma_{12}, p)$ values: (a) (1.0,1.0,1.0,0.5,0.75) (b) (-1.0,1.0,1.0,1.0,0.5,0.75) (c) (5,5,1.0,1.0,0.5,0.5) (d) (1.5,1.5,1.0,1.0,-0.25,0.5) (e) (0.0,0.0,1.0,1.0,-0.25,0.5) (f) (0.0, 0.0, 1.0, 1.0, 0.0, 0.25)

$$\phi_Y(t) = E(e^{itY}) = e^{it\theta} \frac{pe^{-\frac{\sigma^2 t^2}{2}}}{1 - (1-p)e^{-\frac{\sigma^2 t^2}{2}}}, \quad t \in \mathbb{R}.$$

The mean and variance of Y are

$$E(Y) = \theta \quad \text{and} \quad V(Y) = \frac{\sigma^2}{p},$$

respectively.

5.4.2 Maximum Likelihood Estimators

The proposed LS-SGSN distribution has three parameters. Now we will discuss about the estimation of the unknown parameters of the LS-SGSN distribution and the associated confidence intervals.

Suppose we have a random sample of size n , say,

$$\mathcal{D}_1 = \{x_1, \dots, x_n\}$$

from LS-SGSN(θ, σ, p). The log-likelihood function based on the observation \mathcal{D}_1 can be written as

$$l(\theta, \sigma, p) = n \ln p - n \ln \sigma + \sum_{i=1}^n \ln \left\{ \sum_{k=1}^{\infty} \frac{1}{\sqrt{k}} \phi \left(\frac{x_i - \theta}{\sigma \sqrt{k}} \right) (1-p)^{k-1} \right\}. \quad (5.18)$$

Therefore, the ML estimators of the unknown parameters can be obtained by maximizing (5.18) with respect to the unknown parameters. The normal equations can be obtained as

$$\begin{aligned} \dot{l}_\theta &= \frac{\partial l(\theta, \sigma, p)}{\partial \theta} = 0, \quad \dot{l}_\sigma = \frac{\partial l(\theta, \sigma, p)}{\partial \sigma} = 0, \\ \dot{l}_p &= \frac{\partial l(\theta, \sigma, p)}{\partial p} = 0. \end{aligned} \quad (5.19)$$

Hence, the ML estimates can be obtained by solving all the three normal equations in (5.19) simultaneously. Clearly, the ML estimates cannot be obtained in explicit forms, and one needs to use some iterative methods to solve (5.19). One may use the Newton-Raphson-type algorithm to solve these nonlinear equations, but it has its own problem of local convergence and the choice of initial values. To avoid that, we have proposed to use EM-type algorithm to compute the ML estimates. It is observed that at each E-step the corresponding M-step can be obtained explicitly. Hence, it can be implemented very easily.

The basic idea of the proposed EM-type algorithm is to treat this problem as a missing value problem as follows:

Suppose with each x_i we also observe the corresponding value of N , say, m_i . Therefore, the complete observation becomes

$$\mathcal{D}_{1c} = \{(x_1, m_1), \dots, (x_n, m_n)\}. \quad (5.20)$$

Based on the complete data, the log-likelihood function becomes

$$l(\theta, \sigma, p) = n \ln p + \left(\sum_{i=1}^n m_i - n \right) \ln(1-p) - n \ln \sigma - \frac{1}{2\sigma^2} \sum_{i=1}^n \frac{(x_i - \theta)^2}{m_i}. \quad (5.21)$$

Hence, the ML estimates of θ, σ , and p based on the complete observation \mathcal{D}_{1c} can be obtained by maximizing (5.21). If we denote them as $\hat{\theta}_c, \hat{\sigma}_c$ and \hat{p}_c , respectively, then

$$\begin{aligned} \hat{\theta}_c &= \frac{1}{\sum_{i=1}^n \frac{1}{m_i}} \sum_{i=1}^n \frac{x_i}{m_i}, \\ \hat{\sigma}_c^2 &= \frac{1}{n} \sum_{i=1}^n \frac{(x_i - \hat{\theta}_c)^2}{m_i}, \\ \hat{p}_c &= \frac{n}{\sum_{i=1}^n m_i}. \end{aligned} \quad (5.22)$$

Hence, in this case, the EM algorithm takes the following form. Suppose at the k th stage of the EM algorithm the estimates of θ, σ , and p are $\theta^{(k)}, \sigma^{(k)}$, and $p^{(k)}$, respectively. Then at the ‘‘E’’-step of the EM algorithm, the ‘‘pseudo’’ log-likelihood function can be written as

$$l_s(\theta, \sigma, p | \theta^{(k)}, \sigma^{(k)}, p^{(k)}) = n \ln p + \left(\sum_{i=1}^n a_i^{(k)} - n \right) \ln(1-p) - n \ln \sigma - \frac{1}{2\sigma^2} \sum_{i=1}^n b_i^{(k)} (x_i - \theta)^2. \quad (5.23)$$

Here,

$$\begin{aligned} a_i^{(k)} &= E(N | Y = x_i, \theta^{(k)}, \sigma^{(k)}, p^{(k)}) \\ &= \frac{\sum_{n=1}^{\infty} \sqrt{n} (1-p^{(k)})^{n-1} e^{-\frac{(x_i - \theta^{(k)})^2}{2n(\sigma^{(k)})^2}}}{\sum_{j=1}^{\infty} (1-p^{(k)})^{j-1} e^{-\frac{(x_i - \theta^{(k)})^2}{2j(\sigma^{(k)})^2}} / \sqrt{j}} \end{aligned} \quad (5.24)$$

and

$$\begin{aligned} b_i^{(k)} &= E(1/N | Y = x_i, \theta^{(k)}, \sigma^{(k)}, p^{(k)}) \\ &= \frac{\sum_{n=1}^{\infty} n^{-3/2} (1-p^{(k)})^{n-1} e^{-\frac{(x_i - \theta^{(k)})^2}{2n(\sigma^{(k)})^2}}}{\sum_{j=1}^{\infty} (1-p^{(k)})^{j-1} e^{-\frac{(x_i - \theta^{(k)})^2}{2j(\sigma^{(k)})^2}} / \sqrt{j}}. \end{aligned} \quad (5.25)$$

Therefore, at the “M”th step, the maximization of the “pseudo” log-likelihood functions provides

$$\begin{aligned}\theta^{(k+1)} &= \frac{\sum_{i=1}^n b_i^{(k)} x_i}{\sum_{j=1}^n b_j^{(k)}}, \quad \sigma^{(k+1)} = \frac{1}{n} \sum_{i=1}^n b_i^{(k)} (x_i - \theta^{(k+1)})^2, \\ p^{(k+1)} &= \frac{n}{\sum_{i=1}^n a_i^{(k)}}.\end{aligned}\quad (5.26)$$

Note that to start the EM algorithm, we need some initial estimates of θ , σ , and p . We suggest the following. Use the sample mean and the sample standard deviation as the initial estimates of θ and σ , respectively. We can start the EM algorithm for different initial values of p from $(0, 1)$. The EM algorithm can be explicitly written as follows:

EM ALGORITHM

Step 1: Choose some initial estimates of θ , σ , and p , say, $\theta^{(1)}$, $\sigma^{(1)}$, and $p^{(1)}$ as described above. Put $k = 1$.

Step 2: Compute $a_i^{(k)}$ and $b_i^{(k)}$ as in (5.24) and (5.25), respectively.

Step 3: Compute $\theta^{(k+1)}$, $\sigma^{(k+1)}$, and $p^{(k+1)}$ as in (5.26).

Step 4: Check the convergence. If the convergence criterion is satisfied, then stop; otherwise, put $k = k + 1$, and go to Step 2.

The observed Fisher information matrix also can be easily obtained as the last step of the corresponding algorithm. The observed Fisher information matrix can be written as $\mathbf{I} = \mathbf{B} - \mathbf{S}\mathbf{S}^\top$. Here, \mathbf{B} is a 3×3 Hessian matrix of the “pseudo” log-likelihood function (5.23), and \mathbf{S} is the corresponding gradient vector. If we denote $\mathbf{B} = ((b_{ij}))$ and $\mathbf{S} = (s_i)$, then at the k th stage of the EM algorithm,

$$b_{11} = \frac{1}{(\sigma^{(k)})^2} \sum_{i=1}^n b_i^{(k)}, \quad b_{12} = b_{21} = \frac{2}{(\sigma^{(k)})^3} \sum_{i=1}^n b_i^{(k)} (x_i - \theta^{(k)}),$$

$$b_{22} = -\frac{n}{(\sigma^{(k)})^2} + \frac{3}{(\sigma^{(k)})^4} \sum_{i=1}^n b_i^{(k)} (x_i - \theta^{(k)})^2$$

$$b_{33} = \frac{n}{(p^{(k)})^2} + \frac{\sum_{i=1}^n a_i^{(k)} - n}{(1 - p^{(k)})^2}, \quad b_{13} = b_{31} = b_{23} = b_{32} = 0.$$

$$\begin{aligned}s_1 &= \frac{1}{(\sigma^{(k)})^2} \sum_{i=1}^n b_i^{(k)} (x_i - \theta^{(k)}), \quad s_2 = -\frac{n}{\sigma^{(k)}} + \frac{1}{(\sigma^{(k)})^3} \\ &\times \sum_{i=1}^n b_i^{(k)} (x_i - \theta^{(k)})^2, \quad s_3 = \frac{n}{p^{(k)}} - \frac{\sum_{i=1}^n a_i^{(k)}}{1 - p^{(k)}}.\end{aligned}$$

Therefore, if $\mathbf{I}^{-1} = ((f_{ij}))$, then $100(1 - \alpha)\%$ confidence intervals of θ , σ , and p can be obtained as

$$\begin{aligned}(\widehat{\theta} - z_{\alpha/2} f^{11}, \widehat{\theta} + z_{\alpha/2} f^{11}), \quad (\widehat{\sigma} - z_{\alpha/2} f^{22}, \widehat{\sigma} + z_{\alpha/2} f^{22}), \\ (\widehat{p} - z_{\alpha/2} f^{33}, \widehat{p} + z_{\alpha/2} f^{33}),\end{aligned}$$

respectively. Here z_α denotes the α th percentile point of a standard normal distribution.

5.4.3 Testing of Hypothesis

In this section, we discuss some testing of hypotheses problems which have some practical importance.

Problem 1 We want to test

$$H_0 : \theta = \theta_0 \quad \text{vs.} \quad H_1 : \theta \neq \theta_0. \quad (5.27)$$

The problem is of interest as it tests whether the distribution has a specific mean or not. We propose to use the likelihood ratio test (LRT) for this purpose. To compute the LRT statistic, we need to compute the ML estimates of σ and p , when $\theta = \theta_0$. In this case also we can use the same EM algorithm with the obvious modification that at each stage $\theta^{(k)}$ is replaced by θ_0 . Therefore, if $\widehat{\theta}$, $\widehat{\sigma}$, and \widehat{p} denote the ML estimates of θ , σ , and p , respectively, without any restriction, and $\widetilde{\sigma}$ and \widetilde{p} denote the ML estimators of σ and p , respectively, under H_0 , then

$$2(l(\widehat{\theta}, \widehat{\sigma}, \widehat{p}) - l(\theta_0, \widetilde{\sigma}, \widetilde{p})) \longrightarrow \chi_1^2.$$

Problem 2 We want to test

$$H_0 : p = 1 \quad \text{vs.} \quad H_1 : p < 1. \quad (5.28)$$

The problem is of interest as it tests whether the distribution is normal or not. In this case under H_0 , the ML estimates of θ and σ can be obtained as

$$\widetilde{\theta} = \frac{\sum_{i=1}^n x_i}{n} \quad \text{and} \quad \widetilde{\sigma} = \sqrt{\frac{\sum_{i=1}^n (x_i - \widetilde{\theta})^2}{n}}.$$

In this case p is in the boundary under H_0 ; hence, the standard results do not hold. But using Theorem 3 of Self and Liang [28], it follows that

$$2(l(\widehat{\theta}, \widehat{\sigma}, \widehat{p}) - l(\widetilde{\theta}, \widetilde{\sigma}, 1)) \longrightarrow \frac{1}{2} + \frac{1}{2} \chi_1^2.$$

5.5 SGSN Regression Model

In this section, we introduce the following regression model:

$$\mathbf{Y} = \mathbf{X}^\top \boldsymbol{\beta} + \boldsymbol{\epsilon}, \quad (5.29)$$

where \mathbf{Y} is a $n \times 1$ observed vector, $\mathbf{X} = (X_1, X_2, \dots, X_k)^\top$ is a k -dimensional covariate vector, $\boldsymbol{\beta} = (\beta_1, \beta_2, \dots, \beta_k)^\top$ is a k -vector of regression coefficients, \mathbf{a}^\top denotes the transpose of an arbitrary vector \mathbf{a} , and $\epsilon \sim \text{SGSN}(\sigma, p)$. Note that it is a standard multiple linear regression model when ϵ has a normal distribution with mean zero and finite variance. Since the normal distribution is a special case of the proposed SGSN distribution, therefore, the model (5.29) will be more flexible than the standard multiple linear regression model.

The main aim of this section is to discuss the estimation of the unknown parameters of the model (5.29). Let

$$\mathcal{D} = \{(y_1, \mathbf{x}_1), (y_2, \mathbf{x}_2), \dots, (y_n, \mathbf{x}_n)\},$$

be n independent observations from the model (5.29); the problem is to estimate the unknown parameters $\beta_1, \dots, \beta_k, \sigma, p$. We use the following notation $\mathbf{x}_i = (x_{1i}, \dots, x_{ki})^\top$, $i = 1, \dots, n$.

Let us try to compute the ML estimates of the unknown parameters. The log-likelihood function of the observed data \mathcal{D} based on the model (5.29) can be obtained as

$$l(\boldsymbol{\theta}) = n \ln p - n \ln(1-p) - n \ln \sigma + \sum_{i=1}^n \ln \left(\sum_{j=1}^{\infty} \frac{(1-p)^j}{\sqrt{j}} \phi \left(\frac{y_i - \mathbf{x}_i^\top \boldsymbol{\beta}}{\sigma \sqrt{j}} \right) \right), \quad (5.30)$$

where $\boldsymbol{\theta} = (\boldsymbol{\beta}, \sigma, p)^\top$. Therefore, the ML estimates of the unknown parameters can be obtained by maximizing the log-likelihood function (5.30) with respect to the unknown parameters. Taking derivatives with respect to the unknown parameters, the normal equations become

$$\begin{aligned} \dot{l}_{\beta_1} &= \frac{\partial}{\partial \beta_1} l(\boldsymbol{\theta}) = 0, \dots, \dot{l}_{\beta_k} = \frac{\partial}{\partial \beta_k} l(\boldsymbol{\theta}) = 0, \\ \dot{l}_{\sigma} &= \frac{\partial}{\partial \sigma} l(\boldsymbol{\theta}) = 0, \quad \dot{l}_p = \frac{\partial}{\partial p} l(\boldsymbol{\theta}) = 0. \end{aligned} \quad (5.31)$$

Clearly, they cannot be solved explicitly. One needs to solve $k+2$ nonlinear equations simultaneously to compute the ML estimates of the unknown parameters. To avoid that problem, we propose to use this problem as a missing value problem and provide an efficient EM algorithm to compute the ML estimates of the unknown parameters. The main idea is as follows. Suppose along with (y_i, \mathbf{x}_i) we also observe m_i , where m_i denotes the value of N in this case, for $i = 1, 2, \dots, n$. Therefore, the complete data will be of the form

$$\mathcal{D}^c = \{(y_1, \mathbf{x}_1, m_1), \dots, (y_n, \mathbf{x}_n, m_n)\}. \quad (5.32)$$

First, we will show that if m_i 's are known, then the ML estimates of $\boldsymbol{\beta}$, σ , and p can be obtained in explicit forms.

Based on the complete data (5.32), the log-likelihood function without the additive constant becomes

$$l_c(\boldsymbol{\beta}, \sigma, p) = n \ln p + \left(\sum_{i=1}^n m_i - n \right) \ln(1-p) - n \ln \sigma - \frac{1}{2\sigma^2} \sum_{i=1}^n \frac{1}{m_i} (y_i - \mathbf{x}_i^\top \boldsymbol{\beta})^2. \quad (5.33)$$

It can be easily seen that $l_c(\boldsymbol{\beta}, \sigma, p)$ as given in (5.33) is a unimodal function. If $\hat{\boldsymbol{\beta}}_c$, $\hat{\sigma}_c$, and \hat{p} maximize $l_c(\boldsymbol{\beta}, \sigma, p)$, then they can be obtained as

$$\begin{aligned} \hat{\boldsymbol{\beta}}_c &= \left[\sum_{i=1}^n \frac{1}{m_i} \mathbf{x}_i \mathbf{x}_i^\top \right]^{-1}, \quad \hat{\sigma}_c^2 = \frac{1}{n} \sum_{i=1}^n \frac{1}{m_i} (y_i - \mathbf{x}_i^\top \hat{\boldsymbol{\beta}}_c)^2, \\ \hat{p} &= \frac{n}{\sum_{i=1}^n m_i}. \end{aligned} \quad (5.34)$$

Therefore, it is clear that if m_i 's are known, then the ML estimates of $\boldsymbol{\beta}$, σ , and p can be obtained quite conveniently, and one does not need to solve any nonlinear equation. This is the main motivation of the proposed EM algorithm. Now we are ready to provide the EM algorithm for this problem. We will show how to move from the r th step to the $(r+1)$ th step of the EM algorithm.

We will use the following notations. Let us denote $\boldsymbol{\beta}^{(r)}$, $\sigma^{(r)}$, and $p^{(r)}$ as the estimates of $\boldsymbol{\beta}$, σ , and p , respectively, for $i = 1, 2, \dots, n$, at the r th iteration of the EM algorithm. Then at the "E"-step of the EM algorithm, the pseudo log-likelihood function becomes

$$\begin{aligned} l_s(\boldsymbol{\beta}, \sigma, p | \boldsymbol{\beta}^{(r)}, \sigma^{(r)}, p^{(r)}) &= n \ln p + \left(\sum_{i=1}^n c_i^{(r)} - n \right) \ln(1-p) \\ &\quad - n \ln \sigma - \frac{1}{2\sigma^2} \sum_{i=1}^n d_i^{(r)} (y_i - \mathbf{x}_i^\top \boldsymbol{\beta})^2, \end{aligned} \quad (5.35)$$

where

$$\begin{aligned} c_i^{(r)} &= E(N | y_i, \mathbf{x}_i, \boldsymbol{\beta}^{(r)}, \sigma^{(r)}, p^{(r)}) \\ &= \frac{\sum_{n=1}^{\infty} \sqrt{n} (1-p^{(r)})^{n-1} e^{-\frac{(y_i - \mathbf{x}_i^\top \boldsymbol{\beta}^{(r)})^2}{2n(\sigma^{(r)})^2}}}{\sum_{j=1}^{\infty} (1-p^{(r)})^{j-1} e^{-\frac{(y_i - \mathbf{x}_i^\top \boldsymbol{\beta}^{(r)})^2}{2j(\sigma^{(r)})^2}} / \sqrt{j}} \end{aligned} \quad (5.36)$$

and

$$\begin{aligned} d_i^{(r)} &= E(1/N | y_i, \mathbf{x}_i, \boldsymbol{\beta}^{(r)}, \sigma^{(r)}, p^{(r)}) \\ &= \frac{\sum_{n=1}^{\infty} n^{-3/2} (1-p^{(r)})^{n-1} e^{-\frac{(y_i - \mathbf{x}_i^\top \boldsymbol{\beta}^{(r)})^2}{2n(\sigma^{(r)})^2}}}{\sum_{j=1}^{\infty} (1-p^{(r)})^{j-1} e^{-\frac{(y_i - \mathbf{x}_i^\top \boldsymbol{\beta}^{(r)})^2}{2j(\sigma^{(r)})^2}} / \sqrt{j}}. \end{aligned} \quad (5.37)$$

Therefore, at the “M”th step, the maximization of the “pseudo” log-likelihood function provides

$$\begin{aligned}\boldsymbol{\beta}^{(r+1)} &= \left[\sum_{i=1}^n d_i^{(r)} \mathbf{x}_i \mathbf{x}_i^\top \right]^{-1}, \quad \sigma^{(r+1)} \\ &= \sqrt{\frac{1}{n} \sum_{i=1}^n d_i^{(r)} (y_i - \mathbf{x}_i^\top \boldsymbol{\beta}^{(r+1)})^2}, \quad \hat{p} = \frac{n}{\sum_{i=1}^n c_i^{(r)}};\end{aligned}\quad (5.38)$$

moreover, these are unique solutions.

Now to start the EM algorithm, we suggest the following initial guesses. Use ordinary least squares estimates of $\boldsymbol{\beta}$ as the initial estimate of $\boldsymbol{\beta}$ and the corresponding square root of the residual sums of squares as the initial estimate of σ . As before, we can start the EM algorithm with different initial values of $p \in (0, 1)$. The EM algorithm can be written as follows.

EM ALGORITHM

Step 1: Choose some initial estimates of $\boldsymbol{\beta}$, σ , and p , say, $\boldsymbol{\beta}^{(1)}$, $\sigma^{(1)}$, and $p^{(1)}$ as described above. Put $r = 1$.

Step 2: Compute $c_i^{(r)}$ and $\hat{c}_i^{(r)}$ as in (5.36) and (5.37), respectively.

Step 3: Compute $\boldsymbol{\beta}^{(r+1)}$, $\sigma^{(r+1)}$, and $p^{(r+1)}$ as in (5.38).

Step 4: Check the convergence. If the convergence criterion is satisfied, then stop; otherwise, put $r = r + 1$, and go to Step 2.

In this case also the observed Fisher information matrix also can be obtained as before, in the last step of the EM algorithm. The observed Fisher information matrix can be written as $\tilde{\mathbf{I}} = \tilde{\mathbf{B}} - \tilde{\mathbf{S}}\tilde{\mathbf{S}}^\top$. Here, $\tilde{\mathbf{B}}$ is a $(k+3) \times (k+3)$ Hessian matrix of the “pseudo” log-likelihood function (5.35), and $\tilde{\mathbf{S}}$ is the corresponding gradient vector. If we denote $\tilde{\mathbf{B}} = ((\tilde{b}_{ij}))$ and $\tilde{\mathbf{S}} = (\tilde{s}_i)$, then at the r th stage of the EM algorithm, for $j, l = 1, \dots, k$ and for $j \neq l$,

$$\tilde{b}_{jj} = \frac{1}{(\sigma^{(r)})^2} \sum_{i=1}^n d_i^{(r)} x_{ji}^2, \quad \tilde{b}_{jl} = \tilde{b}_{lj} = \frac{1}{(\sigma^{(r)})^3} \sum_{i=1}^n d_i^{(r)} x_{ji} x_{li},$$

$$\tilde{b}_{(k+1)(k+1)} = -\frac{n}{(\sigma^{(r)})^2} + \frac{3}{(\sigma^{(r)})^4} \sum_{i=1}^n d_i^{(k)} (y_i - \mathbf{x}_i^\top \boldsymbol{\beta}^{(r)})^2,$$

$$\tilde{b}_{j(k+1)} = \tilde{b}_{(k+1)j} = \frac{2}{(\sigma^{(r)})^3} \sum_{i=1}^n d_i^{(k)} (y_i - \mathbf{x}_i^\top \boldsymbol{\beta}^{(r)}) x_{ji},$$

$$\tilde{b}_{(k+2)(k+2)} = \frac{n}{(p^{(r)})^2} + \frac{\sum_{i=1}^n c_i^{(r)} - n}{(1-p^{(r)})^2},$$

$$b_{j(k+2)} = 0; \quad j = 1, \dots, k+1.$$

$$s_j = \frac{1}{(\sigma^{(r)})^2} \sum_{i=1}^n d_i^{(r)} (y_i - \mathbf{x}_i^\top \boldsymbol{\beta}^{(r)}) x_{ji}; \quad j = 1, \dots, k,$$

$$s_{(k+1)} = -\frac{n}{\sigma^{(r)}} + \frac{1}{(\sigma^{(r)})^3} \sum_{i=1}^n d_i^{(r)} (y_i - \mathbf{x}_i^\top \boldsymbol{\beta}^{(r)})^2,$$

$$s_{(k+2)} = \frac{n}{p^{(r)}} - \frac{\sum_{i=1}^n c_i^{(r)} - n}{1-p^{(r)}}.$$

Therefore, if $\tilde{\mathbf{I}}^{-1} = ((\tilde{f}_{ij}))$, then $100(1 - \alpha)\%$ confidence intervals of β_j , σ , and p can be obtained as

$$\begin{aligned}(\hat{\beta}_j - z_{\alpha/2} \tilde{f}_{jj}, \hat{\beta}_j + z_{\alpha/2} \tilde{f}_{jj}); \quad j = 1, \dots, k, \\ (\hat{\sigma} - z_{\alpha/2} \tilde{f}_{(k+1)(k+1)}, \hat{\sigma} + z_{\alpha/2} \tilde{f}_{(k+1)(k+1)}), \\ (\hat{p} - z_{\alpha/2} \tilde{f}_{(k+2)(k+2)}, \hat{p} + z_{\alpha/2} \tilde{f}_{(k+2)(k+2)}),\end{aligned}$$

respectively. Here z_{α} denotes the α th percentile point of a standard normal distribution.

5.6 Simulation Results

In this section, we present some simulation results both for the LS-SGSN and SGSN regression models. The main idea is to see how the proposed EM algorithms behave in these cases. All the computations are performed using R software, and it can be obtained from the corresponding author on request.

5.6.1 LS-SGSN Model

In this section, we have generated samples from a LS-SGSN distribution for different sample sizes n and different p values. We have kept the values of θ and σ to be the same, namely, $\theta = 0$ and $\sigma = 1$. We have taken $n = 25, 50, 75$, and 100 and $p = 0.2, 0.4, 0.6$, and 0.8 . We have used the EM algorithm as it has been described in Sect. 5.3. In all the cases, we have used the true value as the initial guesses. We stop the iteration when the absolute difference of the consecutive estimates is less than 10^{-6} , for all the unknown parameters. We have reported the average ML estimates of θ , σ , p , and the associated mean squared errors (MSEs) based on 1000 replications. The results are reported in Table 5.1.

Some of the points are quite clear from the above experimental results. It is observed that ML estimates of θ , σ , and p provide unbiased estimates of the corresponding parameters. As sample size increases, in all the cases considered, the MSEs decrease. It indicates consistency property of the ML estimates. The EM algorithm converges in all the cases. Hence, the EM algorithm works well in this case.

Table 5.1 ML estimates of θ , σ , and p and the associated MSEs (reported below within brackets) for different sample sizes and for different p values

5.6.2 SGSN Regression Model

In this section, we have performed some simulation experiments for SGSN regression model. Here, we have taken $k = 2$, $\beta_1 = 1$, $\beta_2 = 2$, and $\sigma = 1$. We have varied $n = 25, 50, 75$, and 100 and $p = 0.2, 0.4, 0.6$, and 0.8 . We have generated the entries of the \mathbf{X} matrix from i.i.d. normal random variables, with mean zero and variance one. For a fixed, n , the generated \mathbf{X} matrix remains fixed. The error random variables are generated from a SGSN(σ, p) distribution. For each n, σ , and p , we generate Y . We compute the ML estimates of β_1, β_2, σ , and p , based on the EM algorithm as described in Sect. 5.4. In all the cases, we report the average ML estimates and the associated MSEs based on 1000 replications. The results are reported in Table 5.2.

Some of the points are quite clear from both the tables. It is observed that even for the SGSN regression model, the proposed EM algorithm works quite well in all the cases considered. The ML estimates provide consistent estimates of the corresponding unknown parameters, and the EM algorithm also converges in each case.

5.7 Real Data Analysis

5.7.1 LS-SGSN Model

In this section, we present the analysis of one data set based on LS-SGSN model mainly for illustrative purposes. The data set has been obtained from Lawless [21] (page 228). It arose from test on the endurance of deep groove ball bearings. It represents the number of million revolutions before failure for each of the 23 ball bearings in the life test, and they are as follows:

17.88 28.92 33.00 41.52 42.12 45.60 48.40 51.84
51.96 54.12 55.56 67.80 68.64 68.64 68.88 84.12 93.12
98.64 105.12 105.84 127.92 128.04 173.40.

The mean and standard deviation of the data points are 72.2 and 36.7, respectively. We have used the EM algorithm with the initial estimates of θ , σ , and p as 72.2, 36.7, and 0.5, respectively. We stop the iteration when the differences between the consecutive estimates are less than 10^{-4} for all the three parameters. The ML estimates and the associated log-likelihood (ll) value are as follows:

$$\hat{\theta} = 68.443, \quad \hat{\sigma} = 26.088 \quad \hat{p} = 0.554, \quad ll = -127.4590.$$

The corresponding 95% confidence intervals of θ , σ , and p are obtained as

$$(56.513, 80.373), \quad (18.857, 33.320), \quad (0.409, 0.699),$$

respectively. To check the effect of the initial guess to the final estimates, we have used different other initial guesses, mainly the p values ranging from 0.1 to 0.9, but in all the cases it converges to the same estimate. It confirms that the initial estimates do not affect the convergence of the EM algorithm.

5.7.2 SGSN Regression Model

In this section, we have analyzed one rocket propellant data set from Montgomery et al. [23] (Chapter 2). The data represent the shear strength (Y) and the age of the propellant (X). Here the shear strength is in psi, and the age is in weeks. The observations are given below in the format (Y, X) :

(2158.70, 15.50) (1678.15, 23.75) (2316.00, 8.00)
 (2061.30, 17.00) (2207.50, 5.50) (1708.30, 19.00) (1784.70,
 24.00) (2575.00, 2.50) (2357.90, 7.50) (2256.70, 11.00)
 (2165.20, 13.00) (2399.55, 3.75) (1779.80, 25.00) (2336.75,
 9.75) (1765.30, 22.00) (2053.50, 18.00) (2414.40, 6.00)
 (2200.50, 12.50) (2654.20, 2.00) (1753.70, 21.50).

We have used the following model to analyze the data:

$$Y = \beta_1 + \beta_2 X + \epsilon.$$

Here ϵ is assumed to follow a GSSN distribution with mean zero and finite variance. Assuming that ϵ follows normal distribution, we obtain the least squares estimates of β_1 , β_2 , and σ as 2627.82, -37.15 , and 91.17, respectively. We have used these estimates as the initial estimates, and we have used the initial estimate of p as 0.5. Using the EM algorithm, we obtain the ML estimates of the unknown parameters, and the corresponding log-likelihood values are as follows:

$$\hat{\beta}_1 = 2649.58, \quad \hat{\beta}_2 = -37.58, \quad \hat{\sigma} = 53.42,$$

$$\hat{p} = 0.34, \quad ll = -88.97.$$

The associated 95% confidence intervals are as follows:

$$(2584.95, 2714.18), \quad (-41.83, -33.34),$$

$$(36.87, 69.98), \quad (0.22, 0.46).$$

5.8 Conclusions

In this paper, we have considered LS-SGSN distribution. It is symmetric, and it has three parameters. Hence, it is more flexible than the normal distribution. The normal distribution can be obtained as a special case of the LS-SGSN distribution. We have proposed a very efficient EM algorithm, and it is observed that the EM algorithm works quite well. We have further considered SGSN regression model, which is more flexible than the standard Gaussian regression model. In this case also we have proposed a very efficient EM algorithm, and the performance of the proposed EM algorithm is quite satisfactory.

Professor Debasis Kundu received his Ph.D. from the Pennsylvania State University in 1989 under the guidance of Professor C.R. Rao. After finishing his Ph.D. he joined The University of Texas at Dallas as an Assistant Professor before joining Indian Institute of Technology Kanpur in 1990. He served as the Head of the Department of Mathematics and Statistics, IIT Kanpur from 2011 to 2014, and currently he is the Dean of Faculty Affairs at IIT Kanpur. Professor Kundu is holding an Endowed Chair Professor post of the Institute since 2008. Professor Kundu works on different areas of Statistics. His major research interests are on Distribution Theory, Lifetime Data Analysis, Censoring, Statistical Signal Processing and Statistical Computing. He has published more than 300 research papers in different refereed journals and more than 13,000 google scholar citations with H index 58. He has co-authored three research monographs and co-edited one book. He is a Fellow of the National Academy of Sciences, India, a Fellow of the Royal Statistical Society London and a Fellow of the Indian Society of Probability and Statistics. He is currently the Editor-in-Chief of the *Journal of the Indian Society of Probability and Statistics*, and in the editorial boards of *Communications in Statistics – Theory and Methods*, *Communications in Statistics – Simulation and Computation* and *Sankhya, Ser. B*. He was in the editorial boards of the *IEEE Transactions on Reliability*, *Journal of Statistical Theory and Practice* and *Journal of Distribution Theory*.

Deepak Prajapati received his Ph.D. degree from the Department of Mathematics and Statistics, Indian Institute of Technology Kanpur, Kanpur, India, in 2019. He received his Master's degree in Applied Statistics and Informatics from Indian Institute of Technology Bombay, Mumbai, India, in 2013. He was a Postdoctoral Fellow with the Indian Statistical Institute, Delhi, India. He is currently an Assistant Professor in the Decision Sciences Area at the Indian Institute of Management, Lucknow, India. His main research interests are statistical inference, reliability theory and survival analysis, and statistical quality control.

Abstract

Reliability analysis has been using time-to-event data, degradation data, and recurrent event data, while the associated covariates tend to be simple and constant over time. Over the past years, we have witnessed rapid development of sensor and wireless technology, which enables us to track the product usage and use environment. Nowadays, we are able to collect richer information on covariates which provides opportunities for better reliability predictions. In this chapter, we first review recent development on statistical methods for reliability analysis. We then focus on introducing several specific methods that were developed for different types of reliability data by utilizing the covariate information. Illustrations of those methods are also provided using examples from industry. We also provide a brief review on recent developments of test planning and then focus on illustrating the sequential Bayesian designs with examples of fatigue testing for polymer composites. The chapter is concluded with some discussions and remarks.

6.1 Introduction

6.1.1 Background

Traditional reliability data analysis mainly uses time-to-event data, degradation data, and recurrent event data to make reliability predictions [1]. The covariate information involved in the reliability analysis is usually time-invariant, and the number of covariates is typically small. For time-to-event data, parametric models such as the Weibull and lognormal distributions are popular, and accelerated failure-time models are often used to incorporate covariate information on accelerating factors. For degradation data, the general path models and stochastic models are the common choices, and the covariate information is often incorporated through regression type of models. The recurrent event data are often modeled by the event intensity models or mean cumulative functions with regression type of models that are often used to incorporate covariates.

With technological advances, new information on covariates becomes available. Products and systems can be equipped with sensors and smart chips to keep track of various information on the field usage of product units, number of transfers, and environmental conditions such as temperature and humidity. Such covariate information often changes over time, so we refer to them as dynamic covariate information. Because the dynamic covariates often come in large volume and variety, it presents big data opportunities and challenges in the area of reliability analysis (e.g., [2] and [3]). Dynamic covariate data can be used for modeling and prediction of reliability because units under heavy usage often fail sooner than those lightly used. In recent years, more statistical methods for dynamic covariates have been developed to make use of this new type of covariate data.

Another important area of reliability analysis is about test planning, which focuses on how to efficiently collect various types of data to make better predictions of reliability. For accelerated life tests (ALTs), it is especially challenging to timely collect sufficient failure data because the data collection is a time-consuming process and often requires using expensive equipment for testing units under elevated stress conditions. In some laboratories, there is typically one or two machines available for testing certain material. In this case, it is impractical to test multiple samples simultaneously and therefore limits the total obtainable sample size. Another challenge with traditional test planning is that it typically relies on a single set of best guess of parameter values, which may lead to suboptimal designs when the specified parameter values are not accurate. Due to these challenges, sequential designs become popular where earlier test results can be utilized to determine the test conditions for later runs. In addition, Bayesian methods can be used to leverage prior information from the expert's knowledge or related historical

data to inform the test planning. The objective of this chapter is to review current development and then introduce the statistical methods for dynamic covariates and sequential Bayesian designs (SBDs) for ALT.

6.1.2 Related Literature

In lifetime data analysis, product usage information has been used to improve reliability models. Lawless et al. [4] consider warranty prediction problem using product usage information on return units. Constant usage information is used in [5] and [6]. Averaged product use-rate information is used in [7]. Nelson [8] and Voiculescu et al. [9] use a cumulative exposure model in ALT and reliability analysis. Hong and Meeker [10] use a cumulative exposure model to incorporate dynamic covariates and apply it to the Product D2 application.

In degradation data analysis, stochastic process models are widely used. The Wiener process [11–13], gamma process [14], and inverse Gaussian process [15, 16] are among popular models in this class. The general path models are also widely used, which include [17–21]. For accelerated destructive degradation tests, typical work includes [22–24]. Hong et al. [25] and Xu et al. [26] develop degradation models using the general path model framework to incorporate dynamic covariate information.

For recurrent event data, the common models are nonhomogeneous Poisson process (NHPP) and the renewal process (RP) (e.g., [27, 28]). Kijima [29] introduce virtual age models which can model imperfect repairs. Pham and Wang [30] develop a quasi-renewal process, and Doyen and Gaudoin [31] propose models for imperfect repairs. The trend-renewal process (TRP) proposed in [32] is applied in [33–35] and other places. Xu et al. [36] develop a multilevel trend-renewal process (MTRP) model for recurrent event with dynamic covariates.

For test planning, the optimum designs in traditional test planning framework are developed using non-Bayesian approaches (e.g., [37, 38]), and the true parameters are assumed to be known. Bayesian test planning for life data is developed in [39–41]. King et al. [42] develop optimum test plans for fatigue tests for polymer composites. Lee et al. [43] develop SBD test planning for polymer composites, and Lu et al. [44] extend it to test planning with dual objectives.

6.1.3 Overview

For the rest of this chapter, Sect. 6.2 gives an example of traditional reliability analysis. Section 6.3 describes an application on time-to-event data with dynamic covariates. Section 6.4 illustrates modeling of degradation with dynamic covariates. Section 6.5 describes the MTRP model

for describing recurrent event data with dynamic covariates. Section 6.6 introduces SBD strategies for ALTs. Section 6.7 considers sequential test planning with dual objectives. Section 6.8 contains some concluding remarks.

6.2 Traditional Reliability Analysis

In this section, we give one example on how traditional reliability analysis is typically carried out. The time-to-event data, degradation data, and recurrent event data are typically used for reliability models, and then one can use such models to make reliability predictions [1]. In traditional reliability datasets, the covariate information involved in the reliability analysis is usually simple (i.e., the covariate is time-invariant or the number of covariates is small). Here we use one example from time-to-event analysis as an illustration. Some other examples on degradation analysis can be found in [45]. This section is mainly based on [46].

6.2.1 Background and Data

Hong, Meeker, and McCalley [46] present the modeling of the lifetime data for power transformers. High-voltage power transmission transformers are important components in the electrical transmission, which has more than 150,000 units in service in the USA. The energy industry is very much interested in the prediction of the remaining life of transformers. Such prediction is typically based on historical lifetime data collected from the transformers in the field.

The paper [46] describes the modeling and analysis of lifetime data of power transformers collected by an energy company. The main goal is to make prediction for the remaining life of transformers that are still in service. Figure 6.1 shows the event plot for a subset of the power transformer lifetime data, on which the numbers on the left show the counts of transformers for each line. The truncation age is also marked on the line. The lifetime data involve censoring and truncation. Transformers that are still in service at the data freeze date (DFD) are considered to be right censored. There is information on transformers that were installed before January 1, 1980, and then subsequently failed after January 1, 1980. There is no information on transformers installed and also failed before 1980. Hence, units that were installed before 1980 are considered to be samples generated from left truncated distribution(s).

6.2.2 Time-to-Event Models and Parameter Estimation

The first step in lifetime data analysis is to specify a lifetime distribution that is suitable for describing the data. The

Fig. 6.1 Event plot for a subset of the power transformer lifetime data. The numbers in the left show the counts for each line

log-location-scale family of distributions is widely used in the literature. The Weibull and lognormal are widely used members in this family of distributions. Here we briefly introduce the formulae for the Weibull and lognormal distributions.

Let T be the random variable for the lifetime of a power transformer, and we use the log-location-scale distribution to model T . The cumulative distribution function (cdf) of T is

$$F(t; \mu, \sigma) = \Phi \left[\frac{\log(t) - \mu}{\sigma} \right].$$

Here μ is the location parameter and σ is the scale parameter. The probability density function (pdf) of T is

$$f(t; \mu, \sigma) = \frac{1}{\sigma t} \phi \left[\frac{\log(t) - \mu}{\sigma} \right].$$

The cdf and pdf of the lognormal distribution are obtained by replacing Φ and ϕ with the standard normal cdf Φ_{nor} and pdf ϕ_{nor} , respectively. Similarly, the cdf and pdf of the Weibull distribution can be obtained by replacing Φ and ϕ with $\Phi_{\text{sev}}(z) = 1 - \exp[-\exp(z)]$ and pdf $\phi_{\text{sev}}(z) = \exp[z - \exp(z)]$.

To write down the likelihood function, we need to define some notation of the data first. Given a set of n units, the lifetime or time in service of unit i is denoted by t_i . The censoring time is denoted by c_i , and δ_i is the censoring

indicator (i.e., $\delta_i = 1$ if unit i failed and $\delta_i = 0$ if the unit was censored). The left truncation time is denoted by τ_i^L . Note that τ_i^L is the time that the life distribution of unit i was truncated on the left. The truncation indicator is v_i (i.e., $v_i = 0$ if unit i is left truncated and $v_i = 1$ if the unit is not truncated). With this notation, the likelihood function for the lifetime data of the transformers is

$$L(\boldsymbol{\theta}) = \prod_{i=1}^n [1 - F(c_i; \boldsymbol{\theta})]^{(1-\delta_i)v_i} \times \left[\frac{1 - F(c_i; \boldsymbol{\theta})}{1 - F(\tau_i^L; \boldsymbol{\theta})} \right]^{(1-\delta_i)(1-v_i)} \\ \times f(t_i; \boldsymbol{\theta})^{\delta_i v_i} \times \left[\frac{f(t_i; \boldsymbol{\theta})}{1 - F(\tau_i^L; \boldsymbol{\theta})} \right]^{\delta_i(1-v_i)},$$

where $\boldsymbol{\theta}$ is the vector that contains all the unknown parameters (i.e., the location parameters μ_i and scale parameters σ_i).

To incorporate simple covariate information, the parametric regression analysis for lifetime data is used. In a typical setting, the location parameter μ is related to the covariate \mathbf{x} through $\mu(\mathbf{x}) = \mathbf{x}'\boldsymbol{\beta}$, where $\boldsymbol{\beta}$ is the regression coefficient vector. The maximum likelihood (ML) estimate $\hat{\boldsymbol{\theta}}$ can then be obtained by maximizing the likelihood function. Numerical algorithms are usually needed.

6.2.3 Reliability Prediction

Based on the model built for the lifetime data, the prediction of the remaining life of surviving units can be obtained. The conditional distribution is important for this task. Conditional on surviving until t_i , the cdf is

$$F(t|t_i; \boldsymbol{\theta}) = \Pr(T \leq t | T > t_i) = \frac{F(t; \boldsymbol{\theta}) - F(t_i; \boldsymbol{\theta})}{1 - F(t_i; \boldsymbol{\theta})}, \quad t \geq t_i.$$

For an individual prediction, the prediction interval (PI) $[\underline{S}_i, \tilde{S}_i]$ can be used. A simple PI can be obtained by taking the lower and upper $\alpha/2$ quantiles of the estimated conditional distribution. The simple PI then needs to be calibrated to provide better coverage probability. The details of calibration using the random weighted bootstrap are available in [46].

For the prediction at the population level, the cumulative number of failures at a future time point is used. For a surviving unit i , the conditional probability of failure between age t_i and a future age t_i^w can be calculated as $\rho_i = F(t_i^w | t_i, \boldsymbol{\theta})$, and it can be estimated by $\hat{\rho}_i = F(t_i^w | t_i, \hat{\boldsymbol{\theta}})$. The cumulative number of future failures is $N = \sum_{i=1}^{n^*} I_i$. Here $I_i \sim$

Fig. 6.2 Plot of individual PIs for the remaining life for a subset of units

Fig. 6.3 Prediction results for the cumulative number of failures at a future time

Bernoulli(ρ_i), $i = 1, \dots, n^*$ and n^* is the number of units at risk. Based on the distribution of N , the point prediction and PIs can be obtained using the algorithms proposed in [46].

As illustrations, Fig. 6.2 shows the plot of individual PIs for the remaining life for a subset of units. Figure 6.3 visualizes the predicted cumulative number of failures over the next 10 years after DFD. One can see that the PIs are wide due to the limited covariate information in the traditional reliability data.

6.3 Time-to-Event Data Analysis

In this section, we briefly introduce the application of using dynamic covariates for time-to-event prediction as described in Hong and Meeker [10].

6.3.1 Background and Data

A general method was developed by Hong and Meeker [10] to model failure-time data with dynamic covariates. The work was motivated by the Product D2 application, which is a machine used in office/residence. Product D2 is similar to high-end copy machine where the number of pages used could be recorded dynamically. For this product, the use-rate data $R(t)$ (cycles/week) were collected weekly as a time series for those units connected to the network. This information could be downloaded automatically in addition to the failure-time data. In the Product D2 dataset, data were observed within a 70-week period, and 69 out of 1800 units failed during the study period. Figures 6.4 and 6.5 illustrate the event plot of the failure-time data and the use-rate trajectories over time for a subset of the data.

6.3.2 Model for Time-to-Event Data and Parameter Estimation

Three sets of observable random variables, the failure time, censoring indicator, and dynamic covariate, over time are considered, which are denoted by $\{T, \Delta, X(T)\}$.

Fig. 6.4 The event plot for a subset of the Product D2 failure-time data. Figure reproduced with permission from Taylor and Francis

Fig. 6.5 The plot of the use-rate trajectories for the subset in Fig. 6.4. Figure reproduced with permission from Taylor and Francis

The observed data are described by $\{t_i, \delta_i, \mathbf{x}_i(t_i)\}$. Here n denotes the number of units in the dataset, t_i is the failure time or time in service, and δ_i is the observed censoring indicator (i.e., it equals to 1 if unit i fails and 0 otherwise). The $\mathbf{x}_i(t_i) = \{x_i(s) : 0 \leq s \leq t_i\}$ is the observed dynamic covariate information of unit i from the time 0 to t_i , where $x_i(s)$ is the observed covariate value at time s for unit i . Particularly for Product D2, we use $X(t) = \log[R(t)/R_0(t)]$ as the form of the covariate in the model, where $R_0(t)$ is the baseline use rate that is chosen to be a typical constant use rate.

The cumulative exposure model in [47] is used to model the failure-time data with dynamic covariate. The cumulative exposure $u(t)$ is defined as

$$u(t) = u[t; \beta, \mathbf{x}(t)] = \int_0^t \exp[\beta x(s)] ds,$$

where β represents the influence of the covariate on the exposure. When the cumulative exposure of a unit reaches a random threshold U at time T , the unit fails. This establishes a relationship between U and T as in

$$U = u(T) = \int_0^T \exp[\beta x(s)] ds. \quad (6.1)$$

Under the above model and the covariate history $\mathbf{x}(\infty)$, the cdf of the failure time T is

$$\begin{aligned} F(t; \beta, \theta_0) &= \Pr(T \leq t) = \Pr\{U \leq u[t; \beta, \mathbf{x}(t)]\} \\ &= F_0\{u[t; \beta, \mathbf{x}(t)]; \theta_0\} \end{aligned}$$

and pdf is $f(t; \beta, \boldsymbol{\theta}_0) = \exp[\beta x(t)] f_0\{u[t; \beta, \mathbf{x}(t)]; \boldsymbol{\theta}_0\}$. Here $\boldsymbol{\theta}_0$ is the parameter in the baseline cdf of the cumulative exposure threshold U , and $f_0(u; \boldsymbol{\theta}_0)$ is the pdf of U . In the Product D2 application, the baseline cumulative exposure distribution $F_0(u; \boldsymbol{\theta}_0)$ was modeled by the Weibull distribution, of which the cdf and pdf are

$$F_0(u; \boldsymbol{\theta}_0) = \Phi_{\text{sev}} \left[\frac{\log(u) - \mu_0}{\sigma_0} \right] \text{ and}$$

$$f_0(u; \boldsymbol{\theta}_0) = \frac{1}{\sigma_0 u} \phi_{\text{sev}} \left[\frac{\log(u) - \mu_0}{\sigma_0} \right].$$

In the above expression, $\boldsymbol{\theta}_0 = (\mu_0, \sigma_0)'$, where μ_0 and σ_0 are the location and scale parameters. Also, $\Phi_{\text{sev}}(z) = 1 - \exp[-\exp(z)]$, and $\phi_{\text{sev}}(z) = \exp[z - \exp(z)]$. Lognormal and other log-location-scale distributions can also be used if they are considered appropriate for certain applications.

6.3.3 Model for Covariates

To model the covariate process, we use the linear mixed-effect model. In particular, $X(t)$ is modeled as

$$X_i(t_{ij}) = \eta + Z_i(t_{ij})\mathbf{w}_i + \varepsilon_{ij}. \quad (6.2)$$

In model (6.2), η is the constant mean, and the term $Z_i(t_{ij})\mathbf{w}_i$ is used to model variation at individual level. Here $Z_i(t_{ij}) = [1, \log(t_{ij})]$, and \mathbf{w}_i is the vector of random effects of the initial covariate at time 0 and the changing rate for unit i . It is assumed that $\mathbf{w}_i = (w_{0i}, w_{1i})' \sim N(\mathbf{0}, \boldsymbol{\Sigma}_w)$ with the covariance matrix

$$\boldsymbol{\Sigma}_w = \begin{pmatrix} \sigma_1^2 & \rho\sigma_1\sigma_2 \\ \rho\sigma_1\sigma_2 & \sigma_2^2 \end{pmatrix},$$

and $\varepsilon_{ij} \sim N(0, \sigma^2)$ is the error term.

The parameter estimation is done separately using the ML method in two parts since parameters in the failure-time model $\boldsymbol{\theta}_T = (\boldsymbol{\theta}'_0, \beta)'$ and covariate process model $\boldsymbol{\theta}_X = (\eta, \boldsymbol{\Sigma}_w, \sigma^2)$ are separable. The joint likelihood for $\boldsymbol{\theta}_T$ and $\boldsymbol{\theta}_X$ is

$$L(\boldsymbol{\theta}_T, \boldsymbol{\theta}_X) = L(\boldsymbol{\theta}_T) \times L(\boldsymbol{\theta}_X). \quad (6.3)$$

The first component of (6.3) is the likelihood function of the failure-time data, which is

$$L(\boldsymbol{\theta}_T) = \prod_{i=1}^n \{\exp[\beta x_i(t_i)] f_0(u[t_i; \beta, \mathbf{x}_i(t_i)]; \boldsymbol{\theta}_0)\}^{\delta_i} \\ \times \{1 - F_0(u[t_i; \beta, \mathbf{x}_i(t_i)]; \boldsymbol{\theta}_0)\}^{1-\delta_i}. \quad (6.4)$$

The second component of (6.3) is the likelihood of covariate data, which is

$$L(\boldsymbol{\theta}_X) = \prod_{i=1}^n \int_{\mathbf{w}_i} \left\{ \prod_{t_{ij} \leq t_i} f_1[x_i(t_{ij}) - \eta - Z_i(t_{ij})\mathbf{w}_i; \sigma^2] \right\} f_2(\mathbf{w}_i; \boldsymbol{\Sigma}_w) d\mathbf{w}_i. \quad (6.5)$$

In the above equation, $f_1(\cdot)$ is the pdf of a univariate normal, and $f_2(\cdot)$ is the pdf of a bivariate normal distribution.

6.3.4 Reliability Prediction

In order to predict future field failures, the distribution of the remaining life (DRL) is considered in the prediction procedure. The DRL describes the distribution of T_i for unit i given $T_i > t_i$ and $\mathbf{X}_i(t_i) = \mathbf{x}_i(t_i)$. Particularly, the probability of unit i failing within the next s time units given it has survived by time t_i is

$$\rho_i(s; \boldsymbol{\theta}) = \Pr[t_i < T_i \leq t_i + s | T_i > t_i, \mathbf{X}_i(t_i)], \quad s > 0, \quad (6.6)$$

where $\boldsymbol{\theta}$ denotes all the parameters. Then $\rho_i(s; \boldsymbol{\theta})$ can be further expressed as

$$\rho_i(s; \boldsymbol{\theta}) \\ = \mathbf{E}_{X_i(t_i, t_i+s) | X_i(t_i) = \mathbf{x}_i(t_i)} \{ \Pr[t_i < T_i \leq t_i + s | T_i > t_i, \\ \mathbf{X}_i(t_i), \mathbf{X}_i(t_i, t_i + s)] \} \quad (6.7) \\ = \frac{\mathbf{E}_{X_i(t_i, t_i+s) | X_i(t_i) = \mathbf{x}_i(t_i)} \{ F_0(u[t_i + s; \beta, \mathbf{X}_i(t_i, t_i + s)]; \boldsymbol{\theta}_0) \\ - F_0(u[t_i; \beta, \mathbf{x}_i(t_i)]; \boldsymbol{\theta}_0) \}}{1 - F_0(u[t_i; \beta, \mathbf{x}_i(t_i)]; \boldsymbol{\theta}_0)}$$

where $\mathbf{X}_i(t_1, t_2) = \{X_i(s) : t_1 < s \leq t_2\}$. Since model (6.2) is assumed for $\mathbf{X}_i(t_i, t_i + s)$ and $\mathbf{X}_i(t_i) = \mathbf{x}_i(t_i)$, the multivariate normal distribution theory can be used to obtain the conditional distribution.

The Monte Carlo simulation is used to evaluate $\rho_i(s; \hat{\boldsymbol{\theta}})$ since an analytical expression for $\rho_i(s; \boldsymbol{\theta})$ is unavailable. The following procedure is used to compute $\rho_i(s; \hat{\boldsymbol{\theta}})$:

1. Substitute $\boldsymbol{\theta}_X$ with the ML estimates $\hat{\boldsymbol{\theta}}_X$ in the distribution of $\mathbf{X}_i(t_i, t_i + s) | \mathbf{X}_i(t_i) = \mathbf{x}_i(t_i)$, and draw $\mathbf{X}_i^*(t_i, t_i + s)$ from the distribution.
2. Let $\mathbf{X}_i^*(t_i + s) = \{\mathbf{x}_i(t_i), \mathbf{X}_i^*(t_i, t_i + s)\}$ be the simulated covariate process in the time interval $(t_i, t_i + s)$.
3. Compute the DRL given $\mathbf{X}_i^*(t_i, t_i + s)$ and the ML estimates $\hat{\boldsymbol{\theta}}_T$ of $\boldsymbol{\theta}_T = (\boldsymbol{\theta}'_0, \beta)$ by

$$\rho_i^*(s; \hat{\boldsymbol{\theta}}) = \frac{F_0(u[t_i + s; \hat{\beta}, \mathbf{X}_i^*(t_i, t_i + s)]; \hat{\boldsymbol{\theta}}_0) - F_0(u[t_i; \hat{\beta}, \mathbf{x}_i(t_i)]; \hat{\boldsymbol{\theta}}_0)}{1 - F_0(u[t_i; \hat{\beta}, \mathbf{x}_i(t_i)]; \hat{\boldsymbol{\theta}}_0)}.$$

4. Repeat steps 1–3 M times and obtain $\rho_i^{*m}(s; \hat{\boldsymbol{\theta}})$, $m = 1, \dots, M$.
5. The estimate is computed by $\rho_i(s; \hat{\boldsymbol{\theta}}) = M^{-1} \sum_{m=1}^M \rho_i^{*m}(s; \hat{\boldsymbol{\theta}})$.

Fig. 6.6 The estimated DRLs and the 95% pointwise CIs for two representative at-risk units. Figure reproduced with permission from Taylor and Francis

The CONFIDENCE INTERVALS (CIs) for $\rho_i(s; \hat{\theta})$ can be obtained through the following procedure:

1. Draw $\hat{\theta}_T^{*b}$ and $\hat{\theta}_X^{*b}$ from $N(\hat{\theta}_T, \Sigma_{\hat{\theta}_T})$ and $N(\hat{\theta}_X, \Sigma_{\hat{\theta}_X})$, respectively.
2. Let $\hat{\theta}^* = (\hat{\theta}_T^{*b}, \hat{\theta}_X^{*b})'$ and obtain $\rho_i^{**}(s; \hat{\theta}^*)$ following the above algorithm.
3. Repeat steps 1–2 B times to obtain $\rho_i^{**b}(s) = \rho_i^{**b}(s; \hat{\theta}^{*b})$, $b = 1, \dots, B$.
4. The $100(1 - \alpha)\%$ CI is computed by $[\rho_i^{**[\alpha B/2]}(s), \rho_i^{**[(1-\alpha/2)B]}(s)]$. Here $\rho_i^{**[b]}(s)$ is the $[b]$ th ordered value of $\rho_i^{**b}(s)$, and $[\cdot]$ is the function for rounding to the nearest integer.

Figure 6.6 shows the estimated DRL for two representative units. One unit has a higher use rate which increases quickly over time ($\hat{w}_0 = 0.4061$, $\hat{w}_1 = 0.4184$), and the other has a lower use rate which increases slowly over time ($\hat{w}_0 = 0.1704$, $\hat{w}_1 = 0.0168$). The trends in the plot are consistent with our expectation that the unit with a higher use rate tends to have higher failure risk.

To assess the prediction variability, one may also want to calculate the prediction interval (PI) of an individual remaining life, denoted by $[\underline{S}_i, \tilde{S}_i]$. A $100(1 - \alpha)\%$ PI of the remaining lifetime can be obtained by using the method introduced by Lawless and Fredette [48] as in

$$\rho_i(\underline{S}_i; \hat{\theta}) = v_{\alpha/2} \quad \text{and} \quad \rho_i(\tilde{S}_i; \hat{\theta}) = v_{1-\alpha/2}. \quad (6.8)$$

Fig. 6.7 The point predictions and the pointwise 90% PIs for the cumulative number of failures after the DFD out of the 1731 units at risk. Figure reproduced with permission from Taylor and Francis

Here v_α is the α quantile of the $\rho_i(S_i; \hat{\theta})$ distribution, and S_i represents the remaining life for unit i . The v_α can be obtained through a Monte Carlo simulation.

In real applications, obtaining the predicted cumulative number of failures is also important because this could help with the decisions for warranty cost control or the long-term production plan. Suppose $N(s) = \sum_{i \in RS} I_i(s)$ is the total failure counts at time s after DFD. The RS is the risk set at DFD in this expression, and $I_i(s)$ is the binary indicator for the occurrence of a failure at time s with $I_i(s) \sim \text{Bernoulli}[\rho_i(s; \theta)]$. Let $F_N(n_k; \theta)$, $n_k = 0, 1, \dots, n^*$ denote the cdf of $N(s)$, where n^* is the count of units in the risk set. Then $F_N(n_k; \theta)$ can be computed in its explicit form using a discrete Fourier transformation [49]. The PI for $N(s)$ can be calculated similarly as the individual predictions.

For the Product D2 application, 1731 units were remained at risk after 69 failed out of 1800 installed units by the end of the study. The point predictions and the 90% pointwise PIs of the total number of failures for 100 weeks after the DFD are shown in Fig. 6.7.

6.4 Degradation Data Analysis

In this section, we briefly introduce how to leverage the dynamic covariates for modeling degradation data as described in Hong et al. [25].

6.4.1 Background and Data

Hong et al. [25] develop a general path model utilizing shape-restricted splines with random effects to model the degradation process with dynamic covariates. This paper considers an application of modeling the photodegradation process of organic coating materials due to exposure to the time-varying ultraviolet (UV) radiation and the outdoor environmental conditions. In this work, to study the service life of a coating material, scientists at NIST placed 36 specimens in outdoor setting with varied UV spectrum and intensity, temperature, and relative humidity (RH) recorded over an approximate 5-year period. The specimens started at different time points to allow different degradation paths to be observed. For each specimen, degradation measurements were taken periodically using Fourier transform infrared (FTIR) spectroscopy. Since a particular compound or structure is tied with a peak at a certain wavelength on the FTIR spectrum, the change in the height of the peak was used to measure the decrease in the concentration of the compound. One of the compounds of interest for the NIST data was C-O stretching of aryl ether, which was measured at the wavelength 1250 cm. Figure 6.8 shows the degradation paths of nine representative specimens with varied starting times in the study. We can observe very different trajectories with the degradation rate varying over time and among different specimens as well. Figures 6.9, 6.10, and 6.11 show the dynamic covariate information on the daily UV dosage, RH, and temperature as well as the fitted smooth lines for showing the mean process of one specimen over the study period. The vertical lines are used to label time windows separated by every 6 months. We can observe both a seasonal pattern and a random oscillation

Fig. 6.8 Plot of nine representative degradation paths. *Figure reproduced with permission from Taylor and Francis*

Fig. 6.9 Dynamic covariate information on the daily UV dosage for a single sample. The black dots connected by green lines show the daily values. The vertical lines show the time windows by every 6 months from January 2002. The red smooth curves are the estimated mean process. *Figure reproduced with permission from Taylor and Francis*

of the daily records for each individual covariate. There are stronger seasonal patterns for the UV dosage and temperature than the RH. There also appears to be a larger variation of the daily observations in the summer than in the winter, which indicates a varied degree of variability of the covariates over different time periods.

The vertical lines show the time windows by every 6 months from January 2002. The red smooth curves are the estimated mean process. Figure reproduced with permission from Taylor and Francis

6.4.2 Model for Degradation Paths and Parameter Estimation

The general additive model for degradation data with dynamic covariates is given in the form

$$y_i(t_{ij}) = D[t_{ij}; \mathbf{x}_i(t_{ij})] + G(t_{ij}; \mathbf{w}_i) + \varepsilon_i(t_{ij}), \quad (6.9)$$

where $y_i(t_{ij})$ for $i = 1, \dots, n, j = 1, \dots, n_i$ is the degradation measurement at time t_{ij} for unit i , $\varepsilon_i(t_{ij}) \sim N(0, \sigma_\varepsilon^2)$ denotes the measurement error, and $\mathbf{x}_i(t_{ij}) = [x_{i1}(t_{ij}), \dots, x_{ip}(t_{ij})]'$ is the vector containing the dynamic covariate information at the time t_{ij} . The actual degradation level at t_{ij} is modeled by $D[t_{ij}; \mathbf{x}_i(t_{ij})] + G(t_{ij}; \mathbf{w}_i)$ as the sum of a fixed component and a random component. The fixed component is the population common degradation path, modeled in a cumulative damage form given by

$$D[t_{ij}; \mathbf{x}_i(t_{ij})] = \beta_0 + \sum_{l=1}^p \int_0^{t_{ij}} f_l[x_{il}(u); \beta_l] du. \quad (6.10)$$

This model incorporates the dynamic covariates through the covariate-effect functions $f_l(\cdot)$ for $l = 1, \dots, p$. Here, β_0 is the initial degradation, $f_l[x_{il}(u); \beta_l]$ is the l th covariate-effect of $x_{il}(u)$ on the degradation process at time u , and $\int_0^{t_{ij}} f_l[x_{il}(u); \beta_l] du$ is the cumulative effect of x_{il} up to time t_{ij} . The random component includes the random effect terms

for modeling the unit-to-unit variation, which is specified in $G(t_{ij}; \mathbf{w}_i) = w_{0i} + w_{1i}t_{ij}$. Here, $\mathbf{w}_i = (w_{0i}, w_{1i})'$ is the vector of random effects for the initial degradation and the growth rate over time, and it is assumed to follow a bivariate normal distribution $N(\mathbf{0}, \Sigma_w)$ with the covariance matrix

$$\Sigma_w = \begin{bmatrix} \sigma_0^2 & \rho\sigma_0\sigma_1 \\ \rho\sigma_0\sigma_1 & \sigma_1^2 \end{bmatrix}.$$

Also we use $\boldsymbol{\sigma}_w = (\sigma_0, \sigma_1, \rho)'$ to denote all the distinct parameters included in Σ_w .

The ML method is used for estimating the parameters. Since the degradation measurements and the dynamic covariates are observed at discrete time points, the discrete version of the degradation path model is used for computing the likelihood by replacing $D[t_{ij}; \mathbf{x}_i(t_{ij})]$ in (6.10) by

$$D[t_{ij}; \mathbf{x}_i(t_{ij})] = \beta_0 + \sum_{l=1}^p \sum_{u_k \leq t_{ij}} f_l[x_{il}(u_k); \beta_l](u_k - u_{i,k-1}), \quad (6.11)$$

where u_k is the k th time point when the degradation and covariates are measured for unit i and $u_{i0} = 0$. Let $\boldsymbol{\theta}_D = \{\beta, \boldsymbol{\sigma}_w, \sigma_\varepsilon\}$ denote all the model parameters. Then the likelihood is

$$L(\boldsymbol{\theta}_D) = \prod_{i=1}^n \int_{\mathbf{w}_i} \left[\prod_{t_{ij} \leq t_{m_i}} \frac{1}{\sigma_\varepsilon} \phi \left\{ \frac{C[y_i(t_{ij}); \mathbf{x}_i(t_{ij}), \mathbf{w}_i]}{\sigma_\varepsilon} \right\} g_{\mathbf{w}_i}(\mathbf{w}_i; \boldsymbol{\sigma}_w) \right] d\mathbf{w}_i \quad (6.12)$$

where $C[y_i(t_{ij}); \mathbf{x}_i(t_{ij}), \mathbf{w}_i] = y_i(t_{ij}) - D[t_{ij}; \mathbf{x}_i(t_{ij})] - G(t_{ij}; \mathbf{w}_i)$, $\phi(\cdot)$ and $g_{\mathbf{w}_i}(\cdot)$ are the pdfs of a standard normal distribution and a bivariate $N(\mathbf{0}, \Sigma_w)$ distribution, respectively.

Considering there was not sufficient knowledge on what might be a sensible form for the covariate-effect functions, the paper chose to estimate the $f_l(\cdot)$ using a linear combination of spline bases. To leverage the physical understanding of the relationships between the degradation process and the covariates, the shape-restricted splines [50] were used to ensure monotonic decreasing bases (I-splines) for the UV dosage and temperature and concave bases (C-splines) for the RH. Let $B_{lq}[x_{il}(u_k)]$ for $q = 1, \dots, a_l$ denote the spline bases for the covariate x_i ; then, the covariate-effect function is modeled as

$$f_l[x_{il}(u_k); \beta_l] = \sum_{q=1}^{a_l} B_{lq}[x_{il}(u_k)] \beta_{lq},$$

where β_{lq} 's are the spline coefficients. Define $U_{lq}(t_{ij}) = \sum_{u_{ik} \leq t_{ij}} B_{lq}[x_{il}(u_{ik})](u_{ik} - u_{i,k-1})$. Then the model in (6.9) with $D[t_{ij}; \mathbf{x}_i(t_{ij})]$ given in (6.11) can be written as a linear mixed-effect model in the form of $\mathbf{y}_i = \mathbf{X}_i \boldsymbol{\beta} + \mathbf{Z}_i \mathbf{w}_i + \boldsymbol{\varepsilon}_i$, where

$$\mathbf{X}_i = \begin{bmatrix} 1 & U_{11}(t_{i1}) & \cdots & U_{1a_1}(t_{i1}) & \cdots & U_{p1}(t_{i1}) & \cdots & U_{pa_p}(t_{i1}) \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\ 1 & U_{11}(t_{ini}) & \cdots & U_{1a_1}(t_{ini}) & \cdots & U_{p1}(t_{ini}) & \cdots & U_{pa_p}(t_{ini}) \end{bmatrix},$$

$$\mathbf{Z}_i = \begin{bmatrix} 1 & t_{i1} \\ \vdots & \vdots \\ 1 & t_{ini} \end{bmatrix},$$

and the coefficient vector $\boldsymbol{\beta} = (\boldsymbol{\beta}'_w, \boldsymbol{\beta}'_c)'$, where $\boldsymbol{\beta}_w$ and $\boldsymbol{\beta}_c$ denote the unconstrained and constrained parameters, respectively.

The following algorithm was proposed in [25] to obtain the ML estimate $\hat{\boldsymbol{\theta}}_D$ that maximizes (6.12):

1. Initialize $\boldsymbol{\sigma}_w$ and σ_ε by fitting a linear mixed-effect model with no constraints.
2. Compute $V_i = \mathbf{Z}_i \boldsymbol{\Sigma}_w \mathbf{Z}_i' + \sigma_\varepsilon^2 \mathbf{I}_i$.
3. The mixed primal-dual bases algorithm in [51] is used to estimate $\boldsymbol{\beta}$. That is to minimize $\sum_{i=1}^n (\mathbf{y}_i - \mathbf{X}_i \boldsymbol{\beta})' V_i^{-1} (\mathbf{y}_i - \mathbf{X}_i \boldsymbol{\beta})$ subject to $\boldsymbol{\beta}_c \geq \mathbf{0}$.
4. Fit a linear mixed-effect model $r_i = \mathbf{Z}_i \mathbf{w}_i + \boldsymbol{\varepsilon}_i$ with $r_i = \mathbf{y}_i - \mathbf{X}_i \boldsymbol{\beta}$ to get the updated estimates of $\boldsymbol{\sigma}_w$ and σ_ε .
5. Repeat steps 2 to 4 until the estimated parameters converge.

With the shape-restricted splines, the ML estimates of some parameters might locate on the boundary of the parameter space. In this case, the bootstrap method is useful for assessing the variability and making inferences about the parameters. An adjusted bootstrap procedure by Carpenter et al. [52] was applied to resample the residuals and the estimated random effects for constructing bootstrap resamples of the original data to avoid underestimating variability and producing too narrow CIs. Then the bias-corrected bootstrap CIs were constructed based on obtaining the ML estimates of model parameters using the abovementioned algorithm for a large number of bootstrap samples.

6.4.3 Model for Covariates

To predict the degradation process and reliability, it is necessary to model the dynamic covariate process through a parametric model. Hong et al. [25] propose the following model:

$$X_j(t) = \text{Tr}_j(t) + S_j(t) + \xi_j(t),$$

where $\text{Tr}_j(t)$ models the long-term trend of the covariate process for the j th covariate, $S_j(t)$ captures the seasonal

pattern, and $\xi_j(t)$ depicts the random error which is modeled by a stationary process. For the NIST outdoor weathering data, there was no significant long-term trend observed, and hence $\text{Tr}_j(t) = \mu_j$ for $j = 1, 2, 3$. However, the seasonal pattern was quite prominent, and there were seasonal effects observed for both the mean and variance of the process. So two sine functions were included in both the seasonal and error terms (except for RH which shows no seasonal effect assumed for the variation of the process from Figs. 6.8, 6.9, 6.10, and 6.11) in the following form:

$$\begin{bmatrix} S_1(t) \\ S_2(t) \\ S_3(t) \end{bmatrix} = \begin{bmatrix} \kappa_1 \sin \left[\frac{2\pi}{365} (t - \eta_1) \right] \\ \kappa_2 \sin \left[\frac{2\pi}{365} (t - \eta_2) \right] \\ \kappa_3 \sin \left[\frac{2\pi}{365} (t - \eta_3) \right] \end{bmatrix},$$

$$\begin{bmatrix} \xi_1(t) \\ \xi_2(t) \\ \xi_3(t) \end{bmatrix} = \begin{bmatrix} (1 + \nu_1 \{1 + \sin \left[\frac{2\pi}{365} (t - \zeta_1) \right]\}) \varepsilon_1(t) \\ (1 + \nu_2 \{1 + \sin \left[\frac{2\pi}{365} (t - \zeta_2) \right]\}) \varepsilon_2(t) \\ \varepsilon_3(t) \end{bmatrix}. \quad (6.13)$$

To capture the autocorrelation within and among the covariate processes, a lag-2 VAR model [i.e., $\text{Var}(2)$] was used, where the error term was modeled by

$$\begin{bmatrix} \varepsilon_1(t) \\ \varepsilon_2(t) \\ \varepsilon_3(t) \end{bmatrix} = Q_1 \begin{bmatrix} \varepsilon_1(t-1) \\ \varepsilon_2(t-1) \\ \varepsilon_3(t-1) \end{bmatrix} + Q_2 \begin{bmatrix} \varepsilon_1(t-2) \\ \varepsilon_2(t-2) \\ \varepsilon_3(t-2) \end{bmatrix} + \begin{bmatrix} e_1(t) \\ e_2(t) \\ e_3(t) \end{bmatrix}. \quad (6.14)$$

In the above equation, Q_1 and Q_2 are regression coefficient matrices, and $[e_1(t), e_2(t), e_3(t)]' \sim \mathbf{N}(\mathbf{0}, \boldsymbol{\Sigma}_e)$ are multivariate normal random errors that do not change over time.

The parameters in models (6.13) and (6.14) are estimated in two steps. First, the ML estimates of the seasonal effects in the process mean and variance structures are obtained by ignoring the autocorrelation in the error terms. Then the VAR model is fitted to the residuals calculated from the first step using the multivariate least squares approach [53]. The bootstrap method is used for obtaining the CIs of the parameters in the dynamic covariate process.

6.4.4 Reliability Prediction

To predict the failure time and reliability, let \mathcal{D}_f denote the threshold for a soft failure. For any $\mathbf{X}(\infty) = \mathbf{x}(\infty)$ and \mathbf{w} , the degradation path is fixed and the failure time can be determined by

$$t_{\mathcal{D}} = \min\{t : D[t; \mathbf{x}(\infty)] + G(t; \mathbf{w}) = \mathcal{D}_f\}. \quad (6.15)$$

However, for a random unit, the covariate process $X(\infty)$ and w are random. Hence, the cdf of the failure time, $T = T[\mathcal{D}_f, X(\infty), w]$, can be defined as

$$F(t; \theta) = \mathbf{E}_{X(\infty)} \mathbf{E}_w \Pr \{T[\mathcal{D}_f, X(\infty), w] \leq t\}, \quad t > 0, \tag{6.16}$$

with $\theta = \{\theta_D, \theta_X\}$ denoting all the unknown parameters. There is usually no closed form expression of $F(t; \theta)$. Hence, the cdf at any estimated $\hat{\theta}$ is estimated through Monte Carlo simulation outlined in the following steps [25]:

1. Simulate the covariate process based on the estimated parameter $\hat{\theta}_X$.
2. Simulate the random effects w from $N(\mathbf{0}, \Sigma_w)$ with the estimated parameter $\hat{\theta}_D$.
3. Compute $D[t; X(\infty)] + G(t; w)$ based on the simulated covariate process and random effects.
4. For the degradation path in step 3, determine the failure time $t_{\mathcal{D}}$ by Eq. (6.15).
5. Repeat steps 1 to 4 for M times to obtain the simulated failure times $t_{\mathcal{D}}^m, m = 1, \dots, M$. Then $F(t; \hat{\theta})$ is estimated by the empirical cdf, $F(t; \hat{\theta}) = M^{-1} \sum_{m=1}^M \mathbb{1}_{(t_{\mathcal{D}}^m \leq t)}$.

By using the bootstrap approach, the point estimates and the CIs of $F(t; \theta)$ can be calculated using the sample mean and quantiles of the bootstrap estimates of $F(t; \hat{\theta})$ based on a large number of bootstrap estimates $\hat{\theta}$. By using $\mathcal{D}_f = -0.4, M = 200$ Monte Carlo simulations, and 10000 bootstrap samples, Fig. 6.12 shows the predicted $F(t; \theta)$ and its 95% pointwise CIs for the NIST coating degradation data. We can see that for

Fig. 6.12 The estimated cdf and corresponding 95% pointwise CIs for a population of units with random starting time between 161 and 190 days. Figure reproduced with permission from Taylor and Francis

a population of units with random starting time between 161 and 190 days, a majority of the population will fail between 50 and 150 days in service.

6.5 Recurrent Event Data Analysis

In this section, we briefly introduce the multilevel trend-renewal process (MTRP) model and its application on the Vehicle B data as described in Xu et al. [36].

6.5.1 Background and Data

Xu et al. [36] consider the modeling and analysis of the Vehicle B data, which consist of recurrent event data from a batch of industrial systems. Vehicle B is a two-level repairable system. During its life span, Vehicle B may experience events at subsystem level (e.g., engine failures) and/or events at component level (e.g., oil pump failures). In the field data, we have $n = 203$ units from a 110-month observation period. There are 219 component events and 44 subsystem events observed during the study period. Figure 6.13 shows the event plot for ten randomly selected units. We also have the cumulative usage information available for each unit, which is a dynamic covariate. The cumulative usage information is shown in Fig. 6.14. The goal is to make a prediction for the cumulative number of component event occurrences at a future time.

Fig. 6.13 The recurrent event processes for ten randomly selected units in the Vehicle B fleet. Figure reproduced with permission from Taylor and Francis

Fig. 6.14 The cumulative usage processes for ten randomly selected units in the Vehicle B fleet. Figure reproduced with permission from Taylor and Francis

We need some notation to introduce the MTRP model. Suppose there are n units under observation from time 0 to τ_i . Let $X_i(t)$ be the time-dependent covariate at time t for system i . Let $N_{is}(t)$ be the number of subsystem events, and let $N_{ic}(t)$ be the number of component events up to time t . The total number of replacement events is $N_i(t) = N_{is}(t) + N_{ic}(t)$. The subsystem event time is sorted as $0 < t_{i1}^s < \dots < t_{i,N_{is}(\tau_i)}^s < \tau_i$. The component event time is sorted as $0 < t_{i1}^c < \dots < t_{i,N_{ic}(\tau_i)}^c < \tau_i$. Let $0 < t_{i1} < \dots < t_{i,N_i(\tau_i)} < \tau_i$ be the replacement event times, regardless of the types.

6.5.2 The MTRP Model and Parameter Estimation

For a two-level repairable system, Xu et al. [36] propose the following MTRP model to describe events occurred at component level. In particular, the intensity function is

$$\lambda_i^c(t|\mathcal{F}_{i,t^-}; \theta^c) = h^c \left\{ \Lambda_i^s(t|\mathcal{F}_{i,t^-}^s) - \Lambda_i^s \left[t_{i,N_i(t^-)} | \mathcal{F}_{i,t^-}^s \right]; \theta^c \right\} \times \lambda_i^s(t|\mathcal{F}_{i,t^-}^s; \theta^c). \quad (6.17)$$

Here \mathcal{F}_{i,t^-}^s denotes the historical information. In this multi-level model framework, the effect of subsystem events on the

component event process is modeled by $\lambda_i^s(t|\mathcal{F}_{i,t^-}^s; \theta^c)$, which takes the form

$$\lambda_i^s(t|\mathcal{F}_{i,t^-}^s; \theta^c) = h^s \{ \Lambda_i(t) - \Lambda_i[t_{i,N_{is}(t^-)}^s]; \theta^c \} \lambda_i(t; \theta^c). \quad (6.18)$$

Here, θ^c denotes the vector of unknown parameters. The cumulative event intensity functions can be obtained as $\Lambda_i(t) = \int_0^t \lambda_i(u; \theta^c) du$, and $\Lambda_i^s(t|\mathcal{F}_{i,t^-}^s) = \int_0^t \lambda_i^s(u|\mathcal{F}_{i,t^-}^s; \theta^c) du$. The baseline function $\lambda_i(t; \theta^c)$ models the intensity of the component process when there is no event adjustment, and the function $h^s(\cdot)$ is used to model the adjustment for the effect of events from the subsystem. The renewal distribution function $F^c(\cdot)$ is used to describe the distribution of gap times under the transformed scale. The model in (6.18) can be extended to incorporate dynamic covariates and random effects.

To model the dynamic covariates, the intensity function can be extended as

$$\lambda_i(t; \theta^c) = \lambda_b(t) \exp\{\gamma g[X_i(t)]\}, \quad (6.19)$$

where $\lambda_b(t)$ denotes the intensity trend function under the baseline and γ is the regression coefficient. In the Vehicle B application, we use $g[X_i(t)] = \log[X_i(t)]$. To incorporate random effects, the intensity function can be further extended as

$$\lambda_i(t; \theta^c) = \lambda_b(t) \exp\{\gamma \log[X_i(t)] + w_i\}. \quad (6.20)$$

Here w_i 's are independent and identically distributed with $N(0, \sigma_r^2)$. The MTRP with random effects is referred to as HMTRP(F^c, F^s, λ_i), in which the HMTRP stands for heterogenous MTRP.

To estimate the model parameters, one needs to construct the likelihood function. The component event data can be denoted as $\{t_{ij}, \delta_{ij}^c\}$ with t_{ij} being the event time and δ_{ij}^c being the component-event indicator. The event history is denoted as $\mathcal{F} = \{N_{ic}(u), N_{is}(u), X_i(u) : 0 < u \leq \tau_i, i = 1, \dots, n\}$. The likelihood function is given by

$$L(\theta^c) = \prod_{i=1}^n \prod_{j=1}^{N_i(\tau_i)+1} \left(\left\{ f^c[\Lambda_i^s(t_{ij}|\mathcal{F}_{i,t_{ij}^-}^s) - \Lambda_i^s(t_{i,j-1}|\mathcal{F}_{i,t_{i,j-1}^-}^s)] \lambda_i^s(t_{ij}|\mathcal{F}_{i,t_{ij}^-}^s; \theta^c) \right\}^{\delta_{ij}^c} \times \left\{ S^c[\Lambda_i^s(t_{ij}|\mathcal{F}_{i,t_{ij}^-}^s) - \Lambda_i^s(t_{i,j-1}|\mathcal{F}_{i,t_{i,j-1}^-}^s)] \right\}^{1-\delta_{ij}^c} \right). \quad (6.21)$$

Xu et al. [36] use Bayesian methods with diffuse priors to estimate the model parameters. The Metropolis-within-Gibbs algorithm is used to obtain the posterior distributions, and then the inference can be carried out using the Markov chain Monte Carlo (MCMC) samples from the posterior distributions.

6.5.3 Prediction for Component Events

To make predictions for component events, let θ denote the vector of all the parameters and $X_i(t_1, t_2) = \{X_i(t); t_1 < t \leq t_2\}$ is the covariate information between t_1 and t_2 . The prediction for the counts of component events at time t^* is

$$\begin{aligned}
 N_c(t^*; \theta) &= \sum_{i=1}^n N_{ic}(t^*; \theta) \\
 &= \sum_{i=1}^n \mathbf{E}_{X_i(\tau_i, \tau_i+t^*)|X(\tau_i)} \mathbf{E}_{w_i} \{N_{ic}[t^*, X_i(\tau_i, \tau_i + t^*), \\
 &\qquad\qquad\qquad w_i; \theta]\}. \quad (6.22)
 \end{aligned}$$

Here $N_{ic}(t^*; \theta)$ denotes the prediction for unit i . Because there is no closed form expression for (6.22), the Monte Carlo simulation approach is used.

By fitting the MTRP model to the Vehicle B data using Bayesian estimation, one needs to specify the prior distributions for the unknown parameters. The Weibull distribution was used as renewal functions for F^c and F^s . To check the performance of the predictions, the last 15 months of the Vehicle B data were held back, and only the first 95 months of data were used to estimate the MTRP model. Then we generate predictions for the last 15 months. Figure 6.15 shows the predicted cumulative number of component events

Fig. 6.15 Back test based on an early subset of the data. The plot shows the predicted cumulative number of component events for Vehicle B for the last 15 months based on the earlier 95 months of data. *Figure reproduced with permission from Taylor and Francis*

Fig. 6.16 Prediction of future events. The plot shows the predicted cumulative number of component events for Vehicle B in the future 30 months based on all observed data. *Figure reproduced with permission from Taylor and Francis*

for the last 15 months based on the earlier data. One can see that the actual observed cumulative numbers of component events are closely located around the predicted values and also well bounded within the pointwise PIs. Figure 6.16 shows the predicted future events given all the observed data for the next 30 months, which indicates that the total number of component events is expected to range between 62 and 90 with a 95% confidence level.

6.6 Sequential Test Planning of Accelerated Life Tests

In this section, we briefly introduce the sequential Bayesian design (SBD) for fatigue test experiments described in Lee et al. [43].

6.6.1 Background and Historical Data

A sequential Bayesian test planning strategy for the accelerated life tests was proposed by Lee et al. [43]. The fatigue test for glass fiber, a composite material, is considered to illustrate the sequential design strategy. In the test, a tensile/compressive stress s (positive/negative value) is applied to the test unit, and the material life is observed under that stress. In this work, 14 observations of E-glass are made including

Fig. 6.17 The stress-life plot of historical data from a fatigue testing of the glass fiber. Figure reproduced with permission from Taylor and Francis

11 failed and three right censored units. Historical data of the observations are shown in Fig. 6.17. Several other important factors in the test are set as follows. Let $R = \sigma_m / \sigma_M$ denote the stress ratio, where σ_m is the minimum stress and σ_M is the maximum stress. The range of R can reveal different test types, and it is set at $R = 0.1$ for a tension-tension loading test in this application. The ultimate stress σ_{ult} , where the material breaks at the first cycle, is set to be 1339.67 MPa. The frequency of the cyclic stress testing (f) is set at 2 Hz, and the angle (α) between the testing direction and material is set at 0.

6.6.2 Lifetime Model

Consider using a log-location-scale distribution to model the cycles to failure, T . The cdf and pdf are given as

$$F(t; \theta) = \Phi \left[\frac{\log(t) - \mu}{\nu} \right] \quad \text{and}$$

$$f(t; \theta) = \frac{1}{\nu t} \phi \left[\frac{\log(t) - \mu}{\nu} \right],$$

where $\Phi(\cdot)$ and $\phi(\cdot)$ are the standard cdf and pdf, respectively. The lognormal and Weibull distributions are the common choices. In the ALT modeling, we assume a constant scale parameter ν and the location parameter is $\mu = \mu_{\beta}(x)$, where x is the stress level and β is the vector of unknown

parameters. The following nonlinear model for composite materials proposed in [54] is used to describe $\mu = \mu_{\beta}(x)$ in the form of

$$\mu_{\beta}(x) = \frac{1}{B} \log \left\{ \left(\frac{B}{A} \right) h^B \left(\frac{\sigma_{ult}}{x} - 1 \right) \left(\frac{\sigma_{ult}}{x} \right)^{\gamma(\alpha)-1} [1 - \psi(R)]^{-\gamma(\alpha)} + 1 \right\}. \quad (6.23)$$

In the above model, A and B are effects from environment and material, and $\beta = (A, B)'$. The function $\psi(R) = 1/R$ if $R \geq 1$ and $\psi(R) = R$ if $-\infty < R < 1$, and $\gamma(\alpha) = 1.6 - \psi |\sin(\alpha)|$. Then $\theta = (\beta', \nu)'$ denotes the unknown parameters in the ALT modeling.

The lower quantile of the cycles-to-failure distribution is of interest as it contains material life information. The log of the p th quantile is

$$\log(\xi_{p,u}) = \mu_{\beta}(u) + z_p \nu, \quad (6.24)$$

where $\xi_{p,u}$ is the p th quantile at the use condition u and z_p is the p th quantile of the standard distribution. Our goal is to propose test planning under multiple use conditions to approximate the real scenarios. The use stress profile consists of a set of use levels, $\{u_1, \dots, u_K\}$, with weights $\{\omega_1, \dots, \omega_K\}$ and $\sum_{k=1}^K \omega_k = 1$.

Let (x_i, t_i, δ_i) denote the data for the i th testing unit, where x_i is the stress level of the accelerating factor and t_i is the observed cycles to failure (or censoring cycles). Let δ_i be a censoring indicator where $\delta_i = 1$ if the observation is censored and $\delta_i = 0$ if the observation fails. Then, the log-likelihood function is given by

$$l(\theta | \mathbf{x}_n, \mathbf{t}_n, \boldsymbol{\delta}_n) = \sum_{i=1}^n (1 - \delta_i) [\log \phi(z_i) - \log(t_i) - \log(\nu)] + \delta_i \log [1 - \Phi(z_i)], \quad (6.25)$$

where $z_i = [\log(t_i) - \mu_{\beta}(x_i)] / \nu$. Let $\hat{\theta}$ be the ML estimate of θ and let $\log(\hat{\xi}_{p,u})$ be the ML estimate of the logarithm of the p th quantile at the use level u , obtained by substituting β and ν by $\hat{\beta}$ and $\hat{\nu}$ in (6.24). Given the use level u , the asymptotic variance of $\log(\hat{\xi}_{p,u})$ is

$$\text{Avar}[\log(\hat{\xi}_{p,u})] = \mathbf{c}' \Sigma_{\theta}(\mathbf{x}_n) \mathbf{c},$$

where $\mathbf{c} = [\partial \mu_{\beta}(u) / \partial A, \partial \mu_{\beta}(u) / \partial B, z_p]'$, $\Sigma_{\theta}(\mathbf{x}_n) = I_n^{-1}(\theta)$, and $I_n(\theta)$ is the Fisher information matrix based on n observed data. The details for calculating $I_n(\theta)$ can be found in [43]. A weighted version of asymptotic variance can be expressed as

$$\sum_{k=1}^K \omega_k \text{Avar}[\log(\hat{\xi}_{p,u_k})]. \quad (6.26)$$

Given $\{(u_k, \omega_k)\}_{k=1}^K$, the weighted asymptotic variance only depends on the observed testing levels x_i , where $i = 1, \dots, n$.

Therefore, the optimum design should determine x_1, \dots, x_n to minimize the weighted asymptotic variance in (6.26).

6.6.3 Test Plan Development

To obtain an accurate prediction from an efficient ALT, the optimum test planning can be determined by minimizing the asymptotic variance in (6.26). In the literature, when determining an optimal test plan, it often requires pre-specifying the values of parameters (known as the planning values). The optimal design based on some chosen planning values of parameters is known as the local c -optimality design. However, the planning values are not precisely known a priori for many experiments in practice. Hence, the SBD is useful for improving our understanding of the unknown parameters as more data become available during the experiment, when there is little knowledge or historical data available.

Before the test planning, the stress levels are often standardized to be between 0 and 1, denoted by $q_i = x_i / \sigma_{ult}$. In practice, a range of testing levels, $[q_L, q_U]$, is often determined at the very early stage of the test planning, where q_L is the lower bound and q_U is the upper bound. To design an efficient ALT via the sequential planning, the objective function based on (6.26) is chosen as

$$\varphi(q_{\text{new}}) = \int_{\Theta} \left[\sum_{k=1}^K \omega_k \mathbf{c}_k' \Sigma_{\theta}(q_{\text{new}}) \mathbf{c}_k \right] \pi(\boldsymbol{\theta} | \mathbf{q}_n, \mathbf{t}_n, \boldsymbol{\delta}_n) d\boldsymbol{\theta}, \quad (6.27)$$

where $\Sigma_{\theta}(q_{\text{new}}) = [I_n(\boldsymbol{\theta}, \mathbf{q}_n) + I_1(\boldsymbol{\theta}, q_{\text{new}})]^{-1}$, $\mathbf{q}_{\text{new}} = (q'_n, q_{\text{new}})'$, $\mathbf{q}_n = (q_1, \dots, q_n)'$, and $\pi(\boldsymbol{\theta} | \mathbf{q}_n, \mathbf{t}_n, \boldsymbol{\delta}_n)$ is the posterior distribution of $\boldsymbol{\theta}$. Specifically,

$$\pi(\boldsymbol{\theta} | \mathbf{q}_n, \mathbf{t}_n, \boldsymbol{\delta}_n) \propto f(\mathbf{t}_n | \boldsymbol{\theta}, \mathbf{x}_n, \boldsymbol{\delta}_n) \pi(\boldsymbol{\theta}),$$

where $f(\mathbf{t}_n | \boldsymbol{\theta}, \mathbf{x}_n, \boldsymbol{\delta}_n)$ is the joint pdf of the historical data and $\pi(\boldsymbol{\theta})$ is the prior distribution of $\boldsymbol{\theta}$. Then, the optimum $(n + 1)$ th design point is determined by

$$q_{n+1}^* = \arg \min_{q_{\text{new}} \in [q_L, q_U]} \varphi(q_{\text{new}}). \quad (6.28)$$

The procedure of the sequential Bayesian design is summarized as follows:

1. *Specify prior distributions of model parameters.* Specify prior distributions of A and B as $A \sim N(\mu_A, \sigma_A^2)$ and $B \sim N(\mu_B, \sigma_B^2)$, where μ_A , σ_A^2 , μ_B , and σ_B^2 are the parameters of the normal distributions and set to be known constants.

Let $v^2 \sim \text{Inverse Gamma}(\kappa, \gamma)$, where κ and γ can be known from the historical data or experience.

2. *Evaluate the asymptotic variance.* Use the technique of MCMC to approximate (6.27). The details of the related algorithms can be found in [43].
3. *Determine the optimum next testing point q_{n+1}^* .* Given a candidate set of design points, their corresponding values of the objective function in (6.27) can be evaluated in step 2. Then, one can determine the optimum next design point, which offers the smallest value of the asymptotic variance.
4. *Obtain the failure data at the level q_{n+1}^* .* Under the stress level q_{n+1}^* , conduct the experiment and obtain the failure information (t_{n+1}, δ_{n+1}) .
5. *Repeat steps 2 to 4 till the desired number of testing units is obtained.* Add the new lifetime data, $(q_{n+1}^*, t_{n+1}, \delta_{n+1})$, to the historical dataset, and repeat steps 2 to 4 till the desired number of new design points is obtained.

6.6.4 Illustration of Test Plans

For the original data, we can fit the lognormal distribution, and the corresponding ML estimates are $\boldsymbol{\theta}_0 = \hat{\boldsymbol{\theta}} = (0.0157, 0.3188, 0.7259)'$. Before the testing planning, the setup for the sequential Bayesian design is as follows:

1. *Prior information:* Let A and B be from the normal distributions, where $A \sim N(0.08, 0.0008)$ and $B \sim N(1, 0.0833)$. The prior distribution for v^2 is Inverse Gamma(4.5, 3).
2. *Historical data:* In practical implementation, the sample size at the beginning of testing is limited. Hence, three failed observations at stress levels $\mathbf{x}_3 = (621, 690, 965)'$ from Fig. 6.18 were chosen as the historical dataset.
3. *Total size of design points:* Let the sample size of the new design points be 12.
4. *Design candidate:* The standardized levels of historical data are 0.46, 0.52, and 0.72, and the candidate points are from $q_L = 0.35$ to $q_U = 0.75$ with a 5% incremental step.

For the illustrative purpose, we assume the true values of parameters to be $\boldsymbol{\theta}_0$. When an optimum design point is determined, the new observation is generated from the lognormal distribution with parameter $\boldsymbol{\theta}_0$ and the censoring time at 2×10^6 cycles. Repeat steps 2 to 4 in Sect. 6.6.3 till 12 testing locations are obtained. Then, the results of four simulation trials are shown in Fig. 6.19. It consistently shows that only two stress levels at 0.35 and 0.75 are selected, and 8 and 4 units are allocated to the levels 0.35 and 0.75, respectively. Figure 6.20 shows that the resulting asymptotic variance decreases as the size of sequential runs increases for the simulation trials.

Fig. 6.18 The fitted stress-life relationship from a fatigue testing data of the glass fiber. *Figure reproduced with permission from Taylor and Francis*

Using the same historical data, the developed SBD is also compared with the local c -optimality design. For the local c -optimality design, the estimated values of parameters from historical data are usually used as the planning values of the parameters. With only three observations available from the historical data, the ML estimates are $\hat{\theta}_1 = (0.0005, 0.7429, 0.1658)'$. The resulting local c -optimality design chooses 11 and 1 unit at the testing levels at 0.65 and 0.75, respectively. Now, we compare the performance on the value of the asymptotic variance based on the ML estimates of the final dataset including the 12 new testing observations and three historical observations. With 100 simulations, the average asymptotic variances for the SBD and the local c -optimality designs are 0.6048 and 4.0337, respectively. It shows that the SBD is more efficient than the traditional local c -optimality design when there is too little historical data available to provide accurate estimates of the model parameters. The proposed SBD can be also applied when there is no historical data but only prior information based on subject matter expertise.

6.7 Sequential Test Planning Considering Dual Objectives

In the previous section, a sequential test plan was proposed based on the c -optimality, which focuses on obtaining precise prediction of the quantile lifetime at the normal use conditions. The D -optimality designs could be sought for when the focus is on obtaining precise estimates of the model parameters. The selection of optimal test plans requires specifying some planning values of the model parameters. It is often hard to precisely specify these parameter values at the early stage of the test when there is little information available about them. Hence, the chosen test plan based on the imprecisely specified parameter values might be suboptimal for the objective of interest. To quickly obtain good estimates of model parameters to guide more informative test planning, Lu et al. [44] propose a sequential test plan based on considering dual objectives. Particularly, it is recommended to consider D -optimality in the early stage of the sequential test plan to maximize the information gain on the model parameters and then followed by seeking c -optimality in the later stage to maximize the precision of the predictions at the normal use conditions. The idea is to use the early test units to maximally improve our knowledge on the unknown model parameters and then use later runs to gather more information on improving our capability of making predictions. The proposed dual objective sequential design is also applied to the polymer composites fatigue testing and is compared with alternative single objective test plans to demonstrate its performance [44].

6.7.1 Testing Criteria

When using D -optimality in the sequential framework, the criterion for selecting the $(n + 1)$ th run given the first n runs can be expressed as

$$\psi(q_{\text{new}}) = \int_{\Theta} [\log |I_{n+1}(\theta, q_{\text{new}})|] \pi(\theta | q_n, t_n, \delta_n) d\theta, \quad (6.29)$$

where $I_{n+1}(\theta, q_{\text{new}}) = I_n(\theta, q_n) + I_1(\theta, q_{\text{new}})$ and $|I_{n+1}(\theta, q_{\text{new}})|$ is the determinant of the Fisher information matrix based on the first $n + 1$ runs. Under the sequential framework, the total information gained from the first $n + 1$ runs can be updated from what was gained from the first n test units by adding the additional information obtained from testing the $(n + 1)$ th unit at q_{new} . Then, the optimal $(n + 1)$ th design point given the first n test units is determined by maximizing the total expected information gain under the posterior distribution of parameters conditioned on the first n runs as in

$$q_{n+1}^* = \arg \max_{q_{\text{new}} \in [q_L, q_U]} \psi(q_{\text{new}}). \quad (6.30)$$

Since the precision of model parameters is of major concern in the early stage of testing, the test units are determined based on optimizing the conditional information gain given the earlier runs via (6.30). When we have obtained sufficient information about the model parameters, the precision of predictions at the normal use condition is more of interest. Therefore, we switch to choosing further sequential runs by optimizing the asymptotic prediction variance in (6.28).

6.7.2 Procedure of Sequential Planning Based on Dual Objectives

We use N to denote the total number of test units used in the dual objective sequential test plan, and let N_1 and N_2 denote the units selected by the D -optimality and the c -optimality, respectively, where $N_1 + N_2 = N$. Similarly to the sequential test plan discussed in Sect. 6.6.3, the steps for sequential test planning based on considering dual objectives are summarized below:

1. *Specify prior distributions of model parameters.* For the polymer fatigue testing example, we specify prior distributions of A and B as $A \sim N(\mu_A, \sigma_A^2)$ and $B \sim N(\mu_B, \sigma_B^2)$, where μ_A , σ_A^2 , μ_B , and σ_B^2 are the hyperparameters of the normal prior distributions and are assumed to be known constants. Also we assume $v^2 \sim \text{Inverse Gamma}(\kappa, \gamma)$, where κ and γ are the known hyperparameters specified from the historical data or based on the subject matter expertise.

Table 6.1 Five sequential Bayesian designs. *Table reproduced with permission from Springer*

Design	Description
A: 12 <i>c</i> -opt	All 12 sequential runs are generated based on <i>c</i> -optimality
B: 12 <i>D</i> -opt	All 12 sequential runs are generated based on <i>D</i> -optimality
C: 6 <i>D</i> -opt + 6 <i>c</i> -opt	First 6 runs are obtained via <i>D</i> -optimality and last 6 runs via <i>c</i> -optimality
D: 4 <i>D</i> -opt + 8 <i>c</i> -opt	First 4 runs are obtained via <i>D</i> -optimality and last 8 runs via <i>c</i> -optimality
E: 2 <i>D</i> -opt + 10 <i>c</i> -opt	First 2 runs are obtained via <i>D</i> -optimality and last 10 runs via <i>c</i> -optimality

2. Evaluate the asymptotic variance. We recommend using the MCMC approach to approximate (6.29) and (6.27) for *D*-optimality and *c*-optimality, respectively.
3. Determine the optimal next testing point q_{n+1}^* at $(n + 1)$ th run. Given a candidate set of design points, their corresponding values of the objective function in (6.29) or (6.27) can be evaluated in step 2. Then, the optimal next design point is determined by optimizing the criterion over all the candidate points. If the criterion is *D*-optimality, then the optimum point is determined by (6.30). If the criterion is *c*-optimality, the optimum level is determined by (6.28).
4. Obtain the failure data at the selected level q_{n+1}^* . At the selected stress level q_{n+1}^* from step 3, conduct the experiment to obtain the failure information on (t_{n+1}, δ_{n+1}) .
5. Repeat steps 2 to 4 till the desired number of testing units is obtained. Add the new lifetime data at the $(n + 1)$ th run, $(q_{n+1}^*, t_{n+1}, \delta_{n+1})$, to the sequential test dataset. Repeat steps 2 to 4 till N_1 *D*-optimal test units and N_2 *c*-optimal runs are obtained, respectively.

6.7.3 Polymer Composites Fatigue Testing

Here we revisit the example of polymer composites fatigue testing in Sect. 6.6.4. With the same settings of the prior information and historical data in Sect. 6.6.4, we also consider the scenario of collecting 12 new test units as in Sect. 6.6.4. To evaluate the proposed dual objective test plans, we compare five different test plans (summarized in Table 6.1) of the same sample size with two test plans obtained based on a single objective (either *D*- or *c*-optimality) and the remaining three being dual objective test plans with different sample size allocations among the *D*-optimal and *c*-optimal runs. Note that **Design A** is the *c*-optimal sequential test plan proposed in Sect. 6.6.

For each scenario, 100 simulation trials are generated and summarized to compare the performance on the asymptotic variance in (6.26) and the precision of estimated model parameters among the five test plans. To quantify the precision of estimation, the following metric of the relative precision of estimated model parameters is used:

$$m(\theta_j) = \frac{1}{K} \sum_{k=1}^K \left(\frac{|\hat{\theta}_{j,k} - \theta_j|}{\theta_j} \right)^2,$$

Fig. 6.22 Comparison of the *M* measure, the total relative mean square error for all three model parameters for the five designs from Table 6.1. *Figure reproduced with permission from Springer*

Fig. 6.23 Plot of sample size allocation for the five designs. *Figure reproduced with permission from Springer*

where θ_j represents the j th parameter of θ and $\hat{\theta}_{j,k}$ represents the estimates of θ_j from the k th trial for $k = 1, \dots, K = 100$. To summarize $m(\theta_j)$ across the three model parameters,

$$M = \sum_{j=1}^3 m(\theta_j)$$

was used to measure the total relative mean squared error of all the parameters. That is, M quantifies the overall precision of the estimates of all the model parameters in the ALT model. Note that the smaller value of M indicates overall more precisely estimated model parameters.

Figures 6.21 and 6.22 show the values of the asymptotic variance and M for the five scenarios, respectively. We can

see that **Design A** (12 units all generated by the c -optimality) has the smallest values of asymptotic variance $AVar$ and the largest values of M for all the runs. This indicates that **Design A** focuses more on obtaining most precisely predicted quantile of lifetime but less on the precision of estimated parameters. In addition, **Design B** (12 units all generated by the D -optimality) has the largest values of $AVar$ and relatively small M values for all the runs. Particularly, it achieves the best D -optimality after testing 8 units. This suggests that the D -optimal design does not provide the best predictions but instead offers more precise estimation of model parameters. However, the D -optimality is guaranteed at a relatively larger sample size.

Other three designs obtained by the dual objectives (**Designs C, D, and E**) generally perform well on the

Fig. 6.24 Plot of the sample size allocation for the 12 sequential runs for the five designs. *Figure reproduced with permission from Springer*

both metrics, which offer more balanced performance between the asymptotic variance and the prediction of the estimated model parameters. Particularly, **Design D** with 4 D -optimality runs followed by 8 c -optimality runs has slightly better performance than other designs, which offers both the smallest $AVar$ and M . Based on the case study, the dual objective sequential designs outperform the D -optimality design if one is limited to 8 sequential runs. The dual objective sequential designs have better precision in terms of estimating model parameters and predicting quantile of lifetime.

Figure 6.23 shows the sample size allocation of the 12 sequential test units averaged over 100 simulation trials for the five test plans. In general, the test units are allocated to either the lowest or highest levels across the range of stress levels [0.35, 0.75]. The proportion of allocations to the lowest and highest stress levels for the D -optimality design is different from the c -optimality design and the dual objective

test plans. It is noted that there are twice as many units allocated to the highest level than the lowest level by the D -optimality test plan, while both c -optimality and the dual objective test plans allocate more test units to the lowest level. The c -optimality design has almost twice units tested at the lowest level than the highest level, while the dual objective designs provide similar allocation with a slightly larger sample size at the highest stress level. This is intuitive as the c -optimality emphasizes more on the prediction at the normal use condition; hence, testing more units at the lowest stress level with the closest proximity to the normal use condition would offer more useful information on improving the predictions.

Figure 6.24 shows the proportion of sample allocations for the five test plans. The plots show the allocations for each sequential run based on the 100 simulation trials. The light-to-dark gray shades indicate small to large allocation at the different testing levels. First, we can observe a large

middle region in the lightest gray shade for all the test plans, which indicates there is rarely a sample allocated to the middle levels (i.e., between $q = 0.4$ and $q = 0.7$) for all the scenarios. As compared to the c - and D -optimal plans, the D -optimality design allocates more runs at the highest stress level during the later runs, and for the earlier runs, the samples are evenly allocated between the highest and lowest levels. For the c -optimality design, it tends to allocate more units at the lower stress level during the later stage. This is because more samples at the higher stress levels can quickly improve the precision of estimated parameters. Testing units at the lower levels is more relevant for improving the prediction precision.

6.8 Concluding Remarks

In this chapter, we review recent developments on statistical reliability analysis utilizing dynamic covariates and sequential test planning. For time-to-event data, we introduce a cumulative damage model to account for the effect of dynamic covariates and illustrate the method with the Product D2 application. For degradation data, we present the general path model for incorporating dynamic covariates and illustrate the method with the NIST coating degradation data. We also introduce the MTRP model for recurrent events using dynamic covariates and illustrate it with the Vehicle B data. With regard to test planning for ALTs, we focus on the SBDs and illustrate it with the ALTs for polymer composites fatigue testing.

Looking forward, more versatile data become available due to the rapid advance of modern technology, and new statistical methods need to be developed to make use of those new data for improving reliability modeling and prediction. As described in [3], many data types such as spatial data, functional data, image data, and text data all have great potential to be used for reliability modeling and analysis. New methods that are available in statistical and machine learning can also be transformed and integrated with reliability domain knowledge for improving reliability analysis, which provides tremendous opportunity in reliability research.

Acknowledgments The authors thank the editor for his valuable comments which greatly helped improve this chapter. The research by Wang and Hong was partially supported by National Science Foundation Grants CMMI-1904165 to Virginia Tech.

Abstract

This work deals with a comprehensive solution to the problem of finding the joint k -variate probability distributions of random vectors (X_1, \dots, X_k) , given all the univariate marginals. The general and universal analytic form of all solutions, given the fixed (but arbitrary) univariate marginals, was given in proven theorem. In order to choose among these solutions, one needs to determine proper “dependence functions” (joiners) that impose specific stochastic dependences among subsets of the set $\{X_1, \dots, X_k\}$ of the underlying random variables. Some methods of finding such dependence functions, given the fixed marginals, were discussed in our previous papers (Filus and Filus, *J Stat Sci Appl* 5:56–63, 2017; Filus and Filus, General method for construction of bivariate stochastic processes given two marginal processes. Presentation at 7-th International Conference on Risk Analysis, ICRA 7, Northeastern Illinois University, Chicago, 4 May 2017). In applications, such as system reliability modeling and

other, among all the available k -variate solutions, one needs to choose those that may fit particular data, and, after that, test the chosen models by proper statistical methods. The theoretical aspect of the main model, given by formula (7.3) in Sect. 7.2, mainly relies on the existence of one [for any fixed set of univariate marginals] general and universal form which plays the role of paradigm describing the whole class of the k -variate probability distributions for arbitrary $k = 2, 3, \dots$. An important fact is that the initial marginals are arbitrary and, in general, each may belong to a different class of probability distributions. Additional analysis and discussion are provided.

Keywords

Competitive to the copula methodology · Universal form of k -variate probability distributions · Stochastic dependences general structure · Joiners as “dependence functions” · r -independence · Reliability

7.1 Introduction

Consider a new approach to the old problem of finding a k -variate joint probability distributions of a random vector (X_1, \dots, X_k) , given its univariate marginals $S_1(x_1), \dots, S_k(x_k)$. (In this chapter, all the probability distributions will be represented by the corresponding survival functions. Nevertheless, we mostly will call them “distributions” for short, as they are equivalent to probability distributions. At this point also recall that in reliability theory the survival functions are called “reliability functions”). The problem, even if it often appears in literature (see, for example the references in [10]) with a variety of different formulations [3, 4, 8, 9, 11], is actually far from a comprehensive solution.

As an exception may serve the **copula** methodology by Sklar [12], which however has serious drawbacks that make

L. Z. Filus

it difficult to use in most practical applications. The practitioners in their mutual discussions often indicate on the need for other methods of construction that would complement those by copulas. This need becomes especially vital when the dimension of the underlying random vector is higher than 2 or 3. Also the number of models created by use of copulas is rather limited.

In this work, we attempt to build a **new, competitive to the copula methodology**, theory of k -variate survival functions that has three important features. First, of theoretical nature, is providing the general structure (a *universal form*) of any k -variate survival function by means of the joiners [6, 7]. Second, the structure's form facilitates processes of constructions in various applications especially in **reliability** problems. As a result, a huge number of new bivariate and trivariate probability distributions can be found. The third feature of the here created theory is that the considered marginals $S_1(x_1), \dots, S_k(x_k)$ may belong to arbitrary classes of survival functions and that the classes, in general, may be different from each other. Thus, in the general case, some of the univariate marginals may be of the continuous type, some of the discrete, and some neither. The stochastic dependence structure that "connects" finite subsets $\{X_{i(1)}, \dots, X_{i(r)}\}$ ($r \leq k$) of the set of random variables $\{X_1, \dots, X_k\}$ provide the already mentioned dependence functions (joiners) of the r finite real variables $x_{i(1)}, \dots, x_{i(r)}$.

The created general theory starts with the bivariate case as developed in our previous papers [5–7].

In the beginning (in [5]), we started with bivariate models construction as an extension of the Aalen version [1] of the Cox model [3] of stochastic dependence towards construction of bivariate distributions.

Then we realized in [6, 7] that the so obtained construction method, in its full generality, may be formulated independently from the original Cox and the Aalen ideas.

As we have found, the construction can be based on the created notion of (bivariate) joiner.

It was then realized that in so doing one obtains a **universal representation** of any (!) bivariate survival function.

Namely, according to [5, 6], any bivariate survival function, say $S(x_1, x_2)$, can be represented by the factored (universal) form:

$$S(x_1, x_2) = S_1(x_1) S_2(x_2) J(x_1, x_2), \quad (7.0)$$

where $S_1(x_1)$ and $S_2(x_2)$ are the marginal survival functions and the function $J(x_1, x_2)$ determines the stochastic dependencies between the random variables X_1, X_2 is the "joiner."

Whenever a construction process was faced (with the initial data: the marginals $S_1(x_1), S_2(x_2)$ given), the problem reduces to finding a proper joiner $J(x_1, x_2)$ "connecting" the two marginals.

The methods of finding the function $J(x_1, x_2)$, by solving a proper integral equation or inequality, as well other criteria of "fitting" the joiner to the given marginals [2], were developed in our, mentioned above, previous papers. Some important bivariate models were immediately found. Others that require more effort were postponed to a future.

Anyway, the "bivariate part" of our theory can be considered sufficiently developed even if many important particular problems remain open.

The extension of this theory to k -dimensional ($k \geq 3$) cases was initiated in [7] with special emphasis on the $k = 3$ case. The general case was only sketched. Here, we concentrate on the general case for $k = 3, 4, \dots$.

The main result is formulated as theorem 1 and proven by mathematical induction with respect to k (see formula (7.3)).

In discussion that follows the proof, we show some methods that allow simplification of formula (7.3) by assuming that some of the underlying r -variate joiners ($r \leq k$) reduce to 1, which corresponds to "partial independence." Assuming all the r -variate (for $r \geq 3$) joiners are 1, we arrive at the notion of "bi-dependence" which means that all the dependencies reduce to those between pairs of random variables, and in so doing we obtain the corresponding formula (7.11) that determines simplified version of the general pattern (7.3). In the case of bi-dependence, which seems to be quite realistic, the task of construction reduces to finding proper bivariate joiners of (not necessarily all) pairs of underlying random variables (X_i, X_j) for $1 \leq i < j \leq k$.

Consequently, in bi-dependence case, the theory of general k -variate distributions essentially reduces to the, already developed, general theory of bivariate distributions.

All those properties, possibly, make the bi-variate and the general k -variate theories competitive to the copula methodology [2].

7.2 General Structure of Any k -Variate Survival Function

Now, we start with the analysis of the general cases for any k .

The essence of k -dimensional models' general structure ($k = 3, 4, \dots$) relies on recurrence transition from all its $(k - 1)$ -dimensional marginals to the constructed k -dimensional survival function.

Namely, the algebraic structure of any k -dimensional probability distribution $S(x_1, \dots, x_k)$ obeys the following factorization pattern:

$$\begin{aligned} S(x_1, \dots, x_k) &= J_{1, \dots, k}(x_1, \dots, x_{k-1}, x_k) S^{(1)}(x_2, x_3, \dots, x_k) \\ &S^{(2)}(x_1, x_3, \dots, x_k) \dots S^{(k-1)}(x_1, \dots, x_{k-2}, x_k) \\ &S^{(k)}(x_1, \dots, x_{k-1}) \end{aligned} \quad (7.1)$$

where for each $j = 1, \dots, k$ the $(k - 1)$ dimensional marginal survival function

$S^{(j)}(x_1, x_2, \dots, x_{j-1}, x_{j+1}, x_{j+2}, \dots, x_k)$ contains all the arguments x_1, \dots, x_k with exception of x_j .

The function $J_{12\dots k}(x_1, \dots, x_k)$ that we will call “**k-joiner**” determines stochastic “**k – dependence**” between all the $(k - 1)$ – dimensional random vectors

$$(X_1, X_2, \dots, X_{k-1}), (X_1, X_2, \dots, X_{k-2}, X_k), \dots, \\ (X_2, X_3, \dots, X_k).$$

For a, given in advance, survival function $S(x_1, \dots, x_k)$, the corresponding (unique) k -joiner simply is given by the formula that follows from (7.1):

$$J_{12\dots k}(x_1, \dots, x_k) = S(x_1, \dots, x_k) / \{S^{(1)}(x_2, x_3, \dots, x_k) \\ S^{(2)}(x_1, x_3, \dots, x_k) \dots S^{(k-1)}(x_1, \dots, x_{k-2}, x_k) \\ S^{(k)}(x_1, \dots, x_{k-1})\}. \quad (7.1^*)$$

For values of x_1, \dots, x_k that make the denominator in (7.1*) equal zero the k -joiner $J_{12\dots k}(x_1, \dots, x_k)$ is undefined, but in this case we set in (7.1) $S(x_1, \dots, x_k) = 0$ so the k -dimensional survival function in (7.1) is still well defined.

In the case $J_{12\dots k}(x_1, \dots, x_k) = 1$, for all points (x_1, \dots, x_k) , we say that the random vector (X_1, \dots, X_k) is **k-independent**.

The form (7.1) is universal, so every (!) survival function $S(x_1, \dots, x_k)$ can be represented like that. This rather strong statement is the conclusion from the following realization of the common arithmetic identity:

$$S(x_1, \dots, x_k) = [S(x_1, \dots, x_k) / \{S^{(1)}(x_2, x_3, \dots, x_k) \\ S^{(2)}(x_1, x_3, \dots, x_k) \dots S^{(k-1)}(x_1, \dots, x_{k-2}, x_k) \\ S^{(k)}(x_1, \dots, x_{k-1})\}] \{S^{(1)}(x_2, x_3, \dots, x_k) \\ S^{(2)}(x_1, x_3, \dots, x_k) \dots S^{(k-1)}(x_1, \dots, x_{k-2}, x_k) \\ S^{(k)}(x_1, \dots, x_{k-1})\} \quad (7.1^{**})$$

which in light of (7.1*) is another version of (7.1).

The identity (7.1**) is always true whenever the underlying fraction is well defined. Otherwise, we set (7.1**) equal zero which is consistent with determination of (7.1).

Suppose all the $(k - 1)$ – dimensional distributions $S^{(1)}(x_2, x_3, \dots, x_k)$, $S^{(2)}(x_1, x_3, \dots, x_k)$, $\dots, S^{(k-1)}(x_1, \dots, x_{k-2}, x_k)$, $S^{(k)}(x_1, \dots, x_{k-1})$ are given.

The question that arises [2] is:

For which functions $K(x_1, \dots, x_k)$ [that are only candidates for joiners], the product $K(x_1, \dots, x_k) S^{(1)}(x_2, x_3, \dots, x_k) S^{(2)}(x_1, x_3, \dots, x_k) \dots S^{(k-1)}(x_1, \dots, x_{k-2}, x_k) S^{(k)}(x_1, \dots, x_{k-1})$ is a valid k -dimensional survival function,

so that $K(x_1, \dots, x_k) = J_{12\dots k}(x_1, \dots, x_k)$ and formula (7.1) is satisfied for some survival function $S(x_1, \dots, x_k)$.

Solutions of this problem for $k = 2, 3, \dots$ yield solutions of the problem stated in the beginning of Sect. 7.1. To this, however, we need first to be able to solve the problem of finding joint distributions of all random vectors of $(k - 1)$ dimension. For this task, we need in turn to find or have all the joint distributions of dimension $(k - 2)$ and so on, until we encounter the univariate distributions ($k = 1$) that are given in advance.

The structure of the problem solving within here created new theory is then hierarchical. The essence of the structure is the recurrence formula (7.1) that describes the transition from $(k - 1)$ dimensions to k . However, when goes to the construction’s practice, we need to start at the lowest “level zero” where we choose the univariate distributions as given by $S_1(x_1), \dots, S_k(x_k)$ to work with. No new theory at level zero ($k = 1$) needs to be provided. Actual first step of this theory is the transition from $k = 1$ to $k = 2$. This means a need for a theory of forming bivariate distributions from any two univariates. This was the subject of our previous papers already cited.

Now, we start to derive the general formula for $S(x_1, \dots, x_k)$ that “exhibits” all the steps of the construction. The theory for $k = 2$ was (to a satisfactory degree) already developed in [5]. The case $k = 3$ was described in [7]. Since the recent position was submitted but not yet published, we repeat the main result here for 3-dimensional survival function’s universal representation:

$$S(x_1, x_2, x_3) = J_{123}(x_1, x_2, x_3) S^{(3)}(x_1, x_2) S^{(2)}(x_1, x_3) \\ S^{(1)}(x_2, x_3) \\ = J_{123}(x_1, x_2, x_3) [J_{12}(x_1, x_2) S_1(x_1) S_2(x_2)] \\ [J_{13}(x_1, x_3) S_1(x_1) S_3(x_3)] [J_{23}(x_2, x_3) S_2(x_2) \\ S_3(x_3)] \\ = J_{123}(x_1, x_2, x_3) J_{12}(x_1, x_2) J_{13}(x_1, x_3) \\ J_{23}(x_2, x_3) [S_1(x_1)]^2 [S_2(x_2)]^2 [S_3(x_3)]^2, \quad (7.2)$$

where for each pair (i, j) of subscripts, such that $1 \leq i < j \leq 3$, $S_{ij}(x_i, x_j)$ is bivariate distribution of the random vector (X_i, X_j) so it is a bivariate marginal of the tri-variate distribution.

$S(x_1, x_2, x_3)$ of the random vector (X_1, X_2, X_3) , and, for each bivariate distribution $S_{ij}(x_i, x_j)$, $J_{ij}(x_i, x_j)$ denotes the corresponding joiner which “ties” the univariate marginal distributions $S_i(x_i), S_j(x_j)$. In (7.2) we denoted by $S^{(i)}(x_k, x_l)$ the bivariate survival function of those two arguments among x_1, x_2, x_3 that are different from x_i , for $i = 1, 2, 3$.

7.3 The Main Result

The analogical to (7.2) formula for an arbitrary dimension $k \geq 3$ is given by the following theorem, which will be proven by mathematical induction with respect to k .

Theorem 1 Suppose a sequence of random vectors $\{(X_1, X_2, \dots, X_{k-1}, X_k)\}_{k=1}^\infty$ is consistent in the sense of Daniell-Kolmogorov Consistency Theorem (however, the problem of symmetry of the random vectors is not analyzed here).

Under that assumption, for every $k = 2, 3, \dots$ the **“universal” form** of any survival function $S(x_1, x_2, \dots, x_{k-1}, x_k)$ of an arbitrary random vector $(X_1, X_2, \dots, X_{k-1}, X_k)$, whose marginals $X_1, X_2, \dots, X_{k-1}, X_k$ take on finite real values, is given by the following formula:

$$\begin{aligned} S(x_1, x_2, \dots, x_{k-1}, x_k) &= J_{1, \dots, k}(x_1, \dots, x_{k-1}, x_k) S^{(1)}(x_2, x_3, \dots, x_k) \\ &S^{(2)}(x_1, x_3, \dots, x_k) \dots S^{(k-1)}(x_1, \dots, x_{k-2}, x_k) S^{(k)}(x_1, \dots, x_{k-1}) \\ &= J_{1, \dots, k}(x_1, \dots, x_{k-1}, x_k) \prod_{s=1}^{k-1} \prod_{(j(1), \dots, j(k-s))}^{k-1} \\ &\left[J_{(j(1), \dots, j(k-s))}(x_{j(1)}, \dots, x_{j(k-s)}) \right]^{s!} \quad \square \end{aligned} \quad (7.3)$$

As for the middle expression in equalities (7.3), $J_{1, \dots, k}(x_1, \dots, x_{k-1}, x_k)$ is the k -joiner introduced above and (for $j = 1, 2, \dots, k$) $S^{(j)}(\dots)$ are $(k-1)$ -dimensional marginal survival functions of the random vector $(X_1, X_2, \dots, X_{k-1}, X_k)$ obtained from its survival function $S(x_1, x_2, \dots, x_{k-1}, x_k)$ by setting $x_j = 0$.

In the last expression of (7.3) symbol, $\prod_{s=1}^{k-1}$ means the product taken from $s = 1$ to $s = k-1$, while, for each particular s , the symbol $\prod_{(j(1), \dots, j(k-s))}^{k-1}$ denotes product of all expressions (joiners) each being a function of some $(k-s)$ arguments $x_{j(1)}, x_{j(2)}, \dots, x_{j(k-s)}$ only, where:

$$1 \leq j(1) < j(2) < \dots < j(k-s) \leq k, \text{ for some } s.$$

The symbol $J_{(j(1), \dots, j(k-s))}(x_{j(1)}, \dots, x_{j(k-s)})$ denotes the $(k-s)$ -dimensional joiner for the (marginal) random vector $(X_{j(1)}, \dots, X_{j(k-s)})$. Because of the consistency assumption, this joiner is raised to the power $s!$.

To achieve more uniform notation, for $s = k-1$ we introduced the notation

$$\begin{aligned} J_{(j(1), \dots, j(k-s))}(\dots) &= J_{j(1)}(x_{j(1)}) = S_{j(1)}(x_{j(1)}) = S_r(x_r) \\ &\text{for some } r = j(1) = 1, \dots, k. \end{aligned}$$

Thus, the so obtained “one-dimensional joiner” actually is not a joiner but rather the one-dimensional survival function. Realize that these survival functions are raised to the power $(k-1)!$ so that the product

$S_1(x_1)^{(k-1)!} \dots S_k(x_k)^{(k-1)!}$ is always the factor of $S(x_1, x_2, \dots, x_{k-1}, x_k)$ given by (7.3).

Proof of the Theorem We set $k = m+1$ and prove the theorem by mathematical induction with respect to m . According to formulas (7.0) and (7.2), the theorem holds for $m \leq 2$.

Now, suppose that it holds for some arbitrary m .

This means that similarly as in (7.3) we have:

$$\begin{aligned} S(x_1, x_2, \dots, x_{m-1}, x_m) &= J_{1, \dots, m}(x_1, \dots, x_{m-1}, x_m) S^{(1)}(x_2, x_3, \dots, x_m) \\ &S^{(2)}(x_1, x_3, \dots, x_m) \dots S^{(m-1)}(x_1, \dots, x_{m-2}, x_m) \\ &S^{(m)}(x_1, \dots, x_{m-1}) \\ &= J_{1, \dots, m}(x_1, \dots, x_{m-1}, x_m) \prod_{s=1}^{m-1} \\ &\prod_{(j(1), \dots, j(m-s))} J_{(j(1), \dots, j(m-s))}^{s!}(x_{j(1)}, \dots, x_{j(m-s)}), \end{aligned} \quad (7.4)$$

where $1 \leq j(1) < j(2) < \dots < j(m-s) \leq m; s = 1, \dots, m-1$.

According to defining formulas (7.1) and (7.1*), we also have

$$\begin{aligned} S^+(x_1, x_2, \dots, x_m, x_{m+1}) &= (J_{1, \dots, m+1}(x_1, \dots, x_m, x_{m+1})^+ \\ &S^{(1)}(x_2, x_3, \dots, x_{m+1})^+ S^{(2)}(x_1, x_3, \dots, x_{m+1})^+ \\ &\dots + S^{(m)}(x_1, \dots, x_{m-1}, x_{m+1})^+ S^{(m+1)}(x_1, \dots, x_m))^+ \end{aligned} \quad (7.5)$$

where $J_{1, \dots, m+1}(x_1, \dots, x_m, x_{m+1})$ is the $(m+1)$ -joiner for the whole random vector $(X_1, \dots, X_m, X_{m+1})$.

As for the remaining factors on the right hand side of (7.5), the marginal factor $+S^{(m+1)}(x_1, \dots, x_m)$ is (by the Kolmogorov consistency assumption that we adopted) identical to the function $S(x_1, x_2, \dots, x_{m-1}, x_m)$ given by (7.4).

[As the conclusion of that consistency restriction, any $(m+1)$ -dimensional survival function has the product form:

$$\begin{aligned} S^+(x_1, x_2, \dots, x_m, x_{m+1}) &= S(x_1, x_2, \dots, x_m) \\ &\Phi(x_1, x_2, \dots, x_m, x_{m+1}) \end{aligned} \quad]$$

The remaining factors $+S^{(i)}(i = 1, \dots, m)$ in (7.5) must obey the scheme given by (7.3) for any set of m real arguments. Therefore, they are products of the powers $J_{(j(1), \dots, j(m-s))}^{s!}(x_{j(1)}, \dots, x_{j(m-s)})$ of the underlying joiners having nearly the same syntax structure as that of $S(x_1, x_2, \dots, x_{m-1}, x_m)$ given by (7.4).

All the joiners present in the marginals $+S^{(i)}()$ that do not contain the argument $x_{j(m-s)} = x_{m+1}$ are, by the consistency assumption, exactly the same as the corresponding factors of $S(x_1, x_2, \dots, x_{m-1}, x_m)$ whenever they have the same arguments.

Other factors that contain the (“new”) argument x_{m+1} [such as, for example, $J_{2,m+1}(x_2, x_{m+1})$] differ from those which form the expression for $S(x_1, x_2, \dots, x_{m-1}, x_m)$.

Consider again $(m + 1)$ of m -variate marginals of $S^+(x_1, x_2, \dots, x_m, x_{m+1})$, present in (7.5).

Realize that every single variable x_i ($i = 1, 2, \dots, m + 1$) occurs in exactly m out of $m + 1$ marginals:

$$\begin{aligned} & +S^{(1)}(x_2, x_3, \dots, x_{m+1}), +S^{(2)}(x_1, x_3, \dots, x_{m+1}), \\ & \dots, +S^{(m)}(x_1, \dots, x_{m-1}, x_{m+1}), +S^{(m+1)}(x_1, \dots, x_m) \quad (\text{M}) \end{aligned}$$

The above functions are distinct, and each of them contains all the variables $x_1, x_2, \dots, x_m, x_{m+1}$ with exception of exactly one.

Consequently, each variable x_i ($i = 1, \dots, m + 1$) occurs in exactly m out of $m + 1$ functions in (M).

The functions given by (M) represent m -dimensional survival functions. Thus, according to (7.4), for a given i , each such function contains the factor $[S_i(x_i)]^{(m-1)!}$. This factor repeats m -times in the product

$$\begin{aligned} & +S^{(1)}(x_2, x_3, \dots, x_{m+1}) + S^{(2)}(x_1, x_3, \dots, x_{m+1}) \\ & \dots + S^{(m)}(x_1, \dots, x_{m-1}, x_{m+1}) + S^{(m+1)}(x_1, \dots, x_m) \end{aligned}$$

and therefore is raised to the power m , which results in the factor

$$[S_i(x_i)]^m \text{ of } S^+(x_1, x_2, \dots, x_m, x_{m+1}).$$

Since above reasoning is valid for every i , the product $[S_1(x_1)]^m \dots [S_{m+1}(x_{m+1})]^m$ is a factor of $S^+(x_1, x_2, \dots, x_m, x_{m+1})$.

Recall, the corresponding factor of $S(x_1, x_2, \dots, x_{m-1}, x_m)$ was the product $[S_1(x_1)]^{(m-1)!} \dots [S_m(x_m)]^{(m-1)!}$ as in the first product in (7.4) we have $1 \leq s \leq m - 1$.

Before we consider 2-dimensional factors (i.e., all the 2-dimensional joiners in (7.5*) below), we provide in advance the (final) formula for the $(m + 1)$ -dimensional case, which is the continuation of (7.5):

$$\begin{aligned} & S^+(x_1, x_2, \dots, x_m, x_{m+1}) \\ & = J_{1, \dots, m+1}(x_1, \dots, x_m, x_{m+1}) S^{(1)}(x_2, x_3, \dots, x_{m+1}) \\ & \quad S^{(2)}(x_1, x_3, \dots, x_{m+1}) \dots S^{(m)}(x_1, \dots, x_{m-1}, x_{m+1}) \\ & \quad S^{(m+1)}(x_1, \dots, x_m) \\ & = J_{1, \dots, m+1}(x_1, \dots, x_m, x_{m+1}) \\ & \quad \prod_{s=1}^m \prod_{(j(1), \dots, j(m+1-s))} J_{(j(1), \dots, j(m+1-s))} \\ & \quad s!(x_{j(1)}, \dots, x_{j(m+1-s)}), \end{aligned} \quad (7.5^*)$$

where $1 \leq j(1) < j(2) < \dots < j(m + 1 - s) \leq m + 1$.

Now, consider all the bivariate joiners $J_{(j(1), j(2))}(x_{j(1)}, x_{j(2)})$ present in the last expression of (7.4). Similarly, as we proceeded with 1-dimensional joiners (the marginal distributions) realize that [for $s = m - 2$] in (7.4), the bivariate joiners $J_{(j(1), j(2))}(x_{j(1)}, x_{j(2)})$ are all raised to the power $(m - 2)!$.

Roughly the same happens for all the factors

$$\begin{aligned} & S^{(1)}(x_2, x_3, \dots, x_{m+1}) S^{(2)}(x_1, x_3, \dots, x_{m+1}) \dots \\ & S^{(m)}(x_1, \dots, x_{m-1}, x_{m+1}) S^{(m+1)}(x_1, \dots, x_m) \text{ of } (7.5^*). \end{aligned}$$

Thus, in (7.5*) each two-dimensional expression, $J_{(j(1), j(2))}(x_{j(1)}, x_{j(2)})^{(m-2)!}$ is present $(m - 1)$ times [($m + 1$) times but two] as the factors. This is exactly the same as raising it to the power $m - 1$. Thus, as formula (7.4) transforms to formula (7.5*) [$m \rightarrow m + 1$], the factor $J_{(j(1), j(2))}(x_{j(1)}, x_{j(2)})^{(m-2)!}$ transforms to the factor

$$J_{(j(1), j(2))}(x_{j(1)}, x_{j(2)})^{(m-1)!}$$

(in the last case, however, we have $1 \leq j(1) < j(2) \leq m + 1$).

In the same way, one can show that since the factors $J_{(j(1), j(2), j(3))}(x_{j(1)}, x_{j(2)}, x_{j(3)})^{(m-3)!}$ in (7.4) are present in (7.5*) $(m - 2)$ times (again: $m + 1$ times but three) the factor $J_{(j(1), j(2), j(3))}(x_{j(1)}, x_{j(2)}, x_{j(3)})^{(m-3)!}$ transforms (as $m \rightarrow m + 1$) into the factor $J_{(j(1), j(2), j(3))}(x_{j(1)}, x_{j(2)}, x_{j(3)})^{(m-2)!}$.

Doing this successively in the same way, we see that, as the dimension raises from m to $m + 1$, every factor $J_{(j(1), \dots, j(r))}(x_{j(1)}, x_{j(2)}, \dots, x_{j(r)})^{(m-r)!}$ in (7.4) transforms into the factor $J_{(j(1), \dots, j(r))}(x_{j(1)}, x_{j(2)}, \dots, x_{j(r)})^{(m-r+1)!}$, in (7.5*), where $r = 1, 2, \dots, m$.

The single factor $J_{1, \dots, m+1}(x_1, \dots, x_m, x_{m+1})$ in (7.5*) plays the same role as the single factor $J_{1, \dots, m}(x_1, \dots, x_{m-1}, x_m)$ in (7.4).

Concluding, the survival function $S^+(x_1, x_2, \dots, x_m, x_{m+1})$ given by (7.5*) one can obtain from the survival function $S(x_1, x_2, \dots, x_{m-1}, x_m)$ given by (7.4) just by replacing all the indexes $1 \leq j(1) < j(2) < \dots < j(m - s) \leq m$ with the indexes $1 \leq j'(1) < j'(2) < \dots < j'(m + 1 - s) \leq m + 1$ and all the exponents [with the same basis] $(n - r)!$ to the exponents $(n - r + 1)!$. Without going too far into details one may conclude that the syntax form of the survival function $S^+(x_1, x_2, \dots, x_m, x_{m+1})$ is “the same” as that of $S(x_1, x_2, \dots, x_{m-1}, x_m)$, and therefore, the formulas (7.4) and (7.5*) are basically “the same.” Thus, the pattern for the survival function given by (7.4) naturally transforms into the same pattern given by (7.5*).

By mathematical induction, we conclude [upon $k - 1 = m$] that formula (7.3) holds for any $k = 2, 3, \dots$ \square

7.4 Commentaries

Remark 1 For more clarification, in addition to the above proof, notice that the m -dimensional factor $J_{1,\dots,m}(x_1, \dots, x_{m-1}, x_m)$, present only once in (7.4), will be “replaced” in (7.5*) by the product of $m + 1$ distinct factors $J_{(j(1), \dots, j(m))}(x_{j(1)}, x_{j(2)}, \dots, x_{j(m)})$ each of them “raised” to the power 1.

This time, however, $j^*(m) \leq m + 1$.

Hypothetically, if [as a possible “next step”] the random vector dimension would be increased from $m + 1$ to $m + 2$, all the factors corresponding to those m -dimensional would be raised to second (2!) power and next (for $m + 3$ – dimension) to 3! power, and so on.

Thus, for a given random vector $(X_1, \dots, X_m, X_{m+1})$, formula (7.5*) determines its joint survival function, given the joiners of all the [marginal] random vectors $(X_{j(1)}, X_{j(2)}, \dots, X_{j(r)})$, $r = 1, 2, \dots, m$ and one $(m + 1)$ - dimensional joiner $J_{1,\dots,m+1}(x_1, \dots, x_m, x_{m+1})$ which stands for a single factor in (7.5*). \square

Remark 2 For formula (7.5*) to hold, the assumption of the Kolmogorov consistency is the substantial one. Otherwise, for $s = 1, \dots, m - 1$, $m = 2, 3, \dots$ the joiners $J_{(j(1), \dots, j(m-s))}(x_{j(1)}, \dots, x_{j(m-s)})$ with the same arguments could be changed after each transition from m to $m + 1$. Therefore, instead of the powers $J_{(j(1), \dots, j(m+1-s))}^{s!}$, one could encounter fairly long products of distinct factors. The construction of k -variate survival function in such a case would still be possible but the underlying formulas would be much longer. In the 2-dimensional case (see, [7]), this “inconsistency phenomena” is possibly related to two different representations [marginal and baseline] of the same bivariate distribution.

In that, two single random variables are differently distributed when considered separately (baseline distributions) and in bivariate distribution (as the marginals). \square

Because of the complexity of formula (7.3) which is somewhat unintuitive, in our opinion formula (7.2) is not yet sufficient illustration of the pattern of the general k -dimensional survival function. To better exhibit the mechanism of “forming” k -dimensional distribution from a $(k - 1)$ -dimensional, we decided to provide additional example of forming 4-dimensional survival function from the 3-dimensionals whose forms are given by (7.2).

Example In accordance with (7.5) (for $m = 3$) the general form, a 4-dimensional survival function can be expressed by the product of the common 4-joiner and four 3-dimensional marginals. Thus, we have:

$$\begin{aligned} S(x_1, x_2, x_3, x_4) &= \\ &= J_{1234}(x_1, x_2, x_3, x_4) \{S_{123}(x_1, x_2, x_3)\} \{S_{124}(x_1, x_2, x_4)\} \\ &\quad \{S_{134}(x_1, x_3, x_4)\} \{S_{234}(x_2, x_3, x_4)\}. \end{aligned} \quad (7.6)$$

In accordance with the Kolmogorov consistency condition, the factor $S_{123}(x_1, x_2, x_3)$ in (7.6) is the same as $S(x_1, x_2, x_3)$ given by (7.2). Other marginal factors containing arguments different from the triple (x_1, x_2, x_3) are, in general, different. However, their syntax structure (i.e., as long as only the names of the underlying functions in the expressions are considered) is always the same.

Expanding each of the expressions of (7.6) in the parenthesis according to pattern (7.2), one obtains:

$$\begin{aligned} S(x_1, x_2, x_3, x_4) &= J_{1234}(x_1, x_2, x_3, x_4) \left\{ J_{123}(x_1, x_2, x_3) J_{12}(x_1, x_2) \right. \\ &\quad \left. J_{13}((x_1, x_3) J_{23}(x_2, x_3) [S_1(x_1)]^2 [S_2(x_2)]^2 [S_3(x_3)]^2 \right\} \\ &\quad \left\{ J_{124}(x_1, x_2, x_4) J_{12}(x_1, x_2) J_{14}(x_1, x_4) J_{24}(x_2, x_4) \right. \\ &\quad \left. [S_1(x_1)]^2 [S_2(x_2)]^2 [S_4(x_4)]^2 \right\} \\ &\quad \left\{ J_{134}(x_1, x_3, x_4) J_{13}(x_1, x_3) J_{14}(x_1, x_4) J_{34}(x_3, x_4) \right. \\ &\quad \left. [S_1(x_1)]^2 [S_3(x_3)]^2 [S_4(x_4)]^2 \right\} \\ &\quad \left\{ J_{234}(x_2, x_3, x_4) J_{23}(x_2, x_3) J_{24}(x_2, x_4) J_{34}(x_3, x_4) \right. \\ &\quad \left. [S_2(x_2)]^2 [S_3(x_3)]^2 [S_4(x_4)]^2 \right\} \end{aligned} \quad (7.7)$$

After regrouping all the factors in (7.7) and matching repeating factors that occur in different parentheses, we obtain the following formula:

$$\begin{aligned} S(\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3, \mathbf{x}_4) &= J_{1234}(x_1, x_2, x_3, x_4) J_{123}(x_1, x_2, x_3) \\ &\quad J_{124}(x_1, x_2, x_4) J_{134}(x_1, x_3, x_4) J_{234}(x_2, x_3, x_4) \\ &\quad [J_{12}(x_1, x_2)]^2 [J_{13}(x_1, x_3)]^2 [J_{14}(x_1, x_4)]^2 [J_{23}(x_2, x_3)]^2 \\ &\quad [J_{24}(x_2, x_4)]^2 [J_{34}(x_3, x_4)]^2 [S_1(x_1)]^6 [S_2(x_2)]^6 \\ &\quad [S_3(x_3)]^6 [S_4(x_4)]^6 \end{aligned} \quad (7.8)$$

Formula (7.8) seems not to be so complicated, but it is pretty long and the underlying (6-th) powers of the univariate marginals could make us somewhat uncomfortable. And this is only the 4-dimensional case. Raising this dimension only by one [see formula (7.5*) and proof of theorem 1] causes raising the 1-dimensional marginals to the power 24 and all the bivariate joiners to the power 6. That may suggest that such formulas are useless from a practical (reliability, for example) point of view, and what remains would be only the theoretical value of formula (7.5*). This “first impression,” however, is not well grounded. To see this only recall the defining formulae (7.1), (7.1*) and (7.1**). Thus, however small the factors $J_{(j(1), \dots, j(m+1-s))}^{s!}(x_{j(1)}, \dots, x_{j(m+1-s)})$ are, the products forming the corresponding value of the joiner’s $J_{1,\dots,k}(x_1, \dots, x_{k-1}, x_k)$ denominator [see (7.1*)] is proportionally high (much greater than 1).

As the net result, one always obtains a reasonable value, that is, the joint survival function $S(x_1, x_2, \dots, x_{k-1}, x_k)$, we analyzed (see formula (7.1**) and its further expansion (7.3)). \square

In vast majority of “regular” cases, formulas (7.8) and (7.3), in their full extend, are unrealistic especially whenever applications are of interest. Fortunately, the results as given by those formulas are just the first step that comprises the full generality which is seldom met in practice. Obviously, in applications, it is not too realistic situation when “everything depends on everything else.”

In reality (including also “most of” the “mathematical reality”), the vast majority of the joiners (present in (7.5*) and in (7.8)) should be considered to be equal to 1, which means corresponding stochastic independence.

The important theoretical (and practical as well) fact is that all the stochastic dependences (as well as independence) among the random variables X_1, \dots, X_k are entirely described by the set of all the joiners

$$J_{(j(1), \dots, j(r))} (x_{j(1)}, \dots, x_{j(r)}), \text{ where } r = 2, 3, \dots, k.$$

Thus, the dependences’ analysis mathematically reduces to analysis of the functions $J_{(j(1), \dots, j(r))} (x_{j(1)}, \dots, x_{j(r)})$ which fully represent the corresponding stochastic dependence. One can say they play a role similar to that of having only numerical values “correlation coefficients” defined in literature in variety of ways.

Remark 3 At this point is good to notice that the k -joiner $J_{1, \dots, k} (x_1, \dots, x_{k-1}, x_k)$ describes exclusively stochastic dependence of the set of all the $(k - 1)$ -dimensional random vectors

$$\left\{ (X_{j(1)}, \dots, X_{j(k-1)}) \right\}, \text{ where } 1 \leq j(1) < j(2) < \dots < j(k-1) \leq k.$$

This joiner “is responsible” only for the dependence between these $(k - 1)$ -dimensional random vectors. If it equals 1 (which means the **k-independence**; see in above) then, in accordance with (7.3), we have

$$\begin{aligned} S(x_1, x_2, \dots, x_{k-1}, x_k) \\ = S^{(1)}(x_2, x_3, \dots, x_k) S^{(2)}(x_1, x_3, \dots, x_k) \dots \\ S^{(k-1)}(x_1, \dots, x_{k-2}, x_k) S^{(k)}(x_1, \dots, x_{k-1}) \end{aligned} \quad (7.9)$$

so that the survival functions of all the $(k - 1)$ -dimensional marginals simply multiply by each other.

This factorization agrees with the common intuition of stochastic independence’ analytic descriptions.

It may happen that some disjoint proper subsets of the set $\{X_{j(1)}, \dots, X_{j(k-1)}\}$ that form random (sub)vectors marginal to the corresponding $(k - 1)$ -dimensional marginal random

vector $(X_{j(1)}, \dots, X_{j(k-1)})$ are *independent* from each other, while their corresponding (“inner”) “ k -sub-joiners” [factors of the k -joiner] are not equal to 1.

This phenomenon may be called “group independence,” where random variables within each such “group” [subset] may be dependent.

Returning to the general case of the joiners (factored or not), notice that any r -joiner $J_{(j(1), \dots, j(r))} (x_{j(1)}, \dots, x_{j(r)})$ of any r -dimensional marginal random vector $(X_{j(1)}, \dots, X_{j(r)})$ ($r \geq 2$) only describes dependences between the $(r - 1)$ -dimensional marginals of this vector.

The considered r -joiner may be factored or not according to existence or nonexistence of independence between some disjoint proper subsets of the associated sets $\{X_{j(1)}, \dots, X_{j(r)}\}$ that form at most $(r-1)$ -dimensional marginal random sub-vectors of the random vectors $(X_{j(1)}, \dots, X_{j(r)})$.

In particular, if the r -joiner is factored, some of the factors may be equal 1. \square

As already mentioned, in practical reality the number of dependent random subvectors (i.e., r -dimensional [$r \leq k - 1$] marginals) of the random vector (X_1, \dots, X_k) is rather limited.

This means most of the underlying r -variate joiners present in formulas (7.3) or (7.8) are simply equal to 1.

Regarding that phenomenon, the defined below notion of r -independence may be useful in various specific model constructions.

We finalize our present considerations by introducing the following definition of r -independence that may serve as a guidance in future constructions.

Definition For any r such that $2 \leq r \leq k$, by **r-independence**, we will understand the fact that for each $q \geq r$, all the q -dimensional joiners are equal to 1. \square

Thus, 2-independence is equivalent to the ordinary independence of the random variables X_1, \dots, X_k so, as usually, we have: $S(x_1, x_2, \dots, x_{k-1}, x_k) = S_1(x_1) S_2(x_2) \dots S_k(x_k)$.

It seems to be reasonable to assume that the underlying random variables X_1, \dots, X_k are only “pairwise dependent,” that is, to reduce the construction of a joint survival function $S(x_1, x_2, \dots, x_{k-1}, x_k)$ to construction of [not necessarily all] its bivariate marginals, say, $S_{ij}(x_i, x_j)$, where $1 \leq i < j \leq k$. Then we may apply scheme (7.3) by setting all the joiners having at least three arguments (and most of those having two arguments) to 1.

By the way, in this case formula (7.3) and some of its special realizations such as (7.8) should be a little redefined.

As a hint to this task realize that, in this case, instead of the arithmetic identity (7.1**), one may (preserving the main idea) apply the following, corresponding, arithmetic identity:

$$S(x_1, \dots, x_k) = \left[S(x_1, \dots, x_k) / \prod_{i < j} S_{ij}(x_i, x_j) \right] \prod_{i < j} S_{ij}(x_i, x_j). \quad (7.10)$$

Now, the corresponding to the former k -joiner, “bi-joiner” $J^{(2)}(x_1, \dots, x_k)$ is defined as

$$J^{(2)}(x_1, \dots, x_k) = S(x_1, \dots, x_k) / \prod_{i < j} S_{ij}(x_i, x_j),$$

while formula (7.3) is replaced by the following scheme:

$$S(x_1, \dots, x_k) = J^{(2)}(x_1, \dots, x_k) \prod_{i < j} S_{ij}(x_i, x_j). \quad (7.11)$$

Again, in concrete applications, most of the factors $S_{ij}(x_i, x_j)$ in (7.11) are reduced to products $S_i(x_i) S_j(x_j)$, which means the associated bi-joiners are reduced to 1.

As an important special case, one may consider the situation when we have

$$J^{(2)}(x_1, \dots, x_k) = 1.$$

Then (7.11) reduces to:

$$S(x_1, \dots, x_k) = \prod_{i < j} S_{ij}(x_i, x_j) \quad (7.12)$$

and now the theory reduces to the theory of bivariate probability distributions as described in [5] and [7].

This case is especially convincing when the only non-trivial factors in the product $\prod_{i < j} S_{ij}(x_i, x_j)$ are those for which any two element subsets $\{x_i, x_j\}$ of the variables set $\{x_1, \dots, x_k\}$ are disjoint.

Abstract

This chapter briefly discusses stochastic processes, including Markov processes, Poisson processes, renewal processes, quasi-renewal processes, and nonhomogeneous Poisson processes. The chapter also provides a short list of books for readers who are interested in advanced topics in stochastic processes.

Keywords

Markov processes · Poisson processes · Renewal processes · Stochastic processes · Nonhomogeneous Poisson processes

8.1 Introduction

Stochastic processes are used to describe the operation of a system over time. There are two main types of stochastic processes: continuous and discrete. A complex continuous process is a process describing a system transition from state to state. The simplest process that will be discussed here is a Markov process. In this case, the future behavior of the process does not depend on its past or present behavior. In many systems that arise in practice, however, past and present states of the system influence the future states, even if they do not uniquely determine them.

8.2 Markov Processes

In this section, we will discuss discrete stochastic processes. As an introduction to the Markov process, let us examine the following example.

Example 8.1 Consider a parallel system consisting of two components (see Fig. 8.1). From a reliability point of view, the states of the system can be described by

State 1:	Full operation (both components operating);
State 2:	One component is operating and one component has failed;
State 3:	Both components have failed.

Define

$$\begin{aligned}
 P_i(t) &= P[X(t) = i] \\
 &= P[\text{system is in state } i \text{ at time } t]
 \end{aligned}$$

Fig. 8.1 A two-component parallel system

and

$$\begin{aligned} P_i(t + dt) &= P[X(t + dt) = i] \\ &= P[\text{system is in state } i \text{ at time } t + dt]. \end{aligned}$$

Define a random variable $X(t)$ which can assume the values 1, 2, or 3 corresponding to the states mentioned above. Since $X(t)$ is a random variable, one can discuss $P[X(t) = 1]$, $P[X(t) = 2]$ or the conditional probability $P[X(t_1) = 2 | X(t_0) = 1]$. Again, $X(t)$ is defined as a function of time t , while the conditional probability $P[X(t_1) = 2 | X(t_0) = 1]$ can be interpreted as the probability of being in state 2 at time t_1 , given that the system was in state 1 at time t_0 . In this example, the “state space” is discrete, i.e., 1, 2, 3, etc., and the parameter space (time) is continuous. The simple process described above is called a stochastic process: a process that develops over time (or space) in accordance with some probabilistic (stochastic) laws. There are many types of stochastic processes.

Here we emphasize the Markov process, which is a special type of stochastic process. Let the system be observed at discrete moments of time t_n , where $n = 0, 1, 2, \dots$, and let $X(t_n)$ denote the state of the system at time t_n .

Definition 8.1 Let $t_0 < t_1 < \dots < t_n$. If

$$\begin{aligned} &P[X(t_n) = x_n | X(t_{n-1}) \\ &= x_{n-1}, X(t_{n-2}) = x_{n-2}, \dots, X(t_0) = x_0] \\ &= P[X(t_n) = x_n | X(t_{n-1}) = x_{n-1}] \end{aligned} \quad (8.1)$$

then the process is called a *Markov process*.

From the definition of a Markov process, given the present state of the process, its behavior in the future does not depend on its behavior in the past.

The essential characteristic of a Markov process is that it is a process that has no memory; its future is determined by the present and not the past. If, in addition to having no memory, the process is such that it depends only on the difference $(t + dt) - t = dt$ and not the value of t – in other words $P[X(t + dt) = j | X(t) = i]$ is independent of t – then the process is Markov with stationary transition

probabilities or is homogeneous in time. This is the same property noted in exponential event times; in fact, referring back to the graphical representation of $X(t)$, the times between state changes are exponential if the process has stationary transition probabilities.

Thus, a Markov process which is homogeneous in time can describe processes with exponential event occurrence times. The random variable of the process is $X(t)$, the state variable rather than the time to failure used in the exponential failure density. To illustrate the types of processes that can be described, we now review the exponential distribution and its properties. Recall that, if X_1, X_2, \dots, X_n , are independent random variables, each with exponential density and a mean of $1/\lambda_i$, then $\min\{X_1, X_2, \dots, X_n\}$ has an exponential density with a mean of $(\sum \lambda_i)^{-1}$.

The significance of this property is as follows:

1. The failure behavior of components operated simultaneously can be characterized by an exponential density with a mean equal to the reciprocal of the sum of the failure rates.
2. The joint failure/repair behavior of a system where components are operating and/or undergoing repair can be characterized by an exponential density with a mean equal to the reciprocal of the sum of the failure and repair rates.
3. The failure/repair behavior of a system similar to that described in (2) above but further complicated by active and dormant operating states and sensing and switching can be characterized by an exponential density.

The above property means that almost all reliability and availability models can be characterized by a time-homogeneous Markov process if the various failure times and repair times are exponential. The notation for the Markov process is $\{X(t), t > 0\}$, where $X(t)$ is discrete (state space) and t is continuous (parameter space). By convention, this type of Markov process is called a continuous-parameter Markov chain.

From a reliability/availability viewpoint, there are two types of Markov processes. These are defined as follows:

1. *Absorbing process*: Contains an “absorbing state,” which is a state that, once entered, the system can never leave (e.g., a failure which aborts a flight or a mission).
2. *Ergodic process*: Contains no absorbing states, meaning that $X(t)$ can move around indefinitely (e.g., the operation of a ground power plant where failure only temporarily disrupts the operation).

Figure 8.2 presents a summary of Markov processes broken down into absorbing and ergodic categories. Both the reliability and the availability can be described in terms of the probability of the process or system being in defined “up” states, e.g., states 1 and 2 in the initial example. Likewise,

Fig. 8.2 State transition diagram for a two-component system

the mean time between failures (MTBF) can be described as the total time spent in the “up” states before proceeding to the absorbing state or failure state.

Define the incremental transition probability as

$$P_{ij}(dt) = P[X(t + dt) = j | X(t) = i].$$

This is the probability that the process [random variable $X(t)$] will move to state j during the increment t to $(t + dt)$, given that it was in state i at time t . Since we are dealing with time-homogeneous Markov processes (exponential failure and repair times), the incremental transition probabilities can be derived from an analysis of the exponential hazard function. It was shown that the hazard function for an exponential with a mean of $1/\lambda$ was just λ . This means that the limiting (as $dt \rightarrow 0$) conditional probability of an event occurring between t and $t + dt$, given that an event had not occurred at time t , is simply λ , in other words:

$$h(t) = \lim_{dt \rightarrow 0} \frac{P[t < X < t + dt | X > t]}{dt} = \lambda.$$

The equivalent statement for the random variable $X(t)$ is

$$h(t) dt = P[X(t + dt) = j | X(t) = i] = \lambda dt.$$

Now, $h(t) dt$ is in fact the incremental transition probability, so $P_{ij}(dt)$ can be stated in terms of the basic failure and/or repair rates. Define

$P_i(t)$: the probability that the system is in state i at time t

$r_{ij}(t)$: transition rate from state i to state j

In general, the differential equations can be written as follows:

$$\frac{\partial P_i(t)}{\partial t} = - \sum_j r_{ij}(t) P_i(t) + \sum_j r_{ji}(t) P_j(t). \quad (8.2)$$

Solving the above differential equations, one can obtain the time-dependent probability of each state.

Returning to Example 8.1, it is easy to construct a state transition showing the incremental transition probabilities between all possible states for the process:

State 1:	Both components operating
State 2:	One component up and one component down
State 3:	Both components down (absorbing state)

The loops in Fig. 8.2 indicate the probability of remaining in the present state during the dt increment

$$\begin{aligned} P_{11}(dt) &= 1 - 2\lambda dt & P_{12}(dt) &= 2\lambda dt \\ P_{21}(dt) &= 0 & P_{22}(dt) &= 1 - \lambda dt \\ P_{31}(dt) &= 0 & P_{32}(dt) &= 0 \\ P_{13}(dt) &= 0 \\ P_{23}(dt) &= \lambda dt \\ P_{33}(dt) &= 1 \end{aligned}$$

The zeros for P_{ij} , $i > j$ show that the process cannot go backwards: this is not a repair process. The zero on P_{13} shows that, for a process of this type, the probability of more than one event (e.g., failure, repair, etc.) occurring in the incremental time period dt approaches zero as dt approaches zero.

Except for the initial conditions of the process (the state in which the process starts), the process is completely specified by incremental transition probabilities. The reason that this is useful is that assuming exponential event (failure or repair) times allows us to characterize the process at any time t , since the process depends only on what happens between t and $(t + dt)$. The incremental transition probabilities can be arranged into a matrix in a way that depicts all possible statewide movements. Thus, for parallel configurations,

$$[P_{ij}(dt)] = \begin{pmatrix} 1 - 2\lambda dt & 2\lambda dt & 0 \\ 0 & 1 - \lambda dt & \lambda dt \\ 0 & 0 & 1 \end{pmatrix}$$

for $i, j = 1, 2$, or 3 . The matrix $[P_{ij}(dt)]$ is called the incremental, one-step transition matrix. It is a stochastic matrix (the rows sum to 1.0). As mentioned earlier, this matrix, along with the initial conditions, completely describes the process.

Now, $[P_{ij}(dt)]$ gives the probabilities of remaining or moving to all of the various states during the interval t to $t + dt$; hence,

$$\begin{aligned} P_1(t + dt) &= (1 - 2\lambda dt) P_1(t) \\ P_2(t + dt) &= 2\lambda dt P_1(t) + (1 - \lambda dt) P_2(t) \\ P_3(t + dt) &= \lambda dt P_2(t) + P_3(t) \end{aligned}$$

By algebraic manipulation, we have

Fig. 8.3 Markov transition rate diagram for a two-component parallel system

$$\begin{aligned}\frac{[P_1(t+dt) - P_1(t)]}{dt} &= -2\lambda P_1(t), \\ \frac{[P_2(t+dt) - P_2(t)]}{dt} &= 2\lambda P_1(t) - \lambda P_2(t), \\ \frac{[P_3(t+dt) - P_3(t)]}{dt} &= \lambda P_2(t).\end{aligned}$$

Taking limits of both sides as $dt \rightarrow 0$, we obtain (also see Fig. 8.3):

$$\begin{aligned}P_1'(t) &= -2\lambda P_1(t), \\ P_2'(t) &= 2\lambda P_1(t) - \lambda P_2(t), \\ P_3'(t) &= \lambda P_2(t).\end{aligned}\quad (8.3)$$

The above system of linear first-order differential equations can be easily solved for $P_1(t)$ and $P_2(t)$, meaning that the reliability of the configuration can be obtained:

$$R(t) = \sum_{i=1}^2 P_i(t).\quad (8.4)$$

Actually, there is no need to solve all three equations, only the first two, because $P_3(t)$ does not appear and also $P_3(t) = [1 - P_1(t)] - P_2(t)$. The system of linear, first-order differential equations can be solved by various means, including both manual and machine methods. We use manual methods employing the Laplace transform (see Appendix A) here.

$$\begin{aligned}L[P_i(t)] &= \int_0^\infty e^{-st} P_i(t) dt = f_i(s), \\ L[P_i'(t)] &= \int_0^\infty e^{-st} P_i'(t) dt = s f_i(s) - P_i(0).\end{aligned}\quad (8.5)$$

Application of the Laplace transform will allow us to transform the system of linear, first-order differential equations into a system of linear algebraic equations that can easily be solved, and solutions of $P_i(t)$ can be determined via the inverse transforms.

Returning to the example, the initial condition of a parallel configuration is assumed to be “fully up”, such that

$$P_1(t=0) = 1, P_2(t=0) = 0, P_3(t=0) = 0.$$

Transforming the equations for $P_1'(t)$ and $P_2'(t)$ gives

$$\begin{aligned}s f_1(s) - P_1(t)|_{t=0} &= -2\lambda f_1(s), \\ s f_2(s) - P_2(t)|_{t=0} &= 2\lambda f_1(s) - \lambda f_2(s).\end{aligned}$$

Evaluating $P_1(t)$ and $P_2(t)$ at $t = 0$ gives

$$\begin{aligned}s f_1(s) - 1 &= -2\lambda f_1(s), \\ s f_2(s) - 0 &= 2\lambda f_1(s) - \lambda f_2(s).\end{aligned}$$

from which we obtain

$$\begin{aligned}(s + 2\lambda) f_1(s) &= 1, \\ -2\lambda f_1(s) + (s + \lambda) f_2(s) &= 0.\end{aligned}$$

Solving the above equations for $f_1(s)$ and $f_2(s)$, we have

$$\begin{aligned}f_1(s) &= \frac{1}{(s + 2\lambda)}, \\ f_2(s) &= \frac{2\lambda}{[(s + 2\lambda)(s + \lambda)]}.\end{aligned}$$

From the inverse Laplace transforms in Appendix A,

$$\begin{aligned}P_1(t) &= e^{-2\lambda t}, \\ P_2(t) &= 2e^{-\lambda t} - 2e^{-2\lambda t}, \\ R(t) = P_1(t) + P_2(t) &= 2e^{-\lambda t} - e^{-2\lambda t}.\end{aligned}\quad (8.6)$$

The example given above is that of a simple absorbing process where we are concerned about reliability. If a repair capability were added to the model in the form of a repair rate μ , the methodology would remain the same, with only the final result changing. With a repair rate μ added to the parallel configuration (see Fig. 8.4), the incremental transition matrix would be

$$[P_{ij}(dt)] = \begin{pmatrix} 1 - 2\lambda dt & 2\lambda dt & 0 \\ \mu dt & 1 - (\lambda + \mu) dt & \lambda dt \\ 0 & 0 & 1 \end{pmatrix}.$$

The differential equations would become (see Fig. 8.4)

$$\begin{aligned}P_1'(t) &= -2\lambda P_1(t) + \mu P_2(t), \\ P_2'(t) &= 2\lambda P_1(t) + (\lambda + \mu) P_2(t),\end{aligned}$$

and the transformed equations would become

$$\begin{aligned}(s + 2\lambda) f_1(s) - \mu f_2(s) &= 1, \\ -2\lambda f_1(s) + (s + \lambda + \mu) f_2(s) &= 0.\end{aligned}$$

Hence, we obtain

$$\begin{aligned}f_1(s) &= \frac{(s + \lambda + \mu)}{(s - s_1)(s - s_2)}, \\ f_2(s) &= \frac{2\lambda}{(s - s_1)(s - s_2)},\end{aligned}\quad (8.7)$$

Fig. 8.4 Markov transition rate diagram for a two-component parallel repairable system

where

$$s_1 = \frac{-(3\lambda + \mu) + \sqrt{(3\lambda + \mu)^2 - 8\lambda^2}}{2}, \quad (8.8)$$

$$s_2 = \frac{-(3\lambda + \mu) - \sqrt{(3\lambda + \mu)^2 - 8\lambda^2}}{2}.$$

Using the Laplace transform, we obtain

$$P_1(t) = \frac{(s_1 + \lambda + \mu) e^{-s_1 t}}{(s_1 - s_2)} + \frac{(s_2 + \lambda + \mu) e^{-s_2 t}}{(s_2 - s_1)}, \quad (8.9)$$

$$P_2(t) = \frac{2\lambda e^{-s_1 t}}{(s_1 - s_2)} + \frac{2\lambda e^{-s_2 t}}{(s_2 - s_1)},$$

where s_1 and s_2 are given in Eq. (8.8).

Thus, the reliability of a two-component parallel repairable system is given by

$$R(t) = P_1(t) + P_2(t) = \frac{(s_1 + 3\lambda + \mu) e^{-s_1 t} - (s_2 + 3\lambda + \mu) e^{-s_2 t}}{(s_1 - s_2)} \quad (8.10)$$

Example 8.2 Consider a three-unit shared load parallel system where

- λ_0 is the constant failure rate of a unit when all the three units are operational;
- λ_h is the constant failure rate of each of the two surviving units, each of which shares half of the total load; and
- λ_f is the constant failure rate of a unit at full load.

For a shared-load parallel system to fail, all the units in the system must fail. We now derive the reliability of a three-unit shared-load parallel system using the Markov model.

In reliability analysis, for the three-unit load-sharing system to work the following events would be considered:

- Event 1:* All the three units are working until the end of the mission time t where each unit shares one-third of the total load.
- Event 2:* All the three units are working until time t_1 (each shares one-third of the total load). At time t_1 , one of the units (say unit 1) fails, and the other two units (say units 2

Fig. 8.5 Markov model diagram for a three-unit shared-load parallel system

and 3) remain to work until the mission time t . Here, once a unit fails at time t_1 , the remaining two working units would take half each of the total load and have a constant rate λ_h . As for all identical units, there are three possibilities under this situation.

Event 3: All the three units are working until time t_1 (each shares one-third of the total load) when one (say unit 1) of the three units fails. At time t_2 , ($t_2 > t_1$) one more unit fails (say unit 2) and the remaining unit works until the end of the mission time t . Under this event, there are six possibilities that the probability of two units failing before time t and only one unit remains to work until time t .

Define state i represents that i components are working. Let $P_i(t)$ denote the probability that the system is in state i at time t for $i = 0, 1, 2, 3$. Figure 8.5 below shows the Markov diagram of the system.

The Markov modeling system of differential equations based on Fig. 8.1 can be easily derived as follows:

$$\begin{cases} \frac{dP_3(t)}{dt} = -3\lambda_0 P_3(t) \\ \frac{dP_2(t)}{dt} = 3\lambda_0 P_3(t) - 2\lambda_h P_2(t) \\ \frac{dP_1(t)}{dt} = 2\lambda_h P_2(t) - \lambda_f P_1(t) \\ \frac{dP_0(t)}{dt} = \lambda_f P_1(t) \\ P_3(0) = 1 \\ P_j(0) = 0, j \neq 3 \\ P_0(t) + P_1(t) + P_2(t) + P_3(t) = 1 \end{cases} \quad (8.11)$$

Solving the above differential equations using the Laplace transform method (see Appendix A), we can easily obtain the following results:

$$P_3(t) = e^{-3\lambda_0 t}$$

$$P_2(t) = \frac{3\lambda_0}{3\lambda_h - 3\lambda_0} (e^{-3\lambda_0 t} - e^{-2\lambda_h t})$$

$$P_1(t) = \frac{6\lambda_0\lambda_h}{(2\lambda_h - 3\lambda_0)} \left[\frac{e^{-3\lambda_0 t}}{(\lambda_f - 3\lambda_0)} - \frac{e^{-2\lambda_h t}}{(\lambda_f - 2\lambda_h)} + \frac{(2\lambda_h - 3\lambda_0)e^{-\lambda_f t}}{(\lambda_f - 3\lambda_0)(\lambda_f - 2\lambda_h)} \right] \quad (8.12)$$

Hence, the reliability of a three-unit shared load parallel system can be obtained as follows:

$$\begin{aligned} R(t) &= P_3(t) + P_2(t) + P_1(t) \\ &= e^{-3\lambda_0 t} + \frac{3\lambda_0}{2\lambda_h - 3\lambda_0} (e^{-3\lambda_0 t} - e^{-2\lambda_h t}) \\ &\quad + \frac{6\lambda_0\lambda_h}{(2\lambda_h - 3\lambda_0)} \left[\frac{e^{-3\lambda_0 t}}{(\lambda_f - 3\lambda_0)} - \frac{e^{-2\lambda_h t}}{(\lambda_f - 2\lambda_h)} \right. \\ &\quad \left. + \frac{(2\lambda_h - 3\lambda_0)e^{-\lambda_f t}}{(\lambda_f - 3\lambda_0)(\lambda_f - 2\lambda_h)} \right] \end{aligned} \quad (8.13)$$

8.2.1 System Mean Time Between Failures

Another parameter of interest for absorbing Markov processes is the MTBF. Recalling Example 8.1 of a parallel configuration with repair, the differential equations $P_1'(t)$ and $P_2'(t)$ describing the process were

$$\begin{aligned} P_1'(t) &= -2\lambda P_1(t) + \mu P_2(t), \\ P_2'(t) &= 2\lambda P_1(t) - (\lambda + \mu) P_2(t). \end{aligned}$$

Integrating both sides of the above equations yields

$$\begin{aligned} \int_0^\infty P_1'(t) dt &= -2\lambda \int_0^\infty P_1(t) dt + \mu \int_0^\infty P_2(t) dt, \\ \int_0^\infty P_2'(t) dt &= 2\lambda \int_0^\infty P_1(t) dt - (\lambda + \mu) \int_0^\infty P_2(t) dt. \end{aligned}$$

For the repairable system, we have

$$\int_0^\infty R(t) dt = \text{MTBF}. \quad (8.14)$$

Similarly,

$$\begin{aligned} \int_0^\infty P_1(t) dt &= \text{mean time spent in state 1, and} \\ \int_0^\infty P_2(t) dt &= \text{mean time spent in state 2.} \end{aligned}$$

Designating these mean times as T_1 and T_2 , respectively, we have

$$\begin{aligned} P_1(t) dt \Big|_0^\infty &= -2\lambda T_1 + \mu T_2, \\ P_2(t) dt \Big|_0^\infty &= 2\lambda T_1 - (\lambda + \mu) T_2. \end{aligned}$$

But $P_1(t) = 0$ as $t \rightarrow \infty$ and $P_1(t) = 1$ for $t = 0$. Likewise, $P_2(t) = 0$ as $t \rightarrow \infty$ and $P_2(t) = 0$ for $t = 0$. Thus,

$$\begin{aligned} -1 &= -2\lambda T_1 + \mu T_2, \\ 0 &= 2\lambda T_1 - (\lambda + \mu) T_2, \end{aligned}$$

or, equivalently,

$$\begin{pmatrix} -1 \\ 0 \end{pmatrix} = \begin{pmatrix} -2\lambda & \mu \\ 2\lambda & -(\lambda + \mu) \end{pmatrix} \begin{pmatrix} T_1 \\ T_2 \end{pmatrix}.$$

Therefore,

$$\begin{aligned} T_1 &= \frac{(\lambda + \mu)}{2\lambda^2}, \quad T_2 = \frac{1}{\lambda}, \\ \text{MTBF} &= T_1 + T_2 = \frac{(\lambda + \mu)}{2\lambda^2} + \frac{1}{\lambda} = \frac{(3\lambda + \mu)}{2\lambda^2}. \end{aligned} \quad (8.15)$$

The MTBF for unmaintained processes is developed in exactly the same way as just shown.

The last case to consider for absorbing processes is that of the availability of a maintained system. The difference between reliability and availability is somewhat subtle for absorbing processes. A good example is that of a communications system where the mission would continue if such a system failed temporarily, but if it failed permanently the mission would be aborted. Consider a cold-standby system consisting of two units: one main unit and one spare unit [1]:

State 1:	Main unit operating and the spare is OK
State 2:	Main unit out and restoration underway
State 3:	Spare unit is installed and operating
State 4:	Permanent failure (no spare available)

The incremental transition matrix is given by

$$[P_{ij}(dt)] = \begin{pmatrix} 1 - \lambda dt & \lambda dt & 0 & 0 \\ 0 & 1 - \mu dt & \mu dt & 0 \\ 0 & 0 & 1 - \lambda dt & \lambda dt \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

We obtain

$$\begin{aligned} P_1'(t) &= -\lambda P_1(t), \\ P_2'(t) &= \lambda P_1(t) - \mu P_2(t), \\ P_3'(t) &= \mu P_2(t) - \lambda P_3(t). \end{aligned}$$

Using the Laplace transform, we obtain the following results.

The probability of full-up performance $P_1(t)$ is given by

$$P_1(t) = e^{-\lambda t}.$$

The probability of a down system that is under repair $P_2(t)$ is

$$P_2(t) = \left(\frac{\lambda}{\lambda - \mu} \right) (e^{-\mu t} - e^{-\lambda t}).$$

Similarly, the probability of a fully up system with no spare available $P_3(t)$ is

$$P_3(t) = \left(\frac{\lambda\mu}{(\lambda - \mu)^2} \right) [e^{-\mu t} - e^{-\lambda t} - (\lambda - \mu)t e^{-\lambda t}].$$

Hence, the point availability $A(t)$ is given by

$$A(t) = P_1(t) + P_3(t). \tag{8.16}$$

If average or interval availability is required, this is achieved by

$$\left(\frac{1}{t} \right) \int_0^T A(t) dt = \left(\frac{1}{t} \right) \int_0^T [P_1(t) + P_3(t)] dt,$$

where T is the interval of concern.

Ergodic processes, as opposed to absorbing processes, do not have any absorbing states, and hence movement between states can go on indefinitely. For the latter reason, availability (point, steady-state, or interval) is the only meaningful measure. As an example of an ergodic process, we will use a ground-based power unit configured in parallel.

The parallel units are identical, each with exponential failure and repair times with means $1/\lambda$ and $1/\mu$, respectively. Assume a two-repairmen capability if required (both units down), then

State 1:	Fully up (both units operating)
State 2:	One unit down and under repair (other unit up)
State 3:	Both units down and under repair

It should be noted that, as in the case of failure events, two or more repairs cannot be made in the dt interval.

$$[P_{ij}(dt)] = \begin{pmatrix} 1 - 2\lambda dt & 2\lambda dt & 0 \\ \mu dt & 1 - (\lambda + \mu) dt & \lambda dt \\ 0 & 2\mu dt & 1 - 2\mu dt \end{pmatrix}.$$

Case I: *Point Availability – Ergodic Process.* For an ergodic process, as $t \rightarrow \infty$ the availability settles down to a constant level. Point availability allows us to study the process before this “settling down,” and it reflects the initial conditions in the process. We can obtain a solution for the point availability in a similar way to that for absorbing

processes, except that the last row and column of the transition matrix must be retained and entered into the system of equations. For example, the system of differential equations becomes

$$\begin{pmatrix} P_1'(t) \\ P_2'(t) \\ P_3'(t) \end{pmatrix} = \begin{pmatrix} -2\lambda & \mu & 0 \\ 2\lambda & -(\lambda + \mu) & 2\mu \\ 0 & \lambda & -2\mu \end{pmatrix} \begin{pmatrix} P_1(t) \\ P_2(t) \\ P_3(t) \end{pmatrix}.$$

Similar to the absorbing case, the Laplace transform can be used to solve for $P_1(t)$, $P_2(t)$ and $P_3(t)$; the point availability $A(t)$ is given by

$$A(t) = P_1(t) + P_2(t).$$

Case II: *Interval Availability – Ergodic Process.* This is the same as the absorbing case, with integration over the time period T of interest. The interval availability, $A(T)$, is

$$A(T) = \frac{1}{T} \int_0^T A(t) dt. \tag{8.17}$$

Case III: *Steady State Availability – Ergodic Process.* Here, the process is examined as $t \rightarrow \infty$, with complete “washout” of the initial conditions. By letting $t \rightarrow \infty$, the system of differential equations can be transformed into linear algebraic equations. Thus,

$$\begin{aligned} & \lim_{t \rightarrow \infty} \begin{pmatrix} P_1'(t) \\ P_2'(t) \\ P_3'(t) \end{pmatrix} \\ &= \lim_{t \rightarrow \infty} \begin{pmatrix} -2\lambda & \mu & 0 \\ 2\lambda & -(\lambda + \mu) & 2\mu \\ 0 & \lambda & -2\mu \end{pmatrix} \begin{pmatrix} P_1(t) \\ P_2(t) \\ P_3(t) \end{pmatrix}. \end{aligned}$$

As $t \rightarrow \infty$, $P_i(t) \rightarrow \text{constant}$ and $P_i'(t) \rightarrow 0$. This leads to an unsolvable system, namely,

$$\begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix} = \begin{pmatrix} -2\lambda & \mu & 0 \\ 2\lambda & -(\lambda + \mu) & 2\mu \\ 0 & \lambda & -2\mu \end{pmatrix} \begin{pmatrix} P_1(t) \\ P_2(t) \\ P_3(t) \end{pmatrix}.$$

To avoid the above difficulty, an additional equation is introduced:

$$\sum_{i=1}^3 P_i(t) = 1.$$

With the introduction of the new equation, one of the original equations is deleted and a new system is formed:

$$\begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} = \begin{pmatrix} 1 & 1 & 1 \\ -2\lambda & \mu & 0 \\ 2\lambda & -(\lambda + \mu) & 2\mu \end{pmatrix} \begin{pmatrix} P_1(t) \\ P_2(t) \\ P_3(t) \end{pmatrix}$$

or, equivalently,

$$\begin{pmatrix} P_1(t) \\ P_2(t) \\ P_3(t) \end{pmatrix} = \begin{pmatrix} 1 & 1 & 1 \\ -2\lambda & \mu & 0 \\ 2\lambda & -(\lambda + \mu) & 2\mu \end{pmatrix}^{-1} \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}.$$

We now obtain the following results:

$$P_1(t) = \frac{\mu^2}{(\mu + \lambda)^2},$$

$$P_2(t) = \frac{2\lambda\mu}{(\mu + \lambda)^2},$$

and

$$P_3(t) = 1 - P_1(t) - P_2(t)$$

$$= \frac{\lambda^2}{(\mu + \lambda)^2}.$$

Therefore, the steady state availability $A(\infty)$ is given by

$$A_3(\infty) = P_1(t) + P_2(t)$$

$$= \frac{\mu(\mu + 2\lambda)}{(\mu + \lambda)^2}. \quad (8.18)$$

Note that Markov methods can also be employed when failure or repair times are not exponential but can be represented as the sum of exponential times with identical means (an Erlang distribution or gamma distribution with integer-valued shape parameters). Basically, the method involves introducing “dummy” states which, although being of no particular interest in themselves, change the hazard function from constant to increasing.

Example 8.3 A system is composed of eight identical active power supplies, at least seven of the eight are required for the system to function. In other words, when two of the eight power supplies fail, the system fails. When all eight power supplies are operating, each has a constant failure rate λ_a per hour. If one power supply fails, each remaining power supply has a failure rate λ_b per hour where $\lambda_a \leq \lambda_b$. We assume that a failed power supply can be repaired with a constant rate μ per hour. The system reliability function, $R(t)$, is defined as the probability that the system continues to function throughout the interval $(0, t)$. Here we wish to determine the system mean time to failure (MTTF).

Define

State 0: All 8 units are working

State 1: 7 units are working

State 2: More than one unit failed and system does not work

The initial condition: $P_0(0) = 1, P_1(0) = P_2(0) = 0$

Fig. 8.6 Markov transition rate diagram for a 7-out-of-8 dependent system

The Markov modeling of differential equations (see Fig. 8.6) can be written as follows:

$$P'_0(t) = -8\lambda_a P_0(t) + \mu P_1(t)$$

$$P'_1(t) = 8\lambda_a P_0(t) - (7\lambda_b + \mu) P_1(t)$$

$$P'_2(t) = 7\lambda_b P_1(t)$$

Using the Laplace transform, we obtain

$$\begin{cases} sF_0(s) - P_0(0) = -8\lambda_a F_0(s) + \mu F_1(s) \\ sF_1(s) - P_1(0) = 8\lambda_a F_0(s) - (7\lambda_b + \mu) F_1(s) \\ sF_2(s) - P_2(0) = 7\lambda_b F_1(s) \end{cases} \quad (8.19)$$

When $s = 0$:

$$F_i(0) = \int_0^\infty P_i(t) dt.$$

Thus, the system reliability function and system MTTF, respectively, are

$$R(t) = P_0(t) + P_1(t). \quad (8.20)$$

and

$$\text{MTTF} = \int_0^\infty R(t) dt = \int_0^\infty [P_0(t) + P_1(t)] dt = \sum_{i=1}^2 F_i(0). \quad (8.21)$$

From Eq. (8.19), when $s = 0$, we have

$$\begin{cases} -1 = -8\lambda_a F_0(0) + \mu F_1(0) \\ 0 = 8\lambda_a F_0(0) - (7\lambda_b + \mu) F_1(0). \end{cases} \quad (8.22)$$

From Eq. (8.22), after some arrangements, we can obtain

$$7\lambda_b F_1(0) = 1 \Rightarrow F_1(0) = \frac{1}{7\lambda_b}$$

and

$$\begin{aligned} F_0(0) &= \frac{7\lambda_b + \mu}{8\lambda_a} F_1(0) \\ &= \frac{7\lambda_b + \mu}{8\lambda_a} \frac{1}{7\lambda_b} = \frac{7\lambda_b + \mu}{56\lambda_a\lambda_b} \end{aligned}$$

From Eq. (8.21), the system MTTF can be obtained

$$\begin{aligned} \text{MTTF} &= \int_0^\infty R(t) dt = \int_0^\infty [P_0(t) + P_1(t)] dt \\ &= F_0(0) + F_1(0) \\ &= \frac{7\lambda_b + \mu}{56\lambda_a\lambda_b} + \frac{1}{7\lambda_b} = \frac{\mu + 8\lambda_a + 7\lambda_b}{56\lambda_a\lambda_b}. \end{aligned}$$

Given $\lambda_a = 3 \times 10^{-3} = 0.003$, $\lambda_b = 5 \times 10^{-2} = 0.05$, and $\mu = 0.8$, then the system mean time to failure is given by:

$$\begin{aligned} \text{MTTF} &= \frac{\mu + 8\lambda_a + 7\lambda_b}{56\lambda_a\lambda_b} \\ &= \frac{0.8 + 8(0.003) + 7(0.05)}{56(0.003)(0.05)} = \frac{1.174}{0.0084} = 139.762 \text{ hours.} \end{aligned}$$

8.3 Counting Processes

Among various discrete stochastic processes, counting processes are widely used in engineering statistics to describe the appearance of events in time, such as failures, the number of perfect repairs, etc. The simplest counting process is a Poisson process. The Poisson process plays a special role in many applications related to reliability [1]. A classic example of such an application is the decay of uranium. Here, radioactive particles from nuclear material strike a certain target in accordance with a Poisson process of some fixed intensity. One well-known counting process is the so-called renewal process. This process is described as a sequence of events where the intervals between the events are independent and identically distributed random variables. In reliability theory, this type of mathematical model is used to describe the number of occurrences of an event or the number of renewals (i.e., replacements of objects) over a time interval. A light bulb is shining in your living room and it blows up suddenly. You replace it by a new bulb. It lasts for a few months, then burns out again. You then replace it again, and so on. One would be interested to know about the total number of bulbs is needed to be replaced in 2 years.

In this subsection, we discuss the concepts and properties of the Poisson process, renewal process, quasi-renewal process, and nonhomogeneous Poisson process.

A non-negative, integer-valued stochastic process $N(t)$ is called a counting process if $N(t)$ represents the total number of occurrences of an event in the time interval $[0, t]$ and satisfies these two properties:

1. If $t_1 < t_2$, then $N(t_1) \leq N(t_2)$
2. If $t_1 < t_2$, then $N(t_2) - N(t_1)$ is the number of occurrences of the event in the interval $[t_1, t_2]$.

For example, if $N(t)$ equals the number of persons who have entered a restaurant at or prior to time t , then $N(t)$ is a counting process in which an event occurs whenever a person enters the restaurant.

8.3.1 Poisson Processes

One of the most important counting processes is the Poisson process.

Definition 8.3 A counting process $N(t)$ is said to be a Poisson process with intensity λ if

1. The failure process $N(t)$ has stationary independent increments
2. The number of failures in any time interval of length s has a Poisson distribution with a mean of λs ; in other words

$$P\{N(t+s) - N(t) = n\} = \frac{e^{-\lambda s} (\lambda s)^n}{n!} \quad (8.23)$$

$$n = 0, 1, 2, \dots;$$

3. The initial condition is $N(0) = 0$

This model is also called a homogeneous Poisson process, indicating that the failure rate λ does not depend on time t . In other words, the number of failures that occur during the time interval $(t, t+s)$ does not depend on the current time t , only the length of the time interval s . A counting process is said to possess independent increments if the number of events in disjoint time intervals are independent.

For a stochastic process with independent increments, the autocovariance function is

$$\begin{aligned} \text{Cov}[X(t_1), X(t_2)] &= \begin{cases} \text{Var}[N(t_1+s) - N(t_2)] & \text{for } 0 < t_2 - t_1 < s \\ 0 & \text{otherwise} \end{cases}, \end{aligned}$$

where

$$X(t) = N(t+s) - N(t).$$

If $X(t)$ is Poisson-distributed, then the variance of the Poisson distribution is

$$\begin{aligned} \text{Cov}[X(t_1), X(t_2)] &= \begin{cases} \lambda [s - (t_2 - t_1)] & \text{for } 0 < t_2 - t_1 < s \\ 0 & \text{otherwise} \end{cases}. \end{aligned}$$

This result shows that the Poisson increment process is covariance stationary. We now present several properties of the Poisson process.

Property 8.1 The sum of independent Poisson processes $N_1(t), N_2(t), \dots, N_k(t)$ with mean values $\lambda_1 t, \lambda_2 t, \dots, \lambda_k t$, respectively, is also a Poisson process with mean $\left(\sum_{i=1}^k \lambda_i\right)t$. In other words, the sum of the independent Poisson processes is also a Poisson process with a mean that is equal to the sum of the means of the individual Poisson processes.

Property 8.2 The difference between two independent Poisson processes, $N_1(t)$ and $N_2(t)$, with mean $\lambda_1 t$ and $\lambda_2 t$, respectively, is not a Poisson process. Instead, it has a probability mass function of

$$\begin{aligned} P[N_1(t) - N_2(t) = k] \\ = e^{-(\lambda_1 + \lambda_2)t} \left(\frac{\lambda_1}{\lambda_2}\right)^{\frac{k}{2}} I_k(2\sqrt{\lambda_1 \lambda_2} t), \end{aligned}$$

where $I_k(\cdot)$ is a modified Bessel function of order k .

Property 8.3 If the Poisson process $N(t)$ with mean λt is filtered such that not every occurrence of the event is counted, then the process has a constant probability p of being counted. The result of this process is a Poisson process with mean $\lambda p t$.

Property 8.4 Let $N(t)$ be a Poisson process and Y_i a family of independent and identically distributed random variables which are also independent of $N(t)$. A stochastic process $X(t)$ is said to be a compound Poisson process if it can be represented as

$$X(t) = \sum_{i=1}^{N(t)} Y_i.$$

8.3.2 Renewal Processes

A renewal process is a more general case of the Poisson process in which the inter-arrival times of the process or the times between failures do not necessarily follow the exponential distribution. For convenience, we will call the occurrence of an event a renewal, the inter-arrival time the renewal period, and the waiting time the renewal time.

Definition 8.3 A counting process $N(t)$ that represents the total number of occurrences of an event in the time interval $(0, t]$ is called a renewal process if the times between the failures are independent and identically distributed random variables.

The probability that exactly n failures occur by time t can be written as

$$P[N(t) = n] = P[N(t) \geq n] - P[N(t) > n]. \quad (8.24)$$

Note that the times between the failures are T_1, T_2, \dots, T_n , so the failures occurring at time W_k are

$$W_k = \sum_{i=1}^k T_i$$

and

$$T_k = W_k - W_{k-1}.$$

Thus,

$$\begin{aligned} P[N(t) = n] &= P[N(t) \geq n] - P[N(t) > n] \\ &= P[W_n \leq t] - P[W_{n+1} \leq t] \\ &= F_n(t) - F_{n+1}(t), \end{aligned} \quad (8.25)$$

where $F_n(t)$ is the cumulative distribution function for the time of the n th failure and $n = 0, 1, 2, \dots$

Example 8.4 Consider a software testing model for which the time at which an error is found during the testing phase has an exponential distribution with a failure rate of X . It can be shown that the time of the n th failure follows the gamma distribution with parameters k and n . From Eq. (8.24), we obtain

$$\begin{aligned} P[N(t) = n] &= P[N(t) \leq n] - P[N(t) \leq n-1] \\ &= \sum_{k=0}^n \frac{(\lambda t)^k}{k!} e^{-\lambda t} - \sum_{k=0}^{n-1} \frac{(\lambda t)^k}{k!} e^{-\lambda t} \\ &= \frac{(\lambda t)^n}{n!} e^{-\lambda t} \text{ for } n = 0, 1, 2, \dots \end{aligned} \quad (8.26)$$

Several important properties of the renewal function are given below.

Property 8.5 The mean value function of the renewal process, denoted by $m(t)$, is equal to the sum of the distribution functions for all renewal times, that is,

$$\begin{aligned} m(t) &= E[N(t)] \\ &= \sum_{n=1}^{\infty} F_n(t). \end{aligned} \quad (8.27)$$

Property 8.6 The renewal function $m(t)$ satisfies the following equation:

$$m(t) = F_a(t) + \int_0^t m(t-s) dF_a(s), \quad (8.28)$$

where $F_a(t)$ is the distribution function of the inter-arrival time or the renewal period.

In general, let $y(t)$ be an unknown function to be evaluated and $x(t)$ be any non-negative and integrable function associated with the renewal process. Assume that $F_a(t)$ is the distribution function of the renewal period. We can then obtain the following result.

Property 8.7 Let the renewal equation be

$$y(t) = x(t) + \int_0^t y(t-s) dF_a(s). \quad (8.29)$$

Then its solution is given by

$$y(t) = x(t) + \int_0^t x(t-s) dm(s)$$

where $m(t)$ is the mean value function of the renewal process.

The proof of the above property can be easily derived using the Laplace transform. Let $x(t) = a$. Thus, in Property 8.7, the solution $y(t)$ is given by

$$\begin{aligned} y(t) &= x(t) + \int_0^t x(t-s) dm(s) \\ &= a + \int_0^t a dm(s) \\ &= a \{1 + E[N(t)]\}. \end{aligned}$$

8.3.3 Quasi-Renewal Processes

In this section we discuss a general renewal process: the quasi-renewal process. Let $\{N(t), t > 0\}$ be a counting process and let X_n be the time between the $(n-1)$ th and the n th event of this process, $n \geq 1$.

Definition 8.4 [2] If the sequence of non-negative random variables $\{X_1, X_2, \dots\}$ is independent and

$$X_i = \alpha X_{i-1} \quad (8.30)$$

for $i \geq 2$ where $\alpha > 0$ is a constant, then the counting process $\{N(t), t \geq 0\}$ is said to be a quasi-renewal process with parameter α and the first inter-arrival time X_1 .

When $\alpha = 1$, this process becomes the ordinary renewal process. This quasi-renewal process can be used to model reliability growth processes in software testing phases and hardware burn-in stages for $\alpha > 1$, and in hardware maintenance processes when $\alpha \leq 1$.

Assume that the probability density function (pdf), cumulative distribution function (cdf), survival function, and failure rate of random variable X_1 are $f_1(x)$, $F_1(x)$, $s_1(x)$ and

$r_1(x)$, respectively. Then the pdf, cdf, survival function, and failure rate of X_n for $n = 1, 2, 3, \dots$ are, respectively, given below [2]:

$$\begin{aligned} f_n(x) &= \frac{1}{\alpha^{n-1}} f_1\left(\frac{1}{\alpha^{n-1}}x\right), \\ F_n(x) &= F_1\left(\frac{1}{\alpha^{n-1}}x\right), \\ s_n(x) &= s_1\left(\frac{1}{\alpha^{n-1}}x\right), \\ r_n(x) &= \frac{1}{\alpha^{n-1}} r_1\left(\frac{1}{\alpha^{n-1}}x\right). \end{aligned} \quad (8.31)$$

Similarly, the mean and variance of X_n is given as

$$\begin{aligned} E(X_n) &= \alpha^{n-1} E(X_1), \\ \text{Var}(X_n) &= \alpha^{2n-2} \text{Var}(X_1). \end{aligned} \quad (8.32)$$

Because of the non-negativity of X_1 , and the fact that X_1 is not identically 0, we obtain

$$E(X_1) = \mu_1 \neq 0.$$

It is worth noting that the shape parameters for X_n are the same for $n = 1, 2, 3, \dots$ for a quasi-renewal process if X_1 follows the gamma, Weibull, or log normal distribution.

This means that the shape parameters of the inter-arrival time will not change after “renewal”. In software reliability, the assumption that the software debugging process does not change the error-free distribution seems reasonable. Thus, if a quasi-renewal process model is used, the error-free times that occur during software debugging will have the same shape parameters. In this sense, a quasi-renewal process is suitable for modeling the increase in software reliability. It is worth noting that

$$\begin{aligned} \lim_{n \rightarrow \infty} \frac{E(X_1 + X_2 + \dots + X_n)}{n} &= \lim_{n \rightarrow \infty} \frac{\mu_1 (1 - \alpha^n)}{(1 - \alpha) n} \\ &= \begin{cases} 0 & \text{if } \alpha < 1, \\ \infty & \text{if } \alpha > 1. \end{cases} \end{aligned} \quad (8.33)$$

Therefore, if the inter-arrival time represents the error-free time of a software system, then the average error-free time approaches infinity when its debugging process has been operating for a long debugging time.

Distribution of $N(t)$

Consider a quasi-renewal process with parameter α and a first inter-arrival time X_1 . Clearly, the total number of renewals $N(t)$ that occur up to time t has the following relationship to the arrival time of the n th renewal SS_n :

$$N(t) \geq n \quad \text{if and only if} \quad SS_n \leq t.$$

In other words, $N(t)$ is at least n if and only if the n th renewal occurs prior to time t . It is easily seen that

$$SS_n = \sum_{i=1}^n X_i = \sum_{i=1}^n \alpha^{i-1} X_1 \quad \text{for } n \geq 1. \quad (8.34)$$

Here, $SS_0 = 0$. Thus, we have

$$\begin{aligned} P\{N(t) = n\} &= P\{N(t) \geq n\} - P\{N(t) \geq n+1\} \\ &= P\{SS_n \leq t\} - P\{SS_{n+1} \leq t\} \\ &= G_n(t) - G_{n+1}(t), \end{aligned}$$

where $G_n(t)$ is the convolution of the inter-arrival times $F_1, F_2, F_3, \dots, F_n$. In other words,

$$G_n(t) = P\{F_1 + F_2 + \dots + F_n \leq t\}.$$

If the mean value of $N(t)$ is defined as the renewal function $m(t)$, then

$$\begin{aligned} m(t) &= E[N(t)] \\ &= \sum_{n=1}^{\infty} P\{N(t) \geq n\} \\ &= \sum_{n=1}^{\infty} P\{SS_n \leq t\} \\ &= \sum_{n=1}^{\infty} G_n(t). \end{aligned} \quad (8.35)$$

The derivative of $m(t)$ is known as the renewal density

$$\lambda(t) = m'(t).$$

In renewal theory, random variables representing inter-arrival distributions assume only non-negative values, and the Laplace transform of its distribution $F_1(t)$ is defined by

$$\mathcal{L}\{F_1(s)\} = \int_0^{\infty} e^{-sx} dF_1(x).$$

Therefore,

$$\mathcal{L}F_n(s) = \int_0^{\infty} e^{-\alpha^{n-1}st} dF_1(t) = \mathcal{L}F_1(\alpha^{n-1}s)$$

and

$$\begin{aligned} \mathcal{L}m_n(s) &= \sum_{n=1}^{\infty} \mathcal{L}G_n(s) \\ &= \sum_{n=1}^{\infty} \mathcal{L}F_1(s) \mathcal{L}F_1(\alpha s) \dots \mathcal{L}F_1(\alpha^{n-1}s). \end{aligned} \quad (8.36)$$

Since there is a one-to-one correspondence between distribution functions and its Laplace transform, it follows that the first inter-arrival distribution of a quasi-renewal process uniquely determines its renewal function.

If the inter-arrival time represents the error-free time (time to first failure), a quasi-renewal process can be used to model reliability growth in both software and hardware.

Suppose that all software faults have the same chance of being detected. If the inter-arrival time of a quasi-renewal process represents the error-free time of a software system, then the expected number of software faults in the time interval $[0, t]$ can be defined by the renewal function, $m(t)$, with parameter $\alpha > 1$. Denoted by $m_r(t)$, the number of remaining software faults at time t , it follows that

$$m_r(t) = m(T_c) - m(t),$$

where $m(T_c)$ is the number of faults that will eventually be detected through a software lifecycle T_c .

8.3.4 Nonhomogeneous Poisson Processes

The nonhomogeneous Poisson process model (NHPP), which represents the number of failures experienced up to time t , is a nonhomogeneous Poisson process $\{N(t) \text{ with } t \geq 0\}$. The main issue with the NHPP model is to determine an appropriate mean value function to denote the expected number of failures experienced up to a certain time.

Different assumptions mean that the model will end up with different functional forms of the mean value function. Note that the exponential assumption for the inter-arrival time between failures is relaxed in a renewal process, and the stationary assumption is relaxed in the NHPP.

The NHPP model is based on the following assumptions:

- The failure process has an independent increment; in other words, the number of failures during the time interval $(t, t+s)$ depends on the current time t and the length of the time interval s , and does not depend on the past history of the process.
- The failure rate of the process is given by

$$\begin{aligned} &P\{\text{exactly one failure in } (t, t+\Delta t)\} \\ &= P\{N(t+\Delta t) - N(t) = 1\} \\ &= \lambda(t)\Delta t + o(\Delta t), \end{aligned}$$

where $\lambda(t)$ is the intensity function.

- During a small interval Δt , the probability of more than one failure is negligible; that is,

$$P\{\text{two or more failures in } (t, t + \Delta t)\} = o(\Delta t),$$

- The initial condition is $N(0) = 0$.

Based on these assumptions, the probability that exactly n failures occur during the time interval $(0, t)$ for the NHPP is given by

$$\Pr\{N(t) = n\} = \frac{[m(t)]^n}{n!} e^{-m(t)} \quad n = 0, 1, 2, \dots, \quad (8.37)$$

where $m(t) = E[N(t)] = \int_0^t \lambda(s) ds$ and $\lambda(t)$ is the intensity function. It is easily shown that the mean value function $m(t)$ is nondecreasing.

The reliability $R(t)$, defined as the probability that there are no failures in the time interval $(0, t)$, is given by

$$R(t) = P\{N(t) = 0\} = e^{-m(t)}. \quad (8.38)$$

In general, the reliability $R(x | t)$ – the probability that there are no failures in the interval $(t, t + x)$ – is given by

$$R(x | t) = P\{N(t+x) - N(t) = 0\} = e^{-[m(t+x) - m(t)]}$$

and its density is given by

$$f(x) = \lambda(t+x) e^{-[m(t+x) - m(t)]},$$

where

$$\lambda(x) = \frac{\partial}{\partial x} [m(x)].$$

The variance of the NHPP can be obtained as follows:

$$\text{Var}[N(t)] = \int_0^t \lambda(s) ds$$

and the autocorrelation function is given by

$$\begin{aligned} \text{Cor}[s] &= E[N(t)] E[N(t+s) - N(t)] + E[N^2(t)] \\ &= \int_0^t \lambda(s) ds \int_0^{t+s} \lambda(s) ds + \int_0^t \lambda(s) ds \\ &= \int_0^t \lambda(s) ds \left[1 + \int_0^{t+s} \lambda(s) ds \right]. \end{aligned} \quad (8.39)$$

Example 8.5 Assume that the intensity λ is a random variable with pdf $f(\lambda)$. Then the probability that exactly n failures occur during the time interval $(0, t)$ is given by

$$P\{N(t) = n\} = \int_0^\infty e^{-\lambda t} \frac{(\lambda t)^n}{n!} f(\lambda) d\lambda. \quad (8.40)$$

If the pdf $f(\lambda)$ is given as the following gamma density function with parameters k and m :

$$f(\lambda) = \frac{1}{\Gamma(m)} k^m \lambda^{m-1} e^{-k\lambda} \quad \text{for } \lambda \geq 0 \quad (8.41)$$

then it can be shown that

$$P\{N(t) = n\} = \binom{n+m-1}{n} p^m q^n \quad n = 0, 1, 2, \dots \quad (8.42)$$

(this is also called a negative binomial density function), where

$$p = \frac{k}{t+k} \quad \text{and} \quad q = \frac{t}{t+k} = 1 - p. \quad (8.43)$$

8.4 Further Reading

The reader interested in a deeper understanding of advanced probability theory and stochastic processes should note the following citations, which refer to highly recommended books: Feller [3]; Pinsky and Karlin [4], Parzen [5], Melsa and Sage [6].

Appendix A: Laplace Transformation Functions

Let X be a nonnegative life time having probability density function f . The Laplace transform of a function $f(x)$, denote f^* , is defined as

$$\ell\{f(x)\} = f^*(s) = \int_0^\infty e^{-sx} f(x) dx \quad \text{for } s \geq 0. \quad (8.44)$$

The function f^* is called the Laplace transform of the function f . The symbol ℓ in Eq. (8.44) is called the Laplace transform operator. Note that $f^*(0) = 1$. By taking a differential derivative of $f^*(s)$, we obtain

$$\frac{\partial f^*(s)}{\partial s} = - \int_0^\infty x e^{-sx} f(x) dx.$$

Substitute $s = 0$ into the above equation, the first derivative of f^* , it yields the negative of the expected value of X or the first moment of X :

$$\left. \frac{\partial f^*(s)}{\partial s} \right|_{s=0} = -E(X).$$

Similarly, the second derivative yields the second moment of X when $s = 0$, that is,

$$\left. \frac{\partial f^*(s)}{\partial s} \right|_{s=0} = \int_0^\infty x^2 e^{-sx} f(x) dx \Big|_{s=0} = E(X^2).$$

In general, it can be shown that

$$\left. \frac{\partial^n f^*(s)}{\partial^n s} \right|_{s=0} = \int_0^\infty (-x)^n e^{-sx} f(x) dx \Big|_{s=0} = (-1)^n E(X^n)$$

Note that

$$e^{-sx} = \sum_{n=0}^\infty \frac{(-sx)^n}{n!}$$

then $f^*(s)$ can be rewritten as

$$f^*(s) = \sum_{n=0}^\infty \frac{(-s)^n}{n!} \mu_n,$$

where

$$\mu_n = (-1)^n \left. \frac{\partial^n f^*(s)}{\partial^n s} \right|_{s=0} = \int_0^\infty x^n e^{-sx} f(x) dx \Big|_{s=0} = E(X^n).$$

We can easily show that ℓ is a linear operator, that is

$$\ell \{c_1 f_1(x) + c_2 f_2(x)\} = c_1 \ell \{f_1(x)\} + c_2 \ell \{f_2(x)\}.$$

If $\ell\{f(t)\} = f^*(s)$, then we call $f(t)$ the inverse Laplace transform of $f^*(s)$ and write $\ell^{-1}\{f^*(s)\} = f(t)$. A summary of some common Laplace transform functions is listed in Table 8.1.

Example 8.6 Use the Laplace transforms to solve the following

$$\frac{\partial f(t)}{\partial t} + 3f(t) = e^{-t}, \tag{8.45}$$

with an initial condition: $f(0) = 0$. Obtain the solution $f(t)$. Here the Laplace transforms of $\frac{\partial f(t)}{\partial t}$, $f(t)$, and e^{-t} are

$$sf^*(s) - f(0), f^*(s), \text{ and } \frac{1}{s+1}$$

respectively. Thus, the Laplace transform of Eq. (8.45) is given by

$$sf^*(s) - f(0) + 3f^*(s) = \frac{1}{s+1}.$$

Since $f(0) = 0$ we have

$$(s+3)f^*(s) = \frac{1}{s+1} \text{ or } f^*(s) = \frac{1}{(s+1)(s+3)}.$$

Table 8.1 List of common Laplace transforms

$f(t)$	$\ell\{f(t)\} = f^*(s)$
$f^*(s)$	$f^*(s) = \int_0^\infty e^{-st} f(t) dt$
$\frac{\partial f(t)}{\partial t}$	$sf^*(s) - f(0)$
$\frac{\partial^2}{\partial t^2} [f(t)]$	$s^2 f^*(s) - sf(0) - \frac{\partial}{\partial t} f(0)$
$\frac{\partial^n}{\partial t^n} [f(t)]$	$s^n f^*(s) - s^{n-1} f(0) - \dots - \frac{\partial^{n-1}}{\partial t^{n-1}} f(0)$
$f(at)$	$\frac{1}{a} f^*\left(\frac{s}{a}\right)$
1	$\frac{1}{s}$
t	$\frac{1}{s^2}$
a	$\frac{a}{s}$
e^{-at}	$\frac{1}{s+a}$
te^{at}	$\frac{1}{(s-a)^2}$
$(1+at)e^{at}$	$\frac{s}{(s-a)^2}$
$\frac{1}{a} e^{-\frac{t}{a}}$	$\frac{1}{(1+sa)}$
t^p for $p > -1$	$\frac{\Gamma(p+1)}{s^{p+1}}$ for $s > 0$
t^n $n = 1, 2, 3, \dots$	$\frac{n!}{s^{n+1}}$ $s > 0$
$\frac{1}{a} (1 - e^{-at})$	$\frac{1}{s(s+a)}$
$\frac{1}{a} (e^{at} - 1)$	$\frac{1}{s(s-a)}$
$\frac{1}{a^2} (e^{-at} + at - 1)$	$\frac{1}{s^2(s+a)}$
$\frac{1}{b-a} (e^{-at} - e^{-bt})$	$\frac{1}{(s+a)(s+b)}$ $a \neq b$
$\frac{(ae^{at} - be^{bt})}{a-b}$	$\frac{s}{(s-a)(s-b)}$ $a \neq b$
$\frac{\alpha^k t^{k-1} e^{-\alpha t}}{\Gamma(k)}$	$\left(\frac{\alpha}{\alpha+s}\right)^k$

From Table 8.1, the inverse transform is

$$f(t) = \frac{1}{3-1} (e^{-t} - e^{-3t}) = \frac{1}{2} (e^{-t} - e^{-3t}). \tag{8.46}$$

Example 8.7 Let X be an exponential random variable with constant failure rate λ , that is, $f(x) = \lambda e^{-\lambda x}$ then we have

$$f^*(s) = \int_0^\infty \lambda e^{-sx} e^{-\lambda x} dx = \frac{\lambda}{s+\lambda}. \tag{8.47}$$

If X and Y are two independent random variables that represent life times with densities f_1 and f_2 , respectively, then the total life time's Z of those two X and Y , says $Z = X + Y$, has a pdf g that can be obtained as follows

$$g(z) = \int_0^z f_1(x) f_2(z-x) dx.$$

The Laplace transform of g in terms of f_1 and f_2 can be written as

$$\begin{aligned}
 g^*(s) &= \int_0^\infty e^{-sz} g(z) dz = \int_0^\infty \int_0^z e^{-sz} f_1(x) f_2(z-x) dx dz \\
 &= \int_0^\infty e^{-sx} f_1(x) dx \int_x^\infty e^{-s(z-x)} f_2(z-x) dz \\
 &= f_1^*(s) f_2^*(s).
 \end{aligned}
 \tag{8.48}$$

Example 8.8 If X and Y are both independent having the following pdfs: $f_1(x) = \lambda e^{-\lambda x}$ and $f_2(y) = \lambda e^{-\lambda y}$ for $x, y \geq 0$ and $\lambda \geq 0$ then we have

$$g^*(s) = f_1^*(s) f_2^*(s) = \left(\frac{\lambda}{s + \lambda} \right)^2.
 \tag{8.49}$$

From the Laplace transform Table 8.1, the inverse transform to solve for $g(z)$ is

$$g(z) = \frac{\lambda^2 t e^{-\lambda t}}{\Gamma(2)}$$

which is a special case of gamma pdf.

From Eq. (8.48), one can easily show the Laplace transform of the density function g_n of the total life time S_n of n independent life time's X_i with their pdf f_i for $i = 1, 2, \dots, n$, that

$$g_n^*(s) = f_1^*(s) f_2^*(s) \dots f_n^*(s) = \prod_{i=1}^n f_i^*(s)
 \tag{8.50}$$

If the pdf of n life time X_1, X_2, \dots, X_n are independent and identically distributed (i.i.d.) having a constant failure rate λ , then

$$g_n^*(s) = (f^*(s))^n = \left(\frac{\lambda}{s + \lambda} \right)^n.$$

From the Laplace transform table, we obtain the inverse transform for the solution function g as follows

$$g_n(z) = \frac{\lambda^n t^{n-1} e^{-\lambda t}}{\Gamma(n)}.
 \tag{8.51}$$

Abstract

Progressive censoring has received great attention in the last decades especially in life testing and reliability. This review highlights fundamental applications, related models, and probabilistic and inferential results for progressively censored data. Based on the fundamental models of progressive type I and type II censoring, we present related models like adaptive and hybrid censoring as well as, e.g., stress-strength and competing risk models for progressively censored data. Focusing on exponentially and Weibull distributed lifetimes, an extensive bibliography emphasizing recent developments is provided.

Keywords

Censoring models · Ordered data · Hybrid censoring · Exponential distribution · Weibull distribution · Exact statistical inference · Lifetime analysis · Reliability · Step-stress testing · Competing risks · Experimental design · Ageing notions

9.1 Introduction and Fundamental Models

Monograph-length accounts on progressive censoring methodology have been provided by Balakrishnan and Cramer [1] and Balakrishnan and Aggarwala [2], while detailed reviews are due to [3] and [4]. In particular, [1] provides an up-to-date account to progressive censoring including many references and detailed explanations. Therefore, we provide essentially the basic models and results in the following, accompanied by recent developments and references which are not covered in the mentioned monograph.

9.1.1 Basic Ideas of Progressive Censoring

According to [5], a progressively censored life testing experiment is conducted as follows. n items are put simultaneously on a test. At times $\tau_1 < \dots < \tau_m$, some items are randomly chosen among the surviving ones and removed from the experiment (see Fig. 9.1). In particular, at time τ_j , R_j items are withdrawn from the experiment. Originally, [5] had introduced two versions of progressive censoring, called type I and type II progressive censoring. In progressive type I censoring, the censoring times $\tau_1 < \dots < \tau_m$ are assumed to be fixed in advance (e.g., as prefixed inspection or maintenance times). For a better distinction, fixed censoring times are subsequently denoted by $T_1 < \dots < T_m$. Moreover, the censoring plan $\mathcal{R} = (R_1, \dots, R_m)$ is prespecified at the start of the life test. But, as failures occur randomly, it may happen that at some censoring time T_j , less than R_j items have survived. In that case, all the remaining items are withdrawn, and the life test is terminated at T_j . Notice that, due to this construction, observations beyond the largest censoring time T_m are possible. At this point, it is worth mentioning that the understanding of progressive type I censoring has changed over time. As has been noted in [6], the understanding of the term *progressive type I censoring* has been used differently after the publication of monograph [2] [see also 7]. Since then, right censoring has been considered as a feature of progressive type I censoring, that is, T_m is considered as a

termination time of the experiment (see Fig. 9.2). Therefore, in progressive type I censoring, we distinguish the initially planned censoring plan $\mathcal{R}^0 = (R_1^0, \dots, R_{m-1}^0)$ from the effectively applied one denoted by $\mathcal{R} = (R_1, \dots, R_{m-1})$. Notice that we drop the m th censoring number R_m in the plan since it is always random due to the right censoring. In order to distinguish these scenarios, [6] called the original scenario *Cohen's progressive censoring scheme with fixed censoring times*.

The second version of progressive censoring proposed by Cohen [5] is called progressive type II censoring which may be considered as the most popular version of progressive censoring. Here, the censoring times are induced by the lifetimes of the surviving units in the sense that the next withdrawal is carried out the first failure after the removal of items. Suppose the items are numbered by $1, \dots, n$ with lifetimes X_1, \dots, X_n and denote by the set \mathcal{R}_j the numbers of the items available before the j th removal. Then, the next removal time is defined by $X_{j:m:n} = \min_{i \in \mathcal{R}_j} X_i$ (see Fig. 9.3), $j = 1, \dots, m$. Clearly, $\mathcal{R}_1 = \{1, \dots, n\}$ and $X_{1:m:n} = X_{1:n}$ is given by the minimum of the lifetimes. Furthermore, $|\mathcal{R}_j| = n - j + 1 - \sum_{i=1}^{j-1} R_i = \gamma_j$, $j = 1, \dots, m$. The censoring times are iteratively constructed and random so that they are not known in advance (in contrast to the type I censoring scheme). However, the censoring plan and the sample size are fixed here. In fact, given n and m , the set of admissible progressive type II censoring plans is given by

Fig. 9.1 Progressive censoring scheme with censoring times $\tau_1 < \dots < \tau_m$ and censoring plan $\mathcal{R} = (R_1, \dots, R_m)$

Fig. 9.2 Progressive type I censoring with censoring times $T_1 < \dots < T_{m-1}$, time censoring at T_m , and initial censoring plan $\mathcal{R}^0 = (R_1^0, \dots, R_{m-1}^0)$

Fig. 9.3 Progressive type II censoring with censoring times $X_{1:m:n} < \dots < X_{m:m:n}$ and censoring plan $\mathcal{R} = (R_1, \dots, R_m)$

Fig. 9.4 Progressive interval censoring with censoring times $T_1 < \dots < T_m$, initial censoring plan $\mathcal{R}^0 = (R_1^0, \dots, R_m^0)$, and random counters D_1, \dots, D_{m+1}

$$\mathcal{C}_{m,n}^m = \left\{ (r_1, \dots, r_m) \in \mathbb{N}_0^m : \sum_{i=1}^m r_i = n - m \right\}. \quad (9.1)$$

Based on the above fundamental models, further versions of progressive censoring have been proposed. Progressive type I interval censoring uses only partial information from a progressively type I censored life test. In particular, it is assumed that only the number D_j of items failing in an interval $(T_{j-1}, T_j]$ is known (see Fig. 9.4 for Cohen’s progressive censoring with fixed censoring times). The corresponding situation under type I right censoring is depicted in Fig. 9.5.

The above censoring schemes have been extended in various directions. For instance, a wide class of models called progressive hybrid censoring has been generated by combining type I and type II censoring procedures. In type I progressive hybrid censoring, a type I censoring mechanism has been applied to progressively type II censored data $X_{1:m:n}, \dots, X_{m:m:n}$ by Childs et al. [8] [see also 9, 10], extending a model of [11] by introducing a threshold T . The resulting time censored data $X_{j:m:n}^{h,I} = \min\{X_{j:m:n}, T\}$, $j = 1, \dots, m$, will be discussed further in Sect. 9.4.2. Considering the so-called extended progressively type II censored sample by dropping the right censoring (see (9.15)), that is,

$X_{1:m+R_m:n}, \dots, X_{m+R_m:m+R_m:n}$, a type II progressively hybrid censored sample can be defined by the condition $X_{K:m+R_m:n} \leq T < X_{K+1:m+R_m:n}$, $m \leq K \leq m + R_m$. Further versions have been summarized in [12]. An extensive survey on (progressive) hybrid censoring schemes is provided in the recent monograph by [380].

Motivated by the Ng-Kundu-Chan model introduced in [13], adaptive progressive censoring schemes have been proposed by Cramer and Iliopoulos [14] and Cramer and Iliopoulos [15]. In these models, censoring plans and censoring times may be chosen adaptively according to the observed data. Such models are presented briefly in Sect. 9.4.3.

In most cases, progressive censoring is studied under the assumption that the underlying lifetimes X_1, \dots, X_n are independent and identically distributed (iid) random variables. If not noted explicitly, all results presented in the following are based on this assumption. However, relaxations of this assumption have been made. For instance, [16] discussed the case of heterogeneous distributions, that is, $X_i \sim F_i$, $1 \leq i \leq n$, are independent random variables but may have a different cumulative distribution function (see also [17, 18]). Rezapour et al. [19, 20] assumed dependent underlying lifetimes. For a review, we refer to [1, Chapter 10].

Notation	Explanation
cdf	Cumulative distribution function
pdf	(Probability) density function
iid	Independent and identically distributed
BLUE	Best linear unbiased estimator
MLE	Maximum likelihood estimator
UMVUE	Uniformly minimum variance unbiased estimator
PHR model	Proportional hazard rates model
\mathbb{R}	Set of real numbers
\mathbb{N}, \mathbb{N}_0	Set of positive and nonnegative integers, respectively
F^{\leftarrow}	Quantile function of a cdf F
$\mathbb{I}_A(t)$	Indicator function for a set A ; $\mathbb{I}_A(t) = 1$ for $t \in A$, $\mathbb{I}_A(t) = 0$, otherwise
$\stackrel{d}{=}$	Identical in distribution
\mathbf{x}_m	$\mathbf{x}_m = (x_1, \dots, x_m)$
$\mathbf{x}_n \wedge \mathbf{y}_n$	$\mathbf{x}_n \wedge \mathbf{y}_n = (\min(x_1, y_1), \dots, \min(x_n, y_n))$
$\mathbf{x}_n \vee \mathbf{y}_n$	$\mathbf{x}_n \vee \mathbf{y}_n = (\max(x_1, y_1), \dots, \max(x_n, y_n))$
$[x]_+$	$\max(x, 0)$
$d_{\bullet m}$	$d_{\bullet m} = \sum_{i=1}^m d_i$ for $d_1, \dots, d_m \in \mathbb{R}$
\mathcal{R}	Censoring plan $\mathcal{R} = (R_1, \dots, R_m)$ with censoring numbers R_1, \dots, R_m
$\mathcal{C}_{m,n}^m$	Set of admissible (progressive type II) censoring plans defined in (9.1)
$(\gamma_1, \dots, \gamma_m)$	$\gamma_i = \sum_{j=i}^m (R_j + 1)$, $1 \leq i \leq m$, for a censoring plan $\mathcal{R} = (R_1, \dots, R_m)$
$X_{1:m:n}, \dots, X_{m:m:n}, X_{1:m:n}^{\mathcal{R}}, \dots, X_{m:m:n}^{\mathcal{R}}$	Progressively type II censored order statistics based on a sample X_1, \dots, X_n and censoring plan \mathcal{R}
$\mathbf{X}^{\mathcal{R}}$	$\mathbf{X}^{\mathcal{R}} = (X_{1:m:n}^{\mathcal{R}}, \dots, X_{m:m:n}^{\mathcal{R}})$
$U_{1:m:n}, \dots, U_{m:m:n}$	Uniform progressively type II censored order statistics
$X_{1:K:n}^I, \dots, X_{K:K:n}^I$	Progressively type I censored order statistics or progressively censored order statistics with fixed censoring times based on a sample X_1, \dots, X_n
$\mathbf{X}^{I, \mathcal{R}}$	$\mathbf{X}^{I, \mathcal{R}} = (X_{1:K:n}^I, \dots, X_{K:K:n}^I)$
$X_{1:n}, \dots, X_{n:n}$	Order statistics based on a sample X_1, \dots, X_n
$\text{Exp}(\mu, \vartheta)$	Two-parameter exponential distribution with pdf $f(t) = \frac{1}{\vartheta} e^{-(t-\mu)/\vartheta}$, $t > \mu$
$\text{Exp}(\vartheta) = \text{Exp}(0, \vartheta)$	Exponential distribution with mean ϑ and pdf $f(t) = \frac{1}{\vartheta} e^{-t/\vartheta}$, $t > 0$
F_{exp}	cdf of standard exponential distribution $\text{Exp}(1)$; $F_{\text{exp}}(t) = 1 - e^{-t}$, $t \geq 0$
$\text{Wei}(\vartheta, \beta)$	Weibull distribution with parameters $\vartheta, \beta > 0$ and pdf $f(t) = \frac{\beta}{\vartheta} t^{\beta-1} e^{-t^\beta/\vartheta}$, $t > 0$
$U(0, 1)$	Uniform distribution on the interval $(0, 1)$
$\chi^2(r)$	χ^2 -distribution with r degrees of freedom
$X \sim F$	X is distributed according to a cdf F
$X_1, \dots, X_n \stackrel{\text{iid}}{\sim} F$	X_1, \dots, X_n are independent and identically distributed according to a cdf F

9.1.2 Notation

Throughout, we use the following notation and abbreviations.

9.1.3 Organization of the Paper

In the following sections, we discuss the most popular versions of progressive censoring in detail, that is, progressive type II censoring (Sect. 9.2) and progressive type I censoring (Sect. 9.3). Further, progressive censoring with fixed censoring times is also addressed in Sect. 9.3. In Sect. 9.4, related data like progressive interval censoring, progressive hybrid censoring, and adaptive progressive censoring as well as applications in reliability and lifetime analysis are discussed. Due to their importance, we focus on exponentially and

Weibull distributed lifetimes. Except when otherwise stated, the underlying lifetimes X_1, \dots, X_n are supposed to be independent and identically distributed according to a cdf F , that is, $X_1, \dots, X_n \stackrel{\text{iid}}{\sim} F$.

9.2 Progressive Type II Censoring

9.2.1 Probabilistic Results

Fundamental tools in studying properties of progressively type II censored order statistics are the joint pdf of $X_{1:m:n}, \dots, X_{m:m:n}$ and the quantile representation. The joint pdf of progressively type II censored order statistics $X_{1:m:n}, \dots, X_{m:m:n}$ based on an (absolutely continuous) cdf F with pdf f is given by

Fig. 9.5 Progressive type I interval censoring with censoring times $T_1 < \dots < T_{m-1}$, time censoring at T_m , initial censoring plan $\mathcal{R}^0 = (R_1^0, \dots, R_{m-1}^0)$, and random counters D_1, \dots, D_m

$$f^{X^{\mathcal{R}}}(\mathbf{x}_m) = \begin{cases} \prod_{j=1}^m [\gamma_j f(x_j)(1 - F(x_j))^{R_j}], & x_1 \leq \dots \leq x_m \\ 0, & \text{otherwise} \end{cases} \quad (9.2)$$

where $\gamma_j = \sum_{i=j}^m (R_i + 1)$ denotes the number of items remaining in the experiment before the j th failure, $1 \leq j \leq m$. Notice that $n = \gamma_1 > \dots > \gamma_m \geq 1$. It is immediate from (9.2) that progressively type II censored order statistics are connected to the distributional model of generalized order statistics (see [21–23]) which covers progressively type II censored order statistics as a particular case (for details, see [1], Section 2.2).

Exponential Distributions

From (9.2), the pdf for an exponential population $\text{Exp}(\mu, \vartheta)$ can be directly obtained, that is, the pdf of exponential progressively type II censored order statistics $\mathbf{X}^{\mathcal{R}} = (X_{1:m:n}, \dots, X_{m:m:n})$ is given by

$$f^{X^{\mathcal{R}}}(\mathbf{x}_m) = \frac{1}{\vartheta^m} \left(\prod_{j=1}^m \gamma_j \right) \exp\left(-\frac{1}{\vartheta} \sum_{j=1}^m (R_j + 1)(x_j - \mu)\right),$$

$$\mu \leq x_1 \leq \dots \leq x_m.$$

This expression is important in deriving, e.g., properties of exponential progressively type II censored order statistics as well as in developing statistical inference. As pointed out by Thomas and Wilson [24] (see also [25]), the normalized spacings $S_j^{\mathcal{R}} = \gamma_j(X_{j:m:n} - X_{j-1:m:n})$, $1 \leq j \leq m$, with $X_{0:m:n} = \mu$ defined as left endpoint of support are iid random variables, that is (see [1], Theorem 2.3.2),

$$S_1^{\mathcal{R}}, \dots, S_m^{\mathcal{R}} \stackrel{\text{iid}}{\sim} \text{Exp}(\vartheta). \quad (9.3)$$

On the other hand, exponential progressively type II censored order statistics can be written in terms of their spacings yielding the identity

$$X_{r:m:n} = \mu + \sum_{i=1}^r \frac{1}{\gamma_i} S_i^{\mathcal{R}} = X_{r-1:m:n} + \frac{1}{\gamma_r} S_r^{\mathcal{R}}, \quad 1 \leq r \leq m, \quad (9.4)$$

where $X_{0:m:n} = \mu$. This representation allows us to derive many properties of exponential progressively type II censored order statistics. For instance, using (9.3) and (9.4), the one-dimensional marginal pdfs and cdfs are given by (see also [26])

$$f^{X_{r:m:n}}(t) = \left(\prod_{j=1}^r \gamma_j \right) \sum_{j=1}^r a_{j,r} e^{-\gamma_j t},$$

$$F^{X_{r:m:n}}(t) = 1 - \left(\prod_{i=1}^r \gamma_i \right) \sum_{j=1}^r \frac{1}{\gamma_j} a_{j,r} e^{-\gamma_j t}, \quad t > 0,$$

where $a_{j,r} = \prod_{\substack{i=1 \\ i \neq j}}^r \frac{1}{\gamma_i - \gamma_j}$, $1 \leq j \leq r \leq n$. Representations of bivariate and arbitrary marginals can be found in [1, Section 2.4], (see also [27, 28]). Moreover, it follows from (9.4) that $X_{1:m:n}, \dots, X_{m:m:n}$ form a Markov chain, that is, for $2 \leq r \leq m$,

$$X_{r:m:n} \mid (X_{r-1:m:n} = x_{r-1}, \dots, X_{1:m:n} = x_1)$$

$$\stackrel{d}{=} X_{r:m:n} \mid (X_{r-1:m:n} = x_{r-1})$$

$$\stackrel{d}{=} \frac{1}{\gamma_r} S_r^{\mathcal{R}} + x_{r-1} \sim \text{Exp}(x_r, \vartheta / \gamma_r).$$

Furthermore, $X_{1:m:n} \stackrel{d}{=} \text{Exp}(\mu, \vartheta / \gamma_1)$. These representations allow direct calculation of moments. For instance, one gets

$$EX_{r:m:n} = \mu + \vartheta \sum_{j=1}^r \frac{1}{\gamma_j}, \quad \text{Var } X_{r:m:n} = \vartheta^2 \sum_{j=1}^r \frac{1}{\gamma_j^2},$$

$$\text{Cov}(X_{r:m:n}, X_{s:m:n}) = \text{Var } X_{r:m:n} = \vartheta^2 \sum_{j=1}^r \frac{1}{\gamma_j^2}, \quad 1 \leq r \leq s \leq m. \quad (9.5)$$

Further results on moments, e.g., higher order moments, existence of moments, bounds, and recurrence relations, can be found in [1] and the references cited therein.

Other Distributions

Probabilistic results for other distributions can be obtained from the pdf in (9.2) or, alternatively, from the results obtained for the exponential distribution and the following result due to [29,30] (for a proof, see [1]). It shows that most of the distributional results can be obtained for a uniform distribution and then transformed to an arbitrary cdf F .

Theorem 9.2.1 *Suppose $X_{1:m:n}, \dots, X_{m:m:n}$ and $U_{1:m:n}, \dots, U_{m:m:n}$ are progressively type II censored order statistics based on a cdf F and a uniform distribution, respectively. Then,*

$$(X_{j:m:n})_{1 \leq j \leq m} \stackrel{d}{=} (F^{\leftarrow}(U_{j:m:n}))_{1 \leq j \leq m}.$$

Theorem 9.2.1, together with the representation of the joint pdf for uniform distributions, yields an expression for progressively type II censored order statistics based on an arbitrary cdf F , that is,

$$F^{X_{r:m:n}}(t) = 1 - \left(\prod_{i=1}^r \gamma_i \right) \sum_{j=1}^r \frac{1}{\gamma_j} a_{j,r} (1 - F(t))^{\gamma_j}, \quad t \in \mathbb{R}.$$

If F is absolutely continuous with pdf f , then the pdf is given by

$$f^{X_{r:m:n}}(t) = \left(\prod_{j=1}^r \gamma_j \right) f(t) \sum_{j=1}^r a_{j,r} (1 - F(t))^{\gamma_j - 1}, \quad t \in \mathbb{R}.$$

Similar representations can be obtained for multiple progressively type II censored samples (see [1], p.41, [28,31]). Log-concavity and unimodality properties of the distributions are studied in [32–36].

From (9.4), it follows that $F_{\text{exp}}(X_{r:m:n}) = 1 - \prod_{j=1}^r (e^{-S_j^{\mathcal{R}}/\vartheta})^{1/\gamma_j}$ with $S_1^{\mathcal{R}}, \dots, S_m^{\mathcal{R}}$ as in (9.3). Thus, $U_j = e^{-S_j^{\mathcal{R}}/\vartheta}$, $1 \leq j \leq m$, are independent uniformly distributed random variables. This yields the identity

$$U_{r:m:n} \stackrel{d}{=} 1 - \prod_{j=1}^r U_j^{1/\gamma_j}, \quad 1 \leq r \leq m,$$

of $U_{r:m:n}$ as a product of independent random variables. Combining this expression with the quantile representation from Theorem 9.2.1, we arrive at the following representation [see also 37].

Theorem 9.2.2 *Let $X_{1:m:n}, \dots, X_{m:m:n}$ be progressively type II censored order statistics from an arbitrary cdf F and $U_1, \dots, U_m \stackrel{iid}{\sim} U(0, 1)$. Then,*

$$X_{1:m:n}, \dots, X_{m:m:n} \stackrel{d}{=} F^{\leftarrow} \left(1 - \prod_{j=1}^r U_j^{1/\gamma_j} \right), \quad 1 \leq r \leq m.$$

As has been noticed in [38], this representation provides an alternative method to simulate progressively type II censored order statistics from a cdf F (for a survey on simulation methods, see [1, Chapter 8]). Alternatively, one can also write

$$X_{r:m:n} \stackrel{d}{=} F^{\leftarrow} \left(F_{\text{exp}} \left(\sum_{j=1}^r \frac{1}{\gamma_j} Z_j \right) \right), \quad 1 \leq r \leq m,$$

with $Z_1, \dots, Z_m \stackrel{iid}{\sim} \text{Exp}(1)$. This result illustrates that $X_{1:m:n}, \dots, X_{m:m:n}$ form a Markov chain with transition probabilities

$$P(X_{r:m:n} \leq t \mid X_{r-1:m:n} = s) = 1 - \left(\frac{1 - F(t)}{1 - F(s)} \right)^{\gamma_r}, \quad s \leq t \text{ with } F(s) < 1.$$

Further results on the dependence structure of progressively type II censored order statistics are available. For instance, [28] has shown that progressively type II censored order statistics exhibit the MTP₂-property which implies that progressively type II censored order statistics are always positively correlated. The block independence property has been established by Iliopoulos and Balakrishnan [39]. In order to formulate the result, we introduce the number of progressively type II censored order statistics that do not exceed a threshold T , i.e., $D = \sum_{j=1}^m \mathbb{I}_{(-\infty, T]}(X_{j:m:n})$. Then, the probability mass function of D is given by the probabilities

$$\begin{aligned} P(D = 0) &= (1 - F(T))^n, \\ P(D = d) &= \left(\prod_{i=1}^d \gamma_i \right) \sum_{j=1}^{d+1} a_{j,d+1} (1 - F(T))^{\gamma_j}, \quad d = 1, \dots, m - 1, \\ P(D = m) &= F^{X_{m:m:n}}(T). \end{aligned}$$

Given $d \in \{1, \dots, m - 1\}$, a cdf F , and a censoring plan $\mathcal{R} = (R_1, \dots, R_m)$, the block independence property is as follows: Conditionally on $D = d$, the random vectors $(X_{1:m:n}, \dots, X_{d:m:n})$ and $(X_{d+1:m:n}, \dots, X_{m:m:n})$ are independent with

$$\begin{aligned} (X_{1:m:n}, \dots, X_{d:m:n}) &\stackrel{d}{=} (V_{1:d:\kappa_d}^{K_d}, \dots, V_{d:d:\kappa_d}^{K_d}), \\ (X_{d+1:m:n}, \dots, X_{m:m:n}) &\stackrel{d}{=} (W_{1:m-d:\gamma_d}, \dots, W_{m-d:m-d:\gamma_d}) \end{aligned} \tag{9.6}$$

where $\mathbf{K}_d = (K_1, \dots, K_d)$ is a random censoring plan on the Cartesian product $\prod_{j=1}^d \{0, \dots, R_j\}$ with probability mass function

$$p^{\mathbf{K}_d}(\mathbf{k}_d) = \frac{1}{P(D=d)} F^{\eta_1(d)}(T) (1-F(T))^{n-\eta_1(d)} \prod_{i=1}^d \frac{\gamma_i}{\eta_i(d)} \binom{R_i}{k_i},$$

$\kappa_d = \sum_{j=1}^d (1 + K_j)$, and $\eta_i(d) = \sum_{j=i}^d (k_j + 1)$, $1 \leq i \leq d$.
Further:

1. V_1, \dots, V_n are iid random variables with right truncated cdf F_T given by $F_T(t) = \frac{F(t)}{F(T)}$, $t \leq T$.
2. W_1, \dots, W_{γ_d} are iid random variables with left truncated cdf G_T given by $G_T(t) = 1 - \frac{1-F(t)}{1-F(T)}$, $t \geq T$.

The sample size κ_d of the progressively type II censored order statistics $V_{1:d:\kappa_d}^{\mathbf{K}_d}, \dots, V_{d:d:\kappa_d}^{\mathbf{K}_d}$ is a random variable. The above representation means that the distribution of $(X_{1:m:n}, \dots, X_{d:m:n})$, given $D = d$, is a mixture of distributions of progressively type II censored order statistics with mixing distribution $p^{\mathbf{K}_d}$. It is well known that right truncation of progressively type II censored order statistics does not result in progressively type II censored order statistics from the corresponding right truncated distribution [see, e.g., 2]. This is due to the fact that those observations (progressively) censored before T could have values larger than T .

Connection to Order Statistics and Other Models of Ordered Data

Order statistics [see, e.g., 40, 41] can be interpreted as special progressively type II censored order statistics by choosing the censoring plan $\mathcal{O} = (0, \dots, 0)$. Then, we have $m = n$ and $X_{j:n}^{\mathcal{O}} = X_{j:n}$, $1 \leq j \leq n$. Furthermore, the censoring plan $\mathcal{O}^* = (0, \dots, 0, R_m)$ with $n = m + R_m$ yields $X_{j:m:n}^{\mathcal{O}^*} = X_{j:m+R_m}$, $1 \leq j \leq m$, leading to a type II right censored sample. Thus, all the results developed for progressively type II censored order statistics can be specialized to order statistics. Detailed accounts to order statistics are provided by Arnold et al. [40] and David and Nagaraja [41].

As mentioned above, progressively type II censored order statistics can be seen as particular generalized order statistics and sequential order statistics, respectively (see [21, 23, 37]). In this regard, results obtained in these models hold also for progressively type II censored order statistics by specifying model parameters and distributions suitably. For pertinent details, we refer to the references given above.

Moments

Many results on moments have been obtained for progressively type II censored order statistics (see, e.g., [1], Chapter 7). This discussion includes explicit results for selected distributions, e.g., exponential distributions (see (9.5)), Weibull, Pareto, Lomax, reflected power, and extreme value distributions. Further topics are existence of moments (see [42, 43]), bounds (see, e.g., [32, 44, 45]), recurrence relations (see, e.g., [27, 46]), and approximations (see, e.g., [47]). Furthermore, the accurate computation of moments

has been discussed in [48] (see also [49]). It should be noted that an enormous number of papers have discussed moments as well as related recurrence relations for particular distributions.

Stochastic Orders and Stochastic Comparisons

Results on various stochastic orders of progressively type II censored order statistics have been mostly established in terms of generalized and sequential order statistics (see [1], Section 3.2). Therefore, the results can be applied to progressively type II censored order statistics by choosing particular parameter values. For information, we present definitions of the most important stochastic orders discussed for progressively type II censored order statistics. For a general discussion, we refer to [50, 51], and [52]. A review of results on multivariate stochastic orderings for generalized order statistics is provided in [53] (see also [1]).

Let $X \sim F$, $Y \sim G$ be random variables and let f and g denote the respective pdfs. For simplicity, it is assumed that the supports are subsets of the set of positive values. In the following, we present some selected results on stochastic orderings under progressive type II censoring and provide references for further reading.

Stochastic Order/Multivariate Stochastic Order

- (i) X is said to be stochastically smaller than Y , that is, $X \leq_{st} Y$ or $F \leq_{st} G$, iff $\bar{F}(x) \leq \bar{G}(x)$ for all $x \geq 0$.
- (ii) Let $\mathbf{X} = (X_1, \dots, X_n)'$, $\mathbf{Y} = (Y_1, \dots, Y_n)'$ be random vectors. Then, \mathbf{X} is said to be stochastically smaller than \mathbf{Y} , that is, $\mathbf{X} \leq_{st} \mathbf{Y}$ or $F^{\mathbf{X}} \leq_{st} F^{\mathbf{Y}}$, iff $E\phi(\mathbf{X}) \leq E\phi(\mathbf{Y})$ for all nondecreasing functions $\phi : \mathbb{R}^n \rightarrow \mathbb{R}$ provided the expectations exist.

Notice that, for $n = 1$, the definition of the multivariate stochastic order is equivalent to the (common) definition in the univariate case.

Belzunce et al. [54] has established the preservation of the stochastic order when the baseline distributions are stochastically ordered.

Theorem 9.2.3 *Let $\mathbf{X}^{\mathcal{R}}$ and $\mathbf{Y}^{\mathcal{R}}$ be vectors of progressively type II censored order statistics from continuous cdfs F and G with censoring plan \mathcal{R} , respectively. Then, for $F \leq_{st} G$, $\mathbf{X}^{\mathcal{R}} \leq_{st} \mathbf{Y}^{\mathcal{R}}$.*

A comparison in terms of the univariate stochastic order has been established by Khaledi [55] using the following partial ordering of γ -vectors (see [56, 57]). Let \mathcal{R} and \mathcal{S} be censoring plans with corresponding γ -values $\gamma_i(\mathcal{R}) = \sum_{k=i}^{m_1} (R_k + 1)$ and $\gamma_i(\mathcal{S}) = \sum_{k=i}^{m_2} (S_k + 1)$. For $1 \leq j \leq i$,

$$(\gamma_1(\mathcal{S}), \dots, \gamma_j(\mathcal{S})) \leq_p (\gamma_{i-j+1}(\mathcal{R}), \dots, \gamma_i(\mathcal{R})) \quad (9.7)$$

iff

$$\prod_{k=1}^{\ell} \gamma_{i-k+1}(\mathcal{R}) \leq \prod_{k=1}^{\ell} \gamma_k(\mathcal{S}) \text{ for } \ell = 1, \dots, j.$$

Theorem 9.2.4 Let F, G be continuous cdfs with $F \leq_{st} G$ and $X \sim F, Y \sim G$. Moreover, let $\mathcal{R} \in \mathcal{C}_{m_1, n_1}^{m_1}, \mathcal{S} \in \mathcal{C}_{m_2, n_2}^{m_2}$ with $m_1, m_2 \in \mathbb{N}$ be censoring plans. Then:

- (i) $X_{i:m_1:m_1}^{\mathcal{R}} \leq_{st} Y_{i:m_1:m_1}^{\mathcal{R}}, 1 \leq i \leq m_1$.
- (ii) If $1 \leq j \leq i$ and condition (9.7) holds, then $X_{j:m_2:m_2}^{\mathcal{S}} \leq_{st} Y_{i:m_1:m_1}^{\mathcal{R}}$.

Applications to stochastic ordering of spacings of progressively type II censored order statistics can be found in [58].

Failure Rate/Hazard Rate Order, Reversed Hazard Rate Order

- (i) X is said to be smaller than Y in the hazard rate order, that is, $X \leq_{hr} Y$ or $F \leq_{hr} G$, iff $\bar{F}(x)\bar{G}(y) \leq \bar{F}(y)\bar{G}(x)$ for all $0 \leq y \leq x$.
- (ii) X is said to be smaller than Y in the reversed hazard rate order, that is, $X \leq_{rh} Y$ or $F \leq_{rh} G$, iff $F(x)G(y) \leq F(y)G(x)$ for all $0 \leq y \leq x$.

For the hazard rate order, the ratio $\frac{\bar{F}(x)}{\bar{G}(x)}$ is nonincreasing in $x \geq 0$ where $\frac{a}{0}$ is defined to be ∞ . If F and G are absolutely continuous cdfs with pdfs f and g , respectively, then hazard rate ordering is equivalent to increasing hazard rates, that is,

$$\lambda_F(x) = \frac{f(x)}{1 - F(x)} \leq \frac{g(x)}{1 - G(x)} = \lambda_G(x) \text{ for all } x \geq 0.$$

For the reversed hazard rate order, the ratio $\frac{F(x)}{G(x)}$ is nonincreasing in $x \geq 0$, where $\frac{a}{0}$ is defined to be ∞ .

Results for (multivariate) hazard rate orders of progressively type II censored order statistics have been obtained by Belzunce et al. [54], Khaledi [55], and Hu and Zhuang [59]. For instance, replacing the stochastic order by the hazard rate order in Theorem 9.2.4, an analogous result is true (see [1, Theorem 3.2.3]).

Likelihood Ratio Order/Multivariate Likelihood Ratio Order

- (i) X is said to be smaller than Y in the likelihood ratio order, that is, $X \leq_{lr} Y$ or $F \leq_{lr} G$, iff $f(x)g(y) \leq f(y)g(x)$ for all $0 \leq y \leq x$.
- (ii) Let $\mathbf{X} = (X_1, \dots, X_n)'$, $\mathbf{Y} = (Y_1, \dots, Y_n)'$ be random vectors with pdfs f^X and f^Y . Then, \mathbf{X} is said to be smaller than \mathbf{Y} in the multivariate likelihood ratio order, that is, $\mathbf{X} \leq_{lr} \mathbf{Y}$ or $F^X \leq_{lr} F^Y$, iff

$$f^X(\mathbf{x}_n)f^Y(\mathbf{y}_n) \leq f^X(\mathbf{x}_n \wedge \mathbf{y}_n)f^Y(\mathbf{x}_n \vee \mathbf{y}_n)$$

for all $\mathbf{x} = (x_1, \dots, x_n)', \mathbf{y} = (y_1, \dots, y_n)' \in \mathbb{R}^n$.

The (multivariate) likelihood ratio order has been discussed, e.g., by Korwar [60], Hu and Zhuang [59], Cramer et al. [61], Belzunce et al. [54], Zhuang and Hu [62], Balakrishnan et al. [63], Sharafi et al. [64], and Arriaza et al. [65]. The following result is due to [60] (see [59] for generalized order statistics).

Theorem 9.2.5 Let $\mathcal{R} \in \mathcal{C}_{m_1, n_1}^{m_1}, \mathcal{S} \in \mathcal{C}_{m_2, n_2}^{m_2}$ with $m_1, m_2 \in \mathbb{N}$ be censoring plans and $X_{j:m_2:m_2}^{\mathcal{S}}, X_{i:m_1:m_1}^{\mathcal{R}}$ be progressively type II censored order statistics from the same absolutely continuous cdf F . If $1 \leq j \leq i$ and $\gamma_k(\mathcal{R}) \leq \gamma_k(\mathcal{S}), k = 1, \dots, j$, then $X_{j:m_2:m_2}^{\mathcal{S}} \leq_{lr} X_{i:m_1:m_1}^{\mathcal{R}}$.

Comparisons of vectors of progressively type II censored order statistics (generalized order statistics) with different cdfs and different censoring plans have been considered in [54]. In particular, they found the following property.

Theorem 9.2.6 Let $X_{i:m:n}^{\mathcal{R}}, Y_{i:m:n}^{\mathcal{R}}, 1 \leq i \leq m \leq n$, be progressively type II censored order statistics from absolutely continuous cdfs F and G , respectively, with $F \leq_{lr} G$ and censoring plan \mathcal{R} . Then, $X_{i:m:n}^{\mathcal{R}} \leq_{lr} Y_{i:m:n}^{\mathcal{R}}, 1 \leq i \leq m$.

Ordering of p -spacings is discussed in [54, 66–68].

Dispersive Order X is said to be smaller than Y in the dispersive order, i.e., $X \leq_{disp} Y$ or $F \leq_{disp} G$, iff $F^{\leftarrow}(x) - F^{\leftarrow}(y) \leq G^{\leftarrow}(x) - G^{\leftarrow}(y)$ for all $0 < y < x < 1$.

Results for the (multivariate) dispersive order are established in [55, 69–71]. For instance, [55] has shown a result as in Theorem 9.2.4 for the dispersive order provided that the cdf F has the DFR-property. Belzunce et al. [54] have shown that $X^{\mathcal{R}} \leq_{disp} Y^{\mathcal{R}}$ and that $X_{i:m:n}^{\mathcal{R}} \leq_{disp} Y_{i:m:n}^{\mathcal{R}}, 1 \leq i \leq m$, when $F \leq_{disp} G$.

Further orderings like mean residual life, total time on test, and excess wealth orders have also been discussed (see [72–75]). Results for the increasing convex order of generalized order statistics have been established in [76]. Orderings of residual life are discussed in [77, 78]. Stochastic orderings of INID progressively type II censored order statistics have been studied in [79].

Ageing Notions

Ageing properties have also been studied for progressively type II censored order statistics. For general references on ageing notions and their properties, we refer to, e.g., [80–82]. Results have been obtained for various ageing notions, e.g., increasing/decreasing failure rate (IFR/DFR), increasing/

decreasing failure rate on average (IFRA/DFRA), and new better/worse than used (NBU/NWU). Fundamental results on progressively type II censored order statistics for the most common ageing notions are mentioned subsequently.

IFR/DFR A cdf F is said to be IFR (DFR) iff the ratio $\frac{F(t+x)-F(t)}{1-F(t)}$ is increasing (decreasing) in $x \geq 0$ for all t with $F(t) < 1$.

If F exhibits a pdf then the IFR-/DFR-property means that the hazard rate function $\lambda_F = f/(1 - F)$ is increasing (decreasing).

IFRA/DFRA A cdf F is said to be IFRA (DFRA) iff, for the hazard function $R = -\log \bar{F}$, the ratio $R(x)/x$ is increasing (decreasing) in $x > 0$.

NBU/NWU A cdf F is said to be NBU (NWU) iff $\bar{F}(t+x) \leq (\geq) \bar{F}(t)\bar{F}(x)$ for all $x, t \geq 0$.

The IFR- and IFRA-property of progressively type II censored order statistics have been investigated in [33]. It has been shown that all progressively type II censored order statistics are IFR/IFRA provided that the baseline cdf F is IFR/IFRA. The respective result for the NBU-property as well as further results can be found in [83] in terms of sequential order statistics (see also [84]). Preservation properties are presented in [23], e.g., it has been proved that the DFR-property is preserved by spacings (see also [21]). The reversed hazard rate has been studied in [85]. Belzunce et al. [86] considered multivariate ageing properties in terms of nonhomogeneous birth processes and applied their results to generalized order statistics. A restriction to progressive censoring shows that progressively type II censored order statistics $X^{\mathcal{R}}$ are M-IFR if F is an IFR-cdf. Moreover, $X^{\mathcal{R}}$ is multivariate Polya frequency of order 2 (MPF₂) if the pdf of F is log-concave. Further notions of multivariate IFR/DFR and its applications to generalized order statistics have been discussed in [87]. The connection of ageing properties and residual life has been considered in [88] in terms of generalized order statistics.

Further Topics

The following probabilistic topics have also been discussed in progressive type II censoring, but, for brevity, we only mention them here briefly. Many publications deal with various kinds of characterizations of probability distributions [see, e.g., 1, Chapter 3.1]. Limit theorems have also been established imposing different assumptions on the censoring plans and distributions. For instance, [89] considered normal approximations using an approach inspired by Hoadley [90]. Cramer [91] discussed extreme value analysis which includes extreme, central, and intermediate progressively type

II censored order statistics [see also 92,93]. Counting process approaches in combination with limiting distributions have been extensively discussed in [94] [see also 95,96]. Hofmann et al. [97] has discussed a block censoring approach.

Information measures have also found some interest [see, e.g., 1, Chapter 9]. Results on the Fisher information have been established in, e.g., [98–102]. A detailed approach in terms of the more general model of generalized order statistics is discussed in [103, 104]. Asymptotic results are provided in [105]. Entropy-type measures are investigated in [106–110]. Kullback-Leibler-related measures are addressed in [106, 107, 111–115]. Pitman closeness for progressively type II censored data has been considered in, e.g., [116–119].

Concomitants for progressively type II censored order statistics have been addressed [120–122] (see also [1]).

As already mentioned above, progressive type II censoring has also been discussed under nonstandard conditions. Specifically, the underlying random variables X_1, \dots, X_n are supposed to be distributed according to some (multivariate) distribution function F^{X_1, \dots, X_n} . A general mixture representation of the distribution in terms of distributions of order statistics has been established by Fischer et al. [17]. Assuming independence but possibly different marginals, [16] found representations of the joint density functions. Inference in such a model has been discussed in [123]. Given a copula of the lifetimes X_1, \dots, X_n , [19, 20] addressed dependent random variables. Progressive censoring of random vectors has been discussed in [124] [see also 125, 126].

9.2.2 Inference

Inference for progressively type II censored data has been widely discussed in the literature. Most of the material is devoted to parametric inference. In the following, we present a selection of results for exponential and Weibull distribution. In addition, references to other distributions are provided. A standard reference for all these results is [1]. If nothing else is mentioned, we discuss inference on a single progressively type II censored sample $X_{1:m:n}, \dots, X_{m:m:n}$.

Point Estimation

The most popular parametric estimation concepts applied to progressively type II censored data are linear, likelihood, and Bayesian estimation. Assuming a location-scale family of distributions

$$\mathcal{F} = \left\{ F_{\mu, \vartheta} = F\left(\frac{\cdot - \mu}{\vartheta}\right) \mid \mu \in \mathbb{R}, \vartheta > 0 \right\},$$

with a known cdf F , a progressively type II censored sample $X^{\mathcal{R}}$ from $F_{\mu, \vartheta}$ can be written as a linear model:

$$X^{\mathcal{R}} = \mu \cdot \mathbf{1} + \vartheta Y^{\mathcal{R}} = \mu \cdot \mathbf{1} + \vartheta EY^{\mathcal{R}} + W^{\mathcal{R}} = B\theta + W^{\mathcal{R}},$$

where $EW^{\mathcal{R}} = 0$, $\text{Cov}(W^{\mathcal{R}}) = \vartheta^2 \Sigma$ denotes the variance-covariance matrix of $W^{\mathcal{R}}$, $\Sigma = \text{Cov}(Y^{\mathcal{R}})$, $B = [\mathbf{1}, \mathbf{b}]$ is the known design matrix, and $\theta = (\mu, \vartheta)'$ is the (unknown) parameter vector. Notice that the distribution of $Y^{\mathcal{R}}$ is parameter free, and it depends only on the standard member F .

Thus, as pointed out in [1, Chapter 11], least squares estimation can be applied in order to obtain the best linear unbiased estimator (BLUE) of θ (see, e.g., [127]) as

$$\hat{\theta} = (B' \Sigma^{-1} B)^{-1} B' \Sigma^{-1} X^{\mathcal{R}}.$$

Obviously, the estimator can be applied when the first and second moments of $X^{\mathcal{R}}$ can be computed (at least numerically). This has been done for many distributions. For instance, given exponential distributions, explicit expressions result since the respective moments have a closed form expression (see, e.g., [128–130]). For $m \geq 2$, the BLUEs $\hat{\mu}_{\text{LU}}$ and $\hat{\vartheta}_{\text{LU}}$ are given by

$$\begin{aligned} \hat{\mu}_{\text{LU}} &= X_{1:m:n} - \frac{\hat{\vartheta}_{\text{LU}}}{n}, \\ \hat{\vartheta}_{\text{LU}} &= \frac{1}{m-1} \sum_{j=2}^m (R_j + 1)(X_{j:m:n} - X_{1:m:n}). \end{aligned}$$

Further results for particular distributions are summarized in [1, Chapter 11]. In case of Weibull distributions, the model can be transformed to a linear model from extreme value distributions by a log-transformation of the data. Thus, estimators of the Weibull parameters can be obtained by using the BLUEs of the transformed parameters when the data results from an extreme value distribution. Results in this direction can be found in [24, 131, 132]. The mixture representation in terms of order statistics can also be utilized to compute the moments (see [17, 133, 134]).

Similar to least squares estimation, one can consider the best linear equivariant estimators (BLEEs). This problem has been discussed, e.g., by Balakrishnan et al. [135], Burkschat [136] (see also [137] for the best linear (risk) invariant estimators).

The most popular approach to the estimation problem is likelihood inference since the joint pdf given in (9.2) leads to tractable expressions in many situations (see [1, Chapter 12]). For generalized Pareto distributions, explicit expressions result. For exponentially distributed lifetimes with mean ϑ , the MLE is given by

$$\hat{\vartheta}_{\text{MLE}} = \frac{1}{m} \sum_{j=1}^m (R_j + 1) X_{j:m:n} = \frac{1}{m} \sum_{j=1}^m S_j^{\mathcal{R}}, \quad (9.8)$$

which is also the BLUE in this model. The representation in terms of the spacings $S_1^{\mathcal{R}}, \dots, S_m^{\mathcal{R}}$ is important in the analysis of the MLE since it enables easy derivation of

the exact distribution of the MLE. For two-parameter exponential distribution, explicit expressions for the MLEs are also available. For Weibull distribution $\text{Wei}(\vartheta, \beta)$, the MLE $(\hat{\vartheta}, \hat{\beta})$ of (ϑ, β) uniquely exists (see [138]). They are given by $\hat{\vartheta} = \frac{1}{m} \sum_{j=1}^m (R_j + 1) X_{j:m:n}^{\hat{\beta}}$ where, for the observed data $X_{j:m:n} = x_j$, $1 \leq j \leq m$, the estimate $\hat{\beta}$ is the unique solution of the equation:

$$\frac{m}{\beta} + \sum_{j=1}^m \log x_j - \frac{\sum_{j=1}^m (R_j + 1) \log(x_j) x_j^{\beta}}{\sum_{j=1}^m (R_j + 1) x_j^{\beta}} = 0.$$

The above equation has to be solved numerically, e.g., by the Newton-Raphson procedure. Ng et al. [98] proposed an EM-algorithm approach to compute the MLE (see also [139]) which, suitably adapted, has successfully been applied for other distributions, too. Results on likelihood inference for other distributions can be found in [1, Chapter 12]. Recent references for other distributions are, e.g., [140] (Rayleigh), [141] (modified Weibull), [142, 143] (Lindley), and [144] (Gompertz).

For some distributions, related concepts like modified and approximate maximum likelihood estimation have been discussed. The latter concept due to [145] has been successfully applied in many cases, e.g., for extreme value distribution [146] and Weibull distributions [147] (see also [1, Chapter 12.9.2]).

Bayesian inference has also been discussed considerably for progressively type II censored data under various loss functions (see [1, Chapter 15]). Under squared error loss function, the Bayes estimate of the scale parameter $\alpha = 1/\vartheta$ of an exponential lifetime is given by the posterior mean

$$\hat{\alpha}_{\text{B}} = \frac{a + m}{b + \sum_{j=1}^m (R_j + 1) X_{j:m:n}^{\beta}}$$

given a gamma prior

$$\pi_{a,b}(\alpha) = \frac{b^a}{\Gamma(a)} \alpha^{a-1} e^{-b\alpha}, \quad \alpha > 0,$$

with hyperparameters $a, b > 0$. Using a similar inverse gamma prior, [148] obtained the corresponding Bayes estimator of ϑ as

$$\hat{\vartheta}_{\text{B}} = \frac{1}{a + m - 1} \left(\sum_{j=1}^m \gamma_j (X_{j:m:n} - X_{j-1:m:n}) + b \right),$$

where $X_{0:m:n} = 0$. Two-parameter Weibull distribution with appropriate priors has been discussed in [149] and [150]. For further results, we refer to [1, Chapter 15].

Using a counting process approach, [94] and [151] have addressed nonparametric inference with progressively type

II censored lifetime data for the population cdf F and the survival function. For instance, they presented a Nelson-Aalen-type estimator and a smoothed hazard rate estimator as well as asymptotic results for these estimators. A survey is provided in [1, Chapter 20].

Statistical Intervals

Various kinds of statistical intervals have been discussed for progressively type II censored data. In particular, confidence intervals have been studied under different assumptions. In some situations, exact confidence intervals with level $1 - \alpha$ can be constructed using properties of the estimators. For exponential distribution, it follows from the independence of the spacings (9.3) that the distribution of the MLE $\hat{\vartheta}_{MLE}$ in (9.8) can be obtained as $2m\hat{\vartheta}_{MLE}/\vartheta \sim \chi^2(2m)$. Hence, $\left[\frac{2m\hat{\vartheta}_{MLE}}{\chi^2_{1-\alpha/2}(2m)}, \frac{2m\hat{\vartheta}_{MLE}}{\chi^2_{\alpha/2}(2m)} \right]$ is a two-sided $(1 - \alpha)$ -confidence interval for ϑ . Similarly, one may obtain confidence intervals and confidence regions for the two-parameter exponential distribution (see [1, Chapter 17], [152]). For Wei(ϑ, β)-distribution, [153] has obtained confidence intervals for the scale and shape parameters of a Wei(ϑ, β)-distribution using a transformation to exponential data and the independence of the spacings. An exact $(1 - \alpha)$ -confidence interval for β is given by

$$\mathcal{H} = \left[\psi^*(X^{\mathcal{R}}, F_{\alpha/2}(2(m-1), 2)), \psi^*(X^{\mathcal{R}}, F_{1-\alpha/2}(2(m-1), 2)) \right],$$

where $\psi^*(X^{\mathcal{R}}, \omega)$ is the unique solution for β of the equation

$$\sum_{j=2}^m (R_j + 1) \left(\frac{X_{j:m:n}}{X_{1:m:n}} \right)^\beta = \gamma_2 + n(m - 1)\omega.$$

Wang et al. [154] established a confidence interval for β using the pivotal quantity

$$\tau(X^{\mathcal{R}}, \beta) = 2 \sum_{j=1}^{m-1} \log \left(\frac{\sum_{i=1}^m (R_i + 1) X_{i:m:n}^\beta}{\sum_{i=1}^{j-1} (R_i + 1) X_{i:m:n}^\beta + \gamma_j X_{j:m:n}^\beta} \right).$$

They showed that an exact $(1 - \alpha)$ -confidence interval for β is given by

$$\mathcal{H} = \left[\tau^{-1}(X^{\mathcal{R}}, \chi^2_{\alpha/2}(2(m-1))), \tau^{-1}(X^{\mathcal{R}}, \chi^2_{1-\alpha/2}(2(m-1))) \right],$$

where $\tau^{-1}(X^{\mathcal{R}}, \omega)$ is the unique solution for β of the equation $\tau(X^{\mathcal{R}}, \beta) = \omega$ with $\omega > 0$. A simultaneous confidence region has been obtained by Wu [153]. The same ideas may be applied to Pareto distributions (see [155–158]). In [158, 159], and [160], optimal confidence regions are discussed (for a location-scale family, see [161]). Nonparametric confidence intervals for quantiles have been discussed in [133] (for

multiple samples, see [162, 163]). Exact confidence intervals based on conditional inference have been proposed for progressively type II censored data by Viveros and Balakrishnan [25] (see also [2, Chapter 9]). In particular, exponential, extreme value, log-gamma distributions, Pareto, and Laplace have been discussed. Asymptotic confidence intervals have been applied in various situations by assuming asymptotic normality of some pivotal quantities. The asymptotic variance is estimated by the observed likelihood. Generalized confidence intervals for distribution parameters using Weerahandi’s approach (see [164]) can be found in [154].

Furthermore, prediction intervals and tolerance intervals have been discussed. References for the latter concept are [134, 162, 165, 166]. The highest posterior density credible intervals have been established in [148, 149], and [167].

Prediction

Prediction problems have been discussed for both point and interval prediction, respectively (see [1, Chapter 16 & 17.4]). In particular, they have been considered for:

- (I) Progressively censored failure times at censoring steps $1, \dots, m$; in particular, the progressively censored ordered failure times $W_{j,1:R_j}, \dots, W_{j,R_j:R_j}$, $1 \leq j \leq m$, are predicted.
- (II) For future observations in the same sample (this is a particular case of (I) in the sense that the lifetimes of the items removed in the final progressive censoring step are predicted).
- (III) Observations of an independent future sample from the same population.

Problem (I) has been considered by Basak et al. [168] (the special case $W_{m,1:R_m}, \dots, W_{m,R_m:R_m}$ is addressed by Balakrishnan and Rao [169]). Given exponential lifetimes with unknown mean ϑ , they found that the best unbiased predictor of the r th ordered progressively censored lifetime $W_{j,r:R_j}$ in step j is given by

$$\hat{W}_{j,r:R_j}(X^{\mathcal{R}}) = X_{j:m:n} + \hat{\vartheta}_{MLE} \sum_{k=1}^r \frac{1}{R_j - k + 1},$$

where $\hat{\vartheta}_{MLE}$ is the MLE of ϑ . Further results have been obtained for extreme value distribution [168], normal distribution [170], and Pareto distribution [171]. Prediction intervals based on various prediction concepts (e.g., best linear unbiased prediction, maximum likelihood prediction, and median unbiased prediction) have been obtained for exponential and extreme value distributions in [168]. Normal and Pareto distributions are considered in [170] and [171], respectively. Generalized exponential and Rayleigh distributions are discussed in [172] and [173], respectively.

The best linear unbiased/equivariant prediction of future observations $X_{r+1:m:n}, \dots, X_{m:m:n}$, based on the first r progressively type II censored order statistics $X_{1:m:n}, \dots, X_{r:m:n}$, has been discussed in [136]. The same problem has been investigated in a Bayesian framework, too, and the corresponding results can be found in [148] and [152]. Prediction intervals for a general class of distributions, including exponential, Weibull, and Pareto distributions, can be seen in [174]. Results for Weibull distribution have also been presented in [175].

Problem (III) has mainly been discussed in a Bayesian framework. Relevant references are [141, 143, 175–183]. Results on nonparametric prediction of future observations can be found in [134, 162, 184].

Testing

Statistical tests under progressive censoring have mainly been discussed in the context of precedence-type testing, homogeneity, and goodness-of-fit tests. A good source for precedence-type tests is [185] (see also [1, Chapter 21]). Particular results can be found in [186] and [187]. Homogeneity tests based on several progressively type II censored samples have been addressed in [188]. For related results in terms of sequential order statistics, we refer to [23]. A review on goodness-of-fit-tests for exponential distributions, including a power study, has recently been presented in [114] (see also [1, Chapter 19]). Goodness-of-fit tests for location-scale families are discussed in, e.g., [189]. Tests have been constructed by means of spacings and deviations from the uniform distribution as well as from the empirical distribution function (e.g., Kolmogorov-Smirnov-type statistics; see [190, 191]). Furthermore, information measures like (cumulative) Kullback-Leibler information and entropy have been used (see [106, 111, 113]).

9.2.3 Experimental Design

Initiated by Balakrishnan and Aggarwala [2, Chapter 10], problems of experimental design have been discussed extensively for progressively type II censored lifetime experiments. A review on various results and optimality criteria has been provided by Balakrishnan and Cramer [1, Chapter 26]. Assuming that progressive type II censoring is carried out by design, the experimenter has to choose an appropriate censoring plan prior to the start of the experiment. Thus, assuming the sample size n and the number m of observed items as fixed, the censoring plan $\mathcal{R} = (R_1, \dots, R_m)$ has to be chosen in an optimal way. Burkschat [58] has formulated the problem as a mathematical optimization problem in a very general way (see also [192, 193]), that is, given a criterion $\psi : \mathcal{C}_{m,n}^m \rightarrow \mathbb{R}$, a censoring plan \mathcal{S} is said to be ψ -optimal if

$$\psi(\mathcal{S}) = \min_{\mathcal{R} \in \mathcal{C}_{m,n}^m} \psi(\mathcal{R}),$$

where $\mathcal{C}_{m,n}^m$ is given in (9.1). Various optimality criteria have been used, e.g., probabilistic criteria [58], variance criteria [2, 139, 192–194], information measures like Fisher information [100, 104, 105, 139] and entropy [107, 195, 196], optimal estimation of quantiles [139, 149, 197, 198], Pitman closeness [117], and optimal block censoring [97]. A detailed review is provided in [1, Chapter 26].

It turns out that the optimal designs depend heavily on both the optimality criterion to be used and the distributional assumption made. Due to the large number of admissible censoring plans, i.e., $\binom{n-1}{m-1}$ (see [1, p. 531]), [199] proposed a variable neighborhood search algorithm to identify optimal plans in a reasonable time. It should be mentioned that the so-called one-step censoring plans turn out to be optimal in many cases. This means that progressive censoring is carried out only at one failure time, whereas at the other failure times no censoring occurs. Such plans are discussed in [100, 102], and [200]. Recently, restrictions on censoring plans have been addressed in [49].

9.2.4 Connection of Progressive Type II Censoring to Coherent Systems

Cramer and Navarro [201] established a connection of failure data from coherent systems to progressively type II censored order statistics. They showed that the joint distribution of the component failures $(Y_{(1)}, \dots, Y_{(m)})$ (given the number $M = m$ of component failures leading to the system failure) in a coherent system can be seen as a mixture of progressively type II censored order statistics:

$$P^{Y_{(1)}, \dots, Y_{(m)} | M=m} = \sum_{\mathbf{r} \in \mathcal{S}_m} P(\mathcal{R} = \mathbf{r} | M = m) P^{X_{1:m:n}^{\mathbf{r}}, \dots, X_{m:m:n}^{\mathbf{r}}}, \quad (9.9)$$

where \mathcal{S}_m denotes the set of all admissible censoring plans $\mathbf{r} = (r_1, \dots, r_m)$ of length m . The probabilities $P(\mathcal{R} = \mathbf{r} | M = m)$ depend only on the structure of the coherent system and therefore can be calculated directly [see also 202]. Utilizing this connection, inference for coherent system data can be carried out using inferential methods for progressively type II censored data. For exponentially distributed lifetimes as well as PHR models, we refer to [201], while Weibull distribution is discussed in [203].

Cramer and Navarro [202] applied this connection to define a progressive censoring signature (PC-signature) which can be used to compare the lifetimes of different coherent systems with respect to stochastic orderings.

9.2.5 Connection of Progressive Type II Censoring to Ordered Pooled Samples

In (9.9), a mixture of some random variables in terms of progressively type II censored order statistics has been established. A similar mixture representation has been found in the context of pooling two independent type II censored samples. Let $X_{1:m}, \dots, X_{r:n}$ and $Y_{1:m}, \dots, Y_{s:m}$ be independent right censored samples from a uniform distribution with sample sizes n and m , respectively. Without loss of any generality, let $r \geq s$ and denote the ordered pooled sample by $W_{(1)} \leq \dots \leq W_{(r+s)}$. Then, [162] showed that the joint distribution of the ordered pooled sample $W_{(1)}, \dots, W_{(r+s)}$ is a mixture of uniform progressively type II censored order statistics, that is,

$$P^{W_{(1)}, \dots, W_{(r+s)}} = \sum_{j=0}^{r-1} \pi_j P^{(T_{1:r+s:n+m}^{\mathcal{R}_j}, \dots, T_{r+s:r+s:n+m}^{\mathcal{R}_j})} + \sum_{j=0}^{s-1} \pi_j^* P^{(T_{1:r+s:n+m}^{\mathcal{R}_j^*}, \dots, T_{r+s:r+s:n+m}^{\mathcal{R}_j^*})},$$

with appropriately chosen discrete probability distributions π_0, \dots, π_{r-1} and $\pi_0^*, \dots, \pi_{s-1}^*$ and two-step censoring plans $\mathcal{R}_j, 0 \leq j \leq r-1$ and $\mathcal{R}_j^*, 0 \leq j \leq s-1$, respectively [162], [1, Section 17.1.6]. An extension to multiple pooled samples is presented in [204].

9.3 Progressive Type I Censoring

As mentioned in Sect. 9.1, progressive type I censoring as introduced in [5] does not have a prefixed termination time, that is, the last censoring time T_m (see Fig. 9.1) has not been considered as termination time. As pointed out in [6], inference for this model has been considered up to the early 1990s (see, e.g., [5, 205–209], and the monographs by Nelson [210] and Cohen and Whitten [211]). In the following, we call this censoring scheme Cohen’s *progressive censoring with fixed censoring times*. The understanding of T_m as a time censoring point seems to have changed after the publication of the monograph [2] [see also 7]. Since then, almost all publications dealing with progressive type I censoring interpret T_m as the termination time of the experiment.

9.3.1 Distributional Results for Cohen’s Progressive Censoring with Fixed Censoring Times

We start with a short review of progressive censoring with fixed censoring times as presented in [6]. In principle, the

procedure is quite similar to progressive type II censoring, but the censoring times are fixed in advance. Due to this property, we have to distinguish the initially planned censoring plan $\mathcal{R}^0 = (R_1^0, \dots, R_m^0)$ and the effectively applied censoring plan $\mathcal{R} = (R_1, \dots, R_m)$ (see [1, 2]) where

$$\mathcal{R}^0 = (R_1^0, \dots, R_m^0) \in \mathcal{C}_{l,n}^m = \left\{ (r_1, \dots, r_m) \in \mathbb{N}_0^m \mid r_{\bullet m} \leq n - l \right\}, \quad l \in \{0, \dots, n\},$$

with $m, n \in \mathbb{N}$ and $0 \leq R_j \leq R_j^0, 1 \leq j \leq m$, and $\mathcal{C}_{l,n}^m$ denotes the set of admissible censoring plans. As mentioned in the introduction, the censoring times of a progressively type I censored life test are prefixed, and the number of observations is random. Thus, we get a sample $X_{1:K:n}^l \leq \dots \leq X_{K:K:n}^l$ with random censoring plan \mathcal{R} and random sample size K . Notice that the important difference between progressive censoring with fixed censoring times and progressive type I censoring is the fact that we can ensure a minimum number of observations, that is, $K \geq n - R_{\bullet m}^0 \geq n - (n - l) = l$. Moreover, it is possible to observe values exceeding the threshold T_m . Progressive type I censoring can be interpreted as a type I hybrid version of progressive censoring with fixed censoring times (see Sect. 9.4.2). Denoting the number of observations in the intervals

$$(-\infty, T_1], (T_1, T_2], \dots, (T_{m-1}, T_m], (T_m, \infty)$$

by the random variables $D_1, D_2, \dots, D_m, D_{m+1}$ and by d_1, \dots, d_{m+1} their realizations, the effectively applied censoring numbers are given by

$$R_j = R_j(d_j) = \min \{ R_j^0, [n - d_{\bullet j} - R_{\bullet j-1}]_+ \}, \quad 1 \leq j \leq m,$$

where $n - d_{\bullet i} - R_{\bullet i-1}$ equals the number of units still remaining in the experiment before the i th withdrawal at time T_i . Notice that D_{m+1} is a (deterministic) function of D_1, \dots, D_m , i.e., $D_{m+1} = n - D_{\bullet m} - R_{\bullet m}$. Then, the set

$$\mathcal{D}_{(m+1)} = \{ a_{m+1} \in \mathbb{N}_0^{m+1} \mid a_i \leq [n - a_{\bullet i-1} - R_{\bullet i-1}(a_{i-1})]_+, \quad i = 1, \dots, m, \quad a_{m+1} = [n - a_{\bullet m} - R_{\bullet m}(a_m)]_+ \}$$

denotes the support of (D_1, \dots, D_{m+1}) for a progressively censored life test with fixed censoring times.

Similarly to Theorem 9.2.1, we get the following quantile representation.

Theorem 9.3.1 *Suppose $X_{1:K:n}^l \leq \dots \leq X_{K:K:n}^l$ and $U_{1:K:n}^l \leq \dots \leq U_{K:K:n}^l$ are progressively censored order statistics with fixed censoring times based on a continuous cdf F and a standard uniform distribution, respectively. The censoring times*

are given by T_1, \dots, T_m and $F(T_1), \dots, F(T_m)$, respectively. Then,

$$\left(X_{1:K:n}^I, \dots, X_{K:K:n}^I \right) \stackrel{d}{=} \left(F^{\leftarrow}(U_{1:K:n}^I), \dots, F^{\leftarrow}(U_{K:K:n}^I) \right).$$

Assuming $X_1, \dots, X_n \stackrel{iid}{\sim} F$ with an absolutely continuous cdf F and a pdf f , $T_{m+1} = \infty$, and $R_{m+1} = 0$, the joint pdf $f^{X^I, \mathbf{D}_{m+1}}$ of $\mathbf{X}^{I, \mathcal{R}} = (X_{1:K:n}^I, \dots, X_{K:K:n}^I)$ and $\mathbf{D}_{m+1} = (D_1, \dots, D_{m+1})$ is given by

$$\begin{aligned} f^{X^I, \mathcal{R}, \mathbf{D}_{m+1}}(\mathbf{x}_k, \mathbf{d}_{m+1}) &= \left\{ \prod_{j=1}^{m+1} \binom{n - d_{\bullet j-1} - R_{\bullet j-1}}{d_j} d_j! [1 - F(T_j)]^{R_j} \right\} \left\{ \prod_{i=1}^k f(x_i) \right\} \end{aligned} \tag{9.10}$$

for $\mathbf{d}_{m+1} \in \mathcal{D}_{(m+1)}$ with $k = d_{\bullet m+1}$ and $x_1 \leq \dots \leq x_k$. Clearly, (9.10) can be rewritten as

$$f^{X^I, \mathcal{R}, \mathbf{D}_{m+1}}(\mathbf{x}_k, \mathbf{d}_{m+1}) = C(\mathbf{d}_{m+1}) \prod_{j=1}^{m+1} [1 - F(T_j)]^{R_j} \prod_{i=1}^k f(x_i)$$

which illustrates the structural similarities to the pdf under progressive type II censoring given in (9.2). Notice that the value of $\mathbf{D}_{(m+1)}$ is defined uniquely by $\mathbf{X}^{I, \mathcal{R}} = (X_{1:K:n}^I, \dots, X_{K:K:n}^I)$.

The joint probability mass function $p^{\mathbf{D}_{m+1}}$ of \mathbf{D}_{m+1} is given by

$$\begin{aligned} p^{\mathbf{D}_{m+1}}(\mathbf{d}_{m+1}) &= \prod_{j=1}^{m+1} \binom{n - d_{\bullet j-1} - R_{\bullet j-1}}{d_j} [F(T_j) - F(T_{j-1})]^{d_j} \\ &\times [1 - F(T_j)]^{R_j}, \mathbf{d}_{m+1} \in \mathcal{D}_{(m+1)}. \end{aligned}$$

Further, the conditional density function of $\mathbf{X}^{I, \mathcal{R}}$, given \mathbf{D}_{m+1} , is given by

$$f^{X^I, \mathcal{R} | \mathbf{D}_{m+1}}(\mathbf{x}_k | \mathbf{d}_{m+1}) = \prod_{j=1, d_j > 0}^{m+1} f_{1 \dots d_j; d_j}^{(j)}(\mathbf{x}_{d_j}) \mathbb{I}_{(T_{j-1}, T_j]}(\mathbf{x}_{d_j}) \tag{9.11}$$

for $\mathbf{d}_{m+1} \in \mathcal{D}_{(m+1)}$ with $m = d_{\bullet m+1}$ and $x_1 \leq \dots \leq x_k \cdot f_{1 \dots d_j; d_j}^{(j)}$ denotes the density function of order statistics $X_{1:d_j}^{(j)}, \dots, X_{d_j:d_j}^{(j)}$ from the (doubly) truncated cdf F in the interval $(T_{j-1}, T_j]$.

As for progressive type II censoring, the conditional block independence of progressively censored order statistics with fixed censoring times holds which for progressive type I censoring and progressive type II censoring has first been established by Iliopoulos and Balakrishnan [39]. It follows directly from the joint pdf. Conditionally on $(D_1, \dots, D_{m+1}) = (d_1, \dots, d_{m+1})$, the progressively censored order statistics with fixed censoring times are block independent, that is, the random vectors

$$\left(X_{d_{\bullet j-1}+1:d_{\bullet m^*+1}:n}^I, \dots, X_{d_{\bullet j}:d_{\bullet m^*+1}:n}^I \right), \quad j \in \{1 \leq i \leq m+1 \mid d_i > 0\},$$

are independent with

$$\begin{aligned} &\left(X_{d_{\bullet j-1}+1:d_{\bullet m^*+1}:n}^I, \dots, X_{d_{\bullet j}:d_{\bullet m^*+1}:n}^I \right) \\ &\stackrel{d}{=} \left(X_{1:d_j}^{(j)}, \dots, X_{d_j:d_j}^{(j)} \right), \quad j \in \{1 \leq i \leq m+1 \mid d_i > 0\}, \end{aligned}$$

where $X_{1:d_j}^{(j)}, \dots, X_{d_j:d_j}^{(j)}$ are order statistics from the (doubly) truncated cdf F in the interval $(T_{j-1}, T_j]$, $j \in \{1 \leq i \leq k \mid d_i > 0\}$.

9.3.2 Distributional Results for Progressive Type I Censoring

Since progressive type I censoring results from Cohen's progressive censoring model with fixed censoring times by interpreting the final censoring time T_m as a threshold or termination point, the respective sample results from $X_{1:K:n}^I \leq \dots \leq X_{K:K:n}^I$ is given by $\mathbf{X}^{I, \mathcal{R}, T_m} = (X_{1:K:n}^I, \dots, X_{D_{\bullet m}:K:n}^I)$. Notice that this sample may result in an empty sample when all items are either progressively censored at T_1, \dots, T_{m-1} or right censored at T_m . Thus, no failures have been observed due to the time censoring at T_m . As a consequence, inferential results are often obtained and discussed subject to the assumption that at least one failure has been observed, that is, $D_{\bullet m} \geq 1$ which happens with probability

$$P(D_{\bullet m} \geq 1) = 1 - \prod_{i=1}^m (1 - F(T_i))^{R_i^0}.$$

Then, the distributional results presented before can be applied to progressive type I censoring. For instance, the quantile representation in Theorem 9.3.1 holds, too. The pdf of $\mathbf{X}^{I, \mathcal{R}, T_m}$ and \mathbf{D}_m can be seen as a marginal pdf of (9.10) with an appropriate restriction on the domain. This leads to the pdf

$$f^{X^I, \mathcal{R}, T_m, D_m}(x_k, d_m) = \left\{ \prod_{i=1}^m \binom{n - d_{\bullet i-1} - R_{\bullet i-1}}{d_i} d_i! [1 - F(T_i)]^{R_i} \right\} \left\{ \prod_{j=1}^k f(x_j) \right\} \quad (9.12)$$

for $d_m \in \mathcal{D}_{(m)}$ with $k = d_{\bullet m} \geq 1$ and $x_1 \leq \dots \leq x_k \leq T_m$ (see [1, p. 121]). Notice that R_m is defined differently in comparison with (9.10).

Apart from the above presented results, almost no probabilistic results seem to be available for (Cohen’s) progressively type I censored order statistics. Obviously, this is caused by the problems due to the random sample size K and the random censoring plan \mathcal{R} . Nevertheless, numerous inferential results have been obtained.

9.3.3 Inference

Most of the results established in progressive type I censoring are connected to likelihood inference. Since the likelihood functions are given by the joint pdfs (9.10) and (9.12), respectively, the MLEs can be obtained by direct optimization. In the following, we present only the progressive type I censoring model (with time censoring). Similar results can be obtained for Cohen’s progressive censoring with fixed censoring times model (see, e.g., [6]). A summary with more details is provided in [1, Chapter 12]. Notice that, due to the similarity of the likelihood function to the progressive type II censoring case, the computation of MLEs proceeds quite similarly to this case. In particular, explicit expressions result in the same cases, and the likelihood equations are similar (replace the censoring time T_i in progressive type I censoring by the observed failure time $X_{i:m:n}$ in progressive type II censoring; cf. (9.8) and (9.13)). For exponentially distributed lifetimes with mean ϑ , one gets the MLE as

$$\widehat{\vartheta}_{MLE}^I = \frac{1}{K} \left[\sum_{i=1}^K X_{i:K:n}^I + \sum_{j=1}^m R_j T_j \right]. \quad (9.13)$$

Although the structure is similar to the MLE under progressive type II censoring, the distribution of the estimator is quite complicated. Using a moment generating function approach, [212] established the conditional pdf of $\widehat{\vartheta}_{MLE}^I$, given $D_{\bullet m} \geq 1$, as a generalized mixture of (shifted) gamma distributions (for a direct approach under progressive censoring with fixed censoring times, see [6]). Establishing the stochastic monotonicity of the (conditional) survival function by the three monotonicity lemmas (see also [212–214]), constructed exact (conditional) confidence intervals for ϑ using the method of pivoting the cdf (see [215–217]). A multi-

sample model has been studied in [218] who presented an alternate representation of the pdf in terms of B-spline functions. Two-parameter exponential distribution $\text{Exp}(\mu, \vartheta)$ has been considered, e.g., in [211, 219], and [220]. Cohen [219] proposed also modified MLEs. Weibull distribution has been discussed in [205, 219, 221, 222], and [2]. Explicit expressions for the MLEs are not available, and the estimates have to be computed by numerical procedures. Balakrishnan and Kateri [138] have established the existence and uniqueness of the MLEs. Three-parameter Weibull distributions are considered in [206, 208], and [223]. Further distributions considered are, e.g., extreme value distribution [219], normal distribution [5], Burr-XII distribution [209], and logistic distribution [224].

9.4 Sampling Models Based on Progressively Censored Data

Progressively type I and type II censored data have been considered as a basis for inferential purposes in various models. In the following, we sketch some of these applications and provide some recent references.

9.4.1 Progressive (Type I) Interval Censoring

In progressive type I censoring, the number of observations observed between censoring times is random. It is assumed that only these numbers are observed (see Fig. 9.5), whereas the exact values of the failure times are not observed. This kind of data has been introduced in [7] (see also [1, Chapter 12]) assuming an absolutely continuous cdf F_θ . This yields the likelihood function (cf. (9.11))

$$L(\theta) \propto \prod_{j=1}^m (F_\theta(T_j) - F_\theta(T_{j-1}))^{d_j} \overline{F}_\theta^{R_j}(T_j),$$

where $\theta = (\theta_1, \dots, \theta_p)' \in \Theta \subseteq \mathbb{R}^p$ denotes the parameter vector and d_1, \dots, d_m are realizations of the number of observed failures D_1, \dots, D_m . $T_0 = -\infty < T_1 < \dots < T_m$ are the censoring times, and $\mathcal{R} = (R_1, \dots, R_m)$ is the effectively applied censoring plan.

Inferential results have been established for various distributions. Asymptotic results for MLEs with general distribution have been established in [225]. Exponential distribution has been discussed in [7] and [226]. For (inverse) Weibull distribution, we refer to [226, 227], and [228]. Further distributions considered are generalized exponential distributions [228–230], generalized Rayleigh distribution [231], gamma distribution [232], and Burr-XII [233]. Further examples are given in [1, Chapter 18].

Under progressive type I censoring, the optimal choice of both inspection times and censoring proportions has been addressed by many authors [1, Chapter 18.2 & 18.3]. Other relevant references in this direction are [225, 233–241].

9.4.2 Progressive Hybrid Censoring

In progressive hybrid censoring, progressive type II censored data is subject to, e.g., additional time censoring at some threshold T . There are many variations available in the literature so far. For reviews, see [242], [1, Chapter 5 & 14], [12, 243, 244] and the recent monograph [380]. For illustration, we sketch the idea of the two basic hybrid censoring models under progressive censoring. Let $D = \sum_{i=1}^m \mathbb{I}_{(-\infty, T]}(X_{i:m:n})$ denote the total number of observed failures. As in [10], we perceive the data with possibly less than m observed failure times as a sample of size m by adding the censoring time in the required number. For a progressively type II censored sample $X_{1:m:n}, \dots, X_{m:m:n}$ with censoring plan \mathcal{R} , type I progressively hybrid censored order statistics $X_{1:m:n}^{h,I}, \dots, X_{m:m:n}^{h,I}$ are defined via

$$X_{j:m:n}^{h,I} = \min(X_{j:m:n}, T), \quad 1 \leq j \leq m. \tag{9.14}$$

Notice that the names *type I/type II* progressive hybrid censoring are differently used in the literature which may result in some confusion. From (9.14), it is evident that the sample may include both observed failure times and censoring times. Conditionally on $D = d, d \in \{0, \dots, m\}$, we have

$$X_{1:m:n}^{h,I}, \dots, X_{m:m:n}^{h,I} | (D = d) \stackrel{d}{=} X_{1:m:n}, \dots, X_{d:m:n}, \underbrace{T, \dots, T}_{m-d \text{ times}}.$$

For $d = 0$, the experiment has been terminated before observing the first failure, and, thus, the sample is given by the constant data $(T, \dots, T) \in \mathbb{R}^m$. Some probabilistic results have been obtained (see [1, Chapter 5], [10]). For instance, as under progressive type II censoring, a quantile representation similar to that given in Theorem 9.2.1 holds. The (conditional) joint pdf is given by Childs et al. [see also 8, 9]:

$$f_{j:m:n}^{h,I, 1 \leq j \leq m | D=d}(t_d, T^{*(m-d)}) = \frac{C_d}{P(D=d)} (1 - F(T))^{\gamma_{d+1}} f_{1, \dots, d; d:n-\gamma_{d+1}}^{\mathcal{R}_d}(t_d), \quad t_1 \leq \dots \leq t_d \leq T,$$

where $f_{1, \dots, d; d:n-\gamma_{d+1}}^{\mathcal{R}_d}$ denotes the pdf of the progressively type II censored sample with a censoring plan \mathcal{R}_d . In case of the exponential distribution, [10] established the (conditional) joint density function of the spacings $W_{j:m:n}^{h,I} = \gamma_j(X_{j:m:n}^{h,I} - X_{j-1:m:n}^{h,I}), 1 \leq j \leq d$, as

$$f_{j:m:n}^{h,I, 1 \leq j \leq d | D=d}(w_d) = \frac{\gamma_{d+1} e^{-\gamma_{d+1}(T-\mu)/\vartheta}}{\vartheta f_{d+1:m:n}(T)} \times \left[\prod_{j=1}^d \frac{1}{\vartheta} \exp \left\{ - \left(1 - \frac{\gamma_{d+1}}{\gamma_j} \right) \frac{w_j}{\vartheta} \right\} \right],$$

$$w_d \in \mathcal{W}_d(T),$$

with support

$$\mathcal{W}_d(T) = \left\{ w_d \mid w_j \geq 0, 1 \leq j \leq d, \sum_{j=1}^d \frac{w_j}{\gamma_j} \leq T - \mu \right\}.$$

As a difference to the case of progressive type II censoring, the spacings are no longer independent although the pdf exhibits a product structure. These results can be utilized to obtain the exact distribution of the MLE for exponential lifetimes. A moment generating function approach is advocated in, e.g., [8]. The MLE of ϑ exists provided $D > 0$ and is given by

$$\hat{\vartheta} = \frac{1}{D} \left[\sum_{j=1}^D \gamma_j (X_{j:m:n}^{h,I} - X_{j-1:m:n}^{h,I}) + \gamma D_{d+1} T \right].$$

Its distribution can be written in terms of B-spline functions (see [10]) or in terms of shifted gamma functions (see [8]). The connection of the particular representations has been studied in [243]. The result can be applied to construct exact (conditional) confidence intervals by pivoting the cdf since the corresponding survival function is stochastically monotone (see [213, 214, 245]). For the multi-sample case, we refer to [246]. Results for two-parameter exponential distribution are given in [10] and [247]. Inference for Weibull distribution has been discussed in [248]. Results for other distributions can be found in, e.g., [249–255]. Optimal censoring plans are discussed in [256, 257].

Childs et al. [8] and Kundu and Joarder [9] proposed an alternative hybrid censoring procedure called type II progressive hybrid censoring. Given a (fixed) threshold time T , the life test terminates at $T_2^* = \max\{X_{m:m:n}, T\}$. This approach guarantees that the life test yields at least the observation of m failure times. Given the progressively type II censored sample $X_{1:m:n}, \dots, X_{m:m:n}$ with an initially planned censoring plan $\mathcal{R} = (R_1, \dots, R_m)$, the right censoring at time $X_{m:m:n}$ is not carried out. The monitoring of the failure times after $X_{m:m:n}$ is continued until time T is reached or the maximum in the extended progressively type II censored sample

$$X_{1:m+R_m:n}, \dots, X_{m:m+R_m:n}, X_{m+1:m+R_m:n}, \dots, X_{m+R_m:m+R_m:n} \tag{9.15}$$

is observed. Notice that this sample can be viewed as progressively type II censored data with extended censoring plan $\mathcal{R}^* = (R_1, \dots, R_{m-1}, 0, \dots, 0)$ of length $m + R_m$. Furthermore, $\gamma_j = \sum_{i=j}^m (R_i + 1)$, $j = 1, \dots, m - 1$, $\gamma_j = m + R_m - j + 1$, $j = m, \dots, m + R_m$. As in the case of type I progressive hybrid censoring, the random counter $D = \sum_{i=1}^{m+R_m} \mathbb{I}_{(-\infty, T]}(X_{i:m+R_m:n})$ represents the sample size having support $\{0, \dots, m + R_m\}$. Again, the exact distribution of the MLE given by

$$\widehat{\vartheta} = \begin{cases} \frac{1}{m} \sum_{j=1}^m (R_j + 1) X_{j:m:n}, & D < m \\ \frac{1}{D} \left(\sum_{j=1}^m (R_j + 1) X_{j:m:n} + \sum_{j=m+1}^D X_{j:m+R_m:n} + \gamma_{D+1} T \right), & D \geq m \end{cases}$$

can be obtained. Furthermore, exact confidence intervals can be established (see [8, 258]) since the cdf is stochastically monotone (see [214]). For the multi-sample case, we refer to [259]. Inferential results for this kind of data have been obtained in, e.g., [8, 9, 258, 260]. Mokhtari et al. [261], Alma and Arabi Belaghi [262], and Noori Asl et al. [263].

There are many extensions on this basic progressive hybrid censoring. Generalized progressive hybrid censoring is discussed in, e.g., [243, 264–270]. Further extensions can be found in [12] and [271]. The Fisher information in hybrid censoring schemes is discussed in [272] and [273]. Furthermore, interval censored data have been studied in [274].

9.4.3 Adaptive Progressive Censoring

A common feature of the abovementioned progressive censoring schemes is that the design of the experiment (i.e., initially planned censoring plan, censoring times) is prefixed, that is, these quantities are known in advance. Since such a design may not be possible or be useful in practical situations, [13] came up with the idea that the censoring plan may be adapted during the experiment. Given some prefixed censoring plan $\mathcal{S} = (S_1, \dots, S_m)$ and a threshold T , the plan is adapted after step $j^* = \max\{j : X_{j:m:n} < T\}$ such that no further censoring is carried out until the m th failure time has been observed. Hence, the censoring plan is changed at the progressive censoring step $j^* + 1$, i.e., at the first observed failure time exceeding the threshold T . The effectively applied censoring plan in the Ng-Kundu-Chan model is given by $\mathcal{S}^* = (S_1, \dots, S_{j^*}, 0, \dots, 0, n - m - \sum_{i=1}^{j^*} S_i)$. This model has been extensively investigated, and many results have been obtained (see [248, 260, 275, 276]).

A general approach to adaptive progressive censoring has been proposed by Cramer and Iliopoulos [15] allowing for a flexible choice of the censoring plan and the censoring times. This approach covers both adaptive progressive type I and adaptive progressive type II censoring. Adaptive progressive

type II censoring has been discussed in detail in [14] who particularly showed that the model covers the Ng-Kundu-Chan model as well as the model of progressive type II censoring with random removals (see also [1, Chapter 6]). The latter model has been proposed by Yuen and Tse [277] assuming that the censoring numbers are chosen according to some probability distribution on the set of possible censoring numbers. Further references discussing this model are, e.g., [278–280]. For interval censored data, we refer to [281] and [282]. Flexible progressive censoring introduced in [283] can also be seen as a special adaptive progressive censoring model (see also [284, 285]).

9.4.4 Reliability and Stress-Strength Reliability

Applications in reliability based on progressively type II censored data have been addressed by many authors. The analysis is mostly based on a single progressively type II censored sample $X_{1:m:n}, \dots, X_{m:m:n}$, but the situation of multiple samples has also been taken into account. In the following, we summarize some scenarios where this kind of data has been considered.

Given a lifetime X with cdf F , the reliability function $R = \bar{F} = 1 - F$ can be estimated parametrically and nonparametrically. Nonparametric estimators under progressive censoring are mentioned in Sect. 9.2.2. Parametric estimators of R_θ can be constructed as plug-in estimators by replacing θ by an appropriate estimator $\widehat{\theta}$, e.g., the MLE (see, e.g., [142, 286–291]). Furthermore, Bayesian approaches have also been extensively discussed. However, for exponential distributions and $t \in \mathbb{R}$, the UMVUE of $R_\theta(t) = P_\theta(X > t)$ is given by (see (9.8))

$$\widehat{R}(t) = \left(1 - \frac{t}{m\widehat{\vartheta}_{\text{MLE}}} \right)^{m-1} \mathbb{I}_{[t, \infty)}(m\widehat{\vartheta}_{\text{MLE}})$$

(see [292]). The result can be slightly extended to an exponential family with cdf F_ϑ defined by $F_\vartheta(t) = 1 - \exp(-g(t)/\vartheta)$ and a suitable function g (see, e.g., [23, 293]).

Inference for the stress-strength reliability $R = P(X < Y)$ has also been addressed under progressive censoring for various distributions (for a general account, see [294]). For exponential distribution, the problem has been considered in terms of Weibull exponential distributions in [295] and [296]. For two independent progressively type II censored samples $X_{1:m:n}^{\mathcal{R}}, \dots, X_{m:m:n}^{\mathcal{R}}$ and $Y_{1:r:s}^{\mathcal{S}}, \dots, Y_{r:r:s}^{\mathcal{S}}$, based on exponential distributions $\text{Exp}(\vartheta_1)$ and $\text{Exp}(\vartheta_2)$, the MLEs of the parameters are given by $\widehat{\vartheta}_{j,\text{MLE}}$, $j = 1, 2$, as in (9.8). Then, the MLE of $R = \frac{\vartheta_2}{\vartheta_1 + \vartheta_2}$ is given by $R_{\text{MLE}} = \frac{\widehat{\vartheta}_2}{\widehat{\vartheta}_1 + \widehat{\vartheta}_2}$. Furthermore, the UMVUE is given by

$$\widehat{R}_{UMVUE} = \begin{cases} \sum_{j=0}^{r-1} (-1)^j \binom{r-1}{m+j-1} \left(\frac{m\widehat{\vartheta}_{1,MLE}}{r\widehat{\vartheta}_{2,MLE}} \right)^j, & m\widehat{\vartheta}_{1,MLE} \leq r\widehat{\vartheta}_{2,MLE} \\ 1 - \sum_{j=0}^{m-1} (-1)^j \binom{m-1}{r+j-1} \left(\frac{r\widehat{\vartheta}_{2,MLE}}{m\widehat{\vartheta}_{1,MLE}} \right)^j, & m\widehat{\vartheta}_{1,MLE} > r\widehat{\vartheta}_{2,MLE} \end{cases}$$

$$f^{X^{\mathcal{R}}, C}(x_m, c_m) = \left(\prod_{j=1}^m \gamma_j \right) \prod_{i=1}^m \left[[f_1(x_i)\overline{F}_2(x_i)]^{\mathbb{I}_{\{1\}}(c_i)} [f_2(x_i)\overline{F}_1(x_i)]^{\mathbb{I}_{\{2\}}(c_i)} [\overline{F}_1(x_i)\overline{F}_2(x_i)]^{R_i} \right].$$

Saraçoğlu et al. [see also 297, who addressed Bayesian inference, too]. Confidence intervals are discussed in [295, 296], and [297]. Two-parameter exponential distributions with common location parameter are investigated in [295, 296] [see also 1, Chapter 24]. Other distributions considered in the literature are generalized (inverted) exponential distribution [289, 298], Weibull distribution [299, 300], generalized Pareto distributions [301], the PHR model [302, 303], Birnbaum-Saunders distribution [304], generalized logistic distribution [305], and finite mixtures [306].

Stress-strength models under joint progressive censoring have been considered in [307]. Progressively type I interval censored data has been discussed by Bai et al. [306].

9.4.5 Competing Risks

In competing risk modeling, it is assumed that a unit may fail due to several causes of failure. For two competing risks, the lifetime of the i th unit is given by

$$X_i = \min \{X_{1i}, X_{2i}\}, \quad i = 1, \dots, n,$$

where X_{ji} denotes the latent failure time of the i th unit under the j th cause of failure, $j = 1, 2$. In most models considering competing risks under a progressive censoring scheme, the latent failure times are assumed to be independent with $X_{ji} \sim F_j, j = 1, 2, i = 1, \dots, m$. Additionally, the sample X_1, \dots, X_n is progressively type II censored, and it is assumed that the cause of each failure is known. Therefore, the available data are given by

$$(X_{1:m:n}, C_1), (X_{2:m:n}, C_2), \dots, (X_{m:m:n}, C_m),$$

where $C_i = 1$ if the i th failure is due to first cause and $C_i = 2$ otherwise. The observed data is denoted by $(x_1, c_1), (x_2, c_2), \dots, (x_m, c_m)$. Further, we define the indicators

$$\mathbb{I}_{\{j\}}(C_i) = \begin{cases} 1, & C_i = j \\ 0, & \text{otherwise} \end{cases}.$$

Thus, the random variables $m_1 = \sum_{i=1}^m \mathbb{I}_{\{1\}}(C_i)$ and $m_2 = \sum_{i=1}^m \mathbb{I}_{\{2\}}(C_i)$ describe the number of failures due to the first and the second cause of failure, respectively. Given the assumptions, m_1 and m_2 are binomials with sample size m and probability of success $R = P(X_{11} \leq X_{21})$ and $1 - R$, respectively. For a given censoring plan $\mathcal{R} = (R_1, \dots, R_m)$, the joint pdf is given by Kundu et al. [see 308]

[308] discussed competing risks for $\text{Exp}(\vartheta_j)$ -distributions, $j = 1, 2$, under progressive type II censoring. The MLEs of the parameters are given by

$$\widehat{\vartheta}_j = \frac{1}{m_j} \sum_{i=1}^m (R_i + 1)X_{i:m:n}, \quad j = 1, 2,$$

provided that $m_j > 0$. In this framework, inferential topics like point and interval estimation as well as prediction problems have been discussed. To keep things short, we provide references for further reading. Competing risks under progressive type II censoring have been considered for, e.g., Weibull distribution [309–311], Lomax distribution [312], half-logistic distribution [313], and Kumaraswamy distribution [314].

Progressive type I interval censoring in the presence of competing risks has been investigated by Wu et al. [234], Azizi et al. [315], and Ahmadi et al. [316]. Competing risks under hybrid censoring are investigated in, e.g., [317–325].

9.4.6 Applications to System Data

In the standard models of progressive censoring, it is assumed that the underlying random variables are iid random variables distributed according to a cdf F . Progressive censoring has also been studied in terms of iid system data $Y, \dots, Y_n \stackrel{\text{iid}}{\sim} G$, where $G = h \circ F$ with some known function h and a cdf F . F is supposed to model the component lifetime, whereas h describes the technical structure of the system. In a series system with s components, we have $G = F^s$ with $h(t) = t^s$. For a parallel system with s components, the function h is given by $h(t) = 1 - (1 - t)^s$.

As pointed out in [1, Chapter 25], the case of progressively type II censored series system data is included in the standard model by adapting the censoring plan appropriately. Given a censoring plan $\mathcal{R} = (R_1, \dots, R_m)$ and series systems with s components, the corresponding progressively type II censored system data can be interpreted as standard progressively type II censored data with censoring plan

$$\mathcal{S} = s\mathcal{R} + (s - 1)(1^{*m}), \text{ i.e., } S_j = sR_j + s - 1, j = 1, \dots, m.$$

This kind of data has also been entitled *first-failure censored data* (see, e.g., [326, 327]), and many results have been published for this model. However, as mentioned before, the respective results are covered in the standard model by adapting the censoring plan.

The situation is more involved for parallel or, more general, for coherent systems. Parallel systems are studied in [166,328,329], and [330]. k out-of- n system data is addressed in [331], and coherent systems are addressed in [332].

9.4.7 Applications in Quality Control

Applications of progressively censored data in quality control have been discussed in terms of reliability sampling plans (acceptance sampling plans) and the lifetime performance index, respectively.

Reliability sampling plans based on progressively type II censored exponential lifetimes have been considered by Balasooriya and Saw [333], Balakrishnan and Aggarwala [2], and [334] [see also 1, Chapter 22]. For a progressively censored sample $X^{\mathcal{R}}$ from an $\text{Exp}(\mu, \vartheta)$ -distribution, the MLEs of the parameters are used to estimate the parameters and, thus, to construct the decision rule. Since the distributions of the MLEs do not depend on the censoring plan \mathcal{R} , the resulting sampling plans coincide with those for type II right censoring. Pérez-González and Fernández [335] established approximate acceptance sampling plans in the two-parameter exponential case. Balasooriya et al. [147] addressed reliability sampling plans for a Weibull distribution employing the Lieberman-Resnikoff procedure for a lower limit using the approximate MLEs of the parameters. Ng et al. [139] tackled the same problem using the MLEs. Fernández et al. [336] considered progressively censored group sampling plans for Weibull distributions. For a log-normal distribution, [337] applied the Lieberman-Resnikoff approach using approximate BLUEs for the location and scale parameters. Further reference in this direction is [338].

Inference for the lifetime performance index (or capability index) has been discussed for various distributions in [339] including exponential and gamma distributions (see also [340–343]). Weibull distribution has been considered in [344, 345], and Rayleigh distribution in [341]. Lomax and Pareto distributions are discussed by Mahmoud et al. [346] and Ahmadi and Doostparast [347], respectively. Progressively type I interval censored data has been considered in [348–350].

9.4.8 Accelerated Life Testing

In accelerated life testing, progressive censoring has been mostly discussed in terms of step-stress testing. Recent reviews on the topic are provided by Kundu and Ganguly [351] and Balakrishnan and Cramer [1, Chapter 23] (see also [352]). Assuming a cumulative exposure model for the lifetime distribution, the basic model in simple step-stress model with a single stress change point is applied to progressively

type II censored data, that is, at a prefixed time τ , the stress level is to be increased to a level $s_1 > s_0$ (see Fig. 9.6). Then, the data

$$X_{1:r:n} < \cdots < X_{D:r:n} \leq \tau < X_{D+1:r:n} < \cdots < X_{r:r:n}$$

results where D denotes the number of failures observed before τ . Obviously, the sample $X_{1:r:n}, \dots, X_{D:r:n}$ is a type I progressive hybrid censored sample so that the inferential results can be taken from this area. Assuming exponential lifetimes with means ϑ_1 and ϑ_2 (before and after τ) as well as a cumulative exposure model, the MLEs of the parameters are given by

$$\hat{\vartheta}_1 = \frac{1}{D} \left(\sum_{k=1}^D (R_k + 1) X_{k:r:n} + \tau \gamma_{D+1} \right),$$

$$\hat{\vartheta}_2 = \frac{1}{r-D} \sum_{k=D+1}^r (R_k + 1) (X_{k:r:n} - \tau),$$

provided that $1 \leq D \leq r-1$. As mentioned above, distributional results for $\hat{\vartheta}_1$ are directly obtained from type I progressive hybrid censoring leading to, e.g., exact (conditional) confidence intervals (see [353, 354]). Using the result in (9.6), we get $2(r-D)\hat{\vartheta}_2/\vartheta_2|D = d \sim \chi^2(2r-2d)$, $d < r$. In particular, $E(\hat{\vartheta}_2|D = d) = \vartheta_2$ and $\text{Var}(\hat{\vartheta}_2|D = d) = \vartheta_2^2/(r-d)$. Weibull lifetimes are investigated in [355]. Extensions to multiple stress changing times are discussed in [356, 357]. The model has also been discussed for progressive type I interval censored data (see [358–360]).

Wang and Yu [361] discussed a simple step-stress model where the stress changing time τ is replaced by a failure time $X_{r_1:r:n}$. It is shown in [1, p. 492] that this model is connected to sequential order statistics which can be utilized to establish easily properties of the resulting MLEs. Following the ideas of [362], a multiple step-stress model with additional progressive censoring has been proposed in [1, p. 503]. The resulting model corresponds to that proposed in [361] and is further discussed in [363].

Another kind of accelerated life testing model in the presence of progressive censoring, called progressive stress model, has been proposed by Abdel-Hamid and AL-Hussaini [364].

9.4.9 Stage Life Testing

A common argument used to justify progressive censoring is that the intentionally removed objects are utilized for other tests (cf., e.g., [2, p. 3], [365, p. 336]). In order to include such an information in the statistical analysis, [366] connected the notion of progressive censoring with ideas from accelerated

Fig. 9.6 Step-stress testing with single stress change time τ

life testing and proposed a stage life testing model with a single stage change time. In fact, they adapted the idea of step-stress testing and assumed that the *removed* objects are tested on a different level, whereas the remaining items are still tested under standard conditions. The basic situation with a single censoring time τ and two stages s_0, s_1 is depicted in Fig. 9.7.

Inspired by simple step-stress testing (see Fig. 9.6), the stage life testing model is introduced as follows. Assume that n identical objects are placed on a life test. The initial conditions are called stage s_0 . At the prefixed stage-change time τ , $0 \leq R_1^* \leq n$ of the surviving items are randomly withdrawn (if possible) and further tested on stage s_1 . Notice that this may be regarded as a different life test with used components. The testing of the remaining items is continued on stage s_0 . The life test terminates when all n objects have failed.

Let D_1 and D_2 denote the random number of failures occurring on stage s_0 before and after τ_1 , respectively. Furthermore, $M = D_1 + D_2$ and

- $\mathbf{Y}_{1,D_1} = (Y_{1:M:n}, \dots, Y_{D_1:M:n})$ denote the (ordered) observations on stage s_0 before τ .
- $\mathbf{Y}_{2,D_2} = (Y_{D_1+1:M:n}, \dots, Y_{D_1+D_2:M:n})$ denote the (ordered) observations on stage s_0 after τ .
- $\mathbf{Z}_{R_1^*} = (Z_{1:R_1^*}, \dots, Z_{R_1^*:R_1^*})$ denote the (ordered) observations on stage s_1 after τ with $Y_{D_1:M:n} \leq \tau < Z_{1:R_1^*}$.

The order statistics on stage s_0 and the order statistics on stage s_1 are represented by the random vectors $\mathbf{Y} = (\mathbf{Y}_{1,D_1}, \mathbf{Y}_{2,D_2})$ and \mathbf{Z} , respectively. Figure 9.7 illustrates this representation of the *stage life testing* order statistics.

Assuming a cumulative exposure model with cdfs F_0 and F_1 and utilizing progressive censoring with fixed censoring times (see [6]), inferential results have been obtained for

exponential, Weibull, and other lifetime distributions. The results are based on the joint pdf $f_{1..n}^{Y,Z,D_1}$ of (\mathbf{Y}, \mathbf{Z}) and D_1 given by

$$\begin{aligned} f_{1..n}^{Y,Z,D_1}(\mathbf{y}_{1,d_1}, \mathbf{y}_{2,d_2}, \mathbf{z}, d_1) \\ = \binom{n}{d_1} d_1! d_2! r_1^*! \prod_{h=1}^{d_1+d_2} f_0(y_{h:m:n}) \prod_{j=1}^{r_1^*} f_1(z_{j:r_1^*} + v_1 - \tau), \end{aligned}$$

for $\mathbf{y}_{1,d_1} = (y_{1:m:n}, \dots, y_{d_1:m:n})$, $\mathbf{y}_{2,d_2} = (y_{d_1+1:m:n}, \dots, y_{d_1+d_2:m:n})$, and $\mathbf{z} = (z_{1:r_1^*}, \dots, z_{r_1^*:r_1^*})$, where $d_2 = n - d_1 - r_1^*$, and $r_1^* = \varrho(d_1)$ denotes the number of objects selected for testing on stage s_1 . f_i denotes the pdf of F_i , $i \in \{0, 1\}$.

In fact, the function ϱ may be chosen according to the needs of the experimenter. Inspired by procedures to generate the censoring number in progressive censoring (see [7]), [366] proposed two options to define R_1^* , that is,

$$R_1^* = \varrho(D_1) \quad \text{with}$$

$$\varrho(x) = \begin{cases} \lfloor \pi_1 \cdot (n - x) \rfloor, & \text{Type-P} \\ \min \{n - x, R_1^0\}, & \text{Type-M} \end{cases}, \quad x \in \{0, \dots, n\},$$

where the proportion $\pi_1 \in [0, 1]$ and the number $R_1^0 \in \mathbb{N}$ are prespecified, respectively. Under the type P scheme, at τ , a (fixed) proportion π_1 of the surviving objects is selected for testing on stage s_1 . In case of the type M scheme, given a prefixed number R_1^0 , it is intended to select at τ as many items as possible (at most R_1^0) for testing on stage s_1 .

Assuming exponential lifetimes with means ϑ_0 and ϑ_1 , the corresponding MLEs are obtained as

$$\hat{\vartheta}_0 = \frac{1}{D_1 + D_2} \left(\sum_{i=1}^{D_1+D_2} Y_{i:M:n} + R_1^* \tau \right),$$

Fig. 9.7 Stage life testing with single stage change time τ

$$\hat{\vartheta}_1 = \frac{1}{R_1^*} \left(\sum_{j=1}^{R_1^*} Z_{j:R_1^*} - R_1^* \tau \right) \text{ (provided that } R_1^* > 0 \text{)}.$$

As for other progressive censoring models, exact inferential results, e.g., exact confidence intervals, can be established. An extension to multiple stage change times $\tau_1 < \dots < \tau_m$ has been introduced in [367]. Stage changes at failure times are discussed in [368]. For a survey on these models as well as more details, we refer to [369].

9.4.10 Joint Progressive Censoring Schemes

In joint progressive type II censoring, the sample is based on two baseline samples $X_1, \dots, X_{n_1} \stackrel{iid}{\sim} F_1$ (product/type A) and $Y_1, \dots, Y_{n_2} \stackrel{iid}{\sim} F_2$ (product/type B) of independent random variables. The progressive censoring is applied to the pooled sample $X_1, \dots, X_{n_1}, Y_1, \dots, Y_{n_2}$ given a prefixed censoring $\mathcal{R} \in \mathcal{C}_{m, n_1+n_2}^m$. Moreover, it is assumed that the type of the failed unit as well as the types of withdrawn units are known. Therefore, the sample is given by $(\mathbf{C}, \mathbf{W}^{\mathcal{R}}, \mathcal{S})$, where

$$\mathbf{C} = (C_1, \dots, C_m) \in \{0, 1\}^m,$$

$$\mathbf{W}^{\mathcal{R}} = (W_{1:m:n_1+n_2}, \dots, W_{m:m:n_1+n_2}), \mathcal{S} = (S_1, \dots, S_m).$$

The indicators C_j have the value 1 if the failed unit is of type A, and otherwise $C_j = 0$. $W_{j:m:n}$ denotes the j th failure time in the progressively censored experiment. Finally, \mathcal{S} denotes a random censoring plan. S_j is the number of removed units of type A in the j th withdrawal. Thus, $R_j - S_j$ denotes the numbers of withdrawn units of type B at the j th censoring step. This model has been discussed in [370–376]. Joint

progressive type I censoring has been proposed in [377]. A hybrid version is discussed in [378]. Another version of joint progressive censoring leading to more tractable results has been investigated in [376] and [379].

Narayanaswamy Balakrishnan received his B.Sc. and M.Sc. degrees in Statistics from the University of Madras, India, in 1976 and 1978, respectively. He finished his Ph.D. in Statistics from the Indian Institute of Technology, Kanpur, India, in 1981. He is a Distinguished University Professor at McMaster University, Hamilton, ON, Canada. His research interests include distribution theory, ordered data analysis, censoring methodology, reliability, survival analysis, non-parametric inference, and statistical quality control. Prof. Balakrishnan is a Fellow of the American Statistical Association and a Fellow of the Institute of Mathematical Statistics. He is currently the Editor-in-Chief of Communications in Statistics. He has received an honorary doctorate degree from The National University of Athens in 2016 for his valuable contributions to the field of Statistics.

Erhard Cramer received his Ph.D. from RWTH Aachen University in 1997. He worked did research and taught at University of Oldenburg and at TU Darmstadt before he was appointed Professor of Applied Probability at RWTH Aachen University in 2004. He works now on statistical and probabilistic analysis of ordered data, censoring models, lifetime data, and reliability. He currently serves as associate editor of several statistical journals including Computational Statistics and Communications in Statistics.

Abstract

Warranty is a topic that has been studied extensively by different disciplines including engineering, economics, management science, accounting, and marketing researchers (Blischke and Murthy, Warranty cost analysis. Marcel Dekker, New York, 1994, p 47). Warranty policy is a guarantee for the seller of a product to provide the buyer with a specific service, such as replacement or repair, in the event of the product failure. Today warranty policy is an important marketing factor used by the manufacturers and corporates to promote its product to consumers (Park and Pham, IEEE Trans Syst Man Cybern A

40:1329–1340, 2010). This chapter aims to provide an overview on warranties focusing on the cost and benefit perspective of various warranty and maintenance policies. After a brief introduction of the current status of warranty research, the second part of this chapter classifies various existing and several recent promotional warranty policies to extend the taxonomy initiated by *Blischke and Murthy* (Eur J Oper Res 62:127–148, 1993).

Focusing on the quantitative modeling perspective of both the cost and benefit analyses of warranties, we summarize five problems that are essential to warranty issuers. These problems are: (i) what are the warranty cost factors; (ii) how to compare different warranty policies; (iii) how to analyze the warranty cost of multi-component systems; (iv) how to evaluate the warranty benefits; (v) how to determine the optimal warranty policy.

A list of future warranty research topics are presented in the last part of this chapter. We hope that this will stimulate further interest among researchers and practitioners.

Preventive maintenance · Warranty period · Warranty service · Minimal repair · Indifference price · Warrant policies

10.1 Introduction

Warranty is an obligation attached to products (items or systems) that requires the warranty issuers (manufacturers or suppliers) to provide compensation to consumers according to the warranty terms when the warranted products fail to perform their pre-specified functions under normal usage within the warranty coverage period. Similar definitions can be found in *Blischke and Murthy* [1, 2], *McGuire* [3], and *Singpurwalla and Wilson et al.* [4]. Based on this definition, a warranty contract should contain at least three

characteristics: the coverage period (fixed or random), the method of compensations, and the conditions under which such compensations would be offered. The last characteristic is closely related to warranty execution since it clarifies consumers, rights and protects warranty issuers from excessive false claims. From the costing perspective, the first two characteristics are more important to manufacturers because they determine the depth of the protection against premature failures and the direct cost related to those failures.

Traditionally, warranty serves as a protection instrument attached to products sold to consumers. There are two facets of the protection role: on one hand, it guarantees a properly functioning product for at least a period of w , either financially or physically. On the other hand, it also specifies an upper bound on the liability of the supplier induced by the warranty. In addition to the protection role, warranty has always been one of the most important elements in business marketing strategy. As indicated in [3, p. 1], manufacturers, primary rationale for offering warranty is to support their products to gain some advantage in the market, either by expressing the company's faith in the product quality or by competing with other firms. Due to the more than ever fierce competition in the modern economy, the market promotion role of warranty has become even more significant. Manufacturers are fighting with each other through various channels from competitive pricing, improved product reliability, to more comprehensive warranties. Because of technology constraints or time constraint, it is usually difficult to improve product quality in a short time. As a result, warranty has evolved as an essential part of marketing strategy, along with pricing and advertising, which is especially powerful during the introduction period of new, expensive products such as automobiles and complex machinery.

In the last two decades, warranty has been studied extensively among many disciplines such as engineering, economics, statistics, marketing and management science, to name a few. Consequently, the literature on warranty is not only vast, but also disjoint [1]. There are three books and hundreds of journal articles that have addressed warranty-related problems within the last 10 years. A comprehensive collection of related references up to 1996 can be found in [2]. In general, researchers in engineering are interested in quality control and improving product reliability to reduce production and service costs. Some of the major references are Chen et al. [5], Djamaludin et al. [6], Hedge and Kubat [7], Mi [8], Murthy and Hussain [9], Nguyen and Murthy [10], and Sahin [11]. Economists usually treat warranty as a special type of insurance. Consequently, they developed the economic theory of warranties as one of many applications of microeconomics. We refer readers to DeCroix [12], Emons [13, 14], Lutz and Padmanabhan [15], Padmanabhan and Rao [16], Murthy and Asgharizadeh [17] and the references therein. Statisticians mainly focus on warranty

claim prediction, statistical inference of warranty cost, and estimation of product reliability or availability. Some of the key references are Frees [18, 19], Ja et al. [20], Kalbfleisch [21], Kao and Smith [22, 23], Menzefricke [24], Padmanabhan and Worm [25] and Polatoglu [26]. A long-term trend in warranty study is the focus on various warranty-management aspects. Some recent references are Chun and Tang [27], Ja et al. [20], Lam and Lam [28], Wang and Sheu [29], and Yeh et al. [30, 31]. Blischke and Murthy [32] developed a framework for the analytical study of various issues related to warranty. Recently, Murthy and Djamaludin [33] enriched the framework by summarizing the literature since 1992 from an overall business perspective. Another review by Thomas and Rao [34] provided some suggestions for expanding the analysis methods for making warranty decisions. Park and Pham [35] discussed several cost models with consideration of non-renewable and renewable warranty policies based on two-dimension aspects such as failure times and repair times.

In this chapter, we briefly review some recent work in warranty literature from the manufacturers, perspective. The objectives of this chapter are to classify various existing and relatively new warranty policies to extend the taxonomy discussed in [36], and to summarize and illustrate some fundamental warranty economic problems including several warranty-maintenance policies such as the block replacement and age replacement policies.

10.2 Classification of Warranty Policies

Numerous warranty policies have been studied in the last several decades. Blischke and Murthy [37] presented a taxonomy of more than 18 warranty policies and provided a precise statement of each of them. In this section, we extend the taxonomy by addressing several recently proposed policies that might be of interests to warranty managers. It should be noted that we mainly focus on type A policies [37], which, based on the taxonomy, are referred to as policies for single items and not involving product development.

10.2.1 Renewable and Nonrenewable Warranties

One of the basic characteristics of warranties is whether they are renewable or not. For a regular renewable policy with warranty period w , whenever a product fails within w , the buyer is compensated according to the terms of the warranty contract and the warranty policy is renewed for another period w . As a result, a warranty cycle T , starting from the date of sale, ending at the warranty expiration date, is a random variable whose value depends on w , the total number of failures under the warranty, and the actual failure

inter-arrival times. Renewable warranties are often offered for inexpensive, nonrepairable consumer electronic products such as microwaves, coffee makers, and so forth, either implicitly or explicitly. One should notice that theoretically the warranty cycle for a renewable policy can be arbitrarily large. For example, consumers can induce the failures so that they keep on getting new warranties indefinitely. Such moral hazard problems might be one of the reasons that renewable policies are not as popular as nonrenewable ones among warranty issuers.

One way to remedy this problem is to modify the regular renewable policy in the following way: instead of offering the original warranty with a period of w repeatedly upon each renewing, warranty issuers could set $w_i = \alpha w_{i-1}$, $\alpha \in (0, 1]$, for $i = 1, 2, \dots$, where w_i is the warranty length for the i -th renewing, and $w_0 = w$. Actually, this defines a new type of renewable warranty, which we refer to as geometric renewable warranty policies. Clearly, a geometric renewable policy is a generalization of a regular renewable policy, which degenerates to the latter when $\alpha = 1$.

The majority of warranties in the market are nonrenewable; for these the warranty cycle, which is the same as the warranty period, is not random, but predetermined (fixed), since the warranty obligation will be terminated as soon as w units of time pass after sale. This type of policies is also known as a fixed-period warranty.

10.2.2 FRW, FRPW, PRW, CMW, and FSW Policies

According to the methods of compensation specified in a warranty contract upon premature failures, there are three basic types of warranties: free replacement warranty (FRW), free repair warranty (FRPW), and pro-rata warranty (PRW). Combination warranty (CMW) contains both features of FRW/FRPW and PRW. Full-service warranty, (FSW), which is also known as preventive maintenance warranty, is a policy that may be offered for expensive deteriorating complex products such as automobiles. Under this type of policies, consumers not only receive free repairs upon premature failures, but also free (preventive) maintenance.

For nonrepairable products, the failed products under warranty will usually be replaced free of charge to consumers. Such a policy is often referred to as a free replacement warranty or an unlimited warranty. In practice, even if a product is technically repairable, sometimes it will be replaced upon failure since repair may not be economically sound. As a result, for inexpensive repairable products, warranty issuers could simply offer FRW policies. Consequently, these inexpensive repairable products can be treated as nonrepairable. However, for repairable products, if the warranty terms specify that, upon a valid warranty claim, the warranty

issuer will repair the failed product to working condition free of charge to buyers, then such a policy is a so-called free repair warranty. In practice, it is not rare that a warranty contract specifies that the warranty issuer would repair or replace a defective product under certain conditions. This is the reason why most researchers do not treat FRW and FRPW separately. Nevertheless, we feel that it is necessary to differentiate these two type of policies based on the following reasoning: first, repair cost is usually much lower than replacement cost except for inexpensive products; secondly, by clearly defining the compensation terms, warranty issuers may establish a better image among consumers, which can surely be helpful for the marketing purpose.

Under a FRW policy, since every failed product within T is replaced by a new one, it is reasonable to model all the subsequent failure times by a single probability distribution. However, under a FRPW, it is necessary to model the repair impact on failure times of a warranted product. If it is assumed that any repair is as-good-as-new (perfect repair), then from the modeling perspective, there is little difference between FRW and FRPW. For deteriorating complex systems, minimal repair is a commonly used assumption. Under this assumption, a repair action restores the system's failure rate to the level at the time epoch when the last failure happened. Minimal repair was first introduced by *Barlow and Proschan* [38]. Changing a broken fan belt on an engine is a good example of minimal repair since the overall failure rate of the car is nearly unchanged. Perfect repair and minimal repair represent two extremes relating to the degree of repair. Realistically, a repair usually makes a system neither as-good-as-new, nor as-bad-as-old (minimal repair), but to a level in between. This type of repair is often referred to as imperfect repair. In the literature of maintenance and reliability, many researchers have studied various maintenance policies considering imperfect repair. A recent review on imperfect maintenance was given by *Pham and Wang* [39]. In the warranty literature, the majority of researchers consider repairs as either perfect or minimal. Little has been done on warranty cost analysis considering imperfect repair.

Both FRW and FRPW policies provide full coverage to consumers in case of product failures within T . In contrast, a PRW policy requires that buyers pay a proportion of the warranty service cost upon a failure within T in exchange for the warranty service such as repair or replacement, cash rebate or a discount on purchasing a new product. The amount that a buyer should pay is usually an increasing function of the product age (duration after the sale). As an example, suppose the average repair/replacement cost per failure is c_s , which could be interpreted as the seller's cost per product without warranty, if a linear pro-rata function is used, then the cost for a buyer upon a failure at time t , $t < w$, is $c_s \frac{t}{w}$. The corresponding warranty cost incurred to the manufacturer is $c_s \left(1 - \frac{t}{w}\right)$. PRW policies are usually

renewable and are offered for relatively inexpensive products such as tires, batteries, and so forth.

Generally speaking, FRW and FRPW policies are in the favor of buyers since manufacturers take all the responsibility of providing products that function properly during the whole warranty cycle [1, p. 221]. In other words, it is the manufacturers that bear all the warranty cost risk. In contrast, for PRW policies manufacturers have the relative advantage with regard to the warranty cost risk. Although they do have to offer cash rebates or discounts to consumers if failures happen during T , they are usually better off no matter what consumers choose to do. If a consumer decides not to file a warranty claim, then the manufacturer saves himself the cash rebate or other type of warranty service. If instead a warranty claim is filed, the manufacturer might enjoy the increase in sales or at least the warranty service cost is shared by the consumer.

To balance the benefits between buyers and sellers, a combination warranty (CMW) that contains both features of FRW/FRPW and PRW policies was created. CMW is a policy that usually includes two warranty periods: a free repair/replacement period w_1 followed by a pro-rata period w_2 . This type of warranties is not rare today because it has significant promotional value to sellers, while at the same time it provides adequate control over the costs for both buyers and sellers [2, p. 12].

For deteriorating complex products, it is essential to perform preventive maintenance to achieve satisfactory reliability performance. Maintenance involves planned and unplanned actions carried out to retain a system at, or restore it to, an acceptable operating condition [40]. Planned maintenance is usually referred to as preventive maintenance, while unplanned maintenance is labeled as corrective maintenance or repair. The burden of maintenance is usually on the consumers, side. In [41], Bai and Pham proposed a renewable full-service warranty for multi-component systems under which the failed component(s) or subsystem(s) will be replaced; in addition, a (preventive) maintenance action will be performed to reduce the chance of future product failures, both free of charge to consumers. They argue that such a policy is desirable for both consumers and manufacturers since consumers receive better warranty service compared to traditional FRPW policies, while at the same time manufacturers may enjoy cost savings due to the improved product reliability by the maintenance actions. By assuming perfect maintenance, they derived the probability distributions and the first two moments of the warranty cost per warranty cycle for series, parallel, series-parallel, and parallel-series systems.

Many researchers have studied warranty-maintenance problems. Among them Chun [42] determined the optimal number of periodic maintenance actions during the warranty period by minimizing the expected warranty cost (EWC). Jack and Daguniar [43] generalized Chun's idea by

considering unequal preventive maintenance intervals. Yeh [31] further extended the work by including the degree of maintenance as one of the decision variables along with the number of maintenance actions and the maintenance schedule. All of these three researches aim to obtain the optimal maintenance warranty to assist manufacturers, decision-making. A related problem is the determination of the optimal maintenance strategy following the expiration of warranty from the consumers, perspective. Dagpunar and Jack [44] studied the problem by assuming minimal repair. Through a general approach, Sahin and Polatoglu [45] discussed both stationary and non-stationary maintenance strategies following the expiration of warranty. They proved the pseudo-convex property of the cost rate function under some mild conditions.

10.2.3 Repair-Limit Warranty

In maintenance literature, many researchers studied maintenance policies set up in such a way that different maintenance actions may take place depending on whether or not some pre-specified limits are met. Three types of limits are usually considered: repair-number-limit, repair-time-limit, and repair-cost-limit. Those maintenance policies are summarized by Wang [36].

Similarly, three types of repair-limit warranties may be considered by manufacturers: repair-number-limit warranty (RNLW), repair-time-limit warranty (RTLW), and repair-cost-limit warranty (RCLW). Under a RNLW, the manufacturer agrees to repair a warranted product up to m times within a period of w . If there are more than m failures within w , the failed product shall be replaced instead of being repaired again. Bai and Pham [46] recently studied the policy under the imperfect-repair assumption. They derived the analytical expressions for the expected value and the variance of warranty cost per product sold through a truncated quasi-renewal-process approach.

AN RTLW policy specifies that, within a warranty cycle T , any failures shall be repaired by the manufacturer, free of charge to consumers. If a warranty service cannot be completed within τ unit of time, then a penalty cost occurs to the manufacturer to compensate the inconvenience of the consumer. This policy was analyzed by Murthy and Asgharizadeh [17] in the context of maintenance service operation.

For a RCLW policy, there is a repair cost limit τ in addition to an ordinary FRPW policy. That is, upon each failure within the warranty cycle T , if the estimated repair cost is greater than τ , then replacement instead of repair shall be provided to the consumer; otherwise, normal repair will be performed. This policy has been studied by Nguyen and Murthy [47] and others.

It should be noted that various repair limits as well as other warranty characteristics such as renewing may be combined together to define a new complex warranty. For example, it is possible to have a renewable repair-time-limit warranty for complex systems. Such combinations define a large set of new warranty policies that may appear in the market in the near future. Further study is needed to explore the statistical behavior of warranty costs of such policies to assist decisions of both manufacturers and consumers.

10.2.4 One-Attribute Warranty and Two-Attribute Warranty

Most warranties in practice are one-attribute, for which the warranty terms are based on product age or product usage, but not both. Compared to one-attribute warranties, two-attribute warranties are more complex since the warranty obligation depends on both the product age and product usage as well as the potential interaction between them. Two-attribute warranties are often seen in automobile industry. For example, Hyundai, the Korean automobile company, is currently offering 10 years/100,000 miles limited FRPW on the powertrain for most of their new models.

One may classify two-attribute warranties according to the shape of warranty coverage region. *Murthy* et al. defined four types of two-attribute warranties labeled as policy A to policy D (Fig. 1 in [48]). The shapes of the warranty regions are rectangular, L-shaped with no limits on age or usage, L-shaped with upper limits on age and usage, and triangular, respectively. Based on the concept of the iso-cost curve, *Chun* and *Tang* [27] proposed a set of two-attribute warranty policies for which the expected present values of future repair costs are the same. Some other plausible warranty regions for two-attribute warranty policies were discussed by *Singpurwalla* and *Wilson* [4].

In general, there are two approaches in the analysis of two-attribute warranties, namely, the one-dimensional (1-D) approach [48] and the two-dimensional (2-D) approach [49]. The 1-D approach assumes a relationship between product age and usage; therefore it eventually converts a two-attribute warranty into a corresponding one-attribute warranty. This approach is used by *Moskowitz* and *Chun* [50], and *Chun* and *Tang* [27]. The 2-D approach does not impose a deterministic relationship between age and usage. Instead, a bivariate probability distribution is employed for the two warranty attributes. *Murthy* et al. [48] followed the idea and derived the expressions for the expected warranty cost per item sold and for the expected life cycle cost based on a two-dimensional renewal processes. *Kim* and *Rao* [51] obtained the analytical expressions for the warranty cost for the policies A and B defined in [48] by considering a bivariate exponential distribution. Perhaps the most comprehensive

study of two-attribute warranties so far is by *Singpurwalla* and *Wilson* [4], in which, through a game-theory set up, they discussed in detail both the optimum price-warranty problem and the warranty reserve determination problem. *Park* and *Pham* [49] recently discussed several warranty cost models for complex systems considering two types of warranty periods such as warranty period and post warranty period subject to minimal repairs. They presented the long run expected cost models per unit time with consideration of both the manufacturer and the customer perspectives and provided the optimum decision variables including warranty period, repair time limit and periodical maintenance cycles that minimizes the total expected cost.

10.3 Evaluation of Warranty Policies

Two phenomena make the study of warranties important. First, warranty has become common practice for manufacturers. According to the survey conducted by *McGuire*, nearly 95% of producers of industrial products provide warranties on all of their product lines [3, p. 1]; secondly, there is a huge amount of money involved in warranty programs. Based on a report by the Society of Mechanical Engineering (www.sme.org), the annual warranty cost is about 6 billion dollars for Ford, General Motors and Chrysler combined in the year 2001.

Among many issues related to warranty, there are two fundamental questions that must be answered, especially for warranty issuers: (1) how much a warranty will cost; (2) how much benefit can be earned from a certain warranty. This section summarizes some ideas and discussions appeared in the literature that are closely related to these two questions.

10.3.1 Warranty Cost Factors

Due to the random nature of many warranty cost factors such as product failure times, warranty cost is also a random variable whose statistical behavior can be determined by establishing mathematical links between warranty factors and warranty cost. There are numerous factors that may be considered in warranty studies. Among them, we believe that the followings are of great importance: the characteristics of warranty policies; warranty service cost per failure; product failure mechanism; impact of warranty service on product reliability; warranty service time; and warranty-claim-related factors.

Different warranty policies may require different mathematical models for warranty cost. One way to model the warranty cost per item sold is through a stochastic counting process $[N(t), t \geq 0]$, which represents the number of failures over time of a warranted product. Let S_1, S_2, \dots be the

subsequent failure times, and denote by C_{S_i} the warranty cost associated with the i -th failure. Assuming that all product failures are claimed, that all claims are valid, and instant warranty service, then the total warranty cost per item sold, $C(w)$, can be expressed as

$$C(w) = \begin{cases} \sum_{i=0}^{N[T(w)]} C_{S_i}, & \text{for } N[T(w)] = 1, 2, \dots \\ 0, & \text{for } N[T(w)] = 0. \end{cases} \quad (10.1)$$

From (10.1), it is clear that the probabilistic behavior of $C(w)$ solely depends on $N[T(w)]$ (the number of failures within a warranty cycle T) and C_{S_i} , as well as the potential interaction between them. In general it is very difficult to determine the distribution of $C(w)$. However, it is possible to obtain the moments of $C(w)$ using modern stochastic process theory and probability theory.

For nonrepairable products or repairable products with a single component, warranty service cost per failure is often assumed to be constant. However, for repairable multi-component products, warranty service cost per failure in general is a random variable whose distribution is related to the product (system) structure and the warranty service cost for each component.

Product (system) failure mechanism can be described by the distributions of subsequent system failure times. This involves the consideration of system structure, the reliability of components, and the impact of repair on components, reliability and system reliability. System structure is essential in determining system reliability. Extensive research on reliability modeling has been done for different systems such as series-parallel systems, parallel-series systems, standby systems, k -out-of- n systems, and so forth, in the literature of reliability [52]. Unfortunately, to our knowledge, there is no complete theory or methodology in warranty that incorporates the consideration of various system structure.

If a warranted product is nonrepairable or the as-good-as-new repair assumption is used for repairable products, then a single failure-time distribution can be adopted to describe the subsequent product failure times under warranty. However, if a warranted product is repairable and repairs are not as-good-as-new, then the failure time distribution(s) of repaired products differ(s) from that of a new product. This situation may be modeled by considering a failure-time distribution for all repaired products different from that of new products [1]. Strictly speaking, distributions of subsequent failure times of a repairable product are distinct, therefore, such an approach can be only viewed as an approximation.

As mentioned in section "Evaluation of Warranty Policies," warranty compensation includes free replacement, free repair or cash rebate. For the case of free replacement, warranty service cost per failure for manufacturers is simply a constant that does not depend on the product failure times. In the case of cash rebate (pro-rata policy), warranty cost

per failure usually relies on product failure time as well as the rebate function. When repair, especially the not as-good-as-new repair, is involved in warranty service, one has to model the repair impact on product reliability, which in turn has a great impact on warranty cost per failure. One way to model subsequent failure times under this situation is to consider them as a stochastic process. Consequently, modern stochastic theory of renewal processes, nonhomogeneous Poisson processes, quasi-renewal processes [40] and general point processes could be applied.

To our knowledge, most warranty literature assumes that warranty service is instant. This may be justified when the warranty service time is small compared to the warranty period or the warranty cycle. A better model is to incorporate explicitly the service times into warranty cost modeling. One recent attempt to include non-zero service time in warranty analysis is by *Murthy and Asgharizadeh* [17]. In this chapter, they developed a game-theoretic formulation to obtain the optimal decision in a maintenance service operation.

Warranty claims-related factors include the response of consumers to product failures and the validation of warranty claims by warranty issuers. It is no secret that not all consumers will make warranty claims even if they are entitled to do so. It is also true that warranty issuers, to serve their own benefits, usually have a formal procedure to validate warranty claims before honoring them. Such situations may be modeled by assigning two new parameters α and β , where α is the probability that a consumer will file a claim upon a failure within T , and β is the proportion of the rejected claims [53].

There are other factors that may be of importance in warranty cost evaluation such as nonconforming product quality [5], multiple modes of failure, censored observations [19], etc. Unfortunately, it is impossible to consider all the factors in one warranty cost model. Even if such a model exists, it would be too complicated to be applied.

10.3.2 Criteria for Comparison of Warranties

Warranty managers usually have several choices among various warranty policies that might be applied to a certain type of products. This requires some basic measures as the criteria to make the comparison among these policies.

There are several measures available, including expected warranty cost (EWC) per product sold, expected discounted warranty cost (EDWC) per warranty cycle, monetary utility function and weighted objective function. EWC and EDWC are more popular than the others since they are easy to understand and can be estimated relatively easily. The key difference between them is that the latter one considers the value of time, an important factor for warranty cost accounting and financial managers.

To our opinion, monetary utility function, $U(x)$, is a better candidate for the purpose of comparing warranty policies. The functional form of $U(x)$ reflects the manufacturer's risk attitude. If a manufacturer is risk-neutral, then $U(x)$ is linear in x . This implies that maximizing $E[U(x)]$ is the same as maximizing $U[E(x)]$. However, manufacturers may be risk-averse if they are concerned about the variations in profit or in warranty cost. For example, a particular manufacturer may prefer a warranty with less cost variation than another with much larger variation in warranty cost if the difference between the EWCs is small. If this is the case, then it can be shown that the corresponding utility function is concave [54]. The main difficulty of the utility theory approach is that utility functions are subjective.

Weighted objective functions could also be used for the purpose of comparing warranties for manufacturers. One commonly used weighted objective function is $E[\pi(x)] - \rho V[\pi(x)]$, where ρ is a positive parameter representing the subjective relative importance of the risk (variance or standard deviation) against the expectation and $\pi(x)$ is the manufacturer's profit for a given warranty policy x . Interestingly, such an objective function coincides to a special case of the utility theory approach when the manufacturer's subjective utility function is assumed to only depend on the first two centered moments of $\pi(x)$ [55, 56].

In the above discussion, the term *warranty cost* refers to the manufacturer's cost per warranted product. In our opinion, this is the fundamental measure for the purpose of evaluating any warranty for manufacturers since it provides precise information on the additional cost incurred to manufacturers due to warranty. An equally useful measure is the discounted warranty cost (DWC) per cycle. This measure incorporates the value of time, therefore it is useful when warranty managers are interested in determining warranty reserve level. It is also of importance to financial managers performing warranty cost analysis.

Some researchers have proposed warranty cost per unit time, or warranty cost rate, as the primary warranty cost measure. As indicated by *Blischke* and *Murthy* [2], warranty cost rate is useful in managing warranty servicing resources, such as parts inventory over time with dynamic sales.

Another related measure is warranty cost over a product life cycle. *Blischke* and *Murthy* named this cost as *life cycle cost-II* (LCC-II) [1]. A product life cycle begins with the launch of the product onto the market and ends when it is withdrawn. For consumers, warranty cost analysis is usually conducted over the life time of a product. In [1], this cost is labeled as *life cycle cost-I* (LCC-I). LCC-I is a consumer-oriented cost measure and it includes elements such as purchase cost, maintenance and repair costs following expiration of a warranty, operating costs as well as disposal costs.

Park and Pham [35] studied the expected warranty cost models for two maintenance policies such as age replacement

and block replacement policies with various warranty policies. For instant, if a failed product is delivered to the warranty service center, the repair service is provided, and if the repair time exceeds the repair time limit the replacement service is provided.

10.3.3 Warranty Cost Evaluation for Complex Systems

Most products (systems), especially expensive ones, are composed of several nonrepairable components. Upon a failure, the common repair practice is to replace failed components instead of replacing the whole system. For such products, warranty may be offered for each of the individual components, or for the whole system. For the former case, the warranty cost modeling and analysis for single-component products can be applied readily. In fact, most warranty literature focuses on the analysis of warranty for single-component systems via a black-box approach. However, for the latter case, it is necessary to investigate warranty with explicit consideration of system structure because evidently system structure has a huge impact on product reliability, therefore it is a crucial factor in warranty cost study. Unfortunately, as indicated by *Chukova* and *Dimitrov* [57, p. 544], so far there has been only limited study on this topic.

Some researchers have discussed the warranty cost modeling for parallel systems. For example, *Ritchken* [58] provided an example of a two-component parallel system under a two-dimensional warranty. *Hussain* and *Murthy* [59] also discussed warranty cost estimation for parallel systems under the setting that uncertain quality of new products may be a concern for the design of warranty programs. *Chukova* and *Dimitrov* [57] presented a two-component parallel system under a FRPW policy. Actually, for nonrepairable parallel systems, the modeling techniques of warranty cost is essentially the same as that of black-box systems unless the system is considered as repairable.

To our knowledge, the only published work about warranty study on series systems is by *Chukova* and *Dimitrov* [57, pp. 579–580]. They derived the EWC per system sold for a two-component series system under a FRPW policy which offers free replacement of the failed component if any system failure happens within the warranty period w . Recently, *Bai and Pham* [41] obtained the first two moments of a renewable FSW policy for series, parallel, series–parallel, and parallel–series systems. The derivation of the first two moments of the DWC of nonrenewable FRPW and PRW policies for minimally repaired series systems can be found in [60].

It is possible to use a Markovian model to analyze warranty cost for complex systems. *Balachandran* et al. [61] dealt with the problem of determining warranty service cost of a three-component system using the Markovian approach.

A similar discussion can be seen in [57] and the references therein. Although this approach is a powerful tool in the literature of reliability, queuing systems, and supply-chain management, there are some limitations in the applications of warranty. First of all, it is difficult to determine the appropriate state space and the corresponding transition matrix for the applications in warranty. Secondly, most Markovian models only provide the analysis of measures in the steady states by assuming infinite horizon. In other words, the statistical behavior of those measures in finite horizon (short-run) is either too difficult to obtain or not of practical interest. However, in warranty study, it is crucial to understand the finite-horizon statistical behavior of warranty cost. Thirdly, warranty claim data as well as reliability data are scarce and costly. Markovian models usually require more data since they contain more parameters than ordinary probability models that could be applied to warranty cost study.

Using a quasi-renewal process [62], Park and Pham [63, 64] discussed several warranty cost models including repairable models with a fixed warranty period for multicomponent systems subject to imperfect repair service. In their models, they considered that: (i) the interoccurrence failure intervals are independent of each other and its follow an exponential distribution; (ii) the failed products are repairable; and (iii) the inspection time that examines whether the failed components need repair services or not is negligible. Using a quasi-renewal process [62, 65], they derived the expected warranty cost and the standard deviation of the warrant cost for systems including parallel-series and series-parallel systems. Sgarbossa and Pham [66] and Pham and Zhang [67] developed several cost models of software systems with considerations of risk and warranty factors to obtain the software testing policies that minimizes the total system costs.

10.3.4 Assessing Warranty Benefits

As mentioned in the introduction, warranty is increasingly used as a promotional device for marketing purposes. Consequently, it is necessary to predict and assess quantitatively the benefit that a manufacturer might generate from a specific warranty [34, p. 189]. For promotional warranties, such benefit is usually realized through the demand side. Manufacturers generally expect that the increase in profit as a result of the increase in sale, which is boosted by warranty, should cover the future warranty cost.

A simple way to quantify the benefit is to model it as a function of the parameter(s) of a warranty policy, for example, w , the warranty period. A linear form and a quadratic form of w were employed by Thomas [34, 68] for this purpose. As he acknowledged, both forms were not well-founded and shared the problem of oversimplification [34, p. 193]. Another approach is to estimate the demand function

empirically. Menezes and Currim [69] posited a general demand function where the quantity sold by a firm offering a warranty with period w is a function of its price, warranty length, advertising, distribution, quality, product feature, and the corresponding values for the firm,s competitor. Based on the data from *Ward,s Automotive Yearbook*, *Consumer Reports*, *Advertising Age*, *Leading National Advertisers*, and other sources during the period 1981–1987, they obtained the price elasticity and the warranty elasticity, which enabled them to obtain the optimal warranty length through maximizing the present value of cumulative future profit over a finite planning horizon. One of the limitations of this approach, as pointed out by the authors, is that it requires the support of historical sales data. As a result, it cannot be applied to new products or existing products without such historical data [69, p. 188].

A related problem of the demand side of warranty is the modeling of sales over time. Mahajan et al. presented several variant diffusion models that may be appropriate for consumer durables [70]. Ja et al. obtained the first two moments of warranty cost in a product life cycle by assuming a nonhomogeneous Poisson sale process [20]. It seems that such models do not allow the interaction between warranty and sales, therefore, they may not be used in estimating warranty benefit.

There is some research (Emons [14], Lutz and Padmanabhan [15], Padmanabhan and Rao [16], etc.) on the demand side of warranty concerning moral hazard, advertising, consumers satisfaction, and so forth. However, compared to the vast warranty literature on estimating total warranty cost, the study on the demand side of warranty is far behind. Hopefully we will see more studies on this aspect in the future.

10.3.5 On the Optimal Warranty Policy

One of the most important objectives of warranty study is to assist warranty management. In particular, in the design phase of a warranty program, there are often a set of warranties that might be appropriate for a specific type of products. The problem faced by warranty managers therefore is how to determine the optimal warranty policy.

An early attempt to address the warranty design problem is based on the concept of life-cycle costing (Blischke [71], Mamer [72]). It is assumed that a consumer requires the product over a certain time period or life cycle from the same producer repeatedly upon each product failure no matter whether under warranty or not. Under this idealized producer–consumer relationship, the producer,s life-cycle profit and the consumer,s life-cycle cost can be calculated. Consequently, a consumer indifference price may be determined by comparing consumer,s life-cycle costs with or without warranty. Similarly, the producer,s indifference price

may be calculated based on the comparison of the life-cycle profits with or without warranty.

An alternative approach is to set up an optimization problem to determine the optimal price and warranty length combination jointly through a game-theoretic perspective. In general, two parties, a warranty issuer and a representative consumer, participate in the game. The latter acts as a follower who responds rationally to each potential warranty offer by maximizing his/her utility. The former, as a leader, makes the decision on the optimal warranty strategy, which maximizes the expected profit, based on the anticipated rational response by the consumer. *Singpurwalla and Wilson* [4] studied two-attribute warranties through this approach. Some others references are *Chun and Tang* [73], *DeCroix* [12], *Glickman and Berger* [74], *Ritchken* [75], *Thomas* [68], and the references therein. In the context of production planning and marketing, *Mitra and Patankar* [76] presented a multi-criteria model that could be used in warranty design.

Now, we present a general formulation of the warranty design problem with some discussion, which may raise more interest among researchers and practitioners for further study.

Let $\Psi = \{\psi_1, \psi_2, \dots, \psi_n\}$ represent the set of appropriate warranty policies for a given type of products. Policy ψ_i may contain more than one parameter. Denote by w_i the set of warranty parameters for ψ_i ; then we can represent ψ_i by $\psi(w_i)$ or w_i . If w_i contains only one parameter, say, w_i , the warranty period, then $w_i = \{w_i\}$. Denote by $p(w_i)$ the selling price under the policy ψ_i , and by $C_j(w_i)$ the random warranty cost for the j -th product sold under the policy ψ_i . Let p_0 be the production cost per unit (not including the warranty cost), then the optimal warranty policy $\psi(w^*)$ may be obtained by solving

$$\begin{aligned} & \max_{\{w_i, \forall i=1,2,\dots,n\}} E \{U[\pi(w_i)]\} \\ & \text{s.t. } w_i^l \leq w_i \leq w_i^u, \forall i, i = 1, 2, \dots, n \\ & P \left[\sum_{j=1}^{d(w_i)} C_j(w_i) \geq R_0 \right] \leq \alpha, \forall i, i = 1, 2, \dots, n, \end{aligned}$$

where

$U(\cdot)$ is the monetary utility function that reflects the risk attitude of the manufacturer. It is a linear function if the manufacturer is risk-neutral and a concave function in the case of a risk-averse manufacturer;

$$\pi(w_i) = \sum_{j=1}^{d(w_i)} [p(w_i) - p_0 - C_j(w_i)],$$

w_i^l, w_i^u : are some lower and upper bounds of w_i ;
 $d(w_i)$ represents the demand function for $\psi(w_i)$;
 R_0 is the predetermined warranty budget level; and
 α is the risk-tolerance level of the manufacturer with regard to R_0 .

One should note that the second set of constraints is actually related to *value at risk* (VaR), a concept widely used in risk management, which indicates the maximum percentage value of an asset that could be lost during a fixed period within a certain confidence level [77]. It is reasonable to assume that manufacturers want to control VaR such that the probability that the total warranty cost is over the budget is within the accepted level α .

Solving the optimization problem might be a challenge. First of all, it is difficult to determine the demand function $d(w_i)$, although it is possible to estimate it through marketing surveys or historical data. Secondly, it is required that warranty managers have complete knowledge of the selling price $p(w_i)$. This requires a pricing strategy in the design phase of warranty. It should be noted that we could have considered $p(w_i)$ as one of the decision variables, but this makes the problem more complicated. Besides, it is not rare in practice that the price is simply set by adding a fixed margin over the estimated production cost with warranty. Thirdly, it is required that the probability distribution of warranty cost should be known. Little research has been done with regard to this issue except *Polatoglu and Sahin* [26] and *Sahin and Polatoglu* [78]. In general, numerical methods are required for this purpose. Fourthly, the problem is formulated as a nonlinear optimization problem with some constraints, which may be solved by nonlinear optimization software such as GAMS. However, in general there is no guarantee of the existence of a global optimal solution.

10.4 Concluding Remarks

A warranty problem, by its nature, is a multi-disciplinary research topic. Many researchers ranging from the industry engineer, economist, statistician, to marketing researchers have contributed greatly to warranty literature. In this chapter, we present an overview of warranty policies, focusing on the cost and benefit analysis from warranty issuers, perspective. Although we have successfully addressed several problems in this area, there are still a lot of opportunities for future research, a few of which are listed below:

- To advance warranty optimization models and perform empirical study based on the new developed models.
- To develop and apply efficient algorithms to solve warranty optimization problems.
- To propose and analyze new warranty policies appropriate for complex systems.
- To Study the distribution and the moments of discounted warranty cost for various policies.
- Warranty cost modeling for systems with more complex structures, including standby systems, bridge systems, network systems, etc.

- Develop warranty models considering failure dependency between components due to environmental impact.

Abstract

The first section of this chapter introduces statistical process control (SPC) and robust design (RD), two important statistical methodologies for quality and productivity improvement. Section 11.1 describes in-depth SPC theory and tools for monitoring independent and autocorrelated data with a single quality characteristic. The relationship between SPC methods and automatic process control methods is discussed and differences in their philosophies, techniques, efficiencies, and design are contrasted. SPC methods for monitoring multivariate quality characteristics are also briefly reviewed.

Section 11.2 considers univariate RD, with emphasis on experimental design, performance measures and modeling of the latter. Combined and product arrays are featured and performance measures examined, include signal-to-noise ratios SNR, PerMIAs, process response, process variance, and desirability functions. Of central importance is the decomposition of the expected value of squared-error loss into variance and off-target components which sometimes allows the dimensionality of the optimization problem to be reduced. Besides, this section deals with multivariate RD and demonstrates that the objective function for the multiple characteristic case is typically formed by additive or multiplicative combination of the univariate objective functions, and lists RD case studies originating from applications in manufacturing, reliability, and tolerance design.

Section 11.3 discusses the mainstream methods used in the prognostics and health management (PHM) framework, including updated research from the literatures of both statistical science and engineering. Additionally, this section provides an overview of the systems health monitoring and management (SHMM) framework, discusses its basic structure, and lists several applications of SHMM to complex systems and to critical components within the context of a big data environment.

Keywords

Control chart · Minimum mean square error · Robust design · Desirability function · Statistical process control · Health monitoring and management

In the current international marketplace, continuous quality improvement is pivotal for maintaining a competitive advantage. Although quality improvement activities are most efficient and cost-effective when implemented as part of the design and development stages (off-line), on-line activities such as statistical process control (SPC) are vital for maintaining quality during manufacturing.

Statistical process control (SPC) is an effective tool for achieving process stability and improving process capability through variation reduction. Primarily, SPC is used to classify sources of process variation as either common cause or assignable cause. Common cause variations are inherent to a process and can be described implicitly or explicitly by stochastic models. Assignable cause variations are unexpected and difficult to predict beforehand. The basic idea of SPC is to quickly detect and correct assignable cause variation before quality deteriorates and defective units are produced. The primary SPC tool was developed in the 1920s by Walter Shewhart of Bell Telephone Laboratories and has been tremendously successful in manufacturing applications [1–3].

Robust design (RD) is a systematic methodology that uses statistical experimental design to improve the design of products and processes. By making product and process performance insensitive (robust) to hard-to-control disturbances (noise), robust design simultaneously improves product quality, the manufacturing process, and reliability. The RD method was originally developed by the Japanese quality consultant, *Genichi Taguchi* [4]. Taguchi's 1980 introduction of robust parameter design to several major American industries resulted in significant quality improvements in product and process design [5]. Since then, a great deal of research on RD has improved related statistical techniques and clarified underlying principles.

In addition, many RD case studies have demonstrated phenomenal cost savings. In the electronics industry, *Kackar* and *Shoemaker* [6] reported a 60% process variance reduction; *Phadke* [5] reported a fourfold reduction in process variance and a twofold reduction in processing time – both from running simple RD experiments. In other industries, the American Supplier Institute (1983–1990) reported a large number of successful case studies in robust design.

Although most data is multivariate in nature, research in both areas has largely focused on normally distributed univariate characteristics (responses). *Montgomery* and *Woodall* [2] present a comprehensive panel discussion on SPC (see also *Woodall* and *Montgomery* [7]) and multivariate methods are reviewed by *Lowry* and *Montgomery* [8] and *Mason* [9].

Seminal research papers on RD include *Kackar* [10], *Leon* et al. [11], *Box* [12], *Nair* [13], and *Tsui* [14]. RD problems with multiple characteristics are investigated by *Logothetis* and *Haigh* [15], *Pignatiello* [16], *Elsayed* and *Chen* [17], and *Tsui* [18]. This research has yielded techniques allowing engineers to effectively implement SPC and RD in a host of applications.

This chapter briefly revisits the major developments in both SPC and RD that have occurred over the last 30 years and suggests future research directions while highlighting multivariate approaches. Section 11.1 covers SPC of univariate and multivariate random variables for both Shewhart (including \bar{x} and s charts) and non-Shewhart approaches (CUSUM and EWMA), while assessing the effects of autocorrelation and automatic process control. Section 11.2 considers univariate RD, emphasizing performance measures and modeling for loss functions, dual responses, and desirability functions; deals with multivariate and dynamic RD; and recaps RD case studies from the statistics literature in manufacturing, process control, and tolerance design. Finally, Sect. 11.3 provides an overview of PHM and SHMM framework.

11.1 Statistical Process Control for Single Characteristics

The basic idea in statistical process control is a binary view of the state of a process; in other words, it is either running satisfactorily or not. *Shewhart* [19] asserted that the process state is related the type of variation manifesting itself in the process. There are two types of variation, called common cause and assignable or special cause variation. Common cause variation refers to the assumption that “future behavior can be predicted within probability limits determined by the common cause system” [20]. Special cause variation refers to “something special, not part of the system of common causes” [21]. A process that is subject only to common cause variation is “statistically” in control, since the variation is inherent to the process and therefore eliminated only with great difficulty. The objective of statistical process control is to identify and remove special cause variation as quickly as possible.

SPC charts essentially mimic a sequential hypothesis test to distinguish assignable cause variation from common cause variation. For example, a basic mathematical model behind SPC methods for detecting change in the mean is

$$X_t = \eta_t + Y_t,$$

where X_t is the measurement of the process variable at time t , and η_t is the process mean at that time. Here Y_t represents variation from the common cause system. In some

applications, Y_t can be treated as an independently and identically distributed (iid) process. With few exceptions, the mean of the process is constant except for abrupt changes, so

$$\eta_t = \eta + \mu_t,$$

where η is the mean target and μ_t is zero for $t < t_0$ and has nonzero values for $t \geq t_0$. For analytical simplicity step changes are often assumed; in other words μ_t remains at a new constant level μ for $t \geq t_0$.

11.1.1 SPC for I.I.d. Processes

The statistical goal of SPC control charts is to detect the change point t_0 as quickly as possible and trigger corrective action to bring the process back to the quality target. Among many others, the Shewhart chart, the EWMA chart, and the CUSUM chart are three important and widely used control charts.

Shewhart Chart

The Shewhart control chart monitors the process observations directly,

$$W_t = X_t - \eta.$$

Assuming that the standard deviation of W_t is σ_W , the stopping rule of the Shewhart chart is defined as $|W_t| > L\sigma_W$, where L is prespecified to maintain particular probability properties.

EWMA Chart

Roberts [22] introduces a control charting algorithm based on the exponentially weighted moving average of the observations,

$$W_t = \sum_{i=0}^{\infty} w_i (X_{t-i} - \eta),$$

where $w_i = \lambda(1 - \lambda)^i$, ($0 < \lambda \leq 1$). It can be rewritten as

$$W_t = (1 - \lambda)W_{t-1} + \lambda(X_t - \eta), \quad (11.1)$$

where $W_0 = 0$ or the process mean. The stopping rule of the EWMA chart is $|W_t| > L\sigma_W$ where $\sigma_W = \sqrt{\lambda/(2 - \lambda)}\sigma_X$. The Shewhart chart is a special case of the EWMA chart with $\lambda = 1$. When the underlying process is i.i.d., the EWMA chart with small λ values is sensitive to the detection of small and medium shifts in mean [23].

CUSUM Chart

Page [24] introduces the CUSUM chart as a sequential probability test. It can be simply obtained by letting λ approach zero in (11.1). The CUSUM algorithm assigns equal weights to past observations, and its tabular form consists of two quantities,

$$\begin{aligned} W_t^+ &= \max[0, W_{t-1}^+ + (X_t - \eta) - k\sigma_X], \\ W_t^- &= \min[0, W_{t-1}^- + (X_t - \eta) - k\sigma_X], \end{aligned}$$

where $W_0^+ = W_0^- = 0$. It can be shown that the CUSUM chart with $k = \mu/2$ is optimal for detecting a mean change in μ when the observations are i.i.d.

Because of the randomness of the observations, these control charts may trigger false alarms – out-of-control signals issued when the process is still in control. The expected number of units measured between two successive false alarms is called the *in-control* average run length $(ARL)_0$. When a special cause presents itself, the expected period before a signal is triggered is called the *out-of-control* average run length $(ARL)_1$. The ideal control chart has a long ARL_0 and a short ARL_1 . The Shewhart chart typically uses the constant $L = 3$, so that the in-control ARL is 370 when the underlying process is i.i.d. with normal distribution.

These SPC charts are very effective for monitoring the process mean when the process data is i.i.d. It has been shown that the Shewhart chart is sensitive for detecting large shifts while the EWMA and CUSUM charts are sensitive to small shifts [23]. However, a fundamental assumption behind these SPC charts is that the common cause variation is free of serial correlation. Due to the prevalence of advanced sensing and measurement technology in manufacturing processes, the assumption of independence is often invalid. For example, measuring critical in-process dimensions is now possible on every unit in the production of discrete parts. In continuous process production systems, the presence of inertial elements such as tanks, reactors, and recycle streams often result in significant serial correlation in the measured variables. Serial correlation creates many challenges and opportunities for SPC methodologies.

11.1.2 SPC for Autocorrelated Processes

Traditional SPC charts have been shown to function poorly while monitoring and controlling serially correlated processes [25, 26]. To accommodate autocorrelation, the following time series methods have been proposed.

Modifications of Traditional Methods

One common SPC strategy is to plot the autocorrelated data on traditional charts whose limits have been modified to account for the correlation. Johnson and Bagshaw [27] and

Bagshaw and Johnson [28] consider the effects of autocorrelation on CUSUM charts using the weak convergence of cumulative sums to a Wiener process. Another alternative is the exponentially weighted moving average chart for stationary processes (EWMAST) studied by Zhang [29]. Jiang et al. [30] extend this to a general class of control charts based on autoregressive moving average (ARMA) charts. The monitoring statistic of an ARMA chart is defined to be the result of a *generalized* ARMA(1, 1) process applied to the underlying process $\{X_t\}$,

$$\begin{aligned} W_t &= \theta_0 X_t - \theta X_{t-1} + \phi W_{t-1} \\ &= \theta_0 (X_t - \beta X_{t-1}) + \phi W_{t-1}, \end{aligned} \quad (11.2)$$

where $\beta = \theta/\theta_0$ and θ_0 is chosen so that the sum of the coefficients is unity when W_t is expressed in terms of the X_t 's, so $\theta_0 = 1 + \theta - \phi$. The authors show that these charts exhibit good performance when the chart parameters are chosen appropriately.

Forecast-Based Monitoring Methods

Forecast-based charts started with the special-cause charts (SCC) proposed by Alwan and Roberts [31]. The general idea is to first apply a one-step-ahead predictor to the observation $\{X_t\}$ and then monitor the corresponding prediction error,

$$W_t = e_t, \quad (11.3)$$

where $e_t = X_t - \hat{X}_t$ is the forecast error of predictor \hat{X}_t . The SCC method is the first example that uses minimum mean squared error (MMSE) predictors and monitors the MMSE residuals. When the model is accurate, the MMSE prediction errors are approximately uncorrelated. This removal of correlation means that control limits for the SCC can be easily calculated from traditional Shewhart charts, EWMA charts, and CUSUM charts. Another advantage of the SCC method is that its performance can be analytically approximated.

The SCC method has attracted considerable attention and has been extended by many authors. Among them, Harris and Ross [25] and Superville and Adams [32] investigate process monitoring based on the MMSE prediction errors for simple autoregressive [AR(1)] models; Wardell et al. [33, 34] discuss the performance of SCC for ARMA(1, 1) models; and Vander Wiel [35] studies the performance of SCC for integrated moving average [IMA(0, 1, 1)] models. SCC methods perform poorly when detecting small shifts since a constant mean shift always results in a dynamic shift pattern in the error term.

In general this approach can be applied to any predictor. Montgomery and Mastrangelo [36] recommend the use of EWMA predictors in the SCC method (hereafter called the M–M chart). Jiang et al. [37] propose the use of

proportional-integral-derivative (PID) predictors

$$\begin{aligned} \hat{X}_t &= \hat{X}_{t-1} + (k_p + k_i + k_d)e_{t-1} \\ &\quad - (k_p + 2k_d)e_{t-2} + k_d e_{t-3}, \end{aligned} \quad (11.4)$$

where k_p , k_i , and k_d are parameters of the PID controller defined in Sect. 11.1.3. The family of PID-based charts includes the SCC, EWMA, and M–M charts as special cases. Jiang et al. [37] show that the predictors of the EWMA chart and M–M chart may sometimes be inefficient and the SCC over-sensitive to model deviation. They also show that the performance of the PID-based chart is affected by the choice of chart parameters. For any given underlying process, one can therefore tune the parameters of the PID-based chart to optimize its performance.

GLRT-Based Multivariate Methods

Since forecast-based residual methods monitor a single statistic e_t , they often suffer from the problem of a narrow “window of opportunity” when the underlying process is positively correlated [35]. If the shift occurrence time is known, the problem can be alleviated by including more historical observations/residuals in the test. This idea was first proposed by Vander Wiel [35] using a generalized likelihood ratio test (GLRT) procedure. Assuming residual signatures $\{\delta_i\}$ when a shift occurs, the GLRT procedure based on residuals is

$$W_t = \max_{0 \leq k \leq p-1} \left| \sum_{i=0}^k \delta_i e_{t-k+i} \right| / \sqrt{\sum_{i=0}^k \delta_i^2}, \quad (11.5)$$

where p is the prespecified size of the test window. Apley and Shi [38] show that this procedure is very efficient in detecting mean shifts when p is sufficiently large. Similar to the SCC methods, this is model-based and the accuracy of signature strongly depends on the window length p . If p is too small and a shift is not detected within the test window, the signature in (11.5) might no longer be valid and the test statistic no longer efficient.

Note that a step mean shift at time $t - k + 1$ results in a signature

$$d_k = \left(0, \dots, 0, \overbrace{1, \dots, 1}^k \right)' \quad (1 \leq k \leq p)$$

and

$$d_k = (1, 1, \dots, 1)' \quad (k > p)$$

on $U_t = (X_{t-p+1}, X_{t-p+2}, \dots, X_t)'$. To test these signatures, the GLRT procedure based on observation vector W_t

is defined as

$$W_t = \max_{0 \leq k \leq p-1} |d'_k \Sigma_U^{-1} U_t| / \sqrt{d'_k \Sigma_U^{-1} d_k}, \quad (11.6)$$

where Σ_U is the covariance matrix of U_t . Jiang [39] points out that this GLRT procedure is essentially model-free and always matches the true signature of U_t regardless of the timing of the change point. If a non-step shift in the mean occurs, multivariate charts such as Hotelling's T^2 charts can be developed accordingly [40].

Monitoring Batch Means

One of the difficulties with monitoring autocorrelated data is accounting for the underlying autocorrelation. In simulation studies, it is well known that batch means reduce autocorrelation within data. Motivated by this idea, Runger and Willemain [41, 42] use a weighted batch mean (WBM) and a unified batch mean (UBM) to monitor autocorrelated data. The WBM method weighs the mean of observations, defines batch size so that autocorrelation among batches is reduced to zero and requires knowledge of the underlying process model [43]. The UBM method determines batch size so that autocorrelation remains below a certain level and is "model-free". Runger and Willemain show that the UBM method is simple and often more cost-effective in practice.

Batch-means methods not only develop statistics based on batch-means, but also provide variance estimation of these statistics for some commonly used SPC charts. Alexopoulos et al. [44] discuss promising methods for dealing with correlated observations including nonoverlapping batch means (NBM), overlapping batch means (OBM) and standardized time series (STS).

11.1.3 SPC Versus APC

Automatic process control (APC) complements SPC as a variation reduction tool for manufacturing industries. While SPC techniques are used to reduce unexpected process variation by detecting and removing the cause of variation, APC techniques are used to reduce systematic variation by employing feedforward and feedback control schemes. The relationships between SPC and APC are important to both control engineers and quality engineers.

Feedback Control Versus Prediction

The feedback control scheme is a popular APC strategy that uses the deviation of output from target (set-point) to signal a disturbance of the process. This deviation or error is then used to compensate for the disturbance. Consider a pure-gain dynamic feedback-controlled process, as shown in Fig. 11.1. The process output can be expressed as

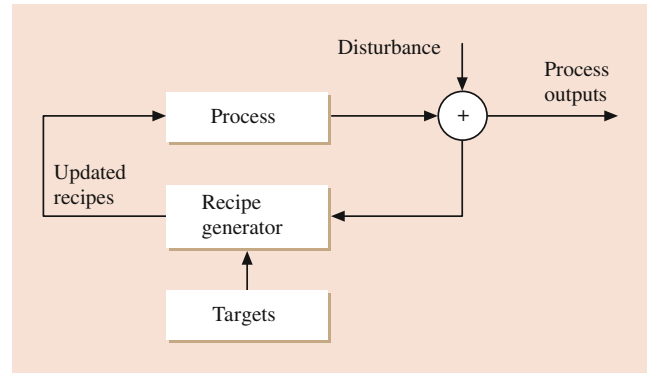

Fig. 11.1 Automatic process control

$$e_t = X_t - Z_{t-1}. \quad (11.7)$$

Suppose \hat{X}_t is an estimator (a predictor) of X_t that can be obtained at time $t - 1$. A realizable form of control can be obtained by setting

$$Z_{t-1} = -\hat{X}_t \quad (11.8)$$

so that the output error at time $t + 1$ becomes

$$e_t = X_t - \hat{X}_t, \quad (11.9)$$

which is equal to the "prediction error". Control and prediction can therefore have a one-to-one corresponding relationship via (11.8) and (11.9).

As shown in Box and Jenkins [45], when the process can be described by an ARIMA model, the MMSE control and the MMSE predictor have exactly the same form. Serving as an alternative to the MMSE predictor, the EWMA predictor corresponds to the integral (I) control [46] and is one of the most frequently used prediction methods due to its simplicity and efficiency. In general, the EWMA predictor is robust against nonstationarity due to the fact that the I control can continuously adjust the process whenever there is an offset.

An extension of the I control is the widely used PID control scheme,

$$Z_t = -k_p e_t - k_I \frac{1}{1-B} e_t - k_D (1-B) e_t, \quad (11.10)$$

where k_p, k_I , and k_D are constants that, respectively, determine the amount of proportional, integral, and derivative control action. The corresponding PID predictor (11.4) can be obtained from (11.8) and (11.10). When $\lambda_3 = 0$, in other words when $k_D = 0$ (and thus $\lambda_1 = k_p + k_I$ and $\lambda_2 = -k_p$), we have a PI predictor corresponding to the proportional-integral control scheme commonly used in industry.

Process Prediction Versus Forecast-Based Monitoring Methods

As discussed in Sect. 11.1.2, one class of SPC methods for autocorrelated processes starts from the idea of “whitening” the process and then monitoring the “whitened” process with time series prediction models. The SCC method monitors MMSE prediction errors and the M–M chart monitors the EWMA prediction error. Although the EWMA predictor is optimal for an IMA(0, 1, 1) process, the prediction error is no longer i.i.d. for predicting other processes. Most importantly, the EWMA prediction error that originated from the I control can compensate for mean shifts in steady state which makes the M–M chart very problematic for detecting small shifts in mean.

Since PID control is very efficient and robust, PID-based charts motivated by PID predictors outperform SCC and M–M charts. APC-based knowledge of the process can moreover clarify the performance of PID-based charts. In summary, the P term ensures that process output is close to the set point and thus sensitive in SPC monitoring, whereas the I term always yields control action regardless of error size which leads to a zero level of steady-state error. This implies that the I term is dominant in SPC monitoring. The purpose of derivative action in PID control is to improve closed-loop stability by making the D term in SPC monitoring less sensitive. Although there is no connection between the EWMA predictor and the EWMA chart, it is important to note that the I control leads to the EWMA predictor and the EWMA prediction-based chart is the M–M chart. As shown in Jiang et al. [37], the EWMA chart is the same as the P-based chart.

11.1.4 SPC for Automatically Controlled Processes

Although APC and SPC techniques share the objective of reducing process variation, their advocates have quarreled for decades. It has recently been recognized that the two techniques can be integrated to produce more efficient tools for process variation reduction [47–52]. This APC/SPC integration employs an APC rule to regulate the system and superimposes SPC charts on the APC-controlled system to detect process departures from the system model. Using Deming’s terminology, the APC scheme is responsible for reducing common cause variation, while the SPC charts are responsible for reducing assignable cause variation. From the statistical point of view, the former part resembles a parameter estimation problem for forecasting and adjusting the process and the latter part emulates a hypothesis test of process location. Figure 11.2 pictures a conceptual integration of SPC charts into the framework of a feedback control scheme. To avoid confusion, Box and Luceno [46] refer to

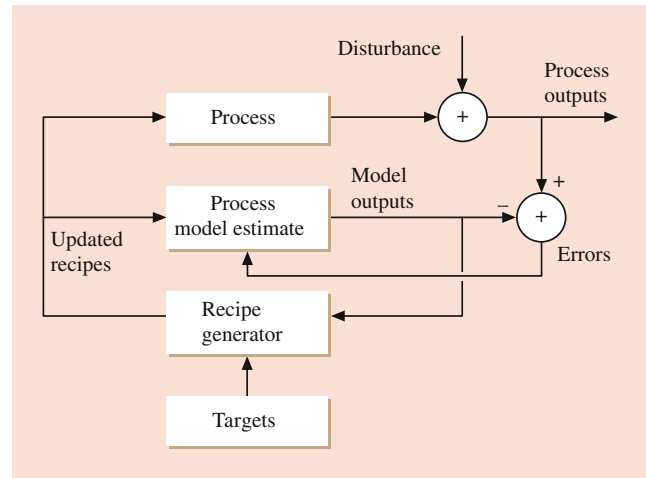

Fig. 11.2 APC/SPC integration

APC activities as process adjustment and to SPC activities as process monitoring. Since this chapter emphasizes SPC methods for quality improvement, we discuss only the monitoring component of APC/SPC integration.

As discussed in Sect. 11.1.3, control charts developed for monitoring autocorrelated observations shed light on the monitoring of integrated APC/SPC systems. Fundamentally, the output of an automatically controlled process is recommended for SPC monitoring. This is equivalent to forecast-based control charts of the corresponding predictor. For example, if the process is controlled by an MMSE controller, monitoring the output is exactly the same as the SCC method. Similar to forecast-based methods, assignable causes have an effect that is always contaminated by the APC control action which results in a limited “window of opportunity” for detection [35]. As an alternative, some authors suggest that monitoring the APC control action may improve the probability of detection [20]. Jiang and Tsui [53] compare the performance of monitoring the output vs. the control action of an APC process and show that for some autocorrelated processes monitoring the control action may be more efficient than monitoring the output of the APC system.

In general, the performance achieved by SPC monitoring an APC process depends on the data stream (the output or the control action) being measured, the APC control scheme employed, and the underlying autocorrelation of the process. If information from process output and control action can be combined, a universal monitor with higher SPC efficiency [51] can be developed. Kourti et al. [54] propose a method of monitoring process outputs conditional on the inputs or other changing process parameters. Li et al. [55] propose multivariate control charts such as Hotelling’s T^2 chart and the Bonferroni approach to monitor output and control action simultaneously. Defining the vector of outputs and control actions as $V_t = (e_t, \dots, e_{t-p+1}, X_t, \dots, X_{t-p+1})'$, a dynamic T^2

chart with window size p monitors statistic

$$W_t = V_t' \Sigma_V^{-1} V_t,$$

where Σ_V is the covariance matrix of V_t [56]. W_t follows a χ^2 distribution during each period given known process parameters. However, strong serial correlation exists so that the χ^2 quantiles cannot be used for control limits. By recognizing the mean shift patterns of V_t , Jiang [57] develops a GLRT procedure based on V_t . This GLRT procedure is basically univariate and more efficient than the T^2 chart.

11.1.5 Design of SPC Methods: Efficiency Versus Robustness

Among many others, the minimization of mean squared error/prediction error is one of the important criteria for prediction/control scheme design. Although the special cause chart is motivated by MMSE prediction/control, many previously mentioned SPC charts such as the PID chart have fundamentally different criteria from those of the corresponding APC controllers. When selecting SPC charts, the desired goal is maximization of the probability of shift detection.

For autocorrelated processes, Jiang [37] propose an ad hoc design procedure using PID charts. They demonstrate how two capability indices defined by signal-to-noise ratios (SNR) play a critical role in the evaluation of SPC charts. They denote σ_w as the standard deviation of charting statistic W_t and μ_T (μ_S) as the shift levels of W_t at the first step (l long enough) after the shift takes place. The transient state ratio is defined as $C_T = \mu_T/\sigma_w$, which measures the capability of the control chart to detect a shift in its first few steps. The steady state ratio is defined as $C_S = \mu_S/\sigma_w$, which measures the ability of the control chart to detect a shift in its steady state. These two signal-to-noise ratios determine the efficiency of the SPC chart and can be manipulated by selecting control chart parameters.

For a particular mean shift level, if the transient state ratio/capability can be tuned to a high value (say 4–5) by choosing appropriate chart parameters, the corresponding chart will detect the shift very quickly. Otherwise the shift will likely be missed during the transient state and will need to be detected in later runs. Since a high steady state ratio/capability heralds efficient shift detection at steady state, a high steady state ratio/capability is also desired. However, the steady state ratio/capability should not be tuned so high that it results in an extremely small transient ratio/capability, indicative of low probability of detection during the transient state. To endow the chart with efficient detection at both states, a tradeoff is needed when choosing the charting parameters. An approximate C_S value of 3 is generally appropriate for balancing the values of C_T and C_S .

One of the considerations when choosing an SPC method is its robustness to autocorrelated and automatically controlled processes. Robustness of a control chart refers to how insensitive its statistical properties are to model misspecification. Reliable estimates of process variation are of vital importance for the proper functioning of all SPC methods [58]. For process X_t with positive first-lag autocorrelation, the standard deviation derived from moving range is often underestimated because

$$E(\hat{\sigma}_{MR}) = E(\overline{MR}/d_2) = \sigma_X \sqrt{1 - \rho_1},$$

where ρ_1 is the first-lag correlation coefficient of X_t [59].

A more serious problem with higher sensitivity control charts such as the PID chart is that they may be less robust than lower sensitivity control charts such as the SCC. Berube et al. [60] and Luceno [61] conclude that PID controllers are generally more robust than MMSE controllers against model specification error. However Jiang [37] shows that PID charts tend to have a shorter “in-control” ARL when the process model is mis-specified since model errors can be viewed as a kind of “shift” from the “true” process model. This seems to be a discouraging result for higher sensitivity control charts. In practice, a trade-off is necessary between sensitivity and robustness when selecting control charts for autocorrelated processes. Apley and Lee [62] recommend using a conservative control limit for EWMA charts when monitoring MMSE residuals. By using the worst-case estimation of residual variance, the EWMA chart can be robustly designed for the in-control state with a slight efficiency loss in the out-of-control state. This design strategy can be easily generalized to other SPC methods for autocorrelated or automatically controlled processes.

11.1.6 SPC for Multivariate Characteristics

Through modern sensing technology that allows frequent measurement of key quality characteristics during manufacturing, many in-process measurements are strongly correlated to each other. This is especially true for measurements related to safety, fault detection and diagnosis, quality control, and process control. In an automatically controlled process, for example, process outputs are often strongly related to process control actions. Joint monitoring of these correlated characteristics ensures appropriate control of the overall process. Multivariate SPC techniques have recently been applied to novel fields such as environmental monitoring and detection of computer intrusion.

The purpose of multivariate on-line techniques is to investigate whether measured characteristics are simultaneously in statistical control. A specific multivariate quality control problem is to consider whether an observed vector of mea-

surements $\mathbf{x} = (x_1, \dots, x_k)$ exhibits a shift from a set of “standard” parameters $\boldsymbol{\mu}^0 = (\mu_1^0, \dots, \mu_k^0)'$. The individual measurements will frequently be correlated, meaning that their covariance matrix Σ will not be diagonal.

Versions of the univariate Shewhart, EWMA and CUSUM charts have been developed for the case of multivariate normality.

Multivariate T^2 Chart

To monitor a multivariate vector, *Hotelling* [63] suggested an aggregated statistic equivalent to the Shewhart control chart in the univariate case,

$$T^2 = (\mathbf{x} - \boldsymbol{\mu}^0)' \hat{\Sigma}_x^{-1} (\mathbf{x} - \boldsymbol{\mu}^0), \quad (11.11)$$

where $\hat{\Sigma}_x$ is an estimate of the population covariance matrix Σ . If the population covariance matrix is known, *Hotelling's* T^2 statistic follows a χ^2 distribution with k degrees of freedom when the process is in-control. A signal is triggered when $\chi^2 > \chi^2_{k,\alpha}$. One of the important features of the T^2 charts is that its out-of-control performance depends solely on the noncentrality parameter $\delta = \sqrt{(\boldsymbol{\mu} - \boldsymbol{\mu}^0)' \hat{\Sigma}_x^{-1} (\boldsymbol{\mu} - \boldsymbol{\mu}^0)}$, where $\boldsymbol{\mu}$ is the actual mean vector. This means that its detectional performance is invariant along the contours of the multivariate normal distribution.

Multivariate EWMA Chart

Hotelling's T^2 chart essentially utilizes only current process information. To incorporate recent historical information, *Lowry* [64] develop a similar multivariate EWMA chart

$$W_t^2 = \mathbf{w}_t' \Sigma_w^{-1} \mathbf{w}_t,$$

where $\mathbf{w}_t = \Lambda(\mathbf{x}_t - \boldsymbol{\mu}^0) + (\mathbf{I} - \Lambda)\mathbf{w}_{t-1}$ and $\Lambda = \text{diag}(\lambda_1, \lambda_2, \dots, \lambda_k)$. For simplicity, $\lambda_i = \lambda$ ($1 \leq i \leq k$) is generally adopted and $\Sigma_w = \lambda/(2 - \lambda)\Sigma_x$.

Multivariate CUSUM Chart

There are many CUSUM procedures for multivariate data. *Crosier* [65] proposes two multivariate CUSUM procedures, cumulative sum of T (COT) and MCUSUM. The MCUSUM chart is based on the statistics

$$s_t = \begin{cases} \mathbf{0} & \text{if } C_t \leq k_1 \\ (s_{t-1} + \mathbf{x}_t) (1 - k_1/C_t) & \text{if } C_t > k_1, \end{cases} \quad (11.12)$$

where $s_0 = \mathbf{0}$, $C_t = \sqrt{(s_{t-1} + \mathbf{x}_t)' \Sigma_x^{-1} (s_{t-1} + \mathbf{x}_t)}$, and $k_1 > 0$. The MCUSUM chart signals when $W_t = s_t' \Sigma_x^{-1} s_t > h_1$. *Pignatiello* and *Runger* [66] propose another multivariate CUSUM chart (MC1) based on the vector of cumulative sums,

$$W_t = \max\left(0, \sqrt{D_t' \Sigma_x^{-1} D_t} - k_2 l_t\right) \quad (11.13)$$

where $k_2 > 0$, $D_t = \sum_{i=t-l_t+1}^t \mathbf{x}_i$, and

$$l_t = \begin{cases} l_{t-1} + 1 & \text{if } W_{t-1} > 0 \\ 1 & \text{otherwise.} \end{cases}$$

Once an out-of-control signal is triggered from a multivariate control chart, it is important to track the cause of the signal so that the process can be improved. Fault diagnosis can be implemented by T^2 decompositions following the signal and large components are suspected to be faulty. Orthogonal decompositions such as principal component analysis are popular tools. *Hayter* and *Tsui* [67] propose other alternatives which integrate process monitoring and fault diagnosis. *Jiang* and *Tsui* [68] provide a thorough review of these methods.

Variable-Selection-Based Multivariate Chart

In high dimensional applications, it is very rare to see all interested variables or quality characteristics change or shift at the same time. Rather, a typical yet common phenomenon observed in practice is that a subset of variables, which is dominated by a common latent physical mechanism or component, deviate from their normal condition due to abnormal changes of the common mechanism or component [69–71]. By penalizing likelihood functions to locate potential out-of-control variables, *Wang* and *Jiang* [72] and *Zou* and *Qiu* [73] independently propose to monitor a variable-dimension T^2 statistic, which has better efficiency than traditional full-size T^2 statistic. *Zou* et al. [74] and *Jiang* et al. [75] further utilized the LASSO algorithm for fault diagnosis.

Multivariate Chart Using Real-Time Contrast

Instead of monitoring departures from a nominal mean vector in Phase II, multivariate RTC control charts monitor distances between real time data and Phase I reference data using classification methods. Mis-classification probabilities serve as a reasonable candidate for monitoring differences between the two populations [76]. Classification methods such as linear discrimination analysis (LDA), support vector machines (SVM), etc. can be deployed and kernel-based methods can also be adapted to account for nonlinear boundary between Phases I and II data [77, 78]. Since these classification methods look for a projection direction such that certain “distance” metric are optimized, projection pursuit can be generalized by measuring empirical divergence between the two probability distributions for real-time monitoring [79].

11.1.7 SPC for Profile Monitoring

In many applications, the quality of a process or product is best characterized and summarized by a functional relationship between a response variable and one or more explanatory variables. Profile monitoring is used to understand and to check the stability of this relationship over time. At each sampling stage one observes a collection of data points that can be represented by a curve (or profile). In some calibration applications, the profile can be represented adequately by a simple linear regression model, while in other applications more complicated models are needed.

Profile monitoring is very useful in an increasing number of practical applications. Much of the work in the past few years has focused on the use of more effective charting methods, the study of more general shapes of profiles, and the study of the effects of violations of assumptions. There are many promising research topics yet to be pursued given the broad range of profile shapes and possible models. Woodall et al. (2004) [80] highlighted the following important issues when monitoring profiles:

1. The usefulness of carefully distinguishing between Phase I and Phase II applications.
2. The decision regarding whether or not to include some between profile variation in common cause variation.
3. The use of methods capable of detecting any type of shift in the shape of the profile.
4. The use of the simplest adequate profile model.

Paynabar et al. [81] developed a new modeling, monitoring, and diagnosis framework for phase-I analysis of multichannel profiles. Woodall et al. [82] conducted a comprehensive review on the use of control charts to monitor process and product quality profiles.

11.2 Design of Experiment and Robust Parameter Design

11.2.1 Robust Design for Single Responses

Taguchi [4] introduced parameter design, a method for designing processes that are robust (insensitive) to uncontrollable variation, to a number of American corporations. The objective of this methodology is to find the settings of design variables that minimize the expected value of squared-error loss defined as

$$L(Y, t) = (Y - t)^2, \quad (11.14)$$

where Y represents the actual process response and t the targeted value. A loss occurs if the response Y deviates from

its target t . This loss function originally became popular in estimation problems considering unbiased estimators of unknown parameters. The expected value of $(Y - t)^2$ can be easily expressed as

$$\begin{aligned} E(L) &= A_0 E(Y - t)^2 \\ &= A_0 [\text{Var}(Y) + (E(Y) - t)^2], \end{aligned} \quad (11.15)$$

where $\text{Var}(Y)$ and $E(Y)$ are the mean and variance of the process response and A_0 is a proportional constant representing the economic costs of the squared error loss. If $E(Y)$ is on target then the squared-error loss function reduces to the process variance. Its similarity to the criterion of least squares in estimation problems makes the squared-error loss function easy for statisticians and engineers to grasp. Furthermore the calculations for most decision analyses based on squared-error loss are straightforward and easily seen as a trade-off between variance and the square of the off-target factor.

Robust design (RD) assumes that the appropriate performance measure can be modeled as a transfer function of the fixed control variables and the random noise variables of the process as follows:

$$Y = f(\mathbf{x}, \mathbf{N}, \boldsymbol{\theta}) + \epsilon, \quad (11.16)$$

where $\mathbf{x} = (x_1, \dots, x_p)^T$ is the vector of control factors, $\mathbf{N} = (N_1, \dots, N_q)^T$ is the vector of noise factors, $\boldsymbol{\theta}$ is the vector of unknown response model parameters, and f is the transfer function for Y . The control factors are assumed to be fixed and represent the fixed design variables. The noise factors \mathbf{N} are assumed to be random and represent the uncontrolled sources of variability in production. The pure error ϵ represents the remaining variability that is not captured by the noise factors and is assumed to be normally distributed with zero mean and finite variance.

Taguchi divides the design variables into two subsets, $\mathbf{x} = (\mathbf{x}_a, \mathbf{x}_d)$, where \mathbf{x}_a and \mathbf{x}_d are called respectively the adjustment and nonadjustment design factors. An adjustment factor influences process location while remaining effectively independent of process variation. A nonadjustment factor influences process variation.

Experimental Designs for Parameter Design

Taguchi's Product Arrays and Combined Arrays

Taguchi's experimental design takes an orthogonal array for the controllable design parameters (an inner array of control factors) and crosses it with another orthogonal array for the factors beyond reasonable control (an outer array of noise factors). At each test combination of control factor levels, the entire noise array is run and a performance measure is calculated. Hereafter we refer to this design as the product

array. These designs have been criticized by *Box* [12] and others for being unnecessarily large.

Welch [83] combined columns representing the control and noise variables within the same orthogonal array. These combined arrays typically have a shorter number of test runs and do not replicate the design. The lack of replication prevents unbiased estimation of random error but we will later discuss research addressing this limitation.

Which to Use: Product Array or Combined Array

There is a wide variety of expert opinion regarding choice of experimental design in *Nair* [13]. The following references complement *Nair*'s comprehensive discussion. *Ghosh and Derderian* [84] derive robustness measures for both product and combined arrays, allowing the experimenter to objectively decide which array provides a more robust option. *Miller et al.* [85] consider the use of a product array on gear pinion data. *Lucas* [86] concludes that the use of classical, statistically designed experiments can achieve the same or better results than Taguchi's product arrays. *Rosenbaum* [87] reinforces the efficiency claims of the combined array by giving a number of combined array designs which are smaller for a given orthogonal array strength or stronger for a given size. Finally, *Wu and Hamada* [88] provide an intuitive approach to choosing between product and combined array based on an effect-ordering principle.

They list the most important class of effects as those containing control–noise interactions, control main effects and noise main effects. The second highest class contains the control–control interactions and the control–control–noise interactions while the third and least important class contains the noise–noise interactions. That array producing the highest number of clear effect estimates in the most important class is considered the best design.

Noting that the combined array is often touted as being more cost-effective due to an implied smaller number of runs, *Wu and Hamada* place the cost comparison on a more objective basis by factoring in both cost per control setting and cost per noise replicate. They conclude that the experimenter must prioritize the effects to be estimated and the realistic costs involved before deciding which type of array is optimal.

Choosing the Right Orthogonal Array for RD

Whether the experimenter chooses a combined or product array, selecting the best orthogonal array is an important consideration. The traditional practice in classical design of experiments is to pick a Resolution IV or higher design so that individual factors are aliased with three factor interactions, of which there are relatively few known physical examples.

However, the estimation of main effects is not necessarily the best way to judge the value of a test design for RD. The control–noise interactions are generally regarded as having equal importance as the control effects for fine tuning the

final control factor settings for minimal product variation. Hence evaluation of an experimental design for RD purposes must take into account the design's ability to estimate the control–noise interactions deemed most likely to affect product performance.

Kackar and Tsui [89] feature a graphical technique for showing the confounding pattern of effects within a two-level fractional factorial. *Kackar et al.* [90] define orthogonal arrays and describe how Taguchi's fixed element arrays are related to well known fractional factorial designs. Other pieces related to this decision are *Hou and Wu* [91], *Berube and Nair* [60], and *Bingham and Sitter* [92].

D-Optimal Designs

In this section several authors show how D-optimal designs can be exploited in RD experiments. A D-optimal design minimizes the area of the confidence ellipsoids for parameters being estimated from an assumed model. Their key strength is their invariance to linear transformation of model terms and their characteristic weakness is a dependence on the accuracy of the assumed model. By using a proper prior distribution to attack the singular design problem and make the design less model-dependent, *Dumouchel and Jones* [93] provide a Bayesian D-optimal design needing little modification of existing D-optimal search algorithms.

Atkinson and Cook [94] extend the existing theory of D-optimal design to linear models with nonconstant variance. With a Bayesian approach they create a compromise design that approximates preposterior loss. *Vining and Schaub* [95] use D-optimality to evaluate separate linear models for process mean and variance. Their comparison of the designs indicates that replicated fractional factorials of assumed constant variance best estimate variance while semi-Bayesian designs better estimate process response.

Chang [96] proposes an algorithm for generating near D-optimal designs for multiple response surface models. This algorithm differs from existing approaches in that it does not require prior knowledge or data-based estimates of the covariance matrix to generate its designs. *Mays* [97] extends the quadratic model methodology of RSM to the case of heterogeneous variance by using the optimality criteria D (maximal determinant) and I (minimal integrated prediction variance) to allocate test runs to locations within a central composite design.

Other Designs

The remaining references discuss types of designs used in RD which are not easily classified under the more common categories previously discussed.

Pledger [98] divides noise variables into observable and unobservable and argues that one's ability to observe selected noise variables in production should translate into better choices of optimal control settings. *Rosenbaum* [99] uses blocking to separate the control and noise variables in

combined arrays, which were shown in *Rosenbaum* [87] to be stronger for a given size than the corresponding product array designs. *Li* and *Nachtsheim* [100] present experimental designs which don't depend on the experimenter's prior determination of which interactions are most likely significant.

Performance Measures in RD

In Sect. 11.2.1, we compared some of the experimental designs used in parameter design. Of equal importance is choosing which performance measure will best achieve the desired optimization goal.

Taguchi's Signal-to-Noise Ratios

Taguchi introduced a family of performance measures called signal-to-noise ratios whose specific form depends on the desired response outcome. The case where the response has a fixed nonzero target is called the nominal-the-best case (NTB). Likewise, the cases where the response has a smaller-the-better target or a larger-the-better target are, respectively, called the STB and LTB cases.

To accomplish the objective of minimal expected squared-error loss for the NTB case, Taguchi proposed the following two-step optimization procedure: (i) Calculate and model the SNRs and find the nonadjustment factor settings which maximize the SNR. (ii) Shift mean response to the target by changing the adjustment factor(s).

For the STB and LTB cases, Taguchi recommends directly searching for the values of the design vector \mathbf{x} which maximize the respective SNR. Alternatives for these cases are provided by *Tsui* and *Li* [101] and *Berube* and *Wu* [102].

Performance Measure Independent of Adjustment (PerMIAs)

Taguchi did not demonstrate how minimizing the SNR would achieve the stated goal of minimal average squared-error loss. *Leon* et al. [11] defined a function called the performance measure independent of adjustment (PerMIA) which justified the use of a two-step optimization procedure. They also showed that Taguchi's SNR for the NTB case is a PerMIA when both an adjustment factor exists and the process response transfer function is of a specific multiplicative form. When Taguchi's SNR complies with the properties of a PerMIA, his two-step procedure minimizes the squared-error loss.

Leon et al. [11] also emphasized two major advantages of the two-step procedure:

- It reduces the dimension of the original optimization problem.
- It does not require reoptimization for future changes of the target value.

Box [12] agrees with *Leon* et al. [11] that the SNR is only appropriately used in concert with models where process sigma is proportional to process mean. *Maghsoodloo* [103] derives and tabulates exact mathematical relationships between Taguchi's STB and LTB measures and his quality loss function.

Leon and *Wu* [104] extend the PerMIA of *Leon* et al. [11] to a maximal PerMIA which can solve constrained minimization problems in a two-step procedure similar to that of Taguchi. For nonquadratic loss functions, they introduce general dispersion, location, and off-target measures, while developing a two-step process. They apply these new techniques in a number of examples featuring additive and multiplicative models with nonquadratic loss functions. *Tsui* and *Li* [101] establish a multistep procedure for the STB and LTB problem based on the response model approach under certain conditions.

Process Response and Variance as Performance Measures

The dual response approach is a way of finding the optimal design settings for a univariate response without the need to use a loss function. Its name comes from its treatment of mean and variance as responses of interest which are individually modeled. It optimizes a primary response while holding the secondary response at some acceptable value.

Nair and *Pregibon* [105] suggest using outlier-robust measures of location and dispersion such as median (location) and interquartile range (dispersion). *Vining* and *Myers* [106] applied the dual response approach to Taguchi's three SNRs while restricting the search area to a spherical region of limited radius. *Copeland* and *Nelson* [107] solve the dual response optimization problem with the technique of direct function minimization. They use the Nelder-Mead simplex procedure and apply it to the LTB, STB, and NTB cases. Other noteworthy papers on the dual response method include *Del Castillo* and *Montgomery* [108] and *Lin* and *Tu* [109].

Desirability as a Performance Measure

The direct conceptual opposite of a loss function, a utility function maps a specific set of design variable settings to an expected utility value (value or worth of a process response). Once the utility function is established, nonlinear direct search methods are used to find the vector of design variable settings that maximizes utility.

Harrington [110] introduced a univariate utility function called the desirability function, which gives a quality value between zero (unacceptable quality) and one (further improvement would be of no value) of a quality characteristic of a product or process. He defined the two-sided desirability function as follows:

$$d_i = e^{-|Y_i|^c}, \quad (11.17)$$

where e is the natural logarithm constant, c is a positive number subjectively chosen for curve scaling, and Y_i' is a linear transformation of the univariate response Y_i whose properties link the desirability values to product specifications. It is of special interest to note that for $c = 2$, a mid-specification target and response values within the specification limits, this desirability function is simply the natural logarithm constant raised to the squared-error loss function.

Other Performance Measures

Ng and *Tsui* [111] derive a measure called q-yield which accounts for variation from target among passed units as well as nonconforming units. It does this by penalizing yield commensurate with the amount of variation measured within the passed units. *Joseph* and *Wu* [102] develop modeling and analysis strategies for a general loss function where the quality characteristic follows a location-scale model. Their three-step procedure includes an adjustment step which moves the mean to the side of the target with lower cost. Additional performance measures are introduced in *Joseph* and *Wu* [112] and *Joseph* and *Wu* [113].

Modeling the Performance Measure

The third important decision the experimenter must grapple with is how to model the chosen performance measure. Linear models are by far the most common way to approximate loss functions, SNR's, and product responses. This section covers response surface models, the generalized linear model, and Bayesian modeling.

Response Surface Models

Response surface models (RSM) are typically second-order linear models with interactions between the first-order model terms. While many phenomena cannot be accurately represented by a quadratic model, the second-order approximation of the response in specific regions of optimal performance may be very insightful to the product designer.

Myers et al. [114] make the case for implementing Taguchi's philosophy within a well established, sequential body of empirical experimentation, RSM. The combined array is compared to the product array and the modeling of SNR compared to separate models for mean and variance. In addition, RSM lends itself to the use of mixed models for random noise variables and fixed control variables. *Myers* et al. [115] incorporate noise variables and show how mean and variance response surfaces can be combined to create prediction limits on future response.

Analysis of Unreplicated Experiments

The most commonly cited advantage of modeling process responses rather than SNR is the use of more efficient

combined arrays. However, the gain in efficiency usually assumes there is no replication for estimating random error. Here we review references for analyzing the data from unreplicated fractional factorial designs.

Box and *Meyer* [116] present an analysis technique which complements normal probability plots for identifying significant effects from an unreplicated design. Their Bayesian approach assesses the size of contrasts by computing a posterior probability that each contrast is active. They start with a prior probability of activity and assume normality of the significant effects and deliver a nonzero posterior probability for each effect.

Lenth [117] introduces a computationally simple and intuitively pleasing technique for measuring the size of contrasts in unreplicated fractional factorials. The Lenth method uses standard T statistics and contrast plots to indicate the size and significance of the contrast. Because of its elegant simplicity, the method of Lenth is commonly cited in RD case studies.

Pan [118] shows how failure to identify even small and moderate location effects can subsequently impair the correct identification of dispersion effects when analyzing data from unreplicated fractional factorials. *Wu* and *Hamada* [88] propose a simple simulation method for estimating the critical values employed by Lenth in his method for testing significance of effects in unreplicated fractional factorial designs.

McGrath and *Lin* [119] show that a model that does not include all active location effects raises the probability of falsely identifying significant dispersion factors. They show analytically that without replication it is impossible to deconfound a dispersion effect from two location effects.

Generalized Linear Model

The linear modeling discussed in this chapter assumes normality and constant variance. When the data does not demonstrate these properties, the most common approach is to model a compliant, transformed response. In many cases, this is hard or impossible. The general linear model (GLM) was developed by *Nelder* and *Wedderburn* [120] as a way of modeling data whose probability distribution is any member of the single parameter exponential family.

The GLM is fitted by obtaining the maximum likelihood estimates for the coefficients to the terms in the linear predictor, which may contain continuous, categorical, interaction, and polynomial terms. *Nelder* and *Lee* [121] argue that the GLM can extend the class of useful models for RD experiments to data-sets, wherein a simple transformation cannot necessarily satisfy the important criteria of normality, separation, and parsimony. Several examples illustrate how the link functions are chosen.

Engel and *Huele* [122] integrate the GLM within the RSM approach to RD. Nonconstant variance is assumed and models for process mean and variance are obtained from a heteroscedastic linear model of the conditional process

response. The authors claim that nonlinear models and tolerances can also be studied with this approach. *Hamada and Nelder* [123] apply the techniques described in *Nelder and Lee* [121] to three quality improvement examples to emphasize the utility of the GLM in RD problems over its wider class of distributions.

Bayesian Modeling

Bayesian methods of analysis are steadily finding wider employment in the statistical world as useful alternatives to frequentist methods. In this section we mention several references on Bayesian modeling of the data.

Using a Bayesian GLM, *Chipman and Hamada* [124] overcome the GLM's potentially infinite likelihood estimates from categorical data taken from fractional factorial designs. *Chipman* [125] uses the model selection methodology of *Box and Meyer* [126] in conjunction with priors for variable selection with related predictors. For optimal choice of control factor settings, he finds posterior distributions to assess the effect of model and parameter uncertainty.

11.2.2 Robust Design for Multiple Responses

Earlier we discussed loss and utility functions and showed how the relation between off-target and variance components underlies the loss function optimization strategies for single responses. Multi-response optimization typically combines the loss or utility functions of individual responses into a multivariate function to evaluate the sets of responses created by a particular set of design variable settings. This section is divided into two subsections which, respectively, deal with the additive and multiplicative combination of loss and utility functions, respectively.

Additive Combination of Univariate Loss, Utility and SNR

The majority of multiple response approaches additively combine the univariate loss or SNR performance measures discussed. In this section, we review how these performance measures are additively combined and their relative advantages and disadvantages as multivariate objective functions.

Multivariate Quadratic Loss

For univariate responses, expected squared-error loss is a convenient way to evaluate the loss caused by deviation from target because of its decomposition into squared off-target and variance terms. A natural extension of this loss function to multiple correlated responses is the multivariate quadratic loss (MQL) function of the deviation vector $(Y - \tau)$ where $Y = (Y_1, \dots, Y_r)^T$ and $\tau = (t_1, \dots, t_r)^T$, i.e.,

$$\text{MQL}(Y, \tau) = (Y - \tau)^T A (Y - \tau), \quad (11.18)$$

where A is a positive definite constant matrix. The values of the constants in A are related to the costs of nonoptimal design, such as the costs related to repairing and/or scrapping noncompliant product. In general, the diagonal elements of A represent the weights of the r characteristics and the off-diagonal elements represent the costs related to pairs of responses being simultaneously off-target.

It can be shown that, if Y follows a multivariate normal distribution with mean vector $E(Y)$ and covariance matrix Σ_Y , the average (expected) loss can be written as:

$$\begin{aligned} E(\text{MQL}) &= E(Y - \tau)^T A (Y - \tau) \\ &= \text{Tr}(A \Sigma_Y) \\ &\quad + [E(Y) - \tau]^T A [E(Y) - \tau]. \end{aligned} \quad (11.19)$$

The simplest approach to solving the RD problem is to apply algorithms to directly minimize the average loss function in (11.19). Since the mean vector and covariance matrix are usually unknown, they can be estimated by the sample mean vector and sample covariance matrix or a fitted model based on a sample of observations of the multivariate responses. The off-target vector product $[E(Y) - \tau]^T A [E(Y) - \tau]$ and $\text{Tr}(A \Sigma_Y)$ are multivariate analogs to the squared off-target component and variance of the univariate squared-error loss function. This decomposition shows how moving all response means to target simplifies the expected multivariate loss to the $\text{Tr}(A \Sigma_Y)$ term. The trace-covariance term shows how the values of A and the covariance matrix Σ_Y directly affect the expected multivariate loss.

Optimization of Multivariate Loss Functions

For the expected multivariate quadratic loss of (11.19), *Pignatiello* [16] introduced a two-step procedure for finding the design variable settings that minimize this composite cost of poor quality. *Tsui* [18] extended *Pignatiello's* two-step procedure to situations where responses may be NTB, STB or LTB.

To this point we have examined squared-error loss functions whose expected value is decomposed into off-target and variance components. *Ribeiro and Elsayed* [127] introduced a multivariate loss function which additionally considers fluctuation in the supposedly fixed design variable settings. *Ribeiro et al.* [128] add a term for manufacturing cost to the gradient loss function of *Ribeiro and Elsayed*.

Additive Formation of Multivariate Utility Functions

Kumar et al. [129] suggest creating a multiresponse utility function as the additive combination of utility functions from the individual responses where the goal is to find the set of design variable settings that maximizes overall utility. Additional papers related to this technique include *Artiles-Leon* [130] and *Ames et al.* [131].

Quality Loss Functions for Nonnegative Variables

Joseph [132] argues that, in general, processes should not be optimized with respect to a single STB or LTB characteristic, rather than a combination of them. He introduces a new class of loss functions for nonnegative variables which accommodates the cases of unknown target and asymmetric loss and which can be additively combined for the multiresponse case.

Multivariate Utility Functions from Multiplicative Combination

In this section, a multivariate desirability function is constructed from the geometric average of the individual desirability functions of each response.

The geometric average (GA) of r components (d_1, \dots, d_r) is the r th root of their products:

$$\text{GA}(d_1, \dots, d_r) = \left(\prod_{i=1}^r d_i \right)^{\frac{1}{r}}. \quad (11.20)$$

The GA is then a multiplicative combination of the individuals. When combining individual utility functions whose values are scaled between zero and one, the GA yields a value less than or equal to the lowest individual utility value. When rating the composite quality of a product, this prevents any single response from reaching an unacceptable value, since a very low value on any crucial characteristic (such as safety features or cost) will render the entire product worthless to the end user.

Modifications of the Desirability Function

In order to allow placement of the ideal target value anywhere within the specifications, *Derringer* and *Suich* [133] introduced a modified version of the desirability functions of *Harrington* [110] which encompassed both one-sided and two-sided response specifications. Additional extensions of the multivariate desirability function were made by *Kim* and *Lin* [134].

Alternative Performance Measures for Multiple Responses

Duffy et al. [135] propose using a reasonably precise estimate of multivariate yield, obtained via Beta distribution discrete point estimation, as an efficient alternative to Monte Carlo simulation. This approach is limited to independently distributed design variables. *Fogliatto* and *Albin* [136] propose using predictor variance as a multiresponse optimization criterion. They measure predictive variance as the coefficient of variance (CV) of prediction since it represents a normalized measure of prediction variance. *Plante* [137] considers the use of maximal process capability as the criterion for choosing control variable settings in multiple response RD situations. He uses the concepts of process capability and

desirability to develop process capability measures for multiple response systems.

11.2.3 Dynamic Robust Design

Taguchi's Dynamic Robust Design

Up to this point, we've discussed only static RD, where the targeted response is a given, fixed level and is only affected by control and noise variables. In dynamic robust design (DRD) a third type of variable exists, the signal variable M whose magnitude directly affects the mean value of the response. The experimental design recommended by Taguchi for DRD is the product array consisting of an inner control array crossed with an outer array consisting of the sensitivity factors and a compound noise factor.

A common choice of dynamic loss function is the quadratic loss function popularized by Taguchi,

$$L[Y, t(M)] = A_0[Y - t(M)]^2, \quad (11.21)$$

where A_0 is a constant. This loss function provides a good approximation to many realistic loss functions. It follows that the average loss becomes

$$\begin{aligned} R(\mathbf{x}) &= A_0 E_M E_{N,\epsilon} [Y - t(M)]^2 \\ &= A_0 E_M \left\{ \text{Var}_{N,\epsilon}(Y) + [E_{N,\epsilon}(Y) - t(M)]^2 \right\}. \end{aligned} \quad (11.22)$$

Taguchi identifies dispersion and sensitivity effects by modeling SNR respectively as a function of control factors and sensitivity factors. His two-step procedure for DRD finds control factor settings to minimize SNR and sets other, non-SNR related control variables to adjust the process to the targeted sensitivity level.

References on Dynamic Robust Design

Ghosh and *Derderian* [138] introduce the concept of robustness of the experimental plan itself to the noise factors present when conducting DRD. For combined arrays they consider blocked and split-plot designs and for product arrays they consider univariate and multivariate models. In product arrays they do this by choosing settings which minimize the noise factor effects on process variability and for the combined array they attempt to minimize the interaction effects between control and noise factors.

Wasserman [139] clarifies the use of the SNR for the dynamic case by explaining it in terms of linear modeling of process response. He expresses the dynamic response as a linear model consisting of a signal factor, the true sensitivity (β) at specific control variable settings, and an error term. *Miller* and *Wu* [140] prefer the term signal-response system to dynamic robust design for its intuitive appeal and its iden-

tification of two distinct types of signal-response systems. They call them measurement systems and multiple target systems, where this distinction determines the performance measure used to find the optimal control variable settings.

Lunani et al. [141] present two new graphical procedures for identifying suitable measures of location and dispersion in RD situations with dynamic experimental designs. *McCaskey and Tsui* [142] show that Taguchi's two-step procedure for dynamic systems is only appropriate for multiplicative models and develop a procedure for dynamic systems under an additive model. For a dynamic system this equates to minimizing the sum of process variance and bias squared over the range of signal values.

Tsui [143] compares the effect estimates obtained using the response model approach and Taguchi's approach for dynamic robust design problems. Recent publications on DRD include *Joseph and Wu* [144], *Joseph and Wu* [145], and *Joseph* [146].

11.2.4 Applications of Robust Design

Manufacturing Case Studies

Mesenbrink [147] applied the techniques of RD to optimize three performance measurements of a high volume wave soldering process. They achieved significant quality improvement using a mixed-level fractional factorial design to collect ordered categorical data regarding the soldering quality of component leads in printed circuit boards. *Lin and Wen* [148] apply RD to improve the uniformity of a zinc coating process.

Chhajer and Lowe [149] apply the techniques of RD to the problem of structured tool management. For the cases of tool selection and tool design, they use Taguchi's quadratic loss function to find the most cost effective way to accomplish the processing of a fixed number of punched holes in sheet metal products.

Reliability Applications

Reliability is the study of how to make products and processes function for longer periods of time with minimal interruption. It is a natural area for RD application and the Japanese auto industry has made huge strides in this area compared to its American counterpart. In this section several authors comment on the application of RD to reliability.

Hamada [150] demonstrates the relevance of RD to reliability improvement. He recommends the response model approach for the additional information it provides on control-noise interactions and suggests alternative performance criteria for maximizing reliability. *Kuhn et al.* [151] extend the methods of *Myers et al.* [114] for linear models and normally distributed data to achieve a robust process when time to an event is the response.

Tolerance Design

This chapter has focused on RD, which is synonymous with Taguchi's methods of parameter design. Taguchi has also made significant contributions in the area of tolerance design. This section reviews articles which examine developments in the techniques of tolerance design.

D'errico and Zaino [152] propose a modification of Taguchi's approach to tolerance design based on a product Gaussian quadrature which provides better estimates of high-order moments and outperforms the basic Taguchi method in most cases. *Bisgaard* [153] proposes using factorial experimentation as a more scientific alternative to trial and error to design tolerance limits when mating components of assembled products.

Zhang and Wang [154] formulate the robust tolerance problem as a mixed nonlinear optimization model and solve it using a simulated annealing algorithm. The optimal solution allocates assembly and machining tolerances so as to maximize the product's insensitivity to environmental factors. *Li and Wu* [55] combined parameter design with tolerance design.

Maghsoodloo and Li [155] consider linear and quadratic loss functions for determining an optimal process mean which minimizes the expected value of the quality loss function for asymmetric tolerances of quality characteristics. *Moskowitz et al.* [156] develop parametric and nonparametric methods for finding economically optimal tolerance allocations for a multivariable set of performance measures based on a common set of design parameters.

11.3 Reliability and Prognostics and Health Management

11.3.1 Prognostics and Health Management

Prognostics and health management (PHM) is a framework that offers comprehensive solutions for monitoring and managing health status of individual machine and engineering systems. In recent years, PHM has emerged to be a popular approach for improving reliability, maintainability, safety, and affordability. Concepts and components in PHM have been applied in many domain areas such as mechanical engineering, electrical engineering, statistical science, etc.

Due to high impact and extreme costs associated with system failures, it is important to develop methods that can predict and prevent such catastrophes before they occur. Many application methods have been developed in domains such as electronics-rich systems, aerospace industries, or even the public health environment [157, 158], which can be grouped under the framework of prognostics and health management (PHM). Prognostics is the process of predicting the future reliability of a product by assessing its degradation

from its expected normal operating conditions; health management is the process of real time monitoring the extent of deviation or degradation from normal operating condition [159, 160]. Traditional reliability prediction methods (e.g., US Department of Defense Mil-Hdbk-217 and Telcordia SR-332 (formerly [161])), make strong assumptions that constant hazard rate of each component can be modified to account for various operating and environmental conditions. In PHM approach, we monitor the system's health status in real time and dynamically update the reliability and hazard function based on in situ measurements and update the current models based on historical data. Due to the success of the PHM approach, new PHM techniques and methods are needed and to apply and implement PHM to other and underdeveloped domains.

Due to the increasing complexity of modern systems, one most prominent problem is called the No Fault Found (NFF) problem (similarly, "trouble not identified," "intermittent malfunctions," etc.) [162–164], particularly in electronics-rich systems. It refers to the situation that no failure or fault can be detected or duplicated during laboratory tests even when the failure has been reported in the field [165]. NFF issues not only make diagnosis extremely difficult but also result in skyrocketing maintenance costs. As reported by Williams et al. [165], NFF failures account for more than 85% or 90% of all filed failures and overall maintenance costs in avionics respectively, which cost the US Department of Defense roughly 2 ~ 10 billion US dollars annually [166]. Similarly, NFF contributes to significant operational costs in many other domain areas. In addition, NFF contributes to potential safety hazards in other industries. For example, both Toyota and National Highway Traffic Safety Administration (NHTSA) spent quite a time and efforts to investigate the root causes of sudden acceleration failures in certain car models, which is linked to 89 deaths in 71 crashes since 2000 [167]. Unfortunately, no conclusive finding has been reached despite efforts to replicate the failures in a variety of laboratory conditions. From these examples, it was found that intermittent faults are often related to environmental conditions and operation histories of the particular individual system, and thus difficult to duplicated repeated under newly unknown random disturbances. Traditional laboratory testing and assessment data only provide information on the characteristics of the population and are insufficient to lead accurate prediction for each individual performance. To reduce maintenance cost and avoid safety hazards caused by NFF, the approach of PHM shifts from traditional population data modeling from individual data modeling.

In response to these challenges, the fast development of information and sensing technology has enabled the collection of many in situ measurements during operations that provides the capability of real time data management and processing for each individual. These advancements provide

a great opportunity to develop sophisticated models with increasing accuracy of prognostics for individual items. For instance, many different types of data during the whole life cycle of the products can be easily retrieved, especially in critical applications. These data could include production process information, quality records, operation logs, and sensor measurements. Moreover, unlike manually entered data, which are slow, costly, and error-prone, many current records are accurate and timely due to advancements in automated technology. The use of Radio Frequency Identification (RFID) technology, for example, is commonly used in supply chain distribution networks, healthcare, and even military applications, because it provides reliable and timely tracking of products/components. Advanced sensor technologies also enable abundant measurements at both macro and micro scales, such as those used to measure vibration, frequency response, magnetic fields, and the current/voltage, to name a few.

In general, typical workflows in a PHM system can be conceptually divided into three major tasks: fault diagnostics, prognostics, and condition-based maintenance. The first task is on diagnose and root causes identification for system failures. The root causes provide useful information for prognostic and feedback for system design improvement. The prognostic task takes the processed data, system models, or failure mode analysis as inputs and employs the developed prognosis algorithms to update the degradation models for failure time prediction. The last task makes use of the prognosis results with consideration of the cost and benefits to determine the optimal maintenance actions to achieve minimal operating costs and risks. All of these three tasks are necessarily executed dynamically and in real time.

11.3.2 Systems Health Monitoring and Management

Systems health monitoring and management (SHMM) refers to the framework of continuous surveillance, analysis, and interpretation of relevant data for system maintenance, management, and strategic planning, where "system" is generally defined as "an organized set of detailed methods, procedures, and routines created to carry out a specific activity or solve a specific problem," ranging from mechanical systems to public health [168–170]. SHMM differs from PHM by its distinct emphasis and its definitions of monitoring, prognostics, and management, and can be considered an extended version of PHM. More specifically, system health monitoring includes detection, forecasting, diagnostics, and prognostics, while system health management includes decision, financial, and risk management. A fundamental problem in SHMM is on how to make use of correlated active and passive data in various tasks of prediction and forecasting,

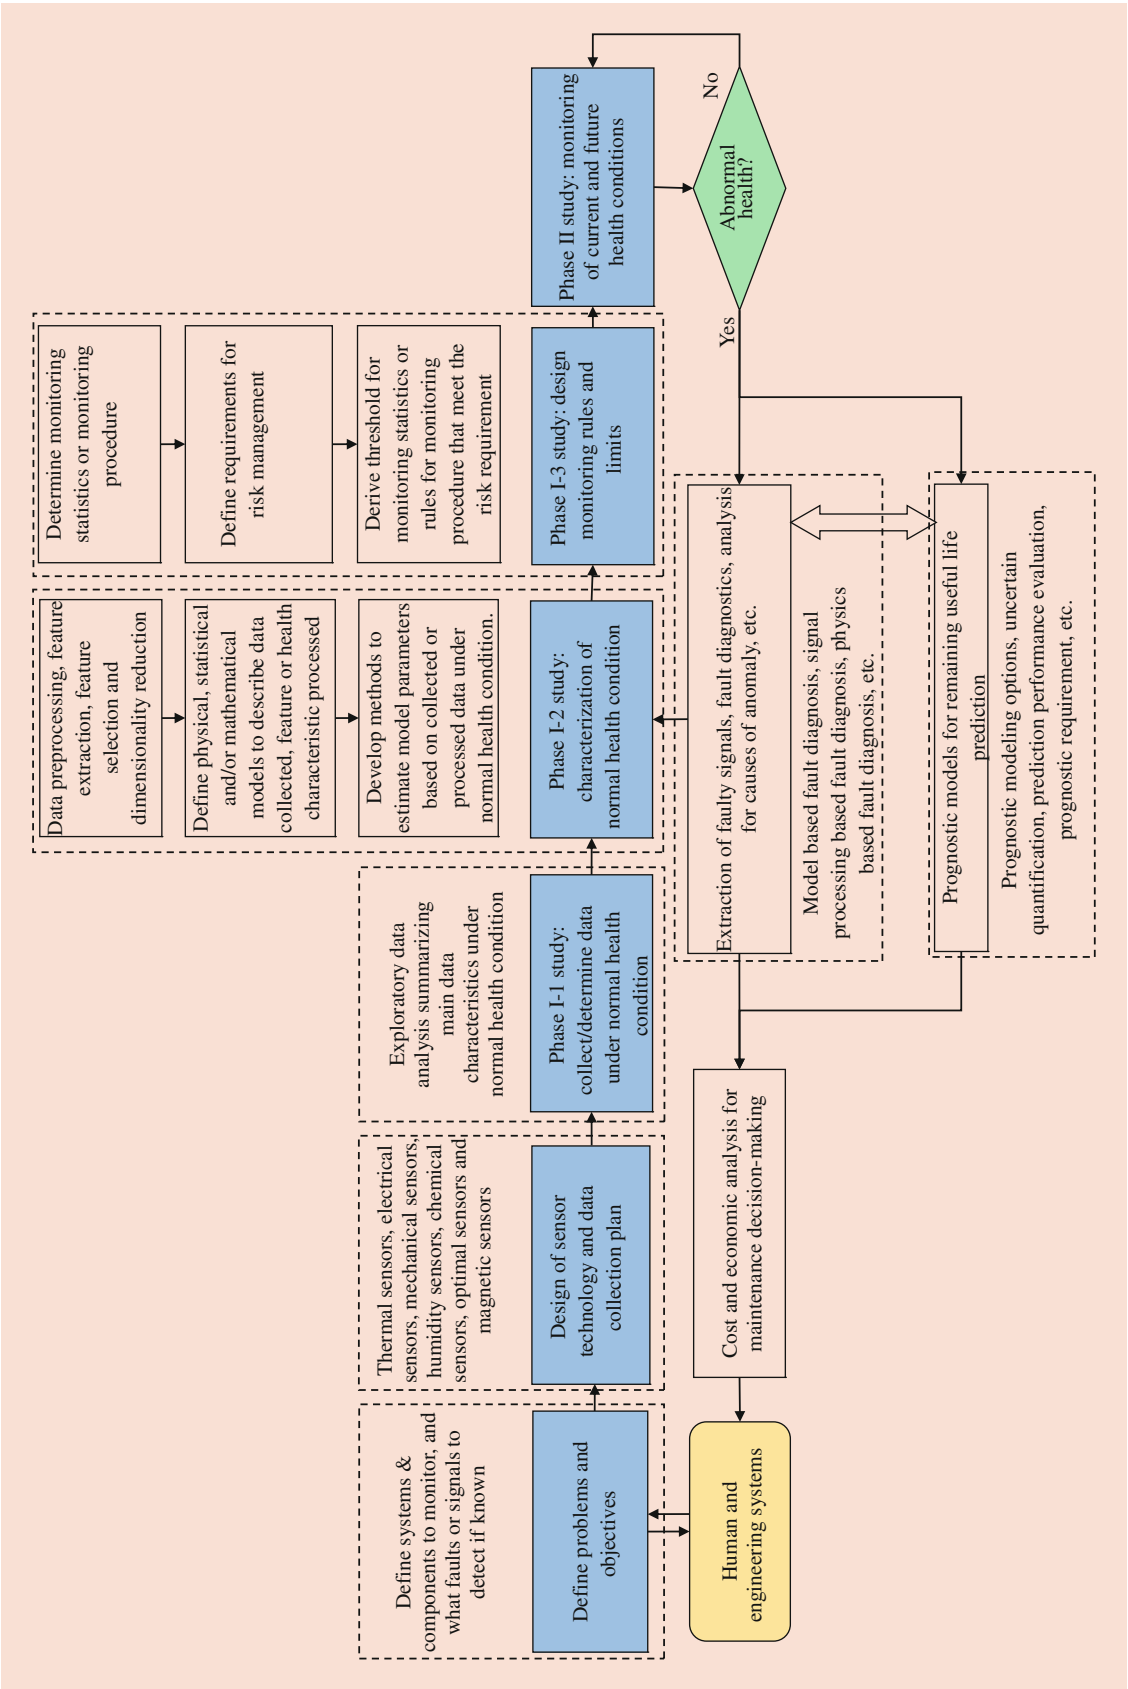

Fig. 11.3 General framework of SHMM

monitoring and surveillance, fault detection and diagnostics, engineering management, supply chain management, and many more. In application to complex human and engineering systems, challenging research problems may arise in various domains driven by big data analytics, such as syndromic surveillance [171, 172], electronics-rich system management [173], simulation and optimization of emergency departments in medical systems [174], and mass transit planning [175].

SHMM covers many broad topics, ranging from experimental design and data collection, data mining and analytics, optimization, decision-making, etc. As more and more systems become data-rich, the theoretical foundation of SHMM is a natural complement to the “data to knowledge to action” paradigm, and therefore to benefit from future developments in data science. Data science shows all the signs of growing into a discipline in its own right, with a strong theoretical foundation at its heart, such foundations being paramount in the development of any new scientific field. Specifically, theoretical research on the foundation of SHMM will build upon theoretical foundational research in data science, which is intrinsically inter-disciplinary. In particular, establishing the theoretical basis of SHMM is likely to involve interdisciplinary collaborations between computer scientists, mathematicians, and statisticians, as these three disciplines are at the heart of the theoretical foundation of SHMM’s closest relative, data science.

For SHMM to make impact to real-life applications, close collaboration is required among SHMM researchers from different disciplines and domain experts. We believe that much of the theoretical foundation of SHMM lies at the intersection of computer science, statistics, and mathematics. Each of those disciplines, however, has been built around particular ideas and in response to particular problems that may have existed for a long time. Thus, the research development of SHMM requires rethinking not only how those three foundational areas interact with each other, but also how each interacts with specific implementations and applications. In particular, the design requirements of business, internet, and social media applications lead to questions that tend to be very different from those in scientific and medical applications in the past. Both the similarities and differences between these areas are striking. Designing the theoretical foundations of SHMM requires paying attention to the problems of researchers implementing SHMM in specific fields as well as to the environments and platforms where computations are to be done. A general framework of SHMM is summarized in Fig. 11.3.

In SHMM, one frequently encounters mixed-type and multi-modality data. For example, a typical dataset may be aggregated from many data sources, including imaging, numerical, graph, text data, etc. Although each specific data type has been researched intensively in isolation, developing

a unified framework will be a more desirable approach to study mixed data systematically. This field has both theoretical and applied implications, and would benefit from a collaboration between statistics, theoretical computer science, mathematics, and practitioners of SHMM. Further research promises to lead to breakthroughs and important progress in science and engineering. A comprehensive review of SHMM can be found in the work by Tsui et al. [176].

Wei Jiang is a distinguished professor in Antai College of Economics and Management at Shanghai Jiao Tong University. He obtained his Ph.D. degree in industrial engineering and engineering management from Hong Kong University of Science and Technology in 2000. His current research activities include statistical methods for quality control, machine learning, and enterprise intelligence.

Terrence E. Murphy is an associate professor at the Yale University School of Medicine and Director of Biostatistics of the Claude D. Pepper Older Americans Independence Center at Yale (P30AG021342). He earned his Ph.D. in industrial and systems engineering from the Georgia Institute of Technology in 2004. Prior to his graduate work in engineering statistics, he worked for the Eastman Kodak and Johnson & Johnson companies in the manufacture and development of clinical instrumentation. His interests include Bayesian statistics and the development and validation of risk prediction models.

Kwok-Leung Tsui is a chaired professor in the School of Data Science at City University of Hong Kong, and the founder and Director of Center for Systems Informatics Engineering. Prior to joining City University of Hong Kong, Professor Tsui was Professor at the School of Industrial and Systems Engineering at the Georgia Institute of Technology. Professor Tsui was a recipient of the National Science Foundation Young Investigator Award. He is Fellow of the American Statistical Association, American Society for Quality, and International Society of Engineering Asset Management; a US representative to the ISO Technical Committee on Statistical Methods. Professor Tsui was Chair of the INFORMS Section on Quality, Statistics, and Reliability and the Founding Chair of the INFORMS Section on Data Mining. Professor Tsui's current research interests include data mining, surveillance in healthcare and public health, prognostics and systems health management, calibration and validation of computer models, process control and monitoring, and robust design and Taguchi methods.

Yang Zhao is a scientific officer in the Centre for Systems Informatics Engineering at City University of Hong Kong. She received her Bachelor's degree in Statistics from Shandong University of Science and Technology in 2011 and her Ph.D. degree from City University of Hong Kong in 2015. Her research interests are in machine learning and statistics, especially their application to real life applications.

sixth section of this chapter is on the relationship between chain/dependent sampling and deferred sentencing type of plans. A review of sampling inspection plans that are based on the ideas of chain or dependent sampling or deferred sentencing is also made in this section. A large number of recent publications based on the idea of chaining past and future lot results are also reviewed. The economics of chain sampling when compared to the two-plan quick switching system is discussed in the seventh section. The eighth section extends the attribute chain sampling rule to variables inspection. In the ninth section, chain sampling is compared with the well-known CUSUM approach for attribute data. The tenth section gives several other interesting extensions such as chain sampling for mixed inspection and process control. The final section gives the concluding remarks.

Abstract

A brief introduction to the concept of chain sampling for quality inspection is first presented. The chain sampling plan of type ChSP-1 selectively chains the past inspection results. A discussion on the design and application of ChSP-1 plans is presented in the second section of this chapter. Various extensions of chain sampling plans such as ChSP-4 plan are discussed in the third part. Representation of the ChSP-1 plan as a two-stage cumulative results criterion plan and its design are discussed in the fourth part. The fifth section relates to the modification of ChSP-1 plan which results in sampling economy. The

12.1 Introduction

Acceptance sampling is the methodology that deals with procedures by which decision to accept or not accept lots of items is based on the results of the inspection of samples. Special purpose acceptance sampling inspection plans (shortly special purpose plans) are tailored for special applications as against general or universal use. Prof. Harold F. Dodge, who is regarded as the father of acceptance sampling, introduced the idea of chain sampling in [1]. Chain sampling inspection can be viewed as a protocol or plan based on a cumulative

results criterion (CRC), where related batch information is chained or cumulated. The phrase *chain sampling* is also used in sample surveys to imply snowball sampling for collection of data. It should be noted that this phrase was originally coined in the acceptance sampling literature and should be distinguished from its usage in other areas.

Chain sampling is extended to two or more stages of cumulation of inspection results with appropriate acceptance criteria for each stage. The theory of chain sampling is also closely related to the various other methods of sampling inspection such as dependent-deferred sentencing, tightened-normal-tightened sampling, quick switching inspection, etc. In this chapter, we provide an introduction to chain sampling and discuss briefly various generalizations of chain sampling plans. We also review a few sampling plans which are related to or based on the methodology of chain sampling. The selection or design of various chain sampling plans is also briefly presented.

12.2 ChSP-1 Chain Sampling Plan

A single sampling attributes inspection plan calls for acceptance of a lot under consideration if the number of nonconforming units found in a random sample of size n is less than or equal to the acceptance number Ac . Whenever the operating characteristic (OC) curve of a single sampling plan is required to pass through a prescribed point, the sample size n will be an increasing function of the acceptance number Ac . This fact can be verified from the table of np or *unity* values given in [2] for various values of the probability of acceptance $P_a(p)$ of the lot under consideration whose fraction nonconforming units is p . The same result is true when the OC curve has to pass through two predetermined points, usually one at the top and the other at the bottom of the OC curve (see [3]). Thus, for situations where small sample sizes are preferred, only single sampling plans with $Ac = 0$ are desirable (see [4]). However, as observed by Dodge [1] and several authors, the $Ac = 0$ plan has a “pathological” OC curve in that the curve starts to drop rapidly even for a very small increase in the proportion or fraction nonconforming. In other words, the OC curve of the $Ac = 0$ plan has no point of inflection. Whenever a sampling plan for costly or destructive testing is required, it is common to force the OC curve to pass through a point, say (LQL, β), where LQL is the limiting quality level for ensuring consumer protection and β is the associated consumer’s risk. All other sampling plans such as double and multiple sampling plans will require more sample size for a one-point protection such as (LQL, β). Unfortunately, the $Ac = 0$ plan has the following two disadvantages:

1. The OC curve of the $Ac = 0$ plan has no point of inflection and hence it starts to drop rapidly even for a smallest increase in the fraction nonconforming p .
2. The producer dislikes an $Ac = 0$ plan because a single occasional nonconformity will call for the rejection of the lot.

The chain sampling plan ChSP-1 of [1] is an answer to the question whether anything can be done to improve the “pathological” shape of the OC curve of a zero acceptance number plan. A production process, when in a state of statistical control, maintains nearly a constant but unknown fraction nonconforming p . If a series of lots formed from such a stable process is submitted for inspection, known as a Type B situation, then the samples drawn from the submitted lots are simply random samples drawn directly from the production process. Hence, it is logical to allow a single occasional nonconforming unit in the current sample whenever the evidence of good past quality, as demonstrated by the i preceding samples containing no nonconforming units, is available. Alternatively, we can *chain* or *cumulate* the results of past lot inspections to take a decision on the current lot without increasing the sample size.

The operating procedure of the chain sampling plan of type ChSP-1 is formally stated below:

1. From each of the lots submitted, draw a random sample of size n and observe the number of nonconforming units d .
2. Accept the lot if d is zero. Reject the lot if $d > 1$. If $d = 1$, the lot is accepted provided all the samples of size n each drawn from the preceding i lots are free from nonconforming units; otherwise, reject the lot.

Thus the ChSP-1 plan has two parameters, namely, the sample size n and i , the number of preceding sample results chained for making a decision on the current lot. It is also required that the consumer has confidence in the producer, and the producer will not deliberately pass a poor-quality lot taking advantage of the small samples used and the utilization of preceding samples for taking a decision on the current lot.

The ChSP-1 plan always accepts the lot if $d = 0$ and conditionally accepts if $d = 1$. The probability of preceding i samples of size n to be free from nonconforming units is $P_{0,n}^i$. Hence, the OC function is $P_a(p) = P_{0,n} + P_{1,n}P_{0,n}^i$ where $P_{d,n}$ is the probability of getting d nonconforming units in a sample of size n . Figure 12.1 shows the improvement in the shape of the OC curve of the zero acceptance number single sampling plan by the use of chain sampling. Clark [5] provided a discussion on the OC curves of chain sampling plans, a modification, and some applications. Lieberman and Hawley [6] argued in favor of chain sampling because the attribute international sampling standards suffer from

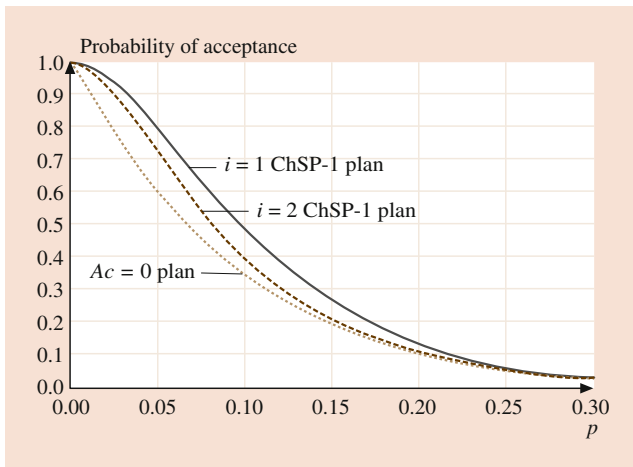

Fig. 12.1 Comparison of OC curves of $Ac = 0$ and ChSP-1 plans

the small or fractional acceptance numbers. Liebesman and Hawley [6] also provided necessary tables and examples for the chain sampling procedures. Most textbooks on statistical quality control also contain a section of chain sampling and provide some applications.

Soundararajan [7, 8] constructed tables for the selection of chain sampling plans for given acceptable quality level (AQL, denoted as p_1), producer’s risk α , LQL (denoted as p_2), and β . ChSP-1 plans found from this source are approximate, and a more accurate procedure that also minimizes the sum of actual producer’s and consumer’s risks is given in [9]. Table 12.1, adapted from [9], is based on the binomial distribution for OC curve of the ChSP-1 plan. This table can also be used to select ChSP-1 plans for given LQL and β which may be used in place of zero acceptance number plans.

Ohta [10] investigated the performance of ChSP-1 plans using the Graphical Evaluation and Review Technique (GERT) and derived measures such as OC, average sample number (ASN) for the ChSP-1 plan. Raju and Jothikumar [11] provided a ChSP-1 plan design procedure based on Kullback-Leibler information and necessary tables for the selection of the plan. Govindaraju [12] discussed the design ChSP-1 plan for minimum average total inspection (ATI). There are a number of other sources where the ChSP-1 plan design is discussed. This chapter provides additional references on designing chain sampling plans, inter alia, discussing various extensions and generalizations.

12.3 Extended Chain Sampling Plans

Frishman [13] extended the ChSP-1 plan and developed ChSP-4 and ChSP-4A plans which incorporate a rejection number greater than 1. Both ChSP-4 and ChSP-4A plans are

Table 12.2 ChSP-4A plan

Stage	Sample size	Acceptance number	Rejection number
1	n	a	r
2	$(k - 1)n$	b	$b + 1$

operated like a traditional double sampling attributes plan but use $(k - 1)$ past lot results instead of actually taking a second sample from the current lot. Table 12.2 is a compact tabular representation of Frishman’s ChSP-4A plan.

ChSP-4 plan restricts r to $b + 1$ which means that the same rejection number is used for both stages. Conditional double sampling plans of [14] and the partial and full link sampling plans of [15] are actually particular cases of the ChSP-4A plan when $k = 2$ and $k = 3$, respectively. However the fact that the OC curves of these plans are the same as the ChSP-4A plan is not reported in both papers (see [16]).

Extensive tables for the selection of ChSP-4 and ChSP-4A plans under various selection criteria were constructed by Raju [17, 18], Raju and Murthy [19, 20], and Raju and Jothikumar [21]. Raju and Jothikumar [21] provided a complete summary of various selection procedures for ChSP-4 and ChSP-4A plans and also discussed two further types of

optimal plans: the first one involving minimum risks and the second one based on Kullback-Leibler information. Unfortunately, the tables given in [17–21] for the ChSP-4 or ChSP-4A design require the user to specify the acceptance and rejection numbers. This serious design limitation is not an issue with the procedures and computer programs developed by Vaerst [22] who discussed the design of ChSP-4A plans involving minimum sample sizes for given AQL, α , LQL, and β without assuming any specific acceptance numbers. Raju [17, 18], Raju and Murthy [19, 20], and Raju and Jothikumar [21] considered a variety of design criteria, while [22] discussed only the (AQL, LQL) criterion. The ChSP-4 and ChSP-4A plans were obtained from [17–21]. The procedure given in [21] can be used in any Type B situation of a series of lots from a stable production process, not necessarily when the product involved costly or destructive testing. This is because the acceptance numbers covered are well over zero. The major disadvantage of [13] extended ChSP-4 and ChSP-4A plans is that the neighboring lot information is not always utilized. Vidya [23] considered the variance of the outgoing quality limit (VOQL) criterion for designing ChSP-4 plans. Even though ChSP-4 and ChSP-4A plans require smaller sample size than the traditional double sampling plans, these plans may not be economical to other comparable conditional sampling plans.

Bagchi [24] presented an extension of the ChSP-1 plan, which calls for additional sampling only when one nonconforming unit is found. The operating procedure of Bagchi's extended chain sampling plan is given below:

1. At the outset, inspect n_1 units selected randomly from each lot. Accept the lot if all the n_1 units are conforming; otherwise, reject the lot.
2. If i successive lots are accepted, then inspect only $n_2 < n_1$ items from each of the submitted lots. Accept the lot as long as no nonconforming units are found. If two or more nonconforming units are found, reject the lot. In the event of one nonconforming unit is found in n_2 inspected units, then inspect a further sample $(n_1 - n_2)$ units from the same lot. Accept the lot under consideration if no further nonconforming units are found in the additional $(n_1 - n_2)$ inspected units; otherwise, reject the lot.

Representing Bagchi's plan as a Markov chain, [25] derived the steady-state OC function and few other performance measures.

Gao [26] considered the effect of inspection errors on a chain sampling plan with two acceptance numbers and also provided design procedures. Application of chain sampling for a reliability acceptance test for exponential life times is also given in [26].

12.4 Two-Stage Chain Sampling

Dodge and Stephens [27] viewed the chain sampling approach as a cumulative result criterion (CRC) applied in two stages and extended it to include larger acceptance numbers. Their approach calls for the first stage of cumulation of a maximum of k_1 consecutive lot results, during which acceptance is allowed if the maximum allowable nonconforming units is c_1 or less. After passing the first stage of cumulation (i.e., when consecutive lots are accepted), the second stage cumulation of $k_2 (> k_1)$ lot results begins. In the second stage of cumulation, an acceptance number of $c_2 (> c_1)$ is applied. Stephens and Dodge [28] presented a further generalization of the family of "two-stage" chain sampling inspection plans by using different sample sizes in the two stages. The complete operating procedure of a generalized two-stage chain sampling plan is stated below:

1. At the outset, draw a random sample of n_1 units from the first lot. In general, a sample of size n_j ($j = 1, 2$) will be taken while operating in j th stage of cumulation.
2. Record d the number of nonconforming units in each sample, as well as D the cumulative number of nonconforming units from the first and up to, and including, the current sample. As long as $D_i \leq c_1$ ($1 \leq i \leq k_1$), accept the i th lot.
3. If k_1 consecutive lots are accepted, continue to cumulate the number of nonconforming units D in the k_1 samples plus additional samples up to but no more than k_2 samples. During this second stage of cumulation, accept the lots as long as $D_i \leq c_2$ ($k_1 < i \leq k_2$).
4. After passing the second stage of k_2 lot acceptances, start cumulation as a moving total over k_2 consecutive samples (by adding the current lot result and dropping the preceding k_2 th lot result). Continue to accept lots as long as $D_i \leq c_2$ ($i > k_2$).
5. In any stage of sampling, reject the lot if $D_i > c_i$ and return to Step 1 (a fresh restart of the cumulation procedure).

Figure 12.2 shows how the cumulative result criterion is used in a two-stage chain sampling plan for $k_1 = 3$ and $k_2 = 5$.

An important subset of the generalized two-stage chain sampling plan is when $n_1 = n_2$, and this subset is designated as ChSP- (c_1, c_2) , which has five parameters n, k_1, k_2, c_1 , and c_2 . The original chain sampling plan ChSP-1 of [1] is a further subset of the ChSP- $(0,1)$ plan with $k_1 = k_2 - 1$, that is, the OC curve of the generalized two-stage chain sampling plan is equivalent to the OC curve of the ChSP-1 plan when $k_1 = k_2 - 1$. Dodge and Stephens [27] derived the OC function of ChSP- $(0,1)$ plan as

Fig. 12.2 Operation of a two-stage chain sampling plan with $k_1 = 3$ and $k_2 = 5$

$$P_a(p) = \frac{P_{0,n}(1 - P_{0,n}) + P_{0,n}^{k_1} P_{1,n} (1 - P_{0,n}^{k_2 - k_1})}{1 - P_{0,n} + P_{0,n}^{k_1} P_{1,n} (1 - P_{0,n}^{k_2 - k_1})}, \quad k_2 > k_1.$$

Both the ChSP-1 and ChSP-(0,1) plans overcome the disadvantages of the zero acceptance number plan mentioned earlier. The operating procedure of the ChSP-(0,1) plan can be succinctly stated as follows:

1. A random sample of size n is taken from each successive lot, and the number of nonconforming units in each sample is recorded, as well as the cumulative number of nonconforming units found so far.
2. Accept the lot associated with each new sample as long as no nonconforming units are found.
3. Once k_1 lots have been accepted, accept subsequent lots as long as the cumulative number of nonconforming units is no greater than one.
4. Once $k_2 > k_1$ lots have been accepted, cumulate the number of nonconforming units over the most k_2 lots, and continue to accept as long as this cumulative number of nonconforming units is one or none.
5. If, at any stage, the cumulative number of nonconforming units becomes greater than one, reject the current lot and return to Step 1.

Procedures and tables for the design of ChSP-(0,1) plan are available in [29, 30]. Govindaraju and Subramani [31] showed that the choice of $k_1 = k_2 - 1$ is always forced on the parameters of the ChSP-(0,1) plan when a plan is selected for given AQL, α LQL, and β , that is, a ChSP-1 plan will be sufficient, and one need not opt for a two-stage cumulation of nonconforming units.

In various technical reports of the Statistics Center, Rutgers University (see [32] for a list), Stephens and Dodge formulated the two-stage chain sampling plan as a Markov chain and evaluated its performance. The performance measures considered by them include the steady-state OC function, ASN, average run length (ARL), etc. For comparison of chain sampling plans with the traditional or noncumulative plans, two types of ARLs are used. The first type of ARL, i.e., ARL_1 , is the average number of samples to the first rejection after a sudden shift in the process level, say from p_0 to p_s . The usual ARL, i.e., ARL_2 , is the average number of samples to the first rejection given the stable process level p_0 . The difference $(ARL_1 - ARL_2)$ measures the extra lag due to chain sampling. However, this extra lag may be compensated by the gains in sampling efficiency as explained in [33].

Stephens and Dodge [34] summarized the Markov chain approach to evaluate the performance of some selected two-stage chain sampling plans, while more detailed derivations were published in their technical reports. Based on the expressions for the OC function derived by Stephens and Dodge in their various technical reports listed in [32]. Raju and Murthy [35] and Jothikumar and Raju [36] discussed various design procedures for the ChSP-(0,2) and ChSP-(1,2) plans. Raju [37] extended the two-stage chain sampling to three stages and evaluated the OC performances of few selected chain sampling plans fixing the acceptance numbers for the three stages. The three-stage cumulation procedure becomes very complex and will play only a limited role for costly or destructive inspections. The three-stage plan will however be useful for general Type B lot by lot inspections.

12.5 Modified ChSP-1 Plan

In [1], chaining of past lot results does not always occur. It occurs only when a nonconforming unit is observed in the current sample. This means that the available historical evidence of quality is not utilized fully. Govindaraju and Lai [38] developed a modified chain sampling plan (MChSP-1) that always utilizes the recently available lot quality history. The operating procedure of the MChSP-1 plan is given below.

1. From each of the submitted lots, draw a random sample of size n . Reject the lot if one or more nonconforming units are found in the sample.
2. Accept the lot if no nonconforming units are found in the sample provided the preceding i samples also contained no nonconforming units except in one sample which may contain at most one nonconforming unit. Otherwise, reject the lot.

Fig. 12.3 Operation of the MChSP-1 plan

A flow chart showing the operation of the MChSP-1 plan is in Fig. 12.3. MChSP-1 plan allows a single nonconforming unit in any one of the preceding i samples, but the lot under consideration is rejected if the current sample has a nonconforming unit. Thus, the plan gives a “psychological” protection to the consumer in that it allows acceptance only when all the current sample units are conforming. Allowing one nonconforming unit in any one of the preceding i samples is essential to offer protection to the producer, i.e., to achieve an OC curve with a point of inflection. In MChSP-1 plan, rejection of lots would occur until the sequence of submissions advances to a stage where two or more nonconforming units were no longer included in the sequence of i samples. In other words, if two or more nonconforming units are found in a single sample, it will result in i subsequent lot rejections. In acceptance sampling, one has to look at the OC curve to have an idea of the protection to the producer as well as to the consumer, and what happens in an individual sample or for a few lots is not very important. If two or more nonconforming units are found in a single sample, it does not mean that the subsequent lots need not be inspected since they will be automatically rejected under the proposed plan. It should be noted that results of subsequent lots will be utilized continuously and the producer has to show an improvement in quality with one or none nonconforming unit in the subsequent samples in order to permit future acceptances. This will act as a strong motivating factor for quality improvement.

The OC function $P_a(p)$ of the MChSP-1 plan is derived by Govindaraju and Lai [38] as $P_a(p) = P_{0,n}(P_{0,n}^i + iP_{0,n}^{i-1}P_{1,n})$. Figure 12.4 compares the OC curves of ChSP-1 and MChSP-1 plans. From Fig. 12.4, we observe that the MChSP-1 plan decreases the probability of acceptance at poor-quality levels but maintains the probability of acceptance at good-quality

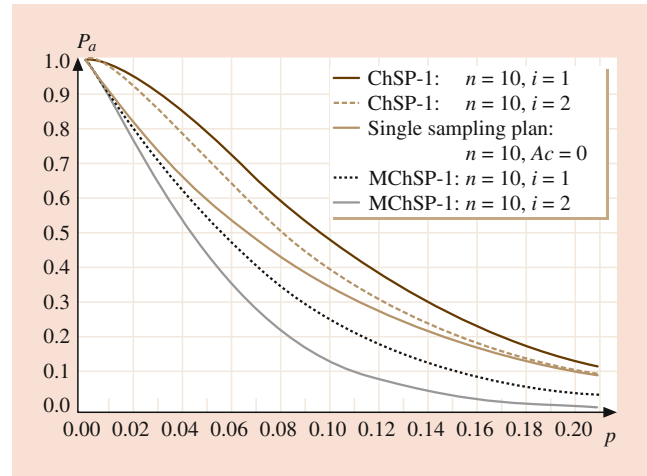

Fig. 12.4 Comparison of OC curves of ChSP-1 and MChSP-1 plans

Fig. 12.5 OC curves of matched ChSP-1 and MChSP-1 plans

levels when compared to the OC curve of the zero acceptance number single sampling plan. The ChSP-1 plan, on the other hand, increases the probability of acceptance at good-quality levels but maintains the probability of acceptance at poor-quality levels. In order to compare the two sampling plans, we need to match them. That is, we need to design sampling plans whose OC curves approximately pass through two prescribed points such as $(AQL, 1 - \alpha)$ and (LQL, β) . Figure 12.5 gives such a comparison and establishes that MChSP-1 plan is efficient in requiring a very small sample size compared to the ChSP-1 plan. A two-stage chain sampling plan would generally require a sample size equal to or more than the sample size of a zero acceptance single sampling plan. The MChSP-1 plan will however require a sample size smaller than the zero acceptance number plan.

12.6 Chain Sampling and Deferred Sentencing

Like chain sampling plans, there are other plans that use the results of neighboring lots for taking a conditional decision of acceptance or rejection. Plans that make use of past lot results are either called chain or dependent sampling plans. Similarly plans that make use of future lot results are known as deferred sentencing plans. These plans have a strategy of accepting the lots conditionally based on the neighboring lot quality history and hence referred to as *conditional* sampling plans. We will briefly review several such conditional sampling plans available in the literature.

Contrary to chain sampling plans that make use of past lot results, deferred sentencing plans use future lot results. The idea of deferred sentencing was first published in a paper by Anscombe et al. [39]. The first simplest type deferred sentencing scheme of [39] requires the produced units be split into small size lots, and one item is selected from each lot for inspection. The lot sentencing rule is that whenever Y nonconforming units are found out of X or fewer consecutive lots tested, all such cluster of consecutive lots starting from the lot that resulted the first nonconforming unit to the lot that resulted the Y th nonconforming unit are rejected. Lots not rejected by this rule are accepted. This rule is further explained in the following sentences. A run of good lots of length X will be accepted at once. If a nonconforming unit occurs, then the lot sentencing or disposition will be deferred until either further $(X - 1)$ lots have been tested or $(Y - 1)$ further nonconforming items are found, whichever occurs the sooner. At the outset, if the $(X - 1)$ succeeding lots result in fewer than $(Y - 1)$ nonconforming units, the lot that resulted the first nonconforming unit and any succeeding lots clear of nonconforming units will be accepted. As soon as Y nonconforming units occur in no more than X lots, all lots not so far sentenced will be rejected. Thus the lot disposition will sometimes be made at once and sometimes with a delay not exceeding $(X - 1)$ lots. Some of the lots to be rejected according to the sentencing rule may already have been rejected through the operation of the rule on a previous cluster of Y nonconforming units partly overlapping the one being considered. The actual number of new lots rejected under the deferred sentencing rule can be any number from 1 to X . Anscombe et al. [39] also considered modifications of the above deferred sentencing rule, including inspection of a sample of size more than one from each lot. Anscombe et al. [39] originally presented their scheme as an alternative to [40] continuous sampling plan of type CSP-1 which is primarily intended for the partial screening inspection of produced units directly (when lot formation is difficult).

The deferred sentencing idea was formally tailored into an acceptance sampling plan by Hill et al. [41]. The operating procedure of [41] scheme is described below:

1. From each lot, select a sample of size n . The lots are accepted as long as no nonconforming units are found in the samples. If one or more nonconforming units are found, the disposition of the current lot will be deferred until $(X - 1)$ succeeding lots are inspected.
2. If the cumulative number of nonconforming units for X consecutive lots is Y or more, then a second sample of size n is taken from each of the lots (beginning with the first lot and ending with the last batch that showed a nonconforming unit in the sequence of X nonconforming units). If there are less than Y nonconforming units in the X , accept all lots from the first up to but not including the next batch that showed a nonconforming unit. The decision on this batch will be deferred until $(X - 1)$ succeeding lots are inspected.

Hill et al. [41] also evaluated the OC function of some selected schemes and found them very economical when compared to the traditional sampling plans, including the sequential attribute sampling plan.

Wortham and Mogg [42] developed a dependent stage sampling plan which is operated under steady state as follows:

1. For each lot, draw a sample of size n and observe the number of nonconforming units d .
2. If $d \leq r$, accept the lot; if $d > r + b$, reject the lot. If $r + 1 \leq d \leq r + b$, accept the lot if the $(r + b + 1 - d)$ th previous lot was accepted; otherwise, reject the current lot.

Govindaraju [43] has observed that the OC function of $DSSP(r; b)$ is the same as the OC function of the repetitive group sampling (RGS) plan of [44]. This means that the existing design procedures for the RGS plan can also be used for the design of $DSSP(r; b)$ plan. The deferred state sampling plan of [45] has a similar operating procedure except in Step 2 in which when the current lot is accepted if the forthcoming $(r + b + 1 - d)$ th lot is accepted. The steady-state OC function of the dependent (deferred) stage sampling plan is given by

$$P_a(p) = \frac{P_{a,r}(p)}{1 - P_{a,r+b}(p) + P_{a,r}(p)}$$

where $P_{a,r}(p)$ is the OC function of the single sampling plan with acceptance number r and sample size n . Similarly $P_{a,r+b}(p)$ is the OC function of the single sampling plan with acceptance number $r + b$ and sample size n . A procedure for

the determination of plan for given AQL, α , LQL, and β was also developed by Vaerst [22].

Wortham and Baker [46] extended the dependent (deferred) state sampling into a multiple dependent (deferred) state (MDS) plan $MDS(r, b, m)$. The operating procedure of the $MDS(r, b, m)$ plan is given below:

1. For each lot, draw a sample of size n and observe the number of nonconforming units d .
2. If $d \leq r$, accept the lot; if $d > r + b$, reject the lot. If $r + 1 \leq d \leq r + b$, accept the lot if the consecutive m preceding lots were all accepted (consecutive m succeeding lots must be accepted for the deferred $MDS(r, b, m)$ plan).

The steady-state OC function of the $MDS(r, b, m)$ plan is given by the recursive equation

$$P_a(p) = P_{a,r}(p) + [P_{a,r+b}(p) - P_{a,r}(p)] (P_a(p))^m$$

Vaerst [47], Soundararajan and Vijayaraghavan [48], Kuralmani and Govindaraju [49], and Govindaraju and Subramani [50] provided detailed tables and procedures for the design of $MDS(r, b, m)$ plans for various requirements. Afshari and Gildeh [51] provided a procedure to design the MDS plan in a fuzzy environment such when testing is imperfect.

Vaerst [22, 47] modified the $MDS(r, b, m)$ plan to make it on par with the ChSP-1 plan. The operating procedure of the modified $MDS(r, b, m)$ plan, called $MDS-1(r, b, m)$, is given below:

1. For each lot, draw a sample of size n and observe the number of nonconforming units d .
2. If $d \leq r$ accept the lot; if $d > r + b$, reject the lot. If $r + 1 \leq d \leq r + b$, accept the lot if r or less nonconforming units are found in each of the consecutive m preceding (succeeding) lots.

When $r = 0$, $b = 1$, and $m = i$, $MDS-1(r, b, m)$ plan becomes the ChSP-1 plan. The OC function of the plan is given by recursive equation

$$P_a(p) = P_{a,r}(p) + [P_{a,r+b}(p) - P_{a,r}(p)] (P_{a,r}(p))^m$$

Vaerst [47, 52], and [53] provided detailed tables and procedures for the design of plans for various requirements. The major but an obvious shortcoming of the chain sampling plans is that since they use sample information from past lots for disposing the current lot, there is a tendency to reject the current lot of given good quality when the process quality is improving or accept the current lot of given bad quality when the process quality is deteriorating. Similar criticisms (in reverse) can be leveled against the deferred sentencing

plans. As mentioned earlier, [33] recognizing this disadvantage of chain sampling defined the ARL performance measures ARL_1 and ARL_2 . Recall that ARL_2 is the average number of lots that will be accepted as a function of the true fraction nonconforming. ARL_1 is the average number of lots accepted after an upward shift in the true fraction nonconforming occurred from the existing level. Stephens and Dodge [54] evaluated the performance of the two-stage chain sampling plans comparing the ARLs with matching single and double sampling plans having approximately the same OC curve. It was noted that the slightly poorer ARL property due to chaining of lot results is well compensated by the gain in sampling economy. For deferred sentencing schemes, [41] investigated trends as well as sudden changes in quality. It was found that the deferred sentencing schemes will discriminate better between fairly constant quality at one level and fairly constant quality at another level than will a lot-by-lot plan scheme with the same sample size. However, when quality varies considerably from lot to lot, the deferred sentencing scheme found to operate less satisfactorily, and in certain circumstances the discrimination between good and bad batches may even be less than for the traditional unconditional plans with the same sample size. Further the deferred sentencing scheme may pose problems of flow, supply storage space, and uneven workload (which is not a problem with chain sampling).

Cox [55] provided a more theoretical treatment and considered one-step forward and two-step backward schemes. The lot sentencing rules and inspection are modeled as a stochastic process and applied Bayes's theorem for the sentencing rule. He did recognize the complexity of modeling a multistage procedure. When the submitted lot fraction nonconforming vary, say when a trend exists, both chain and deferred sentencing rules have disadvantages. But this disadvantage can be overcome by combining chain and deferred sentencing rules into a single scheme. This idea was first suggested by Baker [56] in his dependent deferred state (DDS) plan. Osanaiye [57] provided a complete methodology of combining chain and deferred sentencing rules and developed the chain-deferred (ChDP) plan. The ChDP plan has two stages for lot disposition and its operating procedure is given below:

1. From lot numbered k , inspect n units and count the number of nonconforming units d_k . If $d_k \leq c_1$, accept lot numbered k . If $d_k > c_2$, reject lot numbered k . If $c_1 < d_k \leq c_2$, then combine the number of nonconforming units from the immediate succeeding and preceding samples, namely, d_{k-1} and d_{k+1} .
2. If $d_k \leq c$, accept the k th lot provided $d_k + d_{k-1} \leq c_3$ (chain approach). If $d_k > c$, accept the lot provided $d_k + d_{k+1} \leq c_3$ (deferred sentencing).

One possible choice of c is the average of c_1 and $c_3 + 1$. Osanaiye [57] also provided a comparison of ChDP with the traditional unconditional double sampling plans as the OC curves of the two types of plans are the same (but the ChDP plan utilizes the neighboring lot results). Shankar and Srivastava [58] and Shankar and Joseph [59] provided a GERT analysis of ChDP plans taking the approach of [10]. Shankar and Srivastava [60] discussed the selection ChDP plans using tables. Osanaiye [61] provided a multiple sampling plan extension of the ChDP plan (called MChDP plan). MChDP plan uses several neighboring lot results to achieve sampling economy.

Osanaiye [62] provided a practically useful discussion on the choice of conditional sampling plans considering autoregressive processes, inert processes (constant process quality shift), and linear trends in quality. Based on a simulation study, it was recommended that the chain-deferred schemes are the cheapest if either the cost of 100% inspection or sampling inspection is high. He recommended the use of the traditional single or double sampling plans only if the opportunity cost of rejected items is very high. Osanaiye and Alebiosu [63] considered the effect of inspection errors on dependent and deferred double sampling plans vis-à-vis ChDP plans. They observed that the chain-deferred plan in general has a greater tendency to reject nonconforming items than any other plans irrespective of the magnitude of any inspection error.

Many of the conditional sampling plans, which follow either the approach of chaining or deferring or both, have the same OC curve of a double (or a multiple) sampling plan. Exploiting this equivalence, [64] provided a general selection procedure for conditional sampling plans for given AQL and LQL. The plans considered include the conditional double sampling plan of ChSP-4A plans of [13], conditional double sampling plan of [14], link sampling plan of [15], and ChDP plan of [57]. A perusal of the operating ratio LQL/AQL of [64] tables reveal that these conditional sampling plans apply in all Type B situations because a wide range of discrimination between good and bad qualities is achievable. However, the sample sizes, even though smaller than the traditional unconditional plans, will not be as small as the zero acceptance number single sampling plans. This limits the application of the conditional sampling plans to this special purpose situation, where ChSP-1 or MChSP-1 plan suits the most.

Govindaraju [65] developed a conditional single sampling (CSS) plan, which has desirable properties for general applications as well as for costly or destructive testing. The operating procedure of the CSS plan is as follows:

1. From lot numbered k , select a sample of size n and observe the number of nonconforming units d_k .

2. Cumulate the number of nonconforming units observed for the current lot and the related lots. The related lots will be either past lots, future lots, or a combination depending on whether one is using dependent sampling or deferred sentencing. The lot under consideration is accepted if the total number of nonconforming units in the current lot and the m related lots is less than or equal to the acceptance number, Ac . If d_k is the number of nonconforming units recorded for the k th lot, the rule for disposition for the k th lot is as follows:

- a. For dependent or chain sampling, accept the lot if $(d_{k-m} + \dots + d_{k-1} + d_k) \leq Ac$; otherwise, reject the lot.
- b. For deferred sampling, accept the lot if $(d_k + d_{k+1} + \dots + d_{k+m}) \leq Ac$; otherwise, reject the lot.
- c. For dependent-deferred sampling, where m is desired to be even, accept the lot if $(d_{k-\frac{m}{2}} + \dots + d_k + \dots + d_{k+\frac{m}{2}}) \leq Ac$; otherwise, reject the lot.

Thus, the CSS plan has three parameters, the sample size n , acceptance number Ac , and number of related lot results used, m . As in the case of any dependent sampling procedure, dependent single sampling takes full effect only from the $(m + 1)^{\text{st}}$ lot. In order to maintain *equivalent* OC protection for the first m lots, additional sample mn units can be taken from each lot and the lot can be accepted if the total number of nonconforming units is less than or equal to Ac or additional samples of size $(m + 1 - i)n$ can be taken for the i th lot ($i = 1, 2, \dots, m$) and the same decision rule be applied. In either case, the results of the additional samples should not be used for lot disposition from lot $(m + 1)$. Govindaraju [65] has shown that the CSS plans require much smaller sample sizes than all other conditional sampling plans. In case of trends in quality, the CSS plan can also be operated as a chain-deferred plan, and this will ensure that the changes in lot qualities are somewhat averaged out.

12.7 Comparison of Chain Sampling with Switching Systems

Dodge [66] first proposed the quick switching sampling (QSS) system which basically consists of two intensities of inspection, i.e., normal (N) and tightened (T) plans. Romboski [67] investigated the QSS system and introduced several modifications of the original QSS system. Under the QSS system, if a lot is rejected under the normal inspection, a switch tightened inspection will be made; otherwise, normal inspection shall continue. If a lot is accepted under the tightened inspection, then the normal inspection will be restored; otherwise, tightened inspection will be continued. For a review of quick switching systems, see [68] or [69].

Taylor [68] introduced a new switch number to the original QSS-1 system of [67] and compared it with the chain sampling plans. When the sample sizes of normal and tightened plans are equal, the quick switching systems and the two-stage chain sampling plans were found to give nearly identical performance. Taylor's comparison is only valid for a general situation where acceptance numbers of greater than zero are used. For costly or destructive testing, acceptance numbers are kept at zero for achieving minimum sample sizes. In such situations, both ChSP-1 and ChSP-(0,1) plans will fare poorly against other comparable schemes when the incoming quality is at AQL. This fact is explained in the following paragraph using an example.

For costly or destructive testing, a quick switching system employing zero acceptance number was studied in [70] and [71]. Under this scheme, the normal inspection plan has a sample size of n_N units, while the tightened inspection plan has a higher sample size $n_T (> n_N)$. The acceptance number is kept at zero for both normal and tightened inspections. The switching rule is that a rejection under the normal plan ($n_N, 0$) will invoke the tightened plan ($n_T, 0$). An acceptance under the ($n_T, 0$) plan will revert back to normal inspection. This QSS system, designated as of type QSS-1($n_N, n_T; 0$), can be used in place of the ChSP-1 and ChSP-(0,1) plans. Let AQL = 1%, $\alpha = 5%$, LQL = 15%, and $\beta = 10%$. The ChSP-1 plan for the prescribed AQL and LQL conditions is found as $n = 15$ and $i = 2$ (from Table 12.1 of this chapter). The matching QSS-1 system for the prescribed AQL and LQL conditions can be found as QSS-1($n_N = 5, n_T = 19$) from the tables given in [70] or [72]. At good-quality levels, the normal inspection plan will require sampling only 5 units. Only at poor-quality levels, 19 units will be sampled under the QSS system. Hence, it is obvious that Dodge's chain sampling approach is not truly economical at good-quality levels but fares well at poor-quality levels. However, if the modified chain sampling plan MChSP-1 plan of [38] is used, then the sample size needed will be only 3 units (and i , the number of related lot results to be used is fixed at 7 or 8). The other alternative is to use the chained quick switching system proposed in [73]. For a detailed discussion of this approach, consult [74].

A more general two-plan system having zero acceptance numbers for the tightened and normal plans was studied by Calvin [75], Soundararajan and Vijayaraghavan [76], and Subramani and Govindaraju [77]. Calvin's TNT scheme uses zero acceptance numbers for normal and tightened inspection and employs the switching rules of [78], which is also roughly employed in [79]. The operating procedure of the TNT scheme, designated as TNT($n_N, n_T; 0$), is given below:

1. Start with the tightened inspection plan ($n_T, 0$). Switch to normal inspection (Step 2) when t lots in a row are

accepted; otherwise, continue with the tightened inspection plan.

2. Apply the normal inspection plan ($n_N, 0$). Switch to the tightened plan if a lot rejection is followed by another lot rejection within the next s lots.

Using the tables of [80], the zero acceptance number TNT($n_N, n_T; 0$) plan for given AQL = 1%, $\alpha = 5%$, LQL = 15%, and $\beta = 10%$ is found as TNT($n_N = 5, n_T = 16; A_c = 0$). We again find that the MChSP-1 plan calls for a smaller sample size when compared to Calvin's zero acceptance number TNT plan.

Skip-lot sampling plans of [81] and [82] are based on skipping of sampling inspection of lots on the evidence of good-quality history. For a detailed discussion of skip-lot sampling, [32] may be consulted. In skip-lot sampling plan of type SkSP-2 of [82], once m successive lots are accepted under the reference plan, the chosen reference sampling plan is applied only for a fraction of the time. Govindaraju [83] studied the employment of the zero acceptance number plan as a reference plan (among several other reference sampling plans) in the skip-lot context. For given AQL = 1%, $\alpha = 5%$, LQL = 15%, and $\beta = 10%$, the SkSP-2 plan with a zero acceptance number reference plan is found as $n = 15$, $m = 6$, and $f \approx 1/5$. Hence, the matching ChSP-1 plan $n = 15$ and $i = 2$ is not economical at good-quality levels when compared to the SkSP-2 plan $n = 15$, $m = 6$, and $f \approx 1/5$. This is because the SkSP-2 plan requires the zero acceptance number reference plan with a sample of size 15 to be applied only to one in every five lots submitted for inspection once six consecutive lots are accepted under the reference single sampling plan ($n = 10, A_c = 0$). However, the modified MChSP-1 plan is more economical at poor-quality levels when compared to the SkSP-2 plan. Both plans require about the same sampling effort at good-quality levels.

12.8 Chain Sampling for Variable Inspection

The main assumption made for the various types of chain sampling plans and other attribute schemes such as deferred-dependent plans and quick switching systems is that the fraction nonconforming p in a series of lots roughly remains a constant. No other distributional assumptions are made for attribute sampling inspection plans. If the assumption of constant p for a series of lots is violated, there can be a delay in detection of a change in p . This delay is measured using the difference ($ARL_1 - ARL_2$) (see Sect. 12.4). However, if the rule of chaining lot inspection results is modified as a chain-deferred rule, the overall producer's and consumer's risk will remain the same even if there is a linear trend in p in a series of lots (see the discussion in Sect. 12.5). If the distribution of the

quality characteristic of interest is known, variable inspection becomes feasible. Govindaraju and Balamurali [84] extended the idea of chain sampling to variable inspection assuming normality. This approach is particularly useful when testing is costly or destructive provided the quality variable is measurable on a continuous scale and known to be normally distributed. It is well known that the variable plans do call for a very low sample sizes when compared to the attribute plans. However, not all variable plans possess a satisfactory OC curve as shown by Govindaraju and Kuralmani [85]. Often, a variable plan is unsatisfactory if the acceptability constant is too large particularly when the sample size is small. Only in such cases, it is necessary to follow the chain sampling approach to improve upon the OC curve of the variable plan. Table 12.3 is useful for deciding whether a given variables sampling plan has a satisfactory OC curve or not. If the acceptability constant k_σ of a known sigma variables plan exceeds $k_{\sigma l}$, then the plan is deemed to have an unsatisfactory OC curve like an $A_c = 0$ attribute plan.

The operating procedure of the chain sampling plan for variables inspection is as follows:

1. Draw a random sample of size n_σ , say $(x_1, x_2, \dots, x_{n_\sigma})$, and then compute $v = (U - \bar{X})/\sigma$ where $\bar{X} = \sum_{i=1}^{n_\sigma} x_i/n_\sigma$.
2. Accept the lot if $v \geq k_\sigma$ and reject if $v < k'_\sigma$. If $k'_\sigma \leq v < k_\sigma$, accept the lot provided the preceding i lots were accepted on the condition that $v \geq k_\sigma$.

Thus the variable chain sampling plan has four parameters, namely, the sample size n_σ ; the acceptability constants k_σ and k'_σ ($< k_\sigma$); and i , the number of preceding lots used for conditionally accepting the lot. The OC function of this plan is given by $P_a(p) = P_V + (P'_V - P_V)P_V^i$ where

$P_V = \Pr(v \geq k_\sigma)$ is the probability of accepting the lot under the variables plan (n_σ, k_σ) and $P'_V = \Pr(v \geq k'_\sigma)$ is the probability of accepting the lot under the variables plan (n_σ, k'_σ) . Even though the above operating procedure of the variables chain sampling plan is of a general nature, it would be appropriate to fix $k'_\sigma = k_{\sigma l}$. For example, suppose that a variable plan with $n_\sigma = 5$ and $k_\sigma = 2.46$ is currently under use. From Table 12.3, the limit for the undesirable acceptability constant $k_{\sigma l}$ for $n_\sigma = 5$ is obtained as 1.1278. Since the regular acceptability constant $k_\sigma = 2.26$ is greater than $k'_\sigma = 1.1278$, the variable plan can be declared to possess an unsatisfactory OC curve. Hence, it is desirable to chain the results of neighboring lots to improve upon the shape of the OC curve of the variable plan $(n_\sigma = 5, k_\sigma = 2.26)$, that is, the variable plan currently under use will be operated as a chain sampling plan fixing i as four. A more detailed procedure on designing chain sampling for variable inspection, including the case when sigma is unknown, is available in [84]. The chain sampling for variables will be particularly useful when inspection costs are prohibitively high, and the quality characteristic is measurable on a continuous scale.

Luca [86] extended the modified chain sampling plan MChSP-1 of [38] for variable inspection. The main advantage of the MChSP-1 is the reduction of sample size compared to the ChSP-1 plan. While the variable chain sampling approach reduces the amount inspection substantially, the variable inspection based on the modified chain sampling plan rule can achieve some marginal gains.

The idea of using chain sampling rules for variables inspection proved popular in the recent years, and a large number of plans using conditional lot disposition rules appeared in the literature. Balamurali and Jun [87] extended the variable chain sampling idea to MDS sampling plans based on the normal distribution. Balamurali et al. [88] employed the Weibull distribution so that the plans can be used for lifetime assurance (see [89] and [90]). Aslam et al. [91] extended the MDS rule to a lifetime characteristic following the Burr XII distribution.

Arizono et al. [92] first coined the idea of employing the process capability index for the design of a variables inspection plan. Wu et al. [93] extended the work of [87] to MDS sampling plan using the capability index C_{pk} for normally distributed processes with two-sided specification limits (see [94] who also developed a variables MDS sampling plan for lot sentencing based on the process capability index) (also see [95]). Wu et al. [96] employed the quick switching rules and presented variable quick switching sampling (VQSS) system based on the C_{pk} index. There are numerous papers employing rules based on chaining lot results which employ various process capability indices, and the reader is suggested to refer to the review given in [96]. Kurniati et al. [97] employed the TNT plan rules with a unilateral specification

limit based on one-sided capability indices. Yan et al. [98] extended the MDS rules to assure protection of coefficient of variation of a normally distributed quality characteristic.

12.9 Chain Sampling and CUSUM

In this section, we will discuss some of the interesting relationships between the cumulative sum (CUSUM) approach of [99, 100] and chain sampling approach of [1]. As explained in [101], the CUSUM approach for Gaussian processes is largely popular in the area of statistical process control (SPC), but [99] proposed it to be used with attribute (binomial) inspection problems arising in acceptance sampling as well. Page [99] compares the CUSUM-based inspection scheme with the deferred sentencing schemes of [39] and the continuous sampling plan CSP-1 of [40] for evaluating their relative performance. In fact Dodge's CSP-1 plan forms the theoretical basis for the ChSP-1 chain sampling plan. A more formal acceptance sampling scheme based on the one-sided CUSUM for lot-by-lot inspection was proposed in [102]. Beattie's plan calls for drawing a random sample of size n from each lot and observing the number of nonconforming units d . For each lot, a CUSUM value is calculated for a given slack parameter k . If the computed CUSUM is within the decision interval $(0, h)$, then the lot is accepted. If the CUSUM is within the *return interval* (h, h') , then the lot is rejected. If the CUSUM falls below zero, it is reset to zero. Similarly, if the CUSUM exceeds $h + h'$, it is reset to $h + h'$. In other words, for the j th lot, the plotted CUSUM can be succinctly defined as $S_j = \min(h + h', \max(d_j - k + S_{j-1}))$ with $S_0 = 0$. Beattie's plan is easily implemented using the typical number of nonconforming units CUSUM chart for lot-by-lot inspection (see Fig. 12.6).

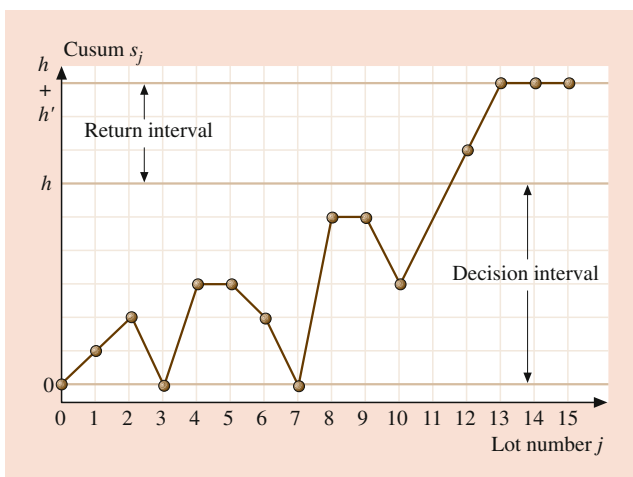

Fig. 12.6 Beattie's CUSUM acceptance sampling plan

Prairie and Zimmer [103] provided detailed tables and nomographs for the selection of Beattie's CUSUM acceptance sampling plan. An application is also reported in [104].

Beattie [105] introduced a "two-stage" semicontinuous plan where the CUSUM approach is followed and the product is accepted as long as the CUSUM S_j is within the decision interval $(0, h)$. For product falling in the return interval (h, h') , an acceptance sampling plan such as the single or double sampling plan is used for lot disposition. Beattie [105] compared the "two-stage" semicontinuous plan with the ChSP-4A plan of [13] and the deferred sentencing scheme of [41]. It is also remarked in [105] that chain sampling plans (ChSP-4A type) call for steady rate of sampling and simple to administer. The two-stage semicontinuous sampling plan achieved some gain in the average sample number at good-quality levels but is more difficult to administer. The two-stage semicontinuous plan also requires more sample size than ChSP-4A plans when the true quality is poorer than acceptable levels.

We will now explore an interesting equivalence between the ChSP-1 plan and a CUSUM scheme intended for high-yield or low-fraction nonconforming production processes for which the traditional p or np control charts are not useful. Lucas [106] gave a signal rule for lack of statistical control if there are two or more counts within an interval of t samples. In case of low-process fraction nonconforming, this means that if two or more nonconforming units are observed in any t consecutive samples or less, a signal for an upward shift in the process fraction level is obtained. It should be noted that if two or more nonconforming units are found even in the same sample, a signal for lack of statistical control will be obtained. Govindaraju and Lai [107] discussed the design given in [106] and provided a method of obtaining the parameters n (the subgroup or sample size) and t (the maximum number of consecutive samples considered for a signal). Lucas [106] has shown that his signal rule is equivalent to a CUSUM scheme having a reference value $k = 1/t$ and decision interval $(0, h = 1)$ for detecting an increase in the process count level. It was also shown that a fast initial response (FIR) feature can be added to the CUSUM scheme (see [108]) with an additional subrule of signaling lack of statistical control if the first count occurs before the t th sample. This FIR CUSUM scheme has a head start of $S_0 = 1 - k$ with $k = 1/t$ and $h = 1$. Consider the ChSP-1 plan of [1] which rejects a lot if two or more counts (of nonconformity or nonconforming units) occur but allows acceptance of the lot if no counts occur or a single count is preceded by t (the symbol i was used before) lots having samples with no counts. If the decision of rejecting a lot is translated as the decision of declaring the process to be not in statistical control, then it is seen that Lucas's scheme and the ChSP-1 plan are the same. This equivalence will be further clearer if one considers the operation of two-stage chain sampling plan ChSP-(0,1) of [27] given in Sect. 12.4. When

$k_2 = k_1 + 1$, the ChSP-(0,1) plan is equivalent to the ChSP-1 plan with $t = k_1$. Hence, it can also be noted that the subrule of not allowing any count for the first t samples suggested for the FIR CUSUM scheme of [106] is an inherent feature of the two-stage chain sampling scheme. This means that the ChSP-1 plan is equivalent to the FIR CUSUM scheme with the head start $(1 - k)$ with $k = 1/t$ and $h = 1$.

12.10 Other Interesting Extensions

If homogeneous lot formation is difficult, and random sampling from the lot is harder, the binomial assumption may not be valid. Gao and Tang [109] considered the chain sampling rule when testing for conformance status which exhibits correlation between successive units. A two-state Markov chain model for the correlation within each sample was assumed as against a two-state Markov chain model for the fraction nonconforming p . In acceptance sampling, random samples are taken; hence, the correlation within the sample is not an issue. The proposal given in [109] may only apply when random samples are difficult to obtain.

Mixed sampling plans are two-phase sampling plans in which both variable quality characteristics and attribute quality measures are used in deciding the acceptance or rejection of the lot. Baker and Thomas [110] reported the application of chain sampling for acceptance testing for armor packages. Their procedure uses chain sampling for testing structural integrity (attributes inspection), and a variable sampling plan is used for testing penetration depth quality characteristic. Baker and Thomas [110] also suggested the simultaneous use of control charts along with their proposed acceptance sampling procedures. Suresh and Devaarul [111] proposed a more formal mixed acceptance sampling plan where a chain sampling plan is used for the attribute phase. Suresh and Devaarul [111] also obtained the OC function for their mixed plan and discussed various selection procedures. For controlling multidimensional characteristics, [112] developed multidimensional mixed sampling plans (MDMSP). This plan handles several quality characteristics during the variable phase of the plan, while the attribute sampling phase can be based on chain sampling or other attribute plans. Aslam et al. [113] presented mixed multiple dependent state sampling plans based on the popular process capability index. Balamurali [114] and Usha and Balamurali [115] extended the mixed chain sampling approach using the process capability index C_{pk} . In a similar vein, another form of mixed modified chain sampling plan is given in [116]. Balamurali et al. [117] generalized the mixed sampling incorporating the multiple dependent state sentencing rule. Balamurali and Usha [118] also extended the mixed sampling incorporating the quick switching system rules. These approaches would

further reduce the sampling effort but no investigation was done on the delay in detection of a shift.

In some situations, it is desirable to adopt three attribute classes where items are classified into three categories, namely, good, marginal, and bad (see [119]). Shankar et al. [120] developed three class chain sampling plans and derived various performance measures through GERT approach and also discussed their design.

Suresh and Deepa [121] provided a discussion on formulating a chain sampling plan given a gamma or beta prior distribution for product quality. Tables are for the selection of the plans and examples are also provided by Suresh and Deepa [121]. Latha and Jeyabharathi [122] considered the beta-binomial process for the operation of the ChSP-1 plan. The main limitation of this approach is that the assumption of nearly constant process fraction nonconforming needed for chain sampling is not fulfilled. As a result, the $(ARL_1 - ARL_2)$ delay will be higher. A number of other lot chaining rules were also proposed such as the rule given in [123] where the number of preceding lot results employed depends on the number of nonconforming results found in the current sample.

Tang and Cheong [124] extended the idea of the chain inspection procedure to enhance its sensitivity in detecting a process shift while monitoring high-quality processes with low fraction nonconforming. The MDS plan rules are also used in control charting (see [125] and [126]).

12.11 Concluding Remarks

Chain sampling attribute inspection plans for a series of lots can be implemented without any distributional assumption. The main requirement is that the fraction nonconforming p in the series of lots submitted for inspection is fairly constant. If there is any linear trend in p , the chain sampling inspection can be modified as a chain-deferred inspection procedure so that the producer's and consumer's risks are maintained the same for the series of lots inspected. If the chain sampling rule is applied for variable inspection, distributional assumptions such as a normality must be met. For costly and destructive testing, the sample size must be kept small. Small sample sizes such as five can be effective when lot results are chained under variable inspection. If the normality assumption is suspect, it is desirable to employ the regular attribute chain sampling in order to assure the set risks.

This chapter largely reviewed the methodology of chain sampling inspection of quality in a series of lots. Various extensions of the original chain sampling plan ChSP-1 of [1] and modifications are briefly reviewed. Chain sampling approach is primarily useful for costly or destructive testing, where small sample sizes are preferred. Chain sampling achieves greater sampling economy when it is combined with

the approach of deferred sentencing so that the combined plan can be used for any general situations. This chapter does not cover designing of chain sampling plans in any great detail. One may consult textbooks such as [74] or [32, 127] for detailed tables. A large number of papers primarily dealing with the design of chain sampling plans are available only in journals, and some of them are listed as references. It is often remarked that designing sampling plans is more of an art than a science. There are statistical, engineering, and other administrative aspects that are to be taken into account for successful implementation of any sampling inspection plan, including the chain sampling plans. For example, the sample size may be fixed due to administrative and other reasons. Given this limitation, what sampling plan should be used requires careful consideration. Several candidate sampling plans, including chain sampling plans, must be sought first, and then the selection of a particular type of plan must be made based on the performance measures such as the OC curve, etc. Sampling plans that make use of related lot results must also be investigated for their performance against trend in the submitted lot quality as well as sudden jumps. The effectiveness of a chosen plan or a sampling scheme must be monitored over time for a series of batches. The severity of inspection is reduced with the chaining-related lot results, but consumer protection should receive more attention by way of minimizing the delay in detection of a poor-quality lot submission.

Abstract

Six Sigma, which was first launched by Motorola in the late 1980s, has become a successful standard-quality initiative to achieve and maintain excellent business performance in today's manufacturing and service industries. In this chapter, we provide a systematic and principled introduction of Six Sigma from its various facets. The first part of this chapter describes what Six Sigma is, why we need Six Sigma, and how to implement Six Sigma in practice. A typical business structure for Six Sigma implementation is introduced, and potential failure modes of Six Sigma are also discussed.

The second part describes the core methodology of Six Sigma, which consists of five phases, i.e., Define, Measure, Analyze, Improve, and Control (DMAIC). Specific operational steps in each phase are described in sequence. Key tools to support the DMAIC process including both statistical tools and management tools are also presented. The third part highlights a specific Six Sigma technique for product development and service design, Design for Six Sigma (DFSS), which is different from DMAIC. DFSS also has five phases: Define, Measure, Analyze, Design, and Verify (DMADV), spread over product development. Each phase is described, and the corresponding key tools to support each phase are presented.

In the fourth part, a real case study on printed circuit board (PCB) improvement is used to demonstrate the application of Six Sigma. The company and process background are provided. The DMAIC approach is specifically followed, and key supporting tools are illustrated accordingly. At the end, the financial benefit of this case is realized through the reduction of cost of poor quality (COPQ). The fifth part provides a discussion of Six Sigma in current Big Data background. A brief introduction of Big Data is first given, and then the tremendous opportunities offered by Big Data analytics to the core methodology of Six Sigma, i.e., DMAIC, are outlined in detail. The capabilities of each phase that would be greatly enhanced are

13.1 Introduction

Since the early 1990s, Six Sigma has been sweeping the business world, driving an unprecedented emphasis on greater manufacturing and service quality. Six Sigma is one of the few quality initiatives that actually originated from industrial practice. Six Sigma was originally devised as a measure of quality that strives for near perfection. It has developed into a disciplined, data-driven, and customer-focused approach to reduce defects and bring about substantial financial growth. Although most of the Six Sigma efforts were focused on manufacturing operations in the early years, the Six Sigma approach has now been more widely used in the nonmanufacturing industry, such as in finance, insurance, health care, and telecommunications. Users include American Express, American International Group (AIG), Bank of America, Citibank, JPMorgan, Chase, Merrill Lynch, Vanguard, etc. These companies have actually seen larger business impacts and cost savings of Six Sigma than those in manufacturing.

13.1.1 What Is Six Sigma?

Motorola first introduced the Six Sigma program in the late 1980s with the aim to increase profitability by reducing defects. General Electric (GE) followed the approach at their manufacturing sites and later at their financial service divisions. After that, Six Sigma is thought to be applicable to all processes and transactions within GE. Six Sigma has now evolved from a quality improvement program to an overall business strategy executive system and business results-oriented program, which seems more “total” than “total quality management (TQM).” We describe the basic definition of Six Sigma in this section and elaborate its systematic methodology and business structure in later sections.

Six Sigma is both a business improvement strategy and a methodology to measure process performance. It is used to increase profits by eliminating defects, waste, and variability, and to find the causes of mistakes in products, processes, and services to increase yields. In Six Sigma, a focus on the

customer is the top priority. Performance standards are based on actual customer input, so that process effectiveness can be measured and customer satisfaction can be predicted.

In terms of business process improvement, variation reduction is the key since variation signals fluctuation in the process output and, often times, is a major source of poor quality. **Variation** is present in all processes and every aspect of work. Unintended variation reduces process performance and decreases customer satisfaction. Because of the existence of variation, producing high-quality products and services in the modern industrial environment is a tough task.

Therefore, Six Sigma aims particularly at reducing variation. The word “sigma” or the symbol “ σ ” is used in statistical notation to represent the standard deviation in a population. The standard deviation is used as a general measure of variation in any kind of product or process. With six standard deviations between the process mean and the customer’s specification limit, we arrive at 3.4 **defects per million opportunities (DPMO)**, that is, a 99.9997 percent yield. Before the Six Sigma technique was introduced, a three-sigma level of variation was regarded as being fairly good-quality performance. Three Sigma may be acceptable for a product or process having only a single or a few stages. It is not good enough for many products that are the result of hundreds of thousands of stages, such as automobiles and computers.

For example, if a production process is made up of ten stages where the yield of each stage is as high as 90%, the probability of producing a satisfactory product in the final run would be $0.9^{10} = 35\%$. This indicates that about 65% of the products are defective. If a production process is made up of 100 stages, the probability of producing a satisfactory product under the **Three Sigma** program could be as low as 0.1%, as shown in Table 13.1. The Six Sigma regime, however, allows only 3.4 defects for every million opportunities, which ensures a quality product even if the process involves a large number of stages (see Table 13.1). Part of the reason for using such a strict requirement in quality management is actually to accommodate the common multistage processes in modern industrial practice.

Table 13.1 Final yield for different sigma levels in multistage processes

Average sigma level	1	2	3	4	5	6
Final yield for 10 stages	0.0%	2.5%	50.1%	94.0%	99.8%	100.0%
Final yield for 100 stages	0.0%	0.0%	0.1%	53.6%	97.7%	100.0%
Final yield for 1000 stages	0.0%	0.0%	0.0%	0.2%	79.2%	99.7%

13.1.2 Why Six Sigma?

The successful implementation of Six Sigma can benefit the areas of cost reduction, increased profit, increased market share, and enhanced business competitiveness, mainly by the reduction of the **cost of poor quality (COPQ)**.

COPQ usually includes appraisal costs, internal failure costs, and external failure costs. Appraisal and inspection costs are often incurred, for example, in checking finished goods before they leave the factory, inspecting purchased equipment/supplies, proofreading financial and legal documents, reviewing charges prior to billing, etc. Internal failure costs are those for repairing, replacing, or discarding work in progress or completed work before the delivery of the product to the customer. External failure costs are those that directly affect the customer and are the most expensive to correct, including the tangible remedial costs and the intangible costs associated with losing dissatisfied customers.

COPQ cannot be underestimated. In manufacturing industries, COPQ sometimes reaches 15% of total sales (source: **Six Sigma Academy**). In service industries, the situation is even more serious. COPQ may account for as much as 50% of total costs. However, these COPQ could be saved with the use of Six Sigma. General Electric has estimated saving of 2 billion US dollars during the first 5 years of Six Sigma implementation, and Allied Signal has estimated saving of 1.1 billion US dollars in 2 years. Indeed, thousands of companies around the world have enjoyed the breakthrough benefits of Six Sigma. For example, Legend Computers in China reported in 2002 savings of \$20 million dollars during the first year of implementation. In the same year, the International Bank of Asia in Hong Kong reported savings of 1.4% of total costs during the first year of Six Sigma implementation.

13.1.3 Six Sigma Implementation

Six Sigma implementation is usually a top-down approach, i.e., from the strong commitment of top management. As most Six Sigma projects span across several departments, the organizational barrier could not be removed without leadership commitment to Six Sigma. Strong commitment, leadership, and strategic involvement have proven to be key factors of Six Sigma's success. Second, as Six Sigma requires a long-term mentality, it needs to be positioned first as a strategic initiative and then be linked to operational goal. It is important to tie the Six Sigma implementation to corporate goals, such as increased profits through lower costs and higher loyalty as an example. Also, effective internal communication is another key issue for the success of Six Sigma implementation.

In the following, a typical business structure for Six Sigma implementation is introduced. Several potential failure modes and practical considerations of Six Sigma implementation are also discussed.

Training and Belt Structure

The deployment of Six Sigma in a company usually starts with education. Without necessary training, people are not able to bring about the breakthrough improvement of Six Sigma. Six Sigma establishes well-defined and structural roles and responsibilities for a project team, and team members are given formal training according to their roles to help the team work effectively. A Six Sigma team is usually organized in a **belt structure** (as in martial arts) as follows.

At the top of the belt structure is the **Six Sigma Executive**. The Six Sigma Executive could be a council that consists of top managers who have the vision and make strategic decisions for a company. They are responsible for establishing the roles and structures of Six Sigma projects. They also need to make decisions on project selection and resources allocations. A progress review is conducted periodically to monitor projects.

Champions are the senior managers who supervise Six Sigma projects. They report directly to the Six Sigma Executive and represent the team to the Executive. They also need to seek resources and to learn the focus of the business from the Executive. In addition, Champions meet Black Belts and Green Belts periodically to review the progress and coach the team.

Master Black Belts work with the Champions to ensure that Six Sigma objectives and targets are set. Meanwhile, they are the statistical problem-solving experts in a company. Their responsibilities include determining plans, providing technical expertise, and training and coaching Black and Green belts.

Black Belts, as on-site Six Sigma experts, usually possess the technical background needed to help Green belts and the other team members to understand the project and apply appropriate statistical techniques. Their roles are to provide formal training to local personnel in new strategies and tools, provide one-on-one support to local personnel, pass on new strategies and tools in the form of training, workshops, case studies, local symposia, etc., and find application opportunities for breakthrough strategies and tools, both internal and external (i.e., to the suppliers and customers).

Green Belts, on the other hand, execute Six Sigma in their specific area as a part of their overall job. They may assist Black belts in completing sections of their projects and apply their learning in their daily performance of their jobs.

According to the Six Sigma Academy, Black Belts are able to save companies approximately US\$230,000 per project and can complete four to six projects per year. The American Society for Quality (ASQ) provides the certification of Six Sigma Black Belts (SSBB) internationally.

Six Sigma Failures (Sick Sigma)

Although Six Sigma is a powerful approach, it can lead to failure when some critical issues are neglected. However, as more companies have implemented Six Sigma since the 1990s, the factors that have led to failure have been identified and summarized. According to [1], project selection and management support are usually the two main sources of failure.

The **failure modes** in project selection usually include projects not tied to financial results, poorly defined project scopes, metrics and goals, projects lasting more than 6 months, the wrong people assigned to projects, project teams that are too large, and infrequent team meetings. On the other hand, the failure modes in management support may include Black belts with little time to work on projects, poor or infrequent management reviews, poor support from finance, information technology (IT), human resource (HR), and poor communication of initiatives and progress [1].

Especially, for a Six Sigma program to sustain without failure, **recognition and reward systems** would be the key. If a lack of or no change on the recognition and reward systems, the program has no way to last. Necessary practices include establishing and using selection and promotion criteria and developing corresponding performance management and reward systems. GE way which links 40% of management bonus to Six Sigma may be too aggressive, but a company must adequately compensate those high-performing members.

Note that the use of statistical methods is not on the list of major failure modes. With the recent advances in information technology, computing and sensing technology, the use of advanced statistical methods has become handy via commercial software packages (such as MINITAB, JMP, etc.). Therefore, the use of statistical tools is no longer a bottleneck in Six Sigma implementation.

Besides, various industry types and company natures are also not an excuse for the Six Sigma failure. Six Sigma has been successfully applied to many processes outside of manufacturing, regardless of their company size or their industry nature. In particular, transactional processes, such as software coding, billing, customer support, etc., often contain variation or excessive cycle time and can be optimized by applying Six Sigma. For example, HR managers may apply it to reduce the cycle time for hiring employees, and regional sellers may apply it to improve forecast reliability, pricing strategies, or variations.

13.2 The DMAIC Methodology

13.2.1 Introduction

The development of Six Sigma is evolutionary, not revolutionary, and it integrates many useful quality management tools. Thus, it is not surprising to find overlaps between Six Sigma, TQM, Lean, and ISO. The core methodology of Six Sigma is driven by the close understanding of customers' needs and the disciplined use of facts, data, and statistical analysis, which consists of five phases, i.e., Define, Measure, Analyze, Improve, and Control (DMAIC).

In the Define phase, the specific problem is identified, and the project goals and deliverables are defined. In the Measure phase, the critical-to-quality (CTQ) characteristics are identified and the measurement system is reviewed. The nature and properties of the data collection have to be understood thoroughly to ensure the quality of the data. In the Analyze phase, both quantitative (i.e., statistical) methods and qualitative (i.e., management) tools are used to isolate the key information that is important to explaining defects. In the Improve phase, the key factors that cause the problem should be discovered. In the Control phase, the key factors and processes are controlled and monitored continuously to ensure that the improvement is sustainable and the problem will not occur again. A detailed case study on the implementation of the DMAIC methodology in printed circuit board (PCB) manufacturing can be found in [2]. The paper "Six Sigma approach to reducing fall hazards among cargo handlers working on top of cargo containers: a case study" [3] is another case study using DMAIC that focuses on a nonmanufacturing case.

13.2.2 The DMAIC Process

More specifically, we implement the DMAIC methodology in detailed steps in sequence in order to shift our focus from the output performance (i.e., y) to the root causes (i.e., the x). Based on these steps, we transfer a practical problem into a statistical problem (e.g., mapping x and y), find out a statistical solution for that (e.g., solving $y = f(x)$) and then transfer the statistical solution back into a practical solution. Each step is described in the following, and the corresponding key tools will be further explained in a later section.

Phase 1. Define (D)

This phase defines the Six Sigma project that includes a problem statement, the objectives of the project, the expected benefits, the team structure, and the project time line. At the end of this phase, we should have a clear operational

definition of the project metrics for the final evaluation. In this phase, the main tasks are to identify who the customer is, select the project area, define the goal, scope, and resources of the project, form a Six Sigma project team, define the team members' responsibilities, and estimate the profit and cost for this project to ensure the value of the project. Key Tools in this phase include the project charter, business process mapping, SIPOC, etc.

Phase 2. Measure (M)

By taking steps in the measure phase, we have a clear understanding of the performance of the current process, and only after knowing where we are now, we can determine where we should be in the future. Three implementation steps in this phase are to select the critical-to-quality (CTQ) measures, determine deliverables, and quantify the measurability of y .

Select the Critical to Quality (CTQ) Measures

In this step, we will identify the external CTQ from the customer point of view (i.e., the big Y) that will be improved, and then link that with the internal CTQ (i.e., the small y), which is a quantitative measure in the company and will be the focus of the project. Key tools in this step include Customer Needs Mapping (CNM), Quality Function Deployment (QFD), Failure Modes and Effects Analysis (FMEA), etc.

Determine Deliverables

We establish a performance standard and develop a data collection plan for the internal CTQ y in this step. If the measure of y from the previous step is attributal, what is the definition of a defect? If the data are continuous, what are the lower and upper specifications for defectiveness? Key tools used in this step include process mapping and yield calculation.

Quantify Measurability

We validate the measurement system on how to ensure the measurement results are accurate for the following analysis. We may need to improve the measurement system before continuing. Key tools include measurement system analysis (MSA), Gauge R&R study.

Phase 3. Analyze (A)

After we identify the “ y ” in the process, we need to determine the x (root causes), which may impact the performance of “ y .” In the analyze phase, we use various management and statistical tools to discover the x 's for future improvements. Three implementation steps in this phase are to establish the baseline, determine the improvement plan, and identify the sources of variation.

Establish the Baseline

We will establish the process capability for the current process to understand where we are now. We need to collect

the current process data, use graphical tools to analyze the data, and calculate the process capability indices, the defect per million opportunities (DPMO), and the sigma level (Z). Key tools include the following: histograms, process capability indices (PCI), etc.

Determine Improvement Plan

We quantify the goals for the improvement to make the aim of the project clear, and we may determine if the goal is significantly different from today's performance (i.e., the baseline) through hypothesis testing. Key tools include benchmarking, hypothesis testing, t test, ANOVA, etc.

Identify Variation Sources

We list all the potential factors (x 's) that may influence the performance of “ y .” Regression analysis may be conducted where applicable to identify potential x 's. Key tools include brainstorming, cause and effect diagram, regression analysis, etc.

Phase 4. Improve (I)

As the root causes for variation are obtained, it becomes possible for us to fix these root causes. In the improve phase, the way that we can achieve a better process needs to be found, where the Design of Experiments (DOE) is a key technique to help us quantify the relation between y and x 's, and to improve the process by finding the optimal setting of x 's for each y . In this phase, we follow three implementation steps: screen potential sources of variation, discover variable relationships, and formulate the implementation plan.

Screen Potential Sources of Variation

We determine the vital few x 's from the trivial many x 's in this step. DOE is a key tool for factor screening. Both full factorial and fractional factorial experiments can be used. If necessary, historical data can be used with care, and a similar model or simulation may be used as well.

Discover Variable Relationships

We develop the transfer function ($y = f(x)$) linking the y to the vital x 's. Based on that, we then determine and confirm the optimal settings for the vital few x 's. DOE is a key tool for characterization and optimization as well. Various DOE techniques, such as the response surface method (RSM), robust design, and the Taguchi method, can be applied in this step. Other than that, simulation or surveys can also be used to find the relationship.

Formulate Implementation Plan

In this step, if a new process or process steps have been put in place, show the new process map. For the new process, indicate the new in-process measurements and associated specifications. If there is not a new process, indicate any new measurements put in place. We list how the changes to the x 's will be implemented and how much flexibility is available in the settings of each x . Key tools in this step include tolerance design, main effects plots, and interaction plots.

Phase 5. Control (C)

After determining how to fix the process, we want the improvement for the process to be sustainable. The control phase is set up to ensure the sustainable improvement and to deploy measurement tools to confirm that the process is in control. It is also critical to realize the financial benefits and develop a transfer plan in this phase. Three implementation steps include validating the implementation plan, controlling the inputs and monitoring the outputs, and finally sustaining the change.

Validate the Implementation Plan

To determine how well the x 's can be controlled, we will validate the measurement system on the x 's, and we may need to improve measurement system before continuing. We will also report new sigma levels and new DPMO levels at this step. Key tools include Gauge R&R, ANOVA, etc.

Control Inputs and Monitor Outputs

We determine how each vital x can be controlled (e.g., attribute control chart, variable control chart, mistake-proofing, etc.) and set up a monitoring plan for the y and x 's in this step. Key tools include statistical process control (SPC), attribute control charts, variable control charts, Poka-Yoke (mistake-proofing), etc.

Sustain the Change

The objective of this step is to ensure that changes last after the improvement strategy has been implemented. Process control plans need to be developed and implemented for each x . We will also verify financial gains can be achieved and if this project is translatable to any other regions, lines, sites, processes, etc. Key tools in the final step include out-of-control plans, mistake-proofing, audit strategy, etc.

13.2.3 Key Tools to Support the DMAIC Process

This section presents the key tools to support the DMAIC process. Only a few key tools can be covered in this section, and each method is outlined briefly with the basic ideas and mechanisms. The books and papers cited in this section give more details.

A. *Business Process Mapping (SIPOC Diagrams)*

Purpose:

SIPOC stands for Suppliers, Inputs, Process, Outputs, and Customer. SIPOC diagrams are graphical tools to identify all relevant elements or stakeholders of a business process and map the process flow before the project begins. They are usually used in the Define phase.

Definition:

Supplier: Whoever produces, provides, or furnishes the products or services for the input of the process, either an internal or an external supplier

Inputs: Material, resources, and data required to execute the process

Process: The manufacturing or service process of interest which transforms the inputs into the outputs

Outputs: The tangible products or intangible services that result from the process

Customer: Whoever receives the outputs of the process, either an internal customer or an external customer

How to do it:

Step 1. Clear statement of CTQ and the process.

Step 2. Clear statement of start/end point.

Step 3. Identify major customers, suppliers, outputs, and inputs.

Step 4. Identify the five to seven major process steps using brainstorming and storyboarding.

Step 5. Decide what step to map in detail.

Step 6. Complete detail map.

B. *Quality Function Deployment (QFD)*

QFD is a systematic approach to prioritize and translate customer requirements (i.e., external CTQ) into appropriate company requirements (i.e., internal CTQ) at each stage from product development to operations to sales/marketing to distribution. This method is usually used in the Measure phase. It is also useful in the design for Six Sigma (DFSS) and will be introduced in more detail in the DFSS section.

C. *Failure Modes and Effects Analysis (FMEA)*

Purpose:

FMEA is a tool to reduce the risk of failures. It is also a tool to identify and prioritize CTQ at the Measure phase.

Definition:

Severity: The assessment of how severe a failure mode is. The severity usually scales from 1 to 10. Scale 1 means a minor failure mode that may not be noticed, and 10 means a very serious failure that may affect safe operations.

Occurrence: The likelihood that a specific cause will result in the failure mode, which scales from 1 to 10 with 10 the highest likelihood.

Detection: The assessment of the ability to identify the failure mode. A 1–10 scale is often used with 10 the lowest detectability.

RPN: The risk priority number (RPN) is the output of an FMEA. $RPN = \text{Severity} \times \text{Occurrence} \times \text{Detection}$.

How to do it (refer to [4, 5]):

- Step 1.** Identify the products, services, or processes.
- Step 2.** Identify the potential failure that would arise in the target process.
- Step 3.** Identify the causes of the effects and their likelihood of occurrence.
- Step 4.** Identify the current controls for detecting each failure mode and the ability of the organization to detect each failure mode.
- Step 5.** Calculate RPN by multiplying the values of severity, potential causes, and detection.
- Step 6.** Identify the action for reducing or eliminating the RPN for each failure mode.

D. Measurement System Analysis (MSA)

Purpose:

A statistical evaluation of the measurement system must be undertaken to ensure effective analysis of any subsequent data generated for a given process/product characteristic. MSA is usually used in the Measure and Control phases to validate the measurement system for y and x 's.

Definition:

- Gauge R&R:** A tool to study the variation in the measurement process arising from the measurement device and the people taking the measurement.
- Repeatability:** The variability that reflects the basic inherent precision of the gauge itself.
- Reproducibility:** The variability due to different operators using the gauge (or different time, different environments) [6].

How to do it:

- Step 1.** Collect the data. Generally, two to three operators, ten units to measure, and each unit is measured two-three times by each operator.
- Step 2.** Perform the calculations to obtain %R&R (see [6]).
- Step 3.** Analyze the results. A rule of thumb is that:
 - %R&R < 10%: measurement system is acceptable.
 - %R&R between 10% and 30%: measurement system may be acceptable. We will make decisions based on the classification of the characteristics, hard applications, customer inputs, and the Sigma levels of the process.
 - %R&R > 30%: measurement system is not acceptable. We should improve the measurement system by finding problems and removing root causes.

E. Process Capability Analysis

Purpose:

Process capability analysis is a statistical technique to quantify process variability, analyze this variability relative to customer requirements or specifications, and assist in reducing the variability [6]. It is used in the Analyze phase.

Definition:

- Cp:** Process/Product capability index is the relationship of the process/product variation to the upper and lower specification limits. It is related to the potential process capability and not a measure of how centered the data are.
- Cpk:** It compares process variability with the specification's width and location. It takes into account that the sample mean may be shifted from the target. Since both the mean shift and the variability of the characteristics are considered, Cpk is better related to the capability of the current process.

How to do it:

The detailed calculation and analysis are given in Chap. ▶ 8 in [6].

F. Cause-Effect Diagram (Fishbone Diagram)

Purpose:

This is a graphical brainstorming tool to explore the potential causes (i.e., x 's) that result in a significant effect on y . It is usually used in the Analyze phase.

How to do it:

- Step 1.** Define clearly the effect or analyzed symptom (y) for which the possible causes (x 's) must be identified.
- Step 2.** Place the effect or symptom (y) being explained on the right of a sheet of paper.
- Step 3.** Use brainstorming or a rational step-by-step approach to identify the possible causes in areas related to man, machine, material, method, and environment.
- Step 4.** Each of the major areas of possible causes should be connected with the central spine by a line.
- Step 5.** Add possible causes (x 's) for each main area.
- Step 6.** Check for completeness.

G. Design of Experiments (DOE)

Purpose:

DOE is a major tool in the Improve phase. It is used for screening the vital few x 's, characterizing the relationship between y and x 's, and optimizing the setting of the vital x 's.

Definition:

Factor: An independent variable (i.e., x) whose state can be varied.

Level of a factor: The state of the factor.

Full Factorial Experiments: Discover the factor effects and relationship between y and x 's by running all the combinations of factor levels.

Fractional Factorial Experiments: An economical approach to discovering the factor effects and to screening the vital few x 's by running only part of the combinations of factor levels.

Response Surface Methodology (RSM): A DOE technique that is useful for modeling and optimization in which a response of interest y is influenced by several factors x 's and the objective is to optimize this response. This method is discussed more in the DFSS section.

How to do it (see [7, 8]):

Step 1. State the problem.

Step 2. Choose the response variable (y).

Step 3. Choose the factors (x 's) and their levels and ranges.

Step 4. Determine the experimental plan (i.e., the design matrix).

- (a) For screening the x 's to obtain vital few x 's, we often use factorial experiments. In such cases, if the number of runs is moderate and we have enough time and resources, we may conduct a full factorial experiment; if the number of runs is large or time and resources are limited, we may consider a fractional factorial experiment.
- (b) For obtaining the optimal response, we may conduct RSM, which is usually conducted after variable screening.

Step 5. Run the experiments under the prescribed conditions and collect the response data.

Step 6. Analyze the data collected using main effect plots, interaction plots, ANOVA, etc.

Step 7. Conclude the experiment and make recommendations. A confirmation run or a follow-up DOE is usually needed.

H. *Statistical Process Control (SPC)**Purpose:*

SPC is a major tool in the Control phase. It is used to control and monitor the stability and capability of the vital few x 's for CTQ.

How to do it:

This method is discussed in more detail in the DFSS section. For a general introduction about SPC, see

[6, 9]. For recent advances in SPC, the readers may refer to <http://qlab.ieda.ust.hk> and references therein.

As a final note, we summarize the main purposes and key tools of each of the five phases demonstrated throughout Sect. 2 in the following figure, so that practitioners can have a better idea on how to systematically implement the DMAIC approach to solve a real quality problem (Fig. 13.1).

13.3 Design for Six Sigma

13.3.1 Introduction

The success of Six Sigma's DMAIC methodology has generated enormous interest in the business world. One of the basic ideas is to measure existing defective processes quantitatively and then to improve them. Compared with this defect-correction methodology, Design for Six Sigma (DFSS) is a proactive methodology, which focuses on the new product/service development to prevent quality defects the first time instead of solving problems when they happen in existing processes.

DFSS is a disciplined and statistical approach to product and service design that ensures the new designs can meet customer requirements at launch. The objective of DFSS is to eliminate and reduce the design vulnerabilities in both the conceptual and operational phases by employing scientific tools and statistical methods.

Unlike the DMAIC methodology, the phases of DFSS are not universally defined. There are many methodologies, such as Woodford's IDOV (Identify, Design, Optimize, Validate), El-haik's ICOV (Identify, Characterize, Optimize, Verify), Tennant's DCCDI (Define, Customer Concept, Design, and Implement), and so on. All these approaches share common themes, objectives, and tools. In this section, we refer to above methodologies, especially General Electric's DFSS approach called DMADV:

Define the project goals and customer requirements.

Measure and determine customer needs and specifications.

Analyze the options of conceptual solutions to meet customer needs.

Design the product/service to meet customer needs.

Verify the design performance and ability to meet customer needs.

13.3.2 Why DFSS?

Proactive Versus Retroactive

During the product/service design process, conceiving, evaluating, and selecting good design solutions are difficult tasks

Define	Identify project, champion and project owner Determine customer requirements and CTQs Define problem, objective, goals and benefits Define stakeholder/resource analysis Map the process Develop project plan	Key analytical tools Process mapping
Measure	Determine critical Xs and Ys Determine operational definitions Establish performance standards Develop data collection and sampling plan Validate the measurements Measurement system analysis Determine process capability and baseline	Measurement system analysis & process capability, QFD, pareto diagram, check sheet
Analyze	Benchmark the process or product Establish causal relationships using data Analysis of the process map Determine root causes using data	Statistical tests, cause-effect diagram, histogram, scatter plot, modeling & root cause analysis
Improve	Develop solution alternatives Assess risks and benefits of solution alternatives Validate solution using a pilot Implement solution Determine solution effectiveness using data	Brainstorming, design of experiments, FMEA, & validation
Control	Determine needed controls (measurement, design, etc.) Implement and validate controls Develop transfer plan Realize benefits of implementing solutions Close project and communicate results	Statistical process control, poka yoke

Fig. 13.1 Six sigma DMAIC road map

with enormous consequences. Usually, organizations operate in two modes: “proactive,” that is, conceiving feasible and healthy conceptual solutions the first time; and “retroactive,” that is, an after-the-fact practice that drives design in a design-test-fix-retest cycle and creates what is broadly known as the “fire fighting” mode of design. If a company follows this practice, it would suffer from high development costs, longer times to market, lower quality levels, and marginal competitive edge [10].

Compared to retroactive approaches such as DMAIC, which apply performance improvement in the later stages of the product/service life cycle, DFSS shifts the attention to improving performance in the front-end design stages. That is, the focus is on problem prevention instead of problem solving. This action is motivated by the fact that the design decisions made during the early stages of the product/service life cycle have the largest impact on both total cost and quality of the system. It is often claimed that up to 80% of the total cost is committed in the concept development stage. Also, at least 80% of the design quality is committed in the early design stages. According to a study of the design community [10], at the early design stage, the impact (influence) of design activity is much higher than a later stage, while the correction cost in the early stage is much lower.

Experience Dependency Versus Scientific and Systematic Methodology

Currently, most design methods are empirical in nature, while the work of the design community is often based on experience. This experience-based tradition often leads to unnecessary variation and is difficult for project manager to control. As a result, vulnerabilities are introduced to the new design that makes it impossible for the product/service to achieve Six Sigma performance. This is another motivation for devising DFSS as a scientific and systematic design method to address such needs.

13.3.3 Design for Six Sigma: The DMADV Process

Generally speaking, DFSS has five phases spread over product development. They are called DMADV, Define, Measure, Analyze, Design, and Verify.

Phase 1. Define (D)

The process of product/service design begins when there is a need (internal or external), which can be a problem to be solved or a new invention. In this phase, design objectives,

scope, and available resources should be simply and clearly defined in the design project charter as the key deliverables.

Phase 2. Measure (M)

In particular, the Voice of Customer (VOC) is the critical input in customer-oriented design. Based on the VOC, the internal CTQ measures (critical to quality or critical to satisfaction, i.e., the y), such as cost, performance, reliability, esthetics, and serviceability, need to be identified quantitatively and to be prioritized according to their importance to customers. This kind of information can help to define the function requirements in a later phase.

Phase 3. Analyze (A)

In this phase, the CTQs will be decomposed into measurable and solution-free Functional Requirements (FRs). Then, a number of conceptual-level design alternatives should be produced by the design team for the FRs, considering cost, physical properties, the difficulties to operate, manufacture, and maintain, etc. Through summarizing the design requirements and conceptual-level design alternatives, an overall set that contains high-potential and feasible solutions can be produced to help the design team to decide on the best solution considering the original design charter including the performance, the constraint of cost, and available resources.

Phase 4. Design (D)

Once the design team fixes the selection of the conceptual solutions, they need to decompose the FRs into Design Parameters (DPs). And at the same time, they need to consider the potential risk to achieve CTQs when they create detailed designs to the level of design parameters. Then, optimization tools will be used to get optimal values for the design parameters. In DFSS, optimization can be reached statistically, and by using statistical tools, the transfer functions can be generated to mathematically represent the relationships between the input and output of a product or a service process. Then, the design team can rely on the transfer function to optimize the design solutions so that the product/service can achieve a target performance and be insensitive to uncontrollable factors (noise factors), such as the environment and production case-to-case variation.

Phase 5. Verify (V)

In this phase, the design team makes a model formed by the simulation of a service process or a physical prototype that is the first working version of the product. Based on these few prototypes, the design team evaluates and tests the whole design to predict if future product's performance can meet the design charter and how to improve the solution when failure occurs.

13.3.4 Key Tools to Support the DMADV Process

Below is a summary of the key tools used to support the DMADV process.

A. Voice of Customer (VOC)

Purpose:

Define customer needs/requirements for the new product/service design or existing product/service redesign.

Input:

Market segment defined – who the customers are and their environment

Output:

Detailed customer requirements

How to do it (refer to [11]):

Step 1. Define market segments – to understand who the customers are and where to go to gather their needs.

Step 2. Identify objective for interviews of customer – to learn which of their needs are new, unique, and difficult (NUD).

Step 3. Select customer groups within the target market segments.

Step 4. Decide on the customer visit team – divide into three roles: leader, subordinate interviewer that helps adding balance and diversity in the discussion, and statement writer that writes down the VOC needs statement.

Step 5. Create an interview guide based on objectives – to get customers' responses that are rich in description of needs.

Step 6. Listen, probe, and observe customers by asking stimulating questions and open-ended statements to gather the VOC. Image data can be gathered by actual observation of customers' responses to existing products or services.

B. KJ Method (See [12])

Purpose:

Structure and rank the customer requirements

Input:

The detailed VOC

Output:

Organized customer requirements

How to do it (refer to [13]):

- Step 1.** Write down customer descriptions as “statements of customer requirements” on a POST-IT note and put them on the wall.
- Step 2.** Group the similar customer requirements together.
- Step 3.** Review the customer requirements statements and throw out redundant ones.
- Step 4.** Write a summary to express the general idea for each group. For those that do not relate to anything else, label it as “independent.”
- Step 5.** Vote for the most important groups and rank the top three groups and assign some relationships. If a group supports another group in a positive manner, we add an arrow pointing from the supporting group to the supported group. If the relationship is contradictory, we add a line pointing between the two groups with blocks on the end.
- Step 6.** Look at each detailed customer requirement and highlight the new, unique, or difficult (NUD) ones.
- Step 7.** Ask customers to rank (on a scale of 1–10) the strength of importance for each requirement.

The result of these ranked and structured customer requirements will flow into the QFD process.

C. **Quality Function Deployment (QFD): The Houses of Quality (HOQ)** (see [14])

QFD is a methodology that establishes “bridges” between qualitative, high-level customer needs/requirements and the quantitative engineering terms that are critical to fulfilling these high-level needs. By following QFD, relationships can be explored among customer requirements, CTQ measures, Function Requirements (FRs), Design Parameters (DPs), and Process Variables (PVs), and the priorities of each CTQ, FR, DP, and PV can be quantitatively calculated.

Generally, the QFD methodology is deployed through a four-phase sequence.

- Phase 1 – critical-to-satisfaction planning (HOQ1)
- Phase 2 – functional requirements planning (HOQ2)
- Phase 3 – design parameters planning (HOQ3)
- Phase 4 – process variable planning (HOQ4)

In this chapter, HOQ 1 will be introduced in detail as an example.

Input:

Structured and ranked New, Unique, and Difficult (NUD) VOC from the KJ diagram

Key Output:

The priorities of each CTQ

How to do it (refer to [10, 15]):

- Step 1.** Convert NUD VOC (“WHATs”) into a list of CTQs (“HOWs”) in terms of the engineering perspective to support customer requirements along the roof of the house. There may be more than one CTQ to achieve each customer requirement.
- Step 2.** Quantify the relationship between each customer requirement to each CTQ on a 1-3-9 scale (9 = Strong fulfillment, 3 = Moderate fulfillment, 1 = Weak fulfillment, or 0 = No relationship). These values help to identify which CTQs are critical while some are not.
- Step 3.** Identify the correlation between each pair of CTQ to address the cooperative and conflicting relationships among CTQs to develop the design to be as cooperative as possible.
- Step 4.** Conduct a competitive assessment with a main competitor. The comparison with the key competitor on each customer requirement is on a 1–5 scale with 5 being high.
- Step 5.** Prioritize customer requirements. These priorities include importance to customer from the KJ method, improvement factor, and absolute weight. Customer requirements with low complete assessments and high importance are candidates for improvement, which will be assigned improvement factors on a 1–5 scale with 5 being the most essential target to improve. The absolute weight can then be calculated by multiplying the customer importance and the improvement factor.
- Step 6.** Priority CTQs. The CTQs are prioritized by determine absolute weight and relative weight. The absolute weight is calculated by the sum of the products of the relationship between customer requirements and CTQs and the importance to the customer. The relative weight is the sum of the products of the relationship between customer requirements and CTQs and customer requirements’ absolute weights. The relative and absolute weights are evaluated to prioritize and select CTQs for improvement.

Furthermore, the design team can apply the same method for identifying the relationship among CTQs, functional requirements, design parameters, and process variables.

D. **The Pugh Concept Evaluation and Selection Process** (See [16])

The Pugh concept evaluation is a solution-iterative selection process. The method alternates between generation and selection activities. The “generation” activity can be enriched by TRIZ (Theory of Inventive Problem Solving, see [17]) methodology to generate conceptual

solutions for each functional requirement. The “selection” activity can use a scoring matrix called the *Pugh Matrix* or the *criteria-based matrix* to evaluate the concepts.

Input:

Functional requirements and conceptual solutions to achieve corresponding FRs

Output:

The conceptual solutions, which are selected and ready to go forward into the design phase

How to do it (refer to [18, 19]):

- Step 1.** Define concept selection criteria from a clear and complete set of requirements.
- Step 2.** Define a best-in-class benchmarked datum concept.
- Step 3.** Provide candidate concepts to evaluate against the datum.
- Step 4.** Evaluate each concept against the datum using (+)s, (-)s, and (S)s to rank the fulfillment of the concept selection criteria.
(+) means the concept is better than the benchmarked datum concept.
(-) means the concept is worse than the benchmarked datum concept.
(S) means the concept is the same with the benchmarked datum concept.
- Step 5.** Refine criteria as necessary during the first cycle of evaluation.
- Step 6.** Analyze the results from the first cycle of evaluation: Sum of (+)s, (-)s, and (S)s.
- Step 7.** Identify weakness in concepts that can be turned into (+)s.
- Step 8.** Create hybrid “super concepts” by integrating the strengths of like concepts to remove (-) s and (S)s.
- Step 9.** Select a new datum based on the scoring that suggests a superior concept after the first cycle of evaluation.
- Step 10.** Add any new concepts that have been developed.
- Step 11.** Repeat the evaluation process through the second cycle.
- Step 12.** The superior concept is selected and ready to go forward into the development or design phase.

E. Design Failure Modes and Effects Analysis (DFMEA) (See [20])

DFMEA is applied to define qualitatively and rank quantitatively the failure modes and effects for new products and service processes across all the phases of DMADV. In particular, the design team can use DFMEA in a design concept for potential failure modes, so it can address them early in the design. Usually, DFMEA is

conducted on the superior concept, which is chosen from all the candidate concepts in the Pugh concept selection process.

Input:

Superior concept architectures, functional requirements, the physical form, etc.

Output:

Causes of failure and corrective action

How to do it (refer to [10, 19]):

- Step 1.** Develop a block diagram of the design element or function being analyzed (at system, subsystem, subassembly, or component level).
- Step 2.** Determine the ways in which each design element or function can fail (failure modes).
- Step 3.** Determine the effects of the failure on the customer(s) for each failure mode associated with the element or function.
- Step 4.** Identify potential causes of each failure mode.
- Step 5.** List the current design controls for each cause or failure mode.
- Step 6.** Assign severity, occurrence, and detection ratings to each cause.
- Step 7.** Calculate risk priority numbers (RPN) for each cause.
- Step 8.** Apply tools and best practices to reduce the sensitivity to root causes of failure or eliminate root causes of failure and recalculate RPNs.
- Step 9.** Document causes of failure and corrective action results qualitatively and quantitatively.

F. Response Surface Methods (See [7, 21])

Purpose:

Optimize the system performance in the *Design* phase by constructing a statistical model and response surface map that represents the relationship between the response and the critical design parameters. If the design parameters are quantitative and there are only a few of them, RSM is an effective tool for modeling and optimization.

Input:

Critical design parameters

Output:

Surface map and equations that determine the level of the factors

How to do it (refer to [22]):

- Step 1.** Choose a CTQ response to be studied by experimentation.

Step 2. Determine the critical parameter to be modified with the experiments. Focus on the significant factors that affect the response.

Step 3. Select the measurement system used to analyze the parameters.

Step 4. Create the transfer function from the experimental data. The transfer function is a mathematical description of the behavior of the system that can be used to create surface plots and optimize the system's performance.

Step 5. Plot the response surface maps to observe the system behavior.

Step 6. Final Output: a surface map and an equation that is used to determine the level of the factors. Sensitivity of the factors can also be analyzed.

G. Inferential Statistics

Inferential statistics is often employed in the *Verify* phase.

Purpose:

Identify and control variation in the critical responses.

Input:

The new product/service's performance data

Output:

The decision on which factors have an effect on the design's response

Definition:

Hypotheses and Risk: There are null hypothesis and alternate hypothesis. Once we have data, we can determine whether we should accept or reject the null hypothesis, by calculating a test statistic.

The t-Test: Used to compare two samples, or one sample with a standard. The null hypothesis is that the means are equal or the difference between the two population means is zero. For example, the t-test can be used to determine if two types of shoe sole materials wear differently, or whether the change to a process can affect the cycle time.

Analysis of Variance (ANOVA): The analysis of variance is a generalization of the two-sample t test which enables us to test for the significance of the difference among k ($k > 2$) factor and/or treatment means. A real scenario can be that a process engineer needs to assess the effect of three process times and three strength levels on the density of plastic. Another example is that an administrative team has four new form layouts to reduce data entry time on license agreements.

In the null hypothesis of ANOVA, the means of multiple populations or different treatments are assumed to be equal, whereas in the alternative hypoth-

esis, at least one mean is different. The key idea of ANOVA is that the total variation in the experiment data can be decomposed into two components: One is the between-treatment (factor) variation, and the other is the within-treatment (error) variation, i.e.,

$$SS_{\text{total}} = SS_{\text{treatment}} + SS_{\text{error}}$$

where SS refers to the sum of squares. If the between-treatment (factor) variation dominates, or the corresponding F score exceeds a threshold at a certain significance level, we will reject the null hypothesis and get a conclusion that the means of different treatments are significantly different.

H. Statistical Process Control (See [6, 9])

Purpose:

Monitor the critical response of the new product/service in the *Verify* phase to assess stability and predictability and detect important changes.

Input:

The new product/service's performance data

Output:

Assessment of the new product/service's stability, predictability, sigma level, and capability for commercialization readiness.

Main Considerations:

Sample size – sample size should be large enough to provide good sensitivity in detecting out-of-control conditions.

Sampling frequency – sampling should be frequent enough to ensure the opportunities for process control and improvement.

Concepts:

A production/service process that is operating with only chance causes (common causes) of variation present is said to be "in statistical control." A process is out of control if there exist assignable causes (special causes) that are not part of the chance cause pattern such as improperly adjusted or controlled machines, operator errors, or defective raw material [6]. An SPC chart is used to distinguish these two types of causes by upper and lower control limits (UCL and LCL). As long as all the sample points plot within the control limits, the process is assumed in statistical control. If a charting point is out of the control limits, this implies that there is evidence that the process is out of control. We then should investigate the assignable causes and take corrective actions.

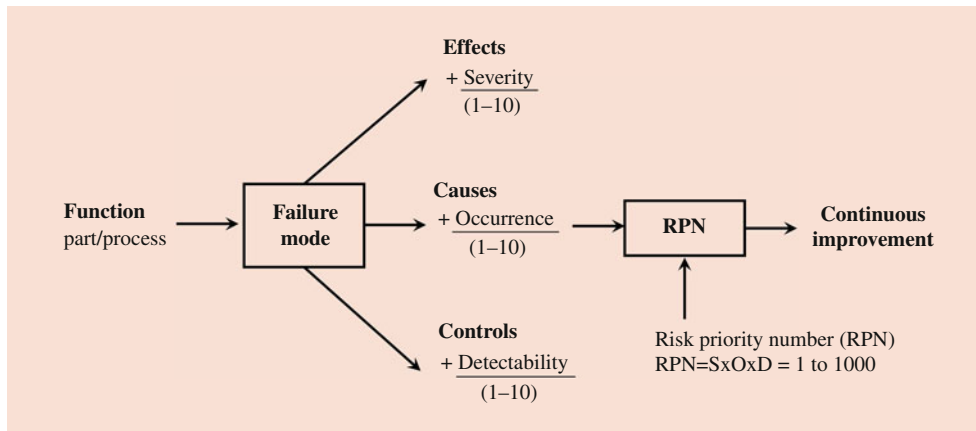

Fig. 13.2 Implementation flowchart of DFMEA

Fig. 13.3 An X-bar control chart

We can use SPC charts to determine if a new product/service's CTQ measure is in control. If it is, the product/service may move to the mass production phase.

How to do it (refer to [6]):

- Step 1.** Select the environment in which the data will be collected.
- Step 2.** Select the responses and parameters that will be monitored.
- Step 3.** Select the measurement systems used to acquire the data.
- Step 4.** Run the system in the prescribed environment and acquire the data.
- Step 5.** Plot the data using the appropriate type of SPC chart.
- Step 6.** Assess the plots for stability and predictability.
- Step 7.** Calculate the estimates of sigma level and process capability.

A typical X-bar control chart with sample size five for monitoring the mean of a process is given as an example

in Figs. 13.2 and 13.3, where the out-of-control points are highlighted as red squares.

13.4 Six Sigma Case Study

13.4.1 Introduction

In this section, a case study on printed circuit board (PCB) quality improvement by the authors is used to demonstrate the application of Six Sigma, which is digested from [2]. A more detailed report of this case may be found in [2]. This study was conducted in reference to the DMAIC approach, and the objective is to improve the sigma level for a series of product called PSSD in the screening process.

13.4.2 Process Background

This case study was conducted in an electronic company, which is located at an industrial park in southern China. The company manufactures multilayer PCB by using the surface

mount technology (SMT), which is a technique of placing surface mount devices (SMDs) on the surface of a PCB. SMDs are microminiature leaded or leadless electronic components that are soldered directly to the pads on the surface of the PCB. The major manufacturing processes in the company are solder screen, component placement, and solder reflow. As any defect in any of the solder joints can lead to the failure of the circuit, the screening process is regarded as the most critical process in the PCB manufacturing.

The screening process is a manufacturing process that transfers solder paste onto the solder pad of a PCB. The application method of solder paste is printing, and the printing technique used is off-contact printing in which there is a snap-off distance between a stencil and a PCB. The type of screening machine used to manufacture PSSD products is semiautomatic. During a printing process, two PCBs are placed side by side on the holder of a screening machine. The solder paste is then placed onto a stencil manually before printing. The front/back blade makes a line contact with the stencil and a close contact with the given amount of solder paste. The solder paste is then rolled in front of the front/back blade. In this way, solder paste is pressed against the stencil and transferred onto the solder pad through the stencil openings. More detailed operation of a screening process is described in [2].

13.4.3 Define Phase

In this case, we specifically focus on the improvement of the sigma level of the PCB screening process. In the screening process, the solder paste volume (height) transferred onto the PCB is the most important factor that needs to be controlled carefully. This is because too little solder paste can cause open circuits and too much solder paste can cause bridging between solder pads in the subsequent processes. As a result, the solder paste height on the solder pads is identified as a critical-to-quality (CTQ) characteristic (i.e., the y) that needs to be controlled in a very precise way by the company. According to that, a project team is formed and a project charter is constructed.

13.4.4 Measure Phase

To control the screening process, the project team in the company has asked operators to measure the solder paste height for the PSSD product on five different points on a PCB. The solder paste height on the five points is measured by using the Cyberoptics Cybersentry system every 4 hours. The gauge repeatability and reproducibility (R&R) of the measurement system was verified before the study on the solder paste height is conducted. The gauge R&R results

ensured that the data from the current measurement system are accurate enough for the following analysis.

13.4.5 Analyze Phase

Currently, six semiautomatic screening machines are used to manufacture the PSSD product. Therefore, the data on solder paste height of these six machines was collected from the company, and the process capability analysis was conducted for these screening machines in order to analyze the current printing performance. According to the analytical results, the process capability in machine no. 12 was not satisfactory because the capability index C_p was only 1.021, which was smaller than 1.33 (the four-sigma level). Moreover, another capability index C_{pk} was 0.387. This showed that the screening process was off-center. As shown in the capability plot in Fig. 13.4, we concluded that there exist both a high variance and a mean shift in the solder paste process. Therefore, we list all the potential factors (x 's) that may cause this through brainstorming and constructing a cause and effect diagram.

13.4.6 Improve Phase

In the analysis of the current printing performance, the result showed that the screening process capability of machine no. 12 was not satisfactory. After brainstorming with the mechanical engineers in the company, the designed experiments were decided to conduct on machine no. 12 in order to determine the optimal settings of all the input factors (x 's) in the screening process. In this phase, DOE was used as a core statistical tool for the sigma level improvement.

In the initial experiments, several possible factors that might have influence on the printing performance were taken into account. These experiments were used to screen out new factors that have influence on the printing performance. A full factorial experiment was carried out, and the considered

Fig. 13.4 Capability plot of machine no. 12

Table 13.2 Four factors and their levels in the initial experiments

Factor	Level 1	Level 2
Age of stencil	Old (25 months)	New (8 months)
Solder paste volume	Small	Large
Blade type	Front	Back
Side of stencil	Left	Right

**Fig. 13.5** Normal probability plot of the standardized effects**Table 13.3** The levels of each factor in the further experiments

Factor	Level 1	Level 2	Level 3
Solder paste viscosity	<150 mPa.s	>190 mPa.s	/
Speed of squeegee	0.4 inch/sec	0.7 inch/sec	1 inch/sec
Pressure of squeegee	18 bar	28 bar	/
Side of stencil	Left	Right	/
Blade type	Front	Back	/

four factors and their levels are given in Table 13.2. From the experimental results, the main effect of the solder paste volume and the side of stencil showed significant influence on the solder paste height. The interaction between the blade type and the side of stencil was also significant. These significant effects were supported by the normal probability plot of the standardized effects shown in Fig. 13.5.

These significant factors (blade type and side of stencil; solder paste volume was excluded since it was difficult to control the operator-to-operator variation in refilling the volume of the solder paste) would then be included together with the already-known significant factors (solder paste viscosity, speed of squeegee, and pressure of squeegee) in the further experiments. The aim of the further experiments was to determine the standard settings of all the significant factors (i.e., the vital few x 's). A full factorial experiment was carried out. The factors and their levels are given in Table 13.3.

To study the influence of these factors on the solder paste height and to draw conclusions, the main effect plots and the interaction plots were used. From the main effect plots shown in Fig. 13.6, the pressure of squeegee, blade type, and

side of stencil were significant factors for the height average. From the main effect plots shown in Fig. 13.7, the solder paste viscosity, speed of squeegee, blade type, and side of stencil were significant factors for the height variation. From the interaction plots for the height average shown in Fig. 13.8, the interaction between solder paste viscosity and blade type showed significant influence on the solder paste printing performance. The interaction between the speed of squeegee and blade type was also significant.

From the analytical results, the solder paste viscosity, speed of squeegee, blade type, and side of stencil were significant factors for the height variation. Therefore, low solder paste viscosity (<150 mPa.s), low speed of squeegee (0.4 inch/sec), front blade, and right side of stencil could result in small height variation. By using these optimal settings, the variation of the solder paste height can be reduced. After reducing the height variation, the sigma level of the screening process on machine no. 12 can be improved.

13.4.7 Control Phase

To sustain the improvement of the sigma level in the screening process, control plans for all the important x 's were proposed to the company. For example, both the CTQ y and the vital x 's should be monitored by SPC charts over time, so that the solder paste height variation and the sigma level can be controlled and sustained continuously. Also, the financial benefits through the reduction of COPQ were calculated.

The comparison of the printing performance before and after the project was reported in Table 13.4. After using the optimal settings, the sigma level of the screening process can be improved from 1.162 to 5.924. This shows that a nearly six-sigma performance can be achieved. According to [23], the level of defects per million opportunities (DPMO) would reduce to near 3.4 and the COPQ would be less than 1% of the sales. As a result, after the Six Sigma practice, the COPQ of the process for this company has been significantly reduced.

13.5 Six Sigma and Big Data

13.5.1 Background

The recent rapid advances in information technologies have reshaped today's business world into a digital regime. The widely deployed Internet-of-Things (IOT) infrastructure in both manufacturing and service industries generates massive amounts of data every moment, such as sensor data, images, videos, texts, etc. [24]. This coming Big Data era where data volume, variety, and velocity have all been increasing at an unprecedented scale is driving forward the next industrial revolution, also acknowledged as Industry 4.0. Many leading

Fig. 13.6 Main effect plots for height average

Fig. 13.7 Main effect plots for height variation

countries including the USA, Germany, China, and Japan have already launched their national strategies to catch this wave of data-enabled revolution.

It is believed that taking advantages of Big Data will become basic competition for today's enterprises. According to a report of McKinsey institute in 2011 [25], up to 50% decrease in product development and assembly costs will be achieved for global manufacturing sectors, and over 60% increase in net margin will be gained for retail markets. Big Data also provides an excellent opportunity for modern quality engineering and Six Sigma as data analytics has performed an essential role in their implementation. This created data-rich environment is pushing the traditional quality control and improvement practices toward an automatic,

intelligent, and integrated paradigm [26–32]. However, challenges also exist due to some intrinsic weaknesses of traditional quality control tools in Six Sigma:

- Most statistical analysis tools in Six Sigma, for example, inferential statistics and hypothesis testing, take sampling-based information which in fact only reflects partial status of underlying production or service processes.
- A universal quality data and information fusion center is not proposed and emphasized. Traditional existing databases in companies do not effectively integrate manufacturing information generated on the shop floor. Hence, it is usually very hard to share and track quality data.

Fig. 13.8 Interaction plots for height average

Table 13.4 Comparison of printing performance before and after using optimal settings

	Mean	S.D.	Cp	Cpk	Sigma level	ppm	COQ
Before	4.974	0.408	1.021	0.387	1.162	122,173	>40% of sales
After	5.750	0.211	1.975	1.975	5.924	3.4	<1% of sales

- Typical Six Sigma tools such as FMEA and cause-effect diagrams for failure root causes analysis rely greatly on intensive human participation and subjective judgment. The automation and intelligence level of these tools are relatively low for efficient Big Data analytics.

Six Sigma has achieved extraordinary levels of success in productivity improvement and cost saving in almost every industry since the early 1990s. To accommodate the current Big Data era, the toolkit of Six Sigma has to be expanded and updated accordingly. *Journal of Quality Technology (JQT)*, a flagship refereed journal of the American Society for Quality (ASQ), has recently published three special issues in 2018 which discuss the potential applications of Big Data analytics in reliability and maintenance, statistical process control (SPC), and advanced manufacturing. We refer interested readers to the papers therein. In the following section, the new specific opportunities brought about by Big Data to the core methodologies of Six Sigma are outlined in detail.

13.5.2 DMAIC: New Opportunities

Six Sigma is usually implemented in a sequential and disciplined manner through five incremental phases, i.e., DMAIC, each phase of which is now faced with tremendous opportunities offered by Big Data to significantly enhance its capabilities. Generally speaking, data become new treasures and resources in an enterprise that should be leveraged by every quality participant from top leaders to floor operators. It is expected the combination of Big Data thinking and methodologies with Six Sigma will become popular in the very near future.

Phase 1. Define (D)

To define current Six Sigma projects, the capability of the Big Data infrastructure in the company should be taken into account in the project charter. The problem may be defined from a new perspective by using Big Data thinking, the objectives may be quantified more clearly, and more benefits can be expected with the usage of Big Data technologies. Additionally, specialists for information technology (IT engineers) as well as for data modeling and analysis (Data scientists) should both be incorporated into a Six Sigma team and collaborate with other engineers within that team. It has been observed by authors that, in many advanced industries, such as semiconductors and smart phones, data collection and knowledge discovery through the cooperation of IT engineers and data scientists has become a routine and essential part in quality initiatives.

Phase 2. Measure (M)

This phase will take more advantage of the available massive data to clarify the status of the processes of interest. The measure data nowadays have more complex characteristics:

- Quality data are no longer only univariate variables; they can be time series or profiles, product images, 3D scanned surfaces, surveillance videos, and customer comments. Each data type needs specific tools to extract relevant quality information.
- Quality data arrive at an extremely high speed, also termed as data streams. The high data velocity requires real-time responses in data collection, processing, and analysis.
- Data visualization, especially when data are of high dimension and huge size, becomes useful for practitioners to understand the inherent data patterns.

The effective handling of the above heterogeneous and massive data streams will generate a global and complete picture of the manufacturing and service processes, which also acts as a solid preparation for the Analyze phase in the following.

Phase 3. Analyze (A)

The Analyze phase will be enhanced to a large extent with the rapid development of machine learning tools. The data analytics has been evolving from the Descriptive level to Diagnostic and Predictive levels. Specifically, two main classes of machine learning tools can be adopted for Big Data analytics [33].

- Unsupervised learning. It discovers an internal representation or features based only on the input data or process variables (x 's). The common method is the clustering. The engineers can grasp the behavior and variation of the process variables to stabilize the processes.
- Supervised learning. It develops a relationship between process variables or input data (x 's) and product quality or output data (y). Upon this predictive model, product quality can be forecast beforehand and accidents can be early signaled. It includes a variety of powerful methods for either classification or regression purpose, such as support vector machines, neural networks, and ensemble methods.

The wide applications of the above machine learning tools, along with the emerging artificial intelligence (AI) methodologies, will definitely promote intelligence prosperity in Six Sigma.

Phase 4. Improve (I)

Quality improvement solutions in the Big Data era can be conducted in a real time basis. As the data are acquired and analyzed without time delay, the optimization solutions for the current process status can also be immediately given by using modern powerful parallel and cloud-computing technologies. The well-developed optimization theory, for example, the convex optimization and combinatorial optimization, can be introduced into this phase to seek for optimal improvement directions. Process variables are thus adjusted in a dynamic manner to maintain high quality level for every process. In a word, the traditional static improvement solution based on historical off-line data will be replaced by an adaptive alternative which flexibly responds to real-time online data.

Phase 5. Control (C)

To ensure the process improvement is sustainable, the Control phase monitors the new improved process to check if it is always in control. Big Data leads to high-dimension, large-scale, and real-time data streams that need to be effectively monitored. The SPC surveillance tools now have developed many computationally efficient versions for these challenges [34]. On the other hand, instead of waiting for abundant reference data before launching a monitoring scheme for a particular process, the collected data from similar processes can be borrowed to start the monitoring task as soon as possible by using current transfer learning techniques [35]. Once an out-of-control signal is issued, the fault diagnosis methods which combine the hypothesis testing, Bayesian network, and variable selection methods with Big Data can quickly track the process variables that have been changed to enable the root causes discovery and correction.

As a final note in this section, we summarize the maturity levels of Big Data analytics when it is applied to quality projects in Six Sigma. By referring to these levels, quality practitioners can have a better understanding of where they are at present and where they should head for in the future.

- Level 1. We only use experience, not data.
- Level 2. We collect data but just look at the numbers.
- Level 3. We group the data so as to form charts and graphs.
- Level 4. We use census data with descriptive statistics.
- Level 5. We use sample data with descriptive statistics.
- Level 6. We use sample data with inferential statistics.
- Level 7. We use real-time heterogeneous sensor data with descriptive statistics/visualization.
- Level 8. We use real-time heterogeneous sensor data with inferential/predictive statistics to support decision-making.

13.6 Conclusion

As Six Sigma is evolving over time, the advantages and benefits of other business excellence approaches can still be learned and utilized in future Six Sigma programs. According to [36], combining other tools or methodologies and the Six Sigma methodology may be a future trend. For example, combining Lean tools to the Six Sigma methodology has become popular during the last few years. And there are expected to be more combinations in the future.

These years, the Six Sigma efforts have been pushed to both the external suppliers and external customers along a supply chain, which have resulted in even larger overall business impacts and cost savings. We have also observed an increasing trend outside the USA, where more and more companies in Asia and Europe, including small-to-medium-sized enterprises, have been in various stages of Six Sigma deployment and discovered its far-reaching benefits. On the other hand, the coming Big Data era has shifted current quality projects in Six Sigma toward data-driven practices, and more new advanced tools in statistical learning, machine learning, and AI are needed to integrate Six Sigma and Big Data.

Abstract

One important application of statistical models in the industry is *statistical process control*. Many control charts have been developed and used in the industry. They are easy to use but have been developed based on statistical principles. However, for today's high-quality processes, traditional control-charting techniques are not applicable in many situations. Research has been going on in the last few decades, and new methods have been proposed. This chapter summarizes some of these techniques.

High-quality processes are generally defined as those with very low defective rate or defect-occurrence rate, which is achieved in six sigma environment and in the advanced manufacturing environment. *Control charts* based on the cumulative count of conforming items are recommended for such processes. The use of such charts has opened up new frontiers in the research and applications of statistical control charts in general. In this chapter, several extended or modified statistical models are described. They are useful when the simple and basic geometric distribution is not appropriate or is insufficient.

In particular, we present some extended Poisson distribution models that can be used for count data with large numbers of zero counts. We also extend the chart to the case of general *time-between-events monitoring*; such an extension can be useful in service or reliability monitoring. Traditionally, the exponential distribution is used for the modeling of time-between-events, although other distributions such as the Weibull or gamma distribution can also be used in this context.

14.1 Introduction

Control charting is one of the most widely used statistical techniques in the industry for process control and monitoring. It dates back to the 1920s when Walter Shewhart introduced the basic charting techniques in the United States [1]. Since then, it has been widely adopted worldwide, mainly in manufacturing and also in the service industries. The simplicity of the application procedure allows a non-specialist user to observe the data and plot the control chart for simple decision making. At the same time, it provides sophisticated statistical interpretation in terms of false-alarm probability and average run length, among other important statistical properties associated with decision-making based on sample information. The implementation of control charts had helped many companies to focus on important quality issues and problems such as those raised by out-of-control points on a control chart.

However, for high-quality or near-zero-defect processes, traditional *Shewhart charts* may not be suitable for process monitoring and decision-making. This is especially the case for Shewhart attribute charts [2]. Many problems, such as high false-alarm probability, inability to detect process improvement, unnecessary plotting of many zeros, etc., have been identified by various researchers [3–6]. To resolve these problems, new models and monitoring techniques have been developed recently.

Traditional charts are all based on the principle of the normal distribution, and the upper control limit (UCL) and lower control limit (LCL) are routinely computed as the mean plus and minus three times the standard deviation. That is, if the plotted quantity Y has mean μ and standard deviation σ , the control limits are given by

$$\text{UCL} = \mu + 3\sigma \quad \text{and} \quad \text{LCL} = \mu - 3\sigma. \quad (14.1)$$

Generally, when the distribution of Y is skewed, the probability of false alarm (FAR), i.e., the probability that a point indicating out-of-control when the process has actually not changed, is different from the nominal value of 0.0027 associated with a truly normal distribution. Note that for attribute charts, the plotted quantities usually follow a binomial or Poisson distribution, and this is far from the normal distribution unless the sample size is very large.

The purpose of this chapter is to review the important models and techniques that can be used to monitor high-quality processes. The procedure based on a general principle of the *cumulative count of conforming* items is first described; this is then extended to other distributions. The emphasis is on recent developments and also on practical methods that can be used by practitioners.

This chapter is organized as follows. First, the use of *probability limits* is described. Next, control charts based on monitoring of the cumulative count of conforming items

and simple extensions are discussed. Control charts based on the zero-inflated Poisson distribution and generalized Poisson distribution are then presented. These charts are widely discussed in the literature, and they are suitable for count or *attribute data*. For process monitoring, time-between-events monitoring is of growing importance, and we also provide a summary of methods that can be used to monitor process change based on time-between-events data. Typical models are the exponential, Weibull and gamma distribution.

14.2 Use of Exact Probability Limits

For high-quality processes, it is important to use *probability limits* instead of traditional *three-sigma limits*. This is true when the quality characteristic that is being plotted follows a skewed distribution. For any plotted quality characteristic Y , the probability limits LCL_Y and UCL_Y can be derived as

$$P(X < \text{LCL}_Y) = P(X > \text{UCL}_Y) = \alpha/2, \quad (14.2)$$

where α is the false-alarm probability, i.e., when the process is in-control (IC), the probability that the control chart raises the alarm. Assuming that the distribution $F(x)$ is known or has been estimated accurately from the data, the control limits can be computed.

Probability limits are very important for attribute charts as the quality characteristics are usually not normally distributed. If this is the case, the false-alarm probability could be much higher than the nominal value ($\alpha = 0.0027$ for traditional three-sigma limits). *Xie and Goh* [7] studied the exact probability limits calculated from the binomial distribution and the Poisson distribution applied for the *np chart* and the *c chart*.

For control-chart monitoring, the number of nonconforming items in samples of size n , assuming that the process fraction nonconforming is p , the probability that there are exactly k nonconforming items in the sample is

$$P(X = k) = \binom{n}{k} p^k (1-p)^{n-k}, \quad k = 0, 1, \dots, n \quad (14.3)$$

and the probability limits can be computed as

$$P(X \leq \text{LCL}) = \sum_{i=0}^{\text{LCL}} \binom{n}{i} p^i (1-p)^{n-i} = \frac{\alpha}{2} \quad (14.4)$$

and

$$P(X \leq \text{UCL}) = \sum_{i=0}^{\text{UCL}} \binom{n}{i} p^i (1-p)^{n-i} = 1 - \frac{\alpha}{2}. \quad (14.5)$$

As discussed, probability limits can be computed for any distribution and should be used when the distribution is

skewed. This will form the basis of the following discussion in this chapter. In some cases, although the solution is analytically intractable, they can be obtained with computer programs. It is advisable that probability limits be used unless the normality test indicates that deviation from a normal distribution is not significant.

14.3 Control Charts Based on Cumulative Count of Conforming Items

High-quality processes are usually characterized by low defective rates. In a near-zero-defect manufacturing environment, items are commonly produced and inspected one-by-one, sometimes automatically. We can record and use the cumulative count of conforming items produced before a nonconforming item is detected. This technique has been intensively studied in recent years.

14.3.1 CCC Type Control Charts

The idea of tracking the *cumulative count of conforming (CCC)* items to detect the onset of assignable causes in an automated (high-quality) manufacturing environment was first introduced by Calvin [13]. Goh [4] further developed this idea into what is known as the CCC charting technique. Some related discussions and further studies can be found in [8–14], among others. Xie et al. [15] provided extensive coverage of this charting technique and further analysis of this procedure.

CCC Chart Based on Geometric Distribution

For a process with a defective rate of p , the cumulative count of conforming items before the appearance of a nonconforming item say Y , follows a *geometric distribution*. This is given by

$$P(Y = n) = (1 - p)^{n-1}p, \quad n = 1, 2, \dots \quad (14.6)$$

The cumulative probability function of count Y is given by

$$P(Y \leq n) = \sum_{i=1}^n (1 - p)^{i-1}p = 1 - (1 - p)^n. \quad (14.7)$$

Assuming that the acceptable false-alarm probability is α , the probability limits for the CCC chart are obtained as

$$UCL = \ln(\alpha/2) / \ln(1 - p) \quad (14.8)$$

and

$$LCL = \ln(1 - \alpha/2) / \ln(1 - p) \quad (14.9)$$

Usually, the center line (CL) is computed as

$$CL = \ln(1/2) / \ln(1 - p). \quad (14.10)$$

Note that the decision rule is different from that of the traditional p or np chart. If a point is plotted above the UCL, the process is considered to have improved. When a point falls below the LCL, the process is judged to have deteriorated. An important advantage is that the CCC chart can detect not only the increase in the defective rate (process deterioration) but also the decrease in the defective rate (process improvement). Further, the relation between the CCC chart based on the geometric and binomial distribution was presented by Riaz et al. [16]. They showed that the survival function of the geometric distribution equals the probability of the binomial distribution. Hence, this relation leads to a new way for the monitoring of CCC charts.

The CUSUM Chart for the Cumulative Count of Conforming (CUSUM-CCC)

Chang and Gan [17] proposed a *Cumulative Sum (CUSUM) control chart*, which is capable of detecting the small number of shifts in the defective rate of the process. The upper and lower CUSUM statistics are defined as:

$$\begin{aligned} C_t^+ &= \max(0, k^+ - Y_t + C_{t-1}^+), \\ C_t^- &= \min(0, k^- - Y_t + C_{t-1}^-), \end{aligned} \quad (14.11)$$

where t indexes the order of observations and k^+ and k^- are the reference values which are based on the *sequential probability ratio test (SPRT)* approach as:

$$k = \frac{\ln[p_1(1 - p_0)/p_0(1 - p_1)]}{\ln[(1 - p_0)/(1 - p_1)]}. \quad (14.12)$$

where the p_0 is the IC defective rate while p_1 is the OOC defective rate. The decision limits h^+ and h^- for the respective charting statistics are obtained for the fixed value of α which is the inverse of the in-control average number of items sampled ($ANIS_0$). The process is declared as detroit when $C_t^+ < h^+$ and the process is declared as improved when $C_t^- < h^-$.

The EWMA Chart for the Cumulative Count of Conforming (EWMA-CCC)

The *Exponentially Weighted Moving Average (EWMA) control chart* is an alternative memory type chart, which is also effective than the Shewhart chart in detecting small changes in the population parameters. The EWMA control chart for the CCC items was proposed by Yeh et al., [18], and its statistic can be defined as:

$$E_t = wY_t + (1 - w)E_{t-1} \quad (14.13)$$

where, t indexes the order of observations and w is the weighted parameter of statistics which lies between zero and one (i.e., $0 < w \leq 1$). By using the properties of geometric series, the mean and variance of the EWMA statistics are defined as:

$$E(E_t) = \frac{1}{p_0}, \tag{14.14}$$

$$\text{Var}(E_t) = \frac{1}{p_0} \frac{w [1 - (1 - w)^{2t}]}{(2 - w)}. \tag{14.15}$$

Note that an increase in the defective rate may lead to a decrease in Y_t so, for the process deterioration, lower control limit (LCL_{E_t}) is defined as follows:

$$LCL_{E_t} = \frac{1}{p_0} - L_{E_t} \times \frac{1}{p_0} \sqrt{\frac{w [1 - (1 - w)^{2t}]}{(2 - w)}}, \tag{14.16}$$

where L_{E_t} is the control charting constant that depends on the choice of w and desired α . A Process is declared as detroit when $E_t < LCL_{E_t}$. Further, an optimal choice of this chart is discussed in [19].

A Simulated Example

For the application purpose, we have simulated 30 in-control (IC) data points with $p_0 = 0.0005$ and the last 20 out-of-control (OOC) data points with $p_1 = 0.00075$. The value of α is set to be 0.0000833 for the calculation of control limits (Table 14.1).

In Fig. 14.1, control charts for the CCC items are plotted, where Fig. 14.1a is about the typical CCC chart. For the conventional CCC chart, LCL is set at 0.08331423 and UCL is set at 20166.57. The amount of shift is too small that’s why CCC chart does not indicate any abnormality. Further, the CUSUM-CCC chart is plotted in Fig. 14.1b where $k^+ = 1622$ and $h^+ = 1607$ are set against the fixed p_0, p_1 , and α (See, Chang and Gan [17]). The findings of the CUSUM-CCC chart showed few FAR and detected all the OOC signals.

The EWMA-CCC chart is plotted in Fig. 14.1c where $w = 0.10$ and $L_{E_t} = 0.315$ are set against the fixed p_0 and α (See, Yeh et al. [18]). The results showed that EWMA-CCC suffered from few FAR as compared to CUSUM-CCC and all the OOC signals are detected.

Table 14.1 A set of cumulative count of conforming items data

14.3.2 CCC-r Chart Based on Negative Binomial Distribution

A simple idea to generalize a CCC chart is to consider plotting of the cumulative count of items inspected until observing two nonconforming items. This was studied in [20] resulting in the CCC-2 control chart. This chart increases the sensitivity of the original CCC chart for the detection of small process shifts in p . The CCC-2 chart has smaller type II error, which is related to chart sensitivity, and steeper OC (Operating Characteristic) curves than the CCC chart with the same type I error, which is the false alarm probability. Further, Bersimis et al. [21] provided a compound methodology based on the CCC-1 and CCC-2 charts, which has better performance ability as compared to individual CCC-1 and CCC-2 charts.

A CCC-r chart [22, 23] plots the cumulative count of items inspected until r nonconforming items are observed. This will further improve the sensitivity and detect small changes faster. However, it requires more counts to be cumulated in order to generate an alarm signal. The CCC-r charting technique was also studied by Xie et al. [22].

Let Y be the cumulative count of items inspected until r nonconforming items have been observed. Suppose p the probability of an item to be nonconforming. Then Y follows a negative binomial distribution and its probability mass function is given by

$$P(Y = n) = \binom{n-1}{r-1} p^r (1-p)^{n-r}, \tag{14.17}$$

$n = r, r + 1, \dots$

The cumulative distribution function of count Y would be

$$F(n, r, p) = \sum_{i=r}^n P(Y = i) = \sum_{i=r}^n \binom{i-1}{r-1} p^r (1-p)^{i-r}. \tag{14.18}$$

If the acceptable false-alarm probability is α , then the upper control limit and the lower control limit, UCL_r and LCL_r , respectively, of the CCC-r chart can be obtained as the solution of the following equations:

$$F(UCL_r, r, p) = \sum_{i=r}^{UCL_r} \binom{i-1}{r-1} p^r (1-p)^{i-r} = 1 - \alpha/2 \tag{14.19}$$

and

$$F(LCL_r, r, p) = \sum_{i=r}^{LCL_r} \binom{i-1}{r-1} p^r (1-p)^{i-r} = \alpha/2. \tag{14.20}$$

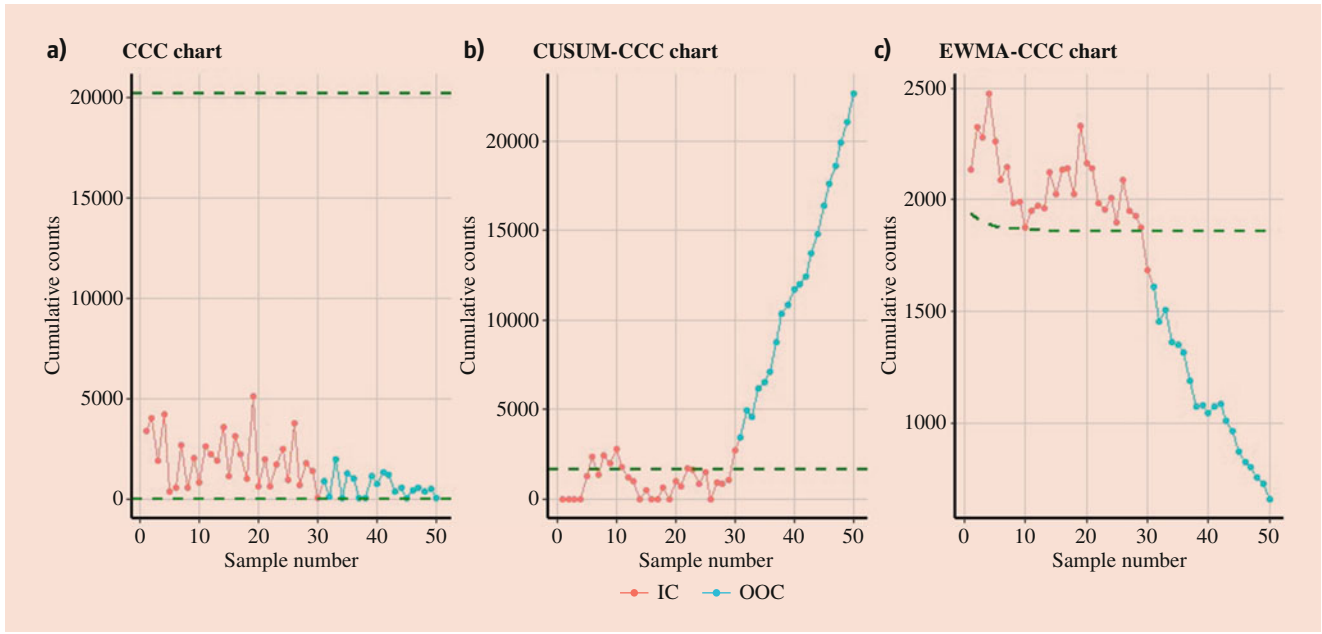

Fig. 14.1 Control charts based on CCC items

Note that this chart is suitable for the *one-by-one inspection process*, and so no subjective sample size is needed. On the other hand, the selection of r is a subjective issue if the cost involved is not a consideration. As the value of r increases, the sensitivity of the chart may increase, but the user probably needs to wait too long to plot a point. For this issue, *Albers [24]* designed a study to demonstrate the optimal value of r , which is related to the increase of p . *Ohta et al. [23]* addressed this issue from an economic design perspective and proposed a simplified design method to select a suitable value of r based on the *economic design method* for control charts that monitor discrete quality characteristics.

A $CCC-r$ chart provides better detection ability when a large amount of drifts are present in the process while to obtain the better detection ability on small to moderate amount of shifts, *Kotani et al. [25]* proposed $EWMA_{CCC-r}$ chart. The statistic of $EWMA_{CCC-r}$ chart can be defined as:

$$E_t = wY_t + (1 - w)E_{t-1} \quad (14.21)$$

where, Y_t is the cumulative count of items inspected until r nonconforming ones, t indexes the order of observations and w is the weighted parameters of statistics, which lies between zero and one (i.e., $0 < w \leq 1$). The mean and variance of the $EWMA_{CCC-r}$ statistics are defined as:

$$E(E_t) = \frac{r}{p}, \quad (14.22)$$

$$\text{Var}(E_t) = \frac{r(1-p)}{p^2} \frac{w[1 - (1-w)^{2t}]}{(2-w)}. \quad (14.23)$$

The decision lines of the $EWMA_{CCC-r}$ are defined as:

$$\begin{aligned} LCL_{E_t} &= \frac{r}{p} - L_{E_t} \times \frac{\sqrt{r(1-p)}}{p} \sqrt{\frac{w[1 - (1-w)^{2t}]}{(2-w)}}, \\ UCL_{E_t} &= \frac{r}{p} + L_{E_t} \times \frac{\sqrt{r(1-p)}}{p} \sqrt{\frac{w[1 - (1-w)^{2t}]}{(2-w)}}. \end{aligned} \quad (14.24)$$

where L_{E_t} is the control charting constant that depends on the choice of w and desired α . When E_t lies between LCL_{E_t} and UCL_{E_t} , the process is declared as stable process otherwise, process is said to be unstable. Further, the $EWMA_{CCC-r}$ is improved by *Kusukawa et al. [26]*.

14.4 Generalization of the c-Chart

The c-chart is based on monitoring of the number of defects in a sample. Traditionally, the number of defects in a sample follows the Poisson distribution. The control limits are computed as

$$UCL = c + 3\sqrt{c} \quad \text{and} \quad LCL = c - 3\sqrt{c}, \quad (14.25)$$

where c is the average number of defects in the sample, and the LCL is set to be zero when the value computed with (14.25) is negative.

However, for high-quality processes, it has been shown that these limits may not be appropriate. Some extensions of this chart are described in this section.

$$E(Y) = p\lambda \tag{14.28}$$

and

$$\text{Var}(Y) = p\lambda + p\lambda(\mu - p\lambda). \tag{14.29}$$

14.4.1 Charts Based on the Zero-Inflated Poisson Distribution

In a near-zero-defect manufacturing environment, many samples will have no defects. However, for those containing defects, we have observed that there could be many defects in a sample, and hence, the data has an over-dispersion pattern relative to the Poisson distribution. To overcome this problem, a generalization of Poisson distribution was used in [6, 27].

This distribution is commonly called the *zero-inflated Poisson (ZIP) distribution*. Let Y be the number of defects in a sample; the probability mass function is given by

$$\begin{cases} P(Y = 0) = (1 - p) + pe^{-\lambda} \\ P(Y = d) = p \frac{\lambda^d e^{-\lambda}}{d!} \quad d = 1, 2, \dots \end{cases} \tag{14.26}$$

This has an interesting interpretation. The process is basically *zero-defect*, although it is affected by causes that lead to one or more defects. If the occurrence of these causes is p , and the severity is λ , then the number of defects in the sample will follow a zero-inflated Poisson distribution.

The Shewhart Chart for ZIP Process

When the zero-inflated Poisson distribution provides an excellent fit to the data, two types of control charts can be applied. One is the exact probability limits control chart, and the other is the CCC chart. When implementing the exact probability limits chart, Xie and Goh [6] suggested that only the upper control limit n_u should be considered, since the process is in a near-zero-defect manufacturing environment and the probability of zero is usually very large. The upper control limit can be determined by:

$$\sum_{d=n_u}^{\infty} p \frac{\lambda^d e^{-\lambda}}{d!} \leq \alpha, \tag{14.27}$$

where α is the probability of the type I error. It should be noticed that n_u could easily be solved because it takes only discrete values.

Control charts based on the zero-inflated Poisson distribution commonly have better performance in the *near-zero-defect manufacturing* environment. However, the control procedure is more complicated than the traditional methods since more effort is required to test the suitability of this model with more parameters.

For the zero-inflation Poisson distribution, we have that [28]

It should be pointed out that the *zero-inflation Poisson model* is straightforward to use, as the mean and variance are of the closed-form. For example, the moment estimates can be obtained straightforward. On the other hand, the maximum-likelihood estimates can also be derived.

The maximum-likelihood estimates can be obtained by solving

$$\begin{cases} p = \frac{1 - n_0/n}{1 - \exp(-\lambda)} \\ \lambda = \bar{y}/p \end{cases} \tag{14.30}$$

where $\bar{y} = \sum_{i=1}^n y_i/n$ [28].

When the count data can be fitted by a zero-inflation Poisson model, statistical process control procedures can be modified. Usually, the lower control limit for zero-inflation Poisson model will not exist, because the probability of zero is larger than the predetermined type I error level. This is common for the *attribute control chart*. In the following section, the upper control limit will be studied.

The upper control limit n_u for a control chart based on the number of nonconformities can be obtained as the smallest integer solution of the following equation:

$$P(n_u \text{ or more nonconformities in a sample}) \leq \alpha_L, \tag{14.31}$$

where α_L is the predetermined false-alarm probability for the upper control limit n_u .

Here our focus is on data modeling with appropriate distribution. It can be noted that the model contains two parameters. To be able to monitor the change in each parameter, a single chart may not be appropriate. Xie and Goh [6] developed a procedure for the monitoring of individual parameter. First, a CCC chart is used for data with zero count. Second, a *c*-chart is used for those with one or more non-zero count. Note that a useful model should have practical interpretations. In this case, p is the occurrence probability of the problem in the process, and λ measures the severity of the problem when it occurs. Hence it is a useful model and important to be able to monitor each of these parameters so that any change from normal behavior can be identified.

Chang and Gan [9] extended the above-mentioned method by considering the *g* chart instead of the *c* chart and obtained better performance in terms of an *average number of samples (ANS)*. Furthermore, the effect of estimation errors in the ZIP control chart was discussed by [27]. Where

p considered as known in the whole study and the estimation effects of λ were discussed. It was recommended that at any given λ value, around 50–100 observations are enough to meet pre-determined FAR.

The MLE estimates of the ZIP distribution consists of the average \bar{y} which leads to misleading results when outliers exist in the dataset. Therefore, robust estimates of the ZIP distribution are necessary under extreme outliers. Hence, Yang et al. [29] and Li et al. [30] proposed control charts based on the robust estimators such as trimmed mean, winsorized mean and middle mean. Furthermore, Rakitzis and Castagliola [31] discussed the estimation effects of ZIP Shewhart control chart under Phase I study. They mentioned that there is no particular trend of historical samples regarding the estimation of appropriate ZIP parameters, but in most of the examined cases, it is necessary that the historical samples exceed 10^5 .

The CUSUM Chart for ZIP Process

The structure of a CUSUM chart consists of the previous and the current sample. Therefore, it is more sensitive to small and moderate parameter shifts. He et al. [32] proposed CUSUM structures for the ZIP distribution to tackle the simultaneous shifts in p and λ . Let p_0 and λ_0 are the IC parameters of the ZIP distribution than the p -CUSUM chart was designed to detect a shift from p_0 to p_1 . The p - CUSUM statistic is designed on the base of the likelihood ratio method, which is defined as follows:

$$B_i = \max(0, B_{i-1} + K_i); i = 1, 2, \dots, \tag{14.32}$$

where the initial value of the p - CUSUM statistic is set at zero and the K_i for the specific shift size is obtained as,

$$K_i = \begin{cases} \ln \frac{1-p_1+p_1e^{-\lambda_0}}{1-p_0+p_0e^{-\lambda_0}} & Y_i = 0 \\ \ln \frac{p_1}{p_0} & Y_i > 0 \end{cases} \tag{14.33}$$

The p - CUSUM chart resulted in a signal when B_i exceeds from the h_p . Where the h_p is selected to achieve the desired IC performance.

Further, the λ - CUSUM chart is designed to detect a shift from λ_0 to λ_1 and the statistic based on the likelihood ratio method is defined as follows:

$$L_i = \max(0, L_{i-1} + M_i); i = 1, 2, \dots \tag{14.34}$$

Where the initial value of the λ - CUSUM statistic is set at zero and the M_i for the specific shift size is obtained as,

$$M_i = \begin{cases} \ln \frac{1-p_1+p_1e^{-\lambda_1}}{1-p_0+p_0e^{-\lambda_0}} & Y_i = 0 \\ Y_i \ln \frac{\lambda_1}{\lambda_0} + (\lambda_0 - \lambda_1) & Y_i > 0 \end{cases} \tag{14.35}$$

The λ - CUSUM chart signals when L_i exceeds from the h_λ . Where the h_λ is also selected to achieve the desired IC performance. The p - λ CUSUM chart is further obtained by the combination of p - CUSUM and λ - CUSUM charts.

For the simultaneous monitoring of the ZIP parameters p and λ . They also proposed another chart known by the t - CUSUM chart. The t - CUSUM chart is designed to detect shifts from p_0 to p_1 and λ_0 to λ_1 . The statistic for t - CUSUM chart is also based on the likelihood ratio method, which is defined as follows:

$$T_i = \max(0, T_{i-1} + N_i); i = 1, 2, \dots \tag{14.36}$$

where the initial value of the t - CUSUM statistic is set at zero and the N_i for the specific shift size is obtained as,

$$N_i = \begin{cases} \ln \frac{1-p_1+p_1e^{-\lambda_1}}{1-p_0+p_0e^{-\lambda_0}} & Y_i = 0 \\ Y_i \ln \frac{\lambda_1}{\lambda_0} + (\lambda_0 - \lambda_1) + \ln \frac{p_1}{p_0} & Y_i > 0 \end{cases} \tag{14.37}$$

The t - CUSUM chart signals when T_i exceeds from the h_t . Where the h_t is also selected to achieve the desired IC performance. Their findings revealed that the t - CUSUM structure outperforms all other charts in all increasing shifts except the increase in parameter p while the p - λ CUSUM structure is effective to detect inverse shifts in both parameters (i.e., one increase while another decrease). Although the t - CUSUM structure is useful to discuss the simultaneous shifts but using this structure, it is very difficult to diagnose and interpret OOC signals.

Furthermore, He et al. [33] proposed a combined CUSUM structure to monitor a ZIP process. In this combined method, a CUSUM chart was designed for the zero part of the process based on Bernoulli distribution while other CUSUM chart was developed for the non-zero portion of the process by using zero-truncated Poisson distribution. The comparison of the combined method is made with simultaneous charts proposed by [32], and findings depicted that the proposed method outperformed all other methods under discussion.

The EWMA Chart for ZIP Process

Fatahi et al. [34] proposed an EWMA structure for the monitoring of ZIP parameters. The proposed structure was designed on the moment method estimates which are defined as,

$$\hat{\lambda} = \frac{\sum_{t=1}^m (Y_t^2 - Y_t)}{\sum_{t=1}^m Y_t}, \tag{14.38}$$

and

$$\hat{p} = \frac{(\sum_{t=1}^m Y_t^2)^2}{m \sum_{t=1}^m (Y_t^2 - Y_t)}. \tag{14.39}$$

Where m denotes the number of subgroups in the Phase I samples. The statistic of ZIP-EWMA chart can be defined as:

$$E_t = wY_t + (1 - w) E_{t-1} \tag{14.40}$$

where, t indexes the order of observations and w is the weighted parameter of statistics which lies between zero and one (i.e., $0 < w \leq 1$). The mean and variance of the ZIP-EWMA statistics are defined as:

$$E(E_t) = \hat{\lambda}\hat{p}, \tag{14.41}$$

$$\text{Var}(E_t) = \left[\hat{\lambda}\hat{p} + \hat{\lambda}\hat{p} (\hat{\lambda} - \hat{\lambda}\hat{p}) \right] \frac{w [1 - (1 - w)^{2t}]}{(2 - w)}. \tag{14.42}$$

The decision lines of the ZIP-EWMA chart are defined as:

$$\text{LCL}_{E_t} = \hat{\lambda}\hat{p} - L_{E_t} \times \left[\hat{\lambda}\hat{p} + \hat{\lambda}\hat{p} (\hat{\lambda} - \hat{\lambda}\hat{p}) \right] \sqrt{\frac{w [1 - (1 - w)^{2t}]}{(2 - w)}},$$

$$\text{UCL}_{E_t} = \hat{\lambda}\hat{p} + L_{E_t} \times \left[\hat{\lambda}\hat{p} + \hat{\lambda}\hat{p} (\hat{\lambda} - \hat{\lambda}\hat{p}) \right] \sqrt{\frac{w [1 - (1 - w)^{2t}]}{(2 - w)}}. \tag{14.43}$$

where L_{E_t} is used to decide the width of control limits and depends on the choice of w and desired α . When E_t lies between LCL_{E_t} and UCL_{E_t} , the process is declared as stable process, otherwise the process is said to be unstable. Further, this method is extended by [35] into a combined structure and a simultaneous structure of EWMA chart (alternative method of simultaneous CUSUM chart proposed by [33]) for the monitoring of ZIP parameters.

An Example

An example is used here for illustration [2]. The data set used in Table 14.2 is the read-write errors discovered in a computer hard disk in the manufacturing process.

For the data set in Table 14.2, it can be seen that it contains many samples with no nonconformities. From the data set, the maximum-likelihood estimates are $\hat{p} = 0.1346$ and $\hat{\mu} = 8.6413$. The overall zero-inflation Poisson model for the data set is

$$f(y) = \begin{cases} 1 - 0.1346 + 0.1346 \exp(-8.6413), & \text{if } y = 0, \\ 0.1346 \frac{8.6413^y \exp(-8.6413)}{y!}, & \text{if } y > 0. \end{cases} \tag{14.44}$$

Table 14.2 A set of defect count data

0	0	0	0	0	0	0	0	0	0	0	0	0	0	1	0	0	0	0	6	0	9
11	0	1	2	0	0	0	0	0	0	0	0	0	0	3	3	0	0	5	0	15	6
0	0	0	4	2	0	0	0	1	1	0	1	0	0	0	0	0	0	0	0	0	0
0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0
75	0	0	0	0	75	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0
0	0	0	2	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	1	0	0
0	0	0	0	1	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0
0	1	0	0	1	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	9	0
0	2	0	0	0	0	0	0	0	0	0	0	0	0	1	0	0	0	0	0	0	0
0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	2	0
0	0	1	0	0	0	0	0														

For the data set in Table 14.2, it can be calculated that the upper control limit is 14 at an acceptable false-alarm rate of 0.01. This means that there should not be an alarm for values less than or equal to 14 when the underlying distribution model is a zero-inflated Poisson distribution.

Note that for the CUSUM structures of ZIP distribution, real-life example about LED packaging process is discussed in He et al. [32, 33] while the ZIP-EWMA chart with health-related illustration is presented in Fatahi et al. [34].

14.4.2 Chart Based on the Generalized Poisson Distribution

The generalized Poisson distribution is another useful model that extends the traditional Poisson distribution, which only has one parameter. A two-parameter model is usually much more flexible and able to model different types of data sets. Since in the situation of over-dispersion or under-dispersion, the Poisson distribution is no longer preferable as it must have equal mean and variance, the generalized Poisson distribution [36] can be used.

This distribution has two parameters (θ, λ) and the probability mass function is defined as

$$P_X(\theta, \lambda) = \frac{\theta(\theta + x\lambda)^{x-1} e^{-\theta-x\lambda}}{x!}, \quad x = 0, 1, 2, \dots, \tag{14.45}$$

where $\lambda, \theta > 0$.

For the generalized Poisson distribution, we have that [36]

$$E(X) = \theta(1 - \lambda)^{-1} \tag{14.46}$$

and

$$\text{Var}(X) = \theta(1 - \lambda)^{-3}. \tag{14.47}$$

It should be pointed out that the generalized Poisson distribution model is straightforward to use as both the mean and variance are of closed-form. For example, the moment estimates can easily be calculated. On the other hand, the maximum-likelihood estimates can also be obtained straightforwardly. Consider a set of observation (X_1, X_2, \dots, X_n) with sample size n , the maximum-likelihood estimation $(\hat{\theta}, \hat{\lambda})$ can be obtained by solving

$$\begin{cases} \sum_{i=1}^n \frac{x_i(x_i - 1)}{\bar{x} + (x_i - \bar{x})\hat{\lambda}} - n\bar{x} = 0, \\ \hat{\theta} = \bar{x}(1 - \hat{\lambda}). \end{cases} \quad (14.48)$$

Here a similar approach as for the zero-inflated Poisson model can be used. One could also develop two charts for practical monitoring. One chart can be used to monitor the severity and another to monitor the dispersion or variability in terms of the occurrence of defects.

Furthermore, Chen et al. [37] proposed three control charts named by the *Shewhart GZIP chart*, ranked probability chart (RPC), and GZIP-CUSUM chart. The findings of the study revealed that the shape of the distribution is severely affected by λ and behave almost similar to a change in parameter θ . When relative difference among λ 's was small, then similar performance was observed for the both Shewhart GZIP and RPC charts, while in the presence of large differences, the RPC performed well as compared to all other charts. The GZIP-CUSUM chart performed well when the shifts are introduced in θ , while for the shifts in λ , the *GZIP-CUSUM chart* has satisfactory performance. In general, with probability control limits, some values are omitted that may have relatively high occurrence possibility, and some are included that may have a relatively small occurrence possibility. In such a case, probability control limits have a credibility issue which is improved by [38] using the narrowest confidence interval for the Shewhart GZIP chart.

An Example

The data in Table 14.2 can also be modeled with a *generalized Poisson distribution*. Based on the data, the maximum-likelihood estimates can be computed as $\hat{\theta} = 0.144297$ and $\hat{\lambda} = 0.875977$. The overall generalized Poisson distribution model for the data set is

$$f(x) = \frac{0.144297(0.144297+0.875977x)^{x-1}}{x!} \times \frac{e^{-0.144297-0.875977x}}{x!}, \quad x = 0, 1, 2, \dots \quad (14.49)$$

With this model, it can be calculated that the upper control limit is 26 at a false-alarm rate of 0.01. This means that there should not be any alarm for the values less than or equal to 26 when the underlying distribution model is the generalized

Poisson distribution. It should be mentioned here that, for this data set, both models can fit the data well, and the traditional Poisson distribution is rejected by statistical tests.

Recently, *Mahmood and Xie* [39] designed a comprehensive review of the control charts based on the *zero-inflated models* and their applications. Moreover, they have provided some future topics which are not covered in the monitoring methodologies of zero-inflated models.

14.5 Control Charts for the Monitoring of Time-Between-Events

Chan et al. [40] proposed a charting method called the cumulative quantity control chart (*CQC chart*). Suppose that defects in a process are observed according to a Poisson process with a mean rate of occurrence equal to $\lambda (>0)$. Then the number of units Q required to observe exactly one defect is an exponential random variable. The control chart for Q can be constructed to monitor possible shifts of λ in the process, which is the CQC chart.

The CQC chart has several advantages. It can be used for low-defective-rate processes as well as moderate-defective-rate processes. When the process defect rate is low or moderate, the CQC chart does not have the shortcoming of showing up frequent false alarms. Furthermore, the CQC chart does not require rational grouping of samples. The data required is the time between defects or defective items. This type of data is commonly available in equipment and process monitoring for production and maintenance.

When process failures can be described by a *Poisson process*, the time between failures will be exponential, and the same procedure can be used in reliability monitoring. Here we briefly describe the procedure for this type of monitoring. Since time is our preliminary concern, the control chart will be termed a *t-chart* in this chapter. This is in line with the traditional *c-chart* or *u-chart*, to which our *t-chart* may be a more suitable alternative. In fact, the notation also makes it easier for the extension to be discussed later.

14.5.1 CQC Chart Based on the Exponential Distribution

The distribution function of the with parameter λ is given by

$$F(t; \lambda) = 1 - e^{-\lambda t}, \quad t \geq 0. \quad (14.50)$$

The control limits for *t-chart* are defined in such a manner that the process is considered to be out of control (OOC) when the time to observe exactly one failure is less than the lower control limit (LCL), T_L , or greater than the upper control limit (UCL), T_U . When the behavior of the process

is normal, there is a chance for this to happen, and it is commonly known as a false alarm. The traditional false-alarm probability is set to be 0.27%, although any other false-alarm probability can be used. The actual acceptable false-alarm probability should, in fact, depend on the actual product or process. Assuming an acceptable probability for false alarms of α , the control limits can be obtained from the exponential distribution as:

$$T_L = \lambda^{-1} \ln \frac{1}{1 - \alpha/2} \quad (14.51)$$

and

$$T_U = \lambda^{-1} \ln \frac{2}{\alpha}. \quad (14.52)$$

The median of the distribution is the center line (CL), T_C , and it can be computed as

$$T_C = \lambda^{-1} \ln 2 = 0.693\lambda^{-1}. \quad (14.53)$$

These control limits can then be utilized to monitor the *failure times* of components. After each failure, the time can be plotted on the chart. If the plotted point falls between the calculated control limits, this indicates that the process is in the state of statistical control and no action is warranted. If the point falls above the upper control limit, this indicates that the process average, or the failure occurrence rate, may have decreased, resulting in an increase in the time between failures. This is an important indication of possible process improvement. If this happens, the management should look for possible causes for this improvement, and if the causes are discovered, then action should be taken to maintain them. If the plotted point falls below the lower control limit, this indicates that the process average, or the failure occurrence rate, may have increased, resulting in a decrease in the failure time. This means that the process may have deteriorated and thus, actions should be taken to identify and remove them.

In either case, the people involved can know when the reliability of the system has changed, and by a proper follow-up, they can maintain and improve the reliability. Another advantage of using the control chart is that it informs the maintenance crew when to leave the process alone, thus saving time and resources.

The CQC chart based on *exponential distribution* under CUSUM structure was studied by Gan [41] and Gan [42] extended this chart under EWMA structure to obtained better performance on the small or moderate shifts in the process. However, computation of run-length properties of exponential EWMA chart was discussed by Gan and Chang [43], and a comparative study based on these charts was reviewed by Liu et al. [43, 44]. Further, the robustness of this chart was discussed in [45, 46], and the estimation effects were

discussed in [47, 48]. Recently, [49, 50] extended this chart into other competitive charting methodologies.

14.5.2 Chart Based on the Weibull Distribution

It is well known that the lifetime distribution of many components follows a *Weibull distribution* [51]. Hence when monitoring reliability or equipment failure, this distribution has been shown to be very useful. The Weibull distribution function is given as

$$F(t) = 1 - \exp \left[- \left(\frac{t}{\theta} \right)^\beta \right], \quad t \geq 0, \quad (14.54)$$

where $\theta > 0$ and $\beta > 0$ are the so-called scale parameter and shape parameter, respectively.

The Weibull distribution is a generalization of the exponential distribution, which is recovered for $\beta = 1$. Although the exponential distribution has been widely used for *time-between-events*, Weibull distribution is more suitable as it is more flexible and is able to deal with different types of the *aging phenomenon in reliability*. Hence in reliability monitoring of equipment failures, the Weibull distribution is a good alternative.

A process can be monitored with a control chart, and the time-between-events can be used. For the Weibull distribution, the control limits can be calculated as:

$$UCL = \theta_0 \left[\ln \left(\frac{2}{\alpha} \right) \right]^{1/\beta_0} \quad (14.55)$$

and

$$LCL = \theta_0 \left[\ln \left(\frac{2}{2 - \alpha} \right) \right]^{1/\beta_0}, \quad (14.56)$$

where α is the acceptable false-alarm probability, and β_0 and θ_0 are the in-control shape and scale parameter, respectively. Generally, the false-alarm probability is fixed at $\alpha = 0.0027$, which is equivalent to the *three-sigma limits* for an X-bar chart under the normal-distribution assumption.

The center line can be defined as

$$CL = \theta_0 [\ln 2]^{1/\beta_0}, \quad (14.57)$$

Xie et al. [52] carried out some detailed analysis of this procedure. Since this model has two parameters, a single chart may not be able to identify changes in a parameter. However, since in a reliability context, it is unlikely that the shape parameter will change, and it is the scale parameter that could be affected by ageing or wear, a control chart as shown in Fig. 14.2 can be useful in reliability monitoring.

Fig. 14.2 A set of Weibull data and the plot

The *CUSUM* structure for the study variable, which follows the Weibull distribution was designed by Shafae et al. [53], and the *mixed EWMA-CUSUM* chart was developed by Aslam [54]. Further, a comparative study on the charts based on Weibull distribution was discussed by Wang et al. [55], and advanced methods related to this chart were presented in [56–58] and references therein.

14.5.3 General t-Chart

In general, to model *time-between-events*, any distribution for positive random variables could be used. Which distribution is used should depend on the actual data, with the exponential, Weibull and Gamma being the most common distributions. However, these distributions are usually very skewed. The best approach is to use probability limits. It is also possible to use a transformation so that the data is transformed to near-normality so that traditional chart for individual data can be used; such charting procedure is commonly available in *statistical process control* software.

In general, if the variable Y follows the distribution $F(t)$, the probability limits can be computed as usual, that is:

$$F(LCL_Y) = 1 - F(UCL_Y) = \alpha/2, \quad (14.58)$$

where α is the fixed false-alarm rate. This is an approach that summarizes the specific cases described earlier. However, it is important to be able to identify the distribution to be used.

Furthermore, to make better use of the traditional monitoring approach, we could use a simple normality transformation. The most common ones are the *Box-Cox transformation* and the log or power transformations. They can be easily realized in software such as MINITAB. Figure 14.2 shows a chart for a Weibull-distributed process characteristic and Fig. 14.3 shows the individual chart with a Box-Cox transformation.

Fig. 14.3 The same data set as in Fig. 14.2 with the plot of the Box-Cox transformation

Recently, real time monitoring of the *time-between-events* applied to several bio-medical applications [59] and discussion on these methods are made in [60, 61].

The traditional t chart is used to monitor the time-between-events while X chart is used to monitor the magnitude of the events. Recently, few researchers suggested *monitoring magnitude* and time-between-events together. Similar to the \bar{X} & R or \bar{X} & S chart, Wu et al., [62] provided a combined scheme T & X chart for the *joint monitoring* of magnitude and time-between-events. Further, the rate chart was proposed by Wu et al. [63] which is more efficient method than the T & X chart while a comparative study for combined structure was designed by Rahali et al. [64]. These proposals were designed by assuming the independence between magnitude and time-between-events which may not hold in real situations. Hence, to alleviate this problem Cheng et al., [65] provided a simultaneous monitoring method based on *bivariate gamma distribution*. Furthermore, joint monitoring methods based on the distance and max-type measures were proposed by Sanusi and Mukherjee [66] which is a flexible scheme for any parametric distribution of *magnitude and time-between-events*.

14.6 Discussion

In this chapter, some effective control-charting techniques are described. The statistical monitoring technique should be tailored to the specific distribution of the data that are collected from the process. Perfunctory use of the traditional chart will not help much in today's manufacturing environment toward the near-zero-defect process. For high-quality processes, it is more appropriate to monitor items inspected between two nonconforming items or the time between two events.

The focus of this chapter is to highlight some common statistical distributions for process monitoring. Several

statistical models such as the geometric, negative binomial, zero-inflated Poisson, and generalized Poisson can be used for count-data monitoring in this context. The exponential, Weibull and Gamma distributions can be used to monitor time-between-events data, which is common in reliability or equipment failure monitoring. Other general distributions of time-between-events can also be used when appropriate. The approach is still simple: by computing the probability limits for a fixed false-alarm probability, any distribution can be used in a similar way. The simple procedure is summarized below:

- Step 1. Study the process and identify the statistical distribution for the process characteristic.
- Step 2. Collect data and estimate the parameters (and validate the model, if needed).
- Step 3. Compute the probability limits or use an appropriate normality transformation with an individual chart.
- Step 4. Identify any assignable cause and take appropriate action.

The distributions presented in this chapter open the door to further implementation of statistical process control techniques in a near-zero-defect era. Several research issues remain. For example, the problem with correlated data and the estimation problem has to be studied. In a high-quality environment, *failure or defect data* is rare, and the estimation problem becomes severe. In the case of continuous production and measurement, data correlation also becomes an important issue. It is possible to extend the approach to consider the exponentially weighted moving average (EWMA) or cumulative-sum (CUSUM) charts that are widely advocated by statisticians. A further area of importance is multivariate quality characteristics. However, a good balance between statistical performance and ease of implementation and understanding by practitioners is essential.

Min Xie received his PhD in Quality Technology from Linköping University, Sweden in 1987. Currently he is Chair Professor of Industrial Engineering at City University Hong Kong and was a Professor at National University Singapore. Prof Xie has authored several book and many journal papers, and he was elected fellow of IEEE in 2005 and elected ISI member in 2010.

Thong Ngee Goh (Ph.D. University of Wisconsin – Madison, USA) is recipient of ASQ, Statistics Division’s William G Hunter Award (2007) and Eugene L Grant Medal (2012). He was Director, Office of Quality Management, NUS, Singapore. Specializing in statistical methodologies for engineering applications, he serves on the editorial boards of several leading research journals on Quality Management and Quality Engineering.

Tahir Mahmood got his degree of BS (Hons.) in Statistics with distinction (Gold Medalist) from the Department of Statistics, University of Sargodha, Sargodha, Pakistan. In 2015, he secured a scholarship from Deanship of Graduate Studies, King Fahd University of Petroleum and Minerals (KFUPM), Dhahran, Saudi Arabia. In April 2017, he received his MS (Applied Statistics) degree from Department of Mathematics and Statistics, KFUPM. He received his Ph.D. (Systems Engineering) from the Department of Systems Engineering and Engineering Management, City University of Hong Kong, Hong Kong. In the past, he has served as a Lecturer in the Department of Technology, School of Science and Technology, The Hong Kong Metropolitan University, Hong Kong. Nowadays, he is an Assistant Professor in the Industrial and Systems Engineering Department, College of Computing and Mathematics, King Fahd University of Petroleum and Minerals (KFUPM), Dhahran, Saudi Arabia. His current research interests include Statistical Process Monitoring, Quality Management, and Quality Engineering.

Abstract

In recent years, increased emphasis has been placed on improving decision-making in business and government. A key aspect of decision-making is being able to predict the circumstances surrounding individual decision situations. Examining the diversity of requirements in planning and decision-making situations, it is clearly stated that no single forecasting methods or narrow set of methods can meet the needs of all decision-making situations. Moreover, these methods are strongly dependent on factors, such as data quantity, pattern, and accuracy, that reflect their inherent capabilities and adaptability, such as intuitive appeal, simplicity, ease application, and, least but not last, cost.

Section 15.1 deals with the placement of demand forecasting problem as one of biggest challenge in the repair and overhaul industry; after this brief introduction, Sect. 15.2 summarizes the most important categories of forecasting methods; paragraphs from 15.3 to 15.4 approach the forecast of spare parts first as a theoretical construct, but some industrial applications and results are added from field training, as in many other parts of this chapter.

Section 15.5 undertakes the question of optimal stock level for spare parts, with particular regards to Low Turnaround Index (LTI) parts conceived and designed for the satisfaction of a specific customer request, by the application of classical Poisson methods of minimal availability and minimum cost; similar considerations are drawn and compared in Sect. 15.6 dealing with models based on binomial distribution. An innovative extension of binomial models based on total cost function is discussed in Sect. 15.7. Finally, Sect. 15.8 adds the Weibull failure rate function to LTI spare parts stock level in maintenance system with declared wear conditions.

15.1 The Forecast Problem of Spare Parts

Demand forecasting is one of the most crucial issues of inventory management. Forecasts, which form the basis for the planning of inventory levels, are probably the biggest challenge in the repair and overhaul industry.

An example is in the airlines industry, when a common problem is the need to forecast short-term demand with the highest possible degree of accuracy. The high cost of modern aircraft and the expense of such repairable spares, as aircraft engines and avionics, greatly contributes to the considerable total investment of many airline operators. These parts, though low in demand, are critical to operations, and their unavailability can lead to excessive down time costs.

This problem is absolutely relevant in case of intermittent demand. A demand of an item is classified as *intermittent* when irregular and sporadic. This type of demand, typical for a great amount of spare parts, is very difficult to predict. This complicates the efficient management and control of the inventory system, which requires an acceptable balance between inventory costs, on the one hand, and stock-outs, on the other. Inventory management models require accurate forecasts in order to true this balance up.

We can consider explicitly both the demand pattern and the size of the demand when it occurs for the classification of the data demand patterns and classify them into four categories [1], as follows:

- *Intermittent demand*, which appears randomly with many time periods having no demand.
- *Erratic demand*, which is (highly) variable, erratic relating to the demand size rather than demand per unit time period.
- *Slow moving* (“smooth”) demand, which also occurs at random with many time periods having no demand. Demand, when it occurs, is for single or very few units.
- *Lumpy demand*, which likewise seems random with many time periods having no demand. Moreover, demand, when it occurs, is (highly) variable. Lumpy concept corresponds to an extremely irregular demand, with great differences between each period’s requirements and with a great number of periods with zero requirements.

Traditionally, the characteristics of intermittent demand are derived from two parameters: the average inter-demand interval (ADI) and the coefficient of variation (CV). ADI measure the average number of time periods between two

successive demands, and CV represents the standard deviation of period requirements divided by the average period requirements.

$$CV = \frac{\sqrt{\frac{\sum_{i=1}^n (\varepsilon_{ri} - \varepsilon_a)^2}{n}}}{\varepsilon_a} \tag{15.1}$$

where n is the number of periods and ε_{ri} and ε_a are real and average demand of spare parts in period i . The four resulting demand categories are graphically presented in Fig. 15.1.

The categorization scheme should suggest the different ways to treat the resulting categories according to the following characteristics:

- The “ $ADI \leq x; CV^2 \leq y$ ” condition tries effectively to test for stock-keeping units, SKUs, which are not very intermittent and erratic (i.e., faster moving parts or parts whose demand pattern does not raise any significant forecasting or inventory control difficulties).
- The “ $ADI > x; CV^2 \leq y$ ” condition tests for low-demand patterns with constant, or more generally, no highly variable demand sizes (i.e., not very erratic).
- The “ $ADI > x; CV^2 > y$ ” condition tests for lumpy demand items. Lumpy demand may be defined as a demand with great differences between each period’s requirements and with a great number of periods having zero requests.
- Finally, the “ $ADI \leq x; CV^2 > y$ ” condition tests for erratic (irregular) demand items with rather frequent demand occurrences (i.e., not very intermittent).

In all these cases, x denotes the ADI cutoff value ($ADI = 1.32$) measuring the average number of time periods between two successive demands and y the corresponding CV^2 cutoff value ($CV^2 = 0.49$) that is equal to the square

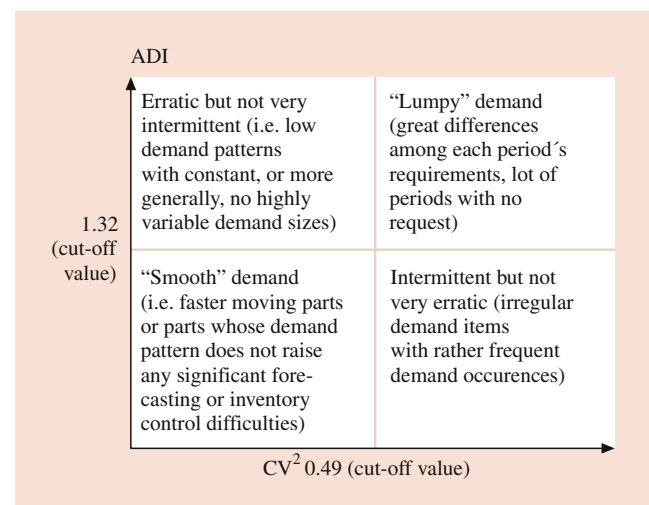

Fig. 15.1 Categorization of demand pattern

standard deviation of period requirements divided by the average period requirements.

Forecasting systems generally depend on the category of part used. Therefore, it is much more important to have two dependent factors to indicate deviation from expected values of demand, in respect of both demand size and inter-demand interval. The performance of a forecasting method should vary with the level and type of lumpiness. A classification of research on intermittent demand forecasting can be arranged according to Willemain as follows:

1. Extension of standard methods (Lau and Wang, Tyworth and O'Neill) [8, 9] and variants of Poisson model (Ward, Williams, Mitchell et al., Van Ness et al., Schultz, Watson, Dunsmuir et al.) [10–15]
2. Reliability theory and expert systems (Petrovic & Petrovic) [16]
3. Single exponential smoothing, Winter's models (Bier, Sani, and Kingsman, Willemain et al.) [17, 18]
4. Croston's variant of exponential smoothing (Croston, Segestedt, Willemain et al., Johnston) [19–21]
5. Bootstrap methods (Bookbinder and Lordahl, Wang and Rao, Kim et al., Park and Willemain) [22–25]
6. Moving average and variants (Ghobbar et al., Bartezzaghi) [26, 27]
7. Model based on binomial distribution (Pareschi et al.) [32–35]

The principle forecasting methods are briefly summarized in Table 15.1.

15.1.1 Exponential Smoothing

Exponential Smoothing methods (ES) are largely used time-series methods when reasonably good forecasts are needed over the short-term horizon, using historical data to obtain a “smoothed” value for the series. This smoothed value is then extrapolated to become the forecast for the future value of the series. The ES methods apply to past data an unequal set of weights exponentially decreasing with time, that is, the more recent the data value, the greater its weighting. In particular, the general form used in computing a forecast by the method of Single Exponential Smoothing (SES) is given by Eq. 15.2, where F_t represents the “smoothed estimate,” X_t the actual value at time t , and α the smoothing constant which has a value between 0 and 1. SES is best suited to data that exhibits a flat trend:

$$F_{t+1} = \alpha X_t + (1 - \alpha) F_t \quad (15.2)$$

When a trend exists, the forecasting technique must consider the trend as well as the series average; ignoring the trend will cause the forecast to underestimate or to overestimate,

according to an increasing or decreasing trend, the actual demand. In fact, Double Exponential Smoothing (DES), useful when the historic data series are not stationary, applies SES twice, and the general form is

$$F''_{t+1} = \alpha F_{t+1} + (1 - \alpha) F_t \quad (15.3)$$

15.1.2 Croston's Method

A little-known alternative to single exponential smoothing is Croston's method that separately forecasts the nonzero demand size and the inter-arrival time between successive demands using simple exponential smoothing (SES), with forecasts being updated only after demand occurrences. Let F_t and Y_t be the forecasts of the $(t + 1)$ th demand size and inter-arrival time, respectively, based on data up to demand t and Q_t the inter-arrival time between two successive nonzero demand. Then Croston's method gives:

$$F_t = (1 - \alpha) F_{t-1} + \alpha Y_t \quad (15.4)$$

$$Y_t = (1 - \alpha) Y_{t-1} + \alpha Q_t \quad (15.5)$$

The predicted demand at time t is the ratio between F_t and Y_t

$$P_t = F_t / Y_t \quad (15.6)$$

SES and Croston methods are most frequently used for low and intermittent demand forecasting; in particular, Croston can be useful with intermittent, erratic, and slow-moving demand, and its use is significantly superior to ES under intermittent demand conditions, accordingly with the categorization scheme of Fig. 15.1. Also, the straight Holt method (EWMA) is applicable only with low levels of lumpiness. The widespread use of SES and MTBR methods for parts with high variation (lumpy demand) is questionable as they consistently create poor forecasting performance which remains poor as the demand variability increases. The only method that fits quite well lumpy demand is the WMA, and its superiority to ES methods is proved: Its use could provide tangible benefits to maintenance service organizations forecasting intermittent demand. We mean for WMA the moving average method in which for computing the average of the most recent n data, the more recent observations are typically given more weight than older observations.

15.1.3 Holt Winter Models

Winter's models (AW, MW) methods consider the seasonal factor and provide the highest forecasting error with high

variation (lumpy demand). While computing Holt-Winter filtering of a given time series, unknown parameters are determined by minimizing the squared prediction error.

α , β , and γ are parameters of Holt-Winter filter, respectively, for level, trend, and seasonal component; if beta is set to 0, the function will perform exponential smoothing, while if gamma parameter is set to 0, a nonseasonal model is fitted.

The additive Holt-Winter prediction function (for time series with period length p) is

$$\bar{Y}[t+h] = a[t] + h \cdot b[t] + s[t+1+(h-1)|p|] \quad (15.7)$$

where $a[t]$, $b[t]$, and $s[t]$ are given by

$$a[t] = \alpha (\bar{Y}[t] - s[t-p]) + (1-\alpha) (a[t-1] + b[t-1]) \quad (15.8)$$

$$b[t] = \beta (a[t] - a[t-1]) + (1-\beta) b[t-1] \quad (15.9)$$

$$s[t] = \gamma (\bar{Y}[t] - a[t]) + (1-\gamma) s[t-p] \quad (15.10)$$

The multiplicative Holt-Winter prediction function (for time series with period length p) is

$$\bar{Y}[t+h] = (a[t] + h \cdot b[t]) \cdot s[t+1+(h-1)|p|] \quad (15.11)$$

where $a[t]$, $b[t]$, and $s[t]$ are given by

$$a[t] = \alpha \left(\frac{\bar{Y}[t]}{s[t-p]} \right) + (1-\alpha) (a[t-1] + b[t-1]) \quad (15.12)$$

$$b[t] = \beta (a[t] - a[t-1]) + (1-\beta) b[t-1] \quad (15.13)$$

$$s[t] = \gamma \left(\frac{\bar{Y}[t]}{a[t]} \right) + (1-\gamma) s[t-p] \quad (15.14)$$

The function tries to find the optimal values of α and/or β and/or γ by minimizing the squared one-step prediction error, if they are omitted. For seasonal models, starting values for a , b , and s are detected by performing a simple decomposition in trend and seasonal component using moving averages on first periods (a simple linear regression on the trend component is used for starting level and trend). For level/trend-models (no seasonal component), starting values for a and b are $X[2]$ and $X[2] - X[1]$, respectively. For level-only models (ordinary exponential smoothing), the start value for a is $X[1]$.

15.2 Forecasting Methods

In our opinion, considering major approaches to forecasting although many different classification schemes could be used, maybe the most significant scheme for their classification divides those methods into three major categories, as summarized in Table 15.2 [2]: judgmental, quantitative, and technological. Each category includes several types of methods, many individual techniques, and variations. *Judgmental methods* are most commonly used in business and government organizations. Such forecasts are most often made as individual judgments or by committee agreements. Nevertheless, quantitative methods are better than judgmental ones in determining spare part-inventory level, and we can suggest judgmental methods only in extremis.

The second category – *quantitative methods* – is the type on which the majority of the forecasting literature has been focused. There are three subcategories of these methods. *Time-series methods* seek to identify historical patterns (using a time reference) and then forecast using a time-based extrapolation of those patterns. *Explanatory methods* seek to identify the relationships that led to observed outcomes in the past and then forecast by applying those relationships to the future. *Monitoring methods*, which are not yet in widespread use, seek to identify changes in patterns and relationships. They are used primarily to indicate when extrapolation of past patterns or relationship is not appropriate.

The third category – *technological methods* – addresses long-term issues of a technological, societal, economic, or political nature. The four subcategories here are extrapolative (using historical patterns and relationships as a basis for forecasts), analogy-based (using historical and other analogies to make forecasts), expert-based, and normative-based (using objectives, goals, and desired outcomes as a basis for forecasting, thereby influencing future events).

15.2.1 Characterizing Forecasting Methods

In describing forecasting methods, we have found 7 most important factors reflecting their inherent capabilities and adaptability.

1. *Time horizon* – two aspects of the time horizon relate to individual forecasting method. First is the span of time in the future for which different forecasting methods are best suited. Generally speaking, qualitative methods of forecasting are used more for longer-term forecasts, whereas quantitative methods are used more with intermediate and shorter-term situations. The second important aspect of the time horizon is the number of periods for which a forecast is desired. Some techniques are appropriate for

Table 15.2 A summary of selected forecasting methods

No.	Method	Abbreviation	Description
1	Additive Winter	AW	Assumes that the seasonal effects are of constant size
2	Multiplicative Winter	MW	Assumes that the seasonal effects are proportional in size to the local de-seasonalized mean level
3	Seasonal regression model	SRM	It is used in time series for modeling data with seasonal effects
4	Component service life (replacement)	MTBR	Estimates of the service life characteristics of the part (MTBR = Mean Time Between Replacement), derived from historical data
5	Croston	Croston	Forecasting in case of low and intermittent demand
6	Single exponential smoothing	SES	Forecasting in case of low and intermittent demand
7	Exponential weighted moving average	EWMA, Holt	An effective forecasting tool for time series data that exhibits a linear trend
8	Trend adjusted exponential smoothing	TAES	Forecasting time series data that have a linear trend
9	Weighted moving averages	WMA	A simple variation on the moving average technique that allows for such a weighing to be assigned to the data being averaged
10	Double exponential smoothing	DES	Forecasting time series data that have a linear trend
11	Adaptive-response-rate single exponential smoothing	ARRSES	Has an advantage over SES in that it allows the value of α to be modified in a controlled manner as changes in the pattern of data occur
12	Poisson's model	POISSON	Models based on Poisson's distribution with the definition of a customer's service level
13	Binomial models	BM	Methods based on binomial distribution

forecasting only one or two periods in advance; others can be used for several periods. There are also approaches for combining forecasting horizons of different lengths.

2. *Pattern of data* – underlying the majority of forecasting methods is an assumption as to the type of pattern(s) found in the data to be forecast, for example, some data series may contain seasonal as well as trend patterns; others may consist simply of an average value with random fluctuations around that, and still others might be cyclical. Because different forecasting methods vary in their ability to predict different types of patterns, it is important to match the presumed pattern(s) in the data with the appropriate technique.
3. *Cost* – generally three direct elements of costs are involved in the application of a forecasting procedure: development, data preparation, and actual operation. The variation in costs obviously affects the attractiveness of different methods for different situations.
4. *Accuracy* – closely related to the level of detail required in a forecast is desired accuracy. For some decision situations, plus or minus 10% may be sufficient while in others a little variation of 2% could spell disaster.
5. *Intuitive appeal, simplicity, and ease of application* – a general principle in the application of scientific methods to management is that only methods that are understood in deep get used by decision makers over time. This is particularly true in the area of forecasting.
6. *Number of data required from past history* – some methods produce good results without consistent number of data from the past, because they are less affected by estimation errors in input parameters.
7. *Availability of computer software* – it is seldom possible to apply a given quantitative forecasting method unless

an appropriate computer program exists. Such a software must be user friendly and well conceived.

15.3 Forecasting Methods Applicability Related to Spare Parts Demands

Companies have to select in advance the appropriate forecasting method matching their cyclical demand for parts at best. Particular attention has to be paid to the demand for service parts inventories that is generally irregular and difficult to predict [3]. A summary of the better forecasting methods in relation to the categorization scheme of Fig. 15.1 is presented in Table 15.3.

15.4 Prediction of Aircraft Spare Parts: A Case Study

Airlines technical divisions are based on total hours flied and on the fleet size. With this data, the purchasing department tries to determine the quantity of stock necessary for a particular operating period. Alternatively, when new types of aircrafts are introduced, the airframe and engine manufacturers normally provide a recommended spares provisioning list, which is based on the projected annual flying hours, and includes forecast usage information on new aircraft. Also, the original equipment manufacturers provide overhaul manuals for aircraft components capable of supporting the assessment of required parts based on reliability information, i.e., on the specified components' operational and life limits. Consequently, the forecast of spare parts is practically based on past usage patterns and personnel experience.

Table 15.3 Summary of the better forecasting methods

Forecasting methods	Categorization of the demand			
	Intermittent	Erratic	Slow moving	Lumpy
Additive Winter – AW		•	•	
Multiplicative Winter – MW		•	•	
Seasonal regression model – SRM		•	•	
Component service life (replacement)		•	•	
Croston	•	•	•	
Single exponential smoothing – SES		•	•	
Double exponential smoothing – DES		•	•	
Exponentially weighted moving average – EWMA		•	•	
Trend-adjusted exponential smoothing		•	•	
Weighted moving averages	•	•	•	•
Adaptive-response-rate single exponential smoothing		•	•	
Poisson models	•		•	
Binomial models	•	•	•	•

Before any consideration about lumpiness and aircraft spare parts forecast, a discussion on the selection of the main variables used as “clock” for spare part life evaluation is absolutely necessary. According to Campbell’s study on maintenance records of United State air force [4], the spare parts demand appears strongly related to flying hours, but this sometimes does not appear the best indicator, e.g., to forecast landing gears, where it does not matter how long the aircraft is in the air, but how often it lands, or radar components that work only when the aircraft is on the ground. In conclusion, often flying hours are the best “clock,” but for each item a demonstration of its effectiveness is necessary [5].

In this study, different forecasting methods have been considered [6, 7], briefly:

- (a) Additive/Multiplicative Winter (AW/MW)

For each forecast, the optimal combination of level, trend, and seasonal parameters is realized. Available values for each variable (level and trend) are 0.2 and 0.01; seasonal length used is 12 periods.
- (b) Seasonal Regression Model (SRM)

Multiplicative model with trend and seasonal components. Seasonal length is 12 periods.
- (c) Single Exponential Smoothing (SES)

The statistical software applied (Minitab 14.0©) supports the research of the optimal weight of smoothing constant. Then the result is the best forecast with this method.
- (d) Double Exponential Smoothing (DES)

Dynamic estimates are calculated for two components: level and trend; the software supports their optimization. Also, in this case the best forecast with DES is guaranteed.
- (e) Moving Average (on the generic i -period) (MA(i))

Moving Averages are calculated with different time horizons (i period). The notation is MA(i).

This analysis employs every period length from 2 to 12.

- (f) Exponentially Weighted Moving Average (EWMA(i))

Also, in this case a weight optimization of smoothing coefficient for MA series has been realized. EWMA(i) is calculated for $i = 3, 4, 5$ and 8 periods.

Despite their importance in literature, we do not evaluate and compare methods based on Poisson approach because they reveal inadequate in intermittent demand prediction.

The case study deals with more than 3000 different items, with different levels of lumpiness, of Airbus fleet belonging to Italian national-flag airline. For each component, records relate to the daily demand level grouped in monthly interval of item usage, from 1998 to 2003. In terms of lumpiness, these avionic spare parts are classified in five different classes of behavior; for each class, a representative item, named $a, x, y, z,$ and w for confidentiality, is indicated.

Figure 15.2 presents an exemplifying demand of item z . The 5 “lumpiness” levels are reported in Fig. 15.3.

The Mean Absolute Deviation (MAD) of the forecast error is adopted as a performance index

$$MAD = \frac{\sum_{i=1}^n |\varepsilon_{fi} - \varepsilon_{fi}|}{n} \tag{15.15}$$

where ε_{fi} is the forecasted demand for period i . Some authors propose the Mean Absolute Percentage Error (MAPE) for this comparison, but in lumpy condition many item demands are zero, and as a consequence MAPE is not defined. For this reason, some authors propose a similar index, called MAD/A, also defined when the demand for items is zero:

$$MAD/A = \frac{MAD}{AVERAGE} \tag{15.16}$$

Fig. 15.2 Demand pattern for item z

Fig. 15.3 CV² and ADI on monthly period for five representative "lumpy" items

where AVERAGE is the average value of historical item demand. Tracking signal (TS), as defined by Brown, is used to check if forecasts are in control or not.

$$TS_t = \left| \frac{CUSUM_t}{EMAD_t} \right| \tag{15.17}$$

where $CUSUM_t = (\varepsilon_{rt} - \varepsilon_{ft}) + CUSUM_{t-1}$ and $EMAD_t = \alpha|\varepsilon_{rt} - \varepsilon_{ft}| + (1 - \alpha) EMAD_{t-1}$

Limit values of TS and the optimal α value (0.25) are derived from Alstrom and Madsen approach. For analyzed items, forecasts are in control since the third year (that is their tracking signals respect the limits). The different forecasting methods are compared for all items and in particular for the proposed five components.

Table 15.4 and Figs. 15.4 and 15.5 show, respectively, some brief and full results of MAD and MAD/A for item z. Table 15.5 presents, for each representative item, the list of forecasting methods ordered by decreasing MAD, thus as-

Fig. 15.4 MADs for item z

Fig. 15.5 MAD/As for item z

signing a "relative weight" related to the ranking position: A simple elaboration of these weights permits a full comparison in terms of total and average scores (* MW not defined for w item, due to its characteristics).

By means of MAD/A, it is possible to compare different forecasting methods on different items and their behavior in

Table 15.4 Comparison among some methods

Item z	MW	AW	SES	DES	MA(3)	MA(4)	MA(5)	MA(8)	SRM	EWMA(3)	EWMA(4)	EWMA(5)	EWMA(8)

face of different lumpiness conditions: SRM, EWMA(i), and Winter are the best forecasting methods. This result is not related to lumpiness level, at least for lumpiness represented by $ADI < 3.3$ and $CV^2 < 1.8$, typical range for aircraft components. Some interesting observations can be drawn:

- Figure 15.6 clearly attests the item lumpiness as a dominant parameter, while the choice of the forecasting method has a secondary relevance; all methods for a “little-lumpy” item (e.g., items y and z) generally perform better than the best method for a “high-lumpy” component (e.g., items x and w). However, lumpiness is an independent variable and is not controllable.
- The value of the average MAD/A calculated for all forecasts generated by all methods is 1.02. The aim of this study is a comparison of different forecasting methods, but we can conclude that demand forecasting for lumpy items is very difficult, and results are not very accurate. Besides, lumpy demand is often equal to zero or one: All prediction lower than 1 must be rounded up to one. This phenomenon introduces another source of error.

- For a single component, the average fluctuation (in terms of MAD/A) of the ratio maximum/minimum, among different techniques, is about 1.55 (usually between 1.40 and 1.70); for a single forecasting method, the average fluctuation (in terms of MAD/A) of the ratio maximum/minimum, among different components, is about 2.17 (usually between 1.57 and 2.18). Then the main relevance of lumpiness is proclaimed again.
- Analyzing the effectiveness of a single model, research demonstrates (Tables 15.3 and 15.4) that the Seasonal Regression Model (SRM), the Exponentially Weighted Moving Average (EWMA(i)), and Winter are the best forecasting methods. It is important to remember that analyzed items are effectively representative of a population of aircraft spare parts. This result is not related to lumpiness level, at least for lumpiness represented by $ADI < 3.3$ and $CV^2 < 1.8$ (typical range for aircraft components).

In conclusion, intermittent demand for service parts, usually highly priced, is a very critical issue, especially for lumpy demand prediction, as typical for avionic spare parts.

Fig. 15.6 MAD/A data and curves

In literature, lumpy demand forecasting is not deeply investigated, Ghobbar interesting research apart, and sometimes conflicting results are recovered. The introduction of economic question is the final development: It is absolutely necessary to check the impact of stocking costs and costs due to component lacks on the forecasting methods; aircraft operator can incur costs of more than 30,000 \$ per hour if a plane is on the ground.

15.5 Poisson Models

For builders of high-technology products, as automatic packaging machines, the supply of spare parts creates a strategic advantage respect to the competitors, with particular regard to Low Turnaround Index (LTI) parts conceived and designed for the satisfaction of a specific customer request. The strategic problem to solve is to individualize the minimum number of spare parts capable of avoiding the customers plants' downtimes for a specific period, called covering period, that coincides with the time between two consecutive consignments.

The procedure actually used by a great number of manufacturers, named "recommended parts," consists in the creation, at design stage, of some different groups of replaceable parts with different covering time for every functional machine group. This methodology is very qualitative, and it strongly depends on the designer opinion; besides, not considering the information feedback from customers, it usually estimates in excess the number of spare parts in respect to the real demands of customers. Even though this way avoids plant downtimes, absolutely forbidden for the high costs of production loss, it normally creates exuberant and expensive stocks, with unsought high risks of damage and obsolescence. For LTI items, the usual economic batch or safety stock methods are not suitable to forecast the spare

Fig. 15.7 Economic approach

parts amount. For such a situation, during last years a lot of different approaches, usually based on Poisson distribution, have been developed: Stock level conditioned to minimal availability or to minimum total cost (see Fig. 15.7) is considered the most interesting.

Every study reported in literature assumes that item's failure time (for spare parts demand) is exponentially distributed and as a consequence the failure rate $\lambda(t)$ is independent from the time. This simplifying hypothesis is due to the difficulties in estimating Mean Time Before Failure (MTBF) real values. Finally, it is important to underline that the quantity of spare parts and its temporal distribution also represent a strategic information during the negotiations with customers for the purchase of the plants and the quantification of related costs.

15.5.1 Stock Level Conditioned to Minimal Availability Method

This method first needs to calculate the asymptotic availability A by the known formula:

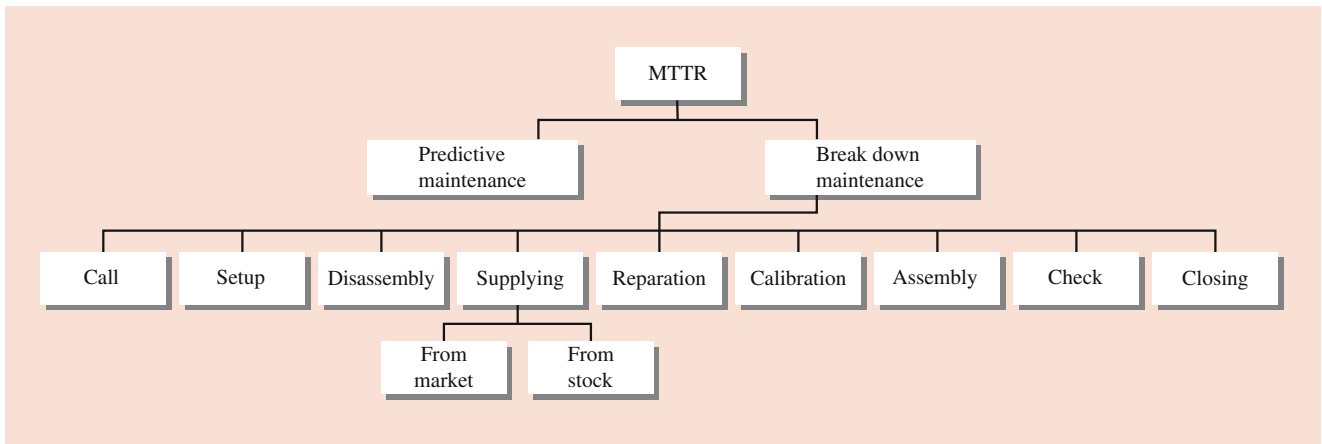

Fig. 15.8 MTTR’s structure

$$A = \frac{MTBF}{MTBF + MTTR} \tag{15.18}$$

The Mean Time To Repair (MTTR) term is derived from different factors, as shown in Fig. 15.8:

Its value strongly depends on the spare part being on consignment or not, and it can be calculated by the formula:

$$MTTR = T_1 + \int_0^{T_s} (T_s - T_x) f(T_x) dT_x = MTTR(N) \tag{15.19}$$

where T_1 is amount of time due to factors except time of supply (for instance, disassembling), T_s lead-time of supply for not available components, N number of spare parts available in stock at the time zero, T_x time interval between the instant when the consumption of the part reaches the value N (empty stock situation) and the consignment of spare part, and $f(t)$ density of failure distribution.

$$P_N = \frac{(\lambda T_s)^N \cdot e^{-\lambda T_s}}{N!} \tag{15.20}$$

It is worth to note that for increasing N we get decreasing MTTR, increasing availability A , and the downtimes costs fall down. Second, the method affords the quantitative definition of the storage cost that requires the definition of the average number of parts storing during the time of supply T_s . If the warehouse contains N parts at time zero, the probability P_N of N failures in T_s can be pointed out by Poisson formula:

In the same way, it is possible to calculate the probability of one, two, or N failures.

Let R indicate the cost of each spare part, and s the stoking cost index per year; the annual stockcosts C can be evaluated by the formula $C = R \cdot s [N \cdot P_0 + (N - 1) \cdot P_1 + (N - 2) \cdot P_2 + \dots P_{N-1}]$ that can be used in an iterative process in order to find the optimum level N that leads to a minimum for the cost C , all the while allowing the minimum level of

availability $A_{MIN}(N)$ to guarantee on-time technical requests to be satisfied (for example, safety questions or productivity level).

$$\begin{cases} \min [C = R \cdot s (NP_0 + (N - 1) P_1 + (N - 2) P_2 + \dots + P_{N-1})] \\ \text{subject to } A(N) = \frac{MTBF}{MTBF + MTTR(N)} \geq A \quad \min \end{cases} \tag{15.21}$$

15.5.2 Stock Level Conditioned to Minimum Total Cost

The aim of this method is to determinate the total amount N of replaceable parts in order to minimize the total cost function C_{tot} defined by

$$C_{tot}(N) = C_1 + C_2 \tag{15.22}$$

The warehousing cost term C_1 can be estimated as in (15.21), while for the cost C_2 it is necessary to quantify the probability of stock-out situations. During the time T_s , production losses could occur if the number of failures exceeds the number N of parts supplied at the consignment time, assumed as zero. The cumulative probability calculated by Poisson distribution is:

$$P = P_{N+1} + P_{N+2} + P_{N+3} + \dots \tag{15.23}$$

Let d indicate the annual part consumption of a customer and CM the cost corresponding to a loss of production; the term due to stock-out is

$$C_2 = CM \cdot d \cdot P \tag{15.24}$$

For a rapid choice, it is possible to employ the following user-friendly abacus (Fig. 15.9):

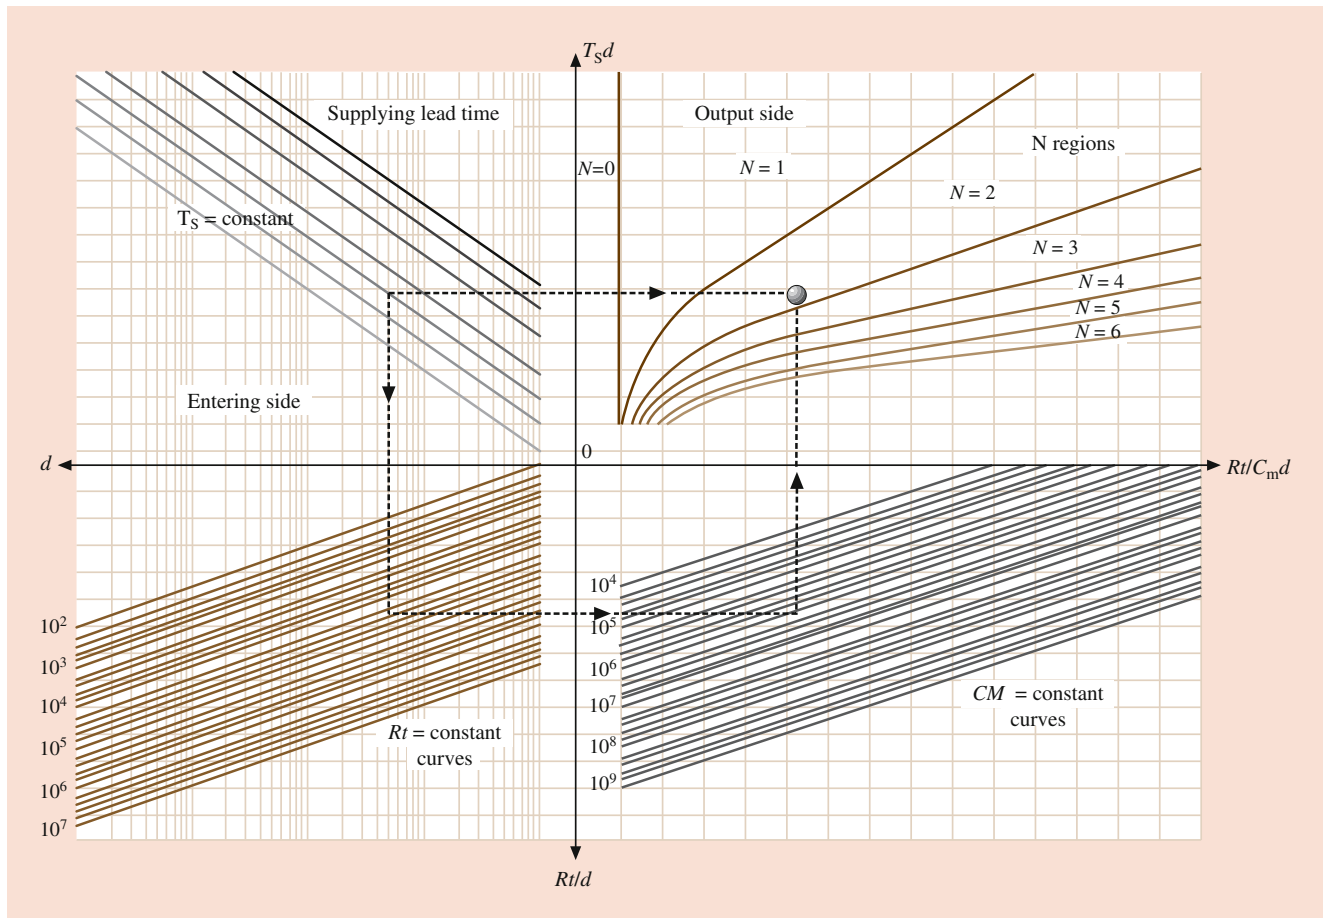

Fig. 15.9 Graphic abacus

15.6 Models Based on Binomial Distribution

Industrial applications show that the methodologies based on Poisson formula usually overestimate the real replacements consumption. To overcome this problem, we present a new quantitative procedure that does not consider the request of parts being linear during time, as Poisson procedure does.

The innovative approach calculates the requirement of components, for a given covering period T , by the addition of two addenda x_1 and x_2 : The first is related to the wear damage of the replaceable component and can be deducted by MTBF value, while the second is related to the randomness of the breakdowns and covers the possibility of failures in advance respect to the average situation. The optimal number of replacements is $N = x_1 + x_2$.

Let n be the number of different employments for component in several machines owned by the customer and T the covering period; x_1 can be expressed by:

$$x_1 = \text{int} \left(\frac{T}{\text{MTBF}} \right) \cdot n \tag{15.25}$$

This average term assumes interesting values only in presence of a high consumption of the component, in particular in the rare situations when an LTI part has a lot of applications, indicated by n . Anyway, this term x_1 represents a scanty information; we have to consider the second term that corresponds to the number of parts to get the required value of the customer service level LS in the residual time T_{residual} , defined as the residue of the ratio between T and MTBF. The customer service level is the probability that the customer finds the parts during the remaining period and can be fixed separately according to strategic and economic assessments.

The value of x_2 is got by the following formulas:

$$T_{\text{residual}} = T - \text{int} \left(\frac{T}{\text{MTBF}} \right) \cdot \text{MTBF} \tag{15.26}$$

$$p = Q(T_{\text{residual}}) = 1 - e^{-\left(\frac{T_{\text{residual}}}{\text{MTBF}}\right)} \quad (15.27)$$

where p represents the failure probability during T_{residual} ; by p and the binomial distribution, it is easy to calculate the probability that a component (with n applications) requires less than x_2 replacements in T_{residual} :

$$P(x \leq x_2; n; Q(T_{\text{residual}})) = \sum_{i=0}^{x_2} \binom{n}{i} (1-p)^{n-i} \cdot p^i \quad (15.28)$$

As a consequence, it is possible to quantify the no-stock-out confidence level to compare with the customer satisfaction as

$$\text{LS}(x_2) = 1 - P(x \leq x_2; n; 0Q(T_{\text{residual}})) \quad (15.29)$$

The main innovative result is that the procedure does not consider the total request of spare parts to be linear versus time, as other methods do; it tries to set the best moment for the supply in order to maximize the customer service level without increasing the average amount of spare parts. In fact, the new method respects the average consumption by the term x_1 and increases the customer service levels planning the requirement for spare parts in the residual time by the term x_2 .

15.6.1 An Industrial Application

This procedure is successfully running on PC systems in an Italian company leader in manufacturing of packaging machines. The supply of spare parts creates a strategic advantage in respect to competitors, because the automatic packaging machines usually present a long-life cycle and contain a lot of functional groups, often ad hoc conceived and designed. The economic impact of replacement activity is not negligible: It usually amounts up to 15% of the global business volume. Surely a good forecast of spares parts can simplify the manufacturer production planning. Before its industrial real-time application, the innovative procedure was tested to forecast the consumption of 190 different spare parts indicated by several customers over a 33-month period (Figs. 15.10 and 15.11).

The experimental results of these procedures were evaluated by two performance indexes:

1. Percentage number of spare parts without stock-out periods
2. Effective utilization of replacements by the customer

As a first test, the new procedure was applied with the restrictive hypothesis of a covering period of 1 month: Using LS equal to 99.8%, the method was good performing for 166 replaceable parts and there was a very good correlation

between prevision and real customer consumption, as shown in comparison in Fig. 15.12 to the real consumption and Poisson linear forecast (LS = 90%) for a pin for hoes gear levers with 26 applications in the customer machine park.

The 88% of components investigated did not present any month with stock-out, 3% presented less than 3 months of underevaluation, and 9% had more than 3 months in stock-out. On the other hand, the utilization index showed that the 87% of the components had a normal or good or optimal customer use: In other words, they did not remain in spare parts warehouse more than 15 days before the installation (see Fig. 15.13).

Moreover, parts with bad forecasts were investigated to understand the reasons with very encouraging results: In fact, errors were usually caused by preventive maintenance operations, machines revision, changes of suppliers, or changes

Fig. 15.13 Simulated stock-out periods (months) and real utilization of dispatched replacements

in the application of the component not pointed out by the customer. The effect of the extension of the covering period was analyzed by testing the new method with different values of T . For increasing T , we get an increasing stock of spare parts, but the number of stock breakages strongly decreases: In fact for $T = 1$ month, the method well-performed for the 88% of the parts is investigated, and this percentage increased up to 90% for $T = 3$ months, to 95% for $T = 6$ months, and to 98% for $T = 1$ year. Therefore, it was possible to study the

Fig. 15.14 Real use compared to supplying time T

Fig. 15.15 Sensibility to MTBF evaluation

optimum extension of the covering period that for the 190 components investigated was found equal to 3 periods (see Fig. 15.14).

Some simulations with different values of MTBF show the influence of its approximate evaluation: Values of MTBF overestimated for 10% and 20% reduce the performance of the method, respectively, of 6% and 9% in terms of percentage number of spare parts without stock-out periods (see Fig. 15.15).

In spite of this important conclusion, it is important to remember that MTBF values have to be updated, starting from the initial value of $MTBF_{initial}$, by the feedback information from the customers; the most suitable control parameter is the component quantity Y employed by the customer during the covering period T and the relation (15.30) that gave the best results, as shown in Figs. 15.16 and 15.17:

$$MTBF_{updated} = \frac{MTBF_{initial} \cdot (MTBF_{initial}) + \frac{nT}{Y} \cdot (nT)}{MTBF_{initial} + nT} \quad (15.30)$$

where $MTBF_{updated}$ is the weighted average of $MTBF_{initial}$, and $\frac{nT}{Y}$ (weights under round brackets).

Fig. 15.17 MTBF correction effect on items' utilization

15.7 Binomial Model Extension Based on Total Cost Function

The proposed model required the assumption of a specific spare part LS defined as the probability of finding the part in case of breakdown. Some simulations with different values of LS show that it is important to assume $LS \leq 80\%$ and to reserve $LS \geq 90\%$ for particular situation, e.g., customers placed in a far country or without skilled workers. It is possible to determinate the number N of replaceable parts needs and therefore the LS value capable of minimizing a total cost function defined by the sum of storage costs and production losses costs [30, 31].

15.7.1 Service Level Optimization: Minimum Total Cost Method

The aim of this paragraph is to determine the requirement N of replaceable parts capable of minimizing a total cost function defined by the sum of production losses costs C_1 and storage costs C_2 . During the time T_s , production losses could occur if the number of failures exceeds the number N of supplied parts which are available after the consignment

Fig. 15.18 Graphical solution for this methodology

internal use and for replacements ordered by customers according to a fixed EOQ (Economic Order Quantity). The application deals with the optimization of supplying time in order to reduce the total management costs of spare parts at assigned EOQ, that is, the aim is to define the time between consignments capable of reducing total costs with the same value of EOQ. Three components (a support grid, the

clamp, and a special gasket) are considered with a downtime calculated as

$$\text{Downtime} = \text{MTTR} \cdot d \cdot n \quad (15.37)$$

In particular, the support grid has $n = 5$ employments, $H = 1760$ total hours per year, $d = 0.5$ annual part consumption [unit/year] on the whole, $\text{MTTR} = 10$ [hours], $\text{MTBF} = 8800$ [hours], down time cost per hour $C_m = 1000$ [€/hour], and as a consequence, $\text{CM} = C_m \cdot \text{MTTR} = 10,000$ [€] cost for a production lack. This component was supplied in fixed EOQ with $N = 3$ elements, at a cost per unit $R = 100$ [€/unit] ($R \ll C_m$); the relative risk of damage and obsolescence suggests $t = 0,1$ for the annual stoking cost index. Entering the abacus with these values for N , CM , and $R \cdot t$ (see Fig. 15.18), we obtain as a result the optimal time for supply $T_s = 400$ [days]; by means of Eqs. (15.31) and (15.32) with $N = x_1 + x_2 = 0 + 3$ ($x_1 = 0$ because $\text{MTBF} < T_s$), we determine $\text{LS} \approx 99\%$: This very high level is due to low values for t and R/C_m rate.

The results following by the use of the graphic abacus are shown in Table 15.8 for the whole set of components.

Table 15.8 Optimization of T_S for fixed number of spare parts N

Component	$N = x_1 + x_2$	T_S (days)	LS
Support grid	3	400	99%
Clamp	4	90	98%
Special gasket	5	90	95%

Results are summarized in Fig. 15.19 and compared with the output of an existent minimum cost method based on Poisson distribution.

15.8 Weibull Extension

The innovative methodology can be extended to the whole lifetime by implementing the Weibull failure rate function to LTI spare parts stock level in maintenance system with declared wear conditions. Weibull distribution is one of the most commonly used lifetime distributions, and it is flexible in modeling failure time data, as the corresponding failure rate function can vary or assumed to be constant. Literature offers a lot of papers dealing with models for bathtub-shaped failure rate. For example, Hjorth [36] proposed a three-parameter distribution; Mudholkar and Srivastava introduced an exponential Weibull distribution [37]; Chen [39] spoke about a two-parameter lifetime distribution with bathtub shape or increasing failure rate function; Xie [39] wrote a very interesting paper about a model that can be seen as a

generalization of the Weibull distribution and tries to improve the procedure of estimation of the parameters.

The estimation of well-known parameters η (scale) and β (shape) in a Weibull distribution can be performed graphically, but this is not accurate unless we have a large sample size, not always available in case of LTI spare parts; anyway, we focus our attention to the final zone in the traditional “bathtub” wear model, and our aim is to understand whether the hypothesis of constant failure rate in our previous works increases or not the spare parts costs, in comparison with more sophisticated distributions. For this reason, we developed our model by the use of traditional Weibull distribution, but any model mentioned above can be easily stretched.

15.8.1 The Modified Model Extension by Weibull Distribution

By historical data, it is possible to determine the cumulative percentage of components failures related to the lifetime. The graphic approach of Fig. 15.20 permits the definition of the Weibull distribution parameters η (scale parameter) and β (shape parameter). This is possible by Plait transformation (Weibull transformation): Starting from the failure rate calculated as in (15.38), the reliability as in (15.39), the cumulative distribution functions as in (15.40), and the definition of a normalized parameter x as in (15.41), find a linear correlation between the parameter x and cumulative distribution function (15.42 and 15.43), represented in Fig. 15.20.

$$\lambda(t) = \frac{d}{dt} \left(\frac{t}{\eta} \right)^\beta = \frac{\beta}{\eta} \left(\frac{t}{\eta} \right)^{\beta-1} = \frac{\beta}{\eta^\beta} t^{\beta-1} \quad (15.38)$$

$$R(t) = e^{-\left(\frac{t}{\eta}\right)^\beta} \quad (15.39)$$

$$F(t) = 1 - R(t) = e^{-\left(\frac{t}{\eta}\right)^\beta} \quad (15.40)$$

$$x = -\frac{t}{\eta} \quad (15.41)$$

$$\beta \text{Ln}(x) = \text{Ln} \left(\text{Ln} \left(\frac{1}{1 - F(x)} \right) \right) \quad (15.42)$$

The optimal replacements number of LTI spare parts are also given by relation (15.25), while relations (15.27) and (15.28) are modified with Weibull parameters η and β :

$$p = Q(T_{\text{residual}}) = 1 - e^{-\left(\frac{t}{\eta}\right)^\beta} \quad (15.43)$$

Fig. 15.20 Graphical estimation of the β value

$$P(x \leq x_2; n; Q(T_{\text{residual}})) = \sum_{i=0}^{x_2} \binom{n}{i} (1-p)^{n-i} \cdot p^i \tag{15.44}$$

It is possible to quantify the no-stock-out confidence level to compare with the customer satisfaction as $LS(x_2) = 1 - P(x \leq x_2; n; Q(T_{\text{residual}}))$. As previously stated, LS must be close to 100% when $C_m \gg R$, while in the opposite case the optimum LS is variable in function of $T_S \cdot d$, but in this case for assigned MTBF the optimum LS increases likewise the number of employments n .

15.8.2 Simulation and Results

This extended model is compared with previously proposed models for different values of the parameters involved. The relation between the parameters MTBF, T_S , and β appears

very interesting. In fact, the first two parameters are fundamental to find the quantity x_2 (15.29), (15.44), while β indicates the gap from the hypothesis of constant failure rate. Surface of Fig. 15.21 (with T_S equal to 500 hours and customer service level 95%) relates the difference of optimal replacement numbers, respectively, calculated by (15.29) or (15.44) for given MTBF and β values. For a fixed value of MTBF, the saving increases with greater values of β , because the use of Weibull distribution takes into account that the failures are grouped in a specific time region where part breakdowns present a high probability to occur. The MTBF value of 500 hours is very important because it defines T_{residual} equal to zero, and so x_2 is equal to zero for any approach. Values of MTBF lower than 500 hours mean that optimal replacements number is influenced by quantity x_1 , while values greater than 500 are defined by the only use of quantity x_2 (x_1 equal to zero). Considering an MTBF range starting from T_S value and for a specific value of β , the saving of spare parts needed decreases with greater values of MTBF,

Fig. 15.21 Difference of optimal replacements numbers respectively calculated by (15.29) or (15.44) respect to the average life of the component MTBF and β values

Fig. 15.22 Share of saving respect failure rate constant hypothesis in case of different values of parameters

as shown in Fig. 15.22 where two different values of the parameter T_S (respectively, 500 and 1000 hours) are compared. Figure 15.23, as Fig. 15.24, relates the difference between the optimal replacements number calculated by (15.29) and by (15.44) for T_S equal to 1500 hours.

Obviously, a low frequency of consignment creates a greater requirement of spare parts. Also in this case, it is important to notice that methods behave as one for MTBF equal to T_S .

15.9 A Differentiated Approach for Spare Parts: Standard Versus Custom-Made Components

There are many situations in which it is necessary to manage different components, commercial components and specific components. The former identify the so-called “standard”

materials, which can be found directly on the common spare parts market, while the construction codes are all those custom-made components. Each macrofamily requires differentiated management depending on different factors, such as the differential cost, which often characterizes the construction materials from the commercial, rather than the supply lead times, usually longer for the former. The case study refers to a large-scale plant engineering sector with a spare

Fig. 15.25 Reference sample of the codes (CM ## commercial code, CS ## constructive code)

parts park consisting of these two macrofamilies; in order to perform detailed and consistent analyzes, a representative sample of the entire spare parts park was extracted. The sample contains different types of codes (5 commercial and 5 constructive) with different characteristics:

- Codes subject to wear – they must be replaced periodically with new ones; therefore, they present a consumption history characterized by significant movement. These are therefore interesting codes to be analyzed in terms of forecasting.
- Planned codes (Fig. 15.25).

The following information is also shown in the table:

- Current forecast value (PREV) set by the spare parts dealer
- Current safety stock value (SS) set by the spare parts dealer
- Repetitiveness (TAB) set by the spare parts dealer
- Current stock value (Giac)
- Service level (LS Des) imposed by company policy
- Calculated service level (LS Giac) based on the current stock value
- Type of code (T.A.)
- Lead time (LT) set to system

The following data was retrieved for each code:

- Average consumption in the past years (from 01/2013 to 06/2018) [units/month]
- Monthly stock trend (from 01/2013 to 06/2018)
- Total number of applications, calculated on the basis of the number of machines in the park installed, globally, in which the code is mounted, and the number of components present in each equipment
- Average consumption calculated as the reciprocal of the component's running time (Fig. 15.26)

All forecasting methods, except for the Poisson method and the binomial method, use only the consumption history as the database and provide the sales trend; on the contrary, the Poisson method and the binomial method provide a sales forecast value for a given time horizon. The results obtained from the application of the models to the components of the commercial (CM) and construction (CS) categories are critically compared below. The results relating to the codes CM01 and CS01 are reported, to which all the models excluded the Poisson method and the binomial method, and CM02 and CS03, to which only the Poisson method and the binomial method are applied. In the following is the historical consumption and monthly trend of stock patterns five years and a half long [units] for codes CM01 (a coupled bearing), CS01 (a belt), CM02 (a roller), and CS03 (a guide) (Figs. 15.27, 15.28, 15.29, and 15.30):

15.9.1 Performance Analysis of Statistical Models

The performance of statistical methods for the analysis of time series with exponential smoothing parameters depends on how the same smoothing parameters are estimated: Significant improvements in the performance of the forecasting methods can be obtained by further analyzing the historical series of consumption relating to the various codes making up the selected reference sample. The following values were used for the applications discussed:

- For the SES and DES models, the optimal parameters are calculated using an ARIMA model.
- For the Winter models (MW and AW), smoothing parameters are used for the various components equal to 0.2, as recommended by the literature.

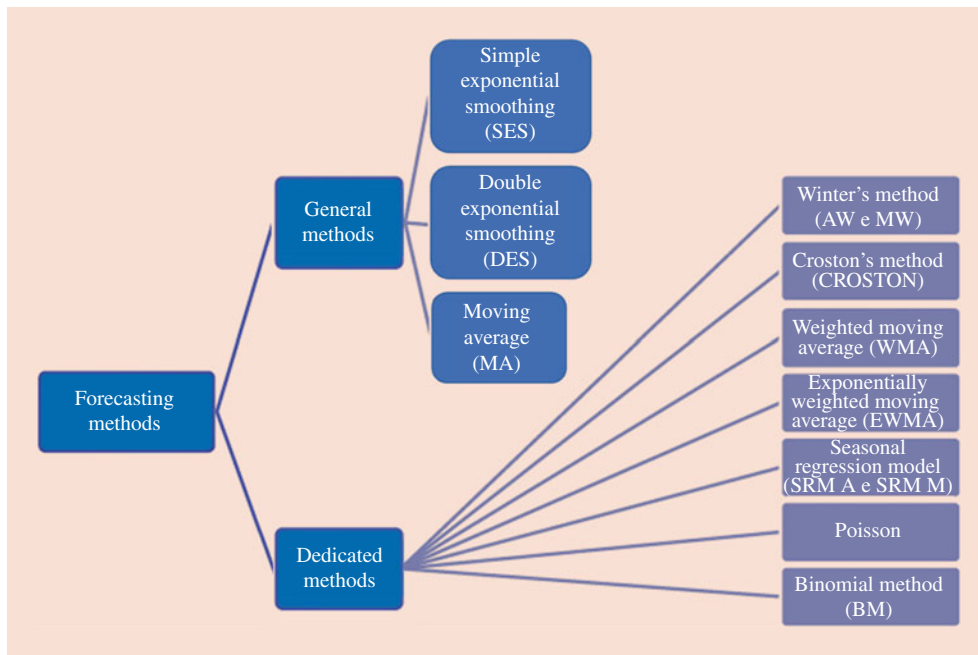

Fig. 15.26 Forecasting methods applied to the reference sample

Fig. 15.27 Historical consumption and monthly trend of stock patterns for code CM01

- For the WMA and EWMA models, it is advisable to carry out the analysis of the optimal value of the parameter N , number of periods considered in the time window.
- For the Croston model, it is advisable to carry out the analysis of the smoothing coefficient α .

The proposed Key Performance Indicator for a quantitative evaluation of the predictive capacity of the models is a standardized MAD:

$$KPI = \frac{MAD}{A} = \frac{\sum_{i=1}^n |\varepsilon_{ri} - \varepsilon_{\hat{r}i}|}{\frac{n}{\sum_{i=1}^n \varepsilon_{ri}}}$$

ε_{ri} = real historical consumption data for the i -th period
 $\varepsilon_{\hat{r}i}$ = forecast for the i -th period
 n = number of periods (months)

The indicator was calculated for each code in the sample codes and for all the models considered in order to draw up

Fig. 15.28 Historical consumption and monthly trend of stock patterns for code CS01

Fig. 15.29 Historical consumption and monthly trend of stock patterns for code CM02

a performance classification; the best performances correspond to MAD/A values much lower than the unit, while the worst ones are characterized by values higher than the unit (Fig. 15.31).

The average value of MAD/A is 0.78, which means that on average the forecasting methods used have performed

well; moreover, best values are obtained for CS03 and CS04 codes having a lumpy demand. The following table shows the ranking of the performance of the different methods for all the codes analyzed (Fig. 15.32).

It is therefore possible to construct a ranking based on the performances obtained by the different methods for the

Fig. 15.30 Historical consumption and monthly trend of stock patterns for code CS03

Fig. 15.31 Rend of the MAD/A indicator by code for different methods

various codes, associating a score to each method, corresponding to its position. For instance, Croston method ranks in fourth position for CM01, in sixth position for CM02, etc.; to this model, 4 points for CM01, 6 points for CM02, etc., are assigned, for a total amount of 62 points. On the basis of this allocation criterion, the lower the score, the better the overall performance of the model. The Additive Seasonal Regression Model (SRM_A) appears to be the most applicable forecasting method to the spare parts fleet.

15.9.2 Performance Analysis of Poisson and Binomial Models

The same methodology of investigation was adopted for the Poisson method and the binomial method, as they can be easily compared; since they both provide a prediction concerning the number of pieces that will be consumed during a certain time horizon, set a certain level of service (LS). The following tables show the forecast values provided by

the Poisson method and the binomial method, as regards the consumption history (Figs. 15.33 and 15.34).

By cross-checking the forecast values obtained by the Poisson model, with those generated by the binomial method, the fact immediately emerges that the former, with the same time horizon and service level adopted, are greater than the

latter. This is in accordance with the technical literature, from which it is derived that the binomial method was precisely introduced as a development of the application of the Poisson formula with which often inaccurate and tending to overestimate forecasts are recorded. It can therefore be stated that based on the information and the methods with which

the forecast analyses were conducted, the binomial method is more efficient than the Poisson model. Also, for this comparison the same KPI used for the comparison between the statistical models was used.

From the observation of the obtained MAD/A values, it can immediately be deduced that, CS04 code apart, the binomial method has excellent performances. The average value of MAD/A is 0.40, which means that the binomial method is the best performing for the spare fleet (Fig. 15.35).

15.9.3 Operational Management of Spare Parts

In addition to identifying the best method for forecasting the quantity of parts for each spare part that the market

will require, the company must also be able to operatively manage its own codes, with the aim of achieving a correct optimization policy. Therefore, the company will have to simultaneously determine the spare parts that will be consumed in the coming **months**, using one of the forecasting models studied, and define what will actually be the correct quantity of components to keep in stock over a given time horizon. The objective of the criterion of minimum global cost is to determine the optimal number of spare parts to keep in stock corresponding to the best trade-off between the overall cost related to their management.

$$\min C_{tot}(N) = C_1 + C_2$$

N = optimal number of spare parts of the code to keep in stock

$C_1 = R \cdot \varphi \cdot [N \cdot pd,T,0 + (N - 1) \cdot pd,T,1 + (N - 2) \cdot pd,T,2 + \dots + pd,T,N - 1]$ storage cost

T = duration of the procurement cycle [unit of time]; it is the sum of the time of issue of the purchase order and the procurement time

d = average code consumption per unit of time [units/unit of time]; it is the average value based on the consumption history

$P_{d,T,x}$ = probability that x requests of the same spare will occur in the interval T

R = purchase cost of the code [€]

φ = distribution overhead [%]; it is the percentage rate expressing the cost of stock

$R \cdot \varphi$ = specific annual cost of storage [€/year]

$C_2 = C_m \cdot d \cdot P$ stock-out cost

C_m = unit cost of stock-out [€/units]

P = probability of higher demand for N spare parts in the interval T

Fig. 15.36 Optimal units in stock and trade-off for the CS04 code ($d = 0.62$ units/month, $T = 4033$ months, $R = 9,59$ €, $\rho = 0.2$)

$$P = P_{d,T,N+1} + P_{d,T,N+2} + P_{d,T,N+3} + \dots$$

$$= 1 - (P_{d,T,0} + P_{d,T,1} + P_{d,T,2} + \dots + P_{d,T,N})$$

The distribution overhead φ depends on the fixed and variable costs related to the management of the materials in stock and the number of movements in a year. The following cost items are considered as follows (annual costs):

- Overhead costs on the “warehouse cost center”
- Cost of the staff involved
- Cost of utilities (electricity, methane gas...)
- Cost for warehouse maintenance
- Cost of material handling
- Depreciation
- Other costs

The total amount of these costs is spread over the number of units handled in a year for each code; this means that the costs of the spare parts in stock, with zero rotation index, are then divided between the materials with nonzero rotation index.

The determination of the costs of stock-out is different for a manufacturing company with respect to a user: The unavailability of a spare part for a customer can have different effects on company costs, depending on different factors; among them may be the importance of this spare code for the requesting customer, which fundamentally depends on the possibility that the unavailability of the component entails the nonproduction of the customer. This situation is reflected in the issue of an urgent request by the customer. In other cases where production is not stopped, for example, for material required to replenish the customer’s spare parts warehouse, the customer’s request follows an ordinary procedure: In these cases, there is no economic damage for the manufacturing company (Fig. 15.36).

$$C_m = \alpha \cdot R + V$$

α = percentage corresponding to the increase in the purchase cost that the producer must incur for his emergency supply [%]; in this case study, $\alpha = 0.1$ and $\alpha = 0.05$ for construction and commercial components, respectively
 V = sale price of the code to the customer [€]

Emilio Ferrari received his MSc in Mechanical engineering at the University of Bologna in 1988. He worked in the industrial sector of packaging. He is Full Professor in Industrial Logistics, Past Deputy Rector of Bologna University, and President of CINECA, Consortium of Universities and Government for services and HPC. He works now on the design and optimization of industrial production systems.

Arrigo Pareschi graduated in Nuclear Engineering at Bologna University in 1969. He was full professor of “Industrial Plants,” Dean of Engineering Faculty (1995–2001), and President of Scientific Research Observatory in the same University. He is author/coauthor of 105 scientific papers, concerning industrial production systems, logistics, and technological innovation and author of four books of interest for university students and engineers.

Alberto Regattieri is a full professor in Logistics and Head of the Management Engineering Master Course at the University of Bologna (Italy). His current research interests include the optimal design of manufacturing systems, innovative approaches (based on Industry 4.0 key technologies) to design and manage handling and stocking systems, to control and manage maintenance of industrial plants. He is/was responsible of several research projects in cooperation with – and funded by – European Commission, private and public companies, universities, and international research centers regarding logistics and manufacturing processes. He published more than 170 scientific papers.

Alessandro Persona is full professor in Logistics at the University of Padua. His current research interests deal with Production, Operations management, Operations research, Supply chain and Flexibility. His Production research includes elements of Industrial engineering, Risk analysis, Relevant cost, Optimal maintenance and Process. His research in the fields of Spare part and Stock-taking overlaps with other disciplines such as Information technology and Order.

D-Efficient Mixed-Level Foldover Designs for Screening Experiments

Abstract

Definitive screening design (DSD) is a new class of three-level screening designs proposed by Jones and Nachtsheim [3] which only requires $2m + 1$ runs for experiments with m three-level quantitative factors. The design matrices for DSDs are of the form $(\mathbf{C}', -\mathbf{C}', \mathbf{0})'$ where \mathbf{C} is a $(0, \pm 1)$ submatrix with zero diagonal and $\mathbf{0}$ is a column vector of 0's. This paper reviews recent development on D-efficient mixed-level foldover designs for screening experiments. It then discusses a fast coordinate-exchange algorithm for constructing D-efficient DSD-augmented designs (ADSDs). This algorithm provides a new class

of conference matrix-based mixed-level foldover designs (MLFODs) for screening experiments as introduced by Jones and Nachtsheim [4]. In addition, the paper also provides an alternative class of D-efficient MLFODs and an exhaustive algorithm for constructing the new designs. A case study comparing two candidate MLFODs for a large mixed-level screening experiment with 17 factors used is used to demonstrate the properties of the new designs.

Conference matrix · Coordinate-exchange algorithm · Foldover design · Hadamard matrix · Plackett-Burman design

16.1 Introduction

Screening experiments are designed to sort a typically long list of factors that can potentially affect the response variables of a product or process. The sorting highlights active factors. This experimentation strategy is widely applied in science and engineering. Another approach, pioneered by Genichi Taguchi, is to follow an experimental path of system design, parameter design, and tolerance design [6]. In this paper we consider the screening-optimizing continuum with the objective of improving the knowledge acquisition effort by increasing its quality and reducing the required effort. Most screening experiments in engineering and science involve both two-level and three-level factors. Yet, the most popular screening designs are two-level designs such as resolution III and IV fractional factorial designs (FFDs). Jones and Nachtsheim [3] pointed out the following disadvantages of using two-level FFDs to study quantitative factors:

- (i) Quadratic effects are not estimable if they are included in the model;

- (ii) Main effects are not completely orthogonal to two-factor interactions as in the case of resolution III FFDs;
- (iii) Certain two-factor interactions are fully aliased with one another as in the case of resolution IV FFDs;

A new class of three-level screening designs called DSDs introduced by Jones and Nachtshiem [3] eliminates these shortcomings. In addition, all quadratic effects of DSDs are orthogonal to main effects and not fully aliased with two-factor interactions. The design matrix for a DSD can be written as:

$$\begin{pmatrix} \mathbf{C} \\ -\mathbf{C} \\ \mathbf{0}' \end{pmatrix}, \tag{16.1}$$

where \mathbf{C} is an $m \times m$ $(0, \pm 1)$ submatrix with zero diagonal and $\mathbf{0}$ is a column vector of 0's. Xiao et al. [14] pointed out that if we use a *conference* matrix of order m for \mathbf{C} , i.e., if $\mathbf{C}'\mathbf{C} = (m - 1) \mathbf{I}_{m \times m}$, then the DSD is also orthogonal for main effects, i.e., all main effects are orthogonal to one another. For even $m \leq 50$ except for $m = 22$ and $m = 34$, the \mathbf{C} matrices which are also conference matrices are given by Xiao et al. [14] and Nguyen and Stylianou [11]. All the \mathbf{C} matrices we use in this paper are conference matrices with the exception of the one of order 22. Figure 16.1 shows the \mathbf{C} matrices of order $m = 4, 6, 8,$ and 10 generated by the cyclic generators given by Nguyen and Stylianou [11].

The limitation of a DSD is that all factors should be quantitative. Jones and Nachtshiem [4] (hereafter abbreviated as JN) introduced two types of conference matrix-based mixed-level screening designs. They called the more D-efficient, more economic one, DSD-augmented designs (ADSDs). ADSDs are in fact belonging to a class of mixed-level foldover designs (MLFODs), and, as such, they retain two advantages of the original DSD, namely, (i) all quadratic effects are orthogonal to main effects and (ii) all main effects are orthogonal to two-factor interactions. The latter feature is extremely useful when the experimenter wishes to include a

specific two-factor interaction in the model. The limitation of this class of designs is that it has a high correlation among the quadratic effects. JN showed that this correlation was $\frac{1}{2} - \frac{2}{n-4}$ where n is the number of runs.

Nguyen et al. [12] introduced a new class of Hadamard matrix-based mixed-level foldover designs (MLFODs) and an algorithm which produces these MLFODs. These MLFODs were constructed by converting some two-level columns of a Hadamard matrix to three-level ones (see [2] for the information on Hadamard matrices and their use in design construction). Like the two-level foldover designs (FODs), each new MLFOD was constructed by a half fraction and its foldover. These Hadamard matrix-based MLFODs require fewer runs and compare favorably with the conference matrix-based MLFODs of [4] in terms of the D-efficiencies and r_{max} , the maximum of the absolute values of the correlation coefficients among the columns of the model matrix. Like the ADSDs, these MLFODs are also *definitive* in the sense that the estimates of all main effects are unbiased with respect to any active second-order effects. The limitation of this class of Hadamard matrix-based MLFODs is that it is not very efficient when the number of three-level factors is greater than the number of two-level ones.

The design matrix of a conference matrix-based MLFOD for m_3 three-level factors and m_2 two-level factors has a foldover structure and can be written as:

$$\begin{pmatrix} \mathbf{D} \\ -\mathbf{D} \end{pmatrix}, \tag{16.2}$$

where the submatrix $\mathbf{D}_{m^* \times (m_3+m_2)}$ can be constructed from a matrix of order m ($m_3 + m_2 \leq m \leq m^*$). In the following sections, we describe (i) a fast coordinate-exchange algorithm (CEA) [8] for constructing ADSDs which are conference matrix based and (ii) an exhaustive search algorithm or ESA for constructing an alternative class of MLFODs. Both algorithms attempt to transform a base matrix to the submatrix \mathbf{D} in (16.2) from which a D-efficient MLFOD can be obtained. For ADSDs, the base matrix is a conference matrix. For the new MLFODs, the base matrix is a two-level orthogonal matrix such as Hadamard matrix or a Plackett-Burman design [13].

16.2 A CEA for Constructing D-efficient ADSDs

The Appendix shows that the first-order and second-order D-efficiencies d_1 and d_2 of an ADSD are functions of $|\mathbf{B}|$ ($= |\mathbf{D}'\mathbf{D}|$) where $|\mathbf{B}|$ is the determinant of matrix \mathbf{B} . Our algorithm minimizes the sum of squares of the off-diagonal elements of \mathbf{B} as an indirect attempt to maximize $|\mathbf{B}|$

(see, e.g., [9]). The steps of our CEA for obtaining a submatrix **D** in (2) from which a D-efficient ADSD for m_3 three-level factors and m_2 two-level factors are:

1. Form a starting design $\mathbf{D}_{(m+1) \times (m_3+m_2)} = (d_{ij})$ by first picking $m_3 + m_2$ columns from a conference matrix of order m at random and add an extra zero row to the bottom of these columns. Mark the positions of the $2m_2$ zero entries in the last m_2 columns of **D**, and replace these 0's by ± 1 in a random manner. Calculate the vector \mathbf{J}_i ($i = 1, \dots, m + 1$) of length $m_3m_2 + \binom{m_2}{2}$ for each row of **D** where \mathbf{J}_i is defined as $(d_{i1}d_{i(m_3+1)}, \dots, d_{im_3}d_{i(m_3+m_2)}, d_{i(m_3+1)}d_{i(m_3+2)}, \dots, d_{i(m_3+m_2-1)}d_{i(m_3+m_2)})$. Let $\mathbf{J} = \sum_{i=1}^{m+1} \mathbf{J}_i$ and f equal the sum of squares of the elements of **J**.
2. Among the $2m_2$ marked positions in Step 1, search for a position such that the sign switch in this position results in the biggest reduction in f . If the search is successful, update f , **J** and **D**. Repeat this step until f equals the length of **J** (i.e., all elements of **J** equal ± 1) or this value cannot be reduced further by any sign switch.

Remarks

- (i) The above steps correspond to one “try” of the CEA and each try produces a matrix **D**. Among a large number of tries whose f value reaches its lower bound, i.e., f equals **J**'s length (or f cannot be reduced further), the one with the largest value of $|\mathbf{B}|$ is selected.
- (ii) The purpose of picking at random $m_3 + m_2$ columns from a conference matrix of order m ($m \geq m_3 + m_2$) to form **D** in a random manner is to avoid being trapped in the local optima.
- (iii) When the input matrix in Step 1 is a conference matrix, the first m_3m_2 elements of **J** always take values ± 1 . This is not the case when the input matrix is not a conference matrix such as the one of order 22.
- (iv) Our CEA is less prone to the curse of dimensionality than JN's exhaustive algorithm for ADSD construction which attempts to maximize $|\mathbf{B}|$ from among the 2^{2m_2} arrangements for $2m_2$ entries in **D**.

Figure 16.2 shows the steps of constructing an ADSD for four three-level factors and four two-level factors. Figure 16.2a displays a starting design in Step 1. Figure 16.2b shows that the eight 0's in the last four columns of the design in Fig. 16.2a are being replaced by ± 1 in a random manner. At this point, the vector **J** is (1, 1, 1, 1, 1, -1, 1, 1, 1, 1, -1, -1, -1, 1, 1, -3, 1, -1, 1, -1, 3) and f is 38. Figure 16.2c,d correspond to Step 2. In Fig. 16.2c, the value 1 in the position (1, 7) of the design in Fig. 16.2b is replaced by -1. At this point,

a)	b)	c)	d)

00000000	0000+---	0000+---	0000+---

Fig. 16.2 Steps of constructing an ADSD for four three-level factors and four two-level factors

the vector **J** is (1, 1, -1, 1, 1, -1, -1, 1, 1, 1, -1, -1, -1, -1, 1, -3, -1, -1, -1, -1, 1) and f is reduced to 30. In Fig. 16.2d, the value -1 in the position (2, 5) of the design in Fig. 16.2c is replaced by 1. At this point, the vector **J** is (-1, 1, -1, 1, -1, -1, -1, 1, -1, 1, -1, -1, 1, -1, -1, 1, -1, 1, 1, -1, -1) and f is reduced to 22 which is its lower bound.

16.3 An ESA for Constructing D-efficient MLFODs

While the CEA attempts to convert some three-level columns of a conference matrix into two-level columns, the ESA attempts to convert some two-level columns of a two-level orthogonal matrix into three-level columns. The ESA requires three simple steps:

1. From each base matrix of order m , generate $m - 1$ additional matrices by shifting the columns of this matrix to the left cyclically. From each matrix, use the first $m_3 + m_2$ ($\leq m$) columns to form a starting design $\mathbf{D}_{m \times (m_3+m_2)} = (d_{ij})$.
2. For each matrix obtained from Step 1, generate $\binom{m}{k}$ new matrices by replacing k elements in each of its first m_3 columns by 0's. Here $k = 2, \dots, x$ where x is an integer chosen to be $\lceil \frac{m}{5} \rceil$ where $\lceil \cdot \rceil$ denotes the ceiling function. The replacement is performed so that if $(i_1, j), \dots, (i_k, j)$ are entries in column j being replaced by 0's, and then the entries being replaced by 0's in the next column are $((i_1 + 1) \bmod m, j + 1), ((i_2 + 1) \bmod m, j + 1), \dots, ((i_k + 1) \bmod m, j + 1)$.
3. For each matrix in Step 2, calculate r_{max} , the maximum in terms of absolute value of the correlation coefficients among the columns of the model matrix. Then among the designs with smallest r_{max} , pick the one with the highest d_2 , the D-efficiency for the pure quadratic model (see Eq. (16.8) in the Appendix).

+00++-	0-0++-	+0++-	+0++-

Fig. 16.3 Some candidate designs generated in Step 2 for an MLFOD for four three-level factors and four two-level factors

Remarks

- (i) In Step 1, the base matrix is a two-level orthogonal matrix. This is a Hadamard matrix or a Plackett-Burman design if m is divisible by 4 or a conference matrix with the 0's on the diagonal being replaced by 1's if m is not divisible by 4 but is divisible by 2. The base matrix slightly affects the goodness of the resulting design.
- (ii) For small m , say $m \leq 12$, the starting designs in Step 1 can also be constructed by randomly selecting a subset of $m_3 + m_2$ from m columns of the base matrix.
- (iii) For each pair (m_3, m_2) and a given x , the number of zeros in each of the m_3 three-level columns, the number of candidate designs we have to consider is $m \sum_{k=2}^x \binom{m}{k}$.
- (iv) r_{max} in Step 3 is calculated from the vector $\mathbf{J} = \sum_{i=1}^m \mathbf{J}_i$ of length $2\binom{m_3}{2} + m_3m_2$ where \mathbf{J}_i is defined as $(d_{i1}^2 d_{i2}^2, \dots, d_{i(m_3-1)}^2 d_{im_3}^2, d_{i1}d_{i2}, \dots, d_{i(m_3-1)}d_{im_3}, d_{i1}d_{i(m_3+1)}, \dots, d_{im_3}d_{i(m_3+m_2)})$.

Figure 16.3 shows some candidate designs generated in Step 2 for an MLFOD for four three-level factors and four two-level factors.

16.4 Results and Discussion

Table 16.1 provides $d_1, d_2,$ and r_{max} of 69 D-efficient ADSDs and two sets of corresponding new MLFODs with $m_3 = 4, \dots, 12, m_2 = 1, \dots, m_3,$ and $n \geq 16$. The goodness statistics are the first-order D-efficiency and the second-order D-efficiency, the maximum in terms of the absolute value of the correlation coefficients among $2m_3 + m_2$ columns of the model matrix \mathbf{X} for the pure quadratic model, respectively. The D-efficiencies d_1, d_2 of ADSDs are calculated according to Eqs. (16.5) and (16.8) in the Appendix. The first set of MLFODs labeled MLFOD₁ was obtained by selecting the first $m_3 + m_2$ columns of a conference matrix and then change the 0's to 1's in the last m_2 columns. The second set of MLFODs labeled MLFOD₂ was constructed by the ESA in Sect. 16.3 using $x = \lceil \frac{m}{5} \rceil$.

The advantage of the MLFODs over the orthogonal arrays (for the same number of three-level and two-level factors) is that the former require much less runs. At the same time, the former, unlike the latter, could guarantee that (i) all quadratic effects are orthogonal to main effects and (ii) all main effects are orthogonal to two-factor interactions. While orthogonality does not help in simplifying the data analysis which is now done entirely by computers, they help in the interpretations of the results which is the aim of the experimenters.

ADSs, due to their method of construction, always have two runs more than the corresponding new MLFODs. It can be seen in Table 16.1 that all ADSs have higher d_1 's than the corresponding MLFOD₂'s (but smaller d_1 's than the corresponding MLFOD₁'s). At the same time, nearly all MLFOD₂'s have higher d_2 's than the corresponding ADSs. The r_{max} 's of the ADSs are always higher than the ones of MLFODs. This is due to the fact that the correlation between any two quadratic effect columns is $\frac{1}{2} - \frac{2}{n-4}$ (see JN p. 129). This value approaches 1/2 as n becomes large. In table 16.1, d_1 (or d_2) values of MLFODs printed in bold are higher than the ones of ADSs for the same set of (m_3, m_2) . r_{max} values of MLFODs printed in bold are smaller than the ones of ADSs for the same set of (m_3, m_2) .

With the exception of the ADS for $m_3 = m_2 = 9$ and four ADSs constructed from a C matrix of order 22 (see Table 16.1), all ADSs in Table 16.1 have the f values reaching their lower bound. This fact guarantees that the constructed ADSs will have minimum correlations between a two-level factor and a three-level factor and between any two two-level factors.

Unlike ADSs, our MLFOD₂'s do not guarantee zero correlation among three-level factors. At the same time, unlike our MLFOD₂'s with $n = 16, 24, 32, 40,$ and 48 (whose D matrices were constructed from the Hadamard matrices or Plackett-Burman designs), ADSs do not have zero correlation among the two-level factors.

16.5 An Industrial Case Study

Lin and Kacker [7] describe an experiment aiming to improve the quality and productivity of wave soldering of circuit pack assemblies (CPA). This experiment, summarized in a study by Kenett et al. [6] (p. 474), has four yield variables and 17 factors (controllable variables). The four yield variables are: (i) Insulation resistance, (ii) Cleaning characterization, (iii) Soldering efficiency, and (iv) Solder mask cracking. The 17 factors are: (A) Type of activator, (B) Amount of activator, (C) Type of surfactant, (D) Amount of surfactant, (E) Amount of antioxidant, (F) Type of solvent, (G) Amount of solvent, (H) Amount of flux, (I) Preheat time, (J) Solder temperature, (K) Conveyor speed, (L) Conveyor angle, (M) Wave height setting, (N) Detergent concentration, (O) Detergent

^aRun size of MLFODs. For the same set of (m_3, m_2) ADSD requires two extra runs

temperature, (P) Cleaning conveyor speed (Q) Rinse water temperature. Out of these 17 factors, 7 factors (A), (C), (F), (M), (N), (O), and (Q) are two-level factors and the rest are three-level factors. The aim of this experiment is to single out the active factors and then apply a full quadratic model in these factors.

Let us consider two candidate MLFODs for ten three-level factors and eight two-level factors (including a blocking factor): (a) a 36-run MLFOD constructed by the ESA and (b) a 38-run ADSD. Both designs were constructed from a conference matrix of size 18. We do not consider the 30-run mixed-level screening design of [10] and the orthogonal arrays (http://support.sas.com/techsup/technote/ts723_Designs.txt) for the same number of three- and two-level factors as they are not MLFODs and as such might not possess the advantages of an MLFOD, namely, (i) all quadratic effects are orthogonal to main effects and (ii) all main effects are orthogonal to two-factor interactions. Besides, a 72-run orthogonal array exceeds the available budget for this experiment. Figure 16.4 displays the **D** matrices of two mentioned candidate MLFODs.

Table 16.1 shows the goodness statistics of the two candidate designs. The $d_1, d_2,$ and r_{\max} of the 38-run ADSD are 0.926, 0.371, and 0.441, and the one of the corresponding 36-run MLFOD are 0.838, 0.410, and 0.2. While the 38-run ADSD is superior to the 36-run MLFOD in terms of d_1 , it is inferior to the latter in terms of d_2 and r_{\max} . This pattern can be observed in Table 16.1 for all MLFOD₂'s with $n \geq 24$.

The correlation cell plots of the two candidate designs are shown in Fig. 16.5. These plots, used in Jones and

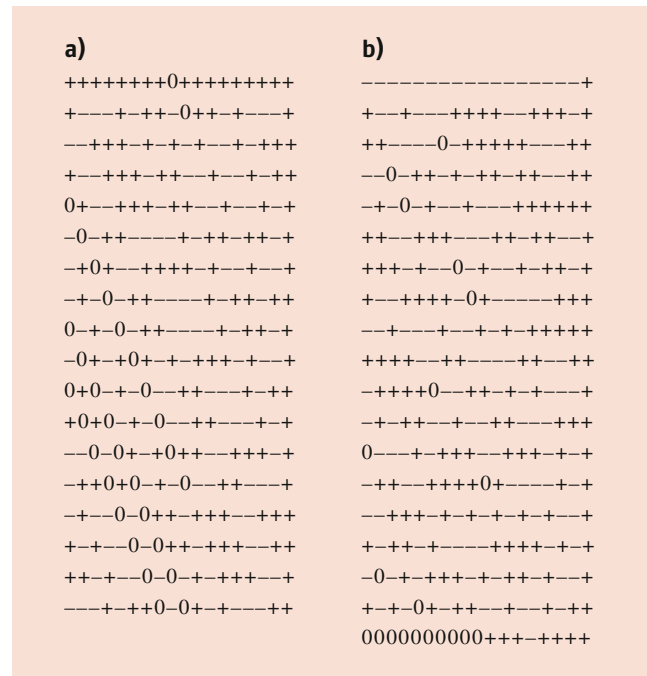

Fig. 16.4 The **D** matrices of two candidate MLFODs for ten three-level factors and eight two-level factors (including a blocking factor) for the PCA experiment described by Kenett et al. [6]: (a) of a 36-run MLFOD constructed by the ESA and (b) of a 38-run ADSD

Nachtsheim [3], display the magnitude of the correlation between main effects, quadratic effects of three-level factors and two-factor interactions in screening designs. The color of each cell in these plots goes from white (no correlation)

Fig. 16.5 Correlation cell plots of (a) 36-run MLFOD constructed by the ESA and (b) a 38-run ADSD for the experiment with ten three-level and eight two-level factors (including a blocking factor)

to dark (correlation of 1 or close to 1). Figure 16.5 confirms that for both designs, the main effects are orthogonal to the quadratic effects and two-factor interactions. It can be seen in Fig. 16.5b that while the main effects of three-level factors have zero correlation, the quadratic effects of these factors have fairly high correlation.

Both algorithms in Sects. 16.2 and 16.3 appear to be very fast and do not seem to be affected by the curse of dimensionality for design optimization. Both algorithms construct the abovementioned 38-run ADSD and 36-run MLFOD for ten three-level factors and eight two-level factors in less than 1 s on an HP EliteBook 8770w laptop. Note that the CEA uses 10,000 tries and out of 10,000 tries, 366 have the f values reaching the lower bound and all of them have the same values of (d_1, d_2, r_{\max}) .

16.6 Conclusion

Screening designs precede efforts to optimize a product or process. Their goal is to reduce a long list of factors so that the optimization effort can focus on a shorter list of factors. The literature on screening experiments in engineering and science popularized experiments with two-level factors such as orthogonal FFDs [1]. This constraint slows down the knowledge acquisition process by producing information only on main effects and interactions. In mixed-level screening designs, one combines factors at two and three levels, thus also producing information on quadratic effects. This paper presents two new classes of MLFODs. Both classes are economical and efficient. These designs provide more choices for the experimenters and help them to “design for

experiments instead of experiment for the design.” A wider scope to this work is the augmentation of data collected in nonexperimental contexts with experimentally designed add-on observations. The analysis of observed data provides initial information on the X space characteristics. To achieve the optimized conditions, the designs discussed in this paper can be used to expand the initial data sets. This approach was mentioned by Kenett and Nguyen [5] with examples of tools used to assess the X space statistical properties. In summary, we aim here at expanding the screening-optimization continuum with more flexible and optimized designs.

The zipped file containing the \mathbf{D} matrices (i.e., half fractions) for the designs in Table 16.1 and the input matrices we use to construct these \mathbf{D} matrices as well as the Java programs implementing the algorithms in Sects. 16.2 and 16.3 is downloadable from <https://drive.google.com/open?id=16thajCMzr4WLib-GkyKrBv2HHnziAIMr>.

Appendix: Calculating (d_1, d_2) Values of an MLFOD

Recall that $\mathbf{D}_{m^* \times (m_3 + m_2)} (= (d_{ij}))$ in (16.2) is the submatrix from which an MLFOD for m_3 three-level factors and m_2 two-level factors can be constructed from a matrix of order m ($m_3 + m_2 \leq m \leq m^*$). For ADSDs $m^* = m + 1$ and for our MLFODs $m^* = m$. The first-order D-efficiency d_1 and the pure quadratic D-efficiency d_2 of this MLFOD can be calculated as:

$$|\mathbf{X}'\mathbf{X}|^{1/p}/n \quad (16.3)$$

where \mathbf{X} , p , and n are the model matrix, the number of parameters for the models, and the number of runs, respectively.

For the first-order model, $p = 1 + m_3 + m_2$ and the i th row of \mathbf{X} can be written as $(1, d_{i1}, \dots, d_{i(m_3+m_2)})$. Thus the (information matrix) $\mathbf{X}'\mathbf{X}$ will be of the form

$$2 \begin{pmatrix} m^* & \mathbf{0}' \\ \mathbf{0} & \mathbf{B} \end{pmatrix}, \quad (16.4)$$

where $\mathbf{0}_{m_3+m_2}$ is a column vector of 0's and $\mathbf{B}_{(m_3+m_2) \times (m_3+m_2)} = \mathbf{D}'\mathbf{D}$. The determinant of $\mathbf{X}'\mathbf{X}$ for the first-order model can now be calculated as

$$|\mathbf{X}'\mathbf{X}| = 2^{1+m_3+m_2} m^* |\mathbf{B}|. \quad (16.5)$$

For the pure quadratic model, $p = 1 + m_3 + m_3 + m_2$ and the i th row of \mathbf{X} can be written as $(1, d_{i1}^2, \dots, d_{im_3}^2, d_{i1}, \dots, d_{i(m_3+m_2)})$. Thus, the matrix $\mathbf{X}'\mathbf{X}$ will be of the form

$$2 \begin{pmatrix} \mathbf{A} & \mathbf{0}' \\ \mathbf{0} & \mathbf{B} \end{pmatrix}, \quad (16.6)$$

where $\mathbf{0}_{(m_3+m_2) \times (1+m_3)}$ a matrix of 0's and $\mathbf{A}_{(1+m_3) \times (1+m_3)}$ is a matrix of the form

$$\begin{pmatrix} m^* & b\mathbf{1}' \\ b\mathbf{1} & \mathbf{A}^* \end{pmatrix} \quad (16.7)$$

assuming each of the m_3 three-level columns of \mathbf{D} has a fixed number b of ± 1 's. Here $\mathbf{1}_{m_3}$ is a column vector of 1's and $\mathbf{A}_{m_3 \times m_3}^*$ the core of \mathbf{A} in (16.7), i.e., the matrix \mathbf{A} without its first row and first column. The determinant of $\mathbf{X}'\mathbf{X}$ for the pure quadratic model can now be calculated as

$$|\mathbf{X}'\mathbf{X}| = 2^{1+2m_3+m_2} m^* |\mathbf{A}^* - \frac{b^2}{m^*} \mathbf{J}| |\mathbf{B}|. \quad (16.8)$$

For some MLFODs such as ADSDs, MLFOD₁, and MLFOD₂ with $n = 16$ and 38, the matrix \mathbf{A}^* in (16.7) will be of the form $c\mathbf{J} + d\mathbf{I}$ where \mathbf{I} is the identity matrix and \mathbf{J} is a matrix of 1's. Nguyen et al. [12] denoted this class of MLFODs as MLFOD*s. In these cases, $\mathbf{A}^* - \frac{b^2}{m^*} \mathbf{J}$ will also be of the form $c\mathbf{J} + d\mathbf{I}$. The determinants of a matrix of this form can be calculated as $d^{m_3} (1 + \frac{c}{d} \frac{m_3}{m})$. For ADSDs, $c = m - 2 - \frac{(m-1)^2}{m+1}$ and $d = 1$. For MLFOD₁, $c = m - 2 - \frac{(m-1)^2}{m}$ and $d = 1$.

Dr Nam-Ky Nguyen got his PhD. at the Indian Agricultural Research Institute, New Delhi, India in 1983. He has been a seasoned statistician with over 20 years of diversified experience in tertiary-level teaching, consulting and research at various universities and research organizations in Australia, USA, Vietnam, Thailand, Cambodia, Nigeria and Ivory Coast. Accredited by the Statistical Society of Australia (ASAT) in 1998. Author of around 50+ publications in applied statistics/computing and collaborative research. Author of the Gendex DOE toolkit. This toolkit is currently in use at several universities and research organizations worldwide. Research interest includes design of experiments, statistical computing and statistical modelling.

Professor Ron Kenett is Chairman of the KPA Group, Israel and Senior Research Fellow at the Neaman Institute, Technion, Haifa, Israel. He is an applied statistician combining expertise in academic, consulting and business domains. He serves on the editorial board of several international journals and was awarded the 2013 Greenfield Medal by the Royal Statistical Society and, in 2018, the Box Medal by the European Network for Business and Industrial Statistics. Ron holds a BSc in Mathematics (with first class honors) from Imperial College, London University and a PhD in Mathematics from the Weizmann Institute of Science, Rehovot, Israel.

Mai Phuong Vuong PhD is a lecturer at the School of Applied Mathematics and Informatics, Hanoi University of Science and Technology. She holds a Bachelor in applied Mathematics and Informatics from Vietnam National University, Hanoi, and a PhD in GeoInformatics from TU Bergakademie Freiberg, Germany. Her current research areas are design of experiments and data science.

Dr Tung Dinh Pham is lecturer at the Vietnam National University – Hanoi University of Science, Vietnam. He is an applied statistician combining expertise in academic, consulting domains. Tung holds a BSc in Mathematics and PhD in Mathematical Statistics from Hanoi University of Science.

Censored Data Prediction Based on Model Selection Approaches

Discrimination · Maximum likelihood estimate · Censored data · Prediction · Location-scale distribution

Abstract

The contribution of this chapter is to solve two common problems in analysis. The first contribution is that we propose two methods to predict censored data. The second contribution is to automatically select the most suitable distribution function instead of subjective judgment. In this chapter, we propose three approaches of model selection. To demonstrate our approach, two members in the location-scale family, the normal distribution and smallest extreme value distribution, are used as candidates to illustrate the best model competition for the underlying distribution via using the proposed prediction methods. According to the result of Monte Carlo simulations, model misspecification has impact on the prediction precision

17.1 Introduction

At present, the advanced manufacturing technology is continuously improving the quality of components. If all test components are to be observed for failure time, it will lead to long experiment time. In order to save testing time and sample resource, censoring schemes are often considered to implement life tests. The type I censoring scheme and type II censoring scheme are two popular censoring schemes based on the criteria of test time censoring and failure number censoring.

In this chapter, the focus is using the type II censoring scheme for predicting the censored data for reliability evaluation when a discriminant problem is considered. In the type II censoring scheme, we consider an experiment where n identical components are placed in the test simultaneously. Assuming that the r th component fails, the experiment would be terminated. Thus, the last $(n - r)$ components are censored. In many engineering applications, censored data are not allowed for implementing statistical methods to obtain information. For example, if practitioners hope to integrate the life test and design of experimental methods, such that manufacturers can introduce a new product into the market quickly. The major difficulty is to implement the design of experimental methods for censored data. Predicting

unobserved order statistics from samples is a way to understand more about the censored data. Once the censored data are predicted, the predicted information with uncensored data can be merged as a pseudo-complete data set. Then the design of experiment methods can be employed for the pseudo-complete data set. The purpose of predicting life length of $s^{\text{th}}(r < s \leq n)$ item is equivalent to the life length of a $(n - s + 1)$ -out-of- n system that was made up of n identical components with independent life lengths. When $s = n$, it is better known as the parallel system. For this issue, various methods have been developed to predict the censored data. In the paper of Kaminsky and Nelson [1], they provided interval and point prediction of order statistics. Fertig et al. [2] proposed Monte Carlo estimates of percentiles of the distribution to construct prediction intervals for samples from a Weibull or extreme value distribution. Kaminsky and Rhodin [3] obtained the maximum likelihood predictor (MLP) to predict the future order statistics for the normal distribution. Wu et al. [4] obtained prediction intervals of future order statistics for the Pareto distribution based on the five new pivotal quantities. Kundu and Raqab [5] proposed the Bayesian prediction for the two-parameter Weibull distribution. Panahi and Sayyareh [6] provided parameter estimation and prediction of order statistics for the Burr type XII distribution. Some of these predictions are complex, or demand complex statistical models. Therefore, these existing methods are not easy to use in the real world.

Many authors also try to simplify the difficulty of the formula, and Raqab [7] provided four modified MLPs (MMLPs) to predict the future order statistics for the normal distribution (ND). Yang and Tong [8] used MMLP method to predict type II censored data from factorial experiments. Chiang [9] provided another three MMLP procedures to predict type II censored data for the Weibull distribution. In his procedures, it is difficult to find the only root solution to the parameter estimation. According to the previous literature, the MMLP method only has simple estimation results under ND, and the prediction results under other distributions are still very complex. So the parameter estimation of MMLP loses the advantage over other commonly used distributions.

The second important problem in life testing experiments is the model selection based on the existing sample. In practical applications, many statistical distributions are much alike, especially in censored data, and the underlying distribution of product quality characteristics is usually unknown. Several candidate models may fit the data well in practical applications. However, the predictions based on different candidate models may lead to a significant difference. Therefore, correct choice of the underlying distribution is of great

importance and has long been studied by many authors. Dumonceaux and Antle [10] used ratio of maximized likelihood (RML) to discriminate between the lognormal and Weibull distributions. Kundu and Manglick [11] proposed a model selection to discriminate between the lognormal and gamma distributions. Kundu and Raqab [12] provided a model selection method to discriminate between the generalized Rayleigh and lognormal distribution. Yu [13] provided a misspecification analysis method for the ND and smallest extreme value distribution (SEV). Ashour and Hashish [14] proposed a numerical comparison study for using RML-procedure, S-procedure, and F-procedure in failure model discrimination. Pakyari [15] proposed diagnostic tools based on the likelihood ratio test and the minimum Kolmogorov distance method to discriminate between the generalized exponential, geometric extreme exponential, and Weibull distributions. Elsherpieny et al. [16] provided a model selection to discriminate the gamma and log-logistic distributions based on progressive type II censored data.

In order to demonstrate our approaches, we take the location-scale family of distributions as an example, due to the well-developed theory and inferential procedures for the location-scale family of distributions, the model discrimination within the location-scale family of distributions is particularly important and it has received much attention. The main purpose of this chapter is to solve these issues and provide simple and satisfactory estimators of parameters and predictors of future order statistics when the underlying model is unknown but belongs to the location-scale family. Specifically, the prediction process of this study for censoring data prediction is presented in Fig. 17.1.

This chapter is based on Chiang et al. [17] and the rest of this chapter is organized as follows. Section 17.2 presents materials and methods. In this section, statistical methods to obtain approximate predictors for type II right-censored variables are studied and two prediction methods are proposed to predict the type II right-censored data based on the AMLEs. The ND and SEV are considered as the candidate distributions in this study to compete for the best model for obtaining the predictors of type II right-censored variables. In Sect. 17.3, we provide three algorithms to implement the three proposed model selection approaches to deal with the discrimination problem when obtaining the predictors of type II right-censored variables based on the proposed methods. An intensive simulation study is conducted in Sect. 17.4 to evaluate the performance of the proposed approaches. Then, three examples are used to demonstrate the applications of the proposed methodologies in Sect. 17.5. Some concluding remarks are provided in Sect. 17.6. The notations used in this chapter are defined in Table 17.1.

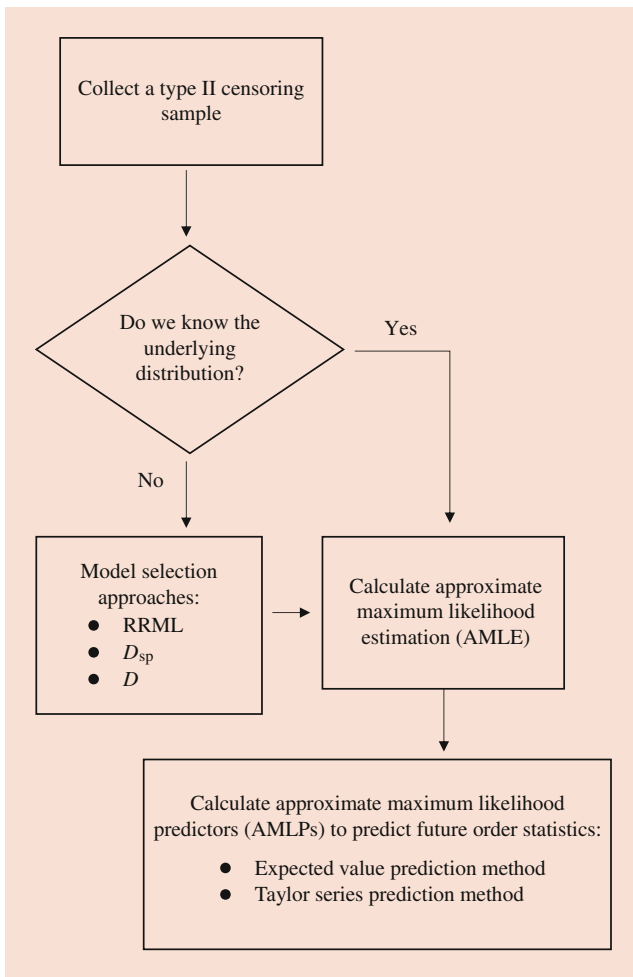

Fig. 17.1 The flow chart of the major contribution of this study

17.2 Methods for Approximate Predictors

17.2.1 Approximate Maximum Likelihood Estimation

Assume that random variable Y_i denotes the failure time of i th item and $X_i = \log(Y_i)$, which follows a location-scale family, having the probability density function (PDF) and cumulative distribution function (CDF):

$$f(x; \mu, \sigma) = \frac{1}{\sigma} g\left(\frac{x - \mu}{\sigma}\right), \quad (17.1)$$

and

$$f(x; \mu, \sigma) = G\left(\frac{x - \mu}{\sigma}\right), \quad -\infty < \mu < \infty, \sigma > 0, \quad (17.2)$$

$$-\infty < x < \infty,$$

respectively, where μ is location parameter and σ is scale parameter. $g(\cdot)$ and $G(\cdot)$ are the PDF and CDF of a member in the location-scale family. Let $\mathbf{x} = (x_{1:n}, x_{2:n}, \dots, x_{r:n})$ denote a type II censored sample and our goal is to predict $x_{s:n}$, where $1 \leq r < s \leq n$. Let $f(x) \equiv f(x; \mu, \sigma)$ and $F(x) \equiv F(x; \mu, \sigma)$ here and after to simplify the notations. Based on the paper of Kaminsky and Rhodin [3], they considered prediction of $X_{s:n}$ having observed. So the predictive likelihood functions (PLF) of $X_{s:n}$, μ and σ is

$$L(X_{s:n}, \mu, \sigma; \mathbf{x}) \equiv f(\mathbf{x}, X_{s:n}; \mu, \sigma) = \frac{n!}{(s-r-1)!(n-s)!} \prod_{j=1}^r f(x_{j:n}) [f(X_{s:n}) - f(x_{r:n})]^{s-r-1} f(X_{s:n}) [1 - f(X_{s:n})]^{n-s}. \quad (17.3)$$

Based on the proposed method by Raqab [7], the PLF of $X_{s:n}$, μ and σ in Eq. (17.3) can be represented as a product of two likelihood functions, the PLF of μ and σ (i.e., which is denoted as L_1) and the PLF of $X_{s:n}$ (i.e., which is denoted as L_2). Both likelihood functions are can be rewritten as

$$L_1(\mu, \sigma; \mathbf{x}) = \frac{n!}{(n-r)!} \prod_{j=1}^r f(x_{j:n}) [1 - f(x_{r:n})]^{n-r}, \quad (17.4)$$

and

$$L_2(X_{s:n}; \mu, \sigma, \mathbf{x}) = \frac{(n-r)!}{(s-r-1)!(n-s)!} \frac{[f(X_{s:n}) - f(x_{r:n})]^{s-r-1}}{[1 - f(x_{r:n})]^{n-r}} \times [1 - f(X_{s:n})]^{n-s} f(X_{s:n}). \quad (17.5)$$

In practice, we can obtain the MLEs of μ and σ , denoted by $\hat{\mu}$ and $\hat{\sigma}$, respectively, through maximizing $L_1(\mu, \sigma; \mathbf{x})$ in Eq. (17.4). Then using $\hat{\mu}$ and $\hat{\sigma}$ to replace μ and σ as the plug-in parameters in Eq. (17.5) to predict $X_{s:n}$. Let $z_{j:n} = (x_{j:n} - \mu)/\sigma$ for $j = 1, \dots, r$, $Z_{s:n} = (X_{s:n} - \mu)/\sigma$ for $s = r + 1, \dots, n$ and $\mathbf{z} = (z_{1:n}, z_{2:n}, \dots, z_{r:n})$, then the Eq. (17.4) and Eq. (17.5) can be rewritten as

$$L_1 \equiv L_1(\mu, \sigma; \mathbf{z}) = C_1 \prod_{j=1}^r \sigma^{-1} f(z_{j:n}) [1 - f(z_{r:n})]^{n-r} \quad (17.6)$$

and

$$L_2 \equiv L_2(Z_{s:n}; \hat{\mu}, \hat{\sigma}, \mathbf{z}) = C_2 \sigma^{-1} \frac{[f(Z_{s:n}) - f(z_{r:n})]^{s-r-1}}{[1 - f(z_{r:n})]^{n-r}} [1 - f(Z_{s:n})]^{n-s} f(Z_{s:n}), \quad (17.7)$$

Table 17.1 Notations and their descriptions

Notations	Descriptions
Y_i	The failure time of i th item of $Y, i = 1, \dots, n$
X_i	Take the logarithm of the Y_i
$f(x; \mu, \sigma), F(x; \mu, \sigma)$	The PDF and CDF of location-scale family with location parameter μ and scale parameter σ , respectively
$g(\cdot), G(\cdot)$	The standard PDF and CDF of location-scale family, respectively
$x_{i:n}$	The i th failure time of n samples of $x, i = 1, \dots, n$
r	The last sample number that can be observed
s	Sample number to prediction, $s = r + 1, \dots, n$
n	Sample size of x
\mathbf{x}	The type II censored sample
z	The standardized value of \mathbf{x}
$L(X_{s:n}, \mu, \sigma; \mathbf{x})$	The PLF of $X_{s:n}$
$L_1(\mu, \sigma; \mathbf{x})$ or L_1	The PLF of μ and σ
$L_2(X_{s:n}; \mu, \sigma, \mathbf{x})$ or L_2	The PLF of $X_{s:n}$
C_1, C_2	The constant in likelihood function
$\hat{\mu}, \hat{\sigma}$	The MLEs of μ and σ
$\tilde{\mu}, \tilde{\sigma}$	The AMLEs of μ and σ
$K, L, \lambda_1, \lambda_2, A_i, B_i, C_r, D_r$	The functions in the AMLE of μ and σ
$T'(\cdot), h'(\cdot), f'(\cdot), \phi'(\cdot)$	The first derivative of $T(\cdot), h(\cdot), f(\cdot)$ and $\phi(\cdot)$, respectively
$\Psi(\cdot), h(\cdot), h_1(\cdot)$	The functions in the log likelihood function
MLP _E , MLP _T	The predictors of $X_{s:n}$ based on the expected prediction method and the Taylor series prediction, respectively
$\hat{X}_{s:n}^{M,1}, \hat{X}_{s:n}^{M,2}$	The MLP _E and MLP _T of the $X_{s:n}$ under the candidate model M , respectively
ND, SEV	The abbreviations of the Normal and smallest extreme value distribution.
$\alpha, \beta, \gamma, \nu_s, \rho$	The functions in the MLP _T of the $X_{s:n}$ under the ND
$\alpha_s, \beta_s, \gamma_E, \nu_E, \rho_E$	The functions in the MLP _T of the $X_{s:n}$ under the SEV
M	The candidate model, $M = N$ (the ND) or SEV
$\hat{L}_{M_i}(\cdot), \hat{L}_N(\cdot), \hat{L}_S(\cdot)$	The PLF of $X_{s:n}$ based on the candidate model M , ND and SEV, respectively
$\hat{\mu}_N, \hat{\sigma}_N$	The MLEs of μ and σ based on the ND
$\phi(\cdot), \Phi(\cdot)$	The PDF and CDF of the standard ND, respectively
$\hat{\mu}_S, \hat{\sigma}_S$	The MLEs of μ and σ based on the SEV.
ϕ_{sev}, Φ_{sev}	The PDF and CDF of the standard SEV, respectively.
$\hat{L}_{A1}(\cdot)$	The maximum likelihood function value in all candidate models
$\hat{\mu}_{A1}, \hat{\sigma}_{A1}$	The MLEs of μ and σ in the distribution corresponding to $\hat{L}_{A1}(\cdot)$.
$\hat{X}_{s:n}^{A1,j}, \hat{X}_{s:n}^{A2,j}, \hat{X}_{s:n}^{A3,j}$	The best prediction value selected by three models respectively, $j = 1, 2$
RRML	The ratio of the maximized likelihood approach
$D_{sp}(\cdot)$	The modification of Michael statistic
$\hat{D}_{SP}^{A2}(\cdot)$	The smallest $D_{sp}(\cdot)$ in all candidate models
$\hat{\mu}_{A2}, \hat{\sigma}_{A2}$	The MLEs of μ and σ in the distribution corresponding to $\hat{D}_{SP}^{A2}(\cdot)$
$D(\cdot)$	The statistic of the Kolmogorov-Smirnov test
$\hat{D}^{A3}(\cdot)$	The smallest $D(\cdot)$ in all candidate models
$\hat{\mu}_{A3}, \hat{\sigma}_{A3}$	The MLEs of μ and σ in the distribution corresponding to $\hat{D}^{A3}(\cdot)$
$\hat{D}_{SP}^N(\cdot), \hat{D}_{SP}^{SEV}(\cdot)$	Evaluate the value of D_{sp} through using the ND and SEV
$\hat{D}^N(\cdot), \hat{D}^{SEV}(\cdot)$	Evaluate the value of D through using the ND and SEV
cp	The censoring proportion
correct(%)	The correct model selection rate
N	The Monte Carlo runs

where $C_1 = n!(n-r)!$ and $C_2 = (n-r)!/(s-r-1)!(n-s)!$. Then, we can obtain the log-likelihood equation as:

$$\frac{\partial \log(L_1)}{\partial \mu} = \frac{1}{\sigma} \left[\sum_{j=1}^r \Psi(z_{j:n}) + (n-r)h(z_{r:n}) \right] = 0 \quad (17.8)$$

$$\frac{\partial \log(L_1)}{\partial \sigma} = \frac{1}{\sigma} \left[-r + \sum_{j=1}^r \Psi(z_{j:n})z_{j:n} + (n-r)h(z_{r:n})z_{r:n} \right] = 0 \quad (17.9)$$

and

$$\frac{\partial \log(L_2)}{\partial Z_{s:n}} = (s-r-1)h_1(z_{r:n}, Z_{s:n}) - \Psi(Z_{s:n}) - (n-s)h(Z_{s:n}) = 0, \quad (17.10)$$

where

$$\Psi(Z_{j:n}) = -\frac{f'(Z_{j:n})}{f(Z_{j:n})}, j = 1, \dots, n, \text{ where } Z_{j:n} = z_{j:n} \text{ if } j \leq r, \quad (17.11)$$

$$h(Z_{j:n}) = \frac{f(Z_{j:n})}{1-f(Z_{j:n})}, j = 1, \dots, n, \text{ where } Z_{j:n} = z_{j:n} \text{ if } j \leq r, \quad (17.12)$$

and

$$h_1(z_{r:n}, Z_{s:n}) = \frac{f(Z_{s:n})}{f(Z_{s:n}) - f(z_{r:n})}. \quad (17.13)$$

We can see that the MLEs of μ and σ cannot be obtained in a closed form. Therefore, the MLEs of μ and σ need to be searched using numerical methods. To obtain proper initial solutions for implementing gradient computation methods, we consider using the AMLEs of μ and σ , denoted by $\tilde{\mu}$ and $\tilde{\sigma}$, respectively, from Hossain and Willan [18] as their initial solutions in this chapter. From the paper of Hossain and Willan [18], the AMLE of μ and σ as:

$$\tilde{\mu} = K - L\tilde{\sigma}, \quad (17.14)$$

and

$$\tilde{\sigma} = \frac{-\lambda_1 + \sqrt{\lambda_1^2 + 4r\lambda_2}}{2r}, \quad (17.15)$$

where

$$K = \frac{\sum_{i=1}^r B_i Z_{j:n} + (n-r)D_r Z_{r:n}}{\sum_{i=1}^r B_i + (n-r)D_r}$$

$$L = \frac{\sum_{i=1}^r A_i - (n-r)C_r}{\sum_{i=1}^r B_i + (n-r)D_r}$$

$$\lambda_1 = \sum_{i=1}^r (Z_{j:n} - K)A_i - (n-r)C_r(Z_{r:n} - K)$$

$$\lambda_2 = \sum_{i=1}^r (Z_{j:n} - K)^2 B_i + (n-r)D_r(Z_{r:n} - K)^2$$

$$A_i = T(v_{i:n}) - v_{i:n}T'(v_{i:n})$$

$$B_i = -T'(v_{i:n})$$

$$C_r = h(v_{r:n}) - v_{r:n}h'(v_{r:n})$$

and

$$D_r = h'(v_{r:n}),$$

where $T'(\cdot)$ and $h'(\cdot)$ are the first derivative of $T(\cdot)$ and $h(\cdot)$, respectively.

17.2.2 Approximate Maximum Likelihood Predictors

We propose two approximation prediction methods to predict $X_{s:n}$, the expected value prediction method and Taylor series prediction method. The resulting predictors of $X_{s:n}$ based on the expected prediction method are denoted by MLP_E , and the resulting predictors of $X_{s:n}$ based on the Taylor series prediction method are denoted by MLP_T . The two approximate methods mainly use two different methods to get the approximate $h_1(z_{r:n}, Z_{s:n})$ and $h(Z_{s:n})$.

The Expected Value Prediction Method

Based on the expected value prediction method, replacing (μ, σ) with $(\hat{\mu}, \hat{\sigma})$, and replacing $h_1(z_{r:n}, Z_{s:n})$ and $h(Z_{s:n})$ by their respective expected values in Eq. (17.10). According to Raqab [7], the expected values of $f(Z_{j:n})$, $h_1(z_{r:n}, Z_{s:n})$, and $h(Z_{s:n})$ can be presented, respectively, by

$$E[f(Z_{j:n})] = \frac{1}{n+1} \sum_{k=j+1}^{n+1} E[\Psi(Z_{k:n+1})], j \leq n \text{ and} \tag{17.16}$$

$$Z_{j:n} = z_{j:n} \text{ if } j \leq r,$$

$$E[h(Z_{j:n})] = \frac{1}{n-j} \sum_{k=j+1}^n E[\Psi(Z_{k:n})], j \leq n-1 \text{ and} \tag{17.17}$$

$$Z_{j:n} = z_{j:n} \text{ if } j \leq r,$$

and

$$E[h_1(Z_{i:n}, Z_{j:n})] = \frac{1}{j-i-1} \sum_{k=j}^n E[\Psi(Z_{k:n})], j-i \geq 2, \text{ and} \tag{17.18}$$

$$Z_{j:n} = z_{j:n} \text{ if } j \leq r.$$

We denote the MLP_E of the $X_{s:n}$ under the candidate model M by $\hat{X}_{s:n}^{M,1}$.

The Taylor Series Prediction Method

Based on the Taylor series prediction method, replacing (μ, σ) with $(\hat{\mu}, \hat{\sigma})$ and replacing $h(Z_{s:n})$ and $h_1(z_{r:n}, Z_{s:n})$ by their Taylor series approximations at the points $F^{-1}(p_s)$ and $(F^{-1}(p_r), F^{-1}(p_s))$, respectively, in Eq. (17.10). We denote the MLP_T of the $X_{s:n}$ under the candidate model M by $\hat{X}_{s:n}^{M,2}$.

In this study, we use ND and SEV as candidates to illustrating the applications of the proposed method. But the suggested algorithms in this study can be applied for the cases with more than two candidate members. The reason to select the ND and SEV as candidates is due to the Weibull distribution and lognormal distribution, which are two widely used distributions for life testing applications. The Weibull and lognormal distributions can be transformed into the SEV and ND, respectively, by taking log-transformation.

- *The normal distribution case:*

If the underlying distribution is normal, the PDF of normal distribution is given by

$$g(Z) = \phi(z) = \frac{1}{\sqrt{2\pi}} e^{-z^2/2}. \tag{17.19}$$

According to Eq. (17.19), we can obtain $\Psi(z) = -\phi'(z)/\phi(z) = z$. The MLEs of ND parameters are denoted by $\hat{\mu}_N$ and $\hat{\sigma}_N$. Replacing μ and σ with $\hat{\mu}_N$ and $\hat{\sigma}_N$ in Eq. (17.6), the Eq. (17.6) can be rewritten as

$$\hat{L}_N(\hat{\mu}_N, \hat{\sigma}_N) = C_1 \prod_{j=1}^r \hat{\sigma}_N^{-1} \phi(z_{j:n}) [1 - \Phi(z_{r:n})]^{n-r}, \tag{17.20}$$

where $\Phi(\cdot)$ is the CDF of the standard ND. According to Eq. (17.17) and Eq. (17.18), $h_1(z_{r:n}, Z_{s:n})$ and $h(Z_{s:n})$ can be replaced by their respective expected values in Eq. (17.10). The Eq. (17.10) can be rewritten as

$$E(Z_{s:n}) - \hat{Z}_{s:n} = 0. \tag{17.21}$$

The value of $E(Z_{j:n})$ is available and has been tabulated by Teichroew [19]. Hence, the MLP_E of $X_{s:n}$ for ND can be derived as

$$\hat{X}_{s:n}^{N,1} = \hat{\mu}_N + \hat{\sigma}_N E(Z_{s:n}). \tag{17.22}$$

Because $E(Z_{s:n}) \geq z_{r:n}$ is a necessary condition, we modify Eq. (17.22) by

$$\hat{X}_{s:n}^{N,1} = \max\{\hat{\mu}_N + \hat{\sigma}_N E(Z_{s:n}), z_{r:n}\} \tag{17.23}$$

and use the $\hat{X}_{s:n}^{N,1}$ in Eq. (17.23) to protect $X_{s:n}$ for $r+1 \leq s \leq n$.

Based on the Taylor series prediction method, the functions $h(Z_{s:n})$ and $h_1(z_{r:n}, Z_{s:n})$ are expand by using the Taylor series around the points $F^{-1}(p_s)$ and $(F^{-1}(p_r), F^{-1}(p_s))$, respectively. According to Raqab [7], we can approximate $h(Z_{s:n})$ and $h_1(z_{r:n}, Z_{s:n})$ by

$$h(Z_{s:n}) = \frac{f(Z_{s:n})}{1-f(Z_{s:n})} \approx \alpha + \beta Z_{s:n}, \tag{17.24}$$

and

$$h_1(z_{r:n}, Z_{s:n}) = \frac{f(Z_{s:n})}{f(Z_{s:n}) - f(z_{r:n})} \approx \gamma + \rho z_{r:n} - \nu_s Z_{s:n}, \tag{17.25}$$

respectively, where

$$\alpha = \frac{f(\eta_s) \{(1 + \eta_s^2) q_s - \eta_s f(\eta_s)\}}{q_s^2},$$

$$\beta = \frac{f(\eta_s) \{f(\eta_s) - q_s \eta_s\}}{q_s^2},$$

$$\gamma = \frac{f(\eta_s) \{(1 + \eta_s^2) p_{sr} + \eta_s f(\eta_s) - \eta_r f(\eta_r)\}}{p_{sr}^2},$$

$$\rho = \frac{f(\eta_r) f(\eta_s)}{p_{sr}^2},$$

$$v_s = \frac{f(\eta_s) \{\eta_s p_{sr} + f(\eta_s)\}}{p_{sr}^2},$$

$$p_{ij} = p_i - p_j, p_i = i / (n + 1).$$

and

$\eta_i = F^{-1}(p_i)$ for $i = 1, 2, \dots, n$. The Eq. (17.10) can be rewritten by

$$(s - r - 1) (\gamma + \rho z_{r:n} - v_s Z_{s:n}) - z_{s:n} - (n - s) (\alpha + \beta Z_{s:n}) = 0. \tag{17.26}$$

The MLP_T of $X_{s:n}$ can be obtained by

$$\hat{X}_{s:n}^{N,2} = \max \left\{ \frac{(s - r - 1) \rho x_{r:n}}{(s - r - 1) v_s + 1 + (n - s) \beta} + \left[1 - \frac{(s - r - 1) \rho}{(s - r - 1) v_s + 1 + (n - s) \beta} \right] \hat{\mu}_N + \frac{(s - r - 1) \gamma - (n - s) \alpha}{(s - r - 1) v_s + 1 + (n - s) \beta} \hat{\sigma}_N, x_{r:n} \right\}, \tag{17.27}$$

where $r + 1 \leq s \leq n$.

• *The smallest extreme value distribution*

If the underlying distribution is SEV, the PDF of the SEV is given by

$$g(z) = \phi_{sev}(z) = e^{z - e^z}. \tag{17.28}$$

Based on the expected value prediction method, the $\Psi(z) = -\phi'_{sev}(z)/\phi_{sev}(z) = e^z - 1$. Using Eqs. (17.8) and (17.9), the MLEs of μ and σ are denoted by $\hat{\mu}_S$ and $\hat{\sigma}_S$, respectively. Replacing μ and σ with $\hat{\mu}_S$ and $\hat{\sigma}_S$ in Eq. (17.6), Eq. (17.6) can be represented by

$$\hat{L}_S(\hat{\mu}_S, \hat{\sigma}_S) = C_1 \prod_{j=1}^r \hat{\sigma}_S^{-1} \phi_{sev}(z_{j:n}) [1 - \Phi_{sev}(z_{r:n})]^{n-r}, \tag{17.29}$$

where $\Phi_{sev}(z) = 1 - \exp[-\exp(z)]$ is the CDF of the standard SEV. Then $h_1(z_{r:n}, Z_{s:n})$ and $h(Z_{s:n})$ are replaced by their respective expected values in Eq. (17.10). The Eq. (17.10) can be rewritten as

$$(s - r - 1) E[h_1(z_{r:n}, Z_{s:n})] - (e^{\hat{z}_{s:n}} - 1) - (n - s) E[h(Z_{s:n})] = 0. \tag{17.30}$$

The MLP_E of $X_{s:n}$ can be obtained as

$$\hat{X}_{s:n}^{SEV,1} = \max \{ \hat{\mu}_S + \hat{\sigma}_S \ln(E[\Psi(Z_{s:n})] + 1), x_{r:n} \} \tag{17.31}$$

for $r + 1 \leq s \leq n$ and $E\Psi(Z_{s:n}) = E(e^{Z_{s:n}} - 1)$.

Based on the Taylor series prediction method, expanding $h(Z_{s:n})$ and $h_1(z_{r:n}, Z_{s:n})$ by using the Taylor series at the points $F^{-1}(p_s)$ and $(F^{-1}(p_r), F^{-1}(p_s))$, respectively. We obtain

$$h(Z_{s:n}) = \frac{f(Z_{s:n})}{1 - f(Z_{s:n})} \approx 1 - \alpha_s - \beta_s Z_{s:n},$$

and

$$h_1(z_{r:n}, Z_{s:n}) = \frac{f(Z_{s:n})}{f(Z_{s:n}) - f(z_{r:n})} \approx \gamma_E + \rho_E z_{r:n} + v_E Z_{s:n}.$$

where

$$\alpha_s = 1 + \ln(q_s) - \ln(q_s) \ln(-\ln(q_s)),$$

$$\beta_s = \ln(q_s),$$

$$\gamma_E = q_s \ln(q_s) \{q_{rs} [-1 + (1 + \ln(q_s)) \ln(-\ln(q_s))] + q_s \ln(q_s) \ln(-\ln(q_s)) - q_r \ln(q_r) \ln(-\ln(q_r))\} / q_{rs}^2,$$

$$\rho_E = -q_s \ln(q_s) [(1 + \ln(q_s)) q_{rs} + q_s \ln(q_s)] / q_{rs}^2,$$

$$v_E = q_s \ln(q_s) q_r \ln(q_r) / q_{rs}^2,$$

and

$q_{ij} = q - q_j$. Eq. (17.10) can be rewritten as

$$(s - r - 1) (\gamma_E + \rho_E z_{r:n} + v_E Z_{s:n}) - e^{\hat{z}_{s:n}} - 1 - (n - s) (1 - \alpha_s - \beta_s Z_{s:n}) = 0 \tag{17.32}$$

The MLP_T of $X_{s:n}$ can be derived as

$$\hat{X}_{s:n}^{SEV,2} = \max \left\{ \frac{-(s-r-1)v_E X_{r:n}}{(s-r-1)\rho_E + \beta_s + (n-s)\beta_s} + \left[1 + \frac{(s-r-1)v_E}{(s-r-1)\rho_E + \beta_s + (n-s)\beta_s} \right] \hat{\mu}_S - \frac{(s-r-1)\gamma_E + \alpha_s - (n-s) + (n-s)\alpha_s}{(s-r-1)\rho_E + \beta_s + (n-s)\beta_s} \hat{\sigma}_S, X_{r:n} \right\}, \tag{17.33}$$

for $r + 1 \leq s \leq n$.

17.3 Three Model Selection Approaches

When we collect a data set, sometimes we cannot determine the best distribution of data. When the assumed distribution is incorrect, it may lead to incorrect results. Therefore, we suggest three approaches to discriminate the candidate distributions, the ratio of the maximized likelihood (RRML) approach, modification D_{SP} approach (shorted as D_{SP} approach), and modification D approach (shorted as the D approach), to obtain the predictor of $\hat{X}_{s:n}$. All these three approaches can be implemented to obtain the predictor of $X_{s:n}$ via using Algorithm 1 to Algorithm 3.

Algorithm 1: The RRML Approach

- Step 1: Collect a type II censoring sample, which has size n and r observed failure times, we consider k candidate distributions.
- Step 2: Obtain $(\hat{\mu}_{M_i}, \hat{\sigma}_{M_i})$ and $\hat{L}_{M_i}(\hat{\mu}_{M_i}, \hat{\sigma}_{M_i})$ for the candidate model $M_i, i = 1, 2, \dots, k$. Obtain the $X_{s:n}$ under the candidate model M_i and label it by $\hat{X}_{s:n}^{M_i, j}$ for $s = r + 1, \dots, n, i = 1, 2, \dots, k$ and $j = 1$ or 2 .
- Step 3: Let $\hat{X}_{s:n}^{A1, j}$ denote the predicted value of $X_{s:n}$ for $j = 1$ or 2 . Based on the method proposed by Dumonceaux and Antle [10], we can obtain $\hat{X}_{s:n}^{A1, j}$, which can provide the largest maximum likelihood information by

$$\hat{L}_{A1}(\hat{\mu}_{A1}, \hat{\sigma}_{A1}) = \max \left\{ \hat{L}_{M_1}(\hat{\mu}_{M_1}, \hat{\sigma}_{M_1}), \hat{L}_{M_2}(\hat{\mu}_{M_2}, \hat{\sigma}_{M_2}), \dots, \hat{L}_{M_k}(\hat{\mu}_{M_k}, \hat{\sigma}_{M_k}) \right\}$$

If the candidate distributions are ND and SEV, the Step 2 and Step 3 in the Algorithm 1 can be reduced to

- Step 2': Obtain $(\hat{\mu}_N, \hat{\sigma}_N), (\hat{\mu}_S, \hat{\sigma}_S), \hat{L}_N(\hat{\mu}_N, \hat{\sigma}_N)$ and $\hat{L}_S(\hat{\mu}_S, \hat{\sigma}_S)$. Obtain the $X_{s:n}$ under the ND ($\hat{X}_{s:n}^{N, j}$) and obtain the $X_{s:n}$ under the SEV ($\hat{X}_{s:n}^{SEV, j}$) for $s = r + 1, \dots, n$ and $j = 1$ or 2 .
- Step 3': Let $\hat{X}_{s:n}^{A1}$ denote the predicted value of $X_{s:n}$. Then

$$\hat{X}_{s:n}^{A1} = \begin{cases} \hat{X}_{s:n}^{N, j} & \text{if } \hat{L}_N(\hat{\mu}_N, \hat{\sigma}_N) > \hat{L}_S(\hat{\mu}_S, \hat{\sigma}_S) \\ \hat{X}_{s:n}^{SEV, j} & \text{, otherwise.} \end{cases} \text{ for } s = r + 1, \dots, n \text{ and } j = 1 \text{ or } 2.$$

Algorithm 2: The D_{SP} Approach

- Step 1: Collect a type II censoring sample, which has size n and r observed failure times.
- Step 2: Obtain $(\hat{\mu}_{M_i}, \hat{\sigma}_{M_i})$ for $i = 1, 2, \dots, k$, and then obtain $\hat{X}_{s:n}^{M_i, j}$ for $s = r + 1, \dots, n, i = 1, 2, \dots, k$ and $j = 1$ or 2 .
- Step 3: Based on the method proposed by Castro-Kuriss et al. [20], the modification of D_{SP} with censored observations can be presented by

$$D_{SP}(\mu, \sigma) = \max_{1 \leq i \leq r} \left\{ \frac{2}{\pi} \left| \arcsin \left(\sqrt{\frac{i-0.5}{n}} \right) - \arcsin \left(\sqrt{U_{i:n}} \right) \right| \right\}, \tag{17.34}$$

where $U_{i:n} = G\left(\frac{x_{i:n} - \mu}{\sigma}\right)$. The definition of $G(\cdot)$ is the same as that of Eq. (17.2); it represents the CDF of the assumed

distribution in model selection. Evaluate the value of D_{SP} through using the candidate model M_i for $i = 1, 2, \dots, k$.

Step 4: Let $\hat{X}_{s:n}^{A2, j}$ be the predicted value of $X_{s:n}$ for $j = 1$ or 2 , then $\hat{X}_{s:n}^{A2, j}$ can be obtained with the smallest \hat{D}_{SP} . That is, $\hat{X}_{s:n}^{A2, j}$ is the value corresponding to $\hat{D}_{SP}^{A2}(\hat{\mu}_{A2}, \hat{\sigma}_{A2})$, which is defined by

$$\hat{D}_{SP}^{A2}(\hat{\mu}_{A2}, \hat{\sigma}_{A2}) = \min \left\{ \hat{D}_{SP}(\hat{\mu}_{M_1}, \hat{\sigma}_{M_1}), \hat{D}_{SP}(\hat{\mu}_{M_2}, \hat{\sigma}_{M_2}), \dots, \hat{D}_{SP}(\hat{\mu}_{M_k}, \hat{\sigma}_{M_k}) \right\}.$$

If the candidate distributions are ND and SEV, the Step 2–Step 4 in the Algorithm 2 can be reduced to

- Step 2': Obtain $(\hat{\mu}_N, \hat{\sigma}_N)$ and $(\hat{\mu}_S, \hat{\sigma}_S)$. Obtain the $\hat{X}_{s:n}^{N, j}$ under the ND and obtain the $\hat{X}_{s:n}^{SEV, j}$ under the SEV distribution for $s = r + 1, \dots, n$ and $j = 1$ or 2 .
- Step 3': The modification of D_{SP} with censored observations can be presented by

$$D_{SP}(\mu, \sigma) = \max_{1 \leq i \leq r} \left\{ \frac{2}{\pi} \left| \arcsin \left(\sqrt{\frac{i-0.5}{n}} \right) - \arcsin \left(\sqrt{U_{i:n}} \right) \right| \right\},$$

where $U_{i:n} = G\left(\frac{x_{i:n}-\mu}{\sigma}\right)$. The definition of $G(\cdot)$ is the same as that of Eq. (17.2); it represents the CDF of the assumed

$$\hat{X}_{s:n}^{A2} = \begin{cases} \hat{X}_{s:n}^{Nj}, & \text{if } \hat{D}_{SP}^N(\hat{\mu}_N, \hat{\sigma}_N) < \hat{D}_{SP}^{SEV}(\hat{\mu}_S, \hat{\sigma}_S) \\ \hat{X}_{s:n}^{SEVj}, & \text{if } \hat{D}_{SP}^N(\hat{\mu}_N, \hat{\sigma}_N) \geq \hat{D}_{SP}^{SEV}(\hat{\mu}_S, \hat{\sigma}_S) \end{cases} \text{ for } s = r + 1, \dots, n \text{ and } j = 1 \text{ or } 2.$$

Algorithm 3: The D Approach

- Step 1: Collect a type II censoring sample, which has size n and r observed failure times.
- Step 2: Obtain $(\hat{\mu}_{M_i}, \hat{\sigma}_{M_i})$ for $i = 1, 2, \dots, k$, and then obtain $\hat{X}_{s:n}^{M_i j}$ for $s = r + 1, \dots, n, i = 1, 2, \dots, k$ and $j = 1$ or 2 .
- Step 3: Based on the method proposed by Castro-Kuriss et al. [20], the modification of $D(\mu, \sigma)$ with censoring observations can be presented by

$$D(\mu, \sigma) = \max_{1 \leq i \leq r} \left\{ \frac{2}{\pi} \left| \sqrt{\frac{i-0.5}{n}} - U_{i:n} \right| \right\} + \frac{0.5}{n}, \tag{17.35}$$

where $U_{i:n} = G\left(\frac{x_{i:n}-\mu}{\sigma}\right)$.

- Step 4: Let $\hat{X}_{s:n}^{A3j}$ be the predicted value of $X_{s:n}$ for $j = 1$ or 2 , then $\hat{X}_{s:n}^{A3j}$ can be obtained with the smallest $\hat{D}(\hat{\mu}_{M_i}, \hat{\sigma}_{M_i})$. That is, $\hat{X}_{s:n}^{A3j}$ is the value corresponding to $\hat{D}^{A3}(\hat{\mu}_{A3}, \hat{\sigma}_{A3})$, which is defined by

$$\hat{X}_{s:n}^{A3j} = \begin{cases} \hat{X}_{s:n}^{Nj}, & \text{if } \hat{D}^N(\hat{\mu}_N, \hat{\sigma}_N) < \hat{D}^{SEV}(\hat{\mu}_S, \hat{\sigma}_S) \\ \hat{X}_{s:n}^{SEVj}, & \text{if } \hat{D}^N(\hat{\mu}_N, \hat{\sigma}_N) \geq \hat{D}^{SEV}(\hat{\mu}_S, \hat{\sigma}_S) \end{cases} \text{ for } s = r + 1, \dots, n \text{ and } j = 1 \text{ or } 2.$$

17.4 Monte Carlo Simulations

In this section, the performance of the proposed three approaches with two predicting methods is investigated. The ND and SEV are considered as the candidate distributions for competing the best lifetime model in the simulation study. The data sets of type II censoring sample, $x_{1:n}, \dots, x_{r:n}$, used in the simulation were randomly generated from the ND

distribution in model selection. Evaluate the value of D_{SP} through using the normal and smallest extreme value distributions, and denoted them by $\hat{D}_{SP}^N(\hat{\mu}_N, \hat{\sigma}_N)$ and $\hat{D}_{SP}^{SEV}(\hat{\mu}_S, \hat{\sigma}_S)$, respectively.

- Step 4': Let $\hat{X}_{s:n}^{A2j}$ denote the predicted value of $X_{s:n}$, then $\hat{X}_{s:n}^{A2j}$ can be obtained by

$$\hat{D}^{A3}(\hat{\mu}_{A3}, \hat{\sigma}_{A3}) = \min \left\{ \hat{D}(\hat{\mu}_{M_1}, \hat{\sigma}_{M_1}), \hat{D}(\hat{\mu}_{M_2}, \hat{\sigma}_{M_2}), \dots, \hat{D}(\hat{\mu}_{M_k}, \hat{\sigma}_{M_k}) \right\}.$$

If the candidate distributions are ND and SEV, the Step 2, Step 3, and Step 4 in the Algorithm 3 can be reduced to

- Step 2': Obtain $(\hat{\mu}_N, \hat{\sigma}_N)$ and $(\hat{\mu}_S, \hat{\sigma}_S)$. Obtain the $\hat{X}_{s:n}^{Nj}$ under the ND and obtain the $\hat{X}_{s:n}^{SEVj}$ under the SEV for $s = r + 1, \dots, n$ and $j = 1$ or 2 .

- Step 3': The modification of $D(\mu, \sigma)$ with censoring observations can be presented by

$$D(\mu, \sigma) = \max_{1 \leq i \leq r} \left\{ \frac{2}{\pi} \left| \sqrt{\frac{i-0.5}{n}} - U_{i:n} \right| \right\} + \frac{0.5}{n},$$

where $U_{i:n} = G\left(\frac{x_{i:n}-\mu}{\sigma}\right)$. Evaluate the value of $D(\mu, \sigma)$ by using the ND and SEV, and denoted them by $\hat{D}^N(\hat{\mu}_N, \hat{\sigma}_N)$ and $\hat{D}^{SEV}(\hat{\mu}_S, \hat{\sigma}_S)$.

- Step 4': Let $\hat{X}_{s:n}^{A3j}$ denote the predicted value of $X_{s:n}$, then $\hat{X}_{s:n}^{A3j}$ can be obtained by

and SEV with location parameter $\mu = 0$ and scale parameter $\sigma = 1$. Then, the s th order statistic is predicted and denoted by $\hat{X}_{s:n}$ for $s = r + 1, r + 2, \dots, n$ for the sample sizes $n = 20, 40$, and 60 . In this simulation, we considered different censoring proportions ($cp = r/n$) $cp = 0.9, 0.8, 0.7, 0.6, 0.5$ and different predicting 100pth percentile ($cp < p \leq 1$). For the purpose of comparison, the values of the bias and mean square error (MSE) of $\hat{X}_{s:n}$ are evaluated with $N = 10000$ Monte Carlo runs:

$$\text{bias} = \frac{1}{N} \sum_{i=1}^N (\hat{X}_{s:n,i} - X_{s:n})$$

and

$$\text{MSE} = \frac{1}{N} \sum_{i=1}^N (\hat{X}_{s:n,i} - X_{s:n})^2,$$

where $\hat{X}_{s:n,i}$ is the predicted value of $X_{s:n}$ that is obtained in the i th iteration of simulation for $i = 1, \dots, N$. All simulation results are displayed in Tables 17.2 and 17.3 with the candidate distributions of ND and SEV. From Tables 17.2 and 17.3, we notice that:

1. The bias and MSE are large when the misspecification model is used.

2. The impact of misspecification depends on the values of r and s .
3. As n or r increases, the simulated bias and MSE decrease.
4. We also find that the MSE based on using the Taylor series prediction method is smaller than that based on using the expected values prediction method when the sample size is or larger than 40.

To evaluate the performance of the three proposed model selection approaches for MLP. Tables 17.4, 17.5, and 17.6 report the simulation results for three model selection approaches from the ND. Tables 17.7, 17.8, and 17.9, respectively, report the simulation results for three model selection approaches from the SEV. The column “correct(%)” presented in Tables 17.4, 17.5, 17.6, 17.7, 17.8, and 17.9 is the correct model selection rate in all simulation runs. From Tables 17.4, 17.5, 17.6, 17.7, 17.8, and 17.9, we find that:

1. The three model selection approaches have good ability to identify the correct underlying distribution with a high probability.
2. The MSEs of these three approaches are close to those simulated MSEs of the cases by using the real underlying distribution.
3. The correct model selection rates through using the D_{SP} approach or D approach are higher than that of using the RRML approach when the sample size is smaller than 40. When the sample size grows to or over 40, the performance of the RRML approach is improved and the correct model selection rate of the RRML approach is higher than that is obtained by using the D_{SP} or D approach.
4. To compare the performance of using two different MLPs, the MSEs of using the expected values prediction method

are smaller than that using the Taylor series prediction method when the sample size is smaller than 40.

5. The proposed approaches can perform well under large sample size cases.

17.5 Illustrative Examples

In this section, three numerical examples are presented to illustrate the proposed approaches in Sects. 17.2, 17.3, and 17.4.

Example 1

In the paper of Mann and Fertig [21], a test airplane component's failure time dataset is provided, in which 13 components were placed on test, and the test was terminated at the

time of the 10th failure. The failure times (in hours) of the 10 components that failed were

$$D_1 : 0.22, 0.50, 0.88, 1.00, 1.32, 1.33, 1.54, 1.76, 2.50, 3.00.$$

Suppose Y_1 is the logs of the ten observations, that is, $Y_1 = \ln(D_1)$. Figure 17.2 presents the histogram and the estimated PDFs of the ND and SEV distribution. From Fig. 17.2, it is difficult to full decide the best distribution for lifetime fitting, because both candidate distributions can provide good fitting for this data set. In this example, the D_{SP} approach is considered to discriminate competing models and use expected values prediction method and Taylor series prediction method to predict the future order statistics, which are censored.

Based on this censored data, the AMLEs of the model parameters via using the normal distribution and extreme value distribution are $(\tilde{\mu}_N, \tilde{\sigma}_N) = (0.474, 0.936)$ and $(\tilde{\mu}_{EV}, \tilde{\sigma}_{EV}) = (0.811, 0.708)$, respectively. Through using Newton-Raphson algorithm with the initial values of $(\tilde{\mu}_N, \tilde{\sigma}_N)$ and $(\tilde{\mu}_{EV}, \tilde{\sigma}_{EV})$, we obtained the MLEs of μ and σ as $(\hat{\mu}_N, \hat{\sigma}_N) = (0.479, 0.938)$ and $(\hat{\mu}_S, \hat{\sigma}_S) = (0.821, 0.705)$ for the ND and SEV, respectively.

The D_{SP} values via using ND and SEV are 0.223 and 0.212, respectively. We claim the best distribution of this data set is SEV. The Taylor series prediction and expected values prediction for $(Y_{11:13}, Y_{12:13}, Y_{13:13})$ under the extreme value distribution with the censored sample can be obtained by $(\hat{Y}_{11:13}^{A2,2}, \hat{Y}_{12:13}^{A2,2}, \hat{Y}_{13:13}^{A2,2}) = (1.098, 1.281, 1.567)$ and $(\hat{Y}_{11:13}^{A2,1}, \hat{Y}_{12:13}^{A2,1}, \hat{Y}_{13:13}^{A2,1}) = (1.186, 1.369, 1.636)$, respectively.

Example 2

Lieblein and Zelen [22] provided a test on endurance of deep groove ball bearings data and further studied by Meeker and Escobar [23], which is used to illustrate the methodologies developed in this chapter. The data are the numbers of million revolutions before failure for each of the 23 ball bearings in the life test. In the paper of Meeker and Escobar [23], they pointed out that this data (D_2) follows lognormal distribution or Weibull distribution. Hence, $Y_2 = \ln(D_2)$ follows a ND or SEV. The data is given below:

D_2 : 17.88, 28.92, 33.00, 41.52, 42.12, 45.60, 48.40, 51.84, 51.96, 54.12, 55.56, 67.80, 68.64, 68.64, 68.88, 84.12, 93.12, 98.64, 105.12, 105.84, 127.92, 128.04, 173.40.

For more information about this carbon fiber breaking strength data set, one can be referred to Meeker and Escobar [23]. In this example, we assume that the censoring proportion is 0.8696 ($r = 20, n = 23$). Figure 17.3 presents the histogram and the estimated PDFs of ND and SEV based on the type II right-censored data. From Fig. 17.3, it is difficult to decide the best distribution from these two candidate distributions.

We consider using D approach in Example 2 for model selection and use expected values prediction method to predict the future order statistics, which are censored. Based on this censored data, the AMLEs of the model parameters are $(\tilde{\mu}_N, \tilde{\sigma}_N) = (4.147, 0.523)$ and $(\tilde{\mu}_{EV}, \tilde{\sigma}_{EV}) = (4.363, 0.426)$ for the ND and SEV, respectively. The MLEs of μ and σ can be obtained via using Newton-Raphson algorithm with the initial

values of $(\tilde{\mu}_N, \tilde{\sigma}_N)$ and $(\tilde{\mu}_{EV}, \tilde{\sigma}_{EV})$; the resulting MLEs are $(\hat{\mu}_N, \hat{\sigma}_N) = (4.148, 0.524)$ and $(\hat{\mu}_S, \hat{\sigma}_S) = (4.369, 0.425)$ for the ND and SEV, respectively. The D values based on using the ND and SEV are 0.181 and 0.297, respectively. Because the D value obtained from ND is smaller than that obtained from SEV, we claim the best model is normal. The expected values prediction of $(Y_{21:23}, Y_{22:23}, Y_{23:23})$ via using ND is $(\hat{Y}_{21:23}^{A3,1}, \hat{Y}_{22:23}^{A3,1}, \hat{Y}_{23:23}^{A3,1}) = (4.784, 4.922, 5.160)$. In addition, we compare our prediction results with the MMLP values that proposed by Yang and Tong [8]. The MMLP of $(Y_{21:23}, Y_{22:23}, Y_{23:23})$ is $(\hat{Y}_{21:23}, \hat{Y}_{22:23}, \hat{Y}_{23:23}) = (4.662, 4.936, 5.175)$. Our predicted results are close to that proposed by Yang and Tong [8] even we cannot initially assume which one of the ND or SEV is the best distribution.

Example 3

A survival time (in days) of pigs injected with different doses of tubercle Bacilli dataset was provided in Bjerkedal [24]. Because guinea pigs have a high susceptibility to human tuberculosis, they are often used for research. There were 72 observations listed below:

- $D_3 : 12, 15, 22, 24, 24, 32, 32, 33, 34, 38, 38, 43, 44, 48, 52, 53,$
- $54, 54, 55, 56, 57, 58, 58, 59, 60, 60, 60, 60, 61, 62, 63, 65,$
- $65, 67, 68, 70, 70, 72, 73, 75, 76, 76, 81, 83, 84, 85, 87, 91, 95,$
- $96, 98, 99, 109, 110, 121, 127, 129, 131, 143, 146, 146, 175,$
- $175, 211, 233, 258, 258, 263, 297, 341, 341, 376.$

Fig. 17.2 The histogram and the estimated PDFs of airplane component's failure time in Example 1

Fig. 17.4 The histogram and the estimated PDFs of survival times (in days) of pigs injected in Example 3

Fig. 17.3 The histogram and the estimated PDFs of tests on endurance of deep groove ball bearings in Example 2

In this example, we assume that the censoring proportion is 0.930 ($r = 67, n = 72$). Let Y_3 be the logs of the ten observations, that is, $Y_3 = \ln(D_3)$.

Figure 17.4 presents the histogram and the estimated PDFs of the ND and SEV of Y_3 . From Fig. 17.4, we find that it is difficult to decide the best distribution from the ND

or SEV distribution. We consider using RML approach for model selection and use Taylor series prediction method to predict the future order statistics, which are censored.

Based on this censored data, the AMLEs of the model parameters in ND and SEV distribution are obtained by $(\tilde{\mu}_N, \tilde{\sigma}_N) = (4.348, 0.723)$ and $(\tilde{\mu}_{EV}, \tilde{\sigma}_{EV}) = (4.671, 0.707)$, respectively. The MLEs of μ and σ are then obtained via using the Newton-Raphson algorithm with the initial values of $(\tilde{\mu}_N, \tilde{\sigma}_N)$ and $(\tilde{\mu}_{EV}, \tilde{\sigma}_{EV})$, and the resulting MLEs are $(\hat{\mu}_N, \hat{\sigma}_N) = (4.348, 0.723)$ and $(\hat{\mu}_{EV}, \hat{\sigma}_{EV}) = (4.671, 0.707)$ for the ND and SEV distribution, respectively. The value of τ is evaluated with $\tau = 7.302$. Because $\hat{L}_N(\hat{\mu}_N, \hat{\sigma}_N) > \hat{L}_S(\hat{\mu}_S, \hat{\sigma}_S)$, we claim that this data is automatically determined to have a ND. The Taylor series prediction of $(Y_{68:72}, Y_{69:72}, Y_{70:72}, Y_{71:72}, Y_{72:72})$ for the ND is $(\hat{Y}_{68:72}^{A1,2}, \hat{Y}_{69:72}^{A1,2}, \hat{Y}_{70:72}^{A1,2}, \hat{Y}_{71:72}^{A1,2}, \hat{Y}_{72:72}^{A1,2}) = (5.553, 5.553, 5.626, 5.711, 5.836)$.

17.6 Conclusions

In the real world, it is possible that we cannot make a clear judgment of the distribution of data, especially in the case of censored data. In this study, we focus on providing reliable methods to obtain predicting values of censored data to reduce the impact of model misspecification. We provide two prediction methods and three model selection approaches for type II censored data, in which the quality characteristic is

assumed to follow a location-scale family. The ND and SEV are considered as the candidate members in the location-scale distribution to compete for the best underlying distribution.

Numerical results show that the three proposed model selection approaches are robust and effective for obtaining good predicted values for the future order statistics, which are censored. In comparing these three proposed approaches, we recommend using D_{SP} approach or D approach for model selection and use expected values prediction method to predict the future order statistics for n is less than 40. When n is larger than 40, we recommend using RRML approach for model selection and using Taylor series prediction method to predict the future order statistics. The simulation results also show that the proposed approaches have strong robustness and can greatly reduce the impact of model assumption uncertainty. If more than two candidate distributions are competing for the optimal distribution, the proposed method can also work well.

In future researches, it is worthwhile to improve the accuracy of model selection or to predict other types of censored data. Other model selection methods from the current three proposed approaches could also be competitive. How to apply the new model selection method for the topic of type II censored data prediction could be studied in the future.

Abstract

In the field of statistical process control, the cumulative sum (CUSUM) control chart is used as a powerful tool to detect process shifts. One of the main features of the CUSUM control chart is that it takes into account the past information at each sampling time of the process. Recently, the rapid development of optimization algorithms and software makes the CUSUM chart easier to be implemented. As a result, the CUSUM control chart has been increasingly applied widely. The goal of this chapter is to present some recent innovative CUSUM control charts monitoring the coefficient of variation (CV). We address several problems related to the CUSUM chart monitoring the CV. The first section provides important definitions of a CUSUM control chart, including the CUSUM sequence, the CUSUM statistics, the implementation of a CUSUM control chart, the average run length (ARL), and the expected average run length (EARL). In the second section, we investigate the effect of measurement error on the CUSUM control chart monitoring the CV. Finally, a fast initial response strategy to improve the performance of the CUSUM control chart is presented.

practitioners to use various control charts to monitor different processes. The practical applications of control charts, which were primarily in manufacturing, now extend far beyond manufacturing into a large number of other fields in real life, such as engineering, environmental science, genetics, epidemiology, medicine, finance, and even law enforcement and athletics (Stoumbos and Reynolds [1]).

A standard Shewhart control chart consists of a center line and the control limits (upper and lower). A process is monitored using this control chart by plotting directly the statistical values of interest on the chart. If these values exceed the control limits, the chart will signal an alarm to show that the process is in out-of-control condition, and a special case could occur that affects the process. Otherwise, the process is considered to be still in control.

It is well documented that in the SPC literature, the traditional Shewhart control chart is quite slow in detecting small or moderate shifts. The main reason is that this type of control chart is based purely on the latest update of observations from the process instead of utilizing the information embedded in the entire sequence of measurements. In other words, it has no “memory.” To overcome this drawback, other advanced control charts with “memory” have been suggested such as the exponentially weighted moving average (EWMA) control chart and the cumulative sum (CUSUM) control chart. During the last decade, the CUSUM control chart has been increasingly used as a powerful tool in SPC to detect small shifts in the process of interest. The CUSUM control chart takes into account the past information at each sampling time of the process. As a result, it is very sensitive to small process shifts. In recent years, the rapid development of optimization algorithms and software makes the CUSUM chart easier to be implemented. Thus, similar to the discussion about the application of the EWMA chart in Castagliola et al. [2], the CUSUM chart could be applied in various industrial environments, such as (1) the semiconductor industry at the level of wafer fabrication where the extremely high level of precision in critical dimensions of parts is required to avoid the rejection of the product at the testing stage or during the operating conditions, (2) automotive manufacturing industry where the technological process of producing mechanical parts like CNC operations in machining centers requires a small variability as possible, and (3) service control activities where healthcare outcomes such as the occurrence of infections are monitored. In general, the CUSUM chart is suitable for any process or service when it is expected to detect small process shifts in the process. In the SPC literature, the CUSUM control chart has also been a major concern in several studies. Chang and McLean [3] used the CUSUM chart as an early performance indicator of a clinical procedure before its implementation. Yashchin [4] studied CUSUM control schemes for serially correlated observations with an

application to the process of galvanic plating used to deposit copper on the surface of certain items. A CUSUM-based method for monitoring simple linear profiles and the variance when parameters are estimated was introduced by Saghaei et al. [5] and Castagliola and Maravelakis [6], respectively. Hawkins and Olwell [7] provided an extensive overview of the CUSUM methodology for quality improvement in SPC.

The coefficient of variation (CV) is a quantity to evaluate the dispersion of a probability distribution. It is defined as the ratio of the standard deviation to the mean of the distribution. In many practical situations, this measure plays an important role in ensuring the quality and stability of the process. More specifically, the mean of the quantity of interest is expected to vary from time to time and its standard deviation changes with the mean. However, the process is still considered to be in control as long as the CV remains stable. Many opportunities for control chart monitoring the sample CV have been discussed in industrial manufacturing. In the field of materials engineering like tool cutting life and sintered materials, some quality characteristics related to the physical properties of products constituted by metal alloys or composite materials often have a standard deviation which is proportional to their population mean due to the way atoms of a metal diffuse into another (Castagliola et al. [8]). In the textile industry, the variation among tensile strength measurements from the thin thread is significantly smaller than that from heavy thread because of the inherent physical properties of fiber (Yeong et al. [9]). In the machining process, monitoring the CV is useful to detect the presence of chatter, a severe form of self-excited vibration which results in many machining problems: by adopting the CV, the process monitoring works for different machining materials and machining parameters (Ye et al. [10]). More applications of monitoring of the CV have been mentioned by Muhammad et al. [11].

On account of the importance of monitoring the CV in many processes, a large number of the CV control charts has been suggested in the literature. Through a clinical chemical example, Kang et al. [12] were pioneering authors to show the efficiency of the Shewhart CV chart in quality improvement, when neither the process mean nor the process variance is constant. However, this control chart is only effective in detecting large CV shifts. For small or moderate CV shifts, it takes a large number of samples plotted beyond the control interval before the Shewhart CV chart signals an alarm. The EWMA CV control chart was then studied by Hong et al. [13] to improve the performance of the Shewhart CV chart. Using the same EWMA control chart, Castagliola et al. [8] pointed out that monitoring the CV squared is more effective than monitoring the CV itself. The performance of the standard Shewhart CV control chart could also be improved by the Shewhart chart with supplementary run

rules (Castagliola et al. [14]). Recently, Tran et al. [15] improved the performance of run rules control chart [14] by using one-sided run rules to monitor CV squared. They also considered the performance of these charts in the presence of measurement errors (ME). Moreover, another strategy that could be used to improve the performance of Shewhart chart is the synthetic CV chart (Calzada and Scariano [16]). A comparison between the performances of synthetic and EWMA charts for monitoring the CV made by Teoh et al. [17] showed that the EWMA CV squared chart outperforms the synthetic CV chart for detecting small shifts in the CV. Based on the preliminary work of Castagliola et al. [8], Zhang et al. [18] presented a modified EWMA CV control chart that is superior to some other competing control charts. Furthermore, Hong et al. [19] developed a CV control chart using a generally weighted moving average (GWMA) technique, called the GWMA CV control chart. The authors showed that this new type of control chart brings more excellent performance than the EWMA control chart in detecting small shifts in the CV. Subsequently, the run sum CV control chart was investigated by Teoh et al. [20]. Tran and Tran [21] considered two one-sided CUSUM CV control charts and their control charts lead to better performance than some previous ones. In addition, the adaptive strategies were also adopted to develop new charts monitoring the CV. Recently, Tran et al. [22] suggested CUSUM control charts to monitor CV squared with a fast initial response (FIR) strategy. The performance of FIR CUSUM CV squared charts in their results is greater than the initial CUSUM CV squared ones. Furthermore, the variable sampling interval (VSI) CV control chart was first proposed by Castagliola et al. on 2013. [23]. Although its performance cannot overcome the performance of other advanced charts like EWMA CV chart or CUSUM CV chart, this kind of chart is still a major concern in several situations because of its simplicity in implementation and its better performance compared to the standard Shewhart CV chart. Then, the variable sample size strategy was adopted for the CV control chart by Castagliola et al. [24] and Yeong et al. [25] where the first author group monitored a transformed statistic of the CV while the second one monitored directly the CV without any transformation. Subsequently, the variable sampling interval and variable sample size (VSSI) CV control charts were investigated by Khaw et al. [26]. At the highest level of adaptive strategies, Yeong et al. [27] designed the variable parameter (VP) chart that includes all VSSI, VSI, and VSS strategies to monitor the CV. It was shown in this study that the VP CV chart outperforms the VSSI CV, VSI CV, VSS CV, and Shewhart CV charts in detecting the CV shifts. The adaptive strategies were also combined efficiently with the advanced control chart. For example, the VSI EWMA CV control chart and the VSS EWMA CV control chart were proposed by Yeong et al. [28] and Muhammad et al. [11] with higher performance than the

original EWMA CV control chart, respectively. Lately, Tran et al. [29] investigated on VSI CUSUM control charts that have highest performance in comparison with previous charts such as, respectively, original CUSUM, EWMA, and VSI EWMA control charts. Other problems related to the design of a control chart monitoring the CV were also considered in the SPC literature. For instance, the CV control charts in short production runs were investigated by Castagliola et al. [30] with a Shewhart chart and Amdouni et al. [31–33] with a VSI chart, a run rules chart, and a VSS chart, respectively. The performance of the CV control charts in Phase I data was considered by Dawod et al. [34]. The effect of ME on the CV control chart is investigated by Yeong et al. [35] with the Shewhart type chart, Tran et al. [36] with the synthetic chart, Nguyen et al. [37] with the VSI type chart, and Tran et al. [38] with the CUSUM-type chart respectively.

Table 18.1 provides a brief overview of control chart monitoring the CV in the literature.

The goal of this chapter is to present some recent innovative CUSUM control charts monitoring the CV. A number of important problems related to the CUSUM CV control chart will be addressed. First, we describe several definitions used in the design of a CUSUM control chart, including the definition of a CUSUM sequence, the CUSUM statistics, the implementation of a CUSUM control chart, and the widely used measures to evaluate the performance of a CUSUM control chart, i.e., the average run length (ARL) and the expected average run length (EARL). This is to provide practitioners with a quick overview and a comprehensive understanding of a CUSUM control chart. Then, the effect of ME on the CUSUM control chart monitoring the CV is investigated using a linear covariate error model. The obtained results from this section are important for applying the CUSUM chart in reality because it is necessary to understand the effect of the ME, which is unavoidable in practice, and discuss the method to reduce the negative effects on the CUSUM CV chart performance. In the next section, we present a fast initial response strategy to improve the performance of the CUSUM control chart. Some perspectives related to designing a control chart monitoring the CV are discussed in the conclusion.

18.1 The CUSUM Control Charts

18.1.1 The Cumulative Sum

Let Y_1, Y_2, \dots be a sequence of independent observations, where Y_i represents the measurement of a quality of interest at time i . Let μ_0 denote the target value. From the sequence Y_1, Y_2, \dots , one can define a new sequence, say the cumulative sum sequence, as

$$C_i = \sum_{j=1}^i (Y_j - \mu_0), \quad i = 1, 2, \dots$$

The new sequence works by accumulating the deviations from μ_0 . Remark that this sequence can be rewritten in a recursive form as

$$C_0 = 0,$$

$$C_i = C_{i-1} + (Y_i - \mu_0), \quad i = 1, 2, \dots$$

This form explains the memory of the actual CUSUM: its mechanism is to add the current value $(Y_i - \mu_0)$ to the previous memory C_{i-1} . The effect of the mean shift on C_i can be seen by the formula

$$E(C_i) = E(C_{i-1}) + \mu_i - \mu_0,$$

where $\mu_i = E(Y_i)$, $i = 1, 2, \dots$. Indeed, if $\mu_i = \mu_0$, then $E(C_i) = E(C_{i-1})$ and the cumulative sum C_i remains where it was. If $\mu_i > \mu_0$, then $E(C_i) > E(C_{i-1})$ and C_i tends to be shifted upward. By contrast, when $\mu_i < \mu_0$, C_i tends to be

shifted downward since $E(C_i) < E(C_{i-1})$. That is to say, the trend in C_i is an indicator of changes in the process.

18.1.2 The CUSUM Statistics

In a practical implementation of the CUSUM control chart, the cumulative sum C_i is not monitored directly. Instead, the following is the statistics of interest:

$$C_i^+ = \max[0, C_{i-1}^+ + Y_i - (\mu_0 + K^+)], \quad (18.1)$$

$$C_i^- = \max[0, C_{i-1}^- + (\mu_0 - K^-) - Y_i], \quad (18.2)$$

where the starting values are $C_0^+ = C_0^- = 0$ and the parameters $K^+(K^-)$ are predetermined positive constants.

Compared to the original CUSUM statistic, the new formulation has more advantages. First, the simultaneous use of two separated statistics C_i^+ and C_i^- , which are called one-sided upper and lower CUSUM, allows decoupling of the positive and negative mean shifts so that they can eliminate the previous effect of each other. Second, the constant $K^+(K^-)$ plays the role of a "safeguarding threshold" to prevent small fluctuations from the accumulation and to cause

the CUSUM chart to signal. In the literature, K^+ (K^-) is called the reference value (or the allowance). For simplicity of presentation, sometimes we denote K as a general reference value for both cases.

18.1.3 The Implementation of a CUSUM Control Chart

Like other control charts, it is necessary to assign a predetermined threshold for the one-sided CUSUM control charts, called the control limit. This threshold is denoted by H^+ or UCL for the upper control chart (the control chart that aims to detect the increasing shifts) and H^- or LCL for the lower one (the control chart that aims to detect the decreasing shifts). Especially, when we do not want to emphasize the one-sided charts, we denote this value by H for a general case. Then, in the implementation of the one-sided CUSUM control chart, the statistics C_i^+ and C_i^- are plotted on it. If either C_i^+ or C_i^- exceeds the control limits, i.e., over H^+ for the upper chart and under H^- for the lower chart, the process is considered to be out-of-control. In contrast, when these statistics are in the interval control, i.e., under H^+ for the upper chart and above H^- for the lower chart, the process is said to be still in-control.

The CUSUM control chart is designed by assigning values for the reference parameter K and the control limit H . There are different advices for choosing K and H depending on the situation under study. For example, in the CUSUM control chart monitoring the process mean, it is suggested to choose K equal to one-half the magnitude of the shift size and H equal to five times the process standard deviation (Douglas [39]). In general cases, these values are usually chosen based on some constraints on the standard measure that is used to evaluate the performance of the control chart. We will present a widely used measure called the average run length (ARL) in the next section. In the design of the CUSUM control charts, the parameters K and H are selected to satisfy two following constraints: (1) the in-control ARL_0 value is equal to a predetermined desired value, and (2) the out-of-control ARL_1 value is minimized.

18.1.4 A Measure to Evaluate the Performance of a CUSUM Control Chart

The Average Run Length

At the beginning of the implementation, the initial states C_0^+ and C_0^- are plotted on the axis (as in the general case, we suppose $C_0^+ = C_0^- = 0$). Then, the change in the process is cumulative and the statistics C_i^+ and C_i^- are added by positive values. The number of points (or samples) from the starting

point up to the point at which the control limit is crossed is called the run length (RL). This is a random variable taking integer values only, $RL \in \{1, 2, 3, \dots\}$.

There is an analogy between a false alarm of a control chart and a Type I in classical hypothesis testing. A false alarm means that the CUSUM signals when there is no shift occurred. It makes the process be interrupted and waste time when one would like to find out nonexistent special causes. Therefore, the runs between unavoidable false alarms are expected to be as long as possible. Similarly, a Type II error in classical hypothesis testing is analogous to the situation where the CUSUM is still within its control limits even though the process has been shifted because of assignable causes. To attain the quality of the process, whenever an assignable cause occurs that shifts the process, we would like to detect them as soon as possible. That is to say, it is expected in practice to have a short run before the chart signals actual shifts. The expectation of long runs before false alarms conflicts with that of short runs before the control chart signals an actual shift. In practice, a trade-off between these two objectives is made by using the average run length (ARL), which is the mean of RL .

By its definition, the ARL represents the expected number of samples on which a control chart first signals, i.e., the number of samples inside the control limits before the first point indicates an out-of-control condition. When the process is in-control, it is normally denoted by ARL_0 ; otherwise, it is denoted by ARL_1 . The trade-off between two conflicting desires is now implemented by fixing the ARL_0 at an acceptable value and minimizing the ARL_1 .

As discussed by Douglas and David [40], the ARL is not a perfect measure for the general tendency toward long or short runs. Since the run length distribution could be highly variable, a high ARL_0 does not always lead to a very short run before a false alarm given by the chart. Similarly, a low ARL_1 does not make sure that an actual shift could be detected after a not long run. However, the ARL measure has its own advantage in that it is easy to be interpreted and well-defined. Therefore, it is considered as a standard measure of performance of the CUSUM control chart. When the CUSUM control chart is combined with other adaptive strategies like variable sampling interval and variable sample size, this measure is transformed into other measures like average time to signal (ATS, the expected length of time from the start of process monitoring until a signal is generated), the average number of observations to signal (ANOS, the expected number of observations from the start of process monitoring until a signal is given), and the average number of samples to signal (ANSS, the expected number of observations and the expected number of samples from the start of process monitoring until a signal is given). However, the calculation of these measures is based on the calculation of the ARL .

The widely used methods to calculate the *ARL* are given in the sequel.

Methods to Calculate the *ARL*

In the literature, several methods to calculate the *ARL* for a CUSUM control chart are available. For the CUSUM control chart monitoring the process mean, one can use Siegmund’s approximation as suggested by Woodall and Adams [41] or Hawkins’s approximation as presented by Hawkins [42]. In general cases, one can use the Fredholm integral equation proposed by Page [43] and Crowder [44] or the Markov chain approach proposed by Brook and Evans [45]. Among these methods, the Markov chain approach and the Fredholm integral equation are widely used due to their flexibility and simplicity.

The Markov Chain Method

The states of the Markov chain are defined by partitioning the control interval into a finite set of subintervals and by considering the midpoint value within each subinterval to approximate the value of the CUSUM statistic. In particular, we assume to have a discrete-time Markov with $p + 1$ different transitional states, where states $0, 1, \dots, p - 1$ are transient states and state p is an absorbing one corresponding to a signal from the CUSUM control chart. This is equivalent to dividing the control interval into p subintervals; each subinterval represents a transient state of a Markov chain. To get a better approximation, the “restart state” should be represented by the first subinterval which has half size of others. Figure 18.1 demonstrates this subdivision for the upward chart, where the threshold is denoted by H^+ . The transition probability matrix \mathbf{P} of this discrete-time Markov chain is

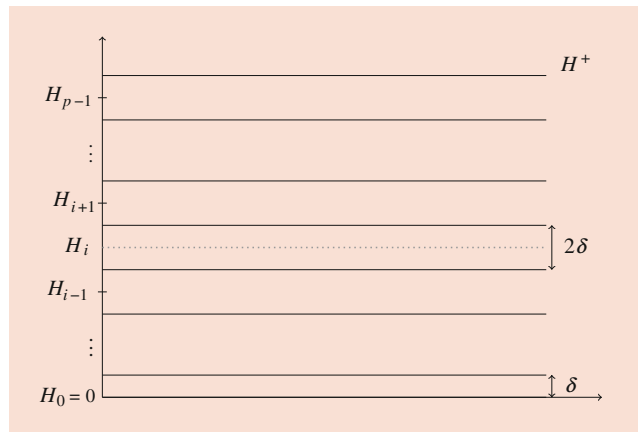

Fig. 18.1 A subdivision of the control limit interval of upward chart

$$\mathbf{P} = \begin{pmatrix} \mathbf{Q} & \mathbf{r} \\ \mathbf{0}^T & 1 \end{pmatrix} = \begin{pmatrix} Q_{0,0} & Q_{0,1} & \dots & Q_{0,p-1} & r_0 \\ Q_{1,0} & Q_{1,1} & \dots & Q_{1,p-1} & r_1 \\ \vdots & \vdots & & & \vdots \\ Q_{p-1,0} & Q_{p-1,1} & \dots & Q_{p-1,p-1} & r_{p-1} \\ 0 & 0 & \dots & 0 & 1 \end{pmatrix},$$

where \mathbf{Q} is the (p, p) matrix of transient probabilities, $\mathbf{0} = (0, 0, \dots, 0)^T$, and the p vector \mathbf{r} satisfies $\mathbf{r} = (1 - \mathbf{Q}\mathbf{1})$ (i.e., row probabilities must sum to 1) with $\mathbf{1} = (1, 1, \dots, 1)^T$. For the upward (downward) CUSUM control chart, the statistic C_i^+ (C_i^-) experiences p different transitional states before being absorbed into the out-of-control state. The states 0 to $(p - 1)$ are in-control states and state p is an out-of-control state. The width δ of the interval of each in-control state is given as $\delta = \frac{2H^+}{2p-1}$ ($\delta = \frac{2H^-}{2p-1}$). By definition, we have $H_j = j \times \delta, j = 0, 1, \dots, p - 1$. When the number p of subintervals is sufficiently large, this finite approach provides an effective method that allows the run-length properties (*ARL*) to be accurately evaluated. In this study, the generic element $Q_{i,j}, i = 0, 1, \dots, p - 1$ of the matrix \mathbf{Q} of transient probabilities is equal to the following:

- for the upward CUSUM control chart

$$\begin{aligned} Q_{i,0} &= F_{Y_k}(\mu_0 - H_i + K^+ + 0.5\delta), \quad (18.3) \\ Q_{i,j} &= F_{Y_k}(\mu_0 + H_j - H_i + 0.5\delta + K^+) \\ &\quad - F_{Y_k}(\mu_0 + H_j - H_i - 0.5\delta + K^+), \\ &\quad j = 1, \dots, p - 1; \end{aligned}$$

- for the downward CUSUM control chart

$$\begin{aligned} Q_{i,0} &= 1 - F_{Y_k}(\mu_0 + H_i - K^- - 0.5\delta), \quad (18.4) \\ Q_{i,j} &= F_{Y_k}(\mu_0 + H_i - H_j + 0.5\delta - K^-) \\ &\quad - F_{Y_k}(\mu_0 + H_i - H_j - 0.5\delta - K^-), \\ &\quad j = 1, \dots, p - 1, \end{aligned}$$

where $F_{Y_k}(\cdot)$ is the *c.d.f.* of Y_k . Let \mathbf{q} be the $(p - 1, 1)$ vector of initial probabilities associated with the p transient states, i.e., $\mathbf{q} = (q_0, q_1, \dots, q_{p-1})^T$. As proposed by Neuts [46] and Latouche [47], since the number of steps RL until the process reaches the absorbing state is a *discrete phase-type* random variable of parameters (\mathbf{Q}, \mathbf{q}) , the mean (*ARL*) and the standard-deviation (*SDRL*) of the RL of the one-sided CUSUM control charts are equal to

$$\begin{aligned} ARL &= \mathbf{q}^T (\mathbf{I} - \mathbf{Q})^{-1} \mathbf{1}, \quad (18.5) \\ SDRL &= \sqrt{2\mathbf{q}^T (\mathbf{I} - \mathbf{Q})^{-1} \mathbf{Q} \mathbf{1} - ARL^2 + ARL}. \quad (18.6) \end{aligned}$$

The ARL of the two-sided CUSUM control chart, denoted by $ARL_{two-sided}$, can be obtained from the ARL of the one-sided CUSUM charts by

$$\frac{1}{ARL_{two-sided}} = \frac{1}{ARL_U} + \frac{1}{ARL_D}, \quad (18.7)$$

where ARL_U and ARL_D stand for the ARL of the upward chart and the downward chart, respectively.

The Fredholm Integral Equation Method

Denote $L(y)$ the ARL for one-sided CUSUM scheme given that the initialization is $C_0^+ = y (C_0^- = y)$. According to Page [43] and Crowder [44], $L(y)$ can be defined in the following form:

$$L(y) = 1 + L(0)F_{Y_k}(-y) + \int_0^H L(s)f_{Y_k}(s - y)ds \quad (18.8)$$

By applying the Gauß-Legendre-Nyström approach, we can numerically solve the integral equation (18.8). In particular, the integration in (18.8) can be replaced by an appropriate quadrature, considering the equation only at the related nodes of the quadrature and solving the resulting linear equation system. Suppose that from the quadrature rule we obtain nodes s_1, s_2, \dots, s_N and weights w_1, w_2, \dots, w_N for given $N \in \mathbb{N}$.

The resulting linear equation system has the following form (for $i = 1, 2, \dots, N$):

$$\mathcal{L}(s_i) = 1 + L(0)F_{Y_k}(-y) + \sum_{j=1}^N w_j f_{Y_k}(s_j - s_i) \mathcal{L}(s_j). \quad (18.9)$$

Then, after solving this linear equation system, $\mathcal{L}(y)$ can be evaluated for arbitrary $y \in [0, H]$ by replacing s_i by y in (18.9). More details regarding this numerical procedure can be seen in a study by Crowder [44].

18.2 CUSUM Control Chart Monitoring the CV

As discussed by Castagliola et al. [8], monitoring the S^2 statistic using the CUSUM control chart is more efficient than monitoring directly the S statistic. Therefore, in this study, we will focus on monitoring the CV squared rather than monitoring the CV itself to obtain a control chart with high performance.

18.2.1 Basic Properties of Sample CV Squared

Let X be a positive random variable. The CV γ of the random variable X is defined as the ratio of its standard deviation $\sigma = \sigma(X)$ to its mean $\mu = E(X)$, that is

$$\gamma = \frac{\sigma}{\mu}.$$

Suppose that a set of *i.i.d.* samples $\{X_1, \dots, X_n\}$ is collected where each sample follows a normal distribution with parameters (μ, σ^2) . Let \bar{X} and S be the sample mean and the sample standard-deviation of X_1, \dots, X_n , i.e.

$$\bar{X} = \frac{1}{n} \sum_{i=1}^n X_i,$$

and

$$S = \sqrt{\frac{1}{n-1} \sum_{i=1}^n (X_i - \bar{X})^2}.$$

Then the sample CV $\hat{\gamma}$ is defined as

$$\hat{\gamma} = \frac{S}{\bar{X}}.$$

In the literature, the distribution of the sample CV $\hat{\gamma}$ has been studied by many authors (see, e.g., McKay [48], Hendricks and Robey [49], Iglewicz and Myers [50], Iglewicz et al. [51], Vangel [52], Waren [53] and Reh and Scheffler [54]). However, the exact cumulative distribution function (*c.d.f.*) of $\hat{\gamma}$ has a complicated form. Furthermore, Iglewicz et al. [51] showed that if $0 < \gamma \leq 0.5$, $\sqrt{n}/\hat{\gamma}$ follows a noncentral t-distribution with $n - 1$ degrees of freedom and noncentrality parameter \sqrt{n}/γ . From this result, it is easy to prove that $n/\hat{\gamma}^2$ follows a noncentral F distribution with $(1, n - 1)$ degrees of freedom and noncentrality parameter n/γ^2 . Therefore, the *c.d.f.* of the sample CV squared $\hat{\gamma}^2$ can be derived as

- for $x \leq 0$, $F_{\hat{\gamma}^2}(x | n, \gamma) = 0$;
- for $x > 0$,

$$\begin{aligned} F_{\hat{\gamma}^2}(x | n, \gamma) &= P(\hat{\gamma}^2 \leq x | n, \gamma) \\ &= P\left(\frac{n}{\hat{\gamma}^2} \geq \frac{n}{x} > 0 | n, \gamma\right) \\ &= 1 - P\left(0 < \frac{n}{\hat{\gamma}^2} \leq \frac{n}{x} | n, \gamma\right) \\ &= 1 - F_F\left(\frac{n}{x} \mid 1, n - 1, \frac{n}{\gamma^2}\right), \end{aligned} \quad (18.10)$$

where $F_F(\cdot)$ is the *c.d.f.* of the noncentral F distribution. Inverting $F_{\hat{\gamma}^2}(x | n, \gamma)$ gives the inverse *c.d.f.* $F_{\hat{\gamma}^2}^{-1}(\alpha | n, \gamma)$ of $\hat{\gamma}^2$ as

$$F_{\hat{\gamma}^2}^{-1}(\alpha | n, \gamma) = \frac{n}{F_F^{-1}\left(1 - \alpha \mid 1, n - 1, \frac{n}{\gamma^2}\right)}, \quad (18.11)$$

Fig. 18.2 The approximate density function of the sample CV squared for $\gamma = 0.2$

Fig. 18.3 The approximate density function of the sample CV squared for $n = 5$

where $F_F^{-1}(\cdot)$ is the inverse *c.d.f.* of the noncentral *F* distribution.

Figures 18.2 and 18.3 display the approximate density function of $\hat{\gamma}^2$ for several situations of parameters.

In the literature, there is no closed form for the mean and the standard deviation of $\hat{\gamma}^2$. Nevertheless, Breunig [55] provided an accurate approximation for $\mu_0(\hat{\gamma}^2)$ and $\sigma_0(\hat{\gamma}^2)$ as

$$\mu_0(\hat{\gamma}^2) = \gamma_0^2 \left(1 - \frac{3\gamma_0^2}{n} \right), \tag{18.12}$$

$$\sigma_0(\hat{\gamma}^2) = \sqrt{\gamma_0^4 \left(\frac{2}{n-1} + \gamma_0^2 \left(\frac{4}{n} + \frac{20}{n(n-1)} + \frac{75\gamma_0^2}{n^2} \right) \right) - (\mu_0(\hat{\gamma}^2) - \gamma_0^2)^2}. \tag{18.13}$$

18.2.2 Implementation and Design of CUSUM- γ^2 Control Charts

As can be seen from Figures 18.2 and 18.3, the distribution of the CV squared is skewed. Monitoring this variable using a two-sided control chart may lead to the *ARL*-biased property. That is to say, the out-of-control value ARL_1 can be larger than the in-control value ARL_0 . The main reason for this *ARL*-biased property is that in a two-sided control chart, the symmetrical control limits above and below the centerline are designed for the variables which follow an asymmetrical distribution. To avoid this situation, the one-sided control charts are proposed in the literature, that is, instead of monitoring both the increase and the decrease of the characteristic of interest simultaneously, each of these changes is monitored separately in different control charts. Castagliola et al. [8] also discussed several reasons for the advantage of using a one-sided control chart to monitor the CV, which is:

- It is able to control separately the in-control value ARL_0 from each one-sided chart.
- In general, the out-of-control tendency is usually known in advance and typically corresponds to an increase (or a decrease) in γ . Thus, it is possible to tune the upward and downward parts separately.

Therefore, we apply two one-sided CUSUM control charts to monitor the CV squared in this study. In particular, these two control charts (denoted by CUSUM- γ^2 from now in this chapter) involved:

- an upward CUSUM chart (denoted by “upward CUSUM- γ^2 ”) for detecting an increase in the CV

$$C_i^+ = \max\{0, C_{i-1}^+ + (\hat{\gamma}_i^2 - \mu_0(\hat{\gamma}^2)) - K^+\}, \tag{18.14}$$

with the initial values $C_0^+ = 0$, reference value $K^+ = k^+ \sigma_0(\hat{\gamma}^2)$, and corresponding upper control limit $H^+ = h^+ \mu_0(\hat{\gamma}^2)$

- a downward CUSUM chart (denoted by “downward CUSUM- γ^2 ”) for detecting a decrease in the CV

$$C_i^- = \max(0, C_{i-1}^- - (\hat{\gamma}_i^2 - \mu_0(\hat{\gamma}^2) - K^-), (18.15)$$

with the initial values $C_0^- = 0$, the reference value $K^- = k^- \sigma_0(\hat{\gamma}^2)$, and the corresponding upper control limit $H^- = h^- \mu_0(\hat{\gamma}^2)$.

The parameters (k^+, h^+) and (k^-, h^-) are the upward and downward CUSUM- γ^2 chart coefficients, respectively. These coefficients define a CUSUM- γ^2 control chart. The performance of the charts is evaluated by using the *ARL* measure which can be numerically calculated for a particular shift size τ . The values $\tau \in (0, 1)$ correspond to a decrease of the nominal CV, while the values $\tau > 1$ correspond to an increase of the nominal CV.

In general, the design of the CUSUM- γ^2 charts is implemented by finding out the optimal couples (k^+, h^+) or (k^-, h^-) that minimize the out-of-control *ARL*₁ for a given in-control value *ARL*₀ where the *ARL* value is calculated based on the formula (18.5) with the *c.d.f.* of $\hat{\gamma}^2$ is defined in (18.24). This procedure includes two main steps:

- Find the potential combinations (k^+, h^+) or (k^-, h^-) such that *ARL* = *ARL*₀, where *ARL*₀ is a predefined in-control *ARL* value.
- Among these combinations, choose an optimal one, say (k^{*+}, h^{*+}) or (k^{*-}, h^{*-}) , that gives the best performance, i.e., the smallest out-of-control *ARL* value for a particular shift τ , from an in-control value γ_0 to an out-of-control value $\gamma_1 = \tau \gamma_0$.

The above procedure is designed for a specific value of the shift size. However, it is usually not possible to predict exactly the shift size of τ in practice. A consequence of the wrong prediction where the actual process shift is different from the one used to design the control chart is that the designed control chart can have a poor performance. In order to overcome this problem, one can consider τ as a random variable and assume a statistical distribution to model it. If the quality practitioners prefer to get an optimal design of a control chart with respect to a range of shifts sizes $[a, b]$ without any preference for a specific size, a uniform distribution $f_\tau(\tau) = \frac{1}{b-a}$ can be used to give equal weight to each shift size included within the interval $[a, b]$. In this situation, the performance of control charts is evaluated by the expected average run length (*EARL*), which is defined by

$$EARL = \int_a^b ARL \times f_\tau(\tau) d\tau. \quad (18.16)$$

Therefore, the optimal coefficients (k^{*+}, h^{*+}) or (k^{*-}, h^{*-}) should satisfy the following conditions:

- for the downward CUSUM- γ^2 control chart

$$(k^{*-}, h^{*-}) = \operatorname{argmin}_{(k^-, h^-)} EARL(\gamma_0, \tau, k^-, h^-, n) \quad (18.17)$$

subject to the constraint

$$EARL(\gamma_0, \tau = 1, k^-, h^-, n) = ARL(\gamma_0, \tau = 1, k^-, h^-, n) = ARL_0, \quad (18.18)$$

- for the upward CUSUM- γ^2 control chart

$$(k^{*+}, h^{*+}) = \operatorname{argmin}_{(k^+, h^+)} EARL(\gamma_0, \tau, k^+, h^+, n) \quad (18.19)$$

subject to the constraint

$$EARL(\gamma_0, \tau = 1, k^+, h^+, n) = ARL(\gamma_0, \tau = 1, k^+, h^+, n) = ARL_0. \quad (18.20)$$

18.2.3 Performance of the CUSUM- γ^2 Control Charts

The performance of the CUSUM- γ^2 control charts and a direct comparison with other control charts monitoring the CV squared have been investigated by Tran and Tran [21]. Given the value of n , γ_0 , the *ARL* and *SDRL* of the CUSUM- γ^2 control charts can be calculated with respect to a specific shift size following the formulas (18.5)–(18.6). The optimal parameters (k^{*+}, h^{*+}) and (k^{*-}, h^{*-}) and the corresponding (*ARL*, *SDRL*) values are presented in Tables 18.2 and 18.3 for the shift size $\tau = \{0.5, 0.65, 0.8, 1.25, 1.5, 2.0\}$, in-control CV $\gamma_0 = \{0.05, 0.1, 0.15, 0.2\}$, sample size $n = \{5, 7\}$ (Table 18.2) and $n = \{10, 15\}$ (Table 18.3). In the optimization procedure, the in-control *ARL* is set at *ARL*₀ = 370.4.

It can be seen from the obtained results that given τ and n , the value of γ_0 has a trivial impact on the performance of the one-sided CUSUM- γ^2 control charts. When γ_0 increases from 0.05 to 0.2, the values of both *ARL*₁ and *SDRL*₁ change insignificantly. For example, with $n = 5$, $\tau = 0.8$ we have *ARL*₁ = 20.0, *SDRL*₁ = 10.0 when $\gamma_0 = 0.05$ and *ARL*₁ = 20.4, *SDRL*₁ = 10.4 when $\gamma_0 = 0.2$. By contrast, the performance of the CUSUM- γ^2 control charts depends strongly on the sample size n : the larger the value of n , the smaller the value of the *ARL*₁. For example, when $\tau = 1.25$, $\gamma_0 = 0.1$, we have *ARL*₁ = 14.8 if $n = 5$, and we have *ARL*₁ = 6.0 if $n = 15$.

Table 18.4 shows the overall performance of the CUSUM- γ^2 control charts according to the *EARL* measure. The unique optimal couples (k^{*+}, h^{*+}) and (k^{*-}, h^{*-}) are found satisfying equations (18.17) and (18.19) subject to the constraints (18.18) and (18.20) where the support of τ is $\Omega_\tau = (1, 2]$

Table 18.2 The optimal couples (k^{*+}, h^{*+}) when $\tau = \{0.5, 0.65, 0.8, 0.9\}$, (k^{*-}, h^{*-}) when $\tau = \{1.1, 1.25, 1.5, 2\}$ (first row) and the corresponding $(ARL_1, SDR L_1)$ values (second row) of the CUSUM- γ^2 charts for $n = \{5, 7\}$ and $\gamma_0 = \{0.05, 0.1, 0.15, 0.2\}$

(increasing case) and $\Omega_D = [0.5, 1)$ (decreasing case), respectively. The values of γ_0 and n are the same as the ones in Tables 18.2 and 18.3. A similar tendency of the dependence of the CUSUM- γ^2 control charts' performance on γ_0 and n can be seen in Table 18.4: the $EARL$ does not change much when γ_0 varies, but it decreases significantly when n increases.

Example

Table 18.5 presents a real phase II dataset from a sintering process in an Italian company that manufactures sintered mechanical parts, which is introduced by Castagliola et al. [8]. Throughout the sintering process, molten copper is used to filling pores, allowing the drop time to be prolonged notably. Moreover, the larger the quantity Q_C of molten copper absorbed within the sintered compact during cooling is, the more the expected pressure drop time T_{pd} is. It is stated that the preliminary regression study relating T_{pd} to the quantity Q_C of molten copper has demonstrated the presence of a constant proportionality $\sigma_{pd} = \gamma_{pd} \times \mu_{pd}$ between the standard deviation of the pressure drop time and its mean. The CV $\gamma_{pd} = \sigma_{pd}/\mu_{pd}$ is then monitored to detect changes in the process variability. The recorded data consists of 20

new samples taken from the process after the occurrence of a special cause increasing process variability.

The upward CUSUM- γ^2 control chart is designed for the unknown shift size case. From the Phase I data, the in-control CV has been estimated as $\hat{\gamma}_0 = 0.417$. The in-control mean and variance are calculated from (18.12) and (18.13) as $\mu_0 = 0.15575$ and $\sigma_0 = 0.164307$. The chart coefficients which are optimal for detecting a shift with a uniform distribution over the interval $(1, 2)$ are found to be $k^{*+} = 0.3898930$ and $h^{*+} = 12.264137$. Then, we obtain $K^+ = 0.064062$ and $H^+ = 1.910097$. The values of C_i^* are then presented in the rightmost column in Table 18.5 and plotted in Fig. 18.4 along with the control limit H^+ . As can be seen from this figure, the CUSUM- γ^2 chart detects several out-of-control samples (in bold in Table 18.5), from the 13th sample onward.

18.3 CUSUM Control Chart Monitoring the CV in the Presence of Measurement Error

The CUSUM- γ^2 control charts designed above are based on an assumption that the quality of interest X_i can be measured

exactly, i.e., without any measurement error. However, this assumption may not be reached in practice since the ME is almost ineluctable no matter how exact the measurement system is. It is proven within the industrial context that the ME may affect the performance of SPC methodologies. Since Bennet [56] investigated the effect of ME on the Shewhart \bar{X} chart, the topic has been widely studied in the SPC literature. Linna and Woodall [57] suggested a linear covariate error model to represent the relation between the observed value and the true value. Following this model, Maravelakis [58] and Maravelakis et al. [59] presented the effect of ME on the EWMA and CUSUM \bar{X} control chart, respectively.

Noorossana and Zerehsaz [60] discussed a problem of ME on the control chart monitoring the linear profiles. Tran et al. [61] provided a synthetic median control chart for monitoring the process mean with ME. The performance of a number of CV control charts in the presence of ME has also been recently studied by Nguyen et al. [37] and Tran et al. [36, 38, 62].

18.3.1 Linear Covariate Error Model for the Coefficient of Variation

In this section, we present briefly the linear covariate error model for the CV as suggested by Tran et al. [62]. Let $\{X_{i,1}, X_{i,2}, \dots, X_{i,n}\}$ be a set of samples of the quality of interest, $i = 1, 2, \dots$. The variable X_{ij} refers to the j^{th} sample taken at times i . Suppose that X_{ij} follows a normal distribution with mean $\mu_0 + a\sigma_0$ and standard deviation $b\sigma_0$. The constants a and b represent a shift of the process. If $a = 0$ and $b = 1$, the process is said to be in-control; otherwise, it is considered to be out-of-control.

Because of the ME problem, the true value of X_{ij} is not observable. Instead, this value can only be assessed through m real observations $\{X_{ij,1}^*, X_{ij,2}^*, \dots, X_{ij,m}^*\}$, $m \geq 1$. Linna and Woodall [57] suggested the following linearly covariate error model:

$$X_{ij,k}^* = A + BX_{ij} + \varepsilon_{ij,k},$$

where $X_{ij,k}^*$ is the observed value in the k^{th} measurement of the item j at the sampling i , A and B are two constants depending on the gauge location error, and $\varepsilon_{ij,k} \sim N(0, \sigma_M)$ is the random error term due to the gauge precision error which is independent of X_{ij} . In particular, A is the constant bias component, B is the parameter modeling the linearity error, and σ_M is the precision error. Figure 18.5 presents a graphical representation of the ME model.

Then, the mean

$$\bar{X}_{ij}^* = \frac{1}{m} \sum_{k=1}^m X_{ij,k}^* = A + BX_{ij} + \frac{1}{m} \sum_{k=1}^m \varepsilon_{ij,k}$$

of m observed quantities of the same item j is considered as a representation of X_{ij} . By its definition, \bar{X}_{ij}^* also follows a normal distribution with parameters

$$\begin{cases} \mu^* = A + B(\mu_0 + a\sigma_0), \\ \sigma^{*2} = B^2b^2\sigma_0^2 + \frac{\sigma_M^2}{m}. \end{cases}$$

Thus, the CV of the measured quantity \bar{X}_{ij}^* is defined by

$$\gamma^* = \frac{\sqrt{B^2b^2\sigma_0^2 + \frac{\sigma_M^2}{m}}}{A + B(\mu_0 + a\sigma_0)} = \frac{\sqrt{B^2b^2 + \frac{\eta^2}{m}}}{\theta + B(1 + a\gamma_0)} \times \gamma_0, \quad (18.21)$$

Fig. 18.5 A representation of the measurement error model

where $\eta = \frac{\sigma_M}{\sigma_0}$, $\gamma_0 = \frac{\sigma_0}{\mu_0}$, $\theta = \frac{A}{\mu_0}$; η and θ represent the precision error ratio and the accuracy error ratio.

It is important to consider that the ME also affects the relation between the in-control and the out-of-control values of the CV. Indeed, without ME, we have $\gamma_1 = \tau \gamma_0$ where τ is the true shift size. With the introduction of a and b , the out-of-control CV is defined by

$$\gamma_1 = \frac{b\sigma_0}{\mu_0 + a\sigma_0} = \frac{b}{1 + a\gamma_0} \gamma_0.$$

Then, the shift size τ can be expressed by $\tau = \frac{b}{1 + a\gamma_0}$. Under the presence of ME, the in-control value of the CV (corresponding to $a = 0$ and $b = 1$) now becomes

$$\gamma_0^* = \frac{\sqrt{B^2 + \frac{\eta^2}{m}}}{\theta + B} \times \gamma_0, \tag{18.22}$$

and the out-of-control value is

$$\gamma_1^* = \frac{\sqrt{B^2 b^2 + \frac{\eta^2}{m}}}{\theta + Bb/\tau} \times \gamma_0. \tag{18.23}$$

Equations (18.22)–(18.23) show that in general $\gamma_1^* \neq \tau \gamma_0^*$.

Let \bar{X}_i^* and S_i^* denote the sample mean and the sample standard deviation of $\bar{X}_{1j}^*, \dots, \bar{X}_{nj}^*$, i.e.,

$$\bar{X}_i^* = \frac{1}{n} \sum_{j=1}^n \bar{X}_{ij}^* \text{ and } S_i^* = \sqrt{\frac{1}{n-1} \sum_{j=1}^n (\bar{X}_{ij}^* - \bar{X}_i^*)^2}.$$

Then, the sample CV squared in the presence of ME, $\hat{\gamma}_i^*$, is defined by

$$\hat{\gamma}_i^* = \frac{S_i^*}{\bar{X}_i^*}.$$

From (18.24) and (18.25), the *c.d.f.* and *i.d.f.* of $\hat{\gamma}^{*2}$ are defined as

$$F_{\hat{\gamma}^{*2}}(x | n, \gamma) = 1 - F_F\left(\frac{n}{x} \mid 1, n-1, \frac{n}{\gamma^{*2}}\right), \tag{18.24}$$

where $F_F(\cdot)$ is the *c.d.f.* of the noncentral F distribution, and

$$F_{\hat{\gamma}^{*2}}^{-1}(\alpha | n, \gamma) \simeq \frac{n}{F_F^{-1}\left(1 - \alpha \mid 1, n-1, \frac{n}{\gamma^{*2}}\right)}, \tag{18.25}$$

where $F_F^{-1}(\cdot)$ is the inverse *c.d.f.* of the noncentral F distribution.

18.3.2 The Effect of Measurement Error on the CUSUM- γ^2 Control Charts

In a recent study on the effect of measurement error on the performance of the CUSUM- γ^2 control chart (Tran et al. [38]), the authors suggested using globally optimized coefficients which optimize the chart's performance in an anticipated interval of the shift size τ . In this study, we consider designing this control chart under the presence of ME for both cases of specific shift sizes and unknown shift sizes.

With the presence of ME, the implementation of the CUSUM- γ^2 control charts is similar to the one in Sect. 18.2.2. The optimal control chart coefficients (k^{*+}, h^{*+}) and (k^{*-}, h^{*-}) are also the solutions of the optimal problem of the function ARL (for a specific shift size) or $EARL$ (for the unknown shift size which is considered within a predetermined range) subject to a constraint on the in-control value ARL_0 . The difference is that the value ARL or $EARL$ should be calculated by using the distribution of γ^{*2} rather than the distribution of γ^2 .

To investigate the effect of ME on the CUSUM- γ^2 control charts' performance, we set the in-control value ARL_0 at 370.4. Without loss of generality, the shift in the variance is assumed to be a unit, i.e., $b = 1$. Several scenarios of other parameters are considered, where $\gamma_0 = \{0.05, 0.1, 0.2\}$, $n = \{5, 7, 10, 15\}$, $m = \{1, 3, 5, 7, 10\}$. Moreover, following the guidelines in the AIAG manual [63] for measurement system analysis, the value of η and θ is chosen less than 0.3, and the value of B is considered within the range [0.8, 1.2].

Given the values of m, n, B, η, θ , and γ_0 , the optimal couples (k^{*-}, h^{*-}) for the downward chart and (k^{*+}, h^{*+}) for the upward chart are solved. Tables 18.6 and 18.7 show the reference coefficients k^{*+}, k^{*-} (first row for each value of τ) and the limit coefficients h^{*+}, h^{*-} (second row for

Fig. 18.6 The effect of η and θ on the overall performance of the CUSUM- γ^2 control charts in the presence of measurement error

each value of τ) for $\theta = 0.05, m = 1, B = 1, \eta = \{0, 0.05, 0.1, 0.15, 0.2, 0.25\}, n = \{5, 7\}$ (Table 18.6) and $n = \{10, 15\}$ (Table 18.7). These coefficients for other situations of parameters are not presented here for the sake of brevity but are available upon requests from authors.

Using these optimized coefficients, we can calculate the corresponding out-of-control ARL_1 value. The results are presented in Tables 18.8, 18.9, 18.10, and 18.11. Some conclusions can be drawn from these tables as follows:

- The accuracy error has a negative effect on the performance of the CUSUM- γ^2 control charts: the larger the value of θ , the larger the value of ARL_1 . For example, with $n = 5, \tau = 1.3, \gamma_0 = 0.05, m = 1, B = 1, \eta = 0.28$, we have $ARL_1 = 14.67$ when $\theta = 0$ and $ARL_1 = 17.28$ when $\theta = 0.1$ (see Table 18.9).
- The increase of the linearity error B leads to the decrease of the ARL_1 . For example, from Table 18.10 we have $ARL_1 = 21.52$ for $B = 0.8$ and $ARL_1 = 21.02$ for $B = 1.2$

when $\eta = 0.28, \theta = 0.05, \gamma_0 = 0.1, m = 1$ and $n = 5$. This can be explained by the fact that the rise of B tends to amplify the actual value of observations, making them run out of the control limits faster. However, this does not mean that increasing the linearity error in the measurement system is encouraged because it affects the quality of the measurement, leading to the misunderstanding of the quantity of interest.

- The precision error ratio has not much effect on the performance of the CUSUM- γ^2 control charts. Indeed, when η varies in $[0, 0.25]$, the value of the ARL_1 changes insignificantly as can be seen in Table 18.8.
- The number of multiple measurements per item m has a positive impact on the proposed charts: when m increases, the ARL_1 decreases. However, this impact is not really significant as the decrease of the ARL_1 is trivial when m increases from $m = 1$ to $m = 10$. For example, in Table 18.11 with $\tau = 0.7\eta = 0.028, \theta = 0.05, B = 1, \gamma_0 = 0.2$ and $n = 7$, we have $ARL_1 = 6.29$ when $m = 1$

Fig. 18.7 The effect of B on the performance of the CUSUM- γ^2 charts in the presence of measurement error for $n = 5$ ($-\square-$) and $n = 15$ ($-\blacksquare-$)

and $ARL_1 = 6.28$ when $m = 10$. We then conclude that increasing the number of multiple measurement per item is not an efficient way to reduce the effect of ME on the CUSUM- γ^2 control chart.

- As expected, when n increases, the value of the ARL_1 decreases sharply. The increase of n also reduces the negative effect of θ on the CUSUM- γ^2 charts' performance. For example, when $n = 5$, we have $ARL_1 = 19.96$ if $\theta = 0$, compared to $ARL_1 = 22.35$ if $\theta = 0.1$, and when $n = 15$, we have $ARL_1 = 7.93$ if $\theta = 0$ compared to $ARL_1 = 8.99$ if $\theta = 0.1$, where $\tau = 0.8$, $\gamma_0 = 0.05$ (Table 18.9).

The overall effect of ME on the CUSUM- γ^2 control charts when the shift size is not predetermined is shown in Figs. 18.6, 18.7, and 18.8, where the reference coefficient $k^+(k^-)$ is set at 0.3, and the support of τ is $\Omega_I = (1, 2]$ for

the upward control chart, $\Omega_D = [0.5, 1)$ for the downward case. These figures show a similar tendency of the effect of ME as for the case of the specific shift size: the increase of θ reduces significantly the chart performance, the increase of B leads to the decrease of the ARL_1 , the variation of m and η has a trivial impact, and the sample size n has a strong impact on the chart performance.

18.4 Using FIR to Improve the Performance of the CUSUM- γ^2 Control Chart

In the previous design of the CUSUM- γ^2 control chart, we have supposed that $C_0^+ = C_0^- = 0$, i.e., the process starts from an in-control state. However, it is not always the case

Fig. 18.8 The effect of m on the performance of the CUSUM- γ^2 charts in the presence of measurement error for $n = 5$ ($-\square-$) and $n = 15$ ($-\blacksquare-$)

as the process may be in the out-of-control state at startup or when the process is restarted after an adjustment has been made to the process in practice. In order to improve the performance of the CUSUM chart in such special situations, Lucas and Crosier [64] suggested a fast initial response (FIR) strategy (FIR) strategy. According to this method, the standard CUSUM procedure is modified by initially setting a CUSUM to a specified positive *headstart* $C_0^+ = C_0^- = c$. The design of the FIR CUSUM chart is still the same as the design of the standard CUSUM chart. However, instead of setting up $c = 0$, in the FIR CUSUM chart, we choose the value of c between 0 and the control limit H .

The FIR strategy has a valuable advantage in that it enhances significantly the CUSUM chart performance when the process starts from an out-of-control state but costs only a

small penalty if the process starts in control. The price for this improvement and for maintaining the same in-control ARL_0 is the somewhat increase of the control limit H . In the literature, the FIR was used to improve the performance of the CUSUM chart monitoring process dispersion in a study by Sanusi et al. [65]. An extensive discussion of the FIR feature can be seen in a study by Hawkins and Olwell [7].

In this section, we apply the FIR strategy in designing the CUSUM- γ^2 control chart. The value of optimal reference coefficients h^{*+} (h^{*-}) and the corresponding ARL_1 of the FIR CUSUM- γ^2 are presented in Tables 18.12 and 18.13, respectively. In the current study, the FIR CUSUM- γ^2 control chart is applied with the values of k^{*+} and k^{*-} in Tables 18.2 and 18.3. We consider several situations of the headstart, that is, $c \in \{0, 0.25H, 0.5H, 0.75H\}$. It can be seen that the use

Table 18.12 The chart parameters h^{*+} when $\tau = \{0.5, 0.7, 0.8\}$, h^{*-} when $\tau = \{1.3, 1.5, 2.0\}$ of the CUSUM- γ^2 charts for $n = \{5, 7, 10, 15\}$, $\gamma_0 = \{0.05, 0.1, 0.2\}$, and different values of the head start c

of FIR leads to the better performance of the CUSUM- γ^2 control chart. In particular, when $C_0 = c$ increases, the ARL_1 decreases. For example, with $n = 5$, $\gamma_0 = 0.1$, $\tau = 0.8$, we have $ARL_1 = 20.025$ when $C_0^- = 0$ and $ARL_1 = 7.6025$ when $C_0^- = 0.75H^-$. In addition, the increase of c increases the value of $h^{*+}(h^{*-})$ (corresponding to the control limit $H^{*+}(H^{*-})$) as well. For example, when $n = 7$, $\gamma_0 = 0.05$, $\tau = 1.3$, the optimal values of reference coefficient h^{*+} is $h^{*+} = 4.0796$ if $C_0 = 0$ and $h^{*+} = 4.2962$ if $C_0 = 0.75H^+$. These results are consistent with the findings by Lucas and Crosier [64]. Using a head start routinely is then recommended as a good strategy to obtain better performance in designing a CUSUM control chart monitoring the CV.

18.5 Conclusions and Perspectives

In this chapter, we have investigated several problems related to the CUSUM control chart monitoring the CV, involving the design of the CUSUM- γ^2 control chart, the effect of ME, and the FIR strategy to improve the performance of the proposed charts. The chart performance is measured by using the ARL , which is the expected number of samples to be taken before a signal from the chart. This measurement has been calculated based on an approximate Markov chain method. We have also considered the measurement of $EARL$ when a specific shift size of the process cannot be predicted accurately in advance.

Thanks to the definition of the CUSUM statistic, the CUSUM- γ^2 control chart is able to cumulate information on the whole process from the past. As a result, it is quite sensitive to the process shift and it outperforms the statistical performance of the traditional Shewhart control chart.

The numerical results have shown that the ME has a significant impact on the chart's performance. In particular, the increase of the accuracy error or the precision error leads to the decrease of the efficiency of the chart in detecting process shifts. Moreover, the traditional method of increasing the number of multiple measurements per item is not an efficient way to reduce these negative effects of ME. By contrast, increasing the sample size is a very effective way to enhance the performance of the CUSUM- γ^2 control chart regardless of ME.

Another way to improve the CUSUM- γ^2 control chart's performance is to apply the FIR strategy. In this strategy, the process is supposed to start from an out-of-control state. Then, the initial values of the CUSUM statistics are chosen to be strictly greater than 0. This choice could lead to somewhat larger interval controls, but it can reduce significantly the average number of samples that need to be taken from the chart to alarm an abnormal state. These findings could be useful for practitioners in designing a CUSUM control chart to monitor the CV.

The obtained results in this chapter can be applied in various industrial environments when the change in the CV is considered as a source that leads to the change of the process output and the small and moderate shifts in the CV are expected to detect as quickly as possible. It is also applied for the case when one considers a practical problem of ME in the implementation of the CUSUM- γ^2 chart.

From this chapter, several important problems related to the CUSUM- γ^2 control chart could be investigated in future research. For example, one can think of combining the CUSUM chart with other adaptive strategies like changing the sample size, changing the sampling interval, or changing both of them to obtain a control chart monitoring the CV (i.e., the VSI CUSUM- γ^2 chart, VSS CUSUM- γ^2 chart, or VSSI CUSUM- γ^2 chart) with higher performance. Moreover, in Sect. 18.3, we have modeled ME by applying a linear co-variate error model. In some situations, the additive linear model could be too simple and it does not model ME well. For such situations, one can think about using a more general model for ME like the two-component error model suggested by Rocke and Lorenzato [66]. However, the general model is such that the observations are no longer normal and simulation is needed to get the control charts' statistical properties. Finally, investigating the effect of skew distributions on the CUSUM- γ^2 is also an interesting problem with a practical meaning. In the SPC literature, this problem has been presented in several studies (see, e.g., Bai and Choi [67], Derya and Canan [68]). Particularly, Stoumbos and Reynolds [1] also studied the robustness and performance of CUSUM control charts based on a double-exponential distribution. However, a CUSUM control chart monitoring the CV with a skew distribution has not been investigated yet, and it is worth considering it to make it more practical for practitioners.

Phuong Hanh TRAN is currently a Ph.D student and researcher at HEC Liège - Management School of the University of Liège and QuantOM (Center of Quantitative Methods and Operations Management), Liège, Belgium. She is also a visiting researcher at the University of Lille, ENSAIT & GEMTEX, Lille, France. Her research is now focused on developing new Statistical Process Control (SPC) and Machine Learning methods for anomaly detection in Business, Finance and Industry Management.

Kim Phuc Tran is currently a Senior Associate Professor (Maître de Conférences HDR, equivalent to a UK Reader) of Artificial Intelligence and Data Science at the ENSAIT and the GEMTEX laboratory, University of Lille, France. He received an Engineer's degree and a Master of Engineering degree in Automated Manufacturing. He obtained a Ph.D. in Automation and Applied Informatics at the University of Nantes, and an HDR (Doctor of Science or Dr. habil.) in Computer Science and Automation at the University of Lille, France. His research deals with Real-time Anomaly Detection with Machine Learning with applications, Decision Support Systems with Artificial Intelligence, and Enabling Smart Manufacturing with IIoT, Federated learning, and Edge computing. He has published more than 64 papers in peer-reviewed international journals and proceedings at international conferences. He edited 3 books with Springer Nature and Taylor & Francis. He is the Associate Editor, Editorial Board Member, and Guest Editor for several international journals such as IEEE Transactions on Intelligent Transportation Systems and Engineering Applications of Artificial Intelligence. He has supervised 9 Ph.D. students and 3 Postdocs. In addition, as the project coordinator (PI), he is conducting 1 regional research project about Healthcare Systems with Federated Learning. He has been or is involved in 8 regional, national, and European projects. He is an expert and evaluator for the Public Service of Wallonia (SPW-EER), Belgium, and the Natural Sciences and Engineering Research Council of Canada. He received the Award for Scientific Excellence (Prime d'Encadrement Doctoral et de Recherche) given by the Ministry of Higher Education, Research and Innovation, France for 4 years from 2021 to 2025 in recognition of his outstanding scientific achievements. From 2017 until now, he has been the Senior Scientific Advisor at Dong A University and the International Research Institute for Artificial Intelligence and Data Science (IAD), Danang, Vietnam where he has held the International Chair in Data Science and Explainable Artificial Intelligence.

Prof. Cédric Heuchenne is a Full Professor of Statistics and Quantitative Methods at HEC Liège - Management School of the University of Liège, and also teaches at the Catholic University of Louvain. More precisely, his research concerns different applied or more theoretical fields like survival or duration data analysis, nonparametric statistical inference, statistical process control, quality management, or risk modelling.

Dr. Huu Du Nguyen is a member of the International Research Institute for Artificial Intelligence and Data Science, Dong A University, Danang, Viet Nam. He is a member of the Faculty of Information Technology, National University of Agriculture, Hanoi, Vietnam. His research is related to reliability assessment, statistical process control, machine learning and deep learning.

Change-Point-Based Statistical Process Controls

first briefly discuss a few commonly used SPC charts along with relevant references and then present a new chart for univariate continuous processes. Unlike most SPC charts in the literature, it neither assumes any “in-control” probability distribution nor requires any “in-control” Phase I data, and it aims to detect arbitrary distributional change. This chart uses a computationally efficient method to find the possible change-point. Moreover, the proposed chart uses a p-value-based data pruning approach to further increase the efficiency, and it combines the strengths of two different tests of hypotheses, which has a potentially broad application. Numerical simulations and two real-data analyses show that the chart can be used in various monitoring problems when the nature of distributional change is unknown.

Abstract

In the current era of computers, statistical monitoring of sequential observations is an important research area. In problems such as monitoring the quality of industrial products, health variables, climatological variables, etc., we are often interested in detecting a change in the process distribution in general, not just in mean or variance. We

19.1 Introduction

Statistical process control (SPC) charts are widely used for monitoring the stability of certain sequential processes in various disciplines including manufacturing and healthcare systems. Typically, the SPC charts assume that there are two causes of variability in the process measurements: one is “common cause” which is due to unavoidable randomness and another is “special cause” when an undesirable variability intervenes, for example, mechanical defects, improper handling of machines, human errors, onset of certain medical conditions, etc. When the variability is only due to common causes, the process is said to be “in-control”. “In-control” process measurements can be considered as realizations of

e-mail: psm@isical.ac.in

a random model, for example, independent and identically distributed (i.i.d.) observations from a cumulative distribution function (c.d.f.) F_1 . When a special cause interferes, the process measurements no longer appear as i.i.d. realizations of F_1 , and then the system is said to be “out-of-control”. Practitioners typically divide SPC into two phases. Initially, a set of process measurements are analyzed in Phase I. If any “unusual” patterns in the process measurements are found, they make necessary adjustments and fine-tuning of the system. After removing all such special causes, we have a clean set of process measurements data under stable operating conditions, and they are representative of the actual process performance. The major goal of Phase II SPC control charts is to detect any change in process distribution after an unknown time-point.

A change in the process distribution may not always be in location and scale only; it can be general, for example, changes in degrees of freedom of chi-squared distribution. Furthermore, changes can either be *isolated*, i.e., the system goes “out-of-control” for a short time and then returns to “in-control”, or *persistent*, i.e., once the system goes “out-of-control,” it remains “out-of-control” or even goes further away from control until the special causes are removed. Among existing SPC charts in the literature, Shewhart-type [1] charts are used to detect *isolated* changes and cumulative sum (CUSUM) type charts (e.g., [2]) are used to detect *persistent* changes. However, most SPC charts consider shifts in location and/or scale, because they are most common and often capture other departures. In real-world problems, shifts in skewness and kurtosis can happen without much change in location and scale. For example, the shape of the process distribution gradually changing over time without much change in mean or variance. If we fail to detect those changes and let the process run, it can eventually become worse and a shift in location and scale can creep in. Moreover, the special causes that initiated the change can cause more damage to the system, and it may become a challenge to fix. If we can detect such a change in skewness, we can avoid subsequent troubles. Therefore, it is imperative to develop an SPC chart that can detect changes in the process distribution in general. The proposed chart precisely focuses on this.

Various types of SPC control charts have been proposed in the literature including Shewhart-type charts [1], cumulative sum (CUSUM)-type charts (e.g., [2]), exponentially weighted moving average (EWMA chart) [3] (e.g., [4, 5]), etc. Many control charts assume that “in-control” process distribution F_1 is either known or has a known parametric form (e.g., normal). In real-life problems, this is usually not the case. It has been demonstrated in the literature that the SPC charts using prespecified distribution in their designs may not be reliable in such cases (e.g., [6, 7]). To address this, a number of non-parametric or distribution-free SPC charts have been proposed. For example [8–18], and so on. [19] provides

an overview of nonparametric SPC charts. Discussions for multivariate cases are provided by Qiu and Hawkins [20, 21] and Qiu [22]. Some SPC charts (e.g., [23–25]) monitor process mean and variance jointly. Moustakides [26] proposes a method to detect distributional changes when both “in-control” and “out-of-control” distributions are known. Ross and Adams [27] propose two nonparametric control charts to detect arbitrary distributional change under the change point detection (CPD) framework when both “in-control” and “out-of-control” distributions are unknown. Mukherjee [28] also proposes a Phase II nonparametric SPC chart for detecting arbitrary distributional change, but it requires a substantial amount of “in-control” Phase I data. A thorough literature review on SPC charts can be found in [29] as well as in [30].

Most existing SPC charts mentioned above focus to detect changes in process location and scale but do not consider an arbitrary distributional change. Moreover, some methods require multiple observations at each time-point; some others require “in-control” Phase I observations. All of these may not be reasonable in many real-life problems. The proposed chart focuses on univariate continuous processes and proposes a p-value-based nonparametric SPC chart to detect an arbitrary distributional change when we can assume that the observations we collect are independent, but “in-control” c.d.f. F_1 is unknown, and “in-control” Phase I data are unavailable. p-value-based SPC charts are new trends as some researchers have already started developing those for better interpretation, e.g., [31, 32], etc.

Additionally, the proposed chart uses the strengths of Cramer-von Mises test and Ansari-Bradley test and demonstrates a better performance in detecting an arbitrary distributional change early. It is demonstrated in the literature [27] that the power of two-sample Cramer-von Mises test to detect a small change in standard deviation or scale is rather weak. The proposed chart overcomes that by integrating this test with Ansari-Bradley test, a nonparametric test for detecting scale change. The integration process is quite general in nature, and hence similar integration techniques can be used to design better control charts in many scenarios.

The major steps of the proposed SPC chart are the following: First, we estimate the possible change-point that gives the minimum p-value of the relevant two-sample Cramer-von Mises test statistic. We use a computationally efficient method to do this. Using that change-point, we calculate the p-value of Ansari-Bradley test and pick the smallest of the two p-values as the effective p-value and use it as the charting statistic. Since it is demonstrated in the literature (e.g., [27]) that Cramer-von Mises test does not have strong power to detect scale changes, if there is indeed a scale change in the process distribution, Ansari-Bradley test gives a smaller p-value than Cramer-von Mises test. Therefore, to detect such changes, it is better to use the smaller of the p-values. If

the process distribution changes without affecting the scale parameter, Cramer-von Mises test gives a smaller p-value than Ansari-Bradley test. It is also better to use the smaller of the two p-values to detect such a change as well. If the p-value is large enough, and our effective sequence of observations is too long, we prune observations from distant past and we collect the next observation. The amount of pruning is a nondecreasing function of the effective p-value as the higher the p-value, the more likely it is that no distributional change has occurred, and it is therefore better to ignore information from distant past to speed up computation. If the p-value is small enough, the chart signals a distributional change.

The remainder of the chapter is organized as follows. At the end of this paragraph, a nomenclature subsection is provided so that this chapter can be read smoothly. Next, brief descriptions of traditionally used SPC charts are provided in Sect. 19.2. The proposed control chart is described in Sect. 19.3. Numerical studies to evaluate its performance in comparison with several existing control charts are presented in Sect. 19.4. A climatological data analysis and a blood sugar monitoring data analysis by the proposed chart and its competitors are presented in Sect. 19.5. A few remarks in Sect. 19.6 conclude this chapter.

19.2 Traditionally Used SPC Charts

Statistical process control of a production process is roughly divided into two phases: Phase I and Phase II. In Phase I, i.e., in the initial stage, we usually do not have enough information about the performance of the production process, and our major goal in this stage is to adjust the production process so that it can run in a stable manner. First, we usually let the process produce a given amount of products, and then the quality characteristics of these products are analyzed. If the statistical analysis of these data shows indication that the process is not running stably, we try to figure out the root causes for that and make adjustments of the process so that it can run stably. After the adjustments, another set of data is collected and analyzed, and the production process should be adjusted again, if necessary. The analysis and adjustment process is iterated several times until we are confident that the performance of the production process is stable. Once all “special causes” have been removed and the production process is “in-control,” we collect an “in-control” dataset from the products manufactured under the stable operating conditions, and the “in-control” data are used for estimating the “in-control” distribution of the quality characteristic(s) of interest. Based on the actual “in-control” distribution if known, or estimated “in-control” distribution otherwise, a Phase II SPC control chart is designed. It is typically used for online monitoring of the production process. When the chart detects a significant change in the distribution of the quality

characteristic(s) from “in-control” distribution, it gives a signal and the production process is stopped immediately for identification of the root cause for such a change and its removal. This online monitoring stage is often called Phase II SPC.

In both Phase I and Phase II of SPC, many statistical tools such as histograms, stem-and-leaf plots, regression, and design of experiments are very helpful. Among all these, control charts are especially useful since they are constructed specifically to detect “out-of-control” performance of the production process. A charting statistic should be chosen such that it contains as much of the information in the observed data about the distribution of the quality characteristic(s) as possible and be sensitive to any distributional change as well. In the literature, different types of control charts have been developed including the Shewhart charts, the cumulative sum (CUSUM) charts, the exponentially weighted moving average (EWMA) charts, charts based on change-point detection (CPD), and so on. Brief descriptions of some of these control charts are provided below.

19.2.1 Shewhart Chart

The first control chart was proposed by Shewhart [1] in 1931. The chart assumes that the quality variable X follows normal distribution $N(\mu_0, \sigma^2)$, and at each time-point we obtain m independent quality observations. Denote $(X_{n1}, X_{n2}, \dots, X_{nm})$ to be the n -th batch of observations, where the batch size is $m \geq 2$. Traditional z-test is used to check if the process observations are “in-control” at the n -th time-point. The process is considered “out-of-control” when

$$\bar{X}_n > \mu_0 + z_{1-\alpha/2} \frac{\sigma}{\sqrt{m}} \quad \text{or} \quad \bar{X}_n < \mu_0 - z_{1-\alpha/2} \frac{\sigma}{\sqrt{m}},$$

where \bar{X}_n is the sample mean of $(X_{n1}, X_{n2}, \dots, X_{nm})$ and $z_{1-\alpha/2}$ is $(1 - \alpha/2)$ -th quantile of the standard normal distribution. This version can be used when both μ_0 and σ are known. However, it is usually not the case in reality. In that case, they have to be estimated from a dataset known to be “in-control.” Suppose, $(X_{i1}^*, X_{i2}^*, \dots, X_{im}^*), i = 1, 2, \dots, M$ be an “in-control” dataset. Let \bar{X}_i^* and R_i^* be the sample mean and sample range of the i -th batch of “in-control” dataset and \bar{X}^* and \bar{R}^* be the sample means of $\{\bar{X}_i^*, i = 1, 2, \dots, M\}$ and $\{R_i^*, i = 1, 2, \dots, M\}$, respectively. It can be easily verified that \bar{X}^* is an unbiased estimator of μ_0 and $\bar{R}^*/d_1(m)$ is an unbiased estimator of σ , where $d_1(m) = E(R_i^*/\sigma)$ is a constant depending on m . When $m = 2$, $d_1(m) = 1.128$, when $m = 5$, $d_1(m) = 2.326$. $d_1(m)$ values for many other commonly used m are provided in Table 3.1 of [30]. Therefore, the Shewhart chart signals a shift in process mean if

$$\begin{aligned} \bar{X}_n &> \bar{X}^* + z_{1-\alpha/2} \frac{\bar{R}^*}{d_1(m)\sqrt{m}} \quad \text{or} \\ \bar{X}_n &< \bar{X}^* - z_{1-\alpha/2} \frac{\bar{R}^*}{d_1(m)\sqrt{m}}. \end{aligned} \tag{19.1}$$

Traditionally, the manufacturing industry uses $\alpha = 0.0027$, and hence $(1 - \alpha/2)$ -th quantile of $N(0, 1)$, i.e., $z_{1-\alpha/2}$ is 3. Therefore, the chart signals mean shift at time-point n if \bar{X}_n falls outside the interval of width six sigma centered at μ_0 and where sigma is the standard deviation of \bar{X}_n . Thus, the terminology ‘‘six sigma’’ originated in the domain of quality control.

The performance of a control chart is traditionally measured by average run length (ARL). Since the charts use control limits for making decision on process performance, an ‘‘in-control’’ process sometimes give false signals of distributional shift. This phenomenon is analogous to having type I error in hypothesis testing. The number of samples or batches collected from the initial time-point of consideration to the occurrence of first false ‘‘out-of-control’’ signal when the process remains ‘‘in-control’’ is called ‘‘in-control’’ run length. The mean of such a run length is called ‘‘in-control’’ average run length denoted as ARL_0 . On the other hand, the number of samples or batches collected from the time-point when the shift actually occurs to the time-point of signal of shift is called ‘‘out-of-control’’ run length. Its mean is called ‘‘out-of-control’’ average run length denoted as ARL_1 . The ideal situation is that, for a control chart, ARL_0 value is large and ARL_1 value is small. However, similar to type I and type II error probabilities in hypothesis testing, it is difficult to achieve. Usually, when ARL_0 is large, ARL_1 is also relatively large and vice versa. In SPC literature, we usually fix the ARL_0 value at a given level and compare the performances of the control charts by comparing how small their ARL_1 values are. In the \bar{X} Shewhart chart as described above, the distribution of ‘‘in-control’’ run length is clearly geometric with parameter α . $\alpha = 0.0027$ makes $ARL_0 = 1/\alpha = 370.37$. ARL_1 can also be computed easily as a function of the shifted mean.

In the literature, there are many versions of Shewhart chart. One of them uses sample standard deviation to estimate σ rather than sample range. In this case, the chart gives a signal for mean shift when

$$\begin{aligned} \bar{X}_n &> \bar{X}^* + z_{1-\alpha/2} \frac{\bar{S}^*}{d_3(m)\sqrt{m}} \\ \text{or } \bar{X}_n &< \bar{X}^* - z_{1-\alpha/2} \frac{\bar{S}^*}{d_3(m)\sqrt{m}}, \end{aligned} \tag{19.2}$$

where \bar{S}^* is the sample mean of the batch-wise sample standard deviations $\{S_i^*, i = 1, 2, \dots, M\}$, i.e.,

$$S_i^* = \sqrt{\frac{1}{m-1} \sum_{j=1}^m (X_{ij} - \bar{X}_i^*)^2} \quad \text{for } 1, 2, \dots, M,$$

and $d_3(m) = E(S_i^*/\sigma)$ is a constant depending on the value of m . Under the same setup, Shewhart charts were constructed to monitor process variability. Defining $d_2(m) = \sqrt{\text{Var}\left(\frac{R_i^*}{\sigma}\right)}$, and using $d_1(m) = E(R_i^*/\sigma)$, we can estimate $\sigma_{R_i^*}$ by $\frac{d_2(m)}{d_1(m)}\bar{R}^*$. Therefore, this version of Shewhart chart gives a signal for a change in variability if

$$R_n > \bar{R}^* + z_{1-\alpha/2} \frac{d_2(m)}{d_1(m)}\bar{R}^* \quad \text{or} \quad R_n < \bar{R}^* - z_{1-\alpha/2} \frac{d_2(m)}{d_1(m)}\bar{R}^*. \tag{19.3}$$

Similarly, another version of Shewhart chart was constructed using sample standard deviation instead of sample range. Using the result $\sigma_{S_i^*} = \sigma\sqrt{1 - d_3^2(m)}$ proved by Kenney and Keeping [34], $\sigma_{S_i^*}$ can be estimated by $\frac{\bar{S}^*}{d_3(m)}\sqrt{1 - d_3^2(m)}$. Therefore, the chart gives a signal of a change in variability if S_n , the sample standard deviation of $(X_{n1}, X_{n2}, \dots, X_{nm})$, satisfies the following condition:

$$\begin{aligned} S_n &> \bar{S}^* + z_{1-\alpha/2} \frac{\sqrt{1 - d_3^2(m)}}{d_3(m)}\bar{S}^* \\ \text{or } S_n &< \bar{S}^* - z_{1-\alpha/2} \frac{\sqrt{1 - d_3^2(m)}}{d_3(m)}\bar{S}^*. \end{aligned} \tag{19.4}$$

Using the result that $\frac{(m-1)S_i^{*2}}{(\sigma^2)} \sim \chi_{m-1}^2$, another chart was constructed using sample variance instead of sample standard deviation. This chart gives a signal for a change in process variance when

$$S_n^2 > \bar{S}^{*2} \frac{\chi_{1-\alpha/2, m-1}^2}{m-1} \quad \text{or} \quad S_n^2 < \bar{S}^{*2} \frac{\chi_{\alpha/2, m-1}^2}{m-1}, \tag{19.5}$$

where \bar{S}^{*2} is the sample average of $\{S_i^{*2}, i = 1, 2, \dots, M\}$.

Next, we discuss \bar{X} Shewhart chart for monitoring individual observations rather than batched observations in Phase I SPC. The idea is to artificially create grouped data by grouping consecutive observations. First, we fix the size of each group $\tilde{m} > 1$. Then, the first \tilde{m} observations form the first group, the next \tilde{m} observations form the second group, and so on. Next, we can apply \bar{X} Shewhart chart (19.1) on the

grouped data. However, one problem here is that consecutive groups are \tilde{m} time-points apart. Hence, it is difficult to know the process behavior at each time-point. To overcome this limitation, most people adopt the idea of moving windows. We artificially create grouped data as follows: Group 1 ($X_1, X_2, \dots, X_{\tilde{m}}$), Group 2 ($X_2, X_3, \dots, X_{\tilde{m}+1}$), and so on until Group $(n - \tilde{m} + 1)$ ($X_{n-\tilde{m}+1}, X_{n-\tilde{m}+2}, \dots, X_n$). Denote $MR_1, MR_2, \dots, MR_{n-\tilde{m}+1}$ to be the sample ranges of the $(n - \tilde{m} + 1)$ groups of data and \overline{MR} to be their sample mean. From the definition of $d_1(\tilde{m})$, we can estimate σ by $\overline{MR}/d_1(\tilde{m})$. Therefore, the \bar{X} Shewhart chart for monitoring individual observations gives a signal of mean shift when

$$X_n > \bar{X} + z_{1-\alpha/2} \frac{\overline{MR}}{d_1(\tilde{m})} \quad \text{or} \quad X_n < \bar{X} - z_{1-\alpha/2} \frac{\overline{MR}}{d_1(\tilde{m})}. \tag{19.6}$$

Similarly, R Shewhart chart for monitoring individual observations gives a signal of a variability shift when

$$MR_i > \overline{MR} + z_{1-\alpha/2} \frac{d_2(\tilde{m})}{d_1(\tilde{m})} \overline{MR} \\ \text{or} \quad MR_i < \overline{MR} - z_{1-\alpha/2} \frac{d_2(\tilde{m})}{d_1(\tilde{m})} \overline{MR}. \tag{19.7}$$

Here, we should check at all time-points that belong to the i -th group, i.e., from the i -th to the $(i + \tilde{m} - 1)$ -th time-points. Other Shewhart charts for monitoring individual observations were constructed similarly.

In many applications, quality characteristics are categorical. Now, we describe some Shewhart charts for monitoring such characteristics. After certain products are randomly chosen for monitoring purposes, they are classified in conforming and nonconforming products based on requirements on the quality characteristics. Now, we monitor the proportion of nonconforming products over time. We assume that when a production process is “in-control,” the true proportion of nonconforming products is π_0 , and we obtain a random sample of m products at each time-point. Let Y be the number of nonconforming products obtained at a given time-point. Therefore, $Y \sim \text{Binomial}(m, \pi_0)$ when the process is “in-control.” Let $p = Y/m$ be the sample proportion of nonconforming products at the time-point. When m is large, the probability distribution of p can be well approximated by $N(\pi_0, \pi_0(1 - \pi_0)/m)$ by the central limit theorem when the process is “in-control.” Hence, the process can be called “out-of-control” if

$$p > \pi_0 + z_{1-\alpha/2} \sqrt{\frac{\pi_0(1 - \pi_0)}{m}} \\ \text{or} \quad p < \pi_0 - z_{1-\alpha/2} \sqrt{\frac{\pi_0(1 - \pi_0)}{m}}.$$

In practice, π_0 is often unknown and should be estimated from collected Phase I data, just like in the original version of \bar{X} Shewhart chart use estimated μ_0 and σ . As before, we assume that we have M batches of Phase I data. Let p_i^* be the sample proportion of nonconforming products in the i -th batch of Phase I data for $i = 1, 2, \dots, M$ and \bar{p}^* be their sample mean. Therefore, we can estimate π_0 by \bar{p}^* , and hence the p Shewhart chart gives a signal for a change in the proportion of nonconforming products at n -th time-point when

$$p_n > \bar{p}^* + z_{1-\alpha/2} \sqrt{\frac{\bar{p}^*(1 - \bar{p}^*)}{m}} \\ \text{or} \quad p_n < \bar{p}^* - z_{1-\alpha/2} \sqrt{\frac{\bar{p}^*(1 - \bar{p}^*)}{m}}. \tag{19.8}$$

There are other versions of Shewhart chart in the literature for monitoring count processes having distributions such as Poisson. Detailed descriptions of such charts are provided in Chapter 3 of [30].

Shewhart charts are good at detecting relatively large isolated shifts, but not so efficient in detecting relatively small but persistent shifts. This is because Shewhart charts evaluate the process performance based on the observed data collected at each individual time-point and ignore observations collected previously. Therefore, Shewhart charts are popular in Phase I SPC where large and isolated shifts are common but less commonly used in Phase II SPC.

As we mentioned before, the \bar{X} , R , and S Shewhart charts are appropriate to use only in cases when the process distribution is normal and the observations are independent of each other. When the process distribution is not normal, the probability of type I error, i.e., the probability of false “out-of-control” signal when the process is actually “in-control,” can substantially differ from the prefixed value of α . If the type I probability of a Shewhart chart is larger than α , then the chart will give false “out-of-control” signal more often than expected. Consequently, much time and resource will be wasted to find the cause of such signals and adjusting the related production process. On the other hand, if the type I probability of a Shewhart chart is smaller than α , then real shifts will be missed more often than expected and hence many nonconforming products could be manufactured. However, when the distribution of X_{ij} is non-normal but the batch size m is large, the issue described above will not be serious, because the distribution of \bar{X}_n can be well approximated by normal distribution due to the central limit theorem. In cases when the distribution of X_{ij} is non-normal and the batch size m is small, mainly two approaches are usually taken. One approach is to transform the non-normal data to normal and then use the conventional Shewhart charts to the transformed data [35,36], and the other approach is to use Shewhart charts that are constructed to monitor non-normal data.

If the performances of the Shewhart charts are evaluated by “in-control” average run length ARL_0 and “out-of-control” average run length ARL_1 , then the performance measures will be not accurate if the observations are correlated [37–39]. In these cases, correlations have to be handled properly.

19.2.2 CUSUM Chart

Shewhart chart makes a decision whether a process is “in-control” or not at a time-point using only the observations obtained at that time-point and ignoring all previous observations. Therefore, it is not very effective in Phase II monitoring in most cases, because previous observations contain helpful information about process performance at present. Page [2] suggested the first cumulative sum (CUSUM) chart to overcome this limitation. Let us first describe the basic CUSUM chart for detecting mean shift of a process following normal distribution. Again, the chart assumes that the process observations X_1, X_2, X_3, \dots follow $N(\mu_0, \sigma^2)$ and are independent. The CUSUM charting statistics are given by

$$C_n^+ = \max(0, C_{n-1}^+ ((X_n - \mu_0)/\sigma) - k), \quad (19.9)$$

$$C_n^- = \min(0, C_{n-1}^- ((X_n - \mu_0)/\sigma) + k) \quad (19.10)$$

where $C_0^+ = C_0^- = 0$, and $k > 0$ is an allowance constant. The CUSUM chart gives a signal of mean shift if

$$C_n^+ > \rho_c \quad \text{or} \quad C_n^- < -\rho_c \quad (19.11)$$

where $\rho_c > 0$ is a control limit. The allowance constant k is prespecified, and the value of ρ_c is chosen so that the average run length when the process is “in-control,” denoted as ARL_0 , equals a given number, say, 200, 370, 500, etc. Table 4.1 of [30] provides the values of ρ_c for various values of allowance constant k and ARL_0 . We can easily see that the charting statistics C_n^+ and C_n^- make use of all available data before the n -th time-point, and they restart from 0 when the cumulative charting statistics suggest no significant evidence for mean shift in the sense that $C_{n-1}^+ ((X_n - \mu_0)/\sigma) < k$ and $C_{n-1}^- ((X_n - \mu_0)/\sigma) > -k$. Because of this restarting mechanism, the CUSUM chart enjoys a good theoretical property that it has smallest “out-of-control” ARL, denoted as ARL_1 , among all control charts having the same value of ARL_0 . Moustakides [26] proved that the CUSUM chart with an allowance constant k has the shortest ARL_1 value among all charts with a fixed ARL_0 value for detecting a persistent shift of size $\delta = 2k$.

To be able to use the above CUSUM chart, the process observations should be independent before and after a potential shift, both “in-control” and “out-of-control” distributions have to be normal, and the parameters μ_0 and σ of the “in-control” distribution have to be known. However, in practice these assumptions may not be reasonable.

If the observations are autocorrelated, then the actual value of ARL_0 will be different from the specified value for which the control limit ρ_c is determined in case of i.i.d. (independent and identically distributed) normal observations as provided by Table 4.1 of [30]. For example, if the production process is autoregressive of order 1, and the autocorrelation is negative, then the actual value of ARL_0 will be larger than the specified value for which ρ_c is determined. Consequently, the chart will not be sensitive enough to mean shifts and a lot of nonconforming products can be manufactured. On the other hand, if the production process is autoregressive of order 1, with positive autocorrelation, then the actual value of ARL_0 will be smaller than the specified value for which ρ_c is determined. That means the chart will give too many false signals of mean shift than expected and the production process has to be stopped too many times unnecessarily, and hence many resources will be wasted. One commonly used approach to accommodate possible autocorrelation among observed data is to group neighboring observations into batches and then apply conventional CUSUM charts for independent data to the batch means. One major reason behind this idea is that possible autocorrelation in the original data will be mostly eliminated in the new batch means [40]. Because of autocorrelation, the standard deviation of standardized group means may not be 1, and it can differ very much from 1. Therefore, the actual ARL_0 may be far away from the specified ARL_0 value. To overcome this limitation of the grouping approach, the group means need to be scaled properly which is difficult to do unless we know the nature of correlation in the original data. For related descriptions, see [40, 41], and [42]. Another disadvantage of the grouping approach is that the control chart cannot detect a mean shift promptly as it has to wait until all observations within a group are obtained. An alternative approach to the grouping idea is to describe the correlation by a statistical model such as autoregressive moving average (ARMA) model. In many practical applications, appropriate special cases of the ARMA model, such as first-order autoregressive model, can be used; otherwise, an appropriate model can be selected by a model selection procedure. After a time-series model is chosen and fitted by a certain routine procedure in time-series analysis, we can calculate the residuals. If the chosen time-series model describes the observed “in-control” data adequately, and the production process is “in-control” until the given time-point, the residuals should approximately be independent with a zero-mean common normal distribution whose variance can be estimated by an appropriate estimator. Then, we can apply the conventional CUSUM chart to the calculated residuals. However, we should be careful that an “out-of-control” signal may not always be due to a shift in mean; it can be due to a change in correlation structure in the observations as well. Related discussions on model-based control charts for monitoring autocorrelated processes can be found in [43–45], and so on.

In cases when the observations are i.i.d. normal but the “in-control” mean μ_0 and variance σ^2 are unknown, a common approach is to estimate those from a large “in-control” dataset. However, even a small randomness of these estimated values affects the performance of the CUSUM charts in a significant way. Hawkins [46] explored this research question in detail. Since in many applications we cannot have an extremely large “in-control” dataset, Hawkins [46] proposed the self-starting CUSUM charts in which “in-control” parameters are estimated from the observations collected in Phase II SPC. Assume that no “out-of-control” signal is given until the $(n-1)$ -th time-point. A new observation is collected at the n -th time-point and we want to make a decision whether a signal of mean shift should be given at this time-point. Since no signal for mean shift is given at $(n-1)$ -th time-point, we can consider all observations collected at that time-point and before, i.e., $X_{n-1}, X_{n-2}, \dots, X_1$, as “in-control” observations. Therefore, μ_0 and σ^2 can be estimated by their sample mean \bar{X}_{n-1} and sample variance S_{n-1}^2 , respectively, as long as $n \geq 3$. Therefore, for constructing a CUSUM chart, it is natural to replace $(X_n - \mu_0)/\sigma$ in (19.9) and (19.10) by $T_n = (X_n - \bar{X}_{n-1})/S_{n-1}$. When X_1, X_2, \dots, X_n are i.i.d. $N(\mu_0, \sigma^2)$ which is the case when the process is “in-control” up to the n -th time-point, we can easily check that $(\sqrt{(n-1)/n})T_n \sim t_{n-2}$. As proved in [47], T_1, T_2, \dots, T_n are independent of each other when the process is “in-control” up to the n -th time-point. Therefore, in that case,

$$Z_n = \Phi^{-1} \left[\Upsilon_{n-2} \left(\sqrt{\frac{n-1}{n}} T_n \right) \right]$$

follow i.i.d. $N(0, 1)$ distribution, where Φ and Υ_{n-2} are cumulative distribution functions (c.d.f.) of $N(0, 1)$ and t_{n-2} , respectively. Since Φ^{-1} and Υ_{n-2} are increasing functions, a mean shift in the original observations X_i , $1 \leq i \leq n$ indicates a mean shift in the transformed observations Z_i , $1 \leq i \leq n$ and vice versa. Therefore, detection of mean shift in Phase II monitoring can be accomplished by using transformed observations Z_n , $n \geq 1$ in place of $(X_n - \mu_0)/\sigma$ in (19.9) and (19.10). It has been demonstrated in the literature that if a persistent mean shift occurs within the first few observations in Phase II monitoring, the self-starting CUSUM chart as described above has a weak power to detect it. Therefore, in practice, at least a dozen or more “in-control” observations should be collected in Phase II before using the self-starting CUSUM chart. Self-starting control charts are now popular in the literature ([48, 49], and so on).

The traditional CUSUM chart (19.9–19.10) has an allowance parameter k , which should be set as $\delta/2$ where δ is the size of potential mean shift. In practice, δ is often unknown at the time when we design the CUSUM chart and hence choice of k is not straightforward. Sparks [50] proposed two approaches to solve this issue. Sparks’ first approach is to use several CUSUM charts with different k

values simultaneously so that these charts target to detect mean shifts of different sizes. Such a joint control scheme gives an “out-of-control” signal of mean shift if at least one of the CUSUM charts detects a mean shift. Of course, the ARL_0 values of these CUSUM charts have to be the same prefixed number. If we have prior information about the potential mean shift, we should incorporate the information while determining the k values. Sparks’ second approach is to estimate the size of mean shift δ recursively at each time-point and updating the value of k accordingly. The control limit should also be updated at each time-point so that we can maintain the prespecified ARL_0 value. These are called adaptive CUSUM charts.

When the “in-control” distribution of the production process is not normal, then the traditional CUSUM charts should not be used. If we know that the “in-control” distribution is in exponential family such as gamma and Weibull distribution, then we can similarly construct CUSUM charts by using sequential probability ratio test. However, if the “in-control” distribution is completely unknown, we can use nonparametric control charts [11–18] that do not assume any “in-control” distribution.

The versions of CUSUM chart mentioned above were designed for detecting a step shift in process mean. However, in many applications, the process mean and/or variance changes gradually with or without a known parametric pattern, after the process becomes “out-of-control.” Such changes are called drifts. Gan [51], Davis and Woodall [52], and many other researchers proposed CUSUM charts for detecting linear drifts.

Recently, CUSUM charts with variable sampling rate become popular ([53, 54] and many others). In this type of CUSUM chart, the sampling rate varies over time based on all observed data. There are many different types of sampling rate such as variable sampling intervals, variable sample sizes, etc. One major advantage of variable sampling rate CUSUM charts compared to fixed sampling rate CUSUM charts is faster detection of small to moderate shift in process mean. Recently, Li and Qiu [32] suggested implementing a CUSUM chart using statistical p-values and proposed the concept of dynamic sampling.

In the literature, researchers have constructed CUSUM charts for monitoring the variance of the process distribution as well.

19.2.3 EWMA Chart

In spite of having good theoretical properties, CUSUM charts were difficult to use in the 1950s when there was no computers. A simpler chart, called exponentially weighted moving average (EWMA) chart, was proposed by Roberts [55] in 1959. Under the same assumptions and notations of CUSUM chart, the EWMA charting statistic is defined as

$$E_n = \lambda X_n + (1 - \lambda)E_{n-1} \quad (19.12)$$

where $E_0 = \mu_0$ and $0 < \lambda \leq 1$ is a weighting parameter. We can easily check that

$$E_n = \lambda \sum_{i=1}^n (1 - \lambda)^{n-i} X_i + (1 - \lambda)^n \mu_0, \quad (19.13)$$

and when the process is “in-control,”

$$E_n \sim N\left(\mu_0, \frac{\lambda}{2 - \lambda} [1 - (1 - \lambda)^{2n}] \sigma^2\right).$$

That means E_n is a weighted average of μ_0 and all observations up to time-point n , and the weight received by X_i decays exponentially fast when i moves away from n . Therefore, it becomes easy to study the properties of E_n when the process is “in-control.” From the probability distribution of E_n , EWMA chart gives a signal for mean shift when

$$|E_n - \mu_0| > \rho_e \sigma \sqrt{\frac{\lambda}{2 - \lambda} [1 - (1 - \lambda)^{2n}]}, \quad (19.14)$$

where $\rho_e > 0$ is a control limit. $\lambda > 0$ is chosen beforehand, and the value of ρ_e is determined such that a specified value of ARL_0 is achieved.

To be able to use the EWMA chart in practice, we need to choose λ values properly and then the value of ρ_e so that the prespecified ARL_0 value is achieved. Just like the CUSUM charts, we need to specify a target shift size first and then we can search for a λ value and the corresponding ρ_e value such that the prespecified ARL_0 value is achieved and the ARL_1 value for detecting the mean shift of target size is minimized. As a general guideline, small λ values are good for detecting relatively small mean shifts, and large λ values are good for detecting relatively large means shifts. Crowder [56] provides a discussion on this issue. While we assume that the “in-control” process distribution is normal, some researchers have demonstrated that the EWMA chart is quite robust to normality assumption [3].

In case of autocorrelated observations, similar approaches as we described in the CUSUM chart can be implemented in case of EWMA charts as well. However, some researchers suggest applying the EWMA charts directly to the original data and then adjusting the control limits to reflect the impact of autocorrelations [57].

For using Shewhart, CUSUM, or EWMA chart as described before, μ_0 and σ has to be known or estimated before the monitoring starts. As we have discussed before, this is not convenient in many applications, and hence we should use self-starting control charts. Just like the self-starting CUSUM control charts, we first transform the original data to Z_i , $i \geq 1$ and then apply the traditional EWMA chart to the

transformed data. In the literature, there are several methods such as [58] where λ is chosen adaptively depending on the size of potential mean shift. These are called adaptive EWMA charts.

In the literature, EWMA charts have been developed when the process distribution follows other parametric forms. Some researchers [59, 60] constructed EWMA charts for monitoring processes following Weibull distributions. Borrer et al. [61], Gan [62], and some others discussed process monitoring when the process distribution is Poisson. Perry and Pignatiello [63], Sparks et al. [64], and many others discussed EWMA process monitoring with binomial or negative binomial distributions.

All versions EWMA charts that we discussed so far are designed for detecting step shift in the process mean. In some practical situations, when the process becomes “out-of-control,” its mean departs gradually from the “in-control” level. It is important that we can detect such gradual departures, called drifts, as early as possible. In the literature, some researchers have modified EWMA charts to detect drifts efficiently ([65] and others).

Just like CUSUM charts, researchers have constructed EWMA charts to monitor the variance of the production processes as well.

19.2.4 Control Charts by Change-Point Detection (CPD)

In change-point detection (CPD), the distribution of the first part of a sequence of random variables is assumed to be the same, the distribution of the remaining part of the random variables of that sequence is also assumed to be the same, but the distributions of the two parts are assumed to be different. The specific position in the sequence at which the distribution of the random variables changes from one to the next is called a change-point. Our major goal is to estimate the position of the change-point. Gombay [66], Hinkley [67], and many others in the literature provide detailed description of this topic. In change-point detection problems, the sample size is usually fixed. In Phase I SPC, the sample size is usually fixed, and then the change-point methods can be applied directly. In Phase II SPC, observations are obtained sequentially over time. Therefore, change-point methods must be applied appropriately in such cases. Recently, change-point methods have been modified and applied to the SPC problems ([4, 5], and others) as well. Change-point-based control charts are good at detecting small and persistent shifts and can estimate the position of change-point efficiently.

Let us describe the change-point based control chart proposed by Hawkins et al. [4]. It assumes that the observations X_1, X_2, \dots, X_n follow this change-point model

$$\begin{aligned}
 X_i &= \mu_0 + \varepsilon_i & \text{for } 1 \leq i \leq r \\
 X_i &= \mu_1 + \varepsilon_i & \text{for } (r + 1) \leq i \leq n
 \end{aligned}$$

where r is the change-point and ε_i , $1 \leq i \leq n$ is a sequence of i.i.d. random variables having the common distribution $N(0, \sigma^2)$. For testing the existence of the change-point, the likelihood ration test statistic is

$$T_{max,n} = \max_{1 \leq j \leq n-1} \sqrt{\frac{j(n-j)}{n}} \left| \bar{X}_j - \bar{X}'_j \right| / \tilde{S}_j \quad (19.15)$$

where \bar{X}_j and \bar{X}'_j are sample means of first j and the remaining $(n-j)$ observations, and $\tilde{S}_j^2 = \sum_{i=1}^j (X_i - \bar{X}_j)^2 + \sum_{i=j+1}^{n-j} (X_i - \bar{X}'_j)^2$. The change-point-based chart gives an “out-of-control” signal of mean shift when

$$T_{max,n} > \rho_n \quad (19.16)$$

where $\rho_n > 0$ is a control limit. If we have an “out-of-control” signal, then the position of change-point r is estimated by the maximizer in (19.15). Hawkins et al. [4] provided formulas to calculate the values of ρ_n for commonly used prespecified values of ARL_0 .

Just like other control charts, change-point-based charts were also constructed to accommodate other situations such as if the “in-control” process distribution is not normal, but other known parametric distribution. Change-point-based charts were also developed to monitor process variance as well.

Although the change-point-based control charts have their advantages over Shewhart, CUSUM, and EWMA charts, their computation is still relatively complex. This is because the estimator of the position of change-point has to be recalculated each time a new observation is obtained which involve a search in a sequence of n time-points. A systematic comparison between the performances of self-starting and adaptive traditional (CUSUM and EWMA) control charts and the change-point-based control charts is currently lacking in the literature.

In practice, many variables do not follow normal distribution. For example, many economic indices, rainfall distribution, lifetime distribution of many products, etc. are usually skewed to the right. In most instances it is difficult to find an appropriate parametric distribution for their modeling. Researchers use nonparametric methods to describe their distributions. When the normality assumption is not reasonable, several researchers have pointed out that the traditional control charts would be unreliable for process monitoring ([6,7,16], and many others). In such cases, nonparametric statistical methods based on the ranking or ordering information of the observations can be considered for making inferences about the underlying process distribution. Another approach is based on data categorization. Clearly, both approaches

have the limitation of losing useful information during ranking and categorization. However, the methods based on data categorization seem to be more efficient in process monitoring as use some information about observation magnitudes. Nonparametric versions of conventional charts such as Shewhart, CUSUM, EWMA, and change-point-based have been developed in the literature. Most nonparametric control charts in the literature are for Phase II SPC. However, there is only a limited discussion on Phase I SPC when the process distribution does not follow any common parametric form [68,69].

Many researchers have developed control charts in the literature to jointly monitor process mean and variance as well. We skip such details in this chapter. We also omit descriptions of multivariate control charts as well. Interested readers should go through [30].

19.3 The Proposed SPC Chart

In this section, we describe our proposed Phase II chart for detecting persistent distributional change in univariate continuous processes. We assume that “in-control” probability distribution of the process is unknown, “in-control” Phase I data are unavailable, and the observations we collect are independent of each other. Let $Y_1, Y_2, \dots, Y_t, \dots$ be a sequence of independent observations during Phase II process monitoring. We start performing statistical monitoring right after time-point $S_0 \geq 4$, because we need to need have at least a few observations so that statistical tests have enough power. This is a common practice as discussed in [4,27], etc. At each time $t \geq S_0$, we consider the following change-point framework. Assuming τ , $2 \leq \tau \leq t - 2$ to be a possible point of distributional change, we consider two samples $\{Y_1, Y_2, \dots, Y_\tau\}$ and $\{Y_{\tau+1}, Y_{\tau+2}, \dots, Y_t\}$, and perform Cramer-von Mises test to check if they are coming from the same unknown continuous cumulative distribution function (cdf). For statistically testing whether two samples are from the same continuous distribution, two tests are commonly used: Kolmogorov-Smirnov test and Cramer-von Mises test. Kolmogorov-Smirnov test does not work well if there are ties in the samples. Also, Cramer-von Mises test usually have more power than Kolmogorov-Smirnov test in many situations. Therefore, we use Cramer-von Mises test ahead of Kolmogorov-Smirnov test. The two-sample Cramer-von Mises test statistic is given by

$$\begin{aligned}
 C_\tau(t) &= \frac{\tau(t-\tau)}{t^2} \left(\sum_{i=1}^{\tau} (F^*(Y_i) - G^*(Y_i))^2 \right. \\
 &\quad \left. + \sum_{j=\tau+1}^t (F^*(Y_j) - G^*(Y_j))^2 \right), \quad (19.17)
 \end{aligned}$$

where F^* and G^* are the empirical distributions associated with the samples $\{Y_1, Y_2, \dots, Y_\tau\}$ and $\{Y_{\tau+1}, Y_{\tau+2}, \dots, Y_t\}$. Large values of C_τ means $\{Y_1, Y_2, \dots, Y_\tau\}$ and $\{Y_{\tau+1}, Y_{\tau+2}, \dots, Y_t\}$ are possibly coming from different cdfs. Suppose $P_\tau^{(CvM)}(t)$ is the p-value of the two-sample Cramer-von Mises test. The details of computing $P_\tau^{(CvM)}(t)$ are provided in Sect. 19.3.5 along with other computational technicalities of the proposed chart. A *natural approach* in this framework is to (i) calculate the p-values of two-sample Cramer-von Mises test for all possible values of τ , i.e., $\tau = 2, 3, \dots, t-2$, (ii) determine $\tau^*(t) = \arg \min_{\tau \in \{2, 3, \dots, (t-2)\}} P_\tau^{(CvM)}(t)$, and (iii) use $P_{\tau^*}^{(CvM)}(t)$ as the charting statistic.

However, there are *two major drawbacks* of this approach. *The first drawback* is that the determination of $\tau^*(t)$ can be computationally expensive because we have to compute $P_\tau^{(CvM)}(t)$ for all possible values of τ , i.e., $2, 3, \dots, (t-2)$. Moreover, we need to execute similar procedures for all values of $t \geq S_0$ until we get a signal. We run into this issue in the change-point framework wherever we need to compute the relevant statistic for each value of the possible change-point. To reduce computation, we consider the following two techniques and both can be applied to the proposed SPC chart. The first technique is to estimate $\tau^*(t)$ efficiently by the method proposed in Sect. 19.2.1 which can be applied to other change-point problems of similar nature. The second technique is the pruning of data from distant past based on p-values as proposed by Mukherjee [28]. *The second drawback* is the weakness of the power of Cramer-von Mises test to detect a change in standard deviation or scale. The proposed chart addresses this issue by integrating Cramer-von Mises test with Ansari-Bradley test which is a nonparametric test to detect scale difference. We describe these approaches below.

19.3.1 A Computationally Efficient Approach to Estimate $\tau^*(t)$

We note that the values of $P_\tau^{(CvM)}(t)$ and $P_{\tau'}^{(CvM)}(t)$ should not be too different as long as τ and τ' are close. In other words, for each t , the values of $P_\tau^{(CvM)}(t)$ for different τ are strongly autocorrelated. Therefore, we can make the procedure faster by first calculating $P_\tau^{(CvM)}(t)$ for τ -values that are multiples of $\lfloor \sqrt{t} \rfloor$ instead of all possible values of τ . For a demonstration purpose, consider the case when $t = 100$. Calculate $P_\tau^{(CvM)}(t)$ for $\tau = 10, 20, \dots, 90$ instead of $\tau = 2, 3, 4, \dots, 98$. Then, select the value of τ for which $P_\tau^{(CvM)}(t)$ is minimum, and calculate $P_\tau^{(CvM)}(t)$ for τ -values in the two adjoining intervals. In other words, if $\tau = 30$ gives the smallest $P_\tau^{(CvM)}(t)$ -value among $\tau = 10, 20, 30, \dots, 90$, compute $P_\tau^{(CvM)}(t)$ for $\tau = 21, 22, \dots, 29, 30, 31, \dots, 39$ and select the τ -value for which $P_\tau^{(CvM)}(t)$ is the smallest. The detailed procedure to estimate $\tau^*(t)$ is described below.

For each t , instead of calculating $P_\tau^{(CvM)}(t)$ for possible values of τ , i.e., $2, 3, \dots, (t-2)$, calculate the statistic for $\tau = i \cdot \lfloor \sqrt{t} \rfloor$, where possible values of i are $1, 2, \dots, I(t)$, where $I(t)$ is the largest integer for which $I(t) \cdot \lfloor \sqrt{t} \rfloor \leq (t-2)$. Here, $\lfloor \sqrt{t} \rfloor$ is the largest integer smaller than or equal to t . Since we start monitoring when the time-point $t \geq S_0 \geq 4$, we always have at least one positive integer i for which we can compute $P_\tau^{(CvM)}(t)$. For example, when $t = S_0 = 4$, we have to compute $P_\tau^{(CvM)}(t)$ for only one value of τ , i.e., when $\tau = 2$. Next, we find $\tilde{\tau} = \arg \min_{i \in \{1, 2, \dots, I(t)\}} P_{i \cdot \lfloor \sqrt{t} \rfloor}^{(CvM)}$. Since the $\tau^*(t)$ should be close to $\tilde{\tau}$, we calculate $P_\tau^{(CvM)}(t)$ for all integer values of τ within $[\max\{\tilde{\tau} - \lfloor \sqrt{t} \rfloor + 1, 2\}, \min\{\tilde{\tau} + \lfloor \sqrt{t} \rfloor - 1, (t-2)\}]$ and pick the integer within that interval for which $P_\tau^{(CvM)}(t)$ is minimum. This is our estimated $\tau^*(t)$ and we call it $\tilde{\tau}^*(t)$. The method is summarized as follows:

- (i) Calculate $P_\tau^{(CvM)}(t)$ for $\tau = i \cdot \lfloor \sqrt{t} \rfloor$, where possible values of i are $1, 2, \dots, I(t)$, where $I(t)$ is the largest integer for which $I(t) \cdot \lfloor \sqrt{t} \rfloor \leq (t-2)$.
- (ii) Find $\tilde{\tau} = \arg \min_{i \in \{1, 2, \dots, I(t)\}} P_{i \cdot \lfloor \sqrt{t} \rfloor}^{(CvM)}$.
- (iii) Calculate $P_\tau^{(CvM)}(t)$ for all integer values of τ within the interval:

$$[\max\{\tilde{\tau} - \lfloor \sqrt{t} \rfloor + 1, 2\}, \min\{\tilde{\tau} + \lfloor \sqrt{t} \rfloor - 1, (t-2)\}].$$

- (iv) Estimate $\tau^*(t)$ by the integer within the interval in (iii) for which $P_\tau^{(CvM)}(t)$ is minimum.

19.3.2 Integration of Ansari-Bradley Test with Cramer-von Mises Test

It is well documented in the literature (e.g., [27]) that Cramer-von Mises test does not have high power to detect changes in scale parameters. However, it has high power to detect changes in location parameters. Because of this weakness, we integrate Cramer-von Mises test with Ansari-Bradley test [70] in the proposed control chart. Ansari-Bradley test is a nonparametric test based on rank sum to detect differences in scale parameters. The integration procedure is as follows. For each t , once $\tau^*(t)$ is estimated by the procedure in Sect. 19.2.1:

- (i) Record the p-value of two-sample Cramer-von Mises test for checking if $\{Y_1, Y_2, \dots, Y_{\tilde{\tau}^*}\}$ and $\{Y_{\tilde{\tau}^*+1}, Y_{\tilde{\tau}^*+2}, \dots, Y_t\}$ are realizations from the same continuous cdf. Obviously, it is $P_{\tilde{\tau}^*}^{(CvM)}(t)$.
- (ii) Perform Ansari-Bradley two-sample test for checking if the scale parameters of $\{Y_1, Y_2, \dots, Y_{\tilde{\tau}^*}\}$ and $\{Y_{\tilde{\tau}^*+1}, Y_{\tilde{\tau}^*+2}, \dots, Y_t\}$ are same. Call the p-value $P_{\tilde{\tau}^*(t)}^{(AB)}$.

(iii) Calculate $p^{(E)}(t) = \min\{P_{\hat{\tau}^*(t)}^{(\text{CvM})}(t), P_{\hat{\tau}^*(t)}^{(\text{AB})}(t)\}$, and use this as charting statistic.

When we integrate two different tests in a change-point-based chart, it is natural to perform change-point analysis for both tests, because the estimated change-points can be different for different tests. However, to avoid extra computation, we do not consider this approach. Numerical studies show that the proposed chart based on the procedures as described performs well in detecting changes in scale parameters. When there is a small change in scale parameters and the p-value of Cramer-von Mises test is not small enough to give a signal, it is still small and hence the change-points based on both tests should be close. The proposed chart just detects such change by integrating a more powerful test appropriately.

19.3.3 Data Pruning Based on P-Values

In case the proposed chart does not detect any distributional change for a long time, the sequence of “in-control” observations will be long, and hence calculation of $\hat{\tau}^*(t)$ as described in Sect. 19.2.1 can be time-consuming as well. If the influx of observations is rapid, then this chart in its present form cannot be used to monitor such processes. To solve this problem, consider datapruning from distant past. If $p^{(E)}(t)$, calculated by the procedure described in Sect. 19.2.2 is large, it is very unlikely that a distributional change has taken place. Therefore, we prune a few observations from distant past and focus on more recent observations. In this way, we make sure that the sequence of “in-control” observations does not become too long. We provide the description of the method below.

When $\tilde{t} \geq T_0$, where \tilde{t} is the current length of the sequence of observations, and T_0 is a threshold parameter of the SPC chart, we consider the possibility of data pruning. If $p^{(E)}(t) \geq P_0$, we prune the oldest $C(\tilde{t}, p^{(E)}(t), P_0) = \left\lceil \tilde{t} \cdot \min\left(0.2, \left(\frac{p^{(E)}(t) - P_0}{1 - P_0}\right)\right) \right\rceil$ number of observations. Here, we make sure not to prune too much in one step, by specifying that we cannot prune more than 20% of the current length of the sequence at one step. Here, we set the maximum amount of pruning at one step to be 20% based on the performance of the chart in our simulation experiments in terms of how fast it can compute and how early it can give a signal when a process goes “out-of-control.” While one can introduce a parameter for the maximum percentage we can prune at one step and select its value based on a reasonable criterion, we set it equal to 20% for simplicity. Once we prune, we can estimate $\tau^*(t)$ faster in the next step, i.e., after the arrival of next observation. The summary of data pruning is as follows:

- (i) When $p^{(E)}(t) < P_0$, give a signal for distributional change and stop process monitoring; otherwise, go to Step (ii).
- (ii) If $\tilde{t} \geq T_0$, prune the oldest $C(\tilde{t}, p^{(E)}(t), P_0) = \left\lceil \tilde{t} \cdot \min\left(0.2, \left(\frac{p^{(E)}(t) - P_0}{1 - P_0}\right)\right) \right\rceil$ number of observations, and collect the next observation. Otherwise, go to Step (iii).
- (iii) Do not prune and collect the next observation.

19.3.4 The Algorithm of the Proposed Control Chart

The summary of the procedures to run the proposed control chart is as follows:

1. When $\tilde{t} < S_0$, collect the next observation. Otherwise, go to Step 2.
2. Calculate $\hat{\tau}^*(t)$, an estimate of $\tau^*(t)$ by the method described in Sect. 19.2.1. Go to Step 3.
3. Calculate $P_{\hat{\tau}^*(t)}^{(\text{CvM})}(t)$, $P_{\hat{\tau}^*(t)}^{(\text{AB})}(t)$, and $p^{(E)}(t)$ by the method described in Sect. 19.2.2. If $p^{(E)}(t) < P_0$, give a signal for distributional change and stop process monitoring; otherwise, go to Step 4.
4. Perform the data pruning procedure as described in Sect. 19.2.3. Go to Step 1.

19.3.5 Implementation

Calculation of p-values for two-sample Cramer-von Mises tests is computationally expensive and time-consuming especially when the sample sizes are large [71]. However, [72] provide the asymptotic distribution of two-sample Cramer-von Mises criterion. We also note that the convergence rate is rapid. Therefore, in our implementation, we use asymptotic p-values rather than the exact ones. Using the software R (<https://www.r-project.org/>) and the R-package *CvM2SL2Test* developed by Xiao [73], we extend the table provided by Anderson and Darling [72] to calculate p-values of two-sample Cramer-von Mises tests when they are smaller than 0.01. We use the same R-package *CvM2SL2Test* to calculate the two-sample Cramer-von Mises test statistics given as in (1) and then calculate their asymptotic p-values. For calculating (1), the R-package uses a C++ program developed by Xiao et al. [74]. We use R-function *ansari.test()* to perform Ansari-Bradley tests. It should be noted that approximate p-values are calculated even for small samples in presence of ties. The proposed method is designed to monitor univariate continuous

processes and hence cannot handle even a moderate number of ties in the observation sequence. However, this chart can still perform well in presence of a small number of ties.

19.4 Numerical Studies

We perform several numerical studies to evaluate the performance of the proposed method in comparison with a number of state-of-the-art change-point-based control charts. Our main goal is to find a chart that shows overall better performance to detect arbitrary distributional changes. We also study how the performances are affected by the number of “in-control” observations before the distributional change. Like most research articles in the literature, we also evaluate the performances of the control charts by the average number of observations, called “run length” after the first observation from the changed distribution is obtained. We call it ARL_1 . The smaller the value of ARL_1 , the better the performance. Of course, we set the control limits of all control charts such that the average number of “in-control” observations required to give a false signal when no distributional change takes place is a prefixed large number. We call it ARL_0 . In all our numerical simulations, we set $ARL_0 = 500$ unless mentioned otherwise.

We compare the proposed method with four other change-point-based methods. The first method is proposed by Hawkins and Deng [13]. It is based on Mann-Whitney test and it aims to detect location shift. We call this method MW. The next competing control chart, proposed by Ross et al. [33], is based on Mood test [75]. This chart aims to detect scale change in the process distribution. We call it Mood. The third competing chart, also proposed by Ross et al. [33], is based on Lepage test [76]. It aims to detect changes in both location and scale of the process distribution, and we call it Lepage. Our fourth competing chart, proposed by Ross and Adams [27], aims to detect arbitrary distributional change using Cramer-von Mises test. We call this chart CvM.

Initially, we consider three “in-control” process distributions: standard normal, $N(0, 1)$; standardized t-distribution with 2.5 degrees of freedom, $ST(2.5)$; and standardized log-normal distribution with parameters 1.0 and 0.5, $SLN(1.0, 0.5)$. Note that the mean and standard deviation of log-normal distribution with parameters 1.0 and 0.5 are 3.08 and 1.64, respectively. However, we approximate those by 3 and 1.6 while standardizing. We first consider shifts in location only, scale only, and both location and scale simultaneously. Finally, we consider arbitrary changes of various distributions. To compare the performances of various methods, we consider two cases: when the distribution change occurs early, right after

time-point $\tau = 50$, and when the change occurs late, right after time-point $\tau = 300$. It should be noted that if a false signal occurs before the actual distributional change, we disregard that sequence in our simulation, as it is a reasonable practice.

We use the R-package *cpm* to run the competing charts. For the proposed method, we need to select S_0 and T_0 . For all methods, we select the startup time to be 20, and for the proposed method, we select $S_0 = 20$ and $T_0 = ARL_0 = 500$. For comparing the performances of the methods when the distributional change is arbitrary, we run four versions of the proposed chart called P_{250} , P_{500} , P_{1000} , and P_∞ when $T_0 = 250, 500, 1000$, and ∞ , respectively. From Table 19.6, we see that $T_0 = 500$ is a reasonable choice considering the fact that larger values of T_0 requires more time for computation. It should be noted that the proposed chart that is designed to detect an arbitrary distributional change may not outperform the charts designed to detect a specific type of distributional changes when the actual distributional change is of that particular type. For example, MW should perform better than the proposed chart when the distributional change involves location change only. However, our goal is to find a chart that performs well to detect all types of distributional changes so that it can be used in various applications where the natures of changes are unknown.

19.4.1 Location Changes

First, we focus on changes in location only. We consider four different amounts of shift, $\delta_L = 0.25, 0.5, 1.0$, and 2.0 . For each of three distributions $N(0, 1)$, $ST(2.5)$, and $SLN(1.0, 0.5)$, we generate 50,000 sequences of observations where the post-change observations right after time-point τ are calculated by adding δ_L . From Table 19.1, we observe that

- MW and CvM are slightly better than the proposed method when δ_L is small or moderate. When δ_L is large, all methods except Mood perform well. The reason is that MW is designed to detect location changes only; therefore, it has better power when detecting location changes compared to the methods designed to detect arbitrary distributional changes. Mood is designed to detect scale changes; therefore, it cannot perform well in this case.
- Detections of location changes are faster when the “in-control” distribution is $ST(2.5)$ or $SLN(1.0, 0.5)$ compared to the $N(0, 1)$ case.
- Changes occurring right after time-point $\tau = 300$ are easier to detect compared to the changes occurring right after $\tau = 50$.

Table 19.1 Mean delay in detection of various location shifts δ_L occurring right after time τ . “In-control” distributions considered are $N(0, 1)$, $ST(2.5)$, and $SLN(1.0, 0.5)$. The results are based on 50,000 random simulations when $ARL_0 = 500$

19.4.2 Scale Changes

Now, we focus on changes in scale only. We consider four scale changes, namely, $\delta_S = 1.50, 0.50, 2.00,$ and 0.25 . For each of three distributions, $N(0, 1)$, $ST(2.5)$, and $SLN(1.0, 0.5)$, we generate 50,000 sequences of observations where the post-change observations are calculated by multiplying δ_S . From Table 19.2, we observe that

- Mood and Lepage are slightly better than the proposed method in some cases. The reason is that Mood is designed

to detect scale changes only and Lepage is designed to detect both location and scale change. Therefore, they have better powers when detecting scale changes compared to the methods designed to detect arbitrary distributional changes. MW is designed to detect location changes; therefore, it cannot perform well in this case. The proposed method performs much better than CvM. The reason is the incorporation of Ansari-Bradley test with Cramer-von Mises test.

- MW performs fairly well when $\delta_S > 1.00$ but performs very poorly when $\delta_S < 1.00$. One explanation of this is

when $\delta_S > 1.00$, extremely large or small numbers are more likely, and MW interprets those as location changes. This phenomenon is commented in [27] and in [24].

- Detections of scale changes are faster when the “in-control” distribution is $ST(2.5)$ and $SLN(1.0, 0.5)$ compared to the $N(0, 1)$ case.
- In this case also, changes occurring right after time-point $\tau = 300$ are easier to detect compared to the changes occurring right after $\tau = 50$. MW, however, cannot detect a decrease in scale at all.

- Lepage performs the best, as it should because it is designed to detect changes in location and scale simultaneously. Mood works well in some cases. The proposed method works well, better than CvM in many cases.
- In these case also, detections of changes in location and scale simultaneously are faster when the “in-control” distribution is $ST(2.5)$ and $SLN(1.0, 0.5)$ compared to $N(0, 1)$ case.
- Changes occurring right after time-point $\tau = 300$ are easier to detect compared to the changes occurring right after $\tau = 50$. MW, however, cannot detect a decrease in scale at all.

19.4.3 Location-Scale Changes

Now, we focus on changes in location and scale simultaneously. We consider 8 changes in location and scale simultaneously, namely, $(\delta_L, \delta_S) = (0.50, 1.50), (0.50, 0.50), (0.50, 2.00), (0.50, 0.25), (1.00, 1.50), (1.00, 0.50), (1.00, 2.00),$ and $(1.00, 0.25)$. For each of the three distributions $N(0, 1), ST(2.5),$ and $SLN(1.0, 0.5)$, we generate 50,000 sequences of observations where the post-change observations are calculated by multiplying δ_S and then adding δ_L . From Tables 19.3, 19.4, and 19.5, we observe that

19.4.4 General Distributional Changes

Finally, we consider general changes of various “in-control” distributions. The corresponding changes in the pair of mean and standard deviations are large in some cases (e.g., Weibull(1) to Weibull(3) and vice versa, Gamma(2,2) to Gamma(3,2) and vice versa) and small or zero in some other cases (e.g., $N(0, 1)$ to $ST(2.5)$ and vice versa, $N(0, 1)$ to $SLN(1.0, 0.5)$ and vice versa). From Table 19.6, we observe that

Table 19.3 Mean delay in detection of various amounts of changes in location and scale simultaneously, i.e., (δ_L, δ_S) , occurring right after time τ . “In-control” distribution considered here is $N(0, 1)$. The results are based on 50,000 random simulations when $ARL_0 = 500$

- No one method is uniformly best. P_{500} works well in all cases. Note that P_{500} is the proposed method when $T_0 = 500$ as defined in the fourth paragraph of Sect. 19.3.
- In cases where another method is the best, P_{500} is not far behind.
- The performance of P_{500} is not far from the best choice of T_0 for the proposed method. The larger the value of T_0 , the more the computing time. Therefore, P_{500} is a good balance between computing time and performance. Hence, we suggest using $T_0 = ARL_0$ in most applications.
- In cases where location change is large, MW works well, and when scale change is large, Mood works well, as expected.
- Distributional change from $N(0, 1)$ to $SLN(1.0, 0.5)$ which does not alter the mean and standard deviation is detected by the proposed method earlier than other charts.
- When we are not sure about the nature of possible distributional change, the proposed method is a good choice.
- Changes occurring right after time-point $\tau = 300$ are easier to detect compared to the changes occurring right after $\tau = 50$. MW cannot detect an arbitrary distributional change well if the median does not change by much.

Table 19.7 Mean delay in detection of various location shifts δ_L occurring right after time τ . “In-control” distributions considered are $N(0, 1)$, $ST(2.5)$, and $SLN(1.0, 0.5)$. The results are based on 10,000 random simulations when $ARL_0 = 200$

Numerical simulations when $ARL_0 = 200$ are provided in Tables 19.7, 19.8, 19.9, 19.10, 19.11, and 19.12. Similar conclusions as provided above can be drawn from these tables as well.

From these simulation studies, we see that the proposed method works well in most applications. When we are trying to detect a specific type of distributional change, its performance is slightly worse than the chart that is designed to detect that particular type of changes. However, in most cases, the differences are not much. Therefore,

when the nature of distributional change is unknown, the proposed chart can be used with anticipation of a good performance.

19.5 Analysis of Various Real-World Data

Now, we focus on applications of the proposed chart on real-world problems. We consider two datasets: a climate data and a blood glucose monitoring data.

19.5.1 Climate Data on Minneapolis, USA

Monitoring for the changes of patterns of various climatological measurements such as maximum and minimum temperatures on a daily, monthly, and yearly basis, amounts of rainfall, snow, measurements of snow depth, number of rainy or snowy days is an emerging research area. In the literature, various statistical methods are demonstrated with the capacity of analyzing such data. Modern statistical process control (SPC) charts also deserve a chance to monitor such climatological variables. In this context, we consider

mean daily maximum temperature in Fahrenheit in the month of January in Minneapolis, USA. We collect the data from http://www.dnr.state.mn.us/climate/twin_cities/listings.html. The data are from 1873 to 2017 with no missing value and are presented in Fig. 19.1. At first, before applying the control charts, we check if our assumption of independence of the observations is reasonable. Durbin-Watson test (R function: *dwtest*, R package: *lmtest*) for two-sided alternative gives a high p-value 0.8359 showing lack of autocorrelation. Therefore, we can assume that the observations are independent. Now, we apply the

Table 19.12 Mean delay in detection of various general changes in distribution. The results are based on 10,000 random simulations when $ARL_0 = 200$

Fig. 19.1 Mean daily maximum temperature in the month of January in Minneapolis, USA. Setting $ARL_0 = 500$, the proposed chart detects a distributional change in the year 1956 estimating the change-point to be just after 1947. Other charts do not detect any distributional change

proposed method along with other competing methods when we set $ARL_0 = 500$. For the proposed method, we set $T_0 = ARL_0 = 500$ as per our suggestion mentioned before. The proposed method detects a distributional change at 1956 while the estimated change-point is 1947. All other methods, i.e., MW, Mood, Lepage, and CvM, do not detect any distributional change. We also run all SPC charts when we set $ARL_0 = 200$. In this case also, the proposed method detects a distributional change at 1956 while the estimated change-point is 1947. Mood also detects distributional change but at

a later time at 1960 while the estimated change point is 1947. MW, Lepage, and CvM still do not detect any distributional change. Now, we study the “in-control” distribution and the estimated “out-of-control” distribution. Table 19.13 shows the first four sample moments of “in-control” observations from 1873 to 1947 and “out-of-control” observations from 1948 to 1956. From Table 19.13, we see that the second moment changed a lot, but not the other three moments. We carry out the calculations using R-package *moments*.

19.5.2 Blood Glucose Monitoring Data

Monitoring blood glucose level on a daily basis is essential for advanced diabetic patients. It gives information on whether the particular lifestyle change and the treatment procedure including the medicine with its administered dosage are working well for the patient. Monitoring such measurements is complicated because we are not just focusing on the mean and the standard deviation only; we need to monitor the stability of its probability distribution as well. We collect a data from UCI Machine Learning Repository [77]. This directory contains a dataset prepared for the use of participants for the 1994 AAAI Spring Symposium on Artificial Intelligence in Medicine. For our analysis, we pick the data from the first patient. We choose to monitor pre-breakfast blood glucose level on a daily basis. We prefer this over blood glucose measurements at other times because they depend too much on many variables like the type of food, amount of food, etc. The data from the first patient contains daily pre-breakfast observations from 21 April 1991 to 3 September 1991 with the number on 18 August 1991 missing. The data are presented in Fig. 19.2 ignoring the only one missing value. As always, before applying the control chart, we check if our assumption of independence of the observations is reasonable. Durbin-Watson test for two-sided

alternative gives a high p-value 0.7727 showing lack of autocorrelation. Therefore, our assumption of independence is reasonable. Now, we apply the proposed method along with other competing methods when we set $ARL_0 = 500$. For the proposed method, we set $T_0 = ARL_0 = 500$ like before. The proposed method detects a distributional change on 11 June 1991 while the estimated change-point is on 5 June 1991. Other competing charts do not detect any distributional change. Running the charts for $ARL_0 = 200$ gives similar results except that the proposed chart detects distributional change one day earlier on 10 June 1991 while the estimated change-point being the same as before. Table 19.14 shows first four moments before and after the distributional change. The standard deviation decreases a lot showing a more stable fasting blood glucose numbers, and also the skewness appears to have decreased considerably. It is to be noted that the phrases “in-control” and “out-of-control” we use are in the sense of standard terminologies in SPC literature, not in the sense of blood glucose control.

Table 19.13 First four sample moments of the observations from 1873 to 1947 and 1948 to 1956

	Mean	St. deviation	Skewness	Kurtosis
1873–1947, “in-control”	21.7067	7.0842	−0.1898	2.3666
1948–1956, “out-of-control”	20.6778	2.0795	−0.1350	2.6056

19.6 Concluding Remarks

This chapter first describes a few commonly used traditional statistical process control (SPC) charts such as Shewhart, CUSUM, EWMA, and change-point-based (CPD) control charts and discusses a number of situations where these charts should be appropriately modified for practical use. Next, this chapter proposes a change-point based nonparametric statistical process control chart for detecting arbitrary distributional changes when the process distribution is univariate continuous. There are two specifically important

Fig. 19.2 Daily pre-breakfast blood glucose measurements of a selected patient. Setting $ARL_0 = 500$, the proposed chart detects a distributional change at the 52nd day estimating the change-point to be the 46th day. Other charts do not detect any distributional change

Table 19.14 First four sample moments of the observations from 21 April 1991 to 5–6 June 1991 to 11 June 1991

	Mean	St. deviation	Skewness	Kurtosis
21st April to 5th June, “in-control”	166.9	80.8	0.3824	1.7221
6th June to 11th June, “out-of-control”	160.8	17.2	−0.0981	1.4267

contributions of the proposed chart. The first one is the combination of the strengths of two statistical tests: Cramer-von Mises test and Ansari-Bradley test. The second one is the introduction of a numerically efficient technique to estimate the possible change-point without sacrificing the accuracy by much. Both these contributions are quite general in nature and have broad applications well beyond the numerical examples and real-world data analyses shown in this chapter including monitoring fast data streams. Another important aspect of this control chart is that runtime distribution is not geometric even when the process is “in-control.” The reason is that the probability of getting a signal is a function of current runtime. However, it appears that such charts can still be used in many applications. However, further research is required to fully understand the pros and cons of such charts.

Abstract

This chapter presents reliability characteristics and optimal redundancy allocation of k -out-of- n warm standby systems consisting of identical components having exponential time to failure distributions. It is shown that the state probabilities of the warm standby system can be represented using the formulas that are applicable for active redundancy system. Subsequently, it is shown that all properties and computational procedures that are applicable for active redundancy are also applicable for the warm standby redundancy. The new results prove that the system reliability can be computed using robust and efficient computational algorithms with $O(n-k + 1)$ time complexity. Further, it is proved that the time-to-failure distribution of k -out-of- n warm standby system is beta-exponential. Using this property, closed-form expressions for various reliability characteristics and statistical measures of system failure time are presented. It has shown that the system reliability function is log-concave in n and this property is used to find efficient algorithms for determining optimal system configurations. Because active redundancy is a special case of the warm standby redundancy, indirectly this chapter also provides some new results for the active redundancy case as well.

Keywords

System reliability · Warm standby system · Log-concave property · k -out-of- n redundancy · Beta-exponential distribution · Regularized incomplete beta function · Optimization

20.1 Introduction

Standby redundancy is one of the primary techniques used to improve the system reliability to meet the requirements. Warm standby is a generic form of redundancy and it has been

S. V. Amari (✉)
BAE Systems, Merrimack, NH, USA

H. Pham
Department of Industrial and Systems Engineering, Rutgers University, Piscataway, NJ, USA

used in a wide range of applications and systems including power systems applications [1], space applications [2], and telecommunications systems [3]. Both hot and cold standby redundancies are special cases of warm standby redundancy [4]. In a cold standby system, inactive components have a zero failure rate, whereas in a hot standby system, both active and redundant (inactive) components have the same failure rates. Examples of a hot standby redundancy include a computing system with multiple servers that operate simultaneously and mirror the data in real time. In this case, both primary and redundant (secondary) servers have the same failure rate. In a warm standby redundancy, the inactive components have a failure rate that falls between cold and hot, inclusive. When switch delays and failures are not considered, the stochastic models for hot standby and active redundancy structures are equivalent [5]. Hence, the active redundancy structure can be considered as a special case of the warm standby structure. Therefore, the reliability characteristics presented in this chapter can also be applicable for the k -out-of- n active redundancy case.

Due to the generic nature of the warm standby redundancy, it is difficult to analyze the systems with these configurations as compared to the corresponding systems with active redundancy as well as cold and hot standby redundancies. Therefore, there are very few articles on reliability modeling for standby redundancy [6–8], nonrepairable warm standby systems in particular. This is because warm standby redundancy introduces complex, temporal, dynamic dependencies among the component lifetimes, and, therefore, the independence assumption of components in active redundancy is no longer valid for these systems [9]. For example, Yearout et al. [10] reviewed and categorized 156 papers specifically focusing research in standby redundancy. However, only 4 out of 156 papers were on non-repairable standby systems and none of them addresses the warm standby redundancy.

She and Pecht [4] derived a general closed-form reliability expression for k -out-of- n warm standby systems with s -identical components following exponential failure time distributions. Gnedenko et al. [11] analyzed the 1-out-of- n warm standby redundancy considering identical components with arbitrary failure time distributions applying the concept of equivalent age associated with cumulative exposure model. Li et al. [12] discussed a warm standby system with component lives following proportional hazard rate model. Morrison and David [13] proposed an efficient method based on counting process to analyze the system reliability of k -out-of- n cold standby redundancy configurations with identical components subject to arbitrary failure time distributions. This method is also described in [14]. Integrating the concepts used in [11, 13], Amari and Dill [9] developed an efficient computational method based on counting processes to evaluate system reliability of k -out-of- n warm standby redundancy with components following arbitrary failure time

distributions. This method was further extended to analyzing systems with components following specific failure time distributions including the Erlang [15], gamma [16], and Rayleigh [17] distributions. Eryilmaz [18] studied reliability of a k -out-of- n system having a single warm standby redundant component where the standby unit is used only after consumption of all active redundant components. In other words, the standby unit is kept into operation after the failure of the k -out-of- n active system by replacing the last failed unit, and then the system works until the failure of one of the k remaining components. Therefore, it can be considered as a nonstandard model that is applicable to a very specific scenario.

Using the reliability evaluation algorithm presented in [9], Amari and Dill [19] studied the constrained redundancy optimization problem for a series system consisting of multiple k -out-of- n warm standby subsystems. Levitin et al. [20] studied the 1-out-of- n :G cold standby systems subject to imperfect even backups and investigated the effects of backup system reliability in connection with other system parameters including data volume, frequency and duration of backups, replacement time and failure probability, and number of system elements. Wang et al. [21] presented a redundancy allocation problem for maximizing system reliability considering cold standby redundancy and degrading components.

Recently, the use of cold/warm standby systems has been expanded to several application areas. Tannous et al. [22] studied the reliability of warm standby systems subjected to imperfect fault coverage in the context of wireless sensor networks. For the identical component case, Amari et al. [23] provided closed-form expressions for reliability of warm standby systems subjected to imperfect coverage. Amari et al. [24] studied warm standby systems in the context of phased mission systems that are used in aerospace and defense applications. Levitin [25] studied the consecutive sliding window systems with warm standby components considering dynamic demands. When nonidentical cold/warm standby spares are used, the reliability and energy consumption of the system can depend on the sequence of standby units used in the operation [26]. Boddu et al. [27] considered optimal sequencing problem considering k -out-of- n :G cold standby systems. Levitin et al. [28] studied the optimal configuration of a series system consisting of 1-out-of- n warm standby subsystems performing operation and rescue functions. Further, Levitin et al. [29] studied heterogeneous warm standby systems and analyzed the effects of failure propagation on mission abort policy. They also [30] analyzed the dynamic checkpointing policy in heterogeneous real-time standby systems subjected to a constraint on allowed task completion time in performing the failure recovery. Jia et al. [31] studied the reliability modeling of standby systems considering multistate components subject to constant state transition rates.

However, as mentioned earlier, reliability characteristics of standby redundancy, in particular for the warm standby configurations, are less explored. For example, most of the research contributions on ageing properties are limited to active redundancy systems. Due to the complex nature of warm standby configurations, neither the closed-form expressions nor closure properties of mean residual life (MRL), probability density function (pdf), and hazard rate function/s/classes are studied for warm standby systems. In addition to studying these properties, it is important to derive closed-form expressions for pdf, hazard (failure) rate, reliability, and MRL functions that can lead to robust and computationally efficient evaluation of these fundamental reliability characteristics for warm standby systems.

This chapter presents recent results on reliability characteristics of k -out-of- n warm standby systems with s -identical components following exponential lifetimes. This model was initially studied in [4]. Later Amari et al. [23, 32] have presented closed-form expressions and efficient computational methods for reliability characteristics of warm standby systems. These results provide new insights into the system behavior and aging properties that in turn lead to efficient algorithms for finding optimal system configurations [33]. This chapter summarizes these results and then provide a set of new formulas on various statistical properties of the system failure time distribution.

20.2 Warm Standby Model and Related Works

Consider a k -out-of- n warm standby system model studied in [4].

20.2.1 Model Description and Assumptions

1. The system consists of n identical components.
2. Initially all components are in good conditional.
3. There shall be a minimum of k operating components for a successful operation.
4. The system redundancy configuration is k -out-of- n :G warm standby.
5. As long as the system is working, only k components are in operation and the remaining components are kept in the warm standby (dormant) mode.
6. Each component has a constant operating-failure rate (λ_o) and a constant dormant-failure rate (λ_d). Usually, $\lambda_d \leq \lambda_o$, and in many practical cases, λ_d is much smaller than λ_o . However, the analysis provided in this chapter is also applicable even when $\lambda_d > \lambda_o$.
7. There are no simultaneous failure of components.
8. Components are nonrepairable (no repair).

9. No sensing and switching delays (instantaneous).
10. Perfect switches (failure free). Note: Imperfect switches are considered in Sect. 20.3.4 by relaxing this assumption.

20.2.2 Related Works

Considering failure time of each component follows the exponential distribution with rate parameter λ_o in the operational state and rate parameter λ_d in the standby state, She and Pecht [4] provided a closed-form expression for system reliability at time t for the warm standby model described in Sect. 20.2.1:

$$\begin{aligned}
 R(t) &\equiv R(t; k, n, \lambda_o, \lambda_d) \\
 &= \frac{1}{(n-k)! \lambda_d^{n-k}} \sum_{i=0}^{n-k} (-1)^i \binom{n-k}{i} \\
 &\quad \times \left[\prod_{j=0, j \neq i}^{n-k} (k\lambda_o + j\lambda_d) \right] \exp \{-(k\lambda_o + i\lambda_d) t\}
 \end{aligned} \tag{20.1}$$

In addition to standby systems, Eq. (20.1) can also be used to evaluate the reliability of system with active redundancy. However, Eq. (20.1) cannot be used directly to evaluate the reliability of a cold standby system, but it should be evaluated at the limit $\lambda_d \rightarrow 0$. At this limit, the reliability expression becomes the survival function (Sf) of the gamma distribution. Hence

$$\begin{aligned}
 R(t) &\equiv \lim_{\lambda_d \rightarrow 0} R(t; k, n, \lambda_o, \lambda_d) \\
 &= \exp \{-k\lambda_o t\} \left[\sum_{i=0}^{n-k} \frac{(k\lambda_o t)^i}{i!} \right] \\
 &= \text{poif}(k\lambda_o t, n-k) \\
 &= \text{gamfc}(k\lambda_o t, n-k+1)
 \end{aligned} \tag{20.2}$$

where $\text{poif}(\cdot)$ is the cdf of Poisson distribution and $\text{gamfc}(\cdot)$ is the Sf of Erlang (gamma with integer shape parameter) distribution and these are available in all standard statistical packages.

Although Eq. (20.1) provides a theoretically exact expression for system reliability, it is unstable for large values of $(n-k)$ and/or small values of $\frac{\lambda_d}{\lambda_o}$, and therefore, it cannot be used directly for these cases. This is because Eq. (20.1) is prone to numerical roundoff errors due to the presence of alternative positive and negative terms [23]. The results of experiments presented in [23] indicate that, in some cases, the computed reliability values are not even within the valid

range for the reliability (probability), i.e., [0,1]. Therefore, the system reliability should be expressed in the forms that can lead to computationally efficient and robust numerical evaluation. A detailed discussion on numerical instability of Eq. (20.1) and the efficiency and robustness of the new results are available in [23, Section IV].

Amari and Pham [32] studied a special case of the warm standby system where $k_d \equiv k\lambda_o/\lambda_d$ is an integer. For this special case, it was shown that the Markov state transition diagram of this model is the same as that of k_d -out-of- $(n-k+k_d)$ active redundancy configuration where hazard (failure) rate of each component is λ_d . Hence, it was shown that the warm standby configuration behaves like an active redundancy configuration with modified parameters. For example, consider a 2-out-of-4 warm standby system where $\lambda_o = 3$ and $\lambda_d = 0.5$. Hence, $k_d \equiv 2 \cdot (3/0.5) = 12$ and $n_d = n - k + k_d = 5 - 3 + 12 = 14$. Hence, from Amari and Pham [32], it behaves like a 12-out-of-14 active redundancy system where the component failure rate is $\lambda_d = 0.5$. Hence, the system reliability function, state probabilities, system hazard (failure) rate function, pdf, MRL function, and failure time moments of the 2-out-of-4 warm standby system (with $\lambda_o = 3$ and $\lambda_d = 0.5$) are equivalent to the corresponding functions for the 12-out-of-14 active redundancy configuration with modified parameters (i.e., failure rate equal to $\lambda = 0.3$).

Further, Amari et al. [23] considered the general case of warm standby system, where $k_d \equiv k\lambda_o/\lambda_d$ is not restricted to an integer, and proved the following results:

- All properties and computational procedures that are available for active redundancy case are also applicable for the warm standby configurations.
- Reliability of both active redundancy and warm standby systems can be expressed and evaluated using beta distribution.
- The system reliability improvement with an additional redundant component follows negative binomial (Pólya) distribution.

In addition, Levitin et al. [23] expressed the system reliability in several forms that can allow and enable robust and efficient evaluation of system reliability, state probabilities, and reliability improvement factors with additional spares. Similarly, closed expressions were provided for higher order moments of the system failure time. Further, it was shown that the hazard rate of the warm system is a monotonically increasing function. Similarly, Levitin et al. [23] provided several closed-form expressions for the MRL function, and some of these forms also provide new and compact closed-form expressions for the MRL function of the k -out-of- n system with active redundancy [8]. In addition, it was shown that the system failure time follows beta-exponential distribution [34]. Using these results, some additional closed-

form expressions are derived in this chapter. These new closed-form expressions derived include moment-generating function, characteristic function, variance, cumulants, moments, skewness, kurtosis, Rényi entropy, and Shannon entropy. The closed-form expression in [23] also allowed proving several log-concave properties and aging properties that are applicable for both active and standby redundancies.

20.3 Reliability Analysis

The system failure time can be expressed as a sum of exponentially distributed random variables as shown in the Markov state transition diagram in Fig. 20.1, where state- i corresponds to the system state with i failures (including active and dormant failures), state 0 is the initial state and the state $(n - k + 1)$ is a failed state.

20.3.1 State Probabilities

The Markov state transition diagram in Fig. 20.1 indicates that the system failure time (T) can be expressed as the sum of exponential random variables

$$T = X_0 + X_1 + \dots + X_{n-k} \tag{20.3}$$

where X_i is the time spent in state i ; $i = 0, \dots, (n - k)$ and it follows exponential distribution with rate parameter $\lambda_i = k\lambda_o + (n - k - i)\lambda_d$. Further, the Laplace transform of probability of state- i , i.e., $P_i(t)$, can be expressed as

$$\mathcal{L}\{P_i(t)\} = \frac{B_i}{\prod_{j=0}^i (s + \lambda_j)}; \quad i = 0, \dots, n - k$$

$$B_i \equiv \prod_{j=0}^{i-1} \lambda_j; \quad i = 1, \dots, n - k \tag{20.4}$$

where $\lambda_j = k\lambda_o + (n - k - j)\lambda_d$ and $B_0 = 1$. Hence, using the closed-form expressions for inverse Laplace transforms in [35], $P_i(t)$ can be expressed as

Fig. 20.1 Markov state transition diagram for k -out-of- n warm standby system [23, 32]

$$P_i(t) = B_i \sum_{j=0}^i A_{ij} \exp(-\lambda_j t); \quad i = 0, \dots, n - k \tag{20.5}$$

$$= \frac{\Gamma(n_d + 1)}{\Gamma(n_d - i + 1)} \exp(-\lambda_i t) \sum_{j=0}^i \frac{[-\exp\{-\lambda_d t\}]^{i-j}}{j!(i-j)!} \tag{20.8}$$

$$A_{ij} \equiv \prod_{\substack{m=0 \\ m \neq j}}^i \frac{1}{\lambda_m - \lambda_j}; \quad j = 0, \dots, i \tag{20.5}$$

Now Eq. (20.8) can be simplified using the following identity for the binomial expansion:

Further,

$$(1 - x)^i = \sum_{j=0}^i \frac{i!}{j!(i-j)!} (-x)^{i-j} \tag{20.9}$$

$$A_{ij} = \left[\prod_{m=0}^{j-1} \frac{1}{\lambda_m - \lambda_j} \right] \left[\prod_{m=j+1}^i \frac{1}{\lambda_m - \lambda_j} \right]$$

$$= \left[\frac{1}{j! \lambda_d^j} \right] \left[\frac{(-1)^{i-j}}{(i-j)! \lambda_d^{i-j}} \right]$$

$$= \frac{(-1)^{i-j}}{j!(i-j)! \lambda_d^i} \tag{20.6}$$

Hence

$$P_i(t) = \frac{\Gamma(n_d + 1)}{i! \Gamma(n_d - i + 1)} \exp\{-\lambda_i t\} [1 - \exp\{-\lambda_d t\}]^i \tag{20.10}$$

Similarly, we can simplify $B_i, i = 1, \dots, n - k$:

Further

$$\lambda_i = k\lambda_o + (n - k - i)\lambda_d = k_d\lambda_d + (n - k - i)\lambda_d = (n_d - i)\lambda_d \tag{20.11}$$

$$B_i = \prod_{j=0}^{i-1} \lambda_j$$

$$= \prod_{j=0}^{i-1} [k\lambda_o + (n - k - j)\lambda_d]$$

$$= \prod_{j=0}^{i-1} [k_d\lambda_d + (n - k - j)\lambda_d]$$

$$= \lambda_d^i \prod_{j=0}^{i-1} [(n - k + k_d) - j]$$

$$= \lambda_d^i \prod_{j=0}^{i-1} (n_d - j)$$

$$= \lambda_d^i \frac{\Gamma(n_d + 1)}{\Gamma(n_d - i + 1)} \tag{20.7}$$

Therefore

$$P_i(t) = \frac{\Gamma(n_d + 1)}{i! \Gamma(n_d - i + 1)} (\exp\{-\lambda_d t\})^{n_d - i} (1 - \exp\{-\lambda_d t\})^i$$

$$= \binom{n_d}{i} (p_d)^{n_d - i} (1 - p_d)^i \tag{20.12}$$

Note that n_d in Eq. (20.7) is not necessarily an integer. If $k_d \equiv k\lambda_o/\lambda_d$ is a real number, then $n_d \equiv n - k + k_d$ also becomes a real number. Hence, the gamma function in Eq. (20.7) can be replaced with a factorial function only when n_d is an integer. Substituting A_{ij} and B_i in Eqs. (20.6) and (20.7) into Eq. (20.5), we have

Note that the n_d in Eq. (20.12) can be a real number. Specifically, if $k_d \equiv k\lambda_o/\lambda_d$ is a real number, then $n_d \equiv n - k + k_d$ is also a real number. Therefore, the binomial coefficient in Eq. (20.12) is expressed using a real valued parameter n_d [36]. Further, note that Eq. (20.12) is also applicable even when $\lambda_d > \lambda_o$. For the active redundancy (hot standby), $\lambda_d = \lambda_o$. Further, $k_d = k, n_d = n, \Gamma(n_d + 1) = n!$, and $\Gamma(n_d - i + 1) = (n - i)!$. Hence, for the active redundancy, Eq. (20.12) reduces to the probability density function (pmf) of the binomial distribution [6, 7]. In addition, as shown in [32], (20.12) is equal to the pmf of the binomial distribution when $k_d = k\lambda_o/\lambda_d$ is an integer. Similarly, it is straightforward to prove that when $\lambda_d \rightarrow 0$ (for cold standby), Eq. (20.12) approaches the cdf of the Poisson distribution in (20.2). Similarly, for the cold standby system, $P_i(t)$ is equal to the pmf of the Poisson distribution. Hence, the state probability distribution in (20.12) includes binomial distribution as the special case and Poisson distribution as the limiting distribution. Hence, the new form of distribution for system state probabilities in (20.12) can be called a generalized truncated binomial distribution with a real valued n .

$$P_i(t) = \frac{\Gamma(n_d + 1)}{\Gamma(n_d - i + 1)} \sum_{j=0}^i \frac{(-1)^{i-j}}{j!(i-j)!} \exp(-\lambda_j t)$$

$$= \frac{\Gamma(n_d + 1)}{\Gamma(n_d - i + 1)} \exp(-\lambda_i t) \sum_{j=0}^i \frac{(-1)^{i-j}}{j!(i-j)!} \exp\{-(i-j)\lambda_d t\}$$

20.3.2 System Reliability

The system reliability can be evaluated as the sum of the probabilities of all good states. Hence, the reliability of the system is

$$\begin{aligned} R(t) &\equiv \sum_{i=0}^{n-k} \Pr\{\text{system is in state } i\} = \sum_{i=0}^{n-k} P_i(t) \\ &= \sum_{i=0}^{n-k} \frac{\Gamma(n_d + 1)}{i! \Gamma(n_d - i + 1)} (p_d)^{n_d - i} (1 - p_d)^i \\ &= \sum_{i=0}^{n-k} \binom{n_d}{i} (p_d)^{n_d - i} (1 - p_d)^i \end{aligned} \quad (20.13)$$

where $p_d \equiv p_d(t) = \exp(-\lambda_d t)$. Note that Eq. (20.13) is applicable for both real and integer values of $k_d \equiv k\lambda_o/\lambda_d$. In other words, $n_d \equiv n - k + k_d$ in Eq. (20.13) can be a real number and the binomial coefficient is defined for both real and integer valued arguments [36]. It is interesting to note that the reliability expression for warm standby system is similar in form to that of the active redundancy case. Therefore, the warm standby redundancy configuration can be viewed as an active redundancy configuration with modified parameters. These results may, at the first glance, seem to be counterintuitive or too good to be true. However, in addition to the detailed proofs provided in the previous section, the equivalence of results in Eqs. (20.1) and (20.13) can easily be cross-verified using numerical examples. In addition, the equivalence of these two expressions in (20.1) and (20.13) can easily be proved, because these are the two different forms of the same regularized incomplete beta function presented in Sections 26.5.6 and 26.5.7 of Abramowitz and Stegun [37], respectively. Hence, Eq. (20.1) is equivalent to Eq. (20.13) that was derived in She and Pecht [4]. However, the system reliability expressed using Eq. (20.13) provides more insight into the system reliability characteristics and leads to robust and computationally efficient numerical evaluation.

Note that $P_0 = p_d^{n_d}$ and $P_i = P_{i-1} \cdot \frac{n_d - i + 1}{i} \cdot \frac{1 - p_d}{p_d}$ for $i = 1, \dots, n - k$. Hence, the system reliability can be evaluated in $O(n-k+1)$ time complexity algorithms [6]. The algorithm evaluating the system reliability is described in Algorithm-A.

Algorithm-A: Reliability Evaluation Using State Probabilities

Inputs: $k, n, \lambda_o, \lambda_d, t$

$n_d = n - k + k\lambda_o/\lambda_d$; $p_d = \exp\{-\lambda_d t\}$

$x = p_d^{n_d}$; $R = x$; $y = (1 - p_d)/p_d$

for $i = 1$ to $(n - k)$ do

$$x = x \cdot y \cdot \frac{n_d - i + 1}{i}; \quad R = R + x$$

done

At the end of the algorithm, R contains the system reliability. At each iteration of i , x is equal to the probability of state i , $P_i(t)$. Hence, the system state probabilities ($P_i(t)$) can also be evaluated in $O(n-k+1)$ computational time. Further, for active redundancy case (when k_d is an integer), the system reliability can be evaluated with $O(\min\{k, n - k + 1\})$ computational time algorithms [6, 32].

Example 1 2-out-of-4 warm standby system where $\lambda_o = 0.0025$, $\lambda_d = 0.0004$, and $t = 100$. Hence, $k_d = 12.5$, $n_d = 14.5$, $(n-k) = 2$, $p_d = 0.960789$, and $\frac{1-p_d}{p_d} = 0.040811$. Further, $P_0 = p_d^{n_d} = (0.960789)^{14.5} = 0.5599$ and $P_i = P_{i-1} \cdot \frac{13.5-i}{i} \cdot (0.040811)$ for $i = 1, 2$. Hence, $P_1 = 0.33132$ and $P_2 = 0.091271$. Finally, the system reliability is $R = P_0 + P_1 + P_2 = 0.98249$.

Further, the system reliability (or unreliability) can be expressed in terms of either Sf or cdf of the beta distribution with parameters a and b . When b is an integer, the cdf of beta distribution, $F_B(x; a, b) \equiv I_x(a, b)$, can be expressed as [37]

$$I_x(a, b) = \sum_{i=0}^{b-1} \frac{\Gamma(a+b)}{\Gamma(i+1)\Gamma(a+b-i)} x^{a+b-1-i} (1-x)^i \quad (20.14)$$

By substituting $a = k_d$, $b = n_d - k_d + 1$, and $x = p_d$, we can express the system reliability in (20.13) using $I_x(a, b)$. Hence

$$R(t) \equiv I_{p_d}(k_d, n_d - k_d + 1) = F_B(p_d; k_d, n_d - k_d + 1) \quad (20.15)$$

where F_B is the cdf of the beta distribution and is available in all standard statistical packages. Further, there are several well-established numerical methods for computing the regularized incomplete beta function $I_x(a, b)$ [38], and this function is available in all standard mathematical software libraries including MATLAB[®], Mathematica[®], Mathcad[®], and Microsoft[®] Excel. In fact, reliability evaluation using (20.15) is preferred for large values of $(n - k)$. Because $I_x(a, b) = 1 - I_{(1-x)}(b, a)$ [37], the system reliability can also be expressed as the Sf of the beta distribution:

$$\begin{aligned} R(t) &\equiv 1 - I_{1-p_d}(n_d - k_d + 1, k_d) \\ &= 1 - F_B(1 - p_d; n_d - k_d + 1, k_d) \\ &= \bar{F}_B(1 - p_d; n_d - k_d + 1, k_d) \end{aligned} \quad (20.16)$$

where \bar{F}_B is the Sf of the beta distribution.

Example 2 Same as *Example 1*, except $R(t)$ is calculated from (20.15) and (20.16) using the MATLAB[®] function `betainc`. From (20.15), the reliability of the system can be calculated as $R(t) = I_{0.960789}(12.5, 3) = \text{betainc}(0.960789, 12.5, 3) = 0.98249$. Similarly, from (20.16), $R(t) = 1 - I_{0.039211}(3, 12.5) = \text{betainc}(0.039211, 3, 12.5, 'upper') = 0.98249$.

Note that $I_x(a, b)$ itself can be expressed in several forms [37]. Therefore, the reliability of warm standby system can be expressed in several forms. Some of these forms are used to derive other reliability characteristics.

20.3.3 Nonidentical Operational Failure Rates

Although the analysis presented in this chapter is based on the assumption that all units are identical, it can also be applied to the case where the active components experience nonidentical operational stresses. Specifically, the same reliability formula can also be applied to the situation where failure rates of k operational units are distinct (or not necessarily identical). In other words, even though the failure rate in the standby mode is the same for every unit (spare), the operational failure rate of a component can depend on its location or configuration of its operation. However, as long as the system is functioning, there will be the same number of operational units (k units) and the sum of their failure rates will be the same throughout the mission. Let $\lambda_{o,j}$ be the operational failure rate of a component located at position j . Because there are k operational units, the sum and average of their failure rates can be computed as $\lambda_{o,sum}$ and $\lambda_{o,avg}$:

$$\begin{aligned}\lambda_{o,sum} &\equiv \sum_{j=1}^k \lambda_{o,j} \\ \lambda_{o,avg} &\equiv \frac{1}{k} \sum_{j=1}^k \lambda_{o,j}\end{aligned}\quad (20.17)$$

These failure rates, i.e., $\lambda_{o,sum}$ and $\lambda_{o,avg}$, are the same for any combination of component failures (i.e., system state). Hence, the state transition diagram in Fig. 20.1 is still applicable for modeling this situation. However, the operational failure rate λ_o in Fig. 20.1 should be replaced with $\lambda_{o,avg}$. Hence, as long as the average of operational rates is used

in the reliability formula, the same analysis can be used even when the operational units experience distinct location-dependent failure rates. Hence, Algorithm-A can also be used for evaluating the system reliability with nonidentical operational failure rates.

20.3.4 Switch Failures

In a standby redundancy configuration, upon a failure of an operational component, the failed component is replaced by a redundant component when available. If the failure occurs in a dormant component, it will be removed. Therefore, a warm standby redundancy configuration requires a switching mechanism to sense the presence of a failed component and to activate a redundant component, if one is available. However, the switch itself can fail on demand, i.e., it may fail to perform its operation upon a failure of a component, which in turn leads to system failure. When the system reliability is expressed as a sum of probabilities of good states, it is straightforward to include the effects of switch failures in the reliability expression [9]. Let p_{sw} be the switch reliability on demand. If there are exactly i failures in the system, the switch needs to operate successfully at all these i requests (corresponding to i failures). Hence, the switch reliability for i requests is p_{sw}^i . Therefore, the reliability of the system with switch failures on demand is

$$R(t) \equiv \sum_{i=0}^{n-k} p_{sw}^i P_i(t) = \sum_{i=0}^{n-k} \binom{n_d}{i} (p_d)^{n_d-i} [p_{sw} (1 - p_d)]^i \quad (20.18)$$

The derivation of Eq. (20.18) is based on the assumption that the switch is needed at each instance of every component failure irrespective of its standby/operational status. Equation (20.18) has important applications in safety critical systems where all failed components must be detected, located, and permanently removed from the system to eliminate the failure propagation due to imperfect fault coverage [39]. However, if the switches are needed only for replacing the failed components in operation with the standby ones, but not the removal of the failed components in the dormant state, then the following equation shall be used (the proof is straightforward and the results can be verified using Markov models):

$$R(t) \equiv \sum_{i=0}^{n-k} \frac{\binom{n_d+k_d[1-p_{sw}]}{i}}{\binom{n_d}{i}} P_i(t) = \sum_{i=0}^{n-k} \binom{n_d+k_d[1-p_{sw}]}{i} (p_d)^{n_d-i} (1-p_d)^i \quad (20.19)$$

Similarly, it is straightforward to modify (20.13) to include the effects of various types of imperfect fault coverage models [39].

20.3.5 Reliability Improvement

It is a well-known fact that increasing the number of spares increases the system reliability. Specifically, when k is fixed, system reliability is an increasing function in n . Understanding the properties of reliability improvement (expressed in terms of n) is important in determining the optimal system configurations [40]. The following identity is used to derive the expression for reliability improvement [37]:

$$I_x(a, b + 1) = I_x(a, b) + \frac{\Gamma(a + b)}{\Gamma(a)\Gamma(b + 1)} x^a (1 - x)^b \quad (20.20)$$

Therefore

$$\begin{aligned} \nabla R(n; k) &\equiv \Delta R(n - 1; k) \equiv R(n; k) - R(n - 1; k) \\ &= \frac{\Gamma(n_d)}{\Gamma(k_d)\Gamma(n_d - k_d + 1)} (p_d)^{k_d} (1 - p_d)^{n_d - k_d} \\ &= \binom{n_d - 1}{k_d - 1} (p_d)^{k_d} (1 - p_d)^{n_d - k_d} \quad (20.21) \end{aligned}$$

It can easily be verified that (20.21) reduces to the reliability improvement equation available in [7, 41] for the active redundancy when $k_d = k$, $n_d = n$, and $p_d = p$. Note that Eq. (20.21) can also be derived using the pivotal decomposition because the warm standby model can be expressed in terms of an active redundancy model with modified parameters. Further, define

$$\begin{aligned} \delta_i &\equiv \nabla R(k + i; k) = \binom{k_d + i - 1}{i} (p_d)^{k_d} (1 - p_d)^i; \\ \text{for } i &= 0, 1, \dots \quad (20.22) \end{aligned}$$

where δ_i is the improvement in system reliability when the number of spares is increased from $(i - 1)$ to i . Further, $R(k, n) = 0$ for $n < k$, and $\delta_0 = R(k, k)$. Hence, the system reliability is the sum of δ_i 's:

$$R(k, n) = \sum_{i=0}^{n-k} \delta_i \quad (20.23)$$

Note that $\delta_0 = p_d^{k_d}$ and $\delta_i = \delta_{i-1} \cdot \frac{k_d + i - 1}{i} \cdot (1 - p_d)$ for $i = 1, \dots, n - k$. Hence, using (20.23), the system reliability can be computed in $O(n-k+1)$ computational time [6]. Refer to Algorithm-B for the detailed steps for evaluating the system reliability.

Algorithm-B: Reliability Evaluation Using Reliability Improvement Factors

Inputs: $k, n, \lambda_o, \lambda_d, t$

$$k_d = k\lambda_o/\lambda_d; \quad p_d = \exp\{-\lambda_d t\}$$

$$x = p_d^{k_d}; \quad R = x; \quad y = 1 - p_d$$

for $i = 1$ to $(n - k)$ do

$$x = x \cdot y \cdot \frac{k_d + i - 1}{i}; \quad R = R + x$$

done

At the end of the algorithm, R contains the system reliability. At each iteration of i , x is equal to the reliability improvement factor corresponding to $\delta_i(t)$. Hence, the reliability improvement factors can also be computed with $O(n-k+1)$ computational time algorithms.

Example 3 Same as *Example 1*, except $R(t)$ is calculated from (20.23). Here, $k_d = 12.5$, $(n-k) = 2$, $p_d = 0.960789$, and $(1 - p_d) = 0.039211$. Further, $\delta_0 = p_d^{k_d} = (0.96079)^{12.5} = 0.60653$ and $\delta_i = \delta_{i-1} \cdot \frac{11.5+i}{i} \cdot (0.039211)$ for $i = 1, 2$. Hence, $\delta_1 = 0.29728$ and $\delta_2 = 0.078682$. Finally, the system reliability is $R = \delta_0 + \delta_1 + \delta_2 = 0.98249$.

It is interesting to note that δ_i is nothing but the probability of state- i of the Markov chain shown in Fig. 20.2, where state-0 is the initial state and state- $(n - k + 1)$ is the final state. Note that the state transition diagrams in Figs. 20.1 and 20.2 are similar, except the occurrence of states are reversed. The time to reach the absorbing state in Fig. 20.1 is equivalent to the corresponding time in Fig. 20.2, because they both represent the sum of the same set of exponential random variables. When $n = k$, the state transition diagrams in Figs. 20.1 and 20.2 are equivalent. Hence, the probability of state-0 in Fig. 20.2 is equal to δ_0 . For $n = k + 1$, it should satisfy the following equation: $P_0(n = k + 1) + P_1(n = k + 1) = R(k, n = k + 1) = \delta_0 + \delta_1$. Hence, from Eq. (20.23), it can be shown that the probability of state-1 in Fig. 20.2 is equal to δ_1 . Using the similar arguments, it can be proved that the probability of state- i in Fig. 20.2 is equal to δ_i for any non-absorbing state- i .

Fig. 20.2 Markov state transition diagram for k -out-of- n warm standby system

Note that δ_i in (20.22) is the pmf of the negative binomial (Pólya) distribution [42]. Therefore, the system reliability in (20.23) can be expressed as the cdf of the negative binomial distribution:

$$\delta_i = f_{NB}(i; p_d, k_d) \quad \text{and} \quad R(k, n) = \sum_{i=0}^{n-k} \delta_i = F_{NB}(n - k; p_d, k_d) \tag{20.24}$$

where $f_{NB}(x; p, r)$ and $F_{NB}(x; p, r)$ are the pmf and cdf of negative binomial distribution.

Although the negative binomial distribution is also defined for the positive real values of r , the applications for this case are rare. Hence, the warm standby system provides a new application for this distribution with a real valued parameter r . Note that the negative binomial is a unimodal distribution. Hence, δ_i attains its maximum value at the mode of the NB distribution. Define

$$m \equiv \max \left\{ 0, \left\lfloor \frac{(k_d - 1)(1 - p_d)}{p_d} \right\rfloor \right\} \tag{20.25}$$

Thus, the δ_i at first increases and then decreases, reaching its maximum value at $i = m$. If $\frac{(k-1)(1-p)}{p}$ is an integer, then $\delta_m = \delta_{m-1}$. The $\nabla R(n; k)$ in (20.21) and δ_i in (20.22) are equivalent, except that i represents the number of spares and $n \equiv k + i$ represents the total number of components. Therefore, $\nabla R(n; k)$ first increases and then decreases, reaching its maximum value at $n = n_{mode} = k + m$. Hence

$$\begin{aligned} n_{mode} &\equiv \max \left\{ k, \left\lfloor \frac{(k_d - 1)(1 - p_d)}{p_d} + k \right\rfloor \right\} \\ &= \max \left\{ k, \left\lfloor \frac{k_d - 1}{p_d} + k - k_d + 1 \right\rfloor \right\} \end{aligned} \tag{20.26}$$

It is interesting to note that $P_i = \delta_i$ for the cold standby system. This can be verified by comparing the individual terms in the cdf of the Poisson distribution. In addition, this equivalence can also be verified by comparing the state transition diagrams in Figs. 20.1 and 20.2 by setting $\lambda_d = 0$. Specifically, it can be easily observed that these two diagrams are equivalent when $\lambda_d = 0$. Hence, $P_i = \delta_i$. Further, using the properties of Poisson distribution, it can be shown that δ_i first increases and then decreases, reaching its maximum value at $i = m_s \equiv \max\{0, \lfloor k\lambda_o t \rfloor\}$.

Example 4 Case 1: Same as *Example 1*, except n is not specified. Here, $k = 2$, $k_d = 12.5$, and $p_d = 0.960789$. Therefore, from (20.26), $n_{mode} = 2$. Hence, $\nabla R(n; k) \equiv \nabla R(n)$ reaches its maximum value at $n = k = 2$, and it always decreases with increase in n . Case 2: Same as Case 1, except $t = 1000$. Hence, $p_d = 0.67032$ and $n_{mode} = 7$.

Therefore, $\nabla R(n; k) \equiv \nabla R(n)$ first increases for $n \leq 7$ and then decreases for $n > 7$, reaching its maximum value at $n = 7$.

It is well known that the pmf of the NB distribution is a log-concave function [43]. Hence, δ_{i+1}/δ_i is a decreasing function in i . In other words, $\delta_i^2 \geq \delta_{i-1}\delta_{i+1}$. Hence, from [43, Theorem 3.1], it can be shown that the cdf of NB distribution is also log-concave. Therefore, from (20.24), $R(n)$ is log-concave in n . In other words, $\frac{R(n+1)}{R(n)}$ is a decreasing function in n . Hence, the reliability improvement percentage with an additional component decreases with the number of redundant components. This log-concave property allows us to apply efficient methods to find optimal redundancy levels [44]. Therefore, the optimal spares allocation procedure proposed in [44] for the series system with 1-out-of- n cold standby subsystems can be extended for the series systems with k -out-of- n warm standby subsystems with exponentially distributed component lifetimes. These details are provided in Sect. 20.5.

20.4 Reliability Characteristics

20.4.1 Cumulative Distribution Function

The cdf, $F(t)$, is equivalent to the system unreliability, $Q(t)$:

$$\begin{aligned} F(t) &= Q(t; k, n) \equiv 1 - R(t; k, n) \\ &= 1 - I_{p_d}(k_d, n_d - k_d + 1) \\ &= I_{1-p_d}(n_d - k_d + 1, k_d) \end{aligned} \tag{20.27}$$

20.4.2 Probability Density Function

The pdf, $f(t)$, can be found as a first-order derivative of $F(t)$ with respect to t :

$$f(t; k, n) \equiv \frac{dF(t)}{dt} = -\frac{dR(t; k, n)}{dt} \tag{20.28}$$

For nonrepairable systems, pdf also equals to system failure intensity (frequency) [45]. From the Markov state transition diagram in Fig. 20.1, it can be noted that the system has only one failed state and it is the state $(n - k + 1)$. The system reaches state $(n - k + 1)$ only from state $(n - k)$. Hence, the transition from state $(n - k)$ to state $(n - k + 1)$ leads to the system failure. The state transition frequency is equal to the product of probability of state $(n - k)$ and the transition rate from state $(n - k)$ to state $(n - k + 1)$. Therefore, the failure frequency is $k\lambda_o P_{n-k}(t)$. Hence, the pdf is

$$\begin{aligned}
 f(t; k, n) &\equiv k\lambda_o P_{n-k}(t) = k_d\lambda_d P_{n-k}(t) \\
 &= k_d\lambda_d \binom{n_d}{n_d - k_d} [p_d]^{k_d} [1 - p_d]^{n_d - k_d} \\
 &= \frac{\lambda_d}{B(n_d - k_d + 1, k_d)} [\exp\{-\lambda_d t\}]^{k_d} [1 - \exp\{-\lambda_d t\}]^{n_d - k_d}
 \end{aligned}
 \tag{20.29}$$

Note that p_d and $(1 - p_d)$ are the Sf and cdf of an exponentially distributed *r.v.* Hence, these are log-concave in t [46]. Further, the product of two log-concave functions is also a log-concave function. Therefore, $f(t; k, n)$ is log-concave in t . Hence, the system reliability, $R(t; k, n)$, and system unreliability, $Q(t; k, n)$, are also log-concave in t [46]. Because $f(t; k, n)$ is log-concave, it can be shown that the system time to failure distribution is in the IFR class [46].

20.4.3 Failure Rate Function

The system failure (hazard) rate function can be determined as $h(t) = f(t)/R(t)$. Hence

$$\begin{aligned}
 h(t) &\equiv h(t; k, n) = \frac{f(t; k, n)}{R(t; k, n)} \\
 &= \frac{k_d\lambda_d \binom{n_d}{n_d - k_d} [p_d]^{k_d} [1 - p_d]^{n_d - k_d}}{\sum_{i=0}^{n-k} \binom{n_d}{i} [p_d]^{n_d - i} [1 - p_d]^i} \\
 &= \frac{k\lambda_o \binom{n_d}{n-k}}{\sum_{i=0}^{n-k} \binom{n_d}{i} [\theta(t)]^{n-k-i}}
 \end{aligned}
 \tag{20.30}$$

where $\theta(t) = \frac{p_d}{1-p_d} = \frac{\exp\{-\lambda_d t\}}{1-\exp\{-\lambda_d t\}}$. The $\theta(t)$ is a decreasing function in t . Hence, even without the knowledge of log-concave properties of pdf, it can be shown that $h(t)$ is strictly an increasing function in t when $k < n$ and is a constant (still IFR) when $k = n$. From (20.30), for any value of t , we have

$$0 = h(0) \leq h(t) \leq h(\infty) = k_d\lambda_d = k\lambda_o \tag{20.31}$$

20.4.4 System Time to Failure Distribution

From the Markov state transition diagram in Fig. 20.1, it can be shown that the system failure time, T , is the sum of independent exponential random variables. Therefore, from [42], it is a hypo-exponential distribution. Further, it can be shown that T follows phase-type (PH) distribution, because it can be viewed as the time to absorption of a finite-state Markov process. However, due to the generic nature of PH distributions, this property does not provide much insight of

the behavior of T . Amari et al. [23] have shown that T follows beta-exponential (BE) distribution proposed by Nadarajah and Kotz [34] as a generalization of beta distribution. The cdf of the BE distribution is

$$F_{BE}(x) = I_{1-\exp(-\lambda x)}(a, b) \tag{20.32}$$

for $x > 0, a > 0, b > 0$, and $\lambda > 0$. The pdf of BE *r.v.* is

$$f_{BE}(x) = \frac{\lambda}{B(a, b)} \exp(-b\lambda x) \{1 - \exp(-\lambda x)\}^{a-1} \tag{20.33}$$

Comparing the cdf expressions in (20.27) and (20.32), Amari et al. [23] have shown that these two expressions are identical when $a = n_d - k_d + 1$ and $b = k_d$. Hence, the failure time distribution of the k -out-of- n warm standby system, as well as its special case k -out-of- n active redundancy system, can be represented as a BE distribution with parameters $a = n_d - k_d + 1 = n - k + 1, b = k_d = k\lambda_o/\lambda_d$, and $\lambda = \lambda_d$. The same results can also be obtained by comparing the pdf expressions in (20.29) and (20.33). For the BE distribution, Nadarajah and Kotz [34] provided closed-form expressions for variance, characteristic function, moment-generating function, moments, cumulants, skewness, kurtosis, Rényi entropy, and Shannon entropy. Therefore, substituting $a = n_d - k_d + 1 = n - k + 1, b = k_d = k\lambda_o/\lambda_d$, and $\lambda = \lambda_d$, these functions can be represented directly in terms of the model parameters of the warm standby system. Note that $a = n - k + 1$ is an integer (even for the generic case). Hence, the corresponding expressions for warm standby systems can be simplified further.

20.4.5 Moment-Generating and Characteristic Functions

This subsection provides derivations for moment-generating function (mgf) and the characteristic function of random variable T having the pdf in Eq. (20.29). From Nadarajah and Kotz [34], the mgf is defined by $M(t) = E[\exp(tX)]$. Hence

$$M(t) = \frac{\lambda}{B(a, b)} \int_0^\infty \exp\{(t - b\lambda)x\} \{1 - \exp(-\lambda x)\}^{a-1} dx \tag{20.34}$$

By substituting $y = \exp(-\lambda x)$, the integral on the right-hand side reduces to

$$\int_0^1 y^{b-t/\lambda-1} (1 - y)^{a-1} dy = \frac{1}{\lambda} B(b - t/\lambda, a) \tag{20.35}$$

Hence, the moment-generating function is

$$\begin{aligned}
 M(t) &= \frac{B(b - t/\lambda, a)}{B(a, b)} \\
 &= \frac{B(k_d - t/\lambda_d, n_d - k_d + 1)}{B(n_d - k_d + 1, k_d)} \\
 &= \frac{B(k\lambda_d - t/\lambda_d, n - k + 1)}{B(n - k + 1, k\lambda_0/\lambda_d)} \tag{20.36}
 \end{aligned}$$

Note that T can be expressed as a sum of s -independent exponential $r.v$. Therefore, $M(t)$ can also be expressed as

$$M(t) = \prod_{j=0}^{n-k} \left[1 - \frac{t}{(k_d + j)\lambda_d} \right]^{-1} \tag{20.37}$$

Hence, the characteristic function of X defined by $\varphi(t) = E[\exp(itX)]$ takes the following form [34]:

$$\begin{aligned}
 \varphi(t) &= \frac{B(b - it/\lambda, a)}{B(a, b)} \\
 &= \frac{B(k_d - it/\lambda_d, n_d - k_d + 1)}{B(n_d - k_d + 1, k_d)} \\
 &= \frac{B(k\lambda_d - it/\lambda_d, n - k + 1)}{B(n - k + 1, k\lambda_0/\lambda_d)} \tag{20.38}
 \end{aligned}$$

Further, $\varphi(t)$ can also be expressed as

$$\varphi(t) = \prod_{j=0}^{n-k} \left[1 - \frac{it}{(k_d + j)\lambda_d} \right]^{-1} \tag{20.39}$$

20.4.6 Mean and Variance

The mean of T can be written as [34]

$$\begin{aligned}
 E[T] &= \{\psi(a + b) - \psi(b)\}/\lambda_d = \{\psi(n_d + 1) - \psi(k_d)\}/\lambda_d \\
 &= \sum_{i=0}^{n-k} \frac{1}{(k_d + i)\lambda_d} = \sum_{i=0}^{n-k} \frac{1}{k\lambda_0 + i\lambda_d} \tag{20.40}
 \end{aligned}$$

The variance of T can be written as

$$\begin{aligned}
 \text{Var}[T] &= \{\psi'(b) - \psi'(a + b)\}/\lambda_d^2 = \{\psi'(k_d) - \psi'(n_d + 1)\}/\lambda_d^2 \\
 &= \sum_{i=0}^{n-k} \frac{1}{[(k_d + i)\lambda_d]^2} = \sum_{i=0}^{n-k} \frac{1}{[k\lambda_0 + i\lambda_d]^2} \tag{20.41}
 \end{aligned}$$

20.4.7 Moments

As shown in Nadarajah and Kotz [34], it is immediate from Eq. (20.29) that the r^{th} moment of T can be written as

$$E[T^r] = \frac{(-1)^r}{\lambda^r B(a, b)} \frac{\partial^r B(a, 1 + p - a)}{\partial p^r} \Bigg|_{p=a+b-1} \tag{20.42}$$

Because $a \equiv n - k + 1$ is an integer, it can be simplified further for the warm standby system. The explicit expression for r^{th} moment of T can be written as [23]

$$\begin{aligned}
 E[T^r] &= \sum_{i=0}^{n-k} \binom{n}{i + k_d} \binom{i + k_d - 1}{i} (-1)^i \frac{r!}{(i + k_d)^r \lambda_d^r} \\
 &= \frac{r! \lambda_d}{B(k\lambda_0/\lambda_d, n - k + 1)} \sum_{i=0}^{n-k} \binom{n - k}{i} \frac{(-1)^i}{(k\lambda_0 + i\lambda_d)^{r+1}} \tag{20.43}
 \end{aligned}$$

Equation (20.43) has several applications in reliability field: (1) estimate parameters of the system using method of moments [34], (2) determine bounds and approximations for reliability of a complex system [47], and (3) dependability analysis considering reliability and performance measures simultaneously [42].

20.4.8 Skewness and Kurtosis

The skewness T can be written as

$$\begin{aligned}
 \text{Skewness}(T) &= \frac{\psi''(a + b) - \psi''(b)}{\{\psi'(b) - \psi'(a + b)\}^{3/2}} \\
 &= \frac{\psi''(n_d + 1) - \psi''(k_d)}{\{\psi'(k_d) - \psi'(n_d + 1)\}^{3/2}} \tag{20.44}
 \end{aligned}$$

The kurtosis of T can be written as

$$\begin{aligned}
 \text{Kurtosis}(T) &= \frac{3\{\psi'(b)\}^2 - 6\{\psi'(b)\psi'(a + b)\} + 3\{\psi'(a + b)\}^2 + \psi'''(b) - \psi'''(a + b)}{\{\psi'(b) - \psi'(a + b)\}^2} \\
 &= \frac{3\{\psi'(b)\}^2 - 6\{\psi'(k_d)\psi'(n_d + 1)\} + 3\{\psi'(n_d + 1)\}^2 + \psi'''(k_d) - \psi'''(n_d + 1)}{\{\psi'(k_d) - \psi'(n_d + 1)\}^2} \tag{20.45}
 \end{aligned}$$

20.4.9 Rényi and Shannon Entropies

An entropy of a random variable T is a measure of variation of the uncertainty [34]. Rényi entropy of order γ is defined by

$$H_\gamma(T) = \frac{1}{1-\gamma} \ln \left\{ \int f^\gamma(x) dx \right\} \quad (20.46)$$

where $\gamma \geq 0$ and $\gamma \neq 1$. For the BE distribution, it can be expressed as [34]

$$H_\gamma(T) = -\ln \lambda + \frac{1}{1-\gamma} \ln \left[\frac{B(\gamma a - \gamma + 1, \gamma b)}{B^\gamma(a, b)} \right] \quad (20.47)$$

Hence, for the warm standby system, it can be expressed as

$$\begin{aligned} H_\gamma(T) &= -\ln \lambda_d + \frac{1}{1-\gamma} \ln \left[\frac{B(\gamma(n_d - k_d) + 1, \gamma k_d)}{B^\gamma(n_d - k_d + 1, k_d)} \right] \\ &= -\ln \lambda_d + \frac{1}{1-\gamma} \ln \left[\frac{B(\gamma(n - k) + 1, \gamma k \lambda_o / \lambda_d)}{B^\gamma(n - k + 1, k \lambda_o / \lambda_d)} \right] \end{aligned} \quad (20.48)$$

Shannon entropy defined by $H(X) \equiv E[-\ln f(X)]$ is the particular case of (20.46) for $\gamma \rightarrow 1$. Limiting $\gamma \rightarrow 1$ in (20.48) and using L'Hospital's rule, the Shannon entropy for warm standby system can be derived:

$$\begin{aligned} H(T) &= E[-\ln f(T)] = -\ln \lambda_d + \ln B(a, b) + (a + b - 1)\psi(a + b) - (a - 1)\psi(a) - b\psi(b) \\ &= -\ln \lambda_d + \ln B(n_d - k_d + 1, k_d) + (n_d)\psi(n_d + 1) - (n_d - k_d)\psi(n_d - k_d + 1) - b\psi(k_d) \end{aligned} \quad (20.49)$$

20.4.10 Mean Residual Life Function

Mean residual life (MRL) is the expected remaining lifetime of the system given that it has survived until time t . Specifically, MRL is defined as $m(t) = E[T - t | T > t]$.

$$m(t) \equiv E[T - t | T > t] = \frac{\int_t^\infty R(x) dx}{R(t)} \quad (20.50)$$

The MRL function of k -out-of- n warm standby system can be represented in several forms. Some of these forms also provide new and compact expressions for the active redundancy model [8]:

$$\begin{aligned} m(t) &= \frac{\sum_{i=0}^{n-k} P_i(t) \mu_i}{\sum_{i=0}^{n-k} P_i(t)} \\ &= \frac{\sum_{i=0}^{n-k} \frac{R(t; k+i, n)}{(k_d+i)\lambda_d}}{R(t; k, n)} \\ &= \frac{\frac{1}{\lambda_d} \sum_{i=0}^{n-k} \binom{n_d}{i+k_d} \binom{i+k_d-1}{i} (-1)^i \frac{p_d^{i+k_d}}{(k_d+i)}}{\sum_{i=0}^{n-k} \binom{n_d}{i+k_d} \binom{i+k_d-1}{i} (-1)^i p_d^{i+k_d}} \end{aligned} \quad (20.51)$$

where μ_i is the MTTF of k -out-of- $(n - i)$ warm standby system: $\mu_i = \sum_{j=0}^{n-k-i} \frac{1}{k\lambda_o + j\lambda_d}$. The MRL expressions can be simplified by canceling the like terms in the numerator and the denominator:

$$m(t) = \frac{\sum_{i=0}^{n-k} \binom{n_d}{i} [\phi(t)]^i \mu_i}{\sum_{i=0}^{n-k} \binom{n_d}{i} [\phi(t)]^i}$$

$$\begin{aligned} &= \frac{\sum_{i=0}^{n-k} \binom{n_d}{i} [\theta(t)]^{k_d+i} \mu_{n-k-i}}{\sum_{i=0}^{n-k} \binom{n_d}{i} [\theta(t)]^{k_d+i}} \\ &= \frac{1}{\lambda_d} \frac{\sum_{i=0}^{n-k} (-1)^i \binom{n-k}{i} \frac{p_d^i}{(k_d+i)^2}}{\sum_{i=0}^{n-k} (-1)^i \binom{n-k}{i} \frac{p_d^i}{k_d+i}} \end{aligned} \quad (20.52)$$

where $\phi(t) = \frac{1-p_d}{p_d} = \frac{1-\exp\{-\lambda_d t\}}{\exp\{-\lambda_d t\}} = \exp\{\lambda_d t\} - 1$ and $\theta(t) = \frac{p_d}{1-p_d} = \frac{1}{\phi(t)}$. Because the system time to failure distribution is IFR, from [46], it can be shown that $m(t)$ is a decreasing function in t . Further, it can be shown that for any t :

$$\sum_{i=0}^{n-k} \frac{1}{k\lambda_o + i\lambda_d} = \mu = m(0) \geq m(t) \geq m(\infty) = \frac{1}{k_d\lambda_d} = \frac{1}{k\lambda_o} \quad (20.53)$$

20.4.11 Mean Past Life or Mean Inactive Time Function

The mean past life (MPL), also called mean inactive time or mean elapsed time, corresponds to the mean time elapsed since the failure of the system at time T until the observed time t given that $T \leq t$ [48, 49]. In this case, the random variable of interest is $\{t - T | T \leq t\}$. This conditional random variable is elapsed time since the failure of the system at T given that it has failed at or before t . The expectation of this random variable, denote by $\kappa(t)$, is known as the MPL. Specifically, MPL is defined as $\kappa(t) = E[t - T | T \leq t]$:

$$\kappa(t) \equiv E[t - T | T \leq t] = \frac{\int_0^t F(x) dx}{F(t)} \quad (20.54)$$

The MPL can be expressed in terms of MRL function, $m(t)$, and mean life function, $E[T]$:

$$\begin{aligned} \kappa(t) &= \frac{\int_0^t F(x) dx}{F(t)} = \frac{t - \int_0^t R(x) dx}{F(t)} \\ &= \frac{t - \int_0^\infty R(x) dx + \int_t^\infty R(x) dx}{F(t)} \\ &= \frac{t - E[T] + m(t)R(t)}{F(t)} \end{aligned} \quad (20.55)$$

Substituting $m(t)$ and $R(t)$ in (20.55), the MPL can be expressed as

$$\begin{aligned} \kappa(t) &= \frac{t - E[T] + \sum_{i=0}^{n-k} P_i(t) \mu_i}{1 - \sum_{i=0}^{n-k} P_i(t)} \\ &= \frac{t - \sum_{i=0}^{n-k} \frac{1}{(k_d+i)\lambda_d} + \sum_{i=0}^{n-k} \frac{R(t; k+i, n)}{(k_d+i)\lambda_d}}{1 - R(t; k, n)} \\ &= \frac{t - \sum_{i=0}^{n-k} \frac{1 - R(t; k+i, n)}{(k_d+i)\lambda_d}}{1 - R(t; k, n)} \\ &= \frac{t - \sum_{i=0}^{n-k} \frac{F(t; k+i, n)}{(k_d+i)\lambda_d}}{F(t; k, n)} \end{aligned} \quad (20.56)$$

where μ_i is the MTTF of k -out-of- $(n-i)$ warm standby system $\mu_i = \sum_{j=0}^{n-k-i} \frac{1}{k\lambda_o + j\lambda_d}$ and $F(t; k+i, n)$ is the unreliability of $(k+i)$ -out-of- n system where $F(t; k+i, n) = 1 - R(t; k+i, n)$.

20.5 Optimal Reliability Design

A primary objective of reliability engineering is designing highly reliable systems considering available resources and design constraints [1, 2]. One of the primary techniques in improving reliability is employing redundancy (spares). However, improvements in reliability must be made without violating system constraints [1]. When redundancy is used to improve reliability of a system consisting of multiple subsystems, it is important to determine the optimal redundancy levels for each subsystem. In general, the optimal spares allocation is a well-known NP-hard problem [1, 2]. Hence, there are no efficient solutions for the generic case of large-scale systems. This is because the computational time to solve this problem increases exponentially with the system size. Hence, all existing methods are applicable to either small-scale problems or to find approximate solutions. This is the case even if system configuration is series structure where all subsystems are connected logically in a series. However, an effective use of log-concave properties can

improve the efficiency of redundancy allocation problem [44]. Specifically, using log-concave properties, Amari [33] proposed an efficient linear-time algorithm to find optimal design configurations for nonrepairable series systems with a single system-level constraint. This section describes the method proposed in [33].

20.5.1 Optimization Model Description

- the system has M subsystems in series. Hence, the system is good only if all of its subsystems are good.
- The subsystems are s -independent.
- The subsystems use a k -out-of- n cold/warm standby or active redundancy. The subsystem- i requires at least k_i components for successful operation.
- The components within each subsystem are S -identical.
- The type of components used can vary with the subsystems.
- Each component has its own operational and dormant (standby) failure rates as well as resource consumption rates.
- The systems and its components are nonrepairable.

The objective is to maximize the system reliability through optimal allocation of spares for different subsystems without violating the system-level constraints such as total system cost/budget, weight, or volume (only one type of constraint is considered).

20.5.2 Optimization Model Formulation

The objective function is the system reliability and it can be expressed as

$$R(t; \mathbf{k}, \mathbf{n}) = \prod_{i=1}^M R(t; k_i, n_i) \quad (20.57)$$

where the reliability of each subsystem can be evaluated using Eqs. (20.13), (20.15), or (20.16).

The optimization method presented here is based on the log-concave properties of the warm standby systems discussed in Sect. 20.3.5. In other words, the optimization method is based on the property that $\frac{R(n+1)}{R(n)}$ is a decreasing function in n . To demonstrate the role of the log-concave properties, a 2-out-of- n warm standby system with varying number of components is considered where $(n-2)$ is the number of spares. Let $\lambda_o = 1$, $\lambda_d = 0.2$, and $t = 1$. The system reliability and its improvement factors at different number of spares are shown in Table 20.1. The results demonstrate that both $\frac{\delta_{i+1}}{\delta_i}$ and $\frac{R(n+1)}{R(n)}$ are decreasing functions.

Table 20.1 Log-concave properties of 2-out-of- n warm standby system

n	$i = n - k$	δ_i	$R(n)$	$\frac{\delta_{i+1}}{\delta_i}$	$\frac{R(n+1)}{R(n)}$
2	0	0.1353	0.1353	1.8127	2.8127
3	1	0.2453	0.3807	0.9970	1.6425
4	2	0.2446	0.6252	0.7251	1.2836
5	3	0.1773	0.8026	0.5891	1.1302
6	4	0.1045	0.9071	0.5076	1.0585
7	5	0.0530	0.9601	0.4532	1.0250

Table 20.2 Log-concave properties of 2-out-of- n cold standby system

n	$i = n - k$	δ_i	$R(n)$	$\frac{\delta_{i+1}}{\delta_i}$	$\frac{R(n+1)}{R(n)}$
2	0	0.1353	0.1353	2.0000	3.0000
3	1	0.2707	0.4060	1.0000	1.6667
4	2	0.2707	0.6767	0.6667	1.2667
5	3	0.1804	0.8571	0.5000	1.1053
6	4	0.0902	0.9473	0.4000	1.0381
7	5	0.0361	0.9834	0.3333	1.0122

Similarly, to demonstrate the log-concave properties of cold standby redundancy, the same 2-out-of- n configuration is considered. However, for the cold standby systems, the dormant failure rate is set to zero: $\lambda_d = 0$. The system reliability and its improvement factors are shown in Table 20.2. The results demonstrate that both $\frac{\delta_{i+1}}{\delta_i}$ and $\frac{R(n+1)}{R(n)}$ are decreasing functions even for the cold standby redundancy.

20.5.3 Optimal Allocation of Fixed Number of Total Spares

Consider a special case of the optimization problem where the total number of spares that are allocated to all subsystems is fixed. Further, consider that there is a fixed budget for procuring the spares and the cost (weight or volume) of each spare is the same. The objective is to find the optimal allocation of spares at each subsystem that maximizes the overall system reliability. From a mathematical point of view, it is a nonlinear integer programming problem. Prior to the publication of [23,33] there were no efficient solutions to find the global optimal allocation spares when subsystems were modeled using k -out-of- n cold/warm standby redundancy.

The system reliability can be obtained from (20.57). Further, the reliability of each subsystem can be expressed as a product of different factors. Specifically,

$$R_i(k_i, n_i) = R_i(k_i, k_i) \prod_{j=0}^{n_i-k_i} \phi_i(j)$$

$$\phi_i(j) = \frac{R_i(k_i, k_i + j)}{R_i(k_i, k_i + j - 1)} \quad (20.58)$$

The number of $\phi_i(j)$ terms in the product is equal to the number of spares in the subsystem. For example, consider a 2-out-of-4 warm standby configuration for a specific subsystem (e.g., subsystem 1). The subsystem reliability can be expressed as

$$R_1(2, 4) = R_1(2, 2) \cdot \frac{R_1(2, 3)}{R_1(2, 2)} \cdot \frac{R_1(2, 4)}{R_1(2, 3)} \quad (20.59)$$

From the log-concave properties of warm standby systems, $\phi_i(j)$ is known to be a decreasing function in j for each i (subsystem). When no spares are added to the subsystems, the system reliability is

$$R_{sys} = \prod_{i=1}^M R_i(k_i, k_i) \quad (20.60)$$

Now assume that s_i spares have already been added to subsystem- i and the total number of spares added to all subsystems is S . In other words, $S = \sum_{i=1}^M s_i$. Hence, the system reliability is

$$R_{sys} = \left[\prod_{i=0}^M R_i(k_i, k_i) \right] \cdot \left[\prod_{i=1}^M \prod_{j=1}^{s_i} \phi_i(j) \right] \quad (20.61)$$

The product term in the first set of square brackets is the same for any given set of spares allocation. Hence, it can be considered as constant. Therefore, system reliability can be maximized by maximizing the product term in the second set of square brackets. The number of terms in the second set of square brackets is equal to the total number of spares (S) added to the system. If this term includes only the highest possible $\phi_i(j)$ values, then the system reliability is maximized. Alternatively, if all possible values of $\phi_i(j)$ can be arranged in a descending order and we were able to select the first S values, the system reliability can be maximized. However, such a selection is valid only if, for any given subsystem- i , the factor corresponding to the j th spare can appear only if the factor corresponding to $(j - 1)$ th spare is already added. Mathematically, $\phi_i(j)$ can be included only if $\phi_i(j - 1)$ has been already included. However, such a selection is possible for the warm standby system due to its log-concave property. Therefore, it plays a key role in finding the solution to optimal allocation problem.

Note that $\phi_i(j - 1) > \phi_i(j)$ for warm standby system. Hence, $\phi_i(j - 1)$ will be included in the list before including $\phi_i(j)$. Further, due to the log-concave property, it is easy to identify the top $\phi_i(j)$ values without explicitly sorting them, because $\phi_i(j)$ is a decreasing function in j for each i . Hence, the highest value among all $\phi_i(j)$ is corresponding to the highest value among $\phi_i(1)$ for $i \in \{1, 2, \dots, M\}$. Let $\phi_i(1)$ be the current set of $\phi_i(j)$ values. It has M elements. Let the

corresponding subsystem that has the highest value of $\phi_i(1)$ be subsystem- m . To find the next highest $\phi_i(j)$ value, only the m^{th} element of the current set of $\phi_i(j)$ values needs to be updated with $\phi_m(2)$. This selection procedure can be continued until the maximum limit on S , i.e., (S_{\max}) , is reached.

Algorithm-C: Optimal Redundancy Allocation for Fixed Number of Spares

The detailed steps of the proposed algorithm are shown below:

- Step 1: **Set** $(s_1^*, \dots, s_M^*) = (0, \dots, 0)$ and $v = 0$.
- Step 2: **If** $(v < S_{\max})$ **then goto** step 3
 else take $s^* = (s_1^*, \dots, s_M^*)$ **as the optimal allocation;**
 Stop
 End If
- Step 3: **Find** m such that

$$\phi_m(s_i^* + 1) = \max_{1 \leq i \leq M} [\phi_i(s_i^* + 1)]$$
- Step 4: **Set** $s_m^* = s_m^* + 1$: increase the allocation to subsystem m by 1 and
 Set $v = v + 1$. **Go to** step 2

The above algorithm can be explained in simple terms. It adds a spare to the system one at a time until the allowed limit is reached. At each step, it allocates a spare to one of its subsystems where the percentage of improvement is the highest. This allocation algorithm is nothing but a simple greedy algorithm based on the steepest increment method. In other words, the allocation algorithm is not only simple but

also leads to global optimal solution in spite of its greedy nature. Note that the optimal allocation method is not the same as the method that improves the least reliable subsystem or allocates a spare to a subsystem where the improvement itself is the highest. The key factor is to allocate the spares to a subsystem where *reliability improvement percentage is the highest* rather than improving the least reliable subsystem or adding spares to a subsystem where the reliability improvement is the highest.

20.5.4 Optimal Allocation with Different Resource Consumption Rates

The allocation method described in Sect. 20.5.3 can also be extended to the case where different spares have different resource consumption rates (costs). In this chapter, we assume that the resource consumption rates are integers. When the consumption rates are real, in most cases, an appropriate multiplication factor can be used to convert them into integers. Further, the cost of spares can be specified in dollars or cents. However, to improve computation efficiency, it is recommended to represent them as the smallest possible integers. For example, if the costs of spares are in thousands of dollars, then the resource consumption rates can be represented in units of thousand dollars.

Algorithm-D: Optimal Redundancy Allocation for Spares with Different Resource Consumption

Let c_i be the cost of a spare (or resource consumption rate) used in subsystem- i . Let C be the total allowed budget for procuring the spares. Note that the proposed method computes the optimal allocation of spares for each integer value of budget B where $B \leq C$. The algorithm to find the optimal allocation of spares is

- Step 1: **Set** $s_1^*(0) = 0, \dots, s_M^*(0) = 0$ and $B = 0$.
- Step 2: **Compute** $R^*(0)$ using $s^*(0)$.
- Step 3: **If** $(B < C)$ **then go to** step 4
 else take $s^* = (s_1^*, \dots, s_M^*)$ **as the optimal allocation; Stop**
 EndIf
- Step 4: **Find** m such that

$$m = \operatorname{argmax}_{1 \leq i \leq M} [R^*(B - c_i) \cdot \phi_i(s_i^*(B - c_i) + 1)]$$
- Step 5: **Set** $R^*(B)$ as:

$$R^*(B) = R^*(B - c_m) \cdot \phi_m(s_m^*(B - c_m) + 1)$$
- Step 6: **Set** $s^*(B) = s^*(B - c_m)$.
 Then update $s^*(B) = s^*(B - c_m)$: increase the allocation to subsystem m by 1 and
 Set $B = B + 1$. **Go to** step 3

20.5.5 Numerical Example

Example 5 Consider a system consisting of five subsystems (I, II, III, IV, and V) in a series. Subsystem-I uses cold standby; subsystems II, III, and IV use warm standby redundancy; and subsystem-V uses active redundancy. Table 20.4 shows the operational and dormant (standby) failure rates of components used in the subsystems and minimum number of components needed for the successful operation of the subsystems.

The objective is to allocate a total of 20 spares among all subsystems to maximize the system reliability for mission time $t = 1$. To demonstrate the allocation method discussed in Sect. 20.5.3, Table 20.4 shows the intermediate results, i.e., $R_i(k_i, k_i)$ and $\phi_i(j)$ values. The table also includes the ranks of $\phi_i(j)$ values as their subscripts for the range of ranks from 1 to 20, i.e., from 1 to S_{\max} (Table 20.3).

At the every step where the first spare is added, the current $\phi_i(j)$ values are nothing but the $\phi_i(1)$ values: [2.60, 1.58, **2.88**, 1.73, 1.54]. The largest value corresponds to subsystem-III. So, a spare is added to subsystem-III and then the $\phi_i(j)$ values are updated to [2.60, 1.58, 1.65, 1.73, 1.54]. Now the largest value corresponds to subsystem-I. So, the next spare is allocated to subsystem-I and then the $\phi_i(j)$ values are updated to [1.49, 1.58, 1.65, **1.73**, 1.54]. Hence, the next spare is added to subsystem-IV. Continuing the same procedure, the final optimal allocation of spares for different subsystems are obtained. The spares are added in the following order: {III, I, IV, III, II, V, I, III, IV, I, V, III, II, I, IV, III, V, II, III, I}, and the final allocation of the spares at subsystems [I, II, III, IV, V] are [5, 3, 6, 3, 3], and the corresponding system reliability is 0.9436.

Further, consider the generic case where the cost of spares is different for different subsystems. Let $[c_1, c_2, c_3, c_4, c_5]$ be [5, 6, 10, 7, 4]. The budget for procuring all spares is 140. Using the Algorithm-D in Sect. 20.5.4, the optimal

spares allocation is [5, 3, 6, 3, 4]. The system reliability corresponding to the optimal allocation is 0.9521. Note that storing all possible values of $s_i(j)$ is not needed. At any given step of the optimization, the algorithm needs to keep track of at most $\max(c_i)$ entries of $s_i(j)$ values for each combination of i and j . Hence, the storage requirement is $M \cdot \max(c_i)$, which is much lower than $M \cdot C$.

20.6 Conclusions

This chapter presents reliability analysis and optimal redundancy allocation of k -out-of- n warm standby redundancy with identical components following exponential failure time distributions. Closed-form expressions for various reliability characteristics and measures are presented. Specifically, expressions for system reliability, state probabilities, failure (hazard) rate, pdf, and MRL & MPL functions are presented in the forms that are similar to the case of active redundancy. Subsequently, the system reliability is expressed in several forms to gain new insights into the system reliability characteristics. The closed-form expressions and computational algorithms presented in this chapter produce robust and numerically stable system reliability evaluation. The analysis accounts for the effects of switch failures on demand on system reliability [9]. Further, it is proved that the time-to-failure distribution of k -out-of- n warm standby system is beta-exponential. Using this property, closed-form expressions for statistical measures of system failure time distribution are presented. Specifically, closed-form expressions are provided for moment-generating function, characteristic function, variance, higher order moments, skewness, kurtosis, and Rényi and Shannon entropies of the random variable representing the system failure time.

The system reliability improvement with an additional redundant component follows a negative binomial (Pólya) distribution and is log-concave. Further, it has shown that the system reliability function is log-concave n . Hence, the percentage improvement in system reliability with an additional spare decreases with the number of spares already added to the system. Using these log-concave properties, efficient linear-time computational algorithms for finding optimal system designs are presented. Because active redundancy is a special case of the warm standby redundancy, indirectly this chapter also provides some new results for the active redundancy case as well.

Table 20.3 Optimization problem parameters of the subsystems

Subsystem index: i	Redundancy type	$\lambda_{o,i}$	$\lambda_{d,i}$	k_i
I	Cold standby	0.8	0	2
II	Warm standby	0.6	0.06	1
III	Warm standby	0.5	0.125	4
IV	Warm standby	0.4	0.2	2
V	Active	0.2	0.2	3

Table 20.4 Intermediate results: $R_i(k_i, k_i)$ and $\phi_i(j)$ Values

Subsystem index: i	$R_i(k_i, k_i)$	$\phi_i(1)$	$\phi_i(2)$	$\phi_i(3)$	$\phi_i(4)$	$\phi_i(5)$	$\phi_i(6)$
I	0.202	2.600 ₂	1.492 ₇	1.176 ₁₀	1.059 ₁₄	1.018 ₂₀	1.004
II	0.549	1.582 ₅	1.118 ₁₃	1.025 ₁₈	1.005	1.0001	1.0001
III	0.135	2.880 ₁	1.652 ₄	1.278 ₈	1.122 ₁₂	1.019 ₁₆	1.019 ₁₉
IV	0.449	1.725 ₃	1.191 ₉	1.058 ₁₅	1.017	1.001	1.0013
V	0.549	1.544 ₆	1.127 ₁₁	1.034 ₁₇	1.009	1.001	1.0005

The exponential component lifetimes assumption made in this paper can be removed by extending the result to proportional hazards models subjected to arbitrary general baseline failure time distributions [50]. Similarly, in addition to switch failures on demand, the results can be extended to account for the failure effects of continuously monitoring switches on the system reliability [7, 9]. The same concepts used in this chapter can also be extended to analyze a k -out-of- n warm standby system with nonidentical components by considering different paths that lead the system failure. Similar to nonrepairable case, the simple formulas presented in this chapter can also be extend to k -out-of- n warm standby system with identical but repairable components. The results presented in this chapter can easily be extended to find the optimal cost-effective designs that consider the cost of spares as well as cost of system failure [41]. We consider these extensions as a future research work.

Acknowledgments The first author of this book chapter, Suprasad Amari, would like to acknowledge that the joint research work presented in this chapter was conducted prior to his joining at the BAE Systems and the opinions expressed in this article are the author's own and do not reflect the views of the BAE Systems. The first author also would like to remember and acknowledge his doctoral research advisor, Professor Ravindra B. Misra, for introducing him to the reliability model discussed in this chapter.

In order to address the above questions, the efficient simulation approaches based on structure function and survival signature have been proposed respectively to analyze the complex repairable systems. Based on this, component importance index has been introduced to perform sensitivity analysis on a specific component or a set of components within the repairable system. In addition, the proposed simulation method can be used to deal with imprecision within the survival signature. Numerical examples are presented to show the applicability of the above approaches.

Abstract

The identification of the components which are responsible for the performance of system is a key task to improve the safety and reliability. However, such analysis is difficult and challenging when large and complex systems are analyzed. The survival signature which is presented recently cannot only hold the merits of the former system signature but is efficient to deal with complex system with multiply component types. In real engineering applications, components can be repaired after failure. Hence, it is essential to identify which component or component set is most critical the complex repairable system. What is more, due to lack of data or the confidential information, it is difficult to know the full configuration of the system, which leads to an imprecise survival signature.

21.1 Introduction

System signature has been introduced recently by Samaniego [25]; it can separate the system structure from the components failure time distributions, which makes it efficient to quantify the reliability of the system. However, system signature has a very important assumption that all components in the coherent system should be in a single type, which makes it intractable to analyze complex system with two or more component types.

In order to overcome the limitations of the system signature, [7] proposed the survival signature, which not only reserves the merits of the system signature but can be applied to analyze system with multiple component types. In essence, it does not have the assumption that components of different types are exchangeable, which overcomes the long-standing limitation of the system signature. This is useful when a system may have components with failure times that follow different probability distributions [8]. Therefore, survival

G. Feng (✉)

e-mail: gfeng@uclan.ac.uk

signature is a promising method for application to complex systems and networks.

Recently, Aslett developed an R package to calculate the survival signature [1], and an efficient algorithm for the exact computation of the survival signature of large systems was put forward by Reed [24]. A nonparametric predictive inference for system reliability using the survival signature was proposed by Coolen et al. [11]. Based on the above concepts, Feng et al. developed an analytical and numerical method to perform reliability analysis on systems with uncertain components parameters [14]. These survival signature-based methods are efficient for non-repairable system reliability analysis; however, they do not take the complex repairable system into consideration. Simulation methods has attractive features for analyzing complex and large systems [22], which makes it possible to deal with the repairable complex systems reliability. Survival signature methodology is extended to analyze systems with common cause failures [13, 18].

The risks are unavoidable, and as such the key challenge in engineering risk analysis is to identify the components of the system that contribute most to risk [20]. Importance and sensitivity analysis is an essential way to find out the most critical component, which helps engineers to allocate the limited resources. Therefore, importance and sensitivity analysis is a key point in tracing bottlenecks in systems and in identifying the most important component [19]. The definition of component importance measure is first introduced by Birnbaum [3], which is obtained by partial differentiation of the system reliability with respect to the given component reliability. An improvement or decline in reliability of the component with the highest importance will cause the greatest increase or decrease in system reliability. Based on this achievement, many other component importance measures have been introduced, e.g., Fussell-Vesely importance measure [17, 27], failure criticality index [28], structure importance measure [4], risk reduction worth, and risk achievement worth [5]. The aforementioned importance measures mainly focus on an individual component of a non-repairable system; however, it is important to calculate the importance degree of component within a repairable system. What is more, it is of interest to evaluate the importance of a set of components or a subsystem with a few components in many practical situations.

Probabilistic uncertainty and imprecision in structural parameters and in environmental conditions and loads are challenging phenomena in engineering analysis [2]. There is a wide variety of reasons why imprecise probability might be of particular relevance in the area of system reliability [6, 23]. For example, due to limited data or confidentiality for the system, it sometimes cannot get the precise survival signature. In order to deal with imprecision, Ferson et al. introduced the probability box, which is also called p-box, to define the set of the imprecise values [15, 16]. Coolen

and Coolen-Maturi [9] linked the (imprecise) probabilistic structure function to the survival signature. The interval of the survival signature will lead to imprecise survival function of the system.

The structure function-based method and the survival signature-based method are both based on the Monte Carlo simulation, which is general and useful for many problems. By generating the state evolution of each component, the structure function is computed to determine the state of the system, while survival signature is a summary of the structure signatures, which is efficient to deal with the complex configuration systems.

A survival signature-based method is proposed in this paper, which is efficient to analysis repairable system reliability. This is essential when dealing with complex repairable systems since they can only be analyzed through simulation method. In order to find out the most “critical” component in the system, new component importance measures which based on survival signature are introduced to analysis individual component and component sets respectively. What is more, a new relative criticality index is used to quantify the importance degree of the component. There exists imprecise survival signature if the full configuration of the system is unknown or only uncertain survival signature is known due to confidential contract, it is essential to deal with the imprecision by simulation methods. Therefore, the intervals of the survival function of the complex system can be gotten. The applicability of the proposed approach is demonstrated by solving the numerical examples.

This paper is organized as follows. Section 21.2 gives a conception and relationship between the structure function and survival signature. The relative importance index and quantitative importance index to perform importance and sensitivity analysis on complex repairable systems are proposed in Sect. 21.3. Section 21.4 shows how to deal with the imprecise survival signature. The applicability and performance of the proposed approaches are presented in Sect. 21.5. Finally Sect. 21.6 closes the paper with conclusions.

21.2 Relationship Between Structure Function and Survival Signature

For a system with m components, let state vector $\underline{x} = (x_1, x_2, \dots, x_m) \in \{0, 1\}^m$, with $x_i = 1$ if the i th component works and $x_i = 0$ if not. The structure function $\phi(\underline{x}) : \{0, 1\}^m \rightarrow \{0, 1\}$, defined for all possible \underline{x} , takes the value 1 if the system functions and 0 if not for state vector \underline{x} . In this paper, attention is restricted to coherent systems, for which $\phi(\underline{x})$ is not decreasing in any of the components of \underline{x} , so system functioning cannot be improved by worse performance of one or more of its components. It is further

assumed that $\phi(0) = 0$ and $\phi(1) = 1$, so the system fails if all its components fail and functions if all its components function.

Now consider a system with $K \geq 2$ types of components, with m_k components of type $k \in \{1, 2, \dots, K\}$ and $\sum_{k=1}^K m_k = m$. Assume that the random failure times of components of the system type are exchangeable, while full independence is assumed for components belong to different types. The components of the same type can be grouped together due to the arbitrary ordering of the components in the state vector, which leads to a state vector can be presented as $\underline{x} = (\underline{x}^1, \underline{x}^2, \dots, \underline{x}^K)$, with $\underline{x}^k = (x_1^k, x_2^k, \dots, x_{m_k}^k)$ illustrating the states of the components of type k . Coolen [7] introduced the survival signature for such a system, denoted by $\Phi(l_1, l_2, \dots, l_K)$, with $l_k = 0, 1, \dots, m_k$ for $k = 1, 2, \dots, K$, which is defined to be the probability that the system functions given that l_k of its m_k components of type k work, for each $k \in \{1, 2, \dots, K\}$.

There are $\binom{m_k}{l_k}$ state vectors \underline{x}^k with $\sum_{i=1}^{m_k} x_i^k = l_k$ ($k = 1, 2, \dots, K$), and let S_{l_1, l_2, \dots, l_K} denote the set of all state vectors for the whole system. Due to independent and identical distributed (*iid*) assumption, all the state vectors $\underline{x}^k \in S_{l_k}^k$ are equally likely to occur, so the survival signature can be written as:

$$\Phi(l_1, \dots, l_K) = \left[\prod_{k=1}^K \binom{m_k}{l_k}^{-1} \right] \times \sum_{\underline{x} \in S_{l_1, \dots, l_K}} \phi(\underline{x}) \quad (21.1)$$

It can be seen from Eq. 21.1 that survival signature is a summary of structure functions. Let $C_k(t) \in \{0, 1, \dots, m_k\}$ denote the number of k components working at time t . Assume that the components of type k have a known cumulative distribution function (*CDF*) $F_k(t)$ and the component failure times of different types are independent; then:

$$\begin{aligned} P\left(\bigcap_{k=1}^K \{C_k(t) = l_k\}\right) &= \prod_{k=1}^K P(C_k(t) = l_k) \\ &= \prod_{k=1}^K \binom{m_k}{l_k} [F_k(t)]^{m_k - l_k} [1 - F_k(t)]^{l_k} \end{aligned} \quad (21.2)$$

Hence, the survival function of the system with K types of components becomes:

$$P(T_s > t) = \sum_{l_1=0}^{m_1} \dots \sum_{l_K=0}^{m_K} \Phi(l_1, \dots, l_K) P\left(\bigcap_{k=1}^K \{C_k(t) = l_k\}\right) \quad (21.3)$$

Equation 21.3 shows that the survival signature can separate the structure of the system from the failure time distribution of its components, which is the main advantage of the system signature. What is more, the survival signature only

needs to be calculated once when perform reliability analysis on the same system. The survival signature is closely related with system signature. For a special case of a system with only one type ($K = 1$) of components, the survival signature and the Samaniego's system signature are directly linked to each other through a simple equation [7]; however, the latter cannot be easily generalized for systems with multiple types ($K \geq 2$) of components. As a result, the survival signature cannot only hold the merits of system signature but is efficient for complex system with multiple components types.

21.3 Importance and Sensitivity Analysis on Repairable System

Component importance measures and sensitivity analysis is evaluable in real engineering world. The existing importance measures are mostly calculated through analytical approaches, and application of these measures to complex repairable systems may be intractable. In order to overcome intractability, two important measures work by figuring out how much each component or a component set contribute to system unavailability. What is more, another index is used to quantify the importance degree of the specific component and component set. It always takes the system with m components which belong to K component types, for example, in this section.

21.3.1 Reliability Analysis on Repairable System

If a system with m components is repairable [12], the state transition diagram of a component is presented in Fig. 21.1. The schematic diagram of the m components status and the corresponding system performance can be seen in Fig. 21.2.

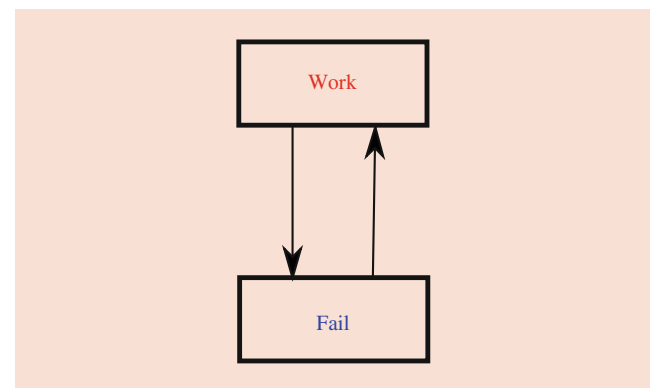

Fig. 21.1 State transition diagram of a component

Fig. 21.2 Schematic diagram of the m components status and the corresponding system performance

The reliability analysis on repairable systems can turn to structure function-based method and survival signature-based method, respectively.

For the structure function-based method, it is essential to estimate the system status at each critical time points, which means the beginning time for each component fails and the its finish time to repair.

While for the second repairable system reliability analysis method, it is based on the survival signature, and it uses the system “production level” idea that is proposed in [29].

The flowchart of the repairable system survival function is evaluated by structure function, and survival signature can be seen in Fig. 21.3. These algorithms can be obtained from the approach proposed by one of the authors in [29].

21.3.2 Importance Measure of a Specific Component

The relative importance index $RI_i(t)$ of the i th component at time t that first used in [14] can be extended to analyze the importance degree of components in the repairable system. To be specific, it is the repairable system survival function probability differences if the i th component works or not. The mathematical expression formula of the relative importance index which is based on survival signature can be expressed as:

$$RI_i^{SS}(t) = P(T_S > t | T_i > t) - P(T_S > t | T_i \leq t) \quad (21.4)$$

where $P(T_S > t | T_i > t)$ represents the probability that the repairable system works knowing that the i th component functions; $P(T_S > t | T_i \leq t)$ denotes the repairable system survival probability if the same component fails.

However, since the relative importance index calculated by survival signature needs to know the survival signature of the new system. If the system is complex, it is a time-consuming work. Therefore, the structure function-based relative importance index has been introduced to identify the specific component’s importance degree; its equation is:

$$RI_i^{SF}(t) = P(T_S > t | x_i \text{ repairable}) - P(T_S > t | x_i \text{ non-repairable}) \quad (21.5)$$

where $P(T_S > t | x_i \text{ repairable})$ means the survival function of the repairable system if the i th component can be repaired normally, while $P(T_S > t | x_i \text{ non-repairable})$ indicates the probability that the system functions knowing that the same component cannot be repaired after failure.

21.3.3 Importance Measure of a Set of Components

It is sometimes important to evaluate the importance of a set of components instead of a specific one in the real engineering world. Therefore, the relative importance index for a specific component can be extended to component set of k , which can be denoted by $RI_k(t)$. The set of components can be either in one single type or different types.

For the first situation, $RI_k(t)$ is convenient to combine with the survival signature, and it is the probability difference values of the repairable system works if the components of type k are repairable or they cannot be repaired. The expression can be written as follows:

$$RI_k^{SS}(t) = P(T_S > t | l_k \text{ repairable}) - P(T_S > t | l_k \text{ non-repairable}) \quad (21.6)$$

where $P(T_S > t | l_k \text{ repairable})$ represents the probability that the repairable system works if components of type k are repairable; $P(T_S > t | l_k \text{ non-repairable})$ denotes the probability that the repairable system functions knowing that the components of type k cannot be repaired.

While for the second condition, it is more efficient to analyze the importance degree of a set of components that belong to different types. The mathematical equation of the structure function-based method is:

$$RI_k^{SF}(t) = P(T_S > t | \underline{x}_i^k \text{ repairable}) - P(T_S > t | \underline{x}_i^k \text{ non-repairable}) \quad (21.7)$$

where $P(T_S > t | \underline{x}_i^k \text{ repairable})$ means the survival probability of the repairable system if the set of the i th component of type k is repairable; here $i \in (1, 2, \dots, m_k)$ and $k \in$

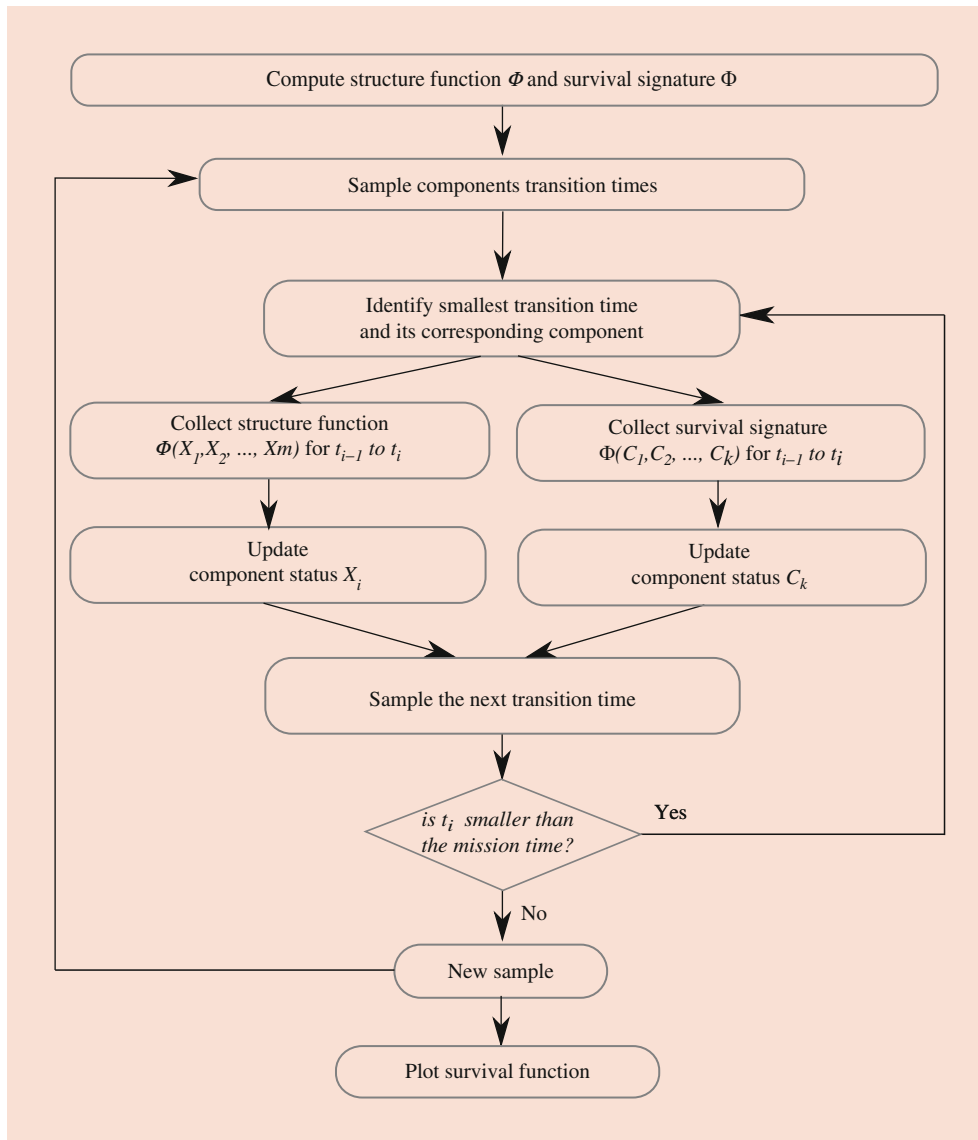

Fig. 21.3 Flowchart of structure function and survival signature based survival function evaluation method for repairable system

$(1, 2, \dots, K)$. $P(T_S > t \mid \underline{x}_i^k \text{ non-repairable})$ represents the survival function of the system given that the i th component of type k set is non-repairable.

It can be seen that both $RI_i(t)$ and $RI_k(t)$ are time-dependent and both of them can be calculated by survival signature-based method and structure function-based method, respectively. What is more, they reveal the trend of the importance degree of a specific component or a set of components within the repairable system during the survival time. The bigger the value of $RI_i(t)$ or $RI_k(t)$ is, the more “critical” is the i th component or the set of components on the repairable system reliability at a specific time t , and vice versa. This helps to allocate resources, which might

include resources for reliability improvement, surveillance and maintenance, design modification, security, operating procedure, training, quality control requirements, and a wide variety of other resource expenditures. By using the importance of a specific component or a set of components, resources expenditure can be properly optimized to reduce the total life cycle resource expenditures while keeping the risk as low as possible. In other words, for a given resource expenditure such as for maintenance, the importance measure of a specific component or set of components can be used to allocate resources to minimize the total system risk. This approach allows the risk manager to offer the “biggest bang for the buck” [21].

21.3.4 Quantify Importance Degree

In order to quantify importance degree of the specific component or a set of components, the quantitative importance index (*QI*) is introduced in this paper. The numerically obtained index for a repairable system is through Monte Carlo simulation method which is based on survival signature and structure function. The failure times of the system can be gotten through each trial; after having simulated many histories of the system, estimates are made of the desired relative criticality index statistically. For a system with *m* components belonging to *K* types, the quantitative importance index of the specific component *i* is expressed as:

$$QI_i = \frac{N_i^f}{\max\{N_1^f, \dots, N_i^f, \dots, N_m^f\}} \tag{21.8}$$

where N_i^f represents average number of system failures if the *i*th component cannot repair while the other components can be repaired normally; and $\max\{N_1^f, \dots, N_i^f, \dots, N_m^f\}$ denotes the biggest value of all N_i^f with $i = 1, 2, \dots, m$.

Similarly, for component set *k*, the *QI* can be written as:

$$QI_k = \frac{N_k^f}{\max\{N_1^f, \dots, N_k^f, \dots, N_K^f\}} \tag{21.9}$$

where N_i^f denotes the average failure number of the system if the component set *k* are non-repairable but the other component sets are repairable, while $\max\{N_1^f, \dots, N_k^f, \dots, N_K^f\}$ denotes the maximum number of all N_k^f with $k = 1, 2, \dots, K$.

These two indexes can quantify the importance degree of a specific component and a component set respectively, and the quantitative importance index values of all the components are compared with the biggest *QI* value. Therefore, the bigger the value is, the bigger influence of the *i*th component or the component set *k* on the repairable system.

21.4 Imprecision Within Survival Signature

Imprecise probability [10] generalizes classical probability in the sense that uncertainty about events are quantified via intervals, instead of single numbers. For example, the interval of an uncertain event *A* is $[\underline{P}(A), \overline{P}(A)]$ with $0 \leq \underline{P}(A) \leq \overline{P}(A) \leq 1$, where $\underline{P}(A)$ is called the lower probability for event *A*, $\overline{P}(A)$ is called the upper probability for event *A*, and $\Delta(A) = \overline{P}(A) - \underline{P}(A)$ is called the imprecision for event *A* [6].

As requirements for system quality have increased, the need for high system reliability is also increasing [26]. In the real industrial world, it is sometimes difficult to know the full configuration of the system if there has confidential contract of the company or only know the bounds of survival signature

due to lack of data. The interval of the survival signature can be presented by $[\underline{\Phi}(l_1, \dots, l_K), \overline{\Phi}(l_1, \dots, l_K)]$; therefore, the lower bound of the survival function of the system is:

$$\underline{P}(T_s > t) = \sum_{l_1=0}^{m_1} \dots \sum_{l_K=0}^{m_K} \underline{\Phi}(l_1, \dots, l_K) P\left(\bigcap_{k=1}^K \{C_k(t) = l_k\}\right) \tag{21.10}$$

and the corresponding upper bound of the survival function is:

$$\overline{P}(T_s > t) = \sum_{l_1=0}^{m_1} \dots \sum_{l_K=0}^{m_K} \overline{\Phi}(l_1, \dots, l_K) P\left(\bigcap_{k=1}^K \{C_k(t) = l_k\}\right) \tag{21.11}$$

It can be seen that the limited information about the survival signature can be used to derive bounds of the lower and upper survival function of the system.

21.5 Numerical Examples

Figure 21.4 shows the block diagram of a simplified auxiliary feed water system, which consists of fourteen components that belong to six component types, while Table 21.1 indicates the distribution types and parameters for failure process ($1 \rightarrow 2$) and repair process ($2 \rightarrow 1$) of all the components.

21.5.1 Importance and Sensitivity Analysis

Let's first perform the importance measure of a specific component which is based on structure function. The results can be seen in Fig. 21.5.

Fig. 21.4 The complex repairable system with six types of components. The numbers inside the component boxes indicate the component type. The numbers above the component boxes indicate the component indices

It is clear that component 14 always has higher relative importance index than the other 13 components, which means it is the most “critical” component in the repairable system. Then it comes to component 8. Component 13 has litter relative importance index values at the first time; however, its relative importance index values become bigger and bigger as time goes on, which just follows components 14 and 8. Component 1 and component 2 have similar relative importance values, which are sometimes crossover. The same circumstance occurs on components 4 and 6. The relative

importance of the five components (3, 5, 7, 9, 10) is always within 0.1, which means they have less importance influence degree than that of other components on the repairable system.

In the real application world, sometimes people want to know the importance degree of a set of components, i.e., the relative importance index of components of set 1 to set 6 in this repairable system. Figure 21.6 shows the results of them.

It can be seen that the relative importance index values of component sets 1 and 2 are bigger than that of other component sets; therefore, components of type 1 and 2 are more important than components of other types in this repairable system. On the contrary, component set 4 is the least important within the system because it has the smallest values of relative importance index. The values of component set 1 are higher than 2 at the beginning time; however, their values are the same as the survival time goes on. Component set 5 has lower relative importance values than component sets 3, but the values go up and rank the third within the six component sets in the last. Component sets 3 and 6 have the same relative importance values trend, although the value of set 5 is bigger than that of set 6 at the beginning time.

When it comes to analyzing the importance degree of a set of components which belong to different types, the efficient structure function method can be used. Suppose it is a necessary to perform sensitivity analysis on six component

Table 21.1 Distribution for failure and repair process of components

Component type	Process	Distribution	Parameters
1	1 → 2	Exponential	2.3
1	2 → 1	Uniform	(0.4,0.6)
2	1 → 2	Exponential	1.2
2	2 → 1	Uniform	(0.9,1.1)
3	1 → 2	Weibull	(1.7,3.6)
3	2 → 1	Uniform	(0.6,0.8)
4	1 → 2	Lognormal	(1.5,2.6)
4	2 → 1	Uniform	(1.0,1.2)
5	1 → 2	Weibull	(3.2,2.5)
5	2 → 1	Uniform	(1.2,1.4)
6	1 → 2	Gamma	(3.1,1.5)
6	2 → 1	Uniform	(1.1,1.3)

Fig. 21.5 Relative importance index of the specific component in the system

Fig. 21.6 Relative importance index of the component sets with same type in system

Fig. 21.7 Relative importance index of the component sets with different types in system

sets, that is, set 1 with three components (5, 7, 9), set 2 with components (1, 6, 10), set 3 with components (3, 4, 13), set 4 with components (2, 8, 13), set 5 with components (12, 14), and set 6 with four components (1, 3, 7, 9). Figure 21.7 indicates the importance degree of these six component sets which belong to different component types.

It can be gotten from the above figure that the relative importance index value of different sets at each time. For example, at time $t = 8$, component set 5 has the biggest influence on this repairable system. Then it comes to component set 4 and 3. The component sets 6 and 2 ranked the fourth and fifth, respectively, while component set 1 has the least relative importance index value.

If using the quantitative importance index to quantify the importance degree during the survival time, the QI of a specific component and different types component set can be seen in Figs. 21.8 and 21.9, respectively.

Fig. 21.8 Quantitative importance index of the specific component in the system

Fig. 21.9 Quantitative importance index of the component sets with different types in the system

The first figure shows that component 14 is the most “critical” one to the whole system, while the second figure indicates set 5 with components (12, 14) has the biggest influence degree on the repairable system.

21.5.2 Imprecision Within the System

Due to lack to exact data or the confidential contract of the company, the precise configuration of the system or the survival signature cannot be gotten. Figure 21.10 shows a coherent system with an imprecise part, that is, the configuration of the fifteen components which belong to five component types cannot be known exactly. To be specific, the unknown part of the system is composed of two components of type 5 and one component of type 3 and 6, respectively. Therefore, the survival signature of this coherent system is imprecise with bounds. What is more, there exists imprecision within the component failure times, just as Table 21.2 indicates.

The upper and lower survival function bounds of the coherent imprecise system can be calculated through the Monte Carlo simulation method, which is performed by using 100,000 samples. The reliability intervals of the imprecise system can be seen in Fig. 21.11. This example indicates that the simulation method is general to deal with imprecise systems, despite the imprecision within the survival signature or component failure parameters.

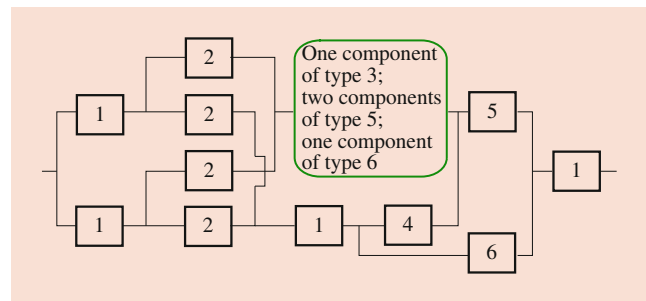

Fig. 21.10 Imprecise coherent system with fifteen components which belong to five types

Table 21.2 Distribution for failure and repair process of components

Component type	Distribution type	Imprecise parameters
1	Exponential	[2.1, 2.5]
2	Exponential	[0.9, 1.4]
3	Weibull	[(1.6, 1.8], [3.3, 3.9])
4	Lognormal	[(1.3, 1.8], [2.3, 2.9])
5	Weibull	[(3.1, 3.3], [2.3, 2.7])
6	Gamma	[(2.9, 3.3], [1.3, 1.8])

21.6 Conclusions

This paper mainly focuses on complex repairable systems. The efficient simulation methods which are based on structure function and survival signature have been proposed, respectively. The survival signature is a summary of structure function, which opens a new pathway for reliability analysis on complex repairable systems.

In order to find out which component or component set is “critical” to the whole repairable system, the importance and sensitivity analysis is needed. Therefore, engineers can allocate the limited resources to the most important component or component set. To be specific, relative importance index of a specific component and a set of components which based on structure function and survival signature are presented in this paper. All of relative importance index are time-dependent, so it is easy to identify which component has the biggest influence degree on the repairable system at each time. In order to quantify importance degree of them during the survival time, the quantitative importance index is introduced.

Sometimes the full configuration of the system is unknown if there has confidential contract or only know the bounds of survival signature due to lack of data. What is more, there exist imprecision within the component failure parameters. All of these will lead to survival function intervals of the system.

The feasibility and effectiveness of the proposed measures which based on simulation method are demonstrated by some numerical examples; the results show that the approaches are useful for analyzing component importance of complex repairable systems and the system with imprecision.

Abstract

Hardware and software together are now part and parcel of almost all the modern devices. Hence, the study of both hardware reliability and software reliability has become very important in order to ensure availability of the devices. There are several distinct differences between hardware and software, and hence, even though the definition of reliability in both the cases remains the same, finding out reliability of a hardware may call for a different methodology than that for a software. Since a software cannot be seen, nor can it be touched, finding out reliability of a software becomes difficult as such. In this chapter we discuss in brief the concepts and methodologies adopted to find out reliabilities of software and hardware. We also discuss some basic differences between hardware and software. A few important methods used for estimating hardware and software reliability have been discussed in brief. A thorough bibliography has been provided for the readers to look into the details of the methodologies wherever required.

Hardware and software reliability · Hazard rate · System reliability · Censoring · Accelerated life testing · Repairable system · Maintainability · Software validation · Software testing · Optimum time for testing

22.1 Hardware Reliability

This chapter discusses about various reliability concepts. It starts with a general introduction to reliability data and usefulness of reliability analysis and modeling. Further, various types of reliability modeling including system reliability, censoring, accelerated life testing, repairable system, etc. are discussed. This chapter also presents a list of references.

22.1.1 Introduction

The reliability engineering field was developed mainly during World War II. Problems related to maintenance and availability of equipment forced the Department of Defense to develop the area of reliability engineering. Initially, Department of Defense, through sponsored research, developed a significant part of reliability theory. Federal Aviation Administration and Department of Defense recognized the urgent need to develop Reliability requirements with the introduction of solid-state electronics and more complex equipments. Reliability is no longer a desirable, but vague, adjective; it is now a well-defined and often specifically required statistic. It has also gained momentum among practicing engineers and researchers. Reliability concepts in all phases of the product life cycle from design to manufacture have resulted in developing cost-effective systems that result in better performance. In the medical field, while studying about the life of patients, survival analysis is widely used.

Earlier, the product designers were primarily responsible for creating a design that would meet the “performance” requirements. For example, a pump should do the needed pumping at good efficiency. Now there is a paradigm shift in this thought process. Designers are strongly influenced by the fact that the “performance” requirements need to be sustainable for a specified period of time.

A general definition of reliability can be the probability that a product will perform the specified functions without failure, under required environmental and operational conditions, for a defined period of time. This definition focuses on four important points: probability of survival, performance requirements of the product, customer usage conditions, and expected life or time to failure [33].

Reliability Function

Let the random variable X be the lifetime or the time to failure of a component. The probability that the component survives until sometime t is called the reliability $R(t)$ of the component:

$$R(t) = P(X > t) = 1 - F(t) \tag{22.1}$$

where F is the distribution function of the component lifetime, X . Thus:

$$R(t) = P(X > t) = \int_t^\infty f(x)dx \tag{22.2}$$

$f(x)$ is the density function.

If the random variable X follows exponential distribution with failure rate λ , then the reliability function $R(t)$ can be estimated as:

$$R(t) = \int_t^\infty \lambda e^{-\lambda x} dx \tag{22.3}$$

Hence, in this case, $R(t) = e^{-\lambda t}$. Thus, the reliability function can be estimated for the failure data of system, sub-system, or component after identifying the underlying distribution.

Expected Life

The expected life or the expected time during which a component will perform successfully, is defined as:

$$E(t) = \int_0^\infty xf(x)dx \tag{22.4}$$

When the system being tested is renewed through maintenance and repairs, $E(t)$ is also known as the mean time between failures (MTBF) otherwise mean time to failure (MTTF).

The Failure Rate and Hazard Rate Function

The probability of failure of a system in a given time interval $[t_1, t_2]$ can be expressed in terms of the reliability function as:

$$\int_{t_1}^{t_2} f(t)dt = \int_{t_1}^\infty f(t)dt - \int_{t_2}^\infty f(t)dt = R(t_1) - R(t_2) \tag{22.5}$$

The rate at which the failure occurs in a certain interval of time $[t_1, t_2]$ is called the failure rate during that interval. It is defined as the conditional probability that a failure occurs in the interval, given that a failure has not occurred prior to t_1 , the beginning of the interval. Thus, the failure rate is:

$$\frac{R(t_1) - R(t_2)}{(t_1 - t_2)R(t_1)} \tag{22.6}$$

If the interval is refined as $[t, t + \Delta t]$, then the above equation becomes:

$$\frac{R(t) - R(t, t + \Delta t)}{\Delta t R(t)} \tag{22.7}$$

The hazard function is defined as the limit of the failure rate as the interval approaches zero. Thus, the hazard function is the instantaneous failure rate. The hazard function $h(t)$ is defined as:

$$h(t) = \lim_{\Delta t \rightarrow 0} \frac{R(t) - R(t, t + \Delta t)}{\Delta t R(t)} = \frac{1}{R(t)} \left[-\frac{d}{dt} R(t) \right] = \frac{f(t)}{R(t)} \tag{22.8}$$

The Concept of the Bathtub Curve

The hazard function $h(t)$ will change over the lifetime of products. The whole pattern of failures could be depicted

Fig. 22.1 Bathtub curve

by a bathtub curve as shown in Fig. 22.1. This curve can be divided into three different parts, viz., infant mortality period, useful life period, and wear-out period (refer Nelson [48]).

Infant Mortality Period

Infant mortality period is characterized by rapidly decreasing failure rate starting with high failure rate, the failures show up in the form of poor welds or seals, poor solder joints, poor connections, contamination on surfaces, chemical impurities in metals, voids/cracks in protective coatings, incorrect positioning of parts, etc. Early failures can be prevented through improved process control during manufacturing. The practice of shaking-off and burning-in on new products and equipment is designed to discover the weak items and get rid of them before further usage or dispatch to customers.

Useful Life Period

Useful life period is characterized by chance failure, which means, any failure whose cause and/or mechanism makes its time of occurrence unpredictable but which is predictable only in a probabilistic or statistical sense. When the lifetime is governed by exponential law, the failure rate during useful life period will be a constant, denoted by, λ . The causes of failure are the limitations inherent in design, usage, and maintenance. The prevention of failures can be achieved through:

- Improvement in design
- Provision for redundancy
- Better maintenance

Wear-Out Period

This period is characterized by rapidly increasing failure rate with increasing age as a result of deterioration processes or mechanical wear. The deterioration process may include corrosion/oxidation, insulation breakdown or leakage, ionic

migration of metals in vacuum or on surfaces, and shrinkage or cracks in plastics. When the failure rate due to wear out becomes unacceptably high, replacement or repair of the item is to be undertaken.

22.1.2 Reliability Models/Distributions

Quite a few distributions are used for modelling the life data. A few of the most commonly used distributions and the corresponding reliability functions are discussed below.

Exponential Distribution

Exponential distribution is widely used in reliability modelling and prediction because of its simple properties. An exponential distribution with failure rate λ is defined as:

$$f(t) = \lambda e^{-\lambda t}, \quad t \geq 0 \text{ and } \lambda > 0 \quad (22.9)$$

The reliability function:

$$R(t) = e^{-\lambda t}, \quad t \geq 0 \quad (22.10)$$

The hazard function is:

$$h(t) = \frac{f(t)}{R(t)} = \lambda \quad (22.11)$$

Log Normal Distribution

The density function of log normal distribution is

$$f(t) = \frac{1}{\rho t \sqrt{2\pi}} \exp \left[-\frac{1}{2} \left(\frac{\ln t - \mu}{\sigma} \right)^2 \right], \quad t \geq 0 \quad (22.12)$$

The cumulative distribution function:

$$F(t) = \int_0^t \frac{1}{\rho x \sqrt{2\pi}} \exp \left[-\frac{1}{2} \left(\frac{\ln x - \mu}{\sigma} \right)^2 \right] dx \quad (22.13)$$

This can be written in terms of the standard normal deviate z as:

$$F(t) = P[X \leq t] = P \left[Z \leq \frac{\ln t - \mu}{\sigma} \right]$$

The reliability function is:

$$R(t) = P[X > t] = P \left[Z > \frac{\ln t - \mu}{\sigma} \right] \quad (22.14)$$

The hazard function is:

$$h(t) = \frac{f(t)}{R(t)} = \frac{\phi \left(\frac{\ln t - \mu}{\sigma} \right)}{t \sigma R(t)} \quad (22.15)$$

where ϕ is the standard normal probability density function and μ and σ are the mean and standard deviation of the natural logarithm of time to failure.

Weibull Distribution

The probability density function for Weibull distribution is:

$$f(t) = \frac{\beta(t-\delta)^{\beta-1}}{(\theta-\delta)^\beta} \exp\left[-\left(\frac{t-\delta}{\theta-\delta}\right)^\beta\right], t \geq \delta \geq 0 \quad (22.16)$$

where β is the shape parameter and $(\theta - \delta)$ is the scale parameter. The reliability and hazard function are, respectively:

$$R(t) = \exp\left[-\left(\frac{t-\delta}{\theta-\delta}\right)^\beta\right] \quad (22.17)$$

$$h(t) = \frac{\beta(t-\delta)^{\beta-1}}{(\theta-\delta)^\beta} \quad (22.18)$$

Gamma Distribution

The density function, reliability function, and the hazard function for gamma distribution are as follows:

$$f(t) = \frac{\lambda^\eta}{\Gamma(\eta)} t^{\eta-1} e^{-\lambda t}, t \geq 0, \eta > 0, \lambda > 0, \quad (22.19)$$

where η is the shape parameter and λ is the scale parameter.

$$R(t) = 1 - F(t) = \sum_{k=0}^{\eta-1} \frac{(\lambda t)^k \exp[-\lambda t]}{k!} \quad (22.20)$$

$$h(t) = \frac{\frac{\lambda^\eta}{\Gamma(\eta)} t^{\eta-1} e^{-\lambda t}}{\sum_{k=0}^{\eta-1} \frac{(\lambda t)^k \exp[-\lambda t]}{k!}} \quad (22.21)$$

Smallest Extreme Value Distribution

The density function, reliability function, and the hazard function for the **smallest extreme value distribution** are as follows:

$$f(t) = \frac{1}{\sigma} \Phi_{SEV} \left(\frac{t-\mu}{\sigma} \right) \quad (22.22)$$

Where $-\infty < \mu < \infty$ is the location parameter, $\sigma > 0$ is the scale parameter, and:

$$\Phi_{SEV} = \exp\left(\frac{t-\mu}{\sigma}\right) \exp\left\{-\exp\left(\frac{t-\mu}{\sigma}\right)\right\} \quad (22.23)$$

$$R(t) = 1 - \Phi_{SEV} \left(\frac{t-\mu}{\sigma} \right) \quad (22.24)$$

$$h(t) = \frac{1}{\sigma} \exp\left(\frac{t-\mu}{\sigma}\right) \quad (22.25)$$

Largest Extreme Value Distribution

The density function, reliability function, and the hazard function for the **largest extreme value distribution** are as follows:

$$f(t) = \frac{1}{\sigma} \Phi_{LEV} \left(\frac{t-\mu}{\sigma} \right) \quad (22.26)$$

where $-\infty < \mu < \infty$ is the location parameter, $\sigma > 0$ is the scale parameter, $-\infty < t < \infty$ and $\Phi_{LEV} = \exp\left(\frac{\mu-t}{\sigma}\right) \exp\left\{-\exp\left(\frac{\mu-t}{\sigma}\right)\right\}$

$$R(t) = 1 - \Phi_{LEV} \left(\frac{t-\mu}{\sigma} \right) \quad (22.27)$$

$$h(t) = \frac{\exp\left(\frac{t-\mu}{\sigma}\right)}{\sigma \left\{ \exp\left[\exp\left(\frac{t-\mu}{\sigma}\right)\right] - 1 \right\}} \quad (22.28)$$

Logistic Distribution

The density function, reliability function, and the hazard function for **logistic distribution** are as follows:

$$f(t) = \frac{1}{\sigma} \Phi_{logis} \left(\frac{t-\mu}{\sigma} \right) \quad (22.29)$$

where $-\infty < \mu < \infty$ is the location parameter and $\sigma > 0$ is the scale parameter.

$$R(t) = 1 - \Phi_{logis} \left(\frac{t-\mu}{\sigma} \right) \quad (22.30)$$

$$h(t) = \frac{1}{\sigma} \Phi_{logis} \left(\frac{t-\mu}{\sigma} \right) \quad (22.31)$$

Loglogistic Distribution

The density function, reliability function, and the hazard function for **log-logistic distribution** are as follows:

$$f(t) = \frac{1}{\sigma t} \Phi_{logis} \left(\frac{\log t - \mu}{\sigma} \right) \quad (22.32)$$

where $\sigma > 0$ is the scale parameter, $t > 0$, and:

$$\Phi_{logis} = \frac{\exp\left(-\frac{\ln t - \mu}{\sigma}\right)}{\left[1 + \exp\left(-\frac{\ln t - \mu}{\sigma}\right)\right]^2}$$

$$R(t) = 1 - \Phi_{logis} \left(\frac{\log t - \mu}{\sigma} \right) \quad (22.33)$$

$$h(t) = \frac{1}{\sigma t} \Phi_{logis} \left(\frac{\log t - \mu}{\sigma} \right) \quad (22.34)$$

22.1.3 System Reliability

A system consisting of two or more parts or components is designed to perform one or more of functions. In different systems, these components can have different configurations. The reliability-wise configuration of the components to be studied to prepare a reliability block diagram. The estimation and prediction of system reliability is based on the type of configuration of the components or subsystems. These configurations can be a pure series or parallel arrangement or a very complex configuration. The following are the most commonly used system configurations.

- Series system
- Parallel system
- k-out-of-n system
- Complex system

Series System

The series system is the one in which every component must function if the system is to function. Complex systems are sometimes subdivided into a series arrangement for analysis by properly grouping components into a unit such that the units are in series. A schematic representation of the series system is provided in Fig. 22.2.

Let t_i be the random variable of the time to failure for the i th component; then for an n component series system, the system reliability is:

$$R_S(t) = P[t_1 > t \cap t_2 > t \cap \dots \cap t_n > t] \quad (22.35)$$

If we assume independence, then:

$$R_S(t) = P(t_1 > t)P(t_2 > t) \dots P(t_n > t)$$

$$\text{or, } R_S(t) = \prod_{i=1}^n P(t_i > t) = \prod_{i=1}^n R_i(t) \quad (22.36)$$

Example 1 A simple computer consists of a processor, a bus, and a memory. The computer will work only if all three are functioning correctly (Fig. 22.3). The probability that the processor is functioning is 0.99, that the bus is functioning 0.95, and that the memory is functioning is 0.99. What is the probability that the computer will work?

Fig. 22.2 Reliability block diagram for series system

Solution: System Reliability = $0.99 \times 0.95 \times 0.99 = 0.931095$. So, even though all the components have 95% or more reliability, the overall system reliability of the system is only 93%.

Example 2 An electronic product contains 100 integrated circuits. The probability that any integrated circuit is defective is 0.001, and the integrated circuits are independent. The product operates only if all the integrated circuits are operational. What is the probability that the product is operational?

Solution: The probability that any component is functioning is 0.999. Since the product operates only if all 100 components are operational, the probability that the 100 components are functioning is system reliability = $(0.999)^{100} = 0.9047921$. The reliability is just over 90% even though each component has a reliability of 99.9%.

Parallel System

This is a system that will fail only if all the components or subsystems fail. This means any of the elements in parallel structure permit the system function. A block diagram of the parallel system is presented in Fig. 22.4.

In this case, the system will work if at least one of the n components works. Hence, the expression for system reliability is:

Fig. 22.3 Reliability block diagram for Example 1

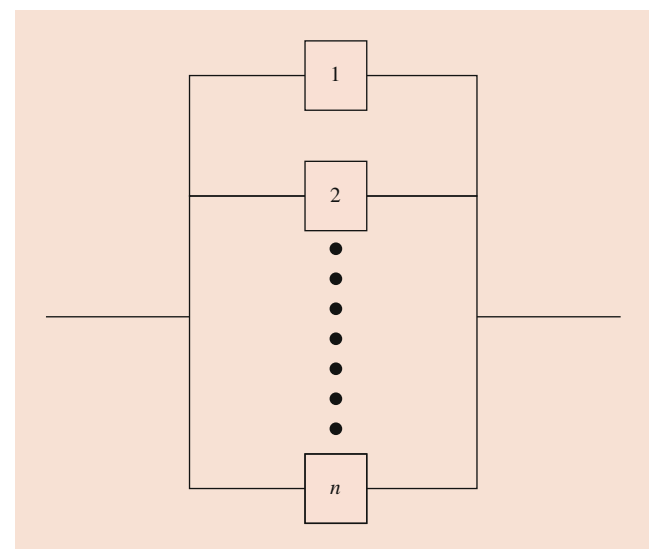

Fig. 22.4 Reliability block diagram for parallel system

$$R_S = 1 - (1 - R_1)(1 - R_2) \cdots (1 - R_n) = 1 - \prod_{i=1}^n (1 - R_i) \tag{22.37}$$

Example 3 A subassembly has a high failure rate of $\lambda = 0.002$ per hour. As an insurance backup, a second subassembly is kept in a standby mode. What is the reliability of such a system for a period of thousand hours?

Solution: Here, $R = R_1 = R_2 = e^{-0.002 \times 1000} = 0.8187$, $R_S = 1 - (1 - R)(1 - R) = 0.9671$.

K-out-of-n-structure

A k-out-of-n structure is defined as a system which works, if and only if, at least k components out of the n the components work where n is the total number of components and $1 \leq k \leq n$. The k-out-of-n system is one of the most commonly used configurations. In this configuration, all the components have the same failure distribution, and the failure of one component is independent of the failure of other components.

The reliability of a k-out-of-n system can be estimated with the help of binomial distribution. In this case, the system reliability R_S can be defined as:

$$R_S = \sum_{r=k}^n \binom{n}{r} R^r (1 - R)^{n-r} \tag{22.38}$$

where n is the number of units in the system and k is the minimum number of units required for functioning of the system and R is the reliability of each unit in the system.

Example 4 A system consists of six components of which at least four must function properly for the system to perform. Each component has a reliability of 0.85 during the functioning of the system. Estimate the probability of successful performance of the system.

Solution: This system can be considered as a k-out-of-n system, where $k = 4$ and $n = 6$,

$$R_S = \sum_{r=4}^6 0.85^r (.85)^{6-r} = 95.26\%$$

The effect of increasing the number of units required for successful performance of the system can be studied while the total number of units remains constant (in this example, six units). The Table 22.1 provides, the reliability of the k-out-of-6 configuration versus different numbers of required units.

Complex Systems

Certain design configurations may produce systems in which pure parallel or series configurations are not appropriate. Most of the smaller systems can be represented either by a

Table 22.1 Reliability for a k-out-6 system for different k values

k	Reliability
1	0.9999
2	0.9996
3	0.9941
4	0.9526
5	0.7765
6	0.3772

Fig. 22.5 Reliability block diagram for Example 5

simple series or parallel configuration. But, there are large systems, which may be a combination of series and parallel configurations. The reliability of such systems can be estimated by considering the individual series or parallel subsystems. These subsystems can be further combined to get the reliability estimate.

Example 5 Suppose a complex system consists of three units/subsystems in which subsystems 1 and 2 are connected in series. Further, subsystem 3 is connected in parallel with the first two subsystems, as shown in Fig. 22.5. Calculate the system reliability at 100 hours if $R_1 = 0.995$, $R_2 = 0.987$, and $R_3 = 0.973$. First, the reliability of the series segment consisting of Units 1 and 2 is calculated as, $R_{1,2} = R_1 \times R_2 = 0.995 \times 0.987 = 0.9820654$. The reliability of the overall system is then calculated by treating Units 1 and 2 as one unit with a reliability of 98.2065% connected in parallel with Unit 3. Therefore, the system reliability R_S is:

$$\begin{aligned} R_S &= 1 - (1 - 0.982065)(1 - 0.973) \\ &= 1 - 0.17935 \times 0.027 \\ &= 0.99515755 \\ &= 99.95\% \end{aligned}$$

Example 6 Consider an equipment/system which has seven subsystems with the following configuration (Fig. 22.6). Estimate the system reliability by considering the subsystem reliability values provided in the diagram.

Fig. 22.6 Reliability block diagram for Example 6

Fig. 22.7 Modified reliability block diagram for Example 6

For calculating the system reliability, first, subsystems which are connected as series or parallel can be considered. Further, by combining the subsystems, the system reliability can be calculated. For example:

$$R_a = R_1 R_2 = 0.72$$

$$R_b = R_3 R_4 R_5 = 0.576$$

Now, R_a and R_b are connected in parallel, and hence its reliability can be estimated as $R_{S1} = 0.881$. Now the system can be represented as presented in Fig. 22.7.

Using similar arguments, the system reliability $R_S = 0.979$. Thus, the reliability of the system is 0.979.

22.1.4 Censoring

Consider a situation of performing reliability testing of n (non-repairable) units taken randomly from a population. We are investigating the population to determine if its failure rate is acceptable.

A life testing or observing the life data for a product/component in real life can be censored at a particular time or when a particular number of failures are observed. In fact the test can continue till all the products/components fail. But this will prolong the test duration and become very expensive. Also sometimes it is not possible to test till all the units in test fail. Hence, most of the life tests are censored. There are various types of censoring schemes available. The most common among them are known as type-1 censoring, type-2 censoring, hybrid censoring, and interval censoring.

Type I Censoring

Consider a life testing scenario with n units under test. This test is continued until time period T and observe how many of these units have failed and how many of them are surviving. This type of censoring scheme is known as *Type I censoring*. During this time period T , let the number of failures be r , $0 \leq r \leq n$. Let t_1, t_2, \dots, t_r be the exact time to failure of these r units. The remaining $n-r$ units survived after the time period T . In this case T is fixed and r is random. The data on time to failure for the r failed units are recorded. This censoring scheme is also known as “right censoring,” as data larger than T is not available. Let, in this case, the mean life $\hat{\theta}$ can be estimated as follows:

Define δ_i , such that $\delta_i = 1$, if the unit has failed and $\delta_i = 0$, if the unit is censored.

$$\hat{\theta} = \frac{\sum_{i=1}^n \{\delta_i t_i + (1 - \delta_i) T\}}{r} \tag{22.39}$$

where “ n ” is the number of units in test, “ T ” is the time interval, and “ r ” is the number of failures. The confidence interval for $\hat{\theta}$ can be obtained as:

$$X_{1-\frac{\alpha}{2}, 2r}^2 \leq \frac{2r\hat{\theta}}{\theta} \leq X_{\frac{\alpha}{2}, 2r}^2 \tag{22.40}$$

Type II Censoring

One disadvantage of Type-1 censoring scheme is that, there may not be any failures at all during the time period T , under observation. Hence, one can perform a life test until r failures are observed out of n units under study. In this case, the test is continued till r units have failed. As an example, consider a life test with 50 units and the reliability engineer would like to continue the test till 25 of them fails. In this case $n = 50$ and $r = 25$. Also, note that the total time of the life test is unknown until the test is completed. This type of censoring scheme is known as Type-II censoring. In this case, the observed failure times are t_1, t_2, \dots, t_r , where r is fixed prior to the test. In this case also, $n - r$ units have survived after the termination of the test.

In this scheme, it is known in advance regarding the total number of failed units during the test. But, the termination time of the test is not known in advance.

Type-II censoring scheme is also known as failure censoring, as the test is terminated after a definite number of failures are observed.

The mean life θ can be estimated as:

$$\hat{\theta} = \frac{\sum_{i=1}^r X_i + (n - r)X_r}{r} \tag{22.41}$$

where “ n ” is the number of units in test and “ r ” is the number of failures. The confidence interval for “ θ ” is defined as:

$$X^2_{1-\frac{\alpha}{2}, 2r} \leq \frac{2r\hat{\theta}}{\theta} \leq X^2_{\frac{\alpha}{2}, 2(r+1)} \tag{22.42}$$

Hybrid Censoring

The hybrid censoring scheme is a mixture of type-I and type-II censoring schemes. The test is terminated when a pre-fixed number, $r < n$, out of n items have failed, or when a pre-fixed time T , has been reached. In other words, the life test is terminated at a random time $T^* = \min(t_r, T)$, where t_r is the failure time corresponding to the r -th failure. It is also usually assumed that the failed units are not replaced in the experiment. This hybrid censoring scheme, which was originally introduced by Epstein [23], has been used quite extensively in reliability acceptance test (Standard [59]).

Interval Censoring

Sometimes exact times of failures are not known; only an interval of time in which the failure occurred is recorded. This type of censoring scheme is known as interval censoring, and the situation is shown in Fig. 22.8.

This type of censoring scheme is used in survival analysis performed in medical field to study the efficacy of drugs or treatment of specific disease, etc.

Progressive Censoring

None of the censoring schemes discussed above allow the items to be withdrawn from the testing before the final termination time of the testing. Sometimes units are lost or removed from experimentation before failure. The loss may occur unintentionally, or it may have been designed so in the study. Unintentional loss may be due to accidental breakage of an experimental unit or the individual under study drops out from the study. Sometimes removal is pre-planned or intentional. For example, to free up testing facilities for other experimentation or to save time and cost, the removal of experimental unit may be pre-planned. Intermediate removal may also be desirable when removed items can be used for some other tests. In view of this, a censoring scheme is developed, known as progressive censoring, where tested

items could be withdrawn at different time points before the end of the experiment [18]. In progressive censoring scheme, items under test could be withdrawn at different time points before the end of the experiment. This type of censoring scheme is widely used in reliability and survival analysis.

To incorporate these situations, censoring is done in several stages. Two important progressive censoring schemes are type-I and type-II progressive censoring. In progressive type-I censoring schemes, m censoring times t_1, t_2, \dots, t_m are prefixed, and n units are put on life test simultaneously [8]. At time point t_i remove R_i units, for $i = 1, \dots, m$ of the surviving units randomly from the test. The experiments terminate at t_m with R_m units still surviving. In progressive type-II censoring scheme, n units are put on life test. At the first failure, R_1 units are randomly removed from the remaining surviving units. At the second failure, R_2 units are randomly removed from the remaining $(n - 2 - R_1)$ units. The test continues until the m -th failure, when all remaining R_m units are removed. More examples are provided in [4-7, 18, 53, 62].

The likelihood function for progressive type – 1 interval censoring can be written as (Aggarwala [2]):

$$\begin{aligned} L(\theta) &= [F(t_1)]^{d_1} \times [1 - F(t_1)]^{R_1} \times [F(t_2) - F(t_1)]^{d_2} \\ &\quad [1 - F(t_2)]^{R_2} \times \dots \\ &\quad \times [F(t_m) - F(t_{m-1})]^{d_m} [1 - F(t_m)]^{R_m} \\ &= \prod_{i=1}^m [F(t_i) - F(t_{i-1})]^{d_i} [1 - F(t_i)]^{R_i} \end{aligned} \tag{22.43}$$

where $F(0) = 0$. For any assumed distribution for t , the parameters can be estimated by using this likelihood function.

As suggested in Aggarwala [2], if one parameter exponential distribution is assumed, then:

$$F(t) = 1 - e^{-\frac{t}{\theta}}, \quad t > 0, \theta > 0. \tag{22.44}$$

The corresponding likelihood function can be written as:

$$L(\theta) = \prod_{i=1}^m [e^{-\frac{t_{i-1}}{\theta}} - e^{-\frac{t_i}{\theta}}]^{d_i} \times [e^{-\frac{t_i}{\theta}}]^{R_i} \tag{22.45}$$

Fig. 22.8 Schematic diagram of interval censoring

If the life time is assumed to have lognormal distribution, as discussed in Roy et al. [55], with PDF

$$f(t) = \frac{1}{t\sigma\sqrt{\pi}} \exp\left\{-\frac{1}{2\sigma^2}(\ln t - \mu)^2\right\},$$

$$t > 0, -\infty < \mu < \infty, \sigma > 0 \quad (22.46)$$

The corresponding likelihood function can be written as:

$$L(\theta) = \prod_{i=1}^m \left[\Phi\left(\frac{\ln t_i - \mu}{\sigma} - \frac{\ln t_{i-1} - \mu}{\sigma}\right) \right]^{d_i}$$

$$\left[1 - \Phi\left(\frac{\ln t_i - \mu}{\sigma}\right) \right]^{R_i} \quad (22.47)$$

$$L(\theta) = \{P[(T \leq C) \cap (t_{i-1} < T \leq t_i)]\}^{d_i} \times \{P[(C \leq T) \cap (t_{i-1} < C \leq t_i)]\}^{r_i}$$

$$= \left\{ \int_{t_{i-1}}^{t_i} f_T(t)[1 - F_C(t)]dt \right\}^{d_i} \times \left\{ \int_{t_{i-1}}^{t_i} f_C(t)[1 - F_T(t)]dt \right\}^{r_i} \quad (22.48)$$

The MLE can be obtained for the parameters of any assumed distribution based on $L(\theta)$.

22.1.5 Accelerated Life Testing

It is important for a manufacturer to study the reliability of components and products, even if it has a very large life span. In such situations, under normal operating conditions, it may take a long time for the components and products to fail and hence calculating reliability based on time to failure data is extremely difficult. Under these circumstances, concept of accelerated life testing is widely used in industry to study the reliability of products. In accelerated life testing, the components and products are subjected to a stress level higher than the usual operating stress so that the failure occurs more quickly. There can be various categories of stress accelerating variables like mechanical, electrical, and environmental (Nelson [48, 49]).

Accelerated Life Testing Models

Under the accelerated life testing scheme, the components and products are subjected to different stress levels, say, s_1, s_2, \dots, s_n . The time to failure of the component or product at each stress levels are then studied. This time to failure data is used to obtain a suitable time to failure probability distribution. Further, the parameters of the selected distribution are estimated. The following can be the basic functional

where $\Phi\left(\frac{\ln t_i - \mu}{\sigma}\right)$ is the CDF for lognormal distribution.

By maximization of $L(\theta)$, one can obtain the MLE of the respective parameters. Similarly, for any distribution of t , $L(\theta)$ can be defined and MLE of the parameters can be obtained.

Random Censoring in the Intervals

In the censoring schemes discussed so far, it was assumed that the censoring occurs at the end of the inspection intervals. If C is a random censoring time, an observation is censored in the interval $(t_{i-1}, t_i]$ if $t_{i-1} < C \leq t_i$, and $C \leq T$ (Meeker and Escobar [40]). Similarly, an observation is a failure in that interval if $t_{i-1} < T \leq t_i$ and $T \leq C$. Then the likelihood function can be written as:

relationship between the normal operating conditions and stress conditions applied to the component or product:

The time to failure, $t_0 = A_F t_s$, where t_0 is the time to failure of the product under usual operating and environmental conditions and t_s is the time to failure under stress conditions and A_F , is defined as the acceleration factor. The cumulative distribution function under normal operating condition is:

$$F_0(t) = F_S\left(\frac{t}{A_F}\right) \quad (22.49)$$

The probability density function is:

$$f_0(t) = \left(\frac{1}{A_F}\right) f_S\left(\frac{t}{A_F}\right) \quad (22.50)$$

The hazard function is:

$$h_0(t) = \left(\frac{1}{A_F}\right) h_S\left(\frac{t}{A_F}\right) \quad (22.51)$$

The most commonly used parametric models are exponential and weibull models.

Exponential Model

In this case, we assume that the time to failure under stress conditions is exponentially distributed with constant failure rate λ_S . Then the cumulative distribution function (CDF) at stress S is:

$$F_S(t) = 1 - e^{-\lambda_S t} \quad (22.52)$$

The CDF under normal condition is:

$$F_0(t) = F_S\left(\frac{t}{A_F}\right) = 1 - e^{-\frac{\lambda_S t}{A_F}} \quad (22.53)$$

The failure rates are related as:

$$\lambda_0 = \frac{\lambda_S}{A_F} \quad (22.54)$$

Weibull Model

The cumulative distribution function (CDF) at stress S for a Weibull model is:

$$F_S(t) = 1 - e^{-\left(\frac{t}{\theta_S}\right)^{\gamma_S}}, \quad t \geq 0, \quad \gamma_S \geq 1, \quad \theta_S > 0 \quad (22.55)$$

where γ_S is the shape parameter of the Weibull distribution under stress condition and θ_S is the scale parameter under stress condition (Pham [52]). The CDF under normal operating condition is:

$$F_0(t) = F_S\left(\frac{t}{A_F}\right) = 1 - e^{-\left(\frac{t}{A_F \theta_S}\right)^{\gamma_S}} \quad (22.56)$$

The MTTF under normal operating condition is:

$$MTTF_0 = \theta_0^{1/\gamma} \Gamma\left(1 + \frac{1}{\gamma}\right) \quad (22.57)$$

and the failure rate under normal operating conditions is:

$$h_0(t) = \frac{\gamma}{A_F \theta_S} \left(\frac{t}{A_F \theta_S}\right)^{\gamma-1} = \frac{h_S(t)}{A_F^\gamma} \quad (22.58)$$

22.1.6 Repairable System Reliability

Consider a repairable system that is put into operation at time $t = 0$. When the first failure happens due to failure of any subsystem or component, it will be brought back to a functioning state after suitable repair or replacement of the component or subsystem. It is assumed that the repair time is negligible in this case. Further, when the second failure occurs, again the system will be repaired and brought back to service. This process continues for all the failures which have occurred in the system. Thus, we get the data on a sequence of time to failure. Let t_1 be the time to first failure. When this failure happens, the system will be restored to a functioning state. The repair time is assumed to be negligible. The second failure will occur at time t_2 and so on. Thus, we get a sequence of failure times t_1, t_2, \dots . Let us define T_i as the time between $(i - 1)$ -th and i -th failure, for $i = 1, 2, \dots$, where t_0 is

considered as 0. The variables T_1, T_2, T_3, \dots , are known as inter-arrival times (time between failures).

This sequence of inter-arrival times T_1, T_2, \dots , will generally not be independently and identically distributed (i.i.d) unless the system is brought back to a state of as good as new condition. Also, for i.i.d assumption, it is necessary that the operational and environmental conditions remain constant throughout the whole period of operation.

Consider a multicomponent repairable system in operation. Depending on how many of its components are in operation, it will have a number of possible states. The state of the system at time t is denoted by a variable $X(t)$. This stochastic process $\{X(t), t \geq 0\}$, is defined as a Markov process and is characterized by its lack of memory property. This means that, if a Markov process is in a state j at time t , we will get no further information about its future states by knowing the past performance of the process up to time period t . Let $N(t)$ be the number of failures in the interval $(0, t]$. Then, the stochastic process $\{N(t), t \geq 0\}$, is called a counting process.

A stochastic process $\{N(t), t \geq 0\}$ is defined as a counting process if $N(t)$ satisfies:

- $N(t) \geq 0$
- $N(t)$ is integer valued
- If $s < t$, then $N(s) < N(t)$
- For $s < t$, $[N(t) - N(s)]$ represents the number of failures that have occurred in $(s, t]$.

Depending on the behavior of $N(t)$, one can determine whether the system is deteriorating or improving. If $N(t)$ is plotted against time t , and if the graph tends to be convex, it indicates that the system is deteriorating. The graph will show concave pattern when the system performance is improving. If $N(t)$ is approximately linear, the system is steady.

Example 7 The failures times (in continuous operating hours) is as follows: 177, 242, 293, 336, 368, 395, 410.

Example 8 The failures times (in continuous operating days) is as follows: 1.0, 4.0, 92.0, 252.0, 277.0, 277.5, 284.5, 374, 440, 444, 475, 536, 568,744, 884, 904, 1017.5, 1288, 1337, 1338, 1351, 1393, 1412.

Some Properties of $N(t)$

Independent Increments

A counting process $\{N(t), t \geq 0\}$ is said to have independent increments if for $0 < t_1 < \dots < t_k, k = 2, 3, \dots$, $[N(t_1) - N(0)], [N(t_2) - N(t_1)], \dots, [N(t_k) - N(t_{k-1})]$ are all independent random variables. In that case, the number of failures in an interval is not influenced by the number of failures in any strictly earlier intervals.

Stationary Increments

A counting process $\{N(t), t \geq 0\}$ is said to have stationary increments if for any two disjoint time points $t > s \geq 0$ and for any constant $c > 0$, the random variable $[N(t) - N(s)]$ and $[N(t + c) - N(s + c)]$ are identically distributed. This means that the distribution of the numbers of failures in a time interval depends only on the length of the interval and not on the intervals distance from the origin.

Availability/Maintainability

Availability and maintainability are two important aspects of any reliability study.

Availability

Availability is the ability of the system to perform required functions over the life of the system. It is the probability that a system is not failed or undergoing a repair action when it needs to be used. It is the proportion of the system “up-time” to the total time (up + down) over a long period.

$$\text{Availability} = \frac{\text{Up time}}{\text{Up time} + \text{down time}} \quad (22.59)$$

Maintainability

Maintainability refers to the measures taken during the development, design, and installation of a manufactured product that reduce required maintenance, tools, logistic cost, and skill levels and ensures that the product meets the requirements for its intended use.

Maintainability is the ability of a component to be retained in, or restored to, a specified condition when maintenance is performed using prescribed procedures and resources. Maintainability is a characteristic of design and is essentially a measure of the ease with which the system can be maintained, because maintainability is often expressed as mean time to repair (MTTR), or how quickly the system can be restored to mission function. Hence, maintainability can be defined as the probability that a device or a system that has failed will be restored to operational effectiveness within a given time [22]. MTTR is defined as:

$$MTTR = \frac{\sum_{i=1}^m \lambda_i T_i}{\sum_{i=1}^m \lambda_i} \quad (22.60)$$

where m is the total number of units and T_i is the corrective maintenance or repair time needed to repair unit for $i = 1, 2, \dots, m$. λ_i is the constant failure rate of unit $i = 1, 2, \dots, m$. Maintainability functions are used to predict the probability that a repair, beginning at time $t = 0$, will be accomplished in a time t . For any identified distribution for repair time, the maintainability function can be estimated.

The maintainability function, $m(t)$, for any distribution is expressed by:

$$m(t) = \int_0^t f_r(t) dt \quad (22.61)$$

where t is time and $f_r(t)$ are the probability density function of the repair time. If the repair time, t follows an exponential distribution with mean time to repair, MTTR, then:

$$\begin{aligned} m(t) &= \int_0^t \left(\frac{1}{MTTR} \right) \exp \left(-\frac{1}{MTTR} \right) dt \\ &= 1 - \exp \left(-\frac{1}{MTTR} \right) \end{aligned} \quad (22.62)$$

Similarly, if the repair time, t , follows lognormal distribution with mean of natural logarithm of t as β and standard deviation of natural logarithm of t as σ , with pdf:

$$f_r(t) = \frac{1}{t\sigma\sqrt{2\pi}} \exp \left\{ -\frac{1}{2\sigma^2} [\ln t - \beta]^2 \right\} \quad (22.63)$$

then

$$m(t) = \frac{1}{\sigma\sqrt{2\pi}} \int_0^\infty \exp \left[-\frac{1}{2} \left(\frac{\ln t - \beta}{\sigma} \right)^2 \right] dt \quad (22.64)$$

22.1.7 Verification and Validation

Verification and validation activities, in short, V&V, are applicable for hardware and software products and also for processes. However, for hardware, the V&V activities are conducted mainly to check whether the design for the product has been correctly carried out. For important medical devices where both hardware and software form part of the device, V&V are to be done both for hardware and software. V&V activities for most software, whether critical or not, are to be done. Hence, verification and testing of software is discussed separately in a later section.

Verification and Validation for Hardware

Verification and validation for hardware is applicable to products which are newly developed and brought to the market. Verification activities mainly ensures that the design for the device is right, whereas, the validation is meant for checking and ensuring that the design is made for the right device that customers will be satisfied with. FDA (<https://www.accessdata.fda.gov/scripts/cfdocs/cfCFR/CFRSearch.cfm?fr=820.3>) defines verification as confirmation by examination and provision of objective evidence that specified requirements have been fulfilled and

validation as confirmation by examination and provision of objective evidence that the particular requirements for a specified intended use can be consistently fulfilled.

Design verification may be carried out using various methods among which inspection, analysis, and tests are more popular. One may refer to FDA guidelines for other methods as well (<https://www.fda.gov/media/116573/download>, Design control guidance for medical device manufacturers).

V&V of design has a lot to do with design inputs. Customer requirements, applicable legal and regulatory requirements, relevant earlier design output which may be used in the current design, feedback from marketing and other departments about an earlier similar design and appropriate guidelines/ procedures or standards etc. form the input to the design process. Inputs for design can also come from the discussion with peer groups. The output of a design and development process could be in the form of a drawing, specification, or results of the analysis. Design output could also be a calculation itself. The ISO 9001 quality management system standard has given guidelines for sufficient control of all such important activities right from its first version released in 1987 [14]. It is also a requirement of the standard that the design or development process output must be documented and be expressed in terms that can be verified as conforming to the input requirements. The users of design output like the production or purchase processes can also sometimes provide important inputs for the design process.

The ISO 9001 standard has categorically stressed upon a planned design review process with appropriate traceability issues to be addressed in all its versions. Two of the important activities under design review is design verification, and validation for all new products that are developed.

Through design and development verification process one needs to ensure that the output of the design and development process meets the requirements given as input to the design process. It is also expected that verification should be planned process to be undertaken by competent personnel. However, there may be several ways for such verification to be conducted by an organization. Verification activities are required for all purchased products as per ISO 9001 standard. Validation of a process is also a must as per the standard, if the product coming out of the process cannot be checked immediately [14].

Validation of design can often be performed by customers or customers representatives. One needs to keep in mind that a proper design evaluation can only be done under user operating conditions. For example, for a motor vehicle, the design would be validated by building a prototype model and driving it over typical road conditions that a variety of customers are expected to use.

Any changes in the design that may be required because of several reasons, calls for a V&V to be conducted again.

22.2 Software Reliability

22.2.1 Introduction

The subject called software reliability was developed as a separate topic of research only in the early seventies of the last century. Most of the people used to consider software as a service giving device and hence were not interested in knowing how its reliability can be measured. It was only after a lot of problems faced with software which started slowly replacing the hardware in developing new devices that researchers and software specialist understood the importance of studying software reliability. But it was known that the theory, that are developed for hardware, cannot be straightaway used for software. Some of the differences between hardware and software are listed in Fig. 22.9. It is, however, noted that day by day, the importance of software will increase and the definition of software reliability can be borrowed from hardware reliability, though the treatment for finding reliability of a software needs to be different.

Under such a scenario, Jelinski and Moranda [29] came out with a very simple model to find out reliability of a software. This model is discussed thoroughly in a later section since their paper throws open the path of thinking about how software reliability can be measured. Subsequent to this development several questions were raised about the sources of uncertainty that is coming into the software, when we know for certain that software does not deteriorate with time unlike hardware items. In fact the term software reliability was not universally accepted, since it is argued that reliability implies that there is some uncertainty about the outcomes, whereas a program either contains one or more error in which case the probability of failure in certain circumstances is unity or it contains no error, in which case the probability of failures is zero.

Considering users point of view, a software output is uncertain since the user will observe software failures at some time point and he would not know when the next failure will occur. Hence, for the software user uncertainty remains.

A software basically transforms an input in the form of data to one or more outputs. Let the input space (totality of all possible inputs) be denoted by I_{total} and that of the output space be O_{total} . The operational profile of the user will however determine the probabilities of selection of different inputs during execution. It is quite likely that different users of a program have different operational profiles.

A software failure occurs when with an input or sometimes it may be called as a case or a test case (during testing of the software); the software is run and the output obtained does not match with the specified output for the case. Let I_F denotes the set of such cases for which the system failures occur. Detection of failures, however, is a nontrivial task [36]. Often

Software reliability	Hardware reliability
1. Without considering program evolution, failure rate is statistically non-increasing.	1. Failure rate has a bathtub curve. The burn-in state is similar to the software debugging state.
2. Failure never occurs if the software is not used.	2. Material deterioration can cause failures even though the system is not used.
3. Most models are analytically derived from assumptions. Emphasis is on developing the model, the interpretation of the model assumptions, and the physical meaning of the parameters.	3. Some distributions are fitted to failure data. The selection of the underlying distribution is based on the analysis of failure data and experiences. Emphasis is placed on analyzing failure data.
4. Incorrect logic, incorrect statements or incorrect input data cause failures. This is similar to design errors of a complex hardware system.	4. Material deterioration, random failures, design errors, misuse and environment are the causes of failures.
5. Increasing the testing effort and correcting detected faults can improve software reliability. Reliability tends to change continuously during testing due to the addition of problems in new code or to the removal of problems by debugging errors.	5. Better design, better material, applying redundancy and accelerated life testing can improve hardware reliability.
6. Software repairs establish a new piece of software.	6. Hardware repairs restore the original conditional.
7. Software failures are rarely preceded by warnings.	7. Hardware failures are usually preceded by warnings.
8. Software components have rarely been standardized.	8. Hardware components can be standardized.
9. Software essentially requires infinite testing.	9. Hardware can usually be tested exhaustively.

Fig. 22.9 Difference between software reliability and hardware reliability

researchers assume that each software failures is caused by only one fault. With the same input space I_{total} , if we randomly choose a case and run it through two programs or software which are made based on the same specification but two different sets of developers; in one the output may match with the expected output whereas for: the other it may result in a software failure. So, apart from the uncertainty about the next input that the software is going to face, probabilistic concepts for software reliability study is valid since the group of developers of the software also contributes to the quality of the software. In a similar way, efficacy of testing and debugging personnel could contribute to the uncertainty in software quality. Broadly software quality can be characterized by two different groups; one for operation of the software and the other for product transition. The following figure (Fig. 22.10) gives the taxonomy of software qualities. However, it is quite obvious that unless the software is reliable, or in other

words, unless it does what we wanted it to do, no matter how good it is with respect to other quality characteristics, the software reliability is the most important quality characteristics.

In satellite launching process, it takes several phases of what is known as rocket technology to lift the satellite to the required height in space, but finally the placement of satellite in the right orbit is done through software. Assume that all the rockets in different phases work as per the requirement, but the software finally fails to deliver its job, then the whole launching process becomes a failure. This also shows the importance of reliability of the software. In fact, in all such modern, sophisticated, and complicated processes software plays a major role; many a times a software replaces a hardware device also. Hence reliability of software has become an interesting topic of research since the 1970s of the last century. There are examples galore, which shows that a small

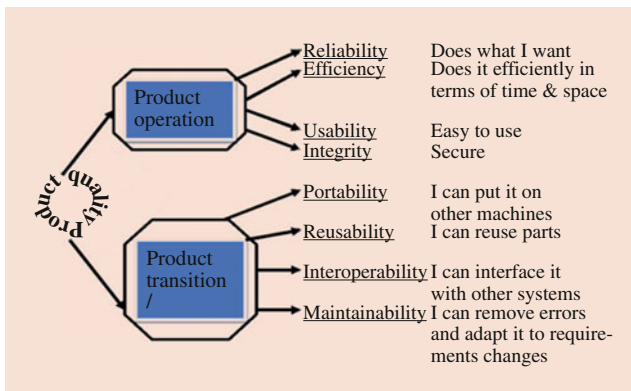

Fig. 22.10 Taxonomy of software qualities

fault in a software had caused havoc in the process. Several such examples can be found in Pham [52] and in many other books. This also shows the importance of software quality characteristics, particularly software reliability. Normally, software is validated using one of the two methods:

- Proving the correctness of the software and
- Testing the software

Proving the correctness of the software is a formal and mathematical process. Methods of proving the correctness of a software include inductive assertion, symbolic execution, and the method of functional verification [34]. In all these methods, a sequence of logically related statements is to be proved. This final statement is usually the output specification statement [26].

Software Testing

Software errors or bugs can arise from the specification, the software system design and from the coding process. Ideally a software should be built in such a way that no bugs are produced during the above three stages of software production [42]. Despite all our efforts to make a reliable software, it is a normal practice to check and test the software before it is released for usage. Formal program checking involving the design team and independent people is called a structured walk through or a code review. An essential part of the software development process is to test the software in such a way that it ensures that the software will operate satisfactorily over the range of possible input conditions. Generally software testing is considered as a planned and disciplined activity so that existence of errors or bugs in the software is minimized. Since a software is a human intensive product, any reasonably large software may carry bugs, even after intensive testing, since testing alone may not be able to guarantee that no bugs will be present in the marketed software. A software normally has several modules and a

full software run may need several module interfacing, which remains a difficult area for software testing.

Software testing group faces several limitations. On the one hand, it is not practical to test a reasonably complex program exhaustively, because the cost and effort for the same could be exorbitant. Software can effectively be considered as having several program paths and testing all the possible paths for the existence of bugs, could be ideal, but remains impractical. Hence, a test strategy needs to be developed wherein the test cases are selected in such a way that will ensure successful operation of the software under the likely range of input conditions without having a cost overrun.

To summarize, a failure is defined as a departure of the output through software operation from requirements. Obviously, a failure occurs when there is some error or fault in the software. This fault is known in the software field as a bug. The process of detecting and removing bugs is known as debugging. For our purposes we assume that when testing of software starts all obvious bugs are removed. This helps us to concentrate and use our resources for detecting and removing nontrivial bugs. We now discuss a bit more detail about software testing since testing is an important activity for evaluating reliability of software. We will use bug, fault, and error in software interchangeably referring to the one and the same thing.

Any mistake in a stage of higher order is going to be more costly than a mistake in a stage of lower order. From the customer point of view, a good software product will have all the eight quality characteristics discussed earlier. All of these requirements should be placed in the very first stage of software development and the stage of understanding customer requirements. The specification or design stage should follow only after the first stage is complete. A good programming technology desires that the specification should not only be developed for the software product but also, at the same time, the specification for testing and validating the software product. Cho [17] calls this as concurrent software design and test design. He also suggests concurrent software implementation and test implementation.

The present-day devices are mostly built with some software as part of the system. Due to the specific nature of software failures, which is not affected by fatigue and which does not fail if it is kept unused for sometime unlike hardware, replacing hardware by software is also very popular. It may be noted that each copy of a software is exactly same as the original. This also helps in avoiding the inherent variation that hardware copies have. Storage of software also become relatively easier and mostly cost effective compared to hardware. Hence, performing functions with software may lead to less complex but more robust systems in the modern-day devices.

Measurement of software reliability is important for the following reasons also.

- Software reliability measures and the information gathered through their use may be exploited to enhance the reliability of the software before releasing it in the market.
- Such measures may be used to predict future behaviors of the software.
- Such measures may be used to monitor the progress of software testing or the operational performance of software using continually updated estimates of current reliability.

The reliability of a unit for a given time is expressed as the probability that no failure occurs in the interval $[0, t]$. Failure for a software occurs when the software results in an output which deviates from the expected output given a particular input. Such failure occurs due to an error or fault in the software. Software reliability at time $t = 0$ is defined to be 1. A couple of problems related to software reliability are

- Determining optimal time for software testing.
- Choosing a suitable model for estimating reliability of software.
 - A Software Developer Dilemma

To understand software reliability better, we have to understand the very process of generating a software. Broadly, like any other product, software when considered as a product, goes through a few stages like:

- Understanding customer requirements
- Developing specification
- Implementation or making the software as per specification
- Validation and
- Delivery which includes packaging and handling also.

Essentially there are three different ways to pursue highly reliable software. They are:

- To avoid the occurrence of faults in the design and development of the program.
- To make use of fault tolerant structures.
- To remove faults during testing phase.

Since software testing is an important activity in the life cycle of a software, a challenging problem being faced by the software manufacturing companies is when to stop testing of the software? There are several authors who worked on this problem (e.g., Chakraborty et al. [15]). We will discuss more about this area in a later section. Also, since several hundreds of software reliability models (SRMs) have already been developed, a common dilemma with the software companies is which model to be used for their particular case.

22.2.2 Software Reliability Models

The very first published work on software reliability is attributed to Jelinski and Moranda [29], in short JM model. The fact that software reliability needs different treatment is quite clear from this model itself. Let us assume that the data available are in terms of time between failures, t_1, t_2, \dots, t_n (assuming that there are n observations taken on a continuous time scale and one has observed the time points $T_i, i = 1, 2, \dots, n$ when the i -th bug is detected). Note that $t_n = T_n - T_{n-1}$. Assume that each of the N faults in the software system will cause a failure after a time which follows exponential distribution with parameter λ , λ being the failure rate of the software. It is also assumed that software faults are independent of each other and are equally likely to cause a failure. It is further assumed that the failure rate λ , at any time point is proportional to the fault content of the software. The authors then assumed that a detected fault is corrected with certainty in a negligible amount of time and no new faults are introduced in the process. Under this set of assumptions, it is clear that the log likelihood function for the observed data t_1, t_2, \dots, t_n is given by

$$\ln L = \sum_{i=1}^n \ln \{\phi(N - i + 1)\} - \sum_{i=1}^n \{\phi(N - i + 1)t_i\} \quad (22.65)$$

where ϕ is the proportionality constant. JM model considers N and ϕ as unknown parameters to be estimated from data. Assuming that N and ϕ are continuous variables, the log-likelihood function is used to find out the partial derivatives with respect to N and ϕ separately. Setting the partial derivatives equal to zero, one gets:

$$\phi = \frac{n}{\sum_{i=1}^n (N - i + 1)t_i} \quad (22.66)$$

and

$$\sum_{i=1}^n \frac{1}{N - i + 1} - \frac{n}{N - c} = 0 \quad (22.67)$$

where,

$$c = \frac{\sum_{i=1}^n (i - 1)t_i}{\sum_{i=1}^n t_i}$$

Though the first published work on software reliability by Jelinski and Moranda was simple to understand, there were a few fundamental mistakes in the model which had been unnoticed for a long time. The unknown constant N in the model being the number of bugs in the software is a discrete

number. Hence taking the partial derivatives with respect to N is not actually valid. However, this model was path breaking which helped many other models to follow. One may refer to Musa et al. [45] to get details of various models developed in the initial years, followed by Chakraborty and Arthanari [13]; Pham [52]; Yang and Xie [63] and many others to know about the software reliability models that were developed later.

The software reliability problems can be broadly classified into two:

1. When one should stop testing software?
2. What is the reliability of the software at any given point in time?

The first problem is also known as optimum testing time problem, whereas the second problem is known as reliability growth problem. For each such problems, several different models are available. The optimum software testing time problem can be based on several different criteria including

1. A threshold value of the reliability of the software to be achieved; typically such software are known as critical or very critical software;
2. The optimal stopping time is based on some cost or reward considerations.

Chaktaborty and his team [15, 16] among many others give the developments in the area of software reliability models to find out optimum software release time. Some authors like Nayak [47] questioned the conventional time-between failure data. Following Nayak [47], Chakraborty and Arthanari [13] showed that the data that are collected particularly for critical and large software are discrete in nature. This shift in data type helped developing several models which assumed a discrete set up. In such a case an input when is used for a software result in either a “success” meaning a bug is detected; or a “failure” meaning the output is as expected.” These terminologies are appropriate since the objective of software testing is to find out as many bugs as possible, so that after debugging the identified bugs, the reliability of the software can be enhanced. Also, in most of the software reliability models, it is assumed that the time-between-failure distribution is exponential. Chakraborty studied this phenomenon and finally concluded that the exponentiality assumption for failure time distribution of a software is a valid assumption.

22.2.3 Software Reliability Growth Models

Time Between Failure Models

In software reliability assessment, this class is one of the oldest. It is expected that during modelling of time between the

failures, the successive time between failures will gradually increase as faults are being removed from the system, and no new faults are introduced during correction. The above statement may not be exactly true, for a given set of observed values since failure times are random and observed values may fluctuate.

Let the time between $(i - 1)$ -th and i -th failures be T_i , a random variable and independent of each other. Usually, it is assumed that T_i follows a distribution with parameters, which depends on the remaining faults after $(i - 1)$ -th failure. Since the faults are detected and debugged from the system, it is assumed that the distribution considered reflects the improvement in the quality of the software. J.M model is one of its kind, which is already explained above. Given below are some of these kinds of models (Fig. 22.11).

Schick and Wolverton (SW) Model

This model (Schick and Wolverton [56]) is based on the same JM model assumptions except that the hazard function is assumed proportional to the time elapsed since the last failure as well as to the current fault content of the program and is given by:

$$Z(t_i) = \phi(N - (i - 1))t_i \quad (22.68)$$

where the various quantities are as defined above. Note that within each failure interval, the above hazard rate is linear with time. It returns to zero when a failure is occurred and again increases linearly but at a reduced slope as the decrease in slope being proportional to ϕ . In 1978 a modification of the above model was proposed, and in test time the hazard function is assumed to be a parabolic and is given by:

$$Z(t_i) = \phi[N - (i - 1)](-at_i^2 + bt_i + c) \quad (22.69)$$

where a , b , and c are constants and the other quantities are same as defined above. The above hazard function consists of two components. The first is the hazard function of the JM model, and the superimposition of the second term indicates that as the test time accumulates within a testing interval, the likelihood of a failure occurring increases rapidly. At failure times $t_i = 0$, the hazard function is proportional to that of the JM model.

Goel and Okumoto Imperfect Debugging Model

Most of the software reliability models, including the ones that are discussed so far, assume that the fault that is detected through testing is completely removed during debugging. But, it has been observed that many a times, this assumption is not valid. One way to model such a phenomenon is to take resort to an imperfect debugging model developed by Goel and Okumoto [27], which is an extension of the JM model. Goel and Okumoto [27] considered that the number of faults X_t , in the software at time t is represented by

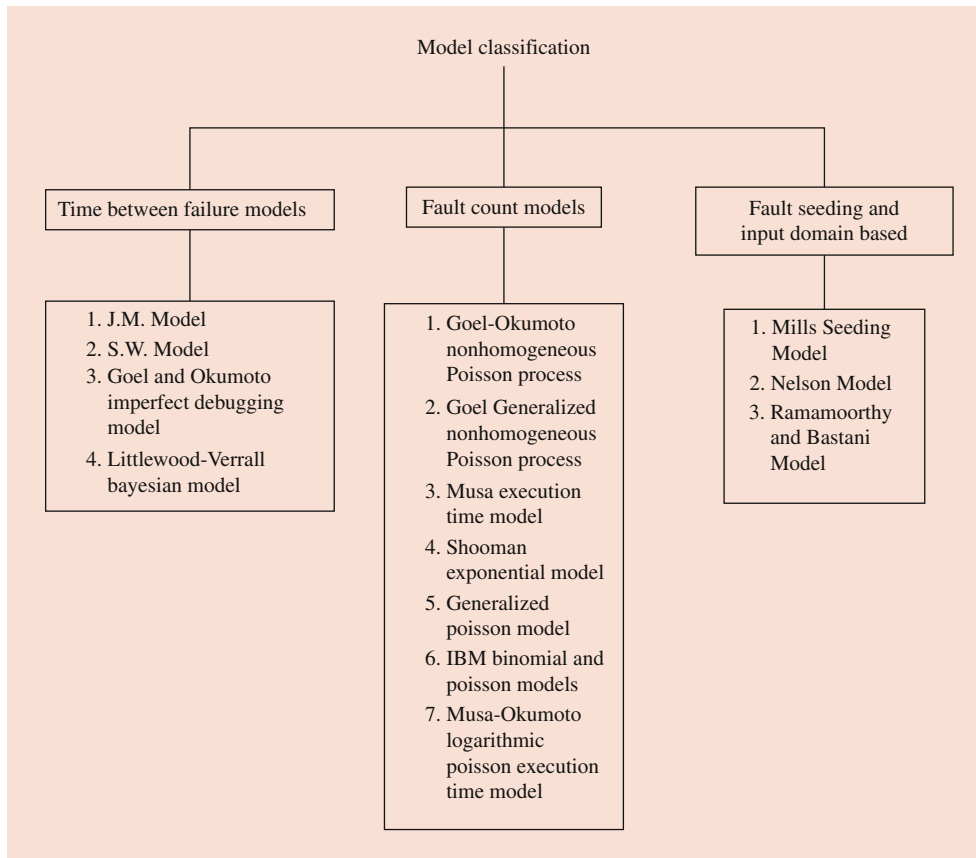

Fig. 22.11 Classification of Growth models

a Markov process, wherein the transition probabilities are based on the probability of perfect debugging. The time intervals between the transitions of X_t s are assumed to be following an exponential distribution whose failure rates are considered as a function of the number of faults that exists in the software at time t . The hazard function during the interval between the $(i - 1)$ -th and the i -th failures is given by:

$$Z(t_i) = [N - p(i - 1)]\lambda, \quad (22.70)$$

where, N is the initial fault content of the system, p is the probability of imperfect debugging, and λ is the failure rate per fault.

Littlewood-Verrall Bayesian Model

Littlewood and Verall [37] took a different approach in the development of a model. They argued that software reliability in terms of the number of errors should not be specified in a program. Specifically, in their model, the times between failures are assumed to follow an exponential distribution but the parameter of this distribution is treated as a random variable with gamma distribution, viz.:

$$f(t_i | \lambda_i) = \lambda_i e^{-\lambda_i t_i} \quad \text{and} \quad (22.71)$$

$$f(t_i | \alpha, \psi(i)) = \frac{(\psi(i))^\alpha \lambda_i^{\alpha-1} e^{-\psi(i)\lambda_i}}{\Gamma(\alpha)} \quad (22.72)$$

In the above, $\psi(i)$ describes the difficulty of the programming task and the quality of the programmer. It is claimed that in this model the failure phenomena can be explained in different environments by taking different forms for the parameter $\psi(i)$.

22.2.4 Fault Count (FC) Models

Fault count models deal with the modelling of the number of faults or failures in the testing intervals. It is expected that after the removing of the faults from the given system, the number of faults will decrease. Here the time used can be calendar time, CPU time, or others. In these models, the time intervals are taken as fixed but the number of failures vary for individual intervals. The concept behind most of these models is that the distribution considered here is Poisson distribution with different parameters for different models. Some common assumptions are like, each testing intervals should be independent, and within the interval, testing should be homogeneous. During the detection of the faults, the

number of faults should be independent in nonoverlapping intervals. Some of the models of this class are given below:

Goel-Okumoto Nonhomogeneous Poisson Process Model (Goel and Okumoto [28])

The authors here assumed that the software system fails at random time points because of the presence of faults in the software. They defined $N(t)$ to be the cumulative number of failures observed by time t . They then modeled $N(t)$ as a nonhomogeneous Poisson process (NHPP) where the failure rate is considered as a function of time. They had the opportunity to study several real-life failure data from many systems. This experience helped them to propose the following model.

$$P[N(t) = y] = \frac{m(t)^y}{y!} e^{-m(t)}, y = 0, 1, 2, \dots \quad (22.73)$$

where $m(t)$ = expected number of failures observed by time $t = a(1 - e^{-bt})$ and $\lambda(t)$ = failure rate = $m'(t) = abe^{-bt}$.

It is easy to note that a = the expected number of failures observed eventually and b = the fault detection rate per fault. Unlike the Jelinski-Moranda [29] and many other models, Goel and Okumoto allowed the number of faults to be detected as a random variable. The value of this random variable may depend on several factors, including the environmental factors.

A big advantage of the nonhomogeneous Poisson process model is that by suitably varying the mean value function, $m(t)$, many other models may be developed.

In an earlier attempt, Schneidewind [57] studied the number of bugs detected during a given time interval using a somewhat different approach. In his approach he considered the failure process to be a nonhomogeneous Poisson process which has an exponentially decaying intensity function given by:

$$d(i) = \alpha e^{-\beta i}, \alpha, \beta > 0, i = 1, 2, \dots \quad (22.74)$$

where α and β are the parameters of the model.

Goels Generalized Nonhomogeneous Poisson Process Model (Goel [26])

Further generalization of the Goel-Okumoto NHPP model was proposed by Goel [26], where he considered $m(t) = a(1 - e^{-btc})$, a is the expected number of faults to be eventually detected, and b and c are constants that reflect the quality of testing. The main formulation of the model remains the same as given in (22.73), that is:

$$P[N(t) = y] = \frac{m(t)^y}{y!} e^{-m(t)}, y = 0, 1, 2, \dots \quad (22.75)$$

The failure rate for the model proposed by Goel is given by:

$$\lambda(t) \equiv m'(t) = abe^{-bct} t^{c-1} \quad (22.76)$$

It is generally assumed that reliability of software improves with testing, since as the testing and debugging increases, it is expected that the remaining number of bugs in the software will decrease. Hence, most of the times between failures and failure count models assume software reliability growth, which in a way assumes that a software system exhibits a decreasing failure rate pattern during testing. However, in reality, it may be observed that in many testing situations, the failure rate first increases and then decreases. In order to model this increasing/decreasing failure rate process, Goels proposed generalization of the Goel-Okumoto NHPP model may be more appropriate.

Musa Execution Time Model (Musa [43])

In this model, the focus is on the number of failures in a specified execution (of the software) time interval. The assumptions for the model are similar to that of the Jelinski-Moranda model. The hazard function, $z(\tau)$, is given by:

$$z(\tau) = \phi f(N - n_c) \quad (22.77)$$

where τ is the execution time utilized in executing the program up to the present; f is the linear execution frequency (average instruction execution rate divided by the number of instructions in the program); ϕ is a proportionality constant, which is a fault exposure ratio that relates fault exposure frequency to the linear execution frequency; and n_c is the number of faults corrected during $(0, \tau)$.

Generalized Poisson Model

This is a variation of the NHPP model of Goel and Okumoto and assumes a mean value function of the following form.

$$m(t_i) = \phi(N - M_{i-1})t_i^\alpha \quad (22.78)$$

where M_{i-1} is the total number of faults removed up to the end of the $(i - 1)$ -th debugging interval, ϕ is a constant of proportionality, and α is a constant used to rescale time t_i .

IBM Binomial and Poisson Models

Brooks and Motley [10], probably for the first time, guessed that the software testing process may be considered as a discrete process. Quite obviously, the number of detected faults may then be modeled under a Binomial or a Poisson distribution. They proposed, as is normally the case, that the software is to be developed and tested incrementally. Further, they advised their models to be applicable both for the modules, as well as, for the whole software.

Musa-Okumoto Logarithmic Poisson Execution Time Model

Taking cue from the Goel-Okumoto model, Musa and Okumoto [44] developed another NHPP model where the mean value function considered was different. Let τ denote the time, then:

$$\mu(\tau) = \frac{1}{\theta} \ln(\lambda_0 \theta \tau + 1) \quad (22.79)$$

where λ_0 and θ represent the initial failure intensity and the rate of reduction in the normalized failure intensity per failure, respectively. It may be noted that Musa-Okumoto model resembled Morandas geometric de-eutrophication model and may be considered as a continuous version of Morandas model.

22.2.5 Fault Seeding and Input Domain based Models

In this section, we will discuss about a few time-independent models for assessing software reliability. The two approaches are fault seeding and input domain-based models.

In fault seeding models, in a program, a known number of faults are seeded. After testing the number of native faults along with the exposed seeded faults are counted. Applying maximum likelihood estimation and using combinatorics, the number of native faults and reliability of the software are estimated in a program. In case of input domain-based models, the basic idea is to generate a set of test cases from an input distribution. The input domains are partitioned into equivalence classes in various models in this group because the input distribution is difficult to estimate. The classes are related with the program path. The reliability measure is calculated from the number of failures observed during physical or symbolic execution of the sampled test case.

Mills Seeding Model

One of the techniques used in estimating the number of bugs present in a software quite early in the development of software reliability is called the error seeding model (Mills [41]). The procedure consists of generating several faults that are randomly seeded into the software that will be tested. The program is then tested in order to find as many faults as possible. Subsequently, among the faults detected, the number of original faults and the specially seeded faults are counted. Based on this data, a hypergeometric distribution is used to estimate the total original number of faults that were originally present in the software. This technique, however, had been used earlier in similar situations, for example, for estimating the number of fish in a pond or for estimating

wildlife population in a given area. Sometimes these models are also known as tagging models since the seeded faults are tagged for identification purpose.

A modification of this problem where the probability of finding a fault, of either kind, is considered by Lipow [35]. Then, assuming independence of tests, the probability of finding given numbers of indigenous and seeded faults can be calculated. In a further modification of this model, Basin [9] used a two-stage procedure with the use of two programmers which can be used to estimate the number of indigenous faults in the program.

Nelson Model

The Nelson model is one of those input domain-based models where the reliability of the software is determined based on the results obtained by testing the software with a sample of n inputs which are chosen randomly from the input domain set $E = (E_i : i = 1, \dots, N)$ where each E_i is the set of data values needed to make a run. The operational profile of the user is represented by a probability distribution $\{P_i : i = 1, \dots, N\}$, and the n random samples are chosen according to the probability distribution P_i . Assuming that n_e represents the number of inputs that resulted in execution failures, an unbiased estimate of the reliability of the software is given by the following formula.

$$\hat{R}_1 = \left(1 - \frac{n_e}{n}\right) \quad (22.80)$$

However, one may observe that the test cases used during the verification phase or even afterwards may not represent the expected operational profile of the users. This may be the case more often than not. In such circumstances, Brown and Lipow [11] suggested an alternative formula for the reliability of the software, R which is:

$$\hat{R}_2 = 1 - \sum_{j=1}^N \left(\frac{f_j}{n_j}\right) p(E_j) \quad (22.81)$$

where n_j denotes the number of runs sampled from input subdomain E_j and f_j is the number of failures observed out of n_j runs. The basic difference between \hat{R}_1 and \hat{R}_2 is that the former explicitly incorporates the usage distribution or the test case distribution while the latter implicitly assumes that the accomplished testing is representative of the expected usage distribution. Hence, both models assume prior knowledge of the operational profile in terms of a probability distribution.

Ramamoorthy and Bastani Model [54]

This model is also an input domain-based model where the authors considered the real-time, critical, process control systems for estimating reliability. It is expected that for such systems, the reliability should be very close to one. Hence, it

is also important that we have high confidence in the estimate for reliability of the software. Using this model one can get an estimate of the conditional probability that the software will give correct output for all possible inputs given that it is correct for a specified set of inputs. The interesting idea used in the model is that each output from the software gives some stochastic information about the behavior of the software for other inputs which are close to the test case used.

One of the important results in this model can be written as:

P (program is correct for all points in $[a, a+V]$ | it is correct for test cases having successive distances $x_j, j = 1, \dots, (n-1)$)

$$= e^{-\lambda V} \prod_{j=1}^{n-1} 2(1 + e^{-\lambda x_j})^{-1} \quad (22.82)$$

where λ is a parameter which is dependent on the complexity of the source code.

This model allows any test case selection strategy, which is unusual. As is practiced in many organizations, test cases are chosen that run through error-prone constructs. This also helps in reducing testing effort. However, the model concerning the parameter λ needs to be validated experimentally.

22.3 Optimum Release Time Models

A very important part of the software testing problem is when to stop testing the software? (Dalal and Mallows [19]). The main aim of testing a software is to find out as many bugs as possible before the software is released. Also, once a bug is identified, it is debugged and hence the reliability of the software is improved. Several authors have worked over this optimization problem and looked into it from various angles. One of the important constraints that is used to solve the optimization problem is the cost or time constraint. Normally this type of constraints is relevant for commercial software. But there are other types of software as well, like the software used for space research. These are called critical or mission critical software. For such software, achieving a high reliability is more important than the cost of testing it (Dewanji et al. [21]). Also, over the decades the type of test data available got changed, which led to the development of discrete framework in the software reliability arena (Chakraborty and Arthanari [13]). Long before that Nayak [47] proposed to log software data in a different way. A few authors worked on a discrete framework for optimum software release time.

The data that are normally available for mission critical and large software are of the discrete data type. In such cases, for each test data the outcome is known in the form of either a success, meaning a bug is found or a failure, meaning no bug is found with the present test case. Also, there is a major

violation of the assumption that most software reliability models have is as soon as a bug is found it is debugged. Such an assumption remained valid for the initial stages of software reliability developments. However, as the software becomes larger and larger, the developer and testers became two different groups and the assumption started getting violated. This necessitates development of different models for optimum software release time (Chakraborty et al. [15]).

However, majority of the models developed for optimum time for software release still adopt the assumption of immediate debugging in order to make the models relatively less complex. Dalal and Mallows [19] derived an optimum stopping rule for testing of a software prior to release, based on a trade-off between the cost of testing for a longer period and expected loss due to any bugs that may remain in the software after release. Singpurwalla [58] addressed the same problem by maximizing expected utility functions of two different types. The information available during the testing phase is, like many other models, the time between failures. Dalal and Mallows [20] later developed methods for optimum stopping with exact confidence limits on the remaining number of bugs in a software. Nayak [47] proposed for the first time that software testing data should capture test case-based information in order to have more insight into the reliability aspect of the software. Chakraborty [12] proposed a discrete framework for software testing data where the information obtained from software testing is for every test case. The outcome is either a success which indicates detection of a bug or a failure indicating that no bugs are found using the test case. This kind of information are largely logged for large and critical softwares (Dewanji et al. [21]).

Usage of Bayesian concepts in software reliability field has not been regular. Chakraborty and Arthanari [13], Vasanthi and Arulmozhi [61], and Chakraborty et al. [15, 16] are some references where the Bayesian concepts were used to solve the problems. In a discrete framework, Chakraborty and Arthanari [13] show how to find out optimal time of testing. They, however, used the standard assumption that as soon as a bug is identified, it is fixed. This assumption does not hold good for many large and critical software (Dewanji et al. [21]). After dropping this critical assumption, Chakraborty et al. [15] developed the Bayesian methodology to find out the optimum time for software release.

A new twist in the development of the software reliability models is given by looking at the software as a bunch of several paths and sub-paths. Each test case is expected to go through a particular path in the software. The test case can identify a bug if and only if the bug lies on the path that the test case is supposed to traverse. This concept, though not new, gives rise to a newly developing theory of size-biased concept in software reliability field (Chakraborty et al. [16]). The idea seems to be very interesting and opens up new areas of research in the software reliability arena.

22.4 Software Testing and Validation

Testing is a group of techniques to determine the correctness of the application under the predefined script, with an intention to detect a major portion of its bugs, so that they are discovered and debugged, and, at the same time, verified that the software product under consideration is fit for use. However, it does not demonstrate that a product functions systematically under all conditions but it only ensures that it is not working in some specific formats (Kaner [31]). In software testing and management, verification and validation (V & V) are the process of checking that a software system meets specifications and that it fulfills its intended purpose. It may also be referred to as software quality control. In general, the quality assurance team conducts the verification process. This is followed by testing of the software and its validation that are both executed by the testing team.

22.4.1 Introduction to Software Testing

Software testing is a process, or a series of processes, designed in such a manner so as to ensure that computer code does what it was designed to do and that it does not do anything unintended. Any software released in the market should be predictable and consistent, offering no surprises to users.

In the present-day circumstances, due to the advancement in operating systems and other very useful software, which provide some intrinsic, well tested routines that can be made use of during software development itself. This helps programmers/testers to develop better software rather easily without developing the routines from scratch. Graphical user interfaces (GUIs) can be built from a development language library, and since they are pre-programmed objects that have been debugged and tested previously, the need for testing them as a part of a custom application is much reduced (Jorgensen [30]).

22.4.2 Some Basic Definitions

The International Software Testing Qualification Board (ISTQB) has produced an extensive glossary of testing terms and some of them need to be considered before moving on to understanding what is actually software testing (Martin [39]).

Error

The mistakes committed while coding of a program are termed as errors or more appropriately as bugs. Errors tend to propagate and can also be magnified during design or amplified even more during coding.

Fault

A fault can be considered as a manifestation of an error in the program. A fault in the program may appear due to design deficiency, incorrect coding, etc. Quite often faults could be elusive. For example, a fault may exist due to an error of omission on the part of the programmer or even designer.

Failure

A failure occurs when a faulty code is executed. Thus, failures occur in the executable source code or loaded object code. In the process, the expected outcome from the input cannot be obtained.

Incident

Failures in a program may occur without the user or testers apparent knowledge. However, a symptom may be apparent that is connected with a failure which usually provides alarms to the user indicating occurrence of a failure. These symptoms are called incidents.

Test

When a software is executed with some test cases, we say that the software is being tested. Testing of a software, using a test case, may lead to either a failure or a success, where success means demonstration of correct execution. Thus, testing is normally connected with failures and incidents which in turn are connected with errors and faults.

Test Case

A test case has a set of inputs for which the outputs are known. Usually a test case has some identification which helps all concerned to understand why the test case was run and is associated with the program behavior.

Figure 22.12 represents a life cycle model for testing a software. It is to be noted that although the development phases of a software, errors may creep in resulting in faults that may propagate through the remainder of the development process. Also, more errors may be added during the fault resolution step as well.

It is important to note that developing appropriate test cases is a key for effective testing. In fact, the whole of the testing process consists of making a proper test plan, developing effective test cases, which is followed by actually running the test cases as per the plan and finally evaluating the test results.

22.4.3 What Is Software Testing?

Testing of a software is considered to be a process through which the software and its components are evaluated with the

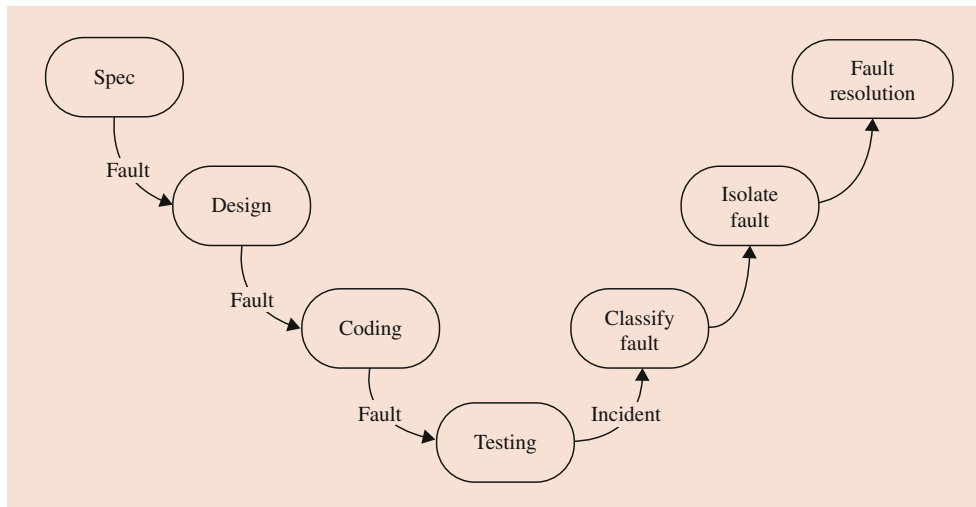

Fig. 22.12 A testing life cycle

aim to find out whether it satisfies the specified and desired requirements or not. In other words, software testing refers to the process of execution of the software based on a plan, in order to identify any gaps, errors or missing requirements in contrary to the actual requirements (Lyu et al. [38]).

According to ANSI/ IEE 1059 Standard, Software Testing can be defined as “A process of analyzing a software item to detect the differences between existing and required conditions (i.e., defects/ errors/ bugs) and to evaluate the features of the software item.

22.4.4 The Psychology of Testing

Commonsense says that if all possible permutation of a software could be tested, it would have been ideal. However, such a possibility is simply remote in most cases. Even if we take a relatively simple program, then also the possible input and output combinations may run into thousands and developing test cases for such a huge number is just impractical. Many software are as such quite complex in nature and trying to test it completely could be economically infeasible.

Also, a software tester must have the proper attitude or vision in achieving the goal towards testing a given software application. One of the primary causes of poor program testing may be the fact that most programmers start with an incorrect definition of the term software testing. They might say that “Software testing is a process of demonstrating that errors are not present.”

But in fact, while software is being tested, the target is to add some value to it. Adding value through testing means enhancing the quality or reliability of the program and hence of the software with finding and debugging of errors. Therefore, the correct approach is to start with the

assumption that the software contains bugs and then test the program to detect as many errors as possible. Thus, a more appropriate definition may be “Software testing is the process of executing a program with the intention of finding errors.”

Human beings tend to be highly goal-oriented, and establishing the proper goal has an important psychological effect. If our goal is to demonstrate that a software is completely non-erroneous, then we will subconsciously be steered towards achieving this goal. On the other hand, if the goal was to demonstrate that a software does possess some errors, then the test data will have a higher probability of finding the same. The latter approach is likely to add more value to the software program as compared to the former (Myers et al. [46]).

22.4.5 Who Does Testing?

Depending on the process and associated stakeholders of the project(s), a person or a group of persons with sufficient experience is chosen to execute the testing process. Testing, as has been said earlier is a planned and a must activity for any software developer. Large IT companies generally engage a set of people who are given the responsibility to test the software against the given requirements. In order to ensure satisfactory output from the software, most organizations start testing at the module and or function level itself, which is known as unit testing. Also, the end user normally checks the software for satisfactory outcomes. Thus, in most organizations the professionals who are associated with the testing process may be designated as software tester, software developer, software quality assurance engineer, quality assurance analyst, project manager/lead, and customer/end user, among others.

22.4.6 The Optimal Time for Testing

Since identifying faults in a software is a nontrivial problem and also it is known that the faults may be created at every stage of the software development process, it is ideal that testing starts right from the first stage called requirement gathering phase and continued till the deployment of the software. This helps in reducing the overall cost associated with the software development life cycle (SDLC). However, the testing strategy may depend upon the development model that is being followed. In many organizations, formal testing is carried out in the testing phase, whereas for others, testing may be conducted at the end of every phase and the whole software is tested at the end (Ammann and Offutt [3]).

In most situations, testing is carried out in different forms at every developmental phase of the software, such as:

- During the requirement gathering phase, the analysis and verification of requirements are considered as testing.
- Reviewing the design in the design phase with the target of improving the design is also considered as testing.
- Testing performed by a developer on completion of the code is also categorized as testing.

It is difficult to determine when one should stop testing, as testing is usually a never-ending process and no one can claim that a software is 100% tested. However, some of these aspects can be considered for stopping the testing process.

- When testing deadlines are met.
- When test case execution is completed.
- When functional and code coverage is completed to a certain extent.
- When the bug rate falls below a certain level with no high-priority bugs being identified further.
- When the management team decides that the given testing can be brought to an end.

Several models for deciding the optimal time for testing a software are discussed in section 22.3.

22.4.7 Black-Box and White-Box Testing

In order to make a software reliable, its testing strategies can broadly be classified as either a black-box testing or a white box testing. In black-box testing strategy, the program is viewed as a black box, whereas for white-box testing, the internal logic and structure of the program becomes the main focus. Black box testing is data-driven or one can say input-output driven whereas white box testing depends on the internal logic (logic-driven) based on which the software has been developed.

As the name suggests, in black box testing, the test data are generated only from the specifications, without trying to know its internal structure. The aim is to find circumstances in which the program behavior does not match with the specifications.

In white box testing on the other hand, the tester examines the internal structure of the software. The test data in this case are generated based on the program logic, even sometimes neglecting the specifications (refer Everett and McLeod Jr. [24]).

22.4.8 To Conclude Testing

Certain principles of testing must be kept in mind before moving on to software validation.

- Testing is the process of executing a program with the aim of finding as many bugs as possible.
- A good test case is considered to be the one that has a high chance of detecting as yet undetected bug(s).
- Hence, a successful test case is the one that detects an as yet undetected bug.

22.4.9 Software Verification and Validation

The Quality System Regulation is harmonized with ISO 8402: 1994, which treats “verification and validation” as separate and distinct terms. However, quite often, many software engineering journals use these two terms interchangeably, or in some cases refer to software “verification, validation and testing (VV&T)” as if it is a single concept with no distinction among the three terms. Boehm succinctly expressed the difference between the two terms as in (refer Pham [51]).

- Verification—Are we building the product right?
- Validation—Are we building the right product?

By verifying the software at each phase of the software development process, we try to provide objective evidence that the design outputs of a particular phase meet all the requirements specified for that phase. It looks for consistency, completeness, and correctness of the software, and its supporting documentation, as it is being developed, and provides support for a subsequent conclusion that the given software under consideration is validated. Software testing is used as one of the several verification techniques intended to assure that software development output meets its input requirements. Other verification methodologies include various static and dynamic analyses code and document inspections, walk through among others (refer Abdeen [1])

Software validation is a part of the design validation for a developed software. It may be formally defined as (refer [60]): *The confirmation by examination and provision of objective evidence that software specifications conform to user needs and intended uses, and that the particular requirements implemented through software can be consistently fulfilled.*

Validation of software, which may be conducted both during as well as at the end of the software development life cycle, is for ensuring that all the expected requirements are satisfied. In many cases, software are used as a part of a larger hardware system. Hence, by validating a software evidence is provided that all software necessities have been correctly and completely catered to and are traceable to the system requirements

A conclusion that software is validated is highly dependent upon comprehensive software testing, inspections, analyses, and other verification tasks performed at each stage of the software development life cycle. Testing of device software functionality in a simulated user environment and user site testing are typically included as components of an overall design validation program for a software automated device.

Verification and validation of software are difficult phases of the software development process, because it is not known to the developer how much evidence can be considered to be enough and also the software cannot be tested forever. Hence, software validation is considered as developing certain level of confidence that the device meets all the requirements and expectations from the users about the software automated functions and features of the device. Different measures which include (i) defects found in specifications, (ii) documented records, (iii) estimates of remaining defects/bugs in the software, (iv) testing coverage, etc. are used to obtain an acceptable level of confidence before a decision is taken to release the software in the market. In terms of some latest developments in the software reliability field, a sufficiently small total remaining bug size [16] may be a better indicator for proving that the software is reliable.

The level of confidence and therefore the level of software validation, verification, and testing effort needed will vary depending upon the safety risk (hazard) posed by the automated functions of the device (refer Freund [25]).

22.4.10 Software Validation as Part of System Design

System functionality is usually implemented in the designing phase of the software. Software requirements, in particular, depend on the overall system requirements as well as the design of the software that has been initially modeled. User needs depend a lot on the expected uses of a finished product,

and these specifications can be addressed by either software, hardware, or a combination of both. Therefore, software validation should be incorporated within the framework of the overall design validation for the system.

In the software requirement analysis phase, user needs and its intended uses based on which the software should be developed are documented. This documented software and system requirements are to be proved to have been satisfied completely during validation of software product. The appropriateness and completeness of both the system requirements and the software requirements should be addressed as part of the design validation process for the device. Thus, software validation includes confirmation of satisfactory conformance to all software specifications and confirmation of traceability to the system specifications of all software requirements. Confirmation is an important part of the overall design validation to ensure that all aspects of the software confirm to user needs and intended uses (refer [60]).

22.4.11 Principles of Software Validation

Some of the general principles that should be considered for the validation of software are defined by (refer Freund [25]).

Requirements

Software requirements analysis phase of the software development life cycle consists of documentation of the requirements from the software and the specifications derived from it forms part of the design phase. These documented versions form the baseline for both verification and validation. Hence, a software validation process cannot be carried out without an established software requirements specification.

Defect Prevention

Quality assurance for software should focus on prevention of introduction of errors during the software development process and definitely not to test quality into the software code that is already written.

Though testing is a part and parcel of any software development process, it cannot ensure detection of all defects in a software code. As such, the complexity of most software prevents it from being exhaustively tested. Software testing alone may not be able to provide sufficient confidence that the software is fit for its intended use, though it is a necessary activity. A better way to develop confidence into the product is to use an ensemble of methods that on one hand will prevent occurrence of errors when the software is being developed and on the other detect as many bugs as possible that has already gone in the software. There is no one best mix of these methods for all software; however, the strategy depends

on several important factors which include the development environment, application, size of project, language, and risk.

Time and Effort

A lot of time and effort is required to build a case that is used to validate a software. In fact, one should prepare for software validation right in the beginning, that is, during design and development planning stage itself. Planned efforts put throughout the software life cycle and the evidence obtained through that should be the basis for finally validating a software.

Software Life Cycle

There are several software life cycle models. All the models aim at developing a software that will ultimately satisfy the intended users. Sufficient documentation and software engineering tasks are required in order to support software verification and validation efforts.

Plans

A software validation plan must necessarily include the ultimate goal of the software validation process. Hence, the plan needs to be defined before the validation process starts. The software validation plan forms an important quality system tool which includes the following: (i) scope, (ii) approach, (iii) resources, and (iv) schedules along with the different types and extent of activities, tasks, and various work items (refer [60]).

Procedures

The software validation process is generally a step-by-step approach which uses some specific procedures to answer the question as to how the software validation effort should be conducted. These procedures also include identification of specific activities or a sequence of activities that need to be followed in order to complete individual validation activities, tasks, and work items (refer [60]).

Software validation After a Change

A seemingly small local change in the software may result in a drastic alteration on the global system, on account of the complexity of software. When any change (even a small change) is made to the software, the validation status of the software needs to be re-established. Any change in the software calls for a validation analysis of not just the particular change that has been effected, but the analysis should determine the extent to which the change has impacted the whole software. Based on this analysis, the software developer needs to carry out a suitable software regression testing in order to ensure that vulnerable portions of the system are not affected adversely. Through design controls and suitable regression testing confidence can be built that the software is validated after a software change (refer [60]).

Validation Coverage

The complexity of the software and issues like safety risk should determine the validation coverage of the software under consideration. Determinants such as firm size or resource constraints cannot be considered to be adequate. The selection of validation activities, tasks, and work items should be adaptable to the complexity of the software design and the risk associated with the use of the software for the specified intended use. For the devices that are not that much vulnerable to risks, only baseline validation activities may suffice. As the risk becomes more and more, additional validation activities need to be fulfilled in order to make up for the additional risk. Validation documentation should be sufficient to demonstrate that all software validation plans and procedures have been completed successfully (refer [60]).

Independence of Review

A number of reviews are essential before final release of the product into the market, but these reviews should not depend on one another. Self-validation is not only extremely difficult, it does not properly serve the purpose. Like most management systems, independent reviews are always better, particularly for complicated and high-risk applications. Some organizations hire from outside a software verification and validation team; however, this may not always work out to be the appropriate one. In most cases, experienced and knowledgeable internal members who are not associated with the design of the software or its implementation are assigned the job of conducting the verification and validation activities. However, for smaller organizations the challenge remains as to how to organize and assign the tasks in order to ensure that the reviews so undertaken are independent.

Flexibility and Responsibility

Like all other quality system management standards, software validation principles also may be implemented in different ways for different software and their applications. The freedom of planning lies with the software developer or the device manufacturer as to how to apply different validation principles in order to demonstrate that the software has been validated.

Software may need to be developed for a wide variety of devices with a wide spectrum of environments having different levels of risk. An example could be the software that are used in medical devices for which FDA regulations are applicable. Such a software could be a component or part or may work as an accessory of a medical device. It could by itself be a medical device, or it may be used in manufacturing, design and development of a system, or it could be used for other parts of a quality management system.

Given an environment, a software may consist of several different components, some of which are developed in-house, some may be purchased off-the-shelf, whereas some may

be contract software or shareware. Also, software components that are developed can be used as application software, operating systems, compilers, debuggers, and configuration management tools, among others.

Validating software in such different environments is a nontrivial task, and hence, it is all the more necessary that software validation process is designed keeping in view all of these software validation principles. The validation process thus developed should normally be equivalent to the safety risk associated with the system, device, or process (refer [60]).

22.4.12 Benefits of Software Validation

Software validation process is an important process step of the overall software development process and it helps build confidence in the product and its automated operations. This process helps in the enhancement of the reliability of the software, which automatically is reflected in decreasing failure rate, less number of recalls and corrective actions required. This also helps in reducing the liability of the software developer and finally helps in minimizing risks to the ultimate users and stakeholders.

It is a known fact that like testing of software, maintenance of software also is an important activity and both the activities take away a large chunk of the cost involved for the entire life cycle of the software. A software validation process which is comprehensive and well documented helps not only to reduce the life cycle cost of the present software; it also helps reducing the long-term cost of development of any subsequent versions of the software (refer Koopman [32]).

In other words, the validation process actually reduces the long-term cost by making it not only easier but less costly, as well, for reliably modifying the software and revalidating software changes.

Though software validation activity may be carried out from different geographical locations involving many different groups, the onus of ultimate responsibility for ensuring that the software is validated, rests on the developer.

22.4.13 Validation vs. Verification

According to the “capability maturity model,” the two terms may be defined as:

- Software Validation: The process of evaluating software during or at the end of the development process to determine whether it satisfies specified requirements.
- Software Verification: The process of evaluating software to determine whether the products of a given development

phase satisfy the conditions imposed at the start of that phase (refer Osherove [50]).

In the above definition of software validation, the “specified requirements” though mean ultimate user requirements, there could, however, be requirements from internal customers as well.

Software verification however, may be done in different phases of software development process in order to ensure that the output of each such phase satisfies the requirements, design, etc. of that phase.

In other words, software validation is a process of ensuring that the final software product meets the requirements (needs) of all the stakeholders, though some of these needs might not have been spoken out clearly. This, in a way, also checks whether the documented requirements could capture all the needs of the stakeholders. The oft-quoted saying is that software verification ensures that “you built it right” and confirms that the product, as provided, fulfills the plans of the developers. Software validation ensures that “you built the right thing” and confirms that the product, as provided, fulfills the intended use and goals of the stakeholders.

22.4.14 Conclusion

Each of software testing, validation and verification are essential in a program and all of them must be executed by balancing each other for the increased efficiency of the software. It must be remembered that different error filters are provided by each of them. All the processes are used to find a defect or a bug in a different manner, so the significance of each needs to be considered and utilized accordingly.

While software testing is an activity to investigate software under test in order to provide quality-related information to stakeholders, verification and validation must meet the compliance requirements of law regulated industries, which are often guided by government agencies. The success of software depends upon the acceptance of its targeted audience, easy graphical user interface, and strong functionality load test, among others. Thus, when a software product is being developed, the organization needs to assess whether it will be beneficial to its purchasers as well as other audience.

Dr. Ashis Kumar Chakraborty is a senior faculty in the Statistical Quality Control and Operations Research (SQC & OR) Division of Indian Statistical Institute (ISI), Kolkata. He has published four books and contributed in many other books. His research publications include the areas of Software and Hardware reliability, Process control, Data Analytics etc. He is a life member of the Operations Research Society of India and also of the Indian Association for productivity, Quality and Reliability. He was elected as Head of the SQC & OR Division, ISI, twice and also served as the leader of Quality Mission under aegis of Government of India.

Dr. E. V. Gijo is a Faculty at Statistical Quality Control and Operations Research unit of Indian Statistical Institute at Bangalore. He has authored a book on Lean Six Sigma and published around 45 articles in international journals related Six Sigma, Statistics, Reliability, Quality

Management and Time Series Forecasting. Dr. Gijo has worked on a number of consultancy projects with quite a few organizations.

Anisha Das is working as a research scholar in Biostatistics at the Florida State University. She was a visiting scholar at the Indian Statistical Institute where she handled a few projects. Her research interests include Bayesian analysis, bootstrapping and artificial intelligence techniques. She is well proficient in R and SAS programming and currently a member of American Association for the Advancement of Science.

Moutushi Chatterjee received her M. Sc. in Statistics from Kalyani University and M. Tech (Quality, Reliability and Operations Research) and PhD from Indian Statistical Institute, Kolkata, India. She is an Assistant Professor of Statistics at Lady Brabourne College (affiliated to University of Calcutta). Her current research interests include statistical quality control, multivariate statistics, reliability and operations research.

OSS Reliability Analysis and Project Effort Estimation Based on Computational Intelligence

Abstract

OSS (open-source software) systems serve as the key components of critical infrastructures in the society. As for the OSS development paradigm, the bug tracking systems are used for software quality management in many OSS projects. It is important to appropriately control the

23.1 Introduction

Many traditional software reliability growth models [1–3] (SRGMs) have been used to assess the reliability for quality management under the system testing phase of waterfall software development. Moreover, we have been energetically proposed several reliability analysis methods based on computational intelligence for an open-source software (OSS) in the last decade; see e.g., [4]. Its measurement and management technologies for OSS are essential to produce and maintain reliable system for OSS. As for the OSS development paradigm, the bug tracking systems are used for software quality management in many OSS projects. In the bug tracking systems, many fault data sets are recorded by several users and developers. It will be helpful for OSS project managers to assess the reliability and maintainability of OSS, if many fault data recorded on the bug tracking

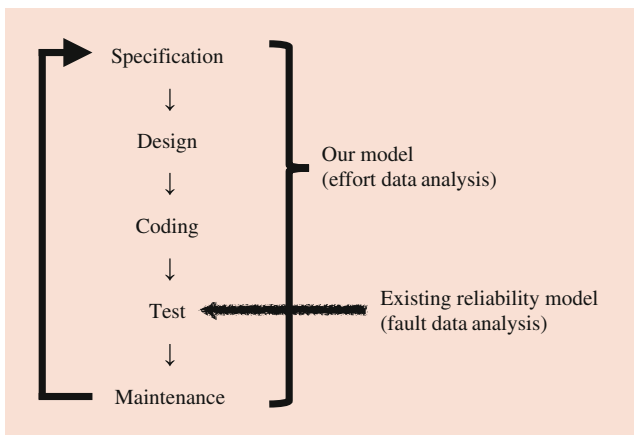

Fig. 23.1 The fault and effort data analysis

system are used for software quality improvement. Further, it is efficient to compare with the conventional methods [1–3] based on SRGMs if the software managers can use the development effort data in bug tracking system in terms of QCD (quality, cost, delivery) [4].

In this chapter, we focus on the method of effort estimation based on the deep learning for OSS project by using the OSS fault big data [5–7]. For example, Fig. 23.1 represents the relationship of fault and effort data analysis in the case of the Waterfall model. It is important to appropriately manage the quality according to the progress status of OSS project, because the software failure is caused by the poor handling of effort control as shown in Fig. 23.1. In particular, we can totally assess the development phase by using the effort data. Also, the appropriate control of management effort for OSS will indirectly link to the quality, reliability, and cost. Also, the GUI of OSS will be frequently made a dramatic difference according to the major version-upgrade.

Then, we discuss the method of effort estimation of OSS project based on the deep learning. In particular, we use the GUI data and the effort data obtained from fault big data. Then, we use the pixel data sets obtained from GUI of OSS for the actual OSS project. Also, several numerical examples of the proposed method based on the deep learning by using the pixel data and maintenance effort data in the actual OSS projects are shown in this chapter. Moreover, we discuss the results of numerical examples by using our proposed method.

23.2 Reliability of OSS

23.2.1 Open-Source Project and Reliability

All over the world, people can obtain a lot of information at the same time by growing rate of Internet access around the world in recent years. In accordance with such a pene-

tration of the Internet, it is increasing public awareness of the importance of online real-time and interactive functions. Therefore, the distributed software development paradigm based on the information technologies are expanding at an explosive pace. Especially, new development paradigm, such as client/server system, web programming, object-oriented development, and also on, by using network technologies have been in heavy usage by the software developers.

At present, there are a number of development paradigms within the same company, the development environment joined hands with several software company, and the collaborative development based on consortia formation in terms of the distributed development environment. Furthermore, a software development paradigm based on an open-source project is rapidly spreading.

The open-source project contains special features so-called software composition. These geographically dispersed several components are developed in all parts of the world. The successful experiences as the distributed development model in open-source projects include GNU/Linux operating system,¹ Apache Web server, and so on.² Especially, OSS is frequently applied as server use, instead of client use. Then, such an open-source system development is still ever-expanding now.

A computer-software is developed by human work; therefore, many software faults must be introduced into the software product during the development process. Thus, these software faults often cause complicated breakdowns of computer systems. Recently, it becomes more difficult for the developers to produce highly reliable software systems efficiently because of the diversified and complicated software requirements. Therefore, it is necessary to control the software development process in terms of quality and reliability. Note that a *software failure* is defined as an unacceptable departure of program operation caused by a *software fault* remaining in the software system. Basically, the software reliability can be evaluated by the number of detected faults or the software failure-occurrence time. Especially, the *software reliability models* which can describe software fault-detection or failure-occurrence phenomena are called SRGMs [1]. The SRGMs are useful to assess the reliability for quality control and testing-process control of software development.

On the other hand, the effective testing management method for distributed development environment as typified by open-source project has only a few presented [8, 9]. In the case of considering the effect of a debugging process on entire system in the development of a method of reliability assessment for the distributed development environment, it is necessary to grasp the deeply intertwined factors, such as

¹Linux is a Registered Trademark of Linus Torvalds.

²Other company, product, or service names may be trademarks or service marks of others.

programming path, size of component, skill of fault reporter, and so on.

23.2.2 OSS and Definitions of Reliability

At present, OSS systems serve as the key components of critical infrastructures in the society. OSS projects possess a unique feature known as software composition by which components are developed by teams that are geographically dispersed throughout the world. Successful OSS projects include Apache HTTP server, MySQL database server, OpenStack cloud software, Firefox Web browser, and GNU/Linux operating system. However, poor handling of quality issues and customer support has limited the progress of OSS, because the development cycle of OSS has no testing phase. For example, mobile OSS has been gaining a lot of attention in the embedded system area, i.e., Android, BusyBox, and Firefox OS. However, the installer software developed under the third-party developers indirectly affects the reliability of a mobile device. Therefore, it is difficult for many companies to assess the reliability of a mobile OSS, because a mobile OSS includes several software versions. Another closely related issue is that of software vulnerability posed by the open-source nature of the code, raising the possibility of security loopholes. For the abovementioned reasons, it is difficult for software managers to assess the reliability of OSS.

We compare the characteristics of software reliability with those of hardware reliability as follows:

Hardware Reliability

1. Hardware failures can be due to wear out.
2. Hardware reliability is affected by deficiencies injected during all phases of the development, operation, and maintenance.
3. Hardware reliability can be improved by redundancy with identical units.
4. A testing method of hardware reliability is established and standardized.
5. A maintenance technology is advanced since the market of hardware products is established and the user environment is seized.

Software Reliability

1. Software failures can be due to no wear-out phenomenon.
2. Software reliability is, inherently, determined during the earlier phase of the development process, i.e., specification and design phases.
3. Software reliability cannot be improved by redundancy with identical versions.

4. A verification method of software reliability has not been established.
5. A maintenance technology is not established since the market of software products is rather recent.

Generally, software failures caused by software faults latent in the software system cannot occur expected for a special occasion when a set of special data is put into the system under a special condition, i.e., the program path including software faults is executed. Therefore, the software reliability is determined by the input data and the internal condition of the program. We summarize the definitions of the terms related to the software reliability in the following.

A software system is a product which consists of the programs and documents as a result of the software development process. Specification derived by analyzing user requirements for the software system is a document which describes the expected performance of the system. When the software performance deviates from the specification and the output variable has an improper value or the normal processing is interrupted, it is said that a software failure occurs. That is, *software failure* is defined as a departure of program operation from the program requirements. The cause of software failure is called a software fault. Then, *software fault* is defined as a defect in the program which causes a software failure. The software fault is usually called software bug. *Software error* is defined as human action that results in the software system containing a software fault. Thus, the software fault is considered to be a manifestation of software errors. In this chapter, software error may be used to mean a defect detected and corrected during the testing or the operation phase without distinction from software fault.

23.2.3 Development Paradigm of OSS

At present, many OSS are developed under several open-source projects. For example, the Firefox Web browser, Firefox OS, and Thunderbird mailer are developed and managed under the Mozilla.org project. Also, Apache HTTP server, Tomcat, and Flex are developed and managed under the Apache software foundation. These open-source projects control the development phase of many open source projects. The open-source project has no the specific testing phase. Also, the specification of OSS continuously changes with the version upgrade, because the software of several versions is uploaded to the website of OSS project.

It is difficult for software managers to assess OSS reliability because of the differences among the development style of OSS and traditional software. Therefore, it is important to assess and manage considering the characteristics of the OSS development paradigm.

In particular, OSS have several versions of the development process as follows:

1. Bug Fix Version (most urgent issue such as patch)
2. Minor Version (minor revision by the addition of a component and module)
3. Major Version (significant revision for specification)

Also, the version number of OSS is generally described as the “(Major version number. Minor version number. Revision number. Build number),” e.g., (2.1.2103.1104). There are several versions for each OSS. Therefore, it is known that it is difficult for software managers to select the appropriate OSS, because several OSS are uploaded to the website of open-source project.

This chapter focuses on the reliability of OSS with the abovementioned characteristics. Several methods of reliability assessment for OSS are presented in this chapter. Also, several numerical examples for each method of reliability assessment based on computational intelligence are given by using actual fault data of OSS. These methods introduced in this chapter may be useful for software managers to assess the reliability of a software system developed using the OSS paradigm.

23.3 Stochastic Modeling Approach

Generally, a mathematical model based on probability theory and statistics is useful to describe the software fault-detection phenomena or the software failure-occurrence phenomena and estimate the software reliability quantitatively. During the testing phase in the software development process, software faults are detected and removed with a lot of test-effort expenditures. Then, the number of remaining faults in the software system is decreasing as the testing goes on. This means that the probability of software failure occurrence is decreasing so the software reliability is increasing and the time-interval between software failures becomes longer with the testing time. A mathematical tool which treats such software reliability aspect is a SRGM [1].

23.3.1 Hazard Rate Model

Based on the definitions discussed previous section, we can make a software reliability growth model based on the assumptions for actual environments during the testing phase or the operation phase. Then, we can define the following random variables on the number of detected faults and the software failure-occurrence time.

- $N(t)$: the cumulative number of detected software faults (or the cumulative number of observed software failures), up to testing time t ,
- S_i : the i -th software failure occurrence time ($i = 1, 2, \dots$; $S_0 = 0$),
- X_i : the time-interval between $(i - 1)$ -st and i -th software failures ($i = 1, 2, \dots$; $X_0 = 0$).

Figure 23.2 shows the occurrence of event $\{N(t) = i\}$ since i th faults have been detected up to time t . From these definitions, we have

$$S_i = \sum_{k=1}^i X_k, \quad X_i = S_i - S_{i-1}. \quad (23.1)$$

Assuming that the hazard rate, i.e., the *software failure rate*, for X_i ($i = 1, 2, \dots$), $z_i(x)$, is proportional to the current number of residual faults remaining in the system, we have

$$z_i(x) = (N - i + 1)\lambda(x), \quad i = 1, 2, \dots, N; x \geq 0, \quad \lambda(x) > 0, \quad (23.2)$$

where N is the initial fault content and $\lambda(x)$ the software failure rate per fault remaining in the system at time x . If we consider two special cases in Eq. (23.2) as:

$$\lambda(x) = \phi, \quad \phi > 0, \quad (23.3)$$

$$\lambda(x) = \phi x^{m-1}, \quad \phi > 0, m > 0, \quad (23.4)$$

then two typical software hazard rate models, respectively, called the Jelinski-Moranda model and the Wagoner model can be derived, where ϕ and m are constant parameters. Usually, it is not completely fault free or failure free. Then, we have a software hazard rate model called the Moranda model for the case of the infinite number of software failure occurrences as

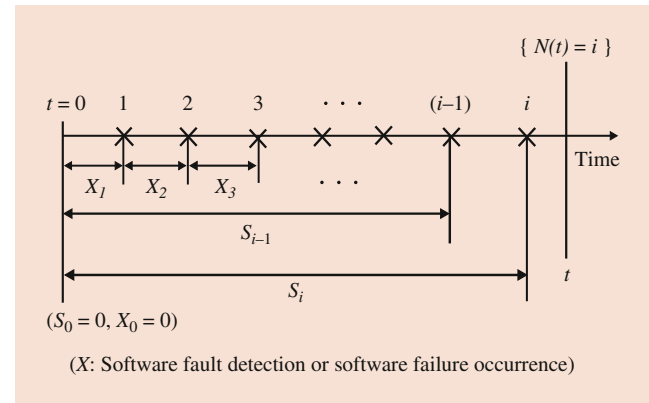

Fig. 23.2 The stochastic quantities related to a software fault detection phenomenon or a software failure occurrence phenomenon

$$z_i(x) = Dk^{i-1}, \quad i = 1, 2, \dots; D > 0, 0 < k < 1, \quad (23.5)$$

where D is the initial software hazard rate and k the decreasing ratio. Equation (23.5) describes a software failure-occurrence phenomenon where a software system has high frequency of software failure occurrence during the early stage of the testing or the operation phase and it gradually decreases thereafter. Based on the software hazard rate models above, we can derive several software reliability assessment measures. For example, the software reliability function for X_i ($i = 1, 2, \dots$) is given as

$$R_i(x) = \exp\left[-\int_0^x z_i(x)dx\right], \quad i = 1, 2, \dots. \quad (23.6)$$

23.3.2 NHPP Model

Further, we also discuss nonhomogeneous Poisson process (NHPP) models, which are modeled for random variable $N(t)$ as typical SRGMs. In the NHPP models, an NHPP is assumed for the random variable $N(t)$, the distribution function of which is given by

$$\Pr\{N(t) = n\} = \frac{H(t)^n}{n!} \exp[-H(t)], \quad n = 1, 2, \dots, \\ H(t) \equiv E[N(t)] = \int_0^t h(x)dx, \quad (23.7)$$

where $\Pr[\cdot]$ and $E[\cdot]$ mean the probability and expectation, respectively. $H(t)$ in Eq. (23.7) is called a mean value function which indicates the expectation of $N(t)$, i.e., the expected cumulative number of faults detected (or the expected cumulative number of software failures occurred) in the time interval $(0, t]$, and $h(t)$ in Eq. (23.7) called an intensity function which indicates the instantaneous fault-detection rate at time t . From Eq. (23.7), various software reliability assessment measures can be derived. For example, the expected number of faults remaining in the system at time t is given by:

$$n(t) = a - H(t), \quad (23.8)$$

where $a \equiv H(\infty)$, i.e., parameter a denotes the expected initial fault content in the software system. Given that the testing or the operation has been going on up to time t , the probability that a software failure does not occur in the time interval $(t, t+x](x \geq 0)$ is given by conditional probability $\Pr\{X_i > x | S_{i-1} = t\}$ as:

$$R(x|t) = \exp[H(t) - H(x+t)], \quad t \geq 0, x \geq 0. \quad (23.9)$$

$R(x|t)$ in Eq. (23.9) is a so-called *software reliability*. Measures of MTBF (mean time between software failures or fault-detections) can be obtained follows:

$$MTBF_i(t) = \frac{1}{h(t)}, \quad (23.10)$$

$$MTBF_c(t) = \frac{t}{H(t)}. \quad (23.11)$$

MTBFs in Eqs. (23.10) and (23.11) are called *instantaneous MTBF* and *cumulative MTBF*, respectively. It is obvious that the lower the value of $n(t)$ in Eq. (23.8), the higher the value $R(x|t)$ for specified x in Eq. (23.9), or the longer the value of MTBFs in Eqs. (23.10) and (23.11), the higher the achieved software reliability is. Then, analyzing actual test data with accepted NHPP models, these measures can be utilized to assess software reliability during the testing or operation phase, where statistical inferences, i.e., parameter estimation and goodness-of-fit test, are usually performed by a method of maximum likelihood.

To assess the software reliability actually, it is necessary to specify the mean value function $H(t)$ in Eq. (23.7). Many NHPP models [1] considering the various testing or operation environments for software reliability assessment have been proposed in the last decade. As discussed above, a software reliability growth is described as the relationship between the elapsed testing or operation time and the cumulative number of detected faults and can be shown as the reliability growth curve mathematically.

Among the NHPP models, the exponential and the modified exponential software reliability growth models are appropriate when the observed reliability growth curve shows an exponential curve. Similarly, the delayed S-shaped and the inflection S-shaped software reliability growth models are appropriate when the reliability growth curve is S-shaped.

In addition, as for computer makers or software houses in Japan, logistic curve and Gompertz curve models have often been used as software quality assessment models, on the assumption that software fault-detection phenomena can be shown by S-shaped reliability growth curves. In these deterministic models, the cumulative number of faults detected up to testing t is formulated by the following growth equations:

$$L(t) = \frac{k}{1+me^{-at}}, \quad m > 0, \alpha > 0, k > 0, \quad (23.12)$$

$$G(t) = ka^{(bt)}, \quad 0 < a < 1, 0 < b < 1, k > 0. \quad (23.13)$$

In Eqs. (23.12) and (23.13), assuming that a convergence value of each curve ($L(\infty)$ or $G(\infty)$), i.e., parameter k , represents the initial fault content in the software system, it can be estimated by a regression analysis.

23.3.3 Stochastic Differential Equation Modeling for OSS

We focus on an OSS developed under the open-source project. We discuss a useful software reliability assessment method in open-source project as a typical case of new distributed development paradigm. Especially, we introduce a software reliability growth model based on stochastic differential equations in order to consider the active state of the open source project. We assume that the software failure intensity depends on the time, and the software fault-report phenomena on the bug tracking system keep an irregular state.

Let $S(t)$ be the number of faults in the OSS system at testing time t ($t \geq 0$). Suppose that $S(t)$ takes on continuous real values. Since latent faults in the OSS system are detected and eliminated during the operational phase, $S(t)$ gradually increases as the operational procedures go on. Thus, under common assumptions for the software reliability growth modeling, we consider the following linear differential equation:

$$\frac{dS(t)}{dt} = \lambda(t)S(t), \quad (23.14)$$

where $\lambda(t)$ is the intensity of inherent software failures at operational time t and is a nonnegative function.

In most cases, the faults of OSS are not reported to the bug tracking system at the same time as fault detect but rather reported to the bug tracking system with the time lag of fault-detection and report. As for the fault report to the bug tracking system, we consider that the software fault-report phenomena on the bug tracking system keep an irregular state. Moreover, the addition and deletion of software component is repeated under the development of OSS, i.e., we consider that the software failure intensity depends on the time.

Therefore, we suppose that $\lambda(t)$ in Eq. (23.14) has the irregular fluctuation. That is, we extend Eq. (23.14) to the following stochastic differential equation [4]:

$$\frac{dS(t)}{dt} = \{\lambda(t) + \sigma\gamma(t)\} S(t), \quad (23.15)$$

where σ is a positive constant representing a magnitude of the irregular fluctuation and $\gamma(t)$ a standardized Gaussian white noise.

We extend Eq. (23.15) to the following stochastic differential equation of an Itô type:

$$dS(t) = \left\{ \lambda(t) + \frac{1}{2}\sigma^2 \right\} S(t)dt + \sigma S(t)dW(t), \quad (23.16)$$

where $W(t)$ is a one-dimensional Wiener process which is formally defined as an integration of the white noise $\gamma(t)$ with

respect to time t . The Wiener process is a Gaussian process and it has the following properties:

$$\Pr[W(0) = 0] = 1, \quad (23.17)$$

$$E[W(t)] = 0, \quad (23.18)$$

$$E[W(t)W(t')] = \text{Min}[t, t']. \quad (23.19)$$

By using Itô's formula [4], we can obtain the solution of Eq. (23.15) under the initial condition $S(0) = v$ as follows:

$$S(t) = v \cdot \exp\left(\int_0^t \lambda(s)ds + \sigma W(t)\right), \quad (23.20)$$

where v is the number of detected faults for the previous software version. Using solution process $S(t)$ in Eq. (23.20), we can derive several software reliability measures.

Moreover, we define the intensity of inherent software failures, $\lambda(t)$, as follows:

$$\int_0^t \lambda(s)ds = (1 - \exp[-\alpha t]), \quad (23.21)$$

where α is an acceleration parameter of the intensity of inherent software failures.

From Eq. (23.20), we can confirm that the number of detected faults cannot converge to a finite value as the following equation:

$$\lim_{t \rightarrow \infty} S(t) = \infty. \quad (23.22)$$

The operation environment of OSS has the characteristics of the susceptible to various operational environments. Therefore, it is different from conventional software systems developed under the identical organization. Then, the expected number of detected faults continues to increase from the effect of the interaction among various operational environments, i.e., the number of detected faults can not converge to a finite value [4].

23.4 Pixel Data-Driven Approach Based on Software GUI

23.4.1 Effort Estimation Model

Considering the characteristic of the operation phase of OSS projects, the time-dependent expenditure phenomena of maintenance effort depend on the change in UI/UX design during the operation phase, because the OSS are developed and maintained by several developers and users. UI means the user interface, UX the user experience. The operation phases of many OSS projects are influenced from external

factors by triggers such as the difference of skill, time lag of development, and maintenance. Considering the above points, we apply the mathematical model to manage the OSS project. Then, let $\lambda(t)$ be the cumulative maintenance effort expenditures up to operational time $t(t \geq 0)$ in the OSS development project. Suppose that $\lambda(t)$ takes on continuous real values. Since the estimated maintenance effort can be observed during the operational phase of the OSS project, $\lambda(t)$ gradually increases as the operational procedures go on. Based on the same approach in software reliability growth modeling [1–3], the following linear differential equation in terms of maintenance effort can be formulated:

$$\frac{d\Lambda(t)}{dt} = \beta \{\alpha - \Lambda(t)\}, \tag{23.23}$$

where β is the increase rate of maintenance effort expenditures at operational time t , and α means the estimated amount of maintenance effort required until the end of operation. Then, we can solve Eq. (23.23) under the initial condition $\lambda(0) = 0$. Therefore, the cumulative maintenance effort expenditures up to time t are obtained as follows:

$$\Lambda(t) = \alpha(1 - e^{-\beta t}). \tag{23.24}$$

Moreover, we discuss the parameter estimation by considering the UX/UI design, because UX/UI design changes with the operation procedure, i.e., we consider that the changing in UX/UI design depends on the cumulative maintenance effort expenditures. We assume that a set of data $(t_i, \lambda_i)(i = 1, 2, \dots, n)$ in terms of development effort data is obtained from the bug tracking system, where λ_i is the cumulative maintenance effort expenditures up to operational time t_i in the OSS development project. Then, we consider the following two kinds of data $o_1 (0 < o_1 < 1)$ and $o_2 (0 < o_2 < 1)$ as the learning data in the deep learning:

$$o_1 = \frac{\lambda_n - \lambda_b}{\lambda_n}, \tag{23.25}$$

where λ_b is the cumulative maintenance effort expenditures up to previous version. Then, the parameter α in Eq. (23.24) is given by $\alpha \equiv \lambda_n (1 + o_1)$. From Eq. (23.24), we can obtain the following equation:

$$\beta \equiv o_2 = \frac{1}{t_n} \ln \left[\frac{\alpha}{\alpha - \lambda_n} \right]. \tag{23.26}$$

Abovementioned $o_1 (0 < o_1 < 1)$ and $o_2 (0 < o_2 < 1)$ are obtained from the actual data on the bug tracking system are used as the learning data.

23.4.2 Parameter Estimation of Maintenance Effort Model Based on the Deep Learning

In this chapter, we apply the deep feedforward neural network (DFNN) and deep convolutional neural network (DCNN) to learn the UX/UI design of open-source projects. In particular, the GUI of OSS will be frequently made a dramatic difference according to the major version upgrade. Then, it is very important to consider the pixel data such as GUI. We apply the following pixel data of UX/UI design to the parameters of pre-training units. Then, the objective variable is given as the numerical value from 0 to 1 in terms of $o_1 (0 < o_1 < 1)$ and $o_2 (0 < o_2 < 1)$, respectively. In other words, we apply two kinds of parameters $o_1 (0 < o_1 < 1)$ and $o_2 (0 < o_2 < 1)$ to the amount of compressed characteristics, respectively.

The structure of the DFNN in this chapter is shown in Fig. 23.3. In Fig. 23.3, $z_l (l = 1, 2, \dots, L)$ and $z_m (m = 1, 2, \dots, M)$ means the pre-training units. Also, $o_n (n = 1, 2, \dots, N)$ is the amount of compressed characteristics. Several algorithms in terms of the deep learning have been proposed [10–15]. In particular, the network structure of DCNN is shown in Fig. 23.4.

23.4.3 The Procedure of Our Method

The procedures of the proposed method based on the deep learning are shown as follows:

- We obtain the fault big data sets from the bug tracking system.
- The development effort is calculated from the fault big data.

Fig. 23.3 The structure of DFNN

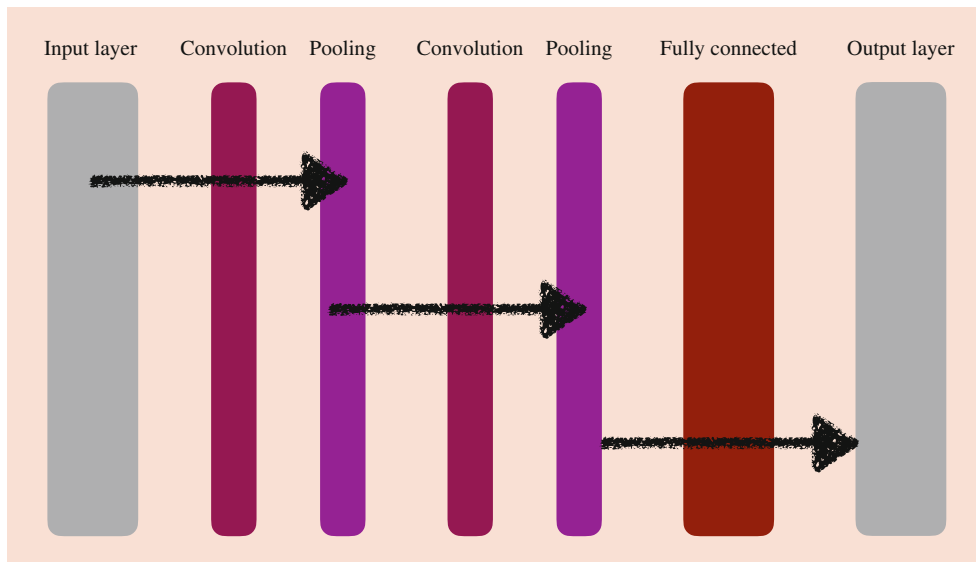

Fig. 23.4 The structure of DCNN

- We collect GUI data as UX/UI design for each software version.
- Then, the pixel data sets of GUI for each software version are given by the standardization of size in GUI.
- The pixel data is used as the input data of the deep learning. Then, the output data is o_1 ($0 < o_1 < 1$) and o_2 ($0 < o_2 < 1$).
- The DFNN and DCNN are used as the deep learning algorithm in this chapter.

23.4.4 Goodness-of-Fit Comparison

We compare the goodness-of-fit of DFNN with DCNN for the observed data set. We adopt the value of the root mean square error (RMSE) as comparison criteria of goodness of fit. Suppose that K data pairs (t_k, y_k) ($k = 1, 2, \dots, K$) are observed during the OSS operating-phase where y_k is the cumulative software effort expenditures observed in the time interval $(0, t_k]$. RMSE can be obtained by using the sum of square errors between the observed value, y_k , and the estimated one, \hat{y}_k , by the number of data pairs, K . That is:

$$\text{RMSE} = \sqrt{\frac{1}{K} \sum_{k=1}^K (y_k - \hat{y}_k)^2}, \quad (23.27)$$

where \hat{y}_k in Eq. (23.27) is obtained from estimated $\hat{\Lambda}(t_k)$ ($k = 1, 2, \dots, K$) in Eq. (23.24). RMSE indicates that the selected model fits better to the observed data as the RMSE becomes small.

23.4.5 Numerical Illustrations

In this chapter, we focus on Apache OpenOffice [16] in order to evaluate the performance of our methods. Several numerical examples by using the data sets for Apache OpenOffice as OSS are shown in this chapter. The data used in this chapter are collected in the bug tracking system on the website of Apache OpenOffice open-source project. We obtain 10,000 fault data sets from the data recorded on bug tracking system of Apache OpenOffice. The development effort data are analyzed by using the obtained 10,000 fault data sets. We show the actual data in Table 23.1.

We show the estimated cumulative maintenance effort expenditures in the case of DFNN and DCNN up to time t in Figs. 23.5 and 23.6. From Figs. 23.5 and 23.6, we find that our method will be helpful for the OSS managers to confirm the trend of maintenance effort by using UX/UI data such as GUI in terms of the long-term prediction. For example, the estimated cumulative software effort expenditures is about 1.20×10^9 man-month in 200 months in Fig. 23.5. The OSS managers can estimate the maintenance effort from the pixel data of GUI by using the proposed method.

Based on the results of DFNN and DCNN, the estimated RMSE in the case of o_1 and o_2 are shown in Figs. 23.7, 23.8, 23.9, 23.10. Moreover, Table 23.2 shows the comparison of goodness of fit based on RMSE in terms of maintenance effort. From Table 23.2, we have found that the estimated RMSE in the case of DCNN fits better than one of DFNN.

Fig. 23.7 The estimated RMSE of o_1 in the case of DFNN

Fig. 23.10 The estimated RMSE of o_2 in the case of DCNN

23.5 Calculation by MXNet Package

In the case of DFNN, we can calculate by using the MXNet package via Statistical Computing R. Then, we can implement the program of DFNN as follows:

Similarly, we can calculate by using the MXNet package via Statistical Computing R in the case of DCNN. Then, we can implement the program of DCNN as follows:

```

23.6 Concluding Remarks

This chapter has focused on the method of maintenance effort estimation related to reliability analysis based on the deep learning by using fault big data on bug tracking system and GUI data. In particular, our method based on the deep learning has used the fault big data and GUI of OSS. Then,

the changing in GUI of OSS will depend on the development and management effort of OSS in the specified version. Considering the relationship between GUI and OSS development process, the UX/UI design of OSS will change with the procedure of OSS development.

Therefore, we have focused on the maintenance effort of OSS and GUI data. Moreover, we have shown the numerical illustrations of our method based on the deep learning.

Abstract

The recent rapid advancement in technology has affected the security of software products. The number of threats and cyber-attacks are intensifying both in number and in complexity. Therefore, software system requires protection against threats and vulnerabilities. When

defects in the software have an effect on the security of the software system, then these defects are called vulnerabilities. It is essential for vendors to rigorously identify and remove vulnerabilities present in the system. This chapter aims to explain the vulnerability discovery and patching process mathematically. Patch is a security update released by software developers to eliminate vulnerabilities from the system. Quantitative measures are discussed in the present study to predict the vulnerability discovery growth function by incorporating various attributes, namely, software users, operational effort, and coverage functions. Joint optimization problem for optimal software and patch time-to-market are also discussed with an aim of minimizing the cost functions. Numerical examples are provided to validate the mathematical models and minimization problem using the actual vulnerability data sets. The results indicate that the discussed models can objectively determine the vulnerability discovery paradigm. Moreover, the optimization models will assist the management team in optimal decision making pertaining to release time of software and security patch in the market.

24.1 Introduction

In the last two decades, the software industry has witnessed tremendous advancements at an accelerated pace. The software is pervasive and has widespread utility. The human activities are notably dependent on the software. Indeed, the employment of the software has transformed humankind in every facet. Therefore, reliability and quality of software

system is most essential aspect of the software development life cycle. In software engineering literature, academicians and practitioners have suggested numerous software reliability growth models (SRGMs) to predict the reliability of software packages over their life cycle. SRGMs are mathematical models that assist testers in identifying the failure occurrence phenomenon and fault content of software systems at any point of time [1]. In software industry, the nonhomogenous process (NHPP)-based SRGMs are often applied to quantify the failure occurrences of software systems.

Software products are designed using varied procedures and are based on diverse technologies [2]. However, every piece of software has its own benefits as well as drawbacks. The main concern associated with the software industry is the security of the software packages. The prime characteristic of security is *confidentiality*, *integrity*, and *availability* [3]. Confidentiality refers to impediment of unauthorized disclosure of information. Integrity involves stopping of unauthorized alteration of information, and availability signifies the accessibility of critical information to the authorized unit. Absence of any of these three aspects from the software indicates security infractions in the system, which can cause loss and exploitation of crucial information. These security breaches in software are commonly known as software vulnerabilities.

In reference of software security, vulnerabilities are all about faults or oversights in the software system, which enables the hackers to sidestep the security measures and perform malicious activities to disrupt the confidentiality, integrity, and availability of the software program. Thus, vulnerabilities are a division of bugs present in the system, which affects the security of the software [4]. The menace caused by the security breaches has different severity degree, depending on the elements such as manipulation intricacy and attack-surface [5]. Several instances have been observed in the recent past in which software vulnerabilities have inflicted substantial harm to people and technological industries [6]. Presently, every software product in the market is confined to security infractions. According to Computer Emergency Response Team (CERT) [7], hundreds of new vulnerabilities are reported every week. National Vulnerability Database (NVD) [8] reports that overall 16,555 vulnerabilities are accounted for the year 2018, which is the largest figure until date. Therefore, discovering vulnerabilities is a preeminent activity that needs momentous human efforts.

Due to the continuous improvement in the information systems, software vulnerabilities pose a severe threat to the software engineers. Owing to the alarming intensity of these vulnerabilities, the research in the area of software security

has gained momentum from the past decade to provide security solutions to the industries. However, most of these studies are qualitative in nature. The quantitative aspect of vulnerability discovery process has not been given high importance in the software engineering literature. With the help of quantitative statistical analysis, team of software developers can predict the vulnerability discovery pattern more precisely by using the data-specific forecasting methods [9]. In recent past, few attempts have been carried out to characterize the security vulnerabilities mathematically. The first quantitative model for vulnerability discovery process was provided by Anderson [10], which is widely known as Anderson's thermodynamic model. Anderson [10] developed the thermodynamic vulnerability discovery model to measure the security in open and closed systems. The model illustrates the discovery rate based on mean time between failures (MTBF). According to their research, there is no difference between open and closed system in the end.

Rescorla [11] determined the economic effectiveness of finding and fixing the identified vulnerabilities for the company especially when they are discovered by the black hat. Their model is based on the nonhomogeneous Poisson process (NHPP) to assess the vulnerability discovery rate over time. Two statistical models, namely, Rescorla Exponential (RE) and Rescorla Linear or Quadratic (RL or RQ) model, were suggested by the author to fit the different growth function of vulnerability data. Further, to investigate the S-shaped behavior of vulnerability discovery process, Alhazmi and Malaiya [12] proposed the logistic vulnerability discovery model that measures the expected vulnerabilities discovered over time. They have also suggested the new metric known as vulnerability density to measure the security risk associated with the software. They segregated the vulnerability discovery process into three phases, namely, linear, learning, and saturation phase. Another significant contribution to the vulnerability discovery modeling literature was provided by Joh et al. [13]. They developed the vulnerability discovery model (VDM) using the Weibull distribution function. Their model is commonly known as Joh Weibull (JW) Model. The model depicts the asymmetric nature of vulnerability discovery rate because of the skewness present in probabilistic density function.

Recently, Kapur et al. [14] have provided a comparative study of vulnerability discovery modeling and its interdisciplinary nature. They have proposed two different VDMs and compared the prediction capability with existing models. Many other studies have also been proposed in the past literature to quantify the vulnerability discovery paradigm [6, 15–20]. The mathematical forms of some existing vulnerability discovery models important to the present study are given in Table 24.1.

Table 24.1 Existing vulnerability discovery models

Vulnerability discovery model	Vulnerability discovery rate	Mean value function
<i>Rescorla Exponential (RE) Model</i>	$\frac{d\Omega(t)}{dt} = A(B - \Omega)$	$\Omega(t) = B(1 - e^{-At})$
<i>Rescorla Linear/Quadratic (RL/RQ) Model</i>	$\frac{d\Omega(t)}{dt} = Bt + k$	$\Omega(t) = \frac{Bt^2}{2} + kt$
<i>Alhazmi Malaiya Logistic (AML) Model</i>	$\frac{d\Omega(t)}{dt} = A\Omega(B - \Omega)$	$\Omega(t) = \frac{B}{1 + BCe^{-AB}}$
<i>Joh Weibull (JW) Model</i>	$\frac{d\Omega(t)}{dt} = B \left\{ \frac{\alpha}{\beta} \cdot \left(\frac{t}{\beta}\right)^{\alpha-1} e^{-\left(\frac{t}{\beta}\right)^\alpha} \right\}$	$\Omega(t) = B \left\{ 1 - e^{-\left(\frac{t}{\beta}\right)^\alpha} \right\}$ or $\Omega(t) = B \{1 - e^{-At^\alpha}\}$

24.1.1 Notations

$\Omega(t)$	Expected number of vulnerabilities discovered in interval $[0, t]$
B	Initial number of vulnerabilities
A/γ	Vulnerability discovery rate
k, C	Integration constants
α	Shape parameter
β	Scale parameter

The defect identification process is affected by various testing and environment conditions. However, all the above-mentioned vulnerability discovery models are the function of time alone. Less or no attention is given to other attributes such as number of software end-users, intensity of operational efforts, and coverage function. Therefore, in this chapter, the influence of these critical factors on the vulnerability discovery process has been studied. The mathematical models describing the prediction of vulnerability discovery growth function on different factors have been described and further validated on the real-life vulnerability data.

Another important stream of literature in the field of software engineering has focused on the optimal release time of a software and patch time management. Developers must understand the market and release the software at an optimum time with minimum cost and maximum reliability. In software reliability literature, various studies have been designed to formulate optimal software time-to-market [21–27]. In addition, several researchers have also focused on patch time problem. Patch is a piece of code designed by the experts to update the software and remove the malicious faults and security breaches from the software system. However, the time to release the patch to its end-users requires crucial examination as it incurs huge cost in a form of testing, vulnerability discovery, goodwill loss, and market opportunity cost. Beattie et al. [28] formulated the cost minimization problem to determine the optimal time to release the patches. The cost function associated with their model considers the cost of attack due to the vulnerability and the cost of depraving due to flawed patches over time. Some authors have also distinguished the time of vulnerability disclosure (publication of vulnerability existence in the system) and patch release. In this regard, Telang and Wattal [29] explore the losses incurred to the software firms because of the public

disclosure of vulnerabilities. Arora et al. [30, 31] also suggested the optimal policy for software vulnerability disclosure and firm's patch release behavior. However, limitations of these studies are that they either have focused on software time-to-market policy or patch release time management. In this chapter, joint optimization of software time-to-market and patch release time policies is described. The objective of the present study is to predict the vulnerability discovery growth function with respect to factors such as number of end-users, effort consumption rate, coverage function, and time. In addition, the optimal policy for software and patch release time is discussed, which can facilitate the software vendors for optimal decision-making.

The rest of the chapter is organized in the following sections. Firstly, the mathematical modeling for vulnerability discovery process is discussed by incorporating different criteria such as software users, operational effort function, and coverage rate. The empirical analysis is described in the next section to assess the prediction capability and estimation efficiency of all the vulnerability discovery models. After that, the chapter deals with three different optimization problems with the aim of determining the optimal patch time-to-market. Numerical illustrations are also provided to comprehend the practical application of the release policies. Finally, the chapter is summarized using the concluding remarks.

24.2 Mathematical Modeling

24.2.1 NHPP-Based Vulnerability Discovery Models

In this chapter, the quantitative techniques described to assess the growth of software vulnerability discovery during the operational phase have been classified using nonhomogenous poison process (NHPP). Different attributes such as software users growth function, intensity of operational efforts, and coverage functions have been applied to illustrate the vulnerability discovery process of software products. According to the NHPP-based models, the software security failures occur at random times during operational phase caused by vulnerabilities lying hidden in the software, which arises due to the instructions executed by users. The counting process $\{N(t), t \geq 0\}$ of an NHPP is defined as:

$$\Pr [V(t) = n] = \frac{[\Omega(t)]^n}{n!} \cdot e^{-\Omega(t)}, \quad n = 0, 1, 2, \dots$$

where $\Omega(t)$ is the basic building block of all the NHPP models and it is defined as the expected number of vulnerabilities discovered by time t .

24.2.2 Notations

$\Omega(t)$	Expected number of vulnerabilities discovered by time t
\bar{V}	Fixed number of vulnerabilities present in the software.
\bar{S}_b	Potential users of a software product
$S_b(t)$	Cumulative number of software users by time t
$I_e(t)$	Expected number of actions performed or instructions executed
$W_e(t)$	Operational effort function; number of users who reports the presence of vulnerability in the system by time t
$C_f(W_e(t))$	Operational coverage function; the proportion of software covered for vulnerability discovery by time t

24.2.3 User-Dependent VDM

In this subsection, a user-dependent vulnerability discovery model is suggested [32]. The model is based on the key theory that total vulnerabilities identified in the software system are a function of the three critical factors: residual vulnerabilities present in the software system, number of instruction performed by the software users, and cumulative users of the software system. The model is described using the following assumptions:

- The software system fails randomly due to vulnerabilities present in the software.
- The total vulnerabilities identified at any instance are directly proportional to the undetected vulnerabilities in the software, number of instructions executed by the users, and the number of users of the system.
- The number of software buyers is a function of time that affects the vulnerability discovery process considerably.
- The vulnerability discovery process is modeled by the nonhomogeneous Poisson process (NHPP).
- Vulnerability discovery is a deterministic process in a continuous-state space.

Thus, the instantaneous vulnerability discovery at a time-point t can be described using the following differential equation [32]:

$$\frac{d\Omega(t)}{dt} = \left(\frac{d\Omega(t)}{dI_e(t)} \right) \cdot \left(\frac{dI_e(t)}{dS_b(t)} \right) \cdot \left(\frac{dS_b(t)}{dt} \right) \quad (24.1)$$

where time-dependent functions $\Omega(t)$, $I_e(t)$, and $S_b(t)$ clearly depend on the functions $I_e(t)$, $S_b(t)$, and t , respectively. The above-stated equation addresses that the vulnerability discovery in any software product is a function of number of instructions implemented, software users, and time. A detailed description of each component (or faction) of the model is presented below.

Component 1 The first component illustrates the rate of change in the number of vulnerabilities discovered with respect to the rate of change in number of instructions performed by the users. When software is released in the market, the developers continuously monitor and test its performance to identify any security breach present in the system. It has also been established that most of the vulnerabilities are interdependent [33]. Therefore, the probability of detecting other vulnerabilities increases when first vulnerability is identified. Thus, the total vulnerabilities can be classified into two classes: *unique* and *interdependent*.

Let *unique* vulnerabilities are discovered with rate x and y is the rate of discovery of *dependent* vulnerabilities, then the mathematical expression for the instantaneous vulnerabilities discovered at a time-point t is a function of two additive terms, that is:

$$\frac{d\Omega(t)}{dI_e(t)} = \left(x + y \cdot \frac{\Omega(t)}{\bar{V}} \right) \cdot (\bar{V} - \Omega(t)) \quad (24.2)$$

where $(\bar{V} - \Omega(t))$ are the vulnerabilities which are not identified as yet; the first term on the right hand describes the discovery of independent or unique vulnerabilities with rate x , and the second term represents the identification of dependent vulnerabilities with rate y , which is dependent on the proportion of already discovered vulnerabilities. It may be noted that the vulnerability discovery is an increasing function of the number of instructions executed. The number of vulnerabilities discovered increases as large number of instructions are executed.

Component 2 When users execute instructions on the software system, they may encounter some irregularities or security breaches. They report these discoveries to the developers for further investigation and timely removal of the vulnerabilities. Thus, the rate of change of instruction executed depends directly on the rate with which the number of users of the software system changes. Let ϕ be the proportionality constant, then the mathematical expression for the instantaneous change in the executed instructions at any time-point t becomes:

$$dI_e(t) = \phi dS_b(t) \quad (24.3)$$

$$\Rightarrow \frac{dI_e(t)}{dS_b(t)} = \phi \quad (24.4)$$

On substituting the expression of Eqs. (24.2) and (24.4) in Eq. (24.1), following mathematical expression is formed:

$$\frac{d\Omega(t)}{dt} = \left\{ \left(x + y \cdot \frac{\Omega(t)}{\bar{V}} \right) \cdot (\bar{V} - \Omega(t)) \right\} \cdot \{\phi\} \cdot \frac{dS_b(t)}{dt} \quad (24.5)$$

The above differential equation can be further expressed as:

$$\frac{\frac{d\Omega(t)}{dt}}{\frac{dS_b(t)}{dt}} = \left\{ \left(x + y \cdot \frac{\Omega(t)}{\bar{V}} \right) \cdot (\bar{V} - \Omega(t)) \right\} \cdot \{\phi\} \quad (24.6)$$

The above-equation can be solved using the boundary condition, $\Omega(t) = 0$, $S_b(t) = 0$ at $t = 0$, to attain the following closed-form solution:

$$\Omega(t) = \bar{V} \cdot \frac{(1 + h \cdot e^{-(x+y) \cdot S_b(t)})^\phi - (1 + h) \cdot e^{-(x+y) \cdot \phi \cdot S_b(t)}}{(1 + h \cdot e^{-(x+y) \cdot S_b(t)})^\phi} \quad (24.7)$$

(VDM1)

where $h = \frac{y}{x}$; $b = x + y$ and Eq. (24.7) represents the user-dependent vulnerability discovery model.

Modeling Software Buyers Growth Function

The third component of Eq. (24.1) relates to the change in the number of software users with time. Numerous expressions have been suggested to represent the relationship between the users and the time. One of the well-known expressions was given by Kenny [34], who has established that the growth rate of software users is a power function of the time. According, to his study, the usage of the software in the field environment is governed by a power law function, that is,

$$S_b(t) = \frac{t^{\lambda+1}}{\lambda + 1} \quad (24.8)$$

where λ is any real constant. However, the power function is seldom used in describing the relation between the users and the time. This is because the parameter of the expression is not interpretable in context of user's growth rate. Moreover, it does not differentiate the two classes of buyers, particularly, *innovators*, who buy the new product under the influence of mass-communication and *imitators*, who purchase a new

product under the influence of interpersonal communication. Therefore, in the present study, the mathematical expression given by Bass [35] is employed to differentiate the two groups of buyers categorically.

According to the Bass study, there exists a finite population of prospective users, say \bar{S}_b , who time increasingly purchases a product. Let p be the rate of innovation and q be the rate of imitation then the differential equation for instantaneous in the change the number of users at any time-point becomes:

$$\frac{dS_b(t)}{dt} = \left(p + q \cdot \frac{S_b(t)}{\bar{S}_b} \right) \cdot (\bar{S}_b - S_b(t)) \quad (24.9)$$

where $(\bar{S}_b - S_b(t))$ signify the probable users who are still left to purchase a software product and $S_b(t)$ is the cumulative software buyers by time t . It is believed that the vulnerabilities discovery increases with the increase in the number of instructions implemented at the user's end and on the other hand, number of executed instruction accelerated with the growth of software buyers. Thus, it can be interpreted that the growth function of software users affects the discovery of vulnerabilities. The above differential equation can be evaluated using the following integral structure:

$$\int dS_b(t) = \int \left(p + q \cdot \frac{S_b(t)}{\bar{S}_b} \right) \cdot (\bar{S}_b - S_b(t)) \cdot dt \quad (24.10)$$

On solving the Eq. (24.10) under the boundary condition, $S_b(t) = 0$ at $t = 0$, following expression for the cumulative software users by time t is formed:

$$S_b(t) = \bar{S}_b \cdot \left(\frac{1 - e^{-(p+q)t}}{1 + \frac{q}{p} e^{-(p+q)t}} \right) \quad (24.11)$$

where $\gamma = q/p$, $r = p + q$

Equation (24.11) denotes the mathematical expression for the total software users by time t . The user's growth can be used to evaluate the vulnerability discovery growth function.

24.2.4 Effort-Dependent VDM

This subsection explores the vulnerability discovery model by examining the consequences of operational effort and operational coverage function [36]. As the total efforts or resources consumed in the operational phase increase, more and more coverage can be provided to the software product. Thus, this increase in coverage will in turn accelerate the vulnerability discovery process. The model is based on the following key assumptions:

- The vulnerability discovery process is a function of number of vulnerabilities present in the system at that instance and the software coverage rate.
- The software coverage function directly depends on the efforts or resources (such as user/reporters) consumed in the operational phase.
- In addition, the rate of operational effort is a function of time.

Based on the above-mentioned assumptions, the instantaneous vulnerability discovery at a time-point t can be expressed as [36]:

$$\frac{d\Omega(t)}{dt} = \frac{d\Omega(t)}{dW_e(t)} \cdot \frac{dW_e(t)}{dt} \quad (24.12)$$

The differential equation described in Eq. (24.12) is a function of two components or fractions. The first component explains that the rate of vulnerability discovery at any time instant depends on the rate of change in operational efforts consumed at that point. The second component describes that the rate of change in efforts is a function of time. The mathematical expression for the two components is provided below:

Component 1 During operational phase, the amount of vulnerabilities discovered is directly proportional to the vulnerabilities present in the software at that instant. As the coverage of the software increased, more vulnerabilities are identified. Therefore, the change of vulnerability discovery with respect to change in operational efforts is considered dependent on the amount of software coverage, that is,

$$\frac{d\Omega(t)}{dW_e(t)} = \left(\frac{C'(W_e(t))}{z - C(W_e(t))} \right) \cdot (\bar{V} - \Omega(t)) \quad (24.13)$$

where $C'(W_e(t))$ is the coverage density function rate, $C(W_e(t))$ is coverage distribution function, z is the maximum proportion of software to be covered with $0 \leq z \leq 1$. Thus, $z - C(W_e(t))$ denotes the proportion of software, which remains uncovered. Coverage distribution functions can be modeled using the following functions:

- (a) When the coverage function is taken as *constant*, then

$$\left(\frac{C'(W_e(t))}{z - C(W_e(t))} \right) = b \quad (24.14)$$

On substituting, the value of Eq. (24.14) in Eq. (24.12), then the vulnerability discovery process can be described as:

$$\frac{d\Omega(t)}{dt} = b(\bar{V} - \Omega(t)) \frac{dW_e(t)}{dt} \quad (24.15)$$

Further, the differential equation (24.15) is solved using the boundary condition, $\Omega(t) = 0$, $W_e(t) = 0$ at $t = 0$ to get the following vulnerability discovery model:

$$\Omega(W_e(t)) = \bar{V}(1 - e^{-bW_e(t)}) \quad (\text{VDM2}) \quad (24.16)$$

Equation (24.16) describes the cumulative vulnerabilities discovered by time t when coverage function hazard-rate is constant.

- (b) When the coverage rate is assumed to follow *logistic* distribution function, then

$$\left(\frac{C'(W_e(t))}{z - C(W_e(t))} \right) = \frac{b}{(1 + h \cdot e^{-bW_e(t)})} \quad (24.17)$$

On substituting, the value of Eq. (24.17) in Eq. (24.12), then the vulnerability discovery process can be described as:

$$\frac{d\Omega(t)}{dt} = \frac{b}{(1 + h \cdot e^{-bW_e(t)})} \cdot (\bar{V} - \Omega(t)) \frac{dW_e(t)}{dt} \quad (24.18)$$

Further, the differential equation (24.18) is solved using the boundary condition, $\Omega(t) = 0$, $W_e(t) = 0$ at $t = 0$ to get the following vulnerability discovery model:

$$\Omega(W_e(t)) = \bar{V} \left(\frac{1 - e^{-bW_e(t)}}{1 + h e^{-bW_e(t)}} \right) \quad (\text{VDM3}) \quad (24.19)$$

Equation (24.19) describes the cumulative vulnerabilities discovered by time t when coverage function follows logistic distribution.

Modeling Operational Effort Function

The pace of almost all the software operations such as in-house testing, debugging faults, vulnerability discoveries is governed by the amount of resources utilized in the process. The second component of Eq. (24.12) represents the rate of change in operational efforts with respect to rate of change in time. In software reliability literature, effort function is modeled using the following distribution functions:

Exponential Effort When the effort consumption rate follows exponential distribution function, then operational effort function is defined as:

$$W_e(t) = \bar{W}(1 - e^{-\lambda t}) \quad (24.20)$$

where λ is a scale parameter specifying the rate with which efforts are being consumed and \bar{W} is the fixed amount of resources available for the vulnerability discovery process.

Weibull Effort When the effort consumption rate follows Weibull distribution function, then operational effort function is defined as:

$$W_e(t) = \bar{W} \left(1 - e^{-\lambda t^k}\right) \quad (24.21)$$

where λ is a scale parameter, k is a shape parameter, and \bar{W} is the total operational efforts to be utilized.

24.2.5 Generalized Coverage-Dependent VDM

In this subsection, the vulnerability discovery models discussed in earlier sections have been extended to include the effect of operational coverage, executed instructions, operational efforts, and time simultaneously. The model discussed in this section forms a generalized coverage-dependent model. Operational coverage is software metric that assists in evaluating the completeness and effectiveness of the usage process [37]. In general, coverage is a criterion to measure the thoroughness in executing the software system. It is considered that in the user environment, the probable vulnerable sites of the software product are covered using the efforts to discover vulnerabilities with some certainty. The model is based on the following assumptions:

- Vulnerabilities exist and uniformly spread in the software system over all potential vulnerable sites.
- When a potential vulnerable site is covered, using efforts at time t , the vulnerabilities at particular site are identified with certain probability.
- The expected vulnerabilities discovered in a small time-interval, say $(t, t + dt)$, are directly dependent on the number of vulnerabilities present in the system.
- The rate with which vulnerabilities are discovered is assumed a function of operational coverage.
- The operational coverage rate is a function of number of instructions executed.
- The number of executed instructions is considered effort dependent.
- The operational effort utilized in the vulnerability discovery process is a function of time.

In operational phase, the security breaches that are left unattended in the testing phase are discovered and patched. An operational coverage-based mathematical model is discussed to understand the underlying assumptions and predict the behavior of vulnerabilities. The model focuses on the effort spend in covering large proportion of the software for discovering vulnerabilities. Operational coverage is very important for both software developers and users. It can determine the effectiveness of a given operational effort. For developers, coverage information estimates the degree

of confidence of vulnerabilities that helps in vulnerability disclosure and patching. Coverage-based vulnerability discovery rate during the operational phase is defined as [38]:

$$\frac{d\Omega(t)}{dt} = \frac{d\Omega(t)}{dC_f(t)} \cdot \frac{dC_f(t)}{dI_e(t)} \cdot \frac{dI_e(t)}{dW_e(t)} \cdot \frac{dW_e(t)}{dt} \quad (24.22)$$

where the functions $\Omega(t)$, $C_f(t)$, $I_e(t)$, and $W_e(t)$ clearly depend on the functions $C_f(t)$, $I_e(t)$, $W_e(t)$, and t , respectively. A detailed description of each fraction on right-hand side is explained below:

Component 1 The instantaneous change of the vulnerability discovery rate with respect to operational coverage rate is directly dependent on the software vulnerabilities present in the software and indirectly proportional to uncovered proportion of software. A perfect coverage demonstrates that at infinity $C_f(\infty) = 1$, which is difficult to achieve in the operational phase. Consequently, for the modeling purpose, a target proportion of software, z has been taken that must be covered to identify vulnerabilities, where $0 < z < 1$. Moreover, the vulnerability discovery rate will enhance with increase in software coverage rate. Accordingly, the first component can be described as:

$$\frac{d\Omega(t)}{dC_f(t)} = A_1 \left(\frac{C'(W_e(t))}{z - C(W_e(t))} \right) (\bar{V} - \Omega(t)) \quad (24.23)$$

where A_1 is the proportionality constant representing the vulnerability discovery rate; $\left(\frac{C'(W_e(t))}{z - C(W_e(t))} \right)$ is the conditional probability that describes the rate with which the software is covered during the operational phase at any time t . Also, the operational coverage is a function of efforts employed in the operation phase.

Component 2 The instantaneous coverage rate corresponding to instantaneous number of executed instructions is taken as constant. As more and more instructions are performed on the software system, more software surface can be covered to discover vulnerabilities, that is,

$$\frac{dC_f(t)}{dI_e(t)} = \phi_1 \quad (24.24)$$

Component 3 The third component demonstrates the rate of change in executed instructions with respect to rate of change in operational efforts. Moreover, this change in execution rate of instructions per operational effort is considered constant. However, for some commercial software, the number of instruction executed is observed to be either increasing or decreasing, but it does not lead to much loss in generality. Thus, the third component is defined as:

$$\frac{dI_e(t)}{dW_e(t)} = \phi_2 \tag{24.25}$$

On combining the differentiable equations of above-mentioned components, and substituting Eqs. (24.23), (24.24), and (24.25) in Eq. (24.22), the following functional form is obtained:

$$\frac{d\Omega(t)}{dt} = \left\{ A_1 \left(\frac{C'(W_e(t))}{z - C(W_e(t))} \right) (\bar{V} - \Omega(t)) \right\} \cdot \{\phi_1\} \cdot \{\phi_2\} \cdot \frac{dW_e(t)}{dt} \tag{24.26}$$

The above differential equation can be further expressed as:

$$\frac{\frac{d\Omega(t)}{dt}}{\frac{dW_e(t)}{dt}} = A_1 \left(\frac{C'(W_e(t))}{z - C(W_e(t))} \right) (\bar{V} - \Omega(t)) \cdot \phi_1 \cdot \phi_2 \tag{24.27}$$

The above equation can be solved using the condition, $\Omega(0) = C(0) = 0$ to obtain the mean value function representing the expected number of discovered vulnerabilities by time t :

$$\Omega(W_e(t)) = \bar{V} \left(1 - \left(1 - \frac{C(W_e(t))}{p} \right)^{A_1 \phi_1 \phi_2} \right) \tag{24.28}$$

Equation (24.28) represents the total vulnerabilities discovered by time t when total $W_e(t)$ operational efforts have been expended.

Modeling Operational Effort Function

As mentioned before, the swiftness in the software operations is highly dependent on the amount of resources employed in the process. By utilizing efforts, the developers can meticulously identify security threats with an accelerated rate. Therefore, it is imperative to incorporate the effect of operational efforts for modeling the vulnerability discovery process. Thus, the fourth component in the differential equation (24.22) addresses the instantaneous rate of change in the operational efforts with respect to time. In present study, following distribution functions are applied to model the operational effort functions:

Weibull Effort When the effort consumption rate follows Weibull distribution function, then operational effort function is defined as:

$$W_e(t) = \bar{W} \left(1 - e^{-\lambda t^k} \right) \tag{24.29}$$

where λ is a scale parameter, k is a shape parameter, and \bar{W} is the total operational efforts to be utilized.

Logistic Effort When the effort consumption rate follows Logistic distribution function, then operational effort function is defined as:

$$W_e(t) = \bar{W} \left(\frac{1 - e^{-\lambda t}}{1 + \beta e^{-\lambda t}} \right) \tag{24.30}$$

where λ is a scale parameter and β is a learning parameter.

Modeling Operational Coverage Function

The operational coverage is assumed to follow following distribution functions:

- (a) When coverage function follows *Weibull distribution* function, then

$$C(W_e(t)) = p \left(1 - e^{-A_2 W_e(t)^h} \right) \tag{24.31}$$

where A_2 is a scale parameter and h is a shape parameter. Thus, the total vulnerability discovered (Eq. 24.28) becomes

$$\Omega(W_e(t)) = \bar{V} \left(1 - e^{-A_2 W_e(t)^{h A_1 \phi_1 \phi_2}} \right) \tag{VDM4} \tag{24.32}$$

Equation (24.32) describes the cumulative vulnerabilities discovered by time t when coverage function follows Weibull distribution function.

- (b) When coverage function follows *Logistic distribution*, then

$$C(W_e(t)) = p \left(\frac{1 - e^{-A_2 W_e(t)}}{1 + r e^{-A_2 W_e(t)}} \right) \tag{24.33}$$

where A_2 is a scale parameter and r is a learning parameter. Thus, the total vulnerability discovered (Eq. 24.28) becomes

$$\Omega(W_e(t)) = \bar{V} \left(1 - \left(1 - \left(\frac{1 - e^{-A_2 W_e(t)}}{1 + r e^{-A_2 W_e(t)}} \right)^{A_1 \phi_1 \phi_2} \right) \right) \tag{VDM5} \tag{24.34}$$

Equation (24.34) describes the cumulative vulnerabilities discovered by time t when coverage function follows Logistic distribution function.

24.3 Empirical Analysis

Empirical analysis is the most crucial phase in the model development process. Use of a better-fit software reliability growth model provides appropriate solutions to the fundamental engineering and technical problems. This section focuses on the validation of the above-discussed vulnerability discovery models and comparison of their prediction efficiency with existing models.

24.3.1 Parameter Estimation and Goodness of Fit Criteria

The nonlinear least square estimation procedure is applied for parameter estimation purpose. Least square estimation is an effective measure for small and medium size samples. For model validation, the unknown parameters, that is, the number of vulnerabilities that are potentially discovered, vulnerability discovery rate, number of software users buying the product, and software usage rate is estimated using the software known as Statistical Package of Social Sciences (SPSS) tool. If the expected value of the total vulnerability discovered by time t is given by $\Omega(t)$, then the least square estimators of the parameters of the model can be defined as:

$$Z = \sum_{i=1}^n \left[\widehat{\Omega}(t_i) - \Omega(t_i) \right]^2 \quad (24.35)$$

where n is the number of observations; $\widehat{\Omega}(t)$ is the predicted value, and $\Omega(t)$ is the actual value of the expected number of vulnerabilities discovered in the software.

The prediction ability of the model is said to be accurate if its simulating behavior matches with the actual software data. Therefore, to compare the goodness-of-fit for different vulnerability discovery models, five statistical measures such as Bias, Mean Square Error (MSE), Mean Absolute Error (MAE), Root Mean Square Prediction Error (RMSPE), and Coefficient of Determination (R^2) are applied.

- (a) **Bias**: It is the sum of the difference between the predicted and actual value. Lower the value of bias, better is the model fit to the data. If the predicted and actual value is same, then the model is known as unbiased model.

$$\text{Bias} = \frac{\left(\sum_{i=1}^n \left[\widehat{\Omega}(t_i) - \Omega(t_i) \right] \right)}{n} \quad (24.36)$$

where n is the number of observations

- (b) **Mean Square Error (MSE)**: It refers to the average value of the deviation between the estimated value and the actual value as follows:

$$\text{MSE} = \frac{\left(\sum_{i=1}^n \left[\widehat{\Omega}(t_i) - \Omega(t_i) \right]^2 \right)}{n} \quad (24.37)$$

where n is the number of observations. The lower MSE represents less fitting error, thus superior goodness of fit.

- (c) **Mean Absolute Error (MAE)**: It measures the closeness of prediction and the eventual outcomes. It is calculated as the absolute difference between the actual and predicted values divided by the difference of number of observations and degree of freedom, that is,

$$\text{MAE} = \frac{\left(\sum_{i=1}^n \left| \widehat{\Omega}(t_i) - \Omega(t_i) \right| \right)}{n} \quad (24.38)$$

- (d) **Root Mean Square Prediction Error (RMSPE)**: It calculates the closeness with which a model predicts the actual observations.

$$\text{RMSPE} = \sqrt{(\text{Bias}^2 + \text{Variation}^2)} \quad (24.39)$$

Lower value of RMSPE Error signifies high predictive accuracy of the model.

- (e) **Coefficient of Determination (R^2)**: It evaluates the percentage of the total variation about the mean accounted for the fitted curve. It ranges in value from 0 to 1. It is calculated as:

$$R^2 = 1 - \frac{\text{residual SS}}{\text{corrected SS}} \quad (24.40)$$

Small values indicate that the model does not fit the data well. The larger the value, the better the model explains the variation in the data.

- (f) **Predictive Ratio Risk (PRR)**: It measures the error between actual and estimated values using the following formula:

$$\text{PRR} = \sum_{i=1}^n \left\{ \frac{\left(\Omega(t_i) - \widehat{\Omega}(t_i) \right)^2}{\Omega(t_i)} \right\} \quad (24.41)$$

- (g) **Akaike Information Criterion (AIC)**: This criterion judge the quality of a set of statistical models to each other. It is evaluated using the following formula:

$$AIC_c = n * \ln(\text{likelihood}) + 2 * K + ((2 * K * (K + 1)) / (n - K - 1)) \quad (24.42)$$

where \ln is the natural algorithm; K is the number of parameters in the model and n is the number of observations.

- (h) **Bayesian Information Criterion (BIC):** It is relatively similar to the AIC. Nevertheless, it describes the over fitting issue by adding a penalty term for the number of parameters in the model. It is defined as:

$$BIC = n * \ln(\text{likelihood}) + K * \ln(n) \quad (24.43)$$

24.3.2 Data

The validation of a model requires some historical data of actual fault count of commercial software project, some metrics, and statistical tools. The first requirement, that is, the historical data, has been obtained from the governmental and private repositories of software vulnerabilities. The data sets have been obtained from the Common Vulnerability Exposure repository [39]. The vulnerability data set of several commercial software applications that are being used very often by software users has been chosen. The detailed description of data sets is described below:

1. **Oracle VM VirtualBox (DS 1):** It is a leading corporation, which is completely integrated with cloud applications and platform services. VirtualBox is free and open-source software (FOSS) whose source code is available for public access. Open-source software packages are type of computer software, which can be modified and shared by its users [40]. In this data set, 66 vulnerabilities were discovered from Jan 2011 to Jan 2017 by 29 software users or buyers. These vulnerabilities belong to Oracle VM Virtual box version 4.x and 5.x. Oracle Virtual box version 4.0 was initially released on 22 December 2010 and its version 5 was released on 9 July 2015.
2. **Google Chrome (DS 2):** The Google chrome is a web browser that offers web services to its clients by connecting them to the Internet. Due to immense dependency on web platforms for day-to-day activities, these platforms are broadly used and as a result, the probability of web attack on Google chrome is quite high. Google Chrome has more than 1300 vulnerabilities in total that are published in CVE until May 2016. For the present analysis purpose, data set has been filtered by “DOS Overflow” vulnerability type with the severity greater than 8 and overall 47 vulnerabilities were observed that were reported by 46 users between September 2008 and May 2016. The objective is to concentrate on only those vulnerabilities that have the potential to harm the developer

economically; therefore, the vulnerabilities with severity level greater than 8 are considered.

24.3.3 Validation Results of User-Dependent and Effort-Dependent VDMs

Firstly, the parameters of the user growth function given in Eq. (24.11) are estimated using the data of actual users of the software. The result is listed in Table 24.2. Moreover, the results of goodness-of-fit criteria such as Mean Square Error (MSE), Coefficient of Determination, R^2 are also evaluated and the result is summarized in Table 24.2. Further, Fig. 24.1a provides the goodness-of-curve for the predicted software users and actual buyers. Secondly, the parameters of the operational effort function given in Eqs. (24.20) and (24.21) are estimated using the actual effort data for the two dataset. Data consist of actual number of reporters over time. Corresponding parameter estimation values are provided in Table 24.2. The results provided in Table 24.2 show that all the estimated coefficients are highly reliable and significant. Moreover, the values of statistical performance for all vulnerability discovery models as provided in Table 24.2 establish the predictive power and prediction efficiency of the vulnerability discovery models. Graphically, the goodness-of-curves for two efforts functions with actual effort data are represented in Fig. 24.1b.

Further, the model parameters are estimated using the vulnerability data. Moreover, the model fitness with the actual data is evaluated and the prediction efficiency of the present model is further compared with the previously established vulnerability models such as Anderson Thermodynamic Vulnerability Discovery model, Rescorla exponential model, Rescorla quadratic model, Alhazmi Malaiya Logistic model, and Joh model. The parameter values obtained during the fit and the corresponding goodness-of-fit criteria for the data set DS1 are given in Table 24.3. The results of the statistical measures as displayed in Table 24.3 depict that all the suggested vulnerability discovery models have high prediction efficacy. Goodness-of-fit curves for VDM1, VDM2, and VDM3 are also illustrated graphically in Fig. 24.2.

VDM3 (Weibull Testing Effort)	4.575	0.987	-0.144	0.15	0.1719	$\bar{V} = 75.433 b = 0.124, h = 6.167$

Fig. 24.2 Goodness of fit for Oracle VM virtual box (a) VDM1 (b) VDM2 & VDM3

The Rescorla exponential (RE) model for vulnerability discovery process is equivalent to the Goel-Okumuto (GO) model for software reliability growth function. In this model, the number of vulnerabilities discovered per unit time assumes to follow a Poisson process. From Table 24.3, it can be interpreted that the model does not provide good fit to the actual vulnerability data of Oracle virtual Machine virtual box with a R^2 value of 0.82. Rescorla Quadratic (RQ) model is also known as Rescorla linear model as it follows a uniform trend. The model provides reasonably good fit to the Oracle virtual box data set with the R^2 value of 0.985. Another established VDM is Alhazmi Malaiya Logistic (AML) model that examines the change in the cumulative number of vulnerabilities by the number of remaining vulnerabilities and the share of the installed base. The AML model follows an S-shaped pattern that contains three phases: learning phase, linear phase, and saturation phase. From the goodness-of-fit measures results, it can be deduced that the model provides good fit to the data with R^2 value of 0.989. The Joh vulnerability discovery model considers the Weibull distribution to model an asymmetric probability density function. This model is also supposed to follow the S-shaped pattern like AML model. It provides good fit to data with R^2 value of 0.987. It has been observed that the estimated and the actual data are following the same trend that shows a significant fit. The results in the Table 24.3 also suggest that for Oracle VM Virtual box, the model with least MSE and highest R^2 value is user-dependent vulnerability discovery model (VDM1), Joh model has least bias value, VDM2 with Weibull effort has the least MAE, while the least value of RMSPE is obtained by AML model.

24.3.4 Validation Result of Generalized Coverage-Dependent VDM

Initially, the parameters of the operational effort function given in Eq. (24.29) and (24.30) are estimated and the results are provided in Table 24.4. Additionally, Table 24.5 lists the estimated values of VDM3 and existing vulnerability discovery models such as RE, RL, and AML. Also, the goodness-of-fit measures such as R^2 , MSE, Bias, AIC, and PRR are calculated for the all the models. Results are summarized in Table 24.5. From the results displayed in Table 24.5, it can be interpreted that the value of MSE for all four VDMs provides good fit to data with low values of MSE, PRR, AIC, and BIC and significantly high value of R^2 . Further, Fig. 24.3 graphically depicts the fitting capability of different VDMs to the Google Chrome data set.

Table 24.4 Estimated values of operational effort function

Effort function	\bar{W}	λ	k/β	MSE	R^2
Weibull	40.672	0.001	2.116	2.414	0.989
Logistic	40.686	0.102	16.84	2.55	0.988

24.4 Optimal Patch Time Release Policies

In operational phase, vulnerability discovery by the developers is an ongoing process and does not end until the software is completely out of use or taken over by a new software. Thus, software is continuously monitored for new threats and flaws. New threats keep popping up and resources are required to correct and completely remove them. As a result, some coding is done to eliminate the threats in the form of a patch. The patch is then applied to the software and after testing, the patch is commercially released for the users. Patches are often released to secure software from new threats and identified flaws.

To evaluate the optimal time to release a patch keeping the cost expenditure minimum poses an insightful study for the software companies. Consequently, in the present section optimal patch release policies are discussed that may provide managerial aid and actionable recommendations to the software firms. There has been substantial argument as to when a company should disclose the discovered vulnerabilities and accordingly release a patch for the users. The software patch release time is a critical issue for the policy-makers that depends on various decisive factors such as companies' desired risk level, vulnerabilities discoverers, competence of patch testing, and market opportunity loss due to delay in software patch. The optimization problems discussed in this section yield optimal patch release-time situation. The optimization models are formulated with an aim of keeping the development cost and risk level minimum and high product reliability. The chapter covers the optimization problem of patch release time for faults and vulnerabilities.

24.4.1 Assumption

The optimization models are based on the following key assumptions:

- The fault and vulnerability discovery process follows a nonhomogeneous Poisson process (NHPP) phenomenon.
- The time lag between the fault detection and its removal is negligible.
- Faults are identified according to a Poisson process with mean value function (MVF) $m(t)$.

Table 24.5 Estimates values of different vulnerability discovery models for Google Chrome data set

Model	MSE	PRR	R^2	AIC_C	BIC	Parameter estimates
Rescorla Exponential (RE) model	21.372	11.616	0.989	281.624	289.128	$B = 55.797, A = 0.019$
Rescorla Quadratic (RQ) model	85.704	53.325	0.953	405.981	411.001	$B = 0.11, k = 0.982$
Alhazmi Malaiya Logistic(AML) model	21.372	11.616	0.989	281.624	289.128	$B = 41.333, A = 0.003, C = 0.528$
VDM4 (Weibull Testing Effort)	2.667	174.417	0.988	96.068	110.128	$\bar{V} = 169.219, h = 0.975$ $A_1 = 0.028, A_2 = 0.281$ $\phi_1 = 0.939, \phi_2 = 1.029$
VDM4 (Logistic Testing Effort)	2.54	28.0740	0.988	91.609	105.668	$\bar{V} = 122.042, h = 1.018$ $A_1 = 0.272, A_2 = 0.027$ $\phi_1 = 1.108, \phi_2 = 1.192$
VDM5 (Weibull Testing Effort)	2.661	216.149	0.988	95.86	109.92	$\bar{V} = 108.615, r = 0.167$ $A_1 = 0.156, A_2 = 0.128$ $\phi_1 = 0.781, \phi_2 = 0.781$
VDM5 (Logistic Testing Effort)	2.526	29.7027	0.989	91.121	105.181	$\bar{V} = 110.584, r = 0.204$ $A_1 = 0.022, A_2 = 0.21$ $\phi_1 = 1.12, \phi_2 = 2.241$

Fig. 24.3 Fitness of VDMs with Google Chrome Data

- Vulnerabilities are also discovered with respect to Poisson process with mean value function $\Omega(t)$
- The debugging process of defects is considered perfect, that is, faults and/or vulnerabilities are removed perfectly without introducing new faults and/or vulnerabilities in the system.
- There is fixed and finite number of defects in the system.
- Every software product has finite life cycle.
- Cost of patch development and delivery to the end-users is negligible.
- Market opportunity cost is assumed monotonically increasing and twice continuously differentiable convex function of the software release time.

- In postpatch release phase, no further patch will be released in the market for remaining defects rather a new upgraded version of the software will be released later by the company by removing the discovered vulnerabilities.

24.4.2 Optimal Release and Patching Time of Software with Warranty

This subsection presents a study to determine the optimal time to release a software and security patch when product is under warranty period [41]. The total life span of software is considered finite and it lies between the interval $[0, T_{lc}]$. The

entire software lifecycle is broadly divided into two phases, namely, testing phase $[0, \tau]$ and operational or maintenance phase $[\tau, T_{lc}]$. A warranty is offered on the software product at the time of the purchase so that if any failure occurs within the warranty period, it is rectified by the software vendors without any charge to the users. In operational phase, software is continuously tested for any security threats. Also, the manager's idea is to release a patch in the warranty period itself for the vulnerabilities discovered by that time. Thus, maintenance phase is further divided into prepatch release phase under warranty $[\tau, \tau_1]$, postpatch release phase under warranty $[\tau_1, \tau + w]$, and operational phase after warranty $[\tau + w, T_{lc}]$. The goal of the current optimization problem is to minimize the overall cost associated with the fault and vulnerability discovery and testing process with a constraint to maintain a desired reliability level.

Mathematical Modeling

In this subsection, the mathematical structure of the expected number of faults encountered in the entire software life cycle is studied in different phases. The pictorial representation of phase-wise description of software life cycle is given in Fig. 24.4.

Phase 1: Pre-release Testing Phase $[0, \tau]$

During this period, software is rigorously tested by the developers for any bugs present in the system. This is the most critical phase of software development life cycle because the stability, availability, and reliability of the software are determined based on testing process. If any test case is failed to perform during this phase, then the probability of failures increases in the operational phase. Therefore, vital importance is given to this phase by the software developers. The expected number of faults identified during this phase can be described using following expression:

$$m(\tau) = aF_1(\tau) \tag{24.44}$$

where a is the total fault content present in the software; $F_1(\tau)$ describes the fault distribution function of the testing team; τ is the release time of software in the market. It is further assumed that the faults detection phenomenon follows an exponential distribution pattern, that is,

$$m(\tau) = a(1 - e^{-b\tau}) \tag{24.45}$$

where b is the fault detection rate and a is the potential fault content present in the system.

Phase 2: Prepatch Release Phase Under Warranty $[\tau, \tau_1]$

After the software is released in the market at time τ , users meticulously identify flaws remaining in the system during its execution and report it to the developers. In this phase, a warranty is provided to the users to assure that if any discrepancy is observed then it will be solved by the developers without any charge. The faults detected during this phase are rectified by the developing team and a patch in the form of piece of code is developed to eliminate the faults. Thus, expected faults identified during this phase become:

$$m(\tau_1 - \tau) = a(1 - F_1(\tau))F_2(\tau_1 - \tau) \tag{24.46}$$

where $a(1 - F_1(\tau))$ are the leftover bugs from the phase 1 that are left unidentified in the pre-release testing phase and $F_2(\tau_1 - \tau)$ is the distribution function of fault detection by the users. Now, when fault detection phenomenon follows exponential distribution function, then mean value function of faults detection is expressed as:

$$m(\tau_1 - \tau) = ae^{-b\tau} (1 - e^{-b \cdot r_1 \cdot (\tau_1 - \tau)}) \tag{24.47}$$

where $b \cdot r_1$ ($0 < r_1 \leq 1$) is the combined fault detection rate of all the users. Since the competency of users in detecting the faults is less as compared to the testing team, the fault detection rate of users is considered some proportion of tester's bug detection rate.

Phase 3: Postpatch Release Phase Under Warranty $[\tau_1, \tau + w]$

For strengthening the position in the market, Software Company makes sure to provide a patch to its users for updating the system within the warranty period. It is considered that τ_1 is the optimal time when company should release its patch. Now, on receiving the patch, users successfully install it to update their product. However, not all faults can be fixed by a single patch. Therefore, there may be few faults that remained undetected in the previous phases and may be identified by the users after time-point τ_1 . It is assumed that the fault detection rate of users improves during postpatch release phase as they have attained experience through previous

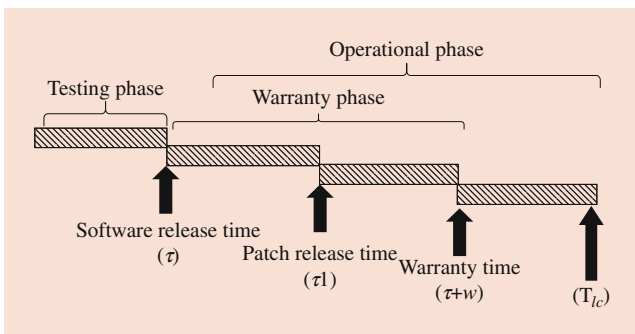

Fig. 24.4 Phase-wise description of software life cycle for fault discovery

phase $[\tau, \tau_1]$. Thus, the bug detection effectiveness increases during this phase. The expected number of bugs identified in third phase may be expressed as:

$$m((\tau + w) - \tau_1) = a(1 - F_1(\tau))(1 - F_2(\tau_1 - \tau)) F_3((\tau + w) - \tau_1) \quad (24.48)$$

where $a(1 - F_1(\tau))(1 - F_2(\tau_1 - \tau))$ represents the proportion of bug content which left undetected in the previous phase. Moreover, it is assumed that the bug detection phenomenon follows exponential distribution function. Then, the expected number of bugs detected during this phase becomes:

$$m((\tau + w) - \tau_1) = ae^{-b\tau} e^{-b \cdot r_1 \cdot (\tau_1 - \tau)} (1 - e^{-br_2(\tau + w - \tau_1)}) \quad (24.49)$$

where $b \cdot r_2$ is the increased bug detection rate of the users in phase 3.

Phase 4: Postwarranty Phase $[\tau + w, T_{lc}]$

It is assumed that warranty is terminated at a fixed time-point $(\tau + w)$. Generally, companies abort their free support to debug the reported faults after the warranty period is over. However, it has been observed that sometimes firms sign an agreement with the software users to correct software failures due to the faults present in the system throughout the product life cycle. Thus, the users continuously monitor and report the bugs to the developers for removal. The mean value function of faults detection during this phase can be modeled as:

$$m(T_{lc} - (\tau + w)) = a(1 - F_1(\tau))(1 - F_2(\tau_1 - \tau)) (1 - F_3((\tau + w) - \tau_1)) F_4(T_{lc} - (\tau + w)) \quad (24.50)$$

where $a(1 - F_1(\tau))(1 - F_2(\tau_1 - \tau))(1 - F_3((\tau + w) - \tau_1))$ correspond to the proportion of remaining faults and $F_4(T_{lc} - (\tau + w))$ is the cumulative fault detection function of the user in this phase. Now, the mean value function when fault detection process follows exponential distribution can be re-written as:

$$m(T_{lc} - (\tau + w)) = ae^{-b\tau} e^{-b \cdot r_1 \cdot (\tau_1 - \tau)} e^{-b \cdot r_2 \cdot (\tau + w - \tau_1)} (1 - e^{-b \cdot r_3 \cdot (T_{lc} - (\tau + w))}) \quad (24.51)$$

Cost Modeling

The following cost components are considered for modeling the cost function:

(a) **Testing cost** : It is the cost to execute testing of each software unit. It includes all the effort expends in developing and running the test cases. In software literature, this cost is assumed to increase linearly with time. Thus, if C_1 is the per unit testing cost, then total testing cost can be defined as:

$$C_{\text{testing_cost}}(t) = C_1 \tau \quad (24.52)$$

(b) **Market Opportunity Cost**: Before initializing the software development project, every company performs a market survey to investigate the expected profit and revenue gained by introducing a new software product. If a firm fall short in delivering the software at the scheduled launch time then the market opportunities are missed. Therefore, a cost in a form of market opportunity is implemented in the cost model, which is a nonlinear increasing function of release time, that is,

$$C_{\text{market_opportunity}}(t) = C_2 \tau^2 \quad (24.53)$$

where C_2 is the market opportunity cost per unit time.

(c) **Cost of fault debugging during testing phase**: It is the cost incurred in fixing the detected faults during the testing period. It is assumed that the debugging cost is directly proportional to the number of faults identified by the testers. If C_3 is the per unit debugging cost during testing phase then the overall cost of debugging in testing phase is represented as:

$$C_{[0, \tau]}(t) = C_3 m(\tau) \quad (24.54)$$

(d) **Cost of fault debugging in prepatch release phase**: After the release of the software in the market, it is in the operational environment where the faults are continuously discovered and reported by the users. The potential loss possessed by developers during this phase is huge as it includes the liability cost, loss of goodwill due to customer's dissatisfaction, the cost of developing and distributing patches, and the cost of revenue loss when failures are observed within warranty, etc. If C_4 is the per unit fault debugging cost in this phase, the total cost incurred by the testing team in prepatch release patch becomes:

$$C_{[\tau, \tau_1]}(t) = c_4 \cdot m(\tau_1 - \tau) \quad (24.55)$$

(e) **Cost of fault debugging in postpatch release phase**: Even after the release of first patch, some proportion of total faults remains undetected in the software. As software is still in the warranty period, developers have to

correct the failure causing bugs. If C_5 is the per unit bug removal cost in this phase, then effective cost incurred in postpatch release warranty phase is given as:

$$C_{[\tau_1, \tau+w]} = C_5 m (\tau + w - \tau_1) \tag{24.56}$$

(f) **Cost of fault debugging in postwarranty phase:** Even after the termination of warranty at time-point $(\tau + w)$, software developers keep on debugging the faults reported by the users. Moreover, the postwarranty period is much longer than the other software lifecycle phases, which results in high utilization of resources during this period. Therefore, per unit cost of bug correction is highest during this phase. The total debugging cost in postwarranty phase when C_6 cost of fault removal per unit can be defined as:

$$C_{[\tau+w, T_{lc}]} = C_6 \cdot m (T_{lc} - (\tau + w)) \tag{24.57}$$

Thus, the total cost can be obtained by adding all the cost components, that is,

$$\begin{aligned} \text{Total_Cost, } C(t) = & C_1 \tau + C_2 \tau^2 + C_{[0, \tau]}(t) + C_{[\tau, \tau_1]}(t) \\ & + C_{[\tau_1, \tau+w]}(t) + C_{[\tau+w, T_{lc}]}(t) \end{aligned} \tag{24.58}$$

Based on the aforementioned assumptions and modeling framework, the following constrained optimization problem is defined with an objective of minimizing the total cost and maintaining the certain level of software reliability.

$$\begin{aligned} \text{Minimize } C(t) = & C_1 \tau + C_2 \tau^2 + C_{[0, \tau]}(t) + C_{[\tau, \tau_1]}(t) \\ & + C_{[\tau_1, \tau+w]}(t) + C_{[\tau+w, T_{lc}]}(t) \end{aligned} \tag{24.59}$$

$$\text{Subject to, } R(x|t) \geq R_0 \tag{24.60}$$

where $R(x|t)$ is the conditional reliability function that states software will perform failure-free in a small time interval $[t, t + x]$ under specified user environment and mathematically it is defined as:

$$R(x|t) = e^{-\{m(t+x)-m(t)\}} \tag{24.61}$$

Numerical Example

The constrained optimization problem defined in the previous section has been numerically illustrated in the present section. The numerical enunciates the procedure for evaluating the optimal release time of software and the security patch in the market. The actual fault count data of Tandem computers is obtained from the software literature [42] for

numerical purpose. In the data set, there are total of 100 faults that are discovered in 20 weeks of testing. The model parameters for the testing period are estimated using the nonlinear least square method, which is solved using the SPSS software. The estimated values of exponential SRGM are $a = 130.201$ and $b = 0.083$. The rest of the software parameters are assumed by making use of the experts option and previous studies. The assumed parameter values (cost values are in dollars) are given as:

$$\begin{aligned} r_1 = 0.2, r_2 = 0.3, r_3 = 0.4, C_1 = 70, C_2 = 5, C_3 = 30, \\ C_4 = 66, C_5 = 90, C_6 = 215, \\ R_0 = 0.9, w = 26 \text{ weeks} \end{aligned}$$

In the present study, an optimization software known as MAPLE has been applied to numerically solve and graphically interpret the optimization problem. After applying the values of all the parameters, following optimal results are obtained: optimal software time-to-market, $\tau^* = 21.86$ weeks and optimal patch time-to-market $\tau_1^* = 2.29$ weeks with the total minimum cost of $C(t)^* = 10061.61$ (in dollars). The convexity of the cost function is pictorially represented in Fig. 24.5. Further, the phase-wise faults discovered by testers and users are summarized in Table 24.6. From Table 24.6, it can be observed that testers are able to debug maximum number of faults (109 out of 130 faults) in the testing phase. However, the remaining untraced faults (21 faults) are being detected and reported by the customers to the testing team after the release of the software. Ten faults were detected during the warranty period and nine faults were detected postwarranty period.

Fig. 24.5 Concavity plot for the minimization function

Table 24.6 Phase-wise quantification of vulnerabilities

Phase	Mean value function	No. of faults removed
Pre-release phase [0, τ]	$m(\tau^*)$	108.9 (109 approx.)
First patch release phase under warranty [τ , τ_1]	$m(\tau_1 - \tau^*)$	0.74 (1 approx.)
Postpatch release phase under Warranty [τ_1 , $\tau + w$]	$m(\tau + w - \tau_1^*)$	9.16 (9 approx.)
Postwarranty phase [τ , w, T_{lc}]	$m(T_{lc} - (\tau + w)^*)$	9.29 (9 approx.)

24.4.3 Optimal Patch Release Time for Both Faults and Vulnerabilities

In this section, the optimization model [43] for patch release time considers the debugging process of both faults and security vulnerabilities. When company develops different patches for faults and vulnerabilities, extra resources are required that increase both the development cost and time. Therefore, software developers tend to release a single patch that fixes both the “faults” and “vulnerabilities” of the software. In the present section, an optimal release time problem is studied with two optimal patch release approaches. According to first approach, both the faults and vulnerabilities are fixed by the developers via single patch. As the severity of vulnerabilities is much higher than the faults, the second approach considers the release of two patches where the first patch corrects both faults and vulnerabilities together while second patch is released by the testing team to specifically fixed vulnerabilities. Hence, two optimization problems are developed by keeping the cost minimization as an objective function.

Mathematical Model

The present software reliability growth model is based on the nonhomogenous Poisson process (NHPP). The hazard rate approach is applied for predicting the mean value function of total number of faults and vulnerabilities detected during the software life cycle. The differential equation of the mean value can be described as:

$$\frac{dm(t)}{dt} = \left(\frac{f(t)}{1 - F(t)} \right) (a \cdot p_i - m(t)) \quad \text{for } i = 1, 2 \tag{24.62}$$

where p_1 is the fraction of faults out of total a defects present in the software and p_2 is the fraction of vulnerabilities, also $p_1 + p_2 = 1$; $\frac{f(t)}{1 - F(t)}$ is the combined hazard rate of fault and vulnerability detection.

The above equation can be further solved using the initial value condition that at $t = 0$, $m(t) = 0$, $F(t) = 0$ to obtain the closed-form solution:

$$m(t) = a \cdot p_i F(t) \quad \text{for } i = 1, 2 \tag{24.63}$$

Two different patch release approaches are considered in this section. In the first, no clear distinction between the faults

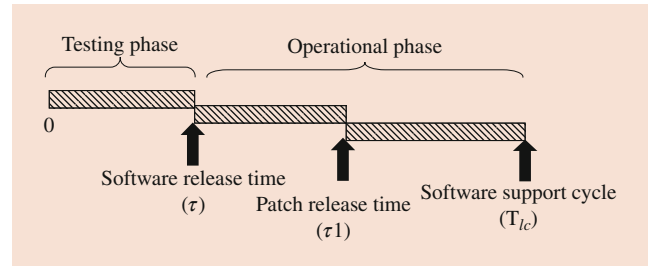

Fig. 24.6 Phase-wise description of software life cycle for faults and vulnerability discovery for approach 1

Fig. 24.7 Phase-wise description of software life cycle for faults and vulnerability discovery for approach 2

and vulnerabilities is employed with respect to criticality, discovery rate, and cost function. The pictorial representation of first approach is provided in Fig. 24.6. In the second approach, vulnerability prioritization is considered. According to this case, first patch specifically for vulnerability is released and then the fixing of faults is considered. The purpose of releasing the vulnerability patch is to make certain that the risks generated due to vulnerability exploitation are reduced on time. The phase-wise description of software life cycle for second approach is represented in Fig. 24.7.

Phase 1: Testing Phase [0, τ]

As mentioned in the previous section, testing team independently works to detect and debug defects present in the software. In this phase, debuggers assess every fault and vulnerability as equally severe. For both the approaches discussed above, the first phase has same mathematical interpretation. Thus, the expected number of faults and vulnerabilities identified during this phase can be described using the following expression:

$$m(\tau) = aF_1(\tau) \tag{24.64}$$

where $F_1(\tau)$ describes the fault distribution function of the testing team; τ is the release time of software in the market. It is further assumed that the faults detection phenomenon follows an exponential distribution pattern, that is,

$$m(\tau) = a(1 - e^{-b\tau}) \quad (24.65)$$

where b is the fault detection rate and a is the potential fault and vulnerability content present in the system.

Phase 2: Prepatch Release Phase $[\tau, \tau_1]$

Approach 1: When only single patch is released for fixing faults and vulnerabilities

After introducing the software in the market, the work of critical identification of faults and vulnerabilities is left with customers. However, the efficiency of users is much lower as compared to the professional testers. Moreover, the seriousness and criticality of vulnerability is much intensive than any other fault. Also, the cost incurred in the discovery and correction of vulnerability is quite higher as compared to the cost employed for debugging faults. Therefore, for developer's convenience, from this interval the defect distinction process starts for evaluating the debugging cost for faults and vulnerabilities separately. The total number of faults discovered and removed in this interval is represented as:

$$m_f(\tau_1 - \tau) = a \cdot p_1 \cdot (1 - F_1(\tau)) \cdot F_2(\tau_1 - \tau) \quad (24.66)$$

where $a \cdot p_1 \cdot (1 - F_1(\tau))$ is defined as the proportion of faults remained to debug from the previous phase; $F_2(\tau_1 - \tau)$ is fault detection function of the users. It is further assumed that the faults detection phenomenon follows an exponential distribution pattern, that is,

$$m_f(\tau_1 - \tau) = a \cdot p_1 \cdot e^{-b\tau} \cdot (1 - e^{-b \cdot r_1 \cdot (\tau_1 - \tau)}) \quad (24.67)$$

where $b \cdot r_1$ ($0 < r_1 \leq 1$) is the fault detection rate of the users which is some fraction of the tester's fault detection rate. In similar lines, the expected vulnerabilities discovered and corrected in this interval are defined as:

$$\Omega(\tau_1 - \tau) = a \cdot p_2 \cdot (1 - F_1(\tau)) \cdot F_3(\tau_1 - \tau) \quad (24.68)$$

where $a \cdot p_2 \cdot (1 - F_1(\tau))$ is defined as the proportion of vulnerability remained to debug from the previous phase; $F_3(\tau_1 - \tau)$ is vulnerability detection function of the users. If vulnerability discovery phenomenon follows exponential distribution function, then

$$\Omega(\tau_1 - \tau) = a \cdot p_2 \cdot e^{-b\tau} \cdot (1 - e^{-b \cdot r_2 \cdot (\tau_1 - \tau)}) \quad (24.69)$$

Approach 2: When two different patches are released for fixing vulnerabilities and both faults and vulnerabilities, respectively

According to this scenario, if developers encounter any vulnerability in the list of reported defects then they construct a patch for vulnerabilities first because they have more severe impact than any other faults. In addition, a second patch is released for correcting both vulnerabilities and faults collectively after releasing the vulnerability patch first. At time point τ_v , the patch for reported vulnerabilities during the time interval $[\tau, \tau_v]$ is released. The expected number of vulnerabilities reported during this interval becomes:

$$\Omega(\tau_v - \tau) = a \cdot p_2 \cdot (1 - F_1(\tau)) \cdot F_2(\tau_v - \tau) \quad (24.70)$$

where $a \cdot p_2 \cdot (1 - F_1(\tau))$ is the proportion of vulnerabilities that remained undetected in the testing phase; $F_2(\tau_v - \tau)$ is the vulnerability detection function of the users. Now, as the vulnerability discovery follows an exponential distribution function, the mean value function of vulnerability discovery can be described as:

$$\Omega(\tau_v - \tau) = a \cdot p_2 \cdot e^{-b\tau} \cdot (1 - e^{-b \cdot r_2 \cdot (\tau_v - \tau)}) \quad (24.71)$$

Further, a second patch is released at time-point τ_1 to fix faults and vulnerabilities simultaneously. The expected number of vulnerabilities reported by the users in the interval $[\tau_v, \tau_1]$ until the second patch is given as:

$$\begin{aligned} \Omega(\tau_1 - \tau_v) &= a \cdot p_2 \cdot (1 - F_1(\tau)) \cdot (1 - F_2(\tau_v - \tau)) \\ &\quad \cdot F_3(\tau_1 - \tau_v) \end{aligned} \quad (24.72)$$

where $a \cdot p_2 \cdot (1 - F_1(\tau)) \cdot (1 - F_2(\tau_v - \tau))$ is defined as the proportion of vulnerabilities that remain undetected by time τ_v ; $F_3(\tau_1 - \tau_v)$ is the cumulative distribution function of vulnerability discovery. When vulnerability discovery phenomenon follows exponential distribution function, then

$$\Omega(\tau_1 - \tau_v) = a \cdot p_2 \cdot e^{-b\tau} \cdot e^{-b \cdot r_2 \cdot (\tau_v - \tau)} \cdot (1 - e^{-b \cdot r_2 \cdot (\tau_1 - \tau_v)}) \quad (24.73)$$

Similarly, the expected number of faults identified and reported by the users in the entire interval $[\tau, \tau_1]$ until the patch for faults is released is given as:

$$m_f(\tau_1 - \tau) = a \cdot p_1 \cdot (1 - F_1(\tau)) \cdot F_4(\tau_1 - \tau) \quad (24.74)$$

where $a \cdot p_1 \cdot (1 - F_1(\tau))$ is the proportion of faults that remain unidentified in the previous phase; $F_4(\tau_1 - \tau)$ is the cumulative distribution function of fault detection by the users in the second phase. If fault detection phenomenon

follows exponential function, then expected number of faults identified during this phase becomes:

$$m_f(\tau_1 - \tau) = a \cdot p_1 \cdot e^{-b\tau} \cdot (1 - e^{-b \cdot r_1 \cdot (\tau_1 - \tau)}) \quad (24.75)$$

Phase 3: Postpatch Release Phase $[\tau_1, T_{lc}]$

Approach 1: When only single patch is released for fixing faults and vulnerabilities

After the patch is delivered to the users, they install it to fix the bugs and vulnerabilities, which were identified and reported by them. However, not all defects will be fixed by the single patch. Therefore, faults and vulnerability discovery phenomenon continues even after the release of a patch. Developers assist their customers for correcting the bugs and security vulnerabilities till the software lifecycle. Thus, the expected number of faults detected by the users during postrelease phase becomes:

$$m_f(T_{lc} - \tau_1) = a \cdot p_1 \cdot (1 - F_1(\tau)) \cdot (1 - F_2(\tau_1 - \tau)) \cdot F_4(T_{lc} - \tau_1) \quad (24.76)$$

Further, the total number of vulnerabilities discovered and removed during this phase is expressed as:

$$\Omega(T_{lc} - \tau_1) = a \cdot p_2 \cdot (1 - F_1(\tau)) \cdot (1 - F_3(\tau_1 - \tau)) \cdot F_5(T_{lc} - \tau_1) \quad (24.77)$$

where $a \cdot p_1 \cdot (1 - F_1(\tau)) \cdot (1 - F_2(\tau_1 - \tau))$ and $a \cdot p_1 \cdot (1 - F_1(\tau)) \cdot (1 - F_3(\tau_1 - \tau))$ are the residual faults and vulnerabilities, respectively, that remain undetected in the previous period; $F_4(T_{lc} - \tau_1)$ is the fault detection function and $F_5(T_{lc} - \tau_1)$ is the vulnerability discovery function in duration $[\tau_1, T_{lc}]$. For exponentially discovery distribution, the expected number of faults and vulnerabilities detection, respectively, becomes:

$$m_f(T_{lc} - \tau_1) = a \cdot p_1 \cdot e^{-b\tau} \cdot e^{-b \cdot r_1 \cdot (\tau_1 - \tau)} \cdot (1 - e^{-b \cdot r_1 \cdot (T_{lc} - \tau_1)}) \quad (24.78)$$

$$\Omega(T_{lc} - \tau_1) = a \cdot p_2 \cdot e^{-b\tau} \cdot e^{-b \cdot r_2 \cdot (\tau_1 - \tau)} \cdot (1 - e^{-b \cdot r_2 \cdot (T_{lc} - \tau_1)}) \quad (24.79)$$

Approach 2: When two different patches are released for fixing vulnerabilities and both faults and vulnerabilities, respectively

After the release of two patches at time-point τ_v and τ_1 , the fault and vulnerability discovery process continues until the software life cycle ends at time T_{lc} . Therefore, the expected number of faults identified in the last phase is given as:

$$m_f(T_{lc} - \tau_1) = a \cdot p_1 \cdot (1 - F_1(\tau)) \cdot (1 - F_4(\tau_1 - \tau)) \cdot F_5(T_{lc} - \tau_1) \quad (24.80)$$

Similarly, the expected number of vulnerabilities discovered is represented as:

$$\Omega(T_{lc} - \tau_1) = a \cdot p_1 \cdot (1 - F_1(\tau)) \cdot (1 - F_2(\tau_v - \tau)) \cdot (1 - F_3(\tau_1 - \tau_v)) \cdot F_6(T_{lc} - \tau_1) \quad (24.81)$$

When detection distribution follows exponential function, then

$$m_f(T_{lc} - \tau_1) = a \cdot p_1 \cdot e^{-b\tau} \cdot e^{-b \cdot r_1 \cdot (\tau_1 - \tau)} \cdot (1 - e^{-b \cdot r_1 \cdot (T_{lc} - \tau_1)}) \quad (24.82)$$

$$\Omega(T_{lc} - \tau_1) = a \cdot p_2 \cdot e^{-b\tau} \cdot e^{-b \cdot r_2 \cdot (\tau_v - \tau)} \cdot e^{-b \cdot r_2 \cdot (\tau_1 - \tau_v)} \cdot (1 - e^{-b \cdot r_2 \cdot (T_{lc} - \tau_1)}) \quad (24.83)$$

Cost Modeling

The cost functions associated with the testing and debugging of faults and vulnerabilities in the software are listed in Table 24.7.

Thus, the total cost can be obtained by adding all the cost components become:

$$\text{Total_Cost, } C(t) = C_{\text{testing_phase}}(t) + C_{[0, \tau]}(t) + C_{[\tau, \tau_1]}(t) + C_{[\tau_1, T_{lc}]}(t) \quad (24.84)$$

The optimization problem with an aim of minimizing the overall cost function is defined as:

Approach 1: Single-patch model

Minimize

$$C^1(t) = C_1 \cdot \tau + C_2 \cdot a (1 - e^{-b\tau}) + C_3 \cdot a p_1 (e^{-b\tau} (1 - e^{-b r_1 (\tau_1 - \tau)}) + C_4 \cdot a p_2 (e^{-b\tau} (1 - e^{-b r_2 (\tau_1 - \tau)}) + C_5 \cdot a p_1 (e^{-b\tau} (e^{-b r_1 (\tau_1 - \tau)}) (1 - e^{-b r_1 (T_{lc} - \tau_1)}) + C_6 \cdot a p_2 (e^{-b\tau} (e^{-b r_2 (\tau_1 - \tau)}) (1 - e^{-b r_2 (T_{lc} - \tau_1)})) \quad (24.85)$$

Table 24.7 Components of different cost functions

Cost components	Description	Cost function
Testing cost	Testing cost refers to per unit testing cost and is associated with the tester’s activities such as test planning, test case generation, test execution, and analysis of testing results.	$C_{\text{testing}}(t) = C_1 \tau$
Faults debugging cost during testing phase	This cost comprises direct cost associated with identifying and fixing the bugs	$C_{[0, \tau]}(t) = C_2 m(\tau)$
Faults debugging cost during prepatch release phase	Debugging cost during this phase is the cost of debugging of the faults and vulnerabilities detected and reported by the users	Approach 1: $C_{[\tau, \tau_1]}(t) = C_3 m_f (\tau_1 - \tau) + C_4 \Omega (\tau_1 - \tau)$ Approach 2: $C_{[\tau, \tau_1]}(t) = C_3 \Omega (\tau_v - \tau) + C_4 \Omega (\tau_1 - \tau_v) + C_5 m_f (\tau_1 - \tau)$ where $\tau < \tau_v < \tau_1$
Faults debugging cost during postpatch release period	This cost includes the debugging cost in operational phase after patch has been released for the faults and vulnerabilities reported by the users	Approach 1: $C_{[\tau_1, T_{lc}]}(t) = C_5 m_f (T_{lc} - \tau_1) + C_6 \Omega (T_{lc} - \tau_1)$ Approach 2: $C_{[\tau_1, T_{lc}]}(t) = C_6 m_f (T_{lc} - \tau_1) + C_7 \Omega (T_{lc} - \tau_1)$

Approach 2: Two-patch model
Minimize

$$\begin{aligned}
 C^2(t) = & C_1 \cdot \tau + C_2 \cdot a (1 - e^{-b\tau}) + C_3 \cdot ap_2 (e^{-b\tau} \\
 & (1 - e^{-br_2(r_v-\tau)}) + C_4 \cdot ap_2 (e^{-b\tau}) (e^{-br_2(r_v-\tau)}) \\
 & (1 - e^{(-br_2(\tau_1-\tau_v))}) + C_5 \cdot ap_1 (e^{-b\tau}) (1 - e^{-br_1(\tau_1-\tau)}) \\
 & + C_6 \cdot ap_1 (e^{-b\tau}) (e^{-br_1(r_1-\tau)}) (1 - e^{-br_1(T_{lc}-\tau_1)}) \\
 & + C_7 \cdot ap_2 (e^{-b\tau}) (e^{-br_2(r_v-\tau)}) (e^{(-br_2(\tau_1-\tau_v))}) \\
 & (1 - e^{-br_2(T_{lc}-\tau_1)})
 \end{aligned}
 \tag{24.86}$$

Numerical Example

To understand the practical application of the above-discussed model, a numerical example is provided. The past data set of fault count consisting of 535 defects that were identified during the testing of 109 days was obtained from Tohma et al. [44]. It is considered that the data set contains both faults and vulnerabilities. The mean value function for exponential model is $m(t) = a \cdot p_1 \cdot (1 - \exp(-b \cdot t))$ for faults and $m(t) = a \cdot p_2 \cdot (1 - \exp(-b \cdot t))$ for vulnerabilities. The estimated values of the parameters of the exponential model using the SPSS software are: $a = 713.889$ and $b = 0.015$. Further, the remaining parameter values are assumed based on the experts opinion, that is, $r_1 = 0.5$, $r_2 = 0.3$, $p_1 = 0.9$, $p_2 = 0.1$, and $T_{lc} = 1000$.

The objective of the optimization problem is to evaluate the optimal time-to-market the new software and optimal time to release the patch for fixing the vulnerabilities and faults. The cost minimization problem is solved using the computational software known as MAPLE using the following cost parameters value (in dollars):

$$C_1 = 350, C_2 = 260, C_3 = 300, C_4 = 2400, C_5 = 310, \\
 C_6 = 2300 \text{ (For Approach 1)}$$

$$C_1 = 350, C_2 = 260, C_3 = 2400, C_4 = 2400,$$

$$C_5 = 300, C_6 = 310, C_7 = 2300 \text{ (For Approach 2)}$$

The optimal results obtained using the above-mentioned values of the parameter set are summarized in Table 24.8. From the results listed in the Table 24.8, it can be comprehend that for the both the approaches whether releasing a single patch or two patches, the optimal time to release a software will be same, that is, the software should be released after approximately 114 days of testing. Nevertheless, according to the actual observation of the debug data, the testing was done only for 109 days in which 535 defects were found. It indicates that the developer should extend the testing for 5 more days in order to debug more faults and vulnerabilities at a minimum cost.

Further, the phase-wise description of number of faults and vulnerabilities debugged is summarized in Table 24.9. From Table 24.9, it can be observed that the number of defects detected/debugged in the testing phase is 584.6 (approximately 585). If testing is continued for extra 5 days, then 50 more defects can be debugged in the testing phase. Also, during operational phase, the number of faults detected in prepatch release phase are 74.12 and number of vulnerabilities discovered/patched are 5.89 when only single patch is released. Similarly, when two patches are released, then the total vulnerabilities discovered until second patch is released are 5.88. Additionally, the total defects debugged in the post patch release in both the approaches are 48.86.

24.4.4 Optimal Patch Release Time for Vulnerable Software Systems

In this section, the debugging process of vulnerabilities in the operational phase is explicitly considered. The optimal patch time-to-market for fixing the software vulnerabilities

Table 24.8 Optimal release time results

Patch policy	Optimal release time	Optimal patch release time		Optimal cost (in dollars)
Approach 1	113.9	135.15		239606.9
		First patch	Second patch	
Approach 2	113.9	75.03	60.12	239606.9

Table 24.9 Phase-wise description of defects using different approaches

Single-patch optimization problem			Two-patch optimization problem		
Phase	Mean value function	No. of defects removed	Phase	Mean value function	No. of defects removed
[0, τ]	$m(\tau)$	584.6	[0, τ]	$m(\tau)$	584.6
[τ, τ ₁]	$m_f(\tau_1 - \tau)$	74.12	[τ, τ _v]	$\Omega(\tau_v - \tau)$	3.7
	$\Omega(\tau_1 - \tau)$	5.89	[τ _v , τ ₁]	$\Omega(\tau_1 - \tau_v)$	2.18
[τ ₁ , T _{lc}]	$m_f(T_{lc} - \tau_1)$	42.07	[τ, τ ₁]	$m_f(\tau_1 - \tau)$	74.12
	$\Omega(T_{lc} - \tau_1)$	6.79	[τ ₁ , T _{lc}]	$m_f(T_{lc} - \tau_1)$	42.07
				$\Omega(T_{lc} - \tau_1)$	6.79

whose severity is much greater than the faults is determined. It is assumed that the software is released at time-point 0. The objective of the study is to determine the optimal patch release time τ that minimizes the total cost incurred by developer in vulnerability discovery process. Further, the vulnerability discovery process in the operational phase is divided into parts: prepatch release phase $[0, \tau]$ and postpatch release phase $[\tau, T_{lc}]$. Also, the time instant at which software vendor releases the patch is also the testing termination time. It is also assumed that the cost of patching is negligible and does not introduce any new vulnerability in the system.

Mathematical Modeling

The mathematical expression for the vulnerability discovery process in the operational phase is described in this subsection. The pictorial representation of phase-wise description of software life cycle is given in Fig. 24.8. When software is in market, the vulnerabilities are identified by both the testers and the users. Users on the other hand may belong to either category of *white hat* or *black hat* depending on their intention of discovering vulnerabilities. Black hat are unethical hackers who attempt to identify security loopholes in order to exploit the system, whereas white hat discover vulnerabilities with the permission of the company. They act as reporters who inform about the security weaknesses to the appropriate authority in order to fix them.

Phase 1: Prepatch Release Phase [0, τ]

It is considered that software product is released in the market at time 0. Even after the release, some security breaches are still present in the system. Therefore, in operational phase, vulnerabilities are being identified by the testers and users (black hat and white hat), that is,

$$\Omega(\tau) = \Omega_{\text{tester}}(\tau) + \Omega_{\text{black_hat}}(\tau) + \Omega_{\text{white_hat}}(\tau) \tag{24.87}$$

Fig. 24.8 Phase-wise description of software life cycle for vulnerability discovery

Besides, it is assumed that the some fraction, say λ_1 , of the total vulnerabilities is discovered by the testing team during this phase and identified by the testing team during field-testing. The λ_2 fraction of undetected vulnerabilities is being exploited by the black hat users and the remaining, that is, $\lambda_3 = (1 - \lambda_1 - \lambda_2)$ proportion of the undiscovered bugs, are detected by the customers who then immediately report it to the developers for correcting it. Thus, the total vulnerability discovery during this phase becomes:

$$\Omega(\tau) = \lambda_1 \bar{V}F_{\text{tester}}(\tau) + \lambda_2 \bar{V}F_{\text{black_hat}}(\tau) + \lambda_3 \bar{V}F_{\text{white_hat}}(\tau) \tag{24.88}$$

where

$F_{\text{tester}}(\tau) = (1 - e^{-b\tau})$ is the exponential distribution function for vulnerability discovery by testers in interval $[0, \tau]$

$F_{\text{black_hat}}(\tau) = (1 - e^{-br\tau})$ is the exponential distribution function for vulnerability discovery by hackers or black hat users

$F_{\text{white_hat}}(\tau) = (1 - e^{-bs\tau})$ is the exponential distribution function for vulnerability discovery by white hat users

Moreover, the vulnerability discovery rate of black-hat ($b \cdot r$) and white hat ($b \cdot s$) users is some fraction of the vulnerability discovery rate of the testing team.

Phase 2: Postpatch Release Phase [τ, T_{lc}]

At time τ , the developers release the patch for the discovered vulnerabilities and at this time point testers stop the vulnerability discovery process. Therefore, during postpatch release phase, only users either black hat or white hat identify the vulnerabilities in the software system. The remaining number of vulnerabilities that were undetected in previous phase is discovered during this period. Let λ_4 proportion of undetected vulnerabilities is identified by the hackers and the remaining proportion of vulnerabilities, that is, $1 - \lambda_4 = \lambda_5$, is detected by the white hat users. Thus, the total number of vulnerabilities discovered in this phase is given by:

$$\Omega(T_{lc} - \tau) = \lambda_4 (\bar{V} - \Omega(\tau)) F_{\text{black_hat}}(T_{lc} - \tau) + \lambda_5 (\bar{V} - \Omega(\tau)) F_{\text{white_hat}}(T_{lc} - \tau) \tag{24.89}$$

where $(\bar{V} - \Omega(\tau))$ is the undiscovered vulnerabilities from phase 1 that are identified by the users in this phase and $\lambda_4 + \lambda_5 = 1$. If vulnerability discovery process follows exponential distribution function, then

$$\begin{aligned} \Omega(T_{lc} - \tau) = & \lambda_4 (\bar{V} - \lambda_1 \bar{V} (1 - e^{-b r \tau}) \\ & - \lambda_2 \bar{V} (1 - e^{-b r \tau}) - \lambda_3 \bar{V} (1 - e^{-b s \tau})) (1 - e^{-b r (T_{lc} - \tau)}) \\ & + \lambda_5 (\bar{V} - \lambda_1 \bar{V} (1 - e^{-b r \tau}) - \lambda_2 \bar{V} (1 - e^{-b r \tau}) \\ & - \lambda_3 \bar{V} (1 - e^{-b s \tau})) (1 - e^{-b s (T_{lc} - \tau)}) \end{aligned} \tag{24.90}$$

Cost Modeling

The cost functions associated with the testing and debugging of vulnerabilities in the software system are listed in Table 24.10.

Thus, the objective function can be obtained by adding all the cost components:

$$\begin{aligned} \text{Minimize Total_Cost, } C(t) = & C_{\text{testing_phase}}(t) + C_{[0, \tau]}(t) \\ & + C_{[\tau, T_{lc}]}(t) \end{aligned} \tag{24.91}$$

Numerical Example

The vulnerability data for numerical illustration purpose is collected from National Vulnerability Database (NVD), the Mitre Corporation website, and ICAT database. The testing and debugging data of an operating system Windows XP (SP2 Professional) is obtained for the present study. In this data set, execution time is reported in terms of months and vulnerabilities in terms of cumulative vulnerabilities at the end of each month. The data set consists of 17 vulnerabilities, which were reported from January 2007 to 2013. Statistical Package for Social Science (SPSS) tool has been used for estimating the parameter values. The estimated values of the parameters are $\bar{V} = 17.902$ and $b = 0.284$.

Furthermore, the vulnerability discovery rate of hacker and white hat users is considered some fraction of the tester’s vulnerability discovery rate, that is, the detection rate of black hat and white hat users are $b \cdot r$ and $b \cdot s$ ($0 < r, s \leq 1$), respectively. The remaining parameter values (cost parameters are in dollars) are assumed based on the expert’s opinion, that is,

$$\begin{aligned} r = 0.1136, \quad s = 0.0568, \quad C_1 = 50, \quad C_2 = 100, \quad C_3 = 250, \\ C_4 = 150, \quad C_5 = 250, \quad C_6 = 150, \\ \lambda_1 = 0.5, \quad \lambda_2 = 0.3, \quad \lambda_3 = 0.2, \quad \lambda_4 = 0.6, \quad \lambda_5 = 0.4, \\ T_{lc} = 50 \end{aligned}$$

The values of the parameters are substituted in the objective function to evaluate the optimal time-to market the patch, which minimizes the total cost function. The optimization problem is solved using MAPLE software and calculated value of optimal patch release time as $\tau^* = 3.320$, that is, software vendors should release the software vulnerability patch after 3 months (approximately) from the

Table 24.10 Components of different cost functions

Cost components	Description	Cost function
Testing cost	Testing cost refers to per unit testing cost and is associated with the tester’s activities such as test planning, test case generation, test execution, and analysis of testing results	$C_{\text{testing}}(t) = C_1 \tau$
Vulnerability discovery cost during prepatch release phase	This cost function includes the efforts expended on discovering the vulnerabilities by the testers and white hat users. It also includes the loss company suffer due the vulnerabilities identified by the black hat users	$C_{[0, \tau]}(t) = C_2 \Omega_{\text{tester}}(\tau) + C_3 \Omega_{\text{black_hat}}(\tau) + C_4 \Omega_{\text{white_hat}}(\tau)$
Vulnerability discovery cost during postpatch release period	This includes the cost of vulnerabilities discovery by the users after patch release	$C_{[\tau, T_{lc}]}(t) = C_5 \Omega_{\text{black_hat}}(T_{lc} - \tau) + C_6 \Omega_{\text{white_hat}}(T_{lc} - \tau)$

Fig. 24.9 Convexity plot for the cost function

release of the software and corresponding minimum cost is $C^*(t) = 2614.76$ (in dollars). The convexity of the objective function is established using the graph as shown in Fig. 24.9.

24.5 Concluding Remarks

The present study focuses on predicting the vulnerability discovery and optimal patching phenomenon of software products. The first part of the chapter examines the vulnerability discovery process by reviewing the mathematical models that examines the discovery pattern of security weaknesses. The role of software users, resource consumption, and coverage function on the defect detection process are analyzed. The actual vulnerability data of the software products were obtained to validate the models. The second part of the chapter centered on determining the optimal time to release the software and security patch in the market. Three different cost models are formulated by considering different scenarios. The results obtained in the current research can help managers in assessing the vulnerability discovery growth rate and optimal patch management practices.

Abstract

After a brief overview of existing models in software reliability in Sects. 25.1 and 25.2 discusses a generalized nonhomogeneous Poisson process model that can be used to derive most existing models in the software reliability literature. Section 25.3 describes a generalized random field environment (RFE) model incorporating both the testing phase and operating phase in the software development cycle for estimating the reliability of software systems in the field. In contrast to some existing models that assume the same software failure rate for the software

Many software reliability models have been proposed to help software developers and managers understand and analyze the software development process, estimate the development cost, and assess the level of software reliability. Among these software reliability models, models based on the nonhomogeneous Poisson process (NHPP) have been successfully applied to model the software failure processes that possess certain trends such as reliability growth or deterioration. NHPP models seem to be useful to predict software failures and software reliability in terms of time and to determine when to stop testing and release the software [1].

Currently most existing NHPP software reliability models have been carried out through the fault intensity rate function and the mean-value functions (MVF) $m(t)$ within a controlled operating environment [2–55]. Obviously, different models use different assumptions and therefore provide different mathematical forms for the mean-value function $m(t)$. Table 25.1 shows a summary of several existing models appearing in the software reliability engineering literature [14]. Generally, these models are applied to software testing data and then to make predictions of software failures and reliability

Table 25.1 Summary of NHPP software reliability models [44, 50]

Model name	MVF $[m(t)]$
Goel–Okumoto (G–O)	$m(t) = a(1 - e^{-bt})$
Delayed S-shaped	$m(t) = a[1 - (1 + bt)e^{-bt}]$
Inflection S-shaped SRGM	$m(t) = \frac{a(1 - e^{-bt})}{1 + \beta e^{-bt}}$
HD/G–O model	$m(t) = \log \left[(e^a - c) / (e^{ae^{-bt}} - c) \right]$
Yamada exponential	$m(t) = a \left(1 - e^{-r\alpha(1 - e^{-(\beta t)})} \right)$
Yamada Rayleigh	$m(t) = a \left(1 - e^{-r\alpha \left(1 - e^{-(\beta t^2/2)} \right)} \right)$
Yamada imperfect debugging model (1)	$m(t) = \frac{ab}{\alpha + b} (e^{\alpha t} - e^{-bt})$
Yamada imperfect debugging model (2)	$m(t) = a \left(1 - e^{-bt} \right) \left(1 - \frac{\alpha}{b} \right) + \alpha at$
PNZ model	$m(t) = \frac{a}{1 + \beta} e^{-bt} \left[(1 - e^{-bt}) \left(1 - \frac{\alpha}{b} \right) + \alpha at \right]$
Pham–Zhang model	$m(t) = \frac{1}{1 + \beta e^{-bt}} \left[(c + a) (1 - e^{-bt}) - \frac{a}{b - \alpha} (e^{-\alpha t} - e^{-bt}) \right]$
Dependent-parameter model (Model 1) [26]	$m(t) = \alpha(1 + \gamma t)(\gamma t + e^{-\gamma t} - 1)$
Dependent-parameter model with $m(t_0) \neq 0$ (Model 1a) [26]	$m(t) = m_0 \left(\frac{\gamma t + 1}{\gamma t_0 + 1} \right) e^{-\gamma(t-t_0)} + \alpha(\gamma t + 1) [\gamma t - 1 + (1 - \gamma t_0) e^{-\gamma(t-t_0)}]$
Vtub-shaped fault-detection rate model [28]	$m(t) = N \left(1 - \left(\frac{\beta}{\beta + a^b - 1} \right)^\alpha \right)$
Pham Inflexion model [29]	$m(t) = N \left(1 - \frac{1}{\left(\frac{\beta + e^{bt}}{1 + \beta} \right)^{\frac{a}{b}}} \right)$
Logistic fault-detection model [44]	$m(t) = \frac{a}{1 + d \left(\frac{1 + \beta}{\beta + e^{bt}} \right)}$
Pham-Zhang model [8]	$m(t) = \frac{1}{1 + \beta e^{-bt}} \left((c + a) (1 - e^{-bt}) - \frac{a}{b - \alpha} (e^{-\alpha t} - e^{-bt}) \right)$

in the field. The underlying assumption for this application is that the field environments are the same as, or close to, a testing environment; this is valid for some software systems that are only used in one environment throughout their entire lifetime. However, this assumption is not valid for many applications where a software program may be used in many different locations once it is released.

The operating environments for the software in the field are quite different. The randomness of the field environment will affect software failure and software reliability in an unpredictable way. *Yang* and *Xie* [15] mentioned that the operational reliability and testing reliability are often different from each other, but they assumed that the operational failure rate is still close to the testing failure rate, and hence that the difference between them is that the operational failure rate decreases with time, while the testing failure rate remains constant. *Zhang* et al. [16] proposed an NHPP software reliability calibration model by introducing a calibration factor. This calibration factor, K , obtained from software failures in both the testing and field operation phases will be a multiplier to the software failure intensity. This calibrated software reliability model can be used to assess and adjust the predictions of software reliability in the operation phase.

Instead of relating the operating environment to the failure intensity λ , in this chapter we assume that the effect of

the operating environment is to multiply the unit failure-detection rate $b(t)$ achieved in the testing environment using the concept of the proportional hazard approach suggested by *Cox* [56]. If the operating environment is more liable to software failure, then the unit fault-detection rate increases by some factor η greater than 1. Similarly, if the operating environment is less liable to software failure, then the unit fault-detection rate decreases by some positive factor η less than 1.

This chapter describes a model based on the NHPP model framework for predicting software failures and evaluating the software reliability in random field environments. A generalized random field environment (RFE) model incorporating both the testing phase and operating phase in the software development cycle with Vtub-shaped fault-detection rate is discussed. An explicit solution of the mean value function for this model is derived. Numerical results of some selected NHPP models are also discussed based on existing criteria such as mean squared error (MSE), predictive power, predictive-ratio risk, and normalized criteria distance from a set of software failure data.

Based on this model, developers and engineers can further develop specific software reliability models customized to various applications.

Notations	
$R(t)$	Software reliability function
η	Random environmental factor
$G(\eta)$	Cumulative distribution function of η
γ	Shape parameter of gamma distributions
θ	Scale parameter of gamma distributions
α, β	Parameters of beta distributions
$N(t)$	Counting process which counts the number of software failures discovered by time t
$m(t)$	Expected number of software failures detected by time t , $m(t) = E[N(t)]$
$a(t)$	Expected number of initial software faults plus introduced faults by time t
$m_1(t)$	Expected number of software failures in testing by time t
$m_2(t)$	Expected number of software failures in the field by time t
$a_1(t)$	Expected number of initial software faults plus introduced faults discovered in the testing by time t
a	Number of initial software faults at the beginning of testing phase, is a <i>software parameter</i> that is directly related to the software itself
T	Time to stop testing and release the software for field operations
a_F	Number of initial software faults in the field (at time T)
$b(t)$	Failure detection rate per fault at time t , is a <i>process parameter</i> that is directly related to testing and failure process
p	Probability that a fault will be successfully removed from the software
q	Error introduction rate at time t in the testing phase
MLE	Maximum likelihood estimation
RFE-model	Software reliability model subject to a random field environment
γ -RFE	Software reliability model with a gamma distributed field environment
β -RFE	Software reliability model with a beta distributed field environment
NHPP	Nonhomogeneous Poisson process
SRGM	Software reliability growth model
HD	Hossain–Ram
PNZ	Pham–Nordman–Zhang
G–O	Goel–Okumoto
MLE	Maximum likelihood estimation
RFE	Random field environment

25.1 A Generalized NHPP Software Reliability Model

A generalized NHPP model studied by Zhang et al. [7] can be formulated as follows:

$$m'(t) = \eta b(t) [a(t) - pm(t)], \tag{25.1}$$

$$a'(t) = q \cdot m'(t), \tag{25.2}$$

where $m(t)$ is the number of software failures expected to be detected by time t . If the marginal conditions are given as $m(0) = 0$ and $a(0) = a$, then for a specific environmental factor η , the solutions to (25.1) and (25.2) are, given in [7], as follows

$$m_\eta(t) = a \int_0^t \eta b(u) e^{-\int_0^u \eta(p-q)b(\tau) d\tau} du, \tag{25.3}$$

$$a_\eta(t) = a \left[1 + \int_0^t \eta q b(u) e^{-\int_0^u \eta(p-q)b(\tau) d\tau} du \right]. \tag{25.4}$$

This is the generalized form of the NHPP software reliability model. When $p = 1$, $\eta = 1$, and $q = 0$, then for any given function $a(t)$ and $b(t)$, all the functions listed in Table 25.1 can easily be obtained.

25.2 Generalized Random Field Environment (RFE) Model

The testing environment is often a controlled environment with much less variation compared to the field environments, which may be quite different for the field application software. Once a software program is released, it may be used in many different locations and various applications in industries. The operating environments for the software are quite different. Therefore, the randomness of the field environment will affect the cumulative software failure data in an unpredictable way.

Figure 25.1 shows the last two phases of the software life cycle: in-house testing and field operation [18]. If T is the time to stop testing and release the software for field operations, then the time period $0 \leq t \leq T$ refers to the time period of *software testing*, while the time period $T \leq t$ refers to the postrelease period – *field operation*.

The environmental factor η is used to capture the uncertainty about the environment and its effects on the software failure rate. In general, software testing is carried out in a controlled environment with very small variations, which can be used as a reference environment where η is constant and equals to 1. For the field operating environment, the

Fig. 25.1 Testing versus field environment where T is the time to stop testing and release the software

environmental factor η is assumed to be a non-negative random variable (RV) with probability density function (PDF) $f(\eta)$, that is,

$$\eta = \begin{cases} 1 & t \leq T \\ \text{RV with PDF } f(\eta) & t \geq T \end{cases} \quad (25.5)$$

If the value of η is less than 1, this indicates that the conditions are less favorable to fault detection than that of testing environment. Likewise, if the value of η is greater than 1, it indicates that the conditions are more favorable to fault detection than that of the testing environment.

From (25.3) and (25.5), the mean-value function and the function $a_1(t)$ during testing can be obtained as

$$\begin{aligned} m_1(t) &= a \int_0^t b(u) e^{-\int_0^u (p-q)b(\tau) d\tau} du \quad t \leq T, \\ a_1(t) &= a \left[1 + \int_0^t qb(u) \times e^{-\int_0^u (p-q)b(\tau) d\tau} du \right] \quad t \leq T. \end{aligned} \quad (25.6)$$

For the field operation where $t \geq T$, the mean-value function can be represented as

$$\begin{aligned} m_2(t) &= m_1(T) + \int_0^\infty m_\eta(t) f(\eta) d\eta = m_1(T) \\ &+ \int_0^\infty \left[a_F \int_T^t \eta b(u) \times e^{-\int_T^u \eta (p-q)b(\tau) d\tau} du \right] f(\eta) d\eta \quad t \geq T \\ &= m_1(T) + \int_T^t a_F b(u) \left[\int_0^\infty \eta \times e^{-\eta \int_T^u (p-q)b(\tau) d\tau} f(\eta) d\eta \right] du, \end{aligned} \quad (25.7)$$

where a_F is the number of faults in the software at time T . Using the Laplace transform formula, the mean-value function can be rewritten as

$$\begin{aligned} m_2(t) &= m_1(T) + \int_T^t a_F b(u) \times \left(-\frac{dF^*(s)}{ds} \Big|_{s=\int_0^u (p-q)b(\tau) d\tau} \right) du, \\ t &\geq T \\ &= m_1(T) + \frac{a_F}{(p-q)} \times \int_T^t \left\{ -dF^* \left[(p-q) \int_T^u b(\tau) d\tau \right] \right\}, \end{aligned}$$

where $F^*(s)$ is the Laplace transform of the PDF $f(x)$ and

$$\int_0^\infty xe^{-x \cdot s} f(x) dx = -\frac{dF^*(s)}{ds}$$

or, equivalently,

$$\begin{aligned} m_2(t) &= m_1(T) - \frac{a_F}{(p-q)} \times F^* \left[(p-q) \int_T^t b(\tau) d\tau \right] \Big|_T^t, \quad t \leq T \\ &= m_1(T) + \frac{a_F}{(p-q)} \times \left\{ F^*(0) - F^* \left[(p-q) \int_T^t b(\tau) d\tau \right] \right\}. \end{aligned}$$

Notice that $F^*(0) = \int_0^\infty e^{-0x} f(x) dx = 1$, so

$$\begin{aligned} m_2(t) &= m_1(T) + \frac{a_F}{(p-q)} \\ &\times \left\{ 1 - F^* \left[(p-q) \int_T^t b(\tau) d\tau \right] \right\} \quad t \geq T. \end{aligned}$$

The expected number of faults in the software at time T is given by

$$\begin{aligned} a_F &= a_1(T) - pm_1(T) \\ &= a \left[1 - \int_0^T (p-q) b(u) e^{-\int_0^u (p-q)b(\tau) d\tau} du \right] \\ &= a e^{-\int_0^T (p-q)b(\tau) d\tau}. \end{aligned}$$

The generalized RFE model can be obtained as

$$m(t) = \begin{cases} \frac{a}{(p-q)} \left(1 - e^{-(p-q) \int_0^t b(\tau) d\tau} \right) & t \leq T \\ \frac{a}{(p-q)} \left\{ 1 - e^{-(p-q) \int_0^T b(\tau) d\tau} \times F^* \left[(p-q) \int_T^t b(\tau) d\tau \right] \right\} & t \geq T. \end{cases} \quad (25.8)$$

The model in (25.8) is a generalized software reliability model subject to random field environments. The next section presents specific RFE models for the gamma and beta distributions of the random field environmental factor η .

25.3 RFE Software Reliability Models

Obviously, the environmental factor η must be non-negative. Any suitable non-negative distribution may be used to describe the uncertainty about η . In this section, we present two RFE models. The first model is a γ -RFE model, based on the gamma distribution, which can be used to evaluate and predict software reliability in field environments where the software failure-detection rate can be either greater or less than the failure detection rate in the testing environment. The second model is a β -RFE model, based on the beta distribution, which can be used to predict software reliability in field environments where the software failure detection rate can only be less than the failure detection rate in the testing environment.

25.3.1 γ -RFE Model

In this model, we use the gamma distribution to describe the random environmental factor η . This model is called the γ -RFE model.

Assume that η follows a gamma distribution with a probability density function as follows:

Fig. 25.2 A gamma density function

$$f_{\gamma}(\eta) = \frac{\theta^{\gamma} \eta^{\gamma-1} e^{-\theta \cdot \eta}}{\Gamma(\gamma)}, \quad \gamma, \theta > 0; \eta \geq 0. \quad (25.9)$$

The gamma distribution has sufficient flexibility and has desirable qualities with respect to computations [18]. Figure 25.2 shows an example of the gamma density probability function. The gamma function seems to be reasonable to describe a software failure process in those field environments where the software failure-detection rate can be either greater (i.e., $\eta > 1$) or less than (i.e., $\eta < 1$) the failure-detection rate in the testing environment.

The Laplace transform of the probability density function in (25.9) is

$$F^*(s) = \left(\frac{\theta}{\theta + s} \right)^{\gamma}. \quad (25.10)$$

Assume that the error-detection rate function $b(t)$ is given by

$$b(t) = \frac{b}{1 + ce^{-bt}}. \quad (25.11)$$

where b is the asymptotic unit software-failure detection rate and c is the parameter defining the shape of the learning curve, then from (25.8) the mean-value function of the γ -RFE model can be obtained as follows

$$m_{\gamma}(t) = \begin{cases} \frac{a}{(p-q)} \left[1 - \left(\frac{1+c}{e^{bt}+c} \right)^{(p-q)} \right] & t \leq T, \\ \frac{a}{(p-q)} \left[1 - \left(\frac{1+c}{e^{bt}+c} \right)^{(p-q)} \times \left(\frac{\theta}{\theta + (p-q) \ln \left(\frac{c+e^{bt}}{c+e^{bT}} \right)} \right)^{\gamma} \right] & t \geq T. \end{cases} \quad (25.12)$$

25.3.2 β -RFE Model

This section presents a model using the beta distribution that describes the random environmental factor η , called the β -RFE model.

Fig. 25.3 A PDF curve of the beta distribution

The beta PDF is

$$f_{\beta}(\eta) = \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha) \Gamma(\beta)} \eta^{\alpha-1} (1 - \eta)^{\beta-1}, \quad \alpha > 0, \beta > 0; 0 \leq \eta \leq 1. \quad (25.13)$$

Figure 25.3 shows an example of the beta density function. It seems that the β -RFE model is a reasonable function to describe a software failure process in those field environments where the software failure-detection rate can only be less than the failure-detection rate in the testing environment. This is not uncommon in the software industry because, during software testing, the engineers generally test the software intensely and conduct an *accelerated* test on the software in order to detect most of the software faults as early as possible.

The Laplace transform of the PDF in (25.13) is

$$F_{\beta}^*(s) = e^{-s} \cdot \text{HG}([\beta], [\alpha + \beta], s), \quad (25.14)$$

where $\text{HG}([\beta], [\alpha + \beta], s)$ is a generalized hypergeometric function such that

$$\text{HG}([a_1, a_2, \dots, a_m], [b_1, b_2, \dots, b_n], s) = \sum_{k=0}^{\infty} \left(\frac{s^k \prod_{i=1}^m \frac{\Gamma(a_i+k)}{\Gamma(a_i)}}{\prod_{i=1}^n \frac{\Gamma(b_i+k)}{\Gamma(b_i)}} \right).$$

Therefore,

$$\begin{aligned} F_{\beta}^*(s) &= e^{-s} \sum_{k=0}^{\infty} \left(\frac{\Gamma(\alpha + \beta) \Gamma(\beta + k) s^k}{\Gamma(\beta) \Gamma(\alpha + \beta + k) k!} \right) \\ &= \sum_{k=0}^{\infty} \left(\frac{\Gamma(\alpha + \beta) \Gamma(\beta + k) s^k e^{-s}}{\Gamma(\beta) \Gamma(\alpha + \beta + k) k!} \right) \\ &= \sum_{k=0}^{\infty} \left(\frac{\Gamma(\alpha + \beta) \Gamma(\beta + k)}{\Gamma(\beta) \Gamma(\alpha + \beta + k)} \text{Poisson}(k, s) \right). \end{aligned}$$

where the Poisson PDF is given by

$$\text{Poisson}(k, s) = \frac{s^k e^{-s}}{k!}.$$

Using the same error-detection rate function in (25.11) and replacing $F^*(s)$ by $F_{\beta}^*(s)$, the mean-value function of the β -RFE model is

$$m_{\beta}(t) = \begin{cases} \frac{a}{(p-q)} \left[1 - \left(\frac{1+c}{e^{bt}+c} \right)^{(p-q)} \right] & t \leq T, \\ \frac{a}{(p-q)} \left[1 - \left(\frac{1+c}{e^{bT}+c} \right)^{(p-q)} \right] \times \sum_{k=0}^{\infty} \left(\frac{\Gamma(\alpha+\beta)\Gamma(\beta+k)\text{Poisson}(k,s)}{\Gamma(\beta)\Gamma(\alpha+\beta+k)} \right) & t \geq T. \end{cases} \quad (25.15)$$

where

$$s = (p - q) \left[\ln \left(\frac{c + e^{bt}}{c + e^{bT}} \right) \right].$$

The next section will discuss the parameter estimation and illustrate the applications of these two RFE software reliability models using software failure data.

25.4 Parameter Estimation

25.4.1 Maximum Likelihood Estimation (MLE)

We use the MLE method to estimate the parameters in these two RFE models. Let y_i be the cumulative number of software faults detected up to time t_i , $i = 1, 2, \dots, n$. Based on the NHPP, the likelihood function is given by

$$L = \prod_{i=1}^n \frac{[m(t_i) - m(t_{i-1})]^{y_i - y_{i-1}}}{(y_i - y_{i-1})!} e^{-[m(t_i) - m(t_{i-1})]}. \quad (25.16)$$

The logarithmic form of the above likelihood function is

$$\begin{aligned} \ln L &= \sum_{i=1}^n \{y_i - y_{i-1}\} \ln [m(t_i) - m(t_{i-1})] \\ &\quad - [m(t_i) - m(t_{i-1})] - \ln [(y_i - y_{i-1})!]. \end{aligned} \quad (25.17)$$

In this analysis, the error-removal efficiency p is given. Each model has five unknown parameters. For example, in the γ -RFE model, we need to estimate the following five unknown parameters: a, b, q, γ , and θ . For the β -RFE model, we need to estimate: a, b, q, α , and β . By taking derivatives of (25.17) with respect to each parameter and setting the results equal to zero, we can obtain five equations for each RFE model. After solving all those equations, we obtain the maximum likelihood estimates (MLEs) of all parameters for each RFE model.

Table 25.2 shows a set of failure data from a telecommunication software application during software testing [16]. The column “Time” shows the normalized cumulative time spent in software testing for this telecommunication application,

Table 25.2 Normalized cumulative failures and times during software testing

and the column “Failures” shows the normalized cumulative number of failures occurring in the testing period up to the given time.

The time to stop testing is $T = 0.0184$. After the time T , the software is released for field operations. Table 25.3 shows the field data for this software release. Similarly, the column “Time” shows the normalized cumulative time spent in the field for this software application, and the time in Table 25.3 is continued from the time to stop testing T . The column “Failures” shows the normalized cumulative number of failures found after releasing the software for field operations up to the given time. The cumulative number of failures is the total number of software failures since the beginning of software testing.

To obtain a better understanding of the software development process, we show the actual results of the MLE solutions instead of the normalized results. In this study, let us assume that testing engineers have a number of years of

Table 25.4 MLE solutions for the γ -RFE model

\hat{a}	\hat{b}	\hat{q}	\hat{c}	$\hat{\gamma}$	$\hat{\theta}$

experience of this particular product and software development skills and therefore conducted perfect debugging during the test. In other word, $p = 1$. The maximum likelihood estimates of all the parameters in the γ -RFE model are obtained as shown in Table 25.4.

Similarly, set $p = 1$, the MLE of all the parameters in the β -RFE model are obtained as shown in Table 25.5.

For both RFE models, the MLE results can be used to obtain more insightful information about the software development process. In this example, at the time to stop testing the software $T = 0.0184$, the estimated number of remaining faults in the system is $a_F = a - (p - q)m(T) = 55$.

25.4.2 Mean-Value Function Fits

After we obtain the MLEs for all the parameters, we can plot the mean-value function curve fits for both the γ -RFE and β -RFE models based on the MLE parameters against the actual software application failures.

Table 25.6 shows the mean-value function curve fits for both the models where the columns $m_\gamma(t)$ and $m_\beta(t)$ show the mean-value function for the γ -RFE model and the β -RFE model, respectively.

The γ -RFE and β -RFE models yield very close fits and predictions on software failures. Figure 25.4 shows the mean-value function curve fits for both the γ -RFE model and β -RFE model. Both models appear to be a good fit for the given data set. Since we are particularly interested in the fits and the predictions for software failure data during field operation, we also plot the detailed mean-value curve fits for both the γ -RFE model and the β -RFE model in Fig. 25.5.

For the overall fitting of the mean-value function against the actual software failures, the MSE is 23.63 for the γ -RFE model fit and is 23.69 for the β -RFE model. We can also obtain the fits and predictions for software failures by applying some existing NHPP software reliability models to the same set of failure data. Since all these existing models assume a constant failure-detection rate throughout both the software testing and operation periods, we only apply the software testing data to the software models and then predict the software failures in the field environments.

Figure 25.6 shows the comparisons of the mean-value function curve fits between the two RFE models and some existing NHPP software reliability models. It appears that the two models that include consideration of the field environment on the software failure-detection rate perform better in terms of the predictions for software failures in the field.

Fig. 25.4 Mean-value function curve fits for both RFE models

Fig. 25.5 Mean-value function fitting comparisons

Fig. 25.6 Model comparisons

25.4.3 Software Reliability

Once the MLEs of all the parameters in (25.12) and (25.14) are obtained, the software reliability within $(t, t + x)$ can be determined as

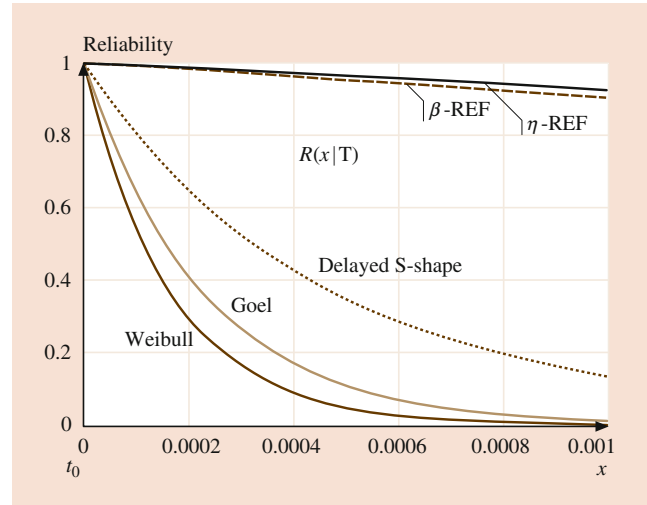

Fig. 25.7 Reliability prediction comparisons

$$R(x|t) = e^{-[m(t+x)-m(t)]}. \tag{25.18}$$

Let $T = 0.0184$, and change x from 0 to 0.004, then we can compare the reliability predictions between the two RFE models and some other NHPP models that assume a constant failure-detection rate for both software testing and operation. The reliability prediction curves are shown in Fig. 25.7. From Fig. 25.7, we can see that the NHPP models without consideration of the environmental factor yield much lower predictions for software reliability in the field than the two proposed RFE software reliability models.

25.4.4 Confidence Interval

γ -RFE Model

To see how good the reliability predictions given by the two RFE models are, in this section we describe how to construct confidence intervals for the prediction of software reliability in the random field environments. From Tables 25.4 and 25.5, the MLEs of c and q are equal to zero and, if p is set to 1, then the model in (25.12) becomes

$$m(t) = \begin{cases} a(1 - e^{-b \cdot t}) & t \leq T, \\ a \left[1 - e^{-b \cdot t} \left(\frac{\theta}{\theta + b(t-T)} \right)^\gamma \right] & t \geq T. \end{cases} \tag{25.19}$$
