This model leads to the same MLE results for the parameters a, b, γ , and θ and also yields exactly the same mean-value function fits and predictions as the model in (25.12). To obtain the confidence interval for the reliability predictions for the γ -RFE model, we derive the variance-covariance matrix for all the maximum likelihood estimates as follows.

If we use $x_i, i = 1, 2, 3,$ and $4,$ to denote all the parameters in the model, or

$$x_1 \rightarrow a \quad x_2 \rightarrow b \quad x_3 \rightarrow \theta \quad x_4 \rightarrow \gamma.$$

The Fisher information matrix H can be obtained as

$$H = \begin{pmatrix} h_{11} & h_{12} & h_{13} & h_{14} \\ h_{21} & h_{22} & h_{23} & h_{24} \\ h_{31} & h_{32} & h_{33} & h_{34} \\ h_{41} & h_{42} & h_{43} & h_{44} \end{pmatrix},$$

where

$$h_{ij} = E \left(-\frac{\partial^2 L}{\partial x_i \partial x_j} \right) i, j = 1, \dots, 6.$$

where L is the log-likelihood function in (25.18).

If we denote $z(t_k) = m(t_k) - m(t_{k-1})$ and $\Delta y_k = y_k - y_{k-1}, k = 1, 2, \dots, n,$ then we have

$$\begin{aligned} \frac{\partial^2 L}{\partial x_i \partial x_j} &= \sum_{k=1}^n \left[-\frac{\Delta y_k}{z(t_k)^2} \frac{\partial z(t_k)}{\partial x_i} \cdot \frac{\partial z(t_k)}{\partial x_j} \right. \\ &\quad \left. + \left(\frac{\Delta y_k - z(t_k)}{z(t_k)} \cdot \frac{\partial^2 z(t_k)}{\partial x_i \partial x_j} \right) \right]. \end{aligned}$$

Then we can obtain each element in the Fisher information matrix $H.$ For example,

$$\begin{aligned} h_{11} &= E \left(-\frac{\partial^2 L}{\partial a^2} \right) \\ &= \sum_{k=1}^n \left\{ \sum_{\Delta y_k=0}^{\infty} \left[\frac{\Delta y_k}{z(t_k)^2} \left(\frac{\partial z(t_k)}{\partial a} \right)^2 \right] \times \frac{[z(t_k)]^{\Delta y_k} e^{-z(t_k)}}{(\Delta y_k)!} \right\} \\ &= \sum_{k=1}^n \left\{ \sum_{\Delta y_k=0}^{\infty} \left[\frac{\Delta y_k}{z(t_k)^2} \left(\frac{z(t_k)}{a} \right)^2 \right] \times \frac{[z(t_k)]^{\Delta y_k} e^{-z(t_k)}}{(\Delta y_k)!} \right\} \\ &= \sum_{k=1}^n \left(\frac{1}{a^2} \sum_{\Delta y_k=0}^{\infty} \Delta y_k \frac{[z(t_k)]^{\Delta y_k} e^{-z(t_k)}}{(\Delta y_k)!} \right) \\ &= \sum_{k=1}^n \left[\frac{1}{a^2} \cdot z(t_k) \right] \\ &= \frac{1}{a^2} m(t_n). \end{aligned}$$

The variance matrix, $V,$ can also be obtained

$$V = (H)^{-1} = \begin{pmatrix} v_{11} & v_{12} & v_{13} & v_{14} \\ v_{21} & v_{22} & v_{23} & v_{24} \\ v_{31} & v_{32} & v_{33} & v_{34} \\ v_{41} & v_{42} & v_{43} & v_{44} \end{pmatrix}.$$

The variances of all the estimate parameters are given by

$$\begin{aligned} \text{Var}(\hat{a}) &= \text{Var}(x_1) = v_{11}, \\ \text{Var}(\hat{b}) &= \text{Var}(x_2) = v_{22}, \\ \text{Var}(\hat{\gamma}) &= \text{Var}(x_3) = v_{33}, \\ \text{Var}(\hat{\theta}) &= \text{Var}(x_4) = v_{44}. \end{aligned}$$

The actual numerical results for the γ -RFE model variance matrix are

$$V\gamma = \begin{pmatrix} 703.8472 & -0.005387 & -88.6906 & -2.6861 \\ -0.005387 & 7.3655 \times 10^{-8} & 1.11 \times 10^{-3} & 3.097 \times 10^{-5} \\ -88.6906 & 1.11 \times 10^{-3} & 92.4287 & 1.1843 \\ -2.6861 & 3.097 \times 10^{-5} & 1.1843 & 0.0238 \end{pmatrix}.$$

β -RFE Model

The model in (25.14) can also be simplified given that the estimates of both q and c are equal to zero and p is set to 1. The mean-value function becomes

$$m_{\beta}(t) = \begin{cases} a(1 - e^{-bt}) & t \leq T, \\ a \left[1 - e^{-bt} \times \sum_{k=0}^{\infty} \left(\frac{\Gamma(\alpha+\beta)\Gamma(\beta+k)\text{Poisson}[k,b(t-T)]}{\Gamma(\beta)\Gamma(\alpha+\beta+k)} \right) \right] & t \geq T. \end{cases}$$

This model leads to the same MLE results for the parameters $a, b, \alpha,$ and β and also yields exactly the same mean-value function fits and predictions. To obtain the confidence interval for the reliability predictions for the β -RFE model, we need to obtain the variance–covariance matrix for all the maximum likelihood estimates.

If we use $x_i, i = 1, 2, 3,$ and $4,$ to denote all the parameters in the model, or

$$x_1 \rightarrow a \quad x_2 \rightarrow b \quad x_3 \rightarrow \alpha \quad x_4 \rightarrow \beta,$$

and go through similar steps as for the γ -RFE model, the actual numerical results for the β -RFE model variance matrix can be obtained as

$$V_{\beta} = \begin{pmatrix} 691.2 & -0.00536 & -2.728 & -66.2172 \\ -0.00536 & 7.4485 \times 10^{-8} & 2.671 \times 10^{-5} & 0.00085 \\ -2.7652 & 2.671 \times 10^{-5} & 0.01820 & 0.8295 \\ -66.2172 & 0.00085 & 0.8295 & 60.5985 \end{pmatrix}$$

Confidence Interval of the Reliability Predictions

If we define a partial derivative vector for the reliability $R(x | t)$ in (25.18) as

$$vR(x|t) = \left(\frac{\partial R(x|t)}{\partial x_1}, \frac{\partial R(x|t)}{\partial x_2}, \frac{\partial R(x|t)}{\partial x_3}, \frac{\partial R(x|t)}{\partial x_4} \right)$$

then the variance of $R(x | t)$ in (25.18) can be obtained as

$$\text{Var} [R(x|t)] = vR(x|t) V[vR(x|t)]^T.$$

Fig. 25.8 γ -RFE model reliability growth curve and its 95% confidence interval

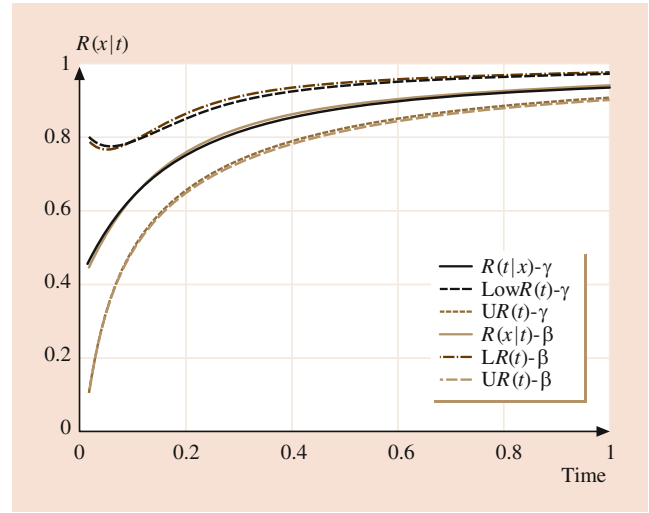

Fig. 25.10 Reliability growth prediction curves and their 95% confidence intervals for the γ -RFE model and the β -RFE model

Fig. 25.9 β -RFE model reliability growth prediction and its 95% confidence interval

Assume that the reliability estimation follows a normal distribution, then the 95% confidence interval for the reliability prediction $R(x | t)$ is

$$\left[R(x|t) - 1.96 \times \sqrt{\text{Var} [R(x|t)]}, R(x|t) + 1.96 \times \sqrt{\text{Var} [R(x|t)]} \right]$$

Figures 25.8 and 25.9 show the 95% confidence interval of the reliability predicted by the γ -RFE and β -RFE models, respectively.

Fig. 25.11 Mean-value function curve fit and its 95% confidence intervals for the γ -RFE model

We plot the reliability predictions and their 95% confidence interval for both the γ -RFE model and the β -RFE model in Fig. 25.10. For this given application data set, the reliability predictions for the γ -RFE model and the β -RFE model are very close to each other, as are their confidence intervals. Therefore, it would not matter too much which one of the two RFE models was used to evaluate the software reliability for this application. However, will these two RFE models always yield similar reliability predictions for all software applications? or which model should one choose for applications if they are not always that close to each other? We will try to answer these two questions in the next section. Figure 25.11 shows the 95% confidence interval for the mean-value function fits and predictions from the γ -RFE model.

Table 25.7 MLEs and fitness comparisons

Parameter	γ -RFE	β -RFE
\hat{a}	236.57930161	236.0745369
\hat{b}	0.001443362	0.001448854

$\hat{\gamma}$	0.213762945	
$\hat{\alpha}$		0.186224489
$\hat{\beta}$		8.692191792
Mean	0.019948	0.020975
Variance	0.0018615	0.002079
MSE	23.63	23.69
Likelihood	-136.1039497	-129.7811199

25.4.5 Concluding and Remarks

Table 25.7 shows all the maximum likelihood estimates of all the parameters and other fitness measures. The maximum likelihood estimates (MLEs) on common parameters, such as a – the initial number of faults in the software and b – the unit software failure-detection rate during testing, are consistent for both models. Both models provide very close predictions for software reliability and also give similar results for the mean and variance of the random environment factor η .

The underlying rationale for this phenomenon is the similarity between the gamma and beta distributions when the random variable η is close to zero. In this application, the field environments are much less liable to software failure than the testing environment. The random field environmental factor, η , is mostly much less than 1 with mean $(\eta) \approx 0.02$.

Figure 25.12 shows the PDF curves of the environmental factor η based on the MLEs of all the parameters for both the γ -RFE model and the β -RFE model. We observe that the PDF curves for the beta and gamma distributions are also very close to each other. The two RFEs models give similar results because this software application is much less likely to fail in the field environment, with mean $(\eta) = 0.02$. If the mean (η) is not so close to 0, then we would expect to have different prediction results from the γ -RFE model and the β -RFE model.

We suggest the following criteria as ways to select between the two models discussed in this chapter for predicting the software reliability in the random field environments:

1. Software less liable to failure in the field than in testing, that is, $\eta \leq 1$

In the γ -RFE model, the random field environmental factor, η following a gamma distribution, ranges from 0 to $+\infty$. For the β -RFE model, the random field environmental factor, η following a beta distribution, ranging from 0 to 1. Therefore, the β -RFE model will be more appropriate for describing field environments in which the software application is likely to fail than in the controlled testing environment.

Fig. 25.12 PDF curves comparison for the environmental factor η

For this given application, we notice that when the field environmental factor η is much less than 1 [mean(η) = 0.02], the γ -RFE model yields similar results to the β -RFE model. However, we also observe that the γ -RFE model does not always yield similar results to the β -RFE model when η is not close to 0. In this case, if we keep using the γ -RFE model instead of the β -RFE model, we would expect to see a large variance in the maximum likelihood estimates for all the unknown parameters, and hence a wider confidence interval for the reliability prediction.

2. Smaller variance of the RFE factor η

A smaller variance of the random environmental factor η will generally lead to a smaller confidence interval for the software reliability prediction. It therefore represents a better prediction in the random field environments.
3. Smaller variances for the common parameters a and b

The software parameter a and the process parameter b are directly related to the accuracy of reliability prediction. They can also be used to investigate the software development process. Smaller variances of a and b would lead, in general, to smaller confidence intervals for the mean-value function predictions and reliability predictions.
4. Smaller MSE of the mean-value function fits

A smaller MSE for the mean-value function fits means a better fit of the model to the real system failures. This smaller MSE will usually lead to a better prediction of software failures in random field environments.

The above criteria can be used with care to determine which RFE model should be chosen in practice. They may sometime provide contradictory results. In the case of contradictions, practitioners can often consider selecting the model with the smaller confidence interval for the reliability prediction.

25.5 A RFE Model with Vtub-Shaped Fault-Detection Rate

In this section, we present a specific RFE model with Vtub-shaped fault-detection rate. Numerical results of some selected NHPP models based on MSE, predictive power, predictive-ratio risk, and normalized criteria distance from a set of software failure data are discussed.

Here we assume that a detected fault will be 100% successfully removed from the software during the software testing period and the software fault-detection rate per unit time, $h(t)$, with a Vtub-shaped function [22], is as follows:

$$h(t) = b \ln(a)t^{b-1}a^{t^b} \quad \text{for } a > 1, b > 0 \quad (25.20)$$

We also assume that the random variable η as defined in (25.1) has a gamma distribution with parameters α and β , that is, $\eta \sim \text{gamma}(\alpha, \beta)$ where the PDF of η is given by

$$g(x) = \frac{\beta^\alpha x^{\alpha-1} e^{-\beta x}}{\Gamma(\alpha)} \quad \text{for } \alpha, \beta > 0; x \geq 0 \quad (25.21)$$

From Eq. (25.1), we can obtain the expected number of software failures detected by time t subject to the uncertainty of the environments as follows:

$$m(t) = N \left(1 - \left(\frac{\beta}{\beta + a^{t^b} - 1} \right)^\alpha \right) \quad (25.22)$$

where N is the expected number of faults that exists in the software before testing.

25.5.1 Model Criteria

We briefly discuss some common criteria such as MSE, predictive-ratio risk (PRR), and predictive power (PP) that will be used to compare the performance of some selected models from Table 25.1 to illustrate the modeling analysis.

The MSE measures the difference between the estimated values and the actual observation and is defined as:

$$\text{MSE} = \frac{\sum_{i=1}^n (\hat{m}(t_i) - y_i)^2}{n - k} \quad (25.23)$$

where y_i = total number of actual failures at time t_i ; $\hat{m}(t_i)$ = the estimated cumulative number of failures at time t_i for $i = 1, 2, \dots, n$; and n and k = number of observations and number of model parameters, respectively.

The predictive-ratio risk (PRR) measures the distance of model estimates from the actual data against the model estimate and is defined as [22]:

$$\text{PRR} = \sum_{i=1}^n \left(\frac{\hat{m}(t_i) - y_i}{\hat{m}(t_i)} \right)^2 \quad (25.24)$$

The predictive power (PP) measures the distance of model estimates from the actual data against the actual data [22]:

$$\text{PP} = \sum_{i=1}^n \left(\frac{\hat{m}(t_i) - y_i}{y_i} \right)^2 \quad (25.25)$$

For all these three criteria – MSE, PRR, and PP – the smaller the value, the better the model fits.

Pham [28] discussed a *normalized criteria distance*, or NCD criteria, to determine the best model from a set of performance criteria. The NCD criteria is defined as follows:

$$D_i = \sum_{j=1}^d \left\{ \left(\left[\sqrt{\sum_{i=1}^2 \left(\frac{C_{ijk}}{\sum_{i=1}^s C_{ijk}} \right)^2} \right] \right) w_j \right\} \quad (25.26)$$

where s and d are the total number of models and criteria, respectively.

w_j = the weight of the j th criteria for $j = 1, 2, \dots, d$

$k = \begin{cases} 1 & \text{represent criteria } j \text{ value} \\ 2 & \text{represent criteria } j \text{ ranking} \end{cases}$

C_{ijl} = the ranking based on specified criterion of model i with respect to (w.r.t.) criteria j

C_{ij2} = criteria value of model i w.r.t. criteria j where $i = 1, 2, \dots, s$ and $j = 1, 2, \dots, d$

Obviously the smaller the NCD value, D_i , it represents the better rank.

25.5.2 Model Analysis

A set of system test data which is referred to as Phase 2 data set [22] is used to illustrate the model performance in this subsection. In this data set, the number of faults detected in each week of testing is found and the cumulative number of faults since the start of testing is recorded for each week. This data set provides the cumulative number of faults by each week up to 21 weeks.

Table 25.8 summarizes the result as well as the ranking of nine selected models from Table 25.1 based on MSE, PRR, PP, and NCD criteria. It is worth to note that one can use the NCD criterion to help in selecting the best model from among model candidates. Table 25.8 shows the NCDs and its corresponding ranking for $w_1 = 2$, $w_2 = 1.5$, and $w_3 = 1$ with respect to MSE, PRR, and PP, respectively.

Table 25.8 [28, page 1488]: Parameter estimation and model comparison when $w_1 = 2$, $w_2 = 1.5$, $w_3 = 1$

Model/criteria	MSE (Rank)	PRR (Rank)	PP (Rank)	NCD value (D_k)	Model rank
1. G-O Model	6.61 (7)	0.69 (1)	1.10 (7)	0.1366837	6
2. Delayed S-shaped	3.27 (5)	44.27 (8)	1.43 (8)	0.1511403	7
3. Inflection S-shaped	1.87 (2)	5.94 (5)	0.90 (4)	0.0801189	2
4. Yamada imperfect debugging model	4.98 (6)	4.30 (4)	0.81 (3)	0.1022629	5
5. PNZ model	1.99 (3)	6.83 (7)	0.96 (6)	0.0855598	4
6. Pham-Zhang model	2.12 (4)	6.79 (6)	0.95 (5)	0.0855490	3
7. Dependent-parameter model (model 1)	43.69 (9)	601.34 (9)	4.53 (9)	1.3395573	9
8. Dependent-parameter model with $m(t_0) \neq 0$, $t_0 \neq 0$ (model 2)	24.79 (8)	1.14 (2)	0.73 (1)	0.3893950	8
9. Vtub-shaped fault-detection rate model	1.80 (1)	2.06 (3)	0.77 (2)	0.0692175	1

Based on the results as shown in Table 25.8, the Vtub-shaped fault-detection rate model seems to provide the best fit based on the normalized criteria distance method.

Abstract

The first part of this chapter provides a brief introduction to statistical maintenance modeling subject to multiple failure processes. It includes a description of general probabilistic degradation processes.

The second part discusses detailed reliability modeling for degraded systems subject to competing failure processes without maintenance actions. A generalized multi-state degraded-system reliability model with multiple competing failure processes including degradation processes and random shocks is presented. The operating condition of the multi-state system is characterized by a finite number of states. A methodology to generate the system states when multi-failure processes exist is also discussed. The model can be used not only to determine the reliability of the degraded systems in the context of multi-state functions but also to obtain the probabilities of being in a given state of the system.

The third part describes the inspection–maintenance issues and reliability modeling for degraded repairable systems with competing failure processes. A generalized condition-based maintenance model for inspected degraded systems is discussed. An average long-run maintenance cost rate function is derived based on an expression for degradation paths and cumulative shock damage, which are measurable. An inspection sequence is determined based on the minimal maintenance cost rate. Upon inspection, a decision will be made on whether to perform preventive maintenance or not. The optimum preventive maintenance thresholds for degradation processes and inspection sequences are also determined based on a modified Nelder–Mead downhill simplex method.

The fourth part briefly discusses some dependent competing risk models with various applications subject to multiple degradation processes and random shocks especially using time-varying copulas.

Finally, the last part is given over to the conclusions and a discussion of future perspectives for degraded-system maintenance modeling.

Degradation process · Preventive maintenance · Maintenance policy · Compound Poisson process · Competing risks

26.1 Introduction

Technology advances mean that most new products are, on one hand, more reliable but, on the other hand, very difficult to maintain during the product life cycle. Designers have been challenged to find new, effective approaches to evaluate reliability in a timely fashion and to maintain such systems in an optimum way. This chapter presents reliability and maintenance models for degraded systems subject to competing failure processes. The accuracy of reliability estimation through a degradation model cannot be ensured unless the unit-to-unit initial variation and within-unit degradation-rate variation are considered. This chapter also discusses a generalized random-coefficient degradation process and randomized logistic degradation process to model the degradation.

26.2 Literature Review

As degradation occurs, system performance changes from perfect functioning to complete failure; the binary assumption used to analyze, model, and compute system reliability is relaxed. Using degradation measures to assess reliability has seen some important findings in the literature. *Tomsky* [1] investigated two regression models for detecting degradation reliability. *Nelson* [2] briefly surveyed the application of accelerated degradation. *Lu* [3] introduced a nonlinear mixed-effects model and estimated model parameters in a two-stage way. Recently, multi-state reliability has received considerable attention. *Levitin* [4] extended the reliability importance measures for multi-state systems with different measures of performance. When the multi-state nature of a system is addressed, a better understanding of the system reliability behavior is obtained. Our third new development is to build a methodology based on the formulation of degradation in terms of a finite discrete state.

It is well known that the effectiveness of a system depends on both the quality of its design and manufacturing process as well as the proper inspection–maintenance actions to prevent it from failing. Inspection–maintenance issues are considered in the second part of this chapter.

Maintenance has evolved from a simple model that deals with machinery breakdowns, to time-based preventive maintenance, to today's condition-based maintenance. It is of great importance to avoid the failure of a system during its actual operating; especially, when such failures are dangerous

and costly. Time-based and condition-based maintenance are the two major approaches for maintenance. Condition-based maintenance is often profitable since it can be used to avoid failure occurrence at the lowest cost and to improve the availability and reliability of complex systems. This chapter examines the problem of developing a mathematical maintenance cost model to determine both the optimal inspection interval time and preventive maintenance threshold of degraded systems with competing failure processes subject to a condition-based maintenance policy.

Pham et al. [5] presented a Markov model for predicting the reliability of k -out-of- n systems in which components are subject to multi-stage degradation as well as catastrophic failures. Due to the aging effect, the failure rate of the component will increase. They considered the state-dependent transition rates for the degradation process. *Pham et al.* [6] derived models for predicting the availability and mean lifetime of multistage degraded systems with partial repairs. In some production systems failures are not possible to detect but can only be determined by inspection [7]. Several authors [8–22] have proposed various inspection policies and models for systems with a degradation process. *Grall et al.* [8] studied a system subject to a random deterioration process. They developed a model based on a stationary process to determine both the preventive maintenance threshold and inspection dates that minimized the average long-run cost rate. *Chelbi and Ait-Kadi* [10] addressed optimal inspection strategies for deteriorating equipment subject to preventive and corrective maintenance. *Klutke and Yang* [11] studied the availability of maintained systems subject to both the effects of the degradation and random shocks. They considered the degradation process as a deterministic function of time t and that shocks occurred according to a Poisson process in which the shock magnitudes are independent and identically distributed (iid) random variables. *Pham and Xie* [13] developed a generalized surveillance model consisting of dual, mutually dependent stochastic processes for surveillance systems. Their model can be used to better understand both the inspection process, the repair unit itself, and to provide information that can be used to assist inspectors in scheduling and prioritizing their future inspections.

The choice of the inspection schedule and preventive maintenance threshold(s) obviously has an important influence on the economic performance of the maintenance policy. The inspection dates and the preventive maintenance threshold(s) are two main decision variables. However, in industrial applications of condition-based maintenance, the preventive maintenance threshold is usually decided based upon the recommendation made by the maintenance people and the inspection schedule often appears to be set by little more than a rule of thumb. Because of the lack of appropriate modeling support, the preventive maintenance threshold is likely to be set conservatively and the inspection schedule may be performed more than is perhaps necessary. The need

for a maintenance model with cost consideration is obvious in this case.

The chapter is organized as follows. The basic concepts and a review of maintenance, as well as a brief description of probabilistic processes for the modeling of degradation and random shocks, is discussed in Sect. 26.3. A general reliability model for degraded nonrepairable systems subject to multiple competing processes is discussed in Sect. 26.4. The inspection–maintenance modeling issues and detection policies for degraded repairable systems considering multiple competing processes are described in Sect. 26.5. Several numerical examples are given in Sects. 26.4 and 26.5. Finally in Sect. 26.6, several future research perspectives and conclusions are briefly discussed.

26.3 General Probabilistic Processes Description

We consider three random processes. The first two are used to model degradation, while the third is a compound Poisson process used for modeling random shocks:

1. $Y(t) = A + Bg(t)$ is called a random-coefficient degradation path, where $A > 0$ and $B > 0$ are independent random variables and $g(t)$ is an increasing time-dependent function. The random variable A measures the initial value of degradation due to a different manufacturer, the manufacturing quality control of new items, variable deterioration during storage until the item is put into service, and so forth [14]. Therefore, the initial degradation value A is a random variable. The variable B is the degradation rate ($B > 0$) and represents the variations among the population; $g(t)$ is an increasing function.
2. $Y(t) = \frac{We^{Bt}}{A+e^{Bt}}$ is called a randomized logistic degradation path function where A and B are independent non-negative random variables, and W is a constant. The random variable A represents the initial threshold level of degradation and B describes the rate at which degradation accumulates. It should be noted that $Y(t) = \frac{We^{Bt}}{A+e^{Bt}}$ is an S-shaped curve and describes the degradation process well. It matches the path of the cumulative degradation of many systems in practice. The S-shaped curve reflects an initial run-in period of low usage, followed by a period of steady rate of usage, and finally ending with an increasing rate of use due to the aging of the system. We establish the relationship between the two random variables A and B via some rearrangements as follows:

$$W \frac{e^{Bt}}{A + e^{Bt}} < H \Rightarrow B < \frac{1}{t} \ln \frac{u_1 A}{1 - u_1}, \quad (26.1)$$

where H is a constant and $u_1 = \frac{H}{W}$.

3. Let $D(t) = \sum_{i=0}^{N(t)} X_i$ represent a sequence of random shocks in which each shock causes independent damage X_i to the whole system where the X_i are iid with a probability distribution function (pdf) of $f_X(x)$, and a cumulative distribution function (cdf) of $F_X(x)$; $\{N(t), t \geq 0\}$ is a Poisson process with parameter $\lambda > 0$ that is independent of the sequence $\{X_i\}$; $F_X^{(k)}(x)$ denotes the k -th convolution.

The stochastic process $D(t) = \sum_{i=0}^{N(t)} X_i$ is called a compound Poisson process where $N(t)$ is the number of shocks that have occurred up to time t , X_i is the damage caused by the i -th shock, and $D(t)$ is the cumulative damage up to time t .

26.4 Nonrepairable Degraded Systems Reliability Modeling

This section addresses reliability models for nonrepairable degraded systems. First, we discuss a model for systems subject to two competing processes. Then, we present a generalized situation where systems are subjected to three competing processes.

26.4.1 Degraded Systems Subject to Two Competing Processes

Model Description

The modeling assumptions are as follows:

1. Each system has a state space $\Omega_U = \{M, \dots, 1, 0, F\}$.
2. The system fails either due to degradation ($Y(t) > G$) or catastrophic failure $[D(t) = \sum_{i=1}^{N_2(t)} X_i > S]$. The system may either go from state i to the next degraded state $i - 1$ or directly to the catastrophic failure state F , $i = M, \dots, 1$.
3. No repair or maintenance is performed on the system.
4. Since $Y(t)$ describes the total damage up to time t , it is natural to assume that it is nondecreasing.
5. The two processes $Y(t)$ and $D(t)$ are independent.
6. At time $t = 0$, the system is in state M .

We consider a degradable system suited at a random environment where degradation and random shocks can contribute to an effect of the life of a system. In this section, we discuss the case where systems are subject to two failure processes, called a continuous and increasing degradation process $Y(t)$, and a random shock process $D(t)$. Whichever process occurs first causes the system to failure.

Figure 26.1 illustrates the system flow diagram of the two competing failure processes. In Fig. 26.1, we use either of the random processes described in Sect. 26.3 to represent a degradation process where random shocks are represented by

Fig. 26.1 The flow diagram of a system subjected to two competing failure processes

a stationary and independent increment process. Then, we discuss a method to formulate these two processes from a multi-state standing point. That is, suppose that the operating conditions of the system at any point in time could be classified into one of a finite number of the states, say $\Omega_U = \{M, \dots, 1, 0, F\}$. We view the degradation process in terms of a finite number of states. For example, when the value of the degradation process $Y(t)$ falls into a predefined interval then its corresponding state will be determined. Let us define as follows:

$[0, W_M], \dots, (W_2, W_1]$ are the intervals associated with the degradation process where $W_M < W_{M-1} < \dots < W_2 < W_1$. A one-to-one relationship between the element of $\Omega = \{M, \dots, 1, 0\}$ and its corresponding interval is set up as follows:

- when $Y(t) \in [0, W_M] \Rightarrow$ in state M ,
- when $Y(t) \in (W_M, W_{M-1}] \Rightarrow$ in state $M - 1$,
- ⋮
- when $Y(t) \in [W_i, W_{i-1}] \Rightarrow$ in state i ,
- when $Y(t) \in [W_2, W_1] \Rightarrow$ in state 1 ,
- when $Y(t) > W_1 \Rightarrow$ in state 0 .

Reliability Evaluation

The most general situation is to allow each degradation process to be described by a number of different discrete states. We now define the probability in each state. Let $P_i(t)$ be the probability that the value of $Y(t)$ will fall within a predefined interval corresponding to state i with $D(t) \leq S$. From state i , the system will make a direct transition to state $i - 1$ due to gradual degradation, or to catastrophic failure state F due to a random shock.

The reliability function is defined as:

$$\begin{aligned}
 R_M(t) &= P(\text{state} \geq 1) \\
 &= \sum_{i=1}^M P_i(t) \\
 &= P[Y(t) \leq G, D(t) \leq S],
 \end{aligned}
 \tag{26.2}$$

where $P_i(t)$ is the probability of being in state i .

Suppose a system fails if the degradation process crosses some threshold, say G ; or the shock damage process crosses some threshold, say S ; T is defined as:

$$T = \inf [t : Y(t) > G \text{ or } D(t) > S]. \tag{26.3}$$

The mean time to failure is expressed as:

$$\begin{aligned}
 E[T] &= \int_0^\infty P[T > t] dt \\
 &= \int_0^\infty P[Y(t) \leq G, D(t) \leq S] dt \\
 &= \int_0^\infty P[Y(t) \leq G] \sum_{j=0}^\infty \frac{(\lambda_2 t)^j e^{-\lambda_2 t}}{j!} F_X^{(j)}(S) dt
 \end{aligned}$$

or, equivalently, that

$$E[T] = \sum_{j=0}^\infty \frac{F_X^{(j)}(S)}{j!} \int_0^\infty P[Y(t) \leq G] (\lambda_2 t)^j e^{-\lambda_2 t} dt. \tag{26.4}$$

The specific expression for $E[T]$ depends on the probability function $P[Y(t) \leq G]$. Sometimes, it is hard to find a closed-form solution. In this case, one can use a numerical method to solve the problem in (26.4).

The probability density function of the time to failure $f_T(t)$ is as follows:

$$\begin{aligned}
 f_T(t) &= -\frac{d}{dt} R(t) \\
 &= -\frac{d}{dt} \{P[Y(t) \leq G] P[D(t) \leq S]\} \\
 &= -\frac{d}{dt} \left\{ P[Y(t) \leq G] \sum_{j=0}^\infty \frac{(\lambda_2 t)^j e^{-\lambda_2 t}}{j!} F_X^{(j)}(S) \right\} \\
 &= -\sum_{j=0}^\infty \frac{F_X^{(j)}(S)}{j!} \frac{d}{dt} \{P[Y(t) \leq G] (\lambda_2 t)^j e^{-\lambda_2 t}\}
 \end{aligned}$$

Let $F_G(t) = P[Y(t) \leq G]$, then $f_G(t) = \frac{d}{dt} F_G(t)$.

$$\begin{aligned}
 f_T(t) &= -\sum_{j=1}^\infty \frac{F_X^{(j)}(S)}{j!} [f_G(t) (\lambda_2 t)^j e^{-\lambda_2 t} \\
 &\quad + F_G(t) j \lambda_2 (\lambda_2 t)^{j-1} e^{-\lambda_2 t} - \lambda_2 F_G(t) (\lambda_2 t)^j e^{-\lambda_2 t}].
 \end{aligned}
 \tag{26.5}$$

Reliability models

Model 1:

$$\begin{cases} Y(t) = A + Bg(t) \\ D(t) = \sum_{i=0}^{N_2(t)} X_i \end{cases}$$

- case 1 : $A \sim \text{normal}, B \sim \text{normal}$
- case 2 : $A \sim U[0, a], B \sim \text{Exp}(b)$

Model 2:

$$\begin{cases} Y(t) = W \frac{e^{Bt}}{A + e^{Bt}}, \text{ where } A \sim U[0, a], B \sim \text{Exp}(b) \\ D(t) = \sum_{i=0}^{N_2(t)} X_i \end{cases}$$

The two reliability models for the system are depicted in Fig. 26.1. In the following, we will take model 2 as an example to illustrate the results in this section. One can also easily apply it for the model 1.

Assume that the degradation process is described by the function $Y(t) = W \frac{e^{Bt}}{A+e^{Bt}}$, where the two random variables A and B are independent, and A follows a uniform distribution with parameter interval $[0, a]$ and B follows an exponential distribution with parameter $\beta > 0$. In short, $A \sim U[0, a], a > 0$ and $B \sim \text{Exp}(\beta), \beta > 0$.

The probability that the system is in state M is as follows:

$$\begin{aligned}
 P_M(t) &= P \left[Y(t) = W \frac{e^{Bt}}{A+e^{Bt}} \leq W_M, D(t) = \sum_{i=0}^{N_2(t)} X_i \leq S \right] \\
 &= \left[\int_{\forall A} \left(B < \frac{1}{t} \ln \frac{u_1 A}{1-u_1} \mid A = x \right) f_A(x) dx \right] \\
 &\quad \times P \left[D(t) = \sum_{i=0}^{N_2(t)} X_i \leq S \right] \\
 &= \left[1 - \frac{1}{a} \left(\frac{1-u_1}{u_1} \right)^{\frac{\beta}{t}} \left(\frac{t}{t-\beta} \right) \left(a^{1-\frac{\beta}{t}} - 1 \right) \right] \\
 &\quad \times e^{-\lambda_2 t} \sum_{j=0}^{\infty} \frac{(\lambda_2 t)^j}{j!} F_X^{(j)}(S).
 \end{aligned} \tag{26.6}$$

The probability that the system is in state i is calculated as follows:

$$\begin{aligned}
 P_i(t) &= P \left[W_{i+1} < W \frac{e^{Bt}}{A+e^{Bt}} \leq W_i, D(t) = \sum_{i=0}^{N_2(t)} X_i \leq S \right] \\
 &= \left[\int_0^a P \left(\frac{1}{t} \ln \frac{u_i A}{1-u_i} < B \leq \frac{1}{t} \ln \frac{u_{i+1} A}{1-u_{i+1}} \mid A = x \right) f_A(x) dx \right] \\
 &\quad \times e^{-\lambda_2 t} \sum_{j=1}^{\infty} \frac{(\lambda_2 t)^j}{j!} F_X^{(j)}(S) \\
 &= \left\{ \frac{1}{a} \left(\frac{t}{t-\beta} \right) \left(a^{1-\frac{\beta}{t}} \right) \left[\left(\frac{1-u_i}{u_i} \right)^{\frac{\beta}{t}} - \left(\frac{1-u_{i+1}}{u_{i+1}} \right)^{\frac{\beta}{t}} \right] \right\} \\
 &\quad \times e^{-\lambda_2 t} \sum_{j=0}^{\infty} \frac{(\lambda_2 t)^j}{j!} F_X^{(j)}(S),
 \end{aligned} \tag{26.7}$$

where $\mu_i = \frac{W_i}{W}, i = M - 1, \dots, 1$.

Similarly, the probability that the system is in state 0 is as follows:

$$\begin{aligned}
 P_0(t) &= P \left[Y(t) = W \frac{e^{Bt}}{A+e^{Bt}} > G, D(t) = \sum_{i=0}^{N_2(t)} X_i \leq S \right] \\
 &= \left[\frac{1}{a} \left(\frac{1-u_M}{u_M} \right)^{\frac{\beta}{t}} \left(\frac{t}{t-\beta} \right) \left(a^{1-\frac{\beta}{t}} \right) \right] e^{-\lambda_2 t} \\
 &\quad \times \sum_{j=0}^{\infty} \frac{(\lambda_2 t)^j}{j!} F_X^{(j)}(S).
 \end{aligned} \tag{26.8}$$

Fig. 26.2 Reliability versus time

The probability for a catastrophic failure state F is given by:

$$\begin{aligned}
 P_F(t) &= P \left[Y(t) = W \frac{e^{Bt}}{A+e^{Bt}} \leq G, D(t) = \sum_{i=0}^{N_2(t)} X_i > S \right] \\
 &= \left[1 - \frac{1}{a} \left(\frac{1-u_1}{u_1} \right)^{\frac{\beta}{t}} \left(\frac{t}{t-\beta} \right) \left(a^{1-\frac{\beta}{t}} \right) \right] \\
 &\quad \times \left[1 - e^{-\lambda_2 t} \sum_{j=0}^{\infty} \frac{(\lambda_2 t)^j}{j!} F_X^{(j)}(S) \right].
 \end{aligned} \tag{26.9}$$

The reliability $R_M(t)$ is expressed as:

$$\begin{aligned}
 R_M(t) &= \sum_{k=1}^M P_k(t) \\
 &= \left[1 - \frac{1}{a} \left(\frac{1-u_M}{u_M a} \right)^{\frac{\beta}{t}} \left(\frac{t}{t-\beta} \right) \left(a^{1-\frac{\beta}{t}} \right) \right] \\
 &\quad \times \left[e^{-\lambda_2 t} \sum_{j=0}^{\infty} \frac{(\lambda_2 t)^j}{j!} F_X^{(j)}(S) \right].
 \end{aligned} \tag{26.10}$$

A Numerical Example

Assume that the degradation is modeled as the function $Y(t) = W \frac{e^{Bt}}{A+e^{Bt}}$ where $A \sim U[0, 5]$ and $B \sim \text{Exp}(10)$. The critical values for the degradation and the shock damage are $G = 500$ and $S = 200$, respectively. The random shocks are measured by the function $D(t) = \sum_{i=1}^{N_2(t)} X_i$, where $X_i \sim \text{Exp}(0.3)$ and X_i s are iid. Figure 26.2 shows the reliability of the system as a function of time, where the solid line represents $N_2(t)$ with $\lambda_2 = 0.12$ and the dotted line represents $N_2(t)$ with $\lambda_2 = 0.20$.

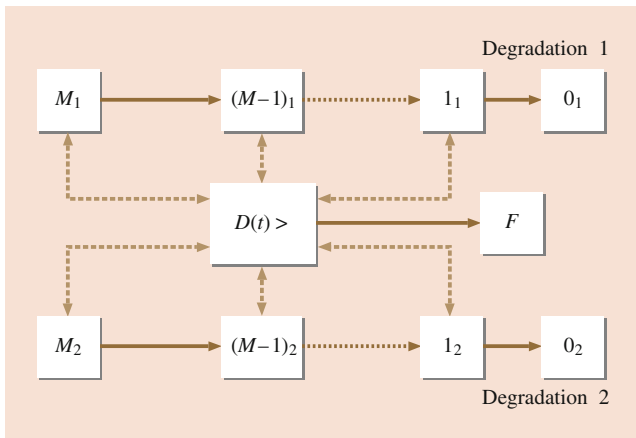

Fig. 26.3 The flow diagram of a system subjected to multiple failure processes [15]

26.4.2 Systems Subject to Three Competing Processes

System Description

In some applications, the systems are subjected to a variety of governing failure processes. In this section, we consider three independent competing failure processes in which two of them are degradation processes (called degradation process 1, which is measured by the function $Y_1(t)$, and degradation process 2, which is measured by $Y_2(t)$), and the third is a random shock process $D(t)$ [15]. Whichever process occurs first causes the system to fail.

Initially, the system is considered to be in its good state (i.e., M_1 and M_2). As time progresses, it can either go to the first degraded state [i.e., $(M-1)_1$ or $(M-1)_2$] upon degradation or can go to a failed state (state F), if subject to random shocks. When a system reaches the first degraded state, it can either stay in that state until the mission time, or it can go to the second degradation state [i.e., $(M-2)_1$ or $(M-2)_2$] upon degradation, or it can go to a failed state (F state) upon random shocks.

The same process will be continued for all stages of degradation except the last degradation, either stage 0_1 or stage 0_2 . If the system reaches the last degradation state, it cannot perform its functions satisfactorily and must be treated as a failure (state 0). Figure 26.3 shows the system flow diagram of the multiple competing transition processes. In Fig. 26.3, the above represents the degradation process 1; the bottom represents the degradation process 2; F represents a catastrophic failure state due to random shocks.

Assumptions

1. The system consists of $(M+2)$ states where state 0 and state F are both complete failure states. State i is a degradation state, $1 \leq i \leq M$.

2. No repair or maintenance is performed on the system.
3. We assume that $Y_i(t)$, $i = 1, 2$ is a nonnegative nondecreasing function at time t , since degradation is an irreversible accumulation of damage.
4. $Y_i(t)$, $i = 1, 2$ and $D(t)$ are statistically independent. The independence assumption implies that the state of one process will have no effect on the state of the others.
5. At time $t = 0$, the system is in state M .
6. The system can fail either due to any of the degradation process when $Y_i(t) > G_i$, $i = 1, 2$ or due to random shocks (in which case it goes to a catastrophic failure state F), i.e., $D(t) = \sum_{i=1}^{N(t)} X_i > S$.
7. The critical threshold value G_i depends upon a function of the states of the degraded systems.

Methodology

In this section, we consider that the degradation paths are modeled by some continuous probabilistic functions. Since the operating condition of the systems is characterized by a finite number of states, let us call the system state space Ω_U . First, we need the discrete continuous processes. In Step 1 below, we discuss a procedure for forcing two degradation processes to become discrete in order to obtain Ω_1 and Ω_2 , which correspond to degradation process 1 and 2, respectively. After we have obtained the degradation process spaces Ω_1 and Ω_2 , we present a methodology for how to establish a relationship between the system state space Ω_U and the degradation and random shock state spaces $\{\Omega_1, \Omega_2, F\}$ in Step 2.

Step 1: Formulate the Degradation Processes in Terms of Discrete State Sets

The two-degradation-process case is considered here. The most general situation is to allow each degradation process to be described by a number of different discrete states. The state space denoted by $\Omega_1 = \{M_1, \dots, 1_1, 0_1\}$ corresponds to degradation process 1 with $M_1 + 1$ states. Similarly, the state space denoted by $\Omega_2 = \{M_2, \dots, 1_2, 0_2\}$ is associated with degradation process 2, having $M_2 + 1$ states. M_1 and M_2 may or may not be the same, and $M_i < \infty$, $i = 1, 2$.

We view the degradation process from the perspective of a finite number of states. For example, when the value of degradation process 1 $Y_1(t)$ falls into a predefined interval, then its corresponding state will be determined. Let us define as follows:

$[0, W_M], \dots, (W_2, W_1]$ are the intervals on the degradation 1 curve (Fig. 26.4a) corresponding to state $M_1, 0_1$, where $W_M < W_{M-1} < \dots < W_1$ and $[0, A_M], \dots, (A_2, A_1]$ are intervals associated with the curve for degradation process 2 (Fig. 26.4b) corresponding to state $M_2, 0_2$, where $A_M < A_{M-1} < \dots < A_1$.

Mathematically, the relationship between the degradation process states $\Omega_1 = \{M_1, \dots, 1_1, 0_1\}$, $\Omega_2 = \{M_2, \dots, 1_2, 0_2\}$

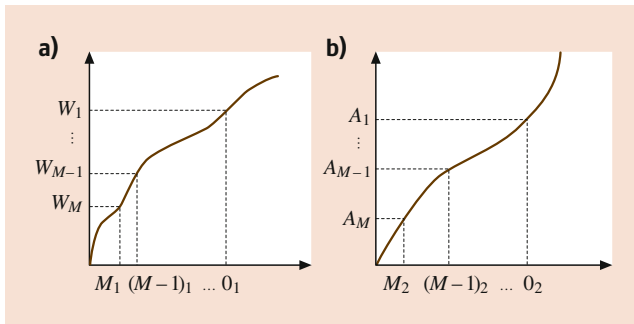

Fig. 26.4 The degradation process functions in multi-state terms for: (a) degradation 1, (b) degradation 2

and their corresponding degradation intervals are given as follows:

$$\begin{aligned}
 &\text{Degradation process 1} \\
 &0 < Y_1(t) \leq W_M : \text{state } M_1 \\
 &W_M < Y_1(t) \leq W_{M-1} : \text{state } (M-1)_1 \\
 &\vdots \\
 &W_2 < Y_1(t) \leq W_1 : \text{state } 1_1 \\
 &G_1 = W_1 < Y_1(t) : \text{state } 0_1
 \end{aligned}$$

$$\begin{aligned}
 &\text{Degradation process 2} \\
 &0 < Y_2(t) \leq A_M : \text{state } M_2 \\
 &A_M < Y_2(t) \leq A_{M-1} : \text{state } (M-1)_2 \\
 &\vdots \\
 &A_2 < Y_2(t) \leq A_1 : \text{state } 1_2 \\
 &G_2 = A_1 < Y_2(t) : \text{state } 0_2
 \end{aligned}$$

Step 2: Generate the System State Space

The system state space is defined as $\Omega_U = \{M, \dots, 1, 0, F\}$, and consists of $M + 2$ states. In this step, we discuss a methodology to develop a function to generate a relationship between the system state space Ω_U and the degradation state spaces $\{\Omega_1, \Omega_2, F\}$. For example, at a given time t , suppose that degradation process 1 is at state $i_1 \in \Omega_1$, and degradation process 2 is at state $j_2 \in \Omega_2$; what is the system state? This question is addressed as follows.

Let us assume that at the current time the system is not in a catastrophic failure state. So state F can be ignored for the time being. Therefore, we can simply look at ways to define a function that has a relationship between Ω and $\{\Omega_1, \Omega_2\}$ instead of Ω_U and $\{\Omega_1, \Omega_2, F\}$.

The operation is described by a mapping function f , which can be written as

$$f : R = \Omega_1 \times \Omega_2 \rightarrow \Omega = \{M, \dots, 1, 0\}$$

Fig. 26.5 A mapping function

where $R = \Omega_1 \times \Omega_2 = \{(i_1, j_2) \mid i_1 \in \Omega_1, j_2 \in \Omega_2\}$ is a Cartesian product as the input space domain, as shown in Fig. 26.5. The matrix H_c given below is an output space consisting of $M + 1$ elements corresponding to each input-space domain through the function f .

$$H_c = \begin{matrix} & 0_1 & 1_1 & \dots & M_1 \\ \begin{matrix} 0_2 \\ 1_2 \\ \vdots \\ M_2 \end{matrix} & \begin{pmatrix} \times & 0 & \dots & 0 \\ 0 & \ddots & & \vdots \\ \vdots & & \ddots & \vdots \\ 0 & \dots & \dots & M \end{pmatrix} \end{matrix}$$

The top row of this matrix H_c represents the state from degradation process 1. The leftmost column represents the state from degradation process 2. The elements of H_c represent $f(i_1, j_2) = k$ where $i_1 \in \Omega_1, j_2 \in \Omega_2$ and $k \in \Omega$. Notice that, in the matrix H_c , all the elements in the first row and first column are zero except that denoted by \times because the system will go to a degraded failure state (state 0) when either of the degradation processes reaches state $0_i, i = 1, 2$. Besides, some elements in the matrix H_c are also zeros since we define that, when degradation 1 is in some low state $l_1 (0_1 < l_1 < M_1)$ and degradation 2 is also in some low state $l_2 (0_2 < l_2 < M_2)$, we consider it a degradation failure. It is also observed that $f(M_1, M_2) = M$, because initially the system is in a brand-new state (perfect state M).

As we mentioned above, the first element in H_c is marked by \times , which means it does not exist. The reason is presented as follows. We define the time to failure as

$$T = \inf [t : Y_1(t) > G_1, Y_2(t) > G_2 \text{ or } D(t) > S]. \quad (26.11)$$

It should be noted that all three processes are competing against each other for the life of a system. However, only one of the three processes (whichever occurs first when its corresponding critical threshold value is exceeded) causing the system to fail. Hence, the following events will not happen:

$$\begin{aligned}
 &P [Y_1(t) > G_1, Y_2(t) > G_2, D(t) \leq S] = 0, \\
 &P [Y_1(t) > G_1, Y_2(t) > G_2, D(t) > S] = 0, \\
 &P [Y_1(t) > G_1, Y_2(t) > G_2, D(t) > S] = 0,
 \end{aligned}$$

and

Fig. 26.6 A representation of a system state-generating box

$$P [Y_1(t) < G_1, Y_2(t) > G_2, D(t) > S] = 0,$$

Because $f(0_1, 0_2) = P[Y_1(t) > G_1, Y_2(t) > G_2, D(t) \leq S]$, so the combination of $f(0_1, 0_2)$ does not exist.

The function $f: R = \Omega_1 \times \Omega_2 \rightarrow \Omega = \{M, \dots, 1, 0\}$ is defined with following requirements:

1. $f(0_1, b) = f(a, 0_2) = 0$, where $b \in \Omega_2, a \in \Omega_1, f(M_1, M_2) = M$
2. f is monotonic and nondecreasing in each argument

For instance,

$$\begin{aligned} f(a_1, b_2) &\geq f(l_1, b_2) && \text{if } a_1 \geq l_1, \\ f(a_1, b_2) &\geq f(a_1, l_2) && \text{if } b_2 \geq l_2. \end{aligned}$$

Figure 26.6 demonstrates the system’s state-generating box. There are two inputs i_1 and j_2 and an output k . The inside mapping mechanism is performed by the function f . At time t , suppose that degradation 1 is at state i_1 and degradation 2 is at state j_2 ; i_1 and j_2 are inputs. Via matrix H_c , the system state k is then generated as output.

In the matrix H_c , different state-combination inputs can generate the same results for the system state. To explain this, we need the following definition of the equivalence class.

Definition 26.1

The i -th equivalence class, R_i , is defined as follows:

$$\begin{aligned} R_i &= \{(k_1, j_2) \mid \text{where } k_1 \in \Omega_1, j_2 \in \Omega_2, f(k_1, j_2) = i\}, \\ i &= 0, 1, \dots, M, \end{aligned} \tag{26.12}$$

R_i represents all possible state combinations that generate the system state i ; R_0, \dots, R_M are disjointed sets that partition R into $(M + 1)$ equivalence classes, so that

$$R = \bigcup_{i=0}^M R_i.$$

26.4.3 Reliability Evaluation

In this section, the probability density functions and the system mean time to failure are derived based on the state probabilities given in Sect. 26.4.1. Now, we derive the probability

of being in each state. Initially, the system is in a brand-new state; i.e., in state $M = f_s(R_M)$. The probability for state M is given by

$$P_t(M) = P_t [f_s (R_M)]. \tag{26.13}$$

As defined previously, R_i represents all possible state combinations generating the system state i . The probability of being in state i is the union of all the elements in R_i

$$P_t(i) = P [f_s (R_i)]. \tag{26.14}$$

The probability for a catastrophic failure state F is given by

$$P_t(F) = P [Y_1(t) \leq G_1, Y_2(t) \leq G_2, D(t) > S]. \tag{26.15}$$

The reliability $R(t)$ can be calculated as follows:

$$\begin{aligned} R(t) &= P(\text{system state} \geq 1) \\ &= \bigcup_{i=1}^M P [f_s (R_i)] \\ &= \sum_{i=1}^M P_t(i), \end{aligned} \tag{26.16}$$

where $P_t(i)$ is the probability of being in state i .

The mean time to failure is expressed as [15]:

$$\begin{aligned} E [T] &= \int_0^\infty P (T > t) dt \\ &= \int_0^\infty P [Y_1(t) \leq G_1] P [Y_2(t) \leq G_2] \times \sum_{j=0}^\infty \frac{(\lambda_2 t)^j e^{-\lambda_2 t}}{j!} F_X^{(j)}(S) \end{aligned}$$

or, equivalently, that

$$\begin{aligned} E [T] &= \sum_{j=0}^\infty \frac{F_X^{(j)}(S)}{j!} \int_0^\infty P [Y_1(t) \leq G_1] \times P [Y_2(t) \leq G_2] \\ &\quad (\lambda_2 t)^j e^{-\lambda_2 t} dt. \end{aligned} \tag{26.17}$$

The result in (26.17) obviously would depend on the expression $P[Y_1(t) \leq G_1]P[Y_2(t) \leq G_2]$. The probability density function of time to failure, $f_T(t)$ is therefore as follows:

$$\begin{aligned} f_T(t) &= -\frac{d}{dt} [P (T > t)] \\ &= -\frac{d}{dt} \left\{ P [Y_1 (t \leq G_1)] P [Y_2(t) \leq G_2] \times \sum_{j=0}^\infty \frac{(\lambda_2 t)^j e^{-\lambda_2 t}}{j!} F_X^{(j)}(S) \right\}. \end{aligned} \tag{26.18}$$

26.4.4 Numerical Examples

This example aims to illustrate the results discussed in the previous sections. Consider a system subjected to two degradation processes and random shocks.

Assume that degradation process 1 is described by the function $Y_1(t) = A + Bg(t)$, where the random variables A and B are independent and both follow normal distributions, with mean 90 and variance 2.5, and mean 78 and variance 6, respectively. In short, $A \sim N(90, 2.5)$ and $B \sim N(78, 6)$. The degradation function is assumed to be $g(t) = t^3$. Also $G_1 = 2500$, $W_3 = 1500$, $W_2 = 2000$, and $W_1 = 2500$.

Assume that degradation process 2 is described by $Y_2(t) = W \frac{e^{BBt}}{AA + e^{BBt}}$, where the random variables AA and BB are independent and follow uniform distributions with parameter interval $[0,100]$ and an exponential distribution with parameter 0.1, respectively. In other words, $AA \sim U[0, 100]$ and $BB \sim \text{Exp}(0.01)$. Also $G_2 = 5000$, $A_2 = 2600$, $A_1 = 5000$, and $W = 7000$. Assume that the random shock is represented by $D(t) = \sum_{i=0}^{N(t)} X_i$ with critical value $S = 200$, where $X_i \sim \text{Exp}(0.1)$ and the X_i are iid.

Assume that the states associated with degradation process 1 and degradation process 2 are, respectively, $\Omega_1 = \{3_1, 2_1, 1_1, 0_1\}$ and $\Omega_2 = \{2_2, 1_2, 0_2\}$. We define the system state space as $\Omega_U = \{3, 2, 1, 0, F\}$ and the matrix H_c is given as

$$H_c = \begin{matrix} & \begin{matrix} 0_1 & 1_1 & 2_1 & 3_1 \end{matrix} \\ \begin{matrix} 0_2 \\ 1_2 \\ 2_2 \end{matrix} & \begin{pmatrix} \times & 0 & 0 & 0 \\ 0 & 0 & 2 & 3 \\ 0 & 1 & 2 & 3 \end{pmatrix} \end{matrix}.$$

Then we obtain

$$R = \left\{ \begin{matrix} (0_1, 1_2), (0_1, 2_2), (1_1, 0_2), (2_1, 0_2), (3_1, 0_2), \\ (1_1, 1_2), (2_1, 1_2), (3_1, 1_2), (1_1, 2_2), (2_1, 2_2), \\ (3_1, 2_2) \end{matrix} \right\}$$

The equivalence classes can be listed as follows:

$$\begin{aligned} R_0 &= \{(0_1, 1_2), (0_1, 2_2), (1_1, 0_2), (2_1, 0_2), (3_1, 0_2), (1_1, 1_2)\}, \\ R_1 &= \{(1_1, 2_2)\}, \\ R_2 &= \{(2_1, 1_2), (2_1, 2_2)\}, \\ R_3 &= \{(3_1, 1_2), (3_1, 2_2)\}, \\ R &= \sum_{i=0}^3 R_i. \end{aligned}$$

According to this expression for H_c , the probability of the system being in state 3 is the sum of the probability $f(3_1, 2_2)$ and of the probability $f(3_1, 1_2)$. That sum is calculated as

$$\begin{aligned} P_t(3) &= P_t[f_s(R_3)] = \Phi\left(\frac{1500 - (90 + 78t)}{\sqrt{2.5 + 6t^6}}\right) \\ &\left[1 - \frac{1}{100}(0.4)^{\frac{0.01}{t}} \times \left(\frac{t}{t-0.01}\right) (0.01)^{1 - \frac{0.01}{t}}\right] \\ &\times e^{-\lambda_2 t} \sum_{j=0}^{\infty} \left(\frac{\lambda_2 t}{j!}\right) F_X^{(j)}(200), \end{aligned} \tag{26.19}$$

where Φ is a standard normal distribution.

Fig. 26.7 Probability plot for state 3 versus time

Figure 26.7 shows the probability for the system to be in state 3 as a function of time t , where the solid line represents the compound Poisson process $D(t) = \sum_{i=0}^{N(t)} X_i$ with rate $\lambda = 0.04$ and the dotted line represents the compound Poisson process with rate $\lambda = 0.8$. In Fig. 26.7 we observe that, as t progresses to 50, the probability that the system is in state 3 quickly approaches 0 when the rate is given as $\lambda = 0.8$, and is stable with $\lambda = 0.04$.

Because $R_2 = \{(2_1, 1_2), (2_1, 2_2)\}$, the probability of being in state 2 is given by

$$\begin{aligned} P_t(2) &= P_t[f(2_1, 1_2)] + P_t[f(2_1, 2_2)] \\ &= (UV) e^{-\lambda_2 t} \sum_{j=0}^{\infty} \left(\frac{\lambda_2 t}{j!}\right) F_X^{(j)}(200), \end{aligned} \tag{26.20}$$

where

$$U = \Phi\left(\frac{2000 - (90 + 78t)}{\sqrt{2.5 + 6t^6}}\right) - \Phi\left(\frac{1500 - (90 + 78t)}{\sqrt{2.5 + 6t^6}}\right),$$

and

$$V = 1 - \frac{1}{100} \left(\frac{1}{t - 0.01}\right) (0.4)^{\frac{0.01}{t}} \times \left(\frac{t}{t - 0.01}\right) (0.01)^{1 - \frac{0.01}{t}}.$$

Figure 26.8 shows the probability of being in state 2 as a function of time t , where the solid line represents the compound Poisson process $D(t) = \sum_{i=0}^{N(t)} X_i$ with rate $\lambda = 0.04$, and the dotted line represents the compound Poisson process with rate $\lambda = 0.8$. In Fig. 26.8, we observe that, before the time t progresses to 5, the probability of being in state 2 stays close to zero for both rates $\lambda = 0.8$ and $\lambda = 0.04$. It should be noted that the two curves are almost the same for the different values of the rate $\lambda = 0.8$ and $\lambda = 0.04$.

Similarly, the probability of being in state 1 is calculated as:

Fig. 26.8 Probability plot for state 2 versus time

Fig. 26.10 Probability plot for state 0 versus time

Fig. 26.9 Probability plot for state 1 versus time

$$\begin{aligned}
 P_t(1) &= P_t[f(1_1, 2_2)] \\
 &= E_1 E_2 e^{-\lambda_2 t} \sum_{j=0}^{\infty} \left(\frac{\lambda_2 t}{j!}\right) F_X^{(j)}(200),
 \end{aligned}$$

where $E_1 = \Phi\left(\frac{2500 - (90 + 78t)}{\sqrt{2.5 + 6t^6}}\right) - \Phi\left(\frac{2000 - (90 + 78t)}{\sqrt{2.5 + 6t^6}}\right)$,

$$E_2 = 1 - \frac{1}{100} \left(\frac{t}{t-0.01}\right) \left(\frac{22}{13}\right)^{\frac{0.01}{t}} (0.01)^{1 - \frac{0.01}{t}}. \tag{26.21}$$

Figure 26.9 shows the probability of being in state 1 versus time t , where the solid line represents the compound Poisson process $D(t) = \sum_{i=0}^{N(t)} X_i$ with rate $\lambda = 0.04$, and the dotted line represents the compound Poisson process with rate $\lambda = 0.8$. In Fig. 26.9, we observe that, before the time t progresses to 15, the probability of being in state 1 for both rates $\lambda = 0.8$ and $\lambda = 0.04$ are about the same.

We can also easily obtain the probability of being in state 0 as follows:

$$\begin{aligned}
 P_t(0) &= P[f(0_1, 1_2) + f(0_1, 2_2) + f(1_1, 0_2) \\
 &\quad + f(2_1, 0_2) + f(3_1, 0_2) + f(1_1, 1_2)] \\
 &= (X_1 Y_1 + X_2 Y_2 + X_3 Y_3) e^{-\lambda_2 t} \\
 &\quad \times \sum_{j=0}^{\infty} \left(\frac{\lambda_2 t}{j!}\right) F_X^{(j)}(200),
 \end{aligned}$$

where $X_1 = 1 - \Phi\left(\frac{2500 - (90 + 78t)}{\sqrt{2.5 + 6t^6}}\right)$,

$$X_2 = \Phi\left(\frac{2500 - (90 + 78t)}{\sqrt{2.5 + 6t^2}}\right),$$

$$Y_1 = 1 - \frac{1}{100} (0.4)^{\frac{0.01}{t}} \left(\frac{t}{t-0.01}\right) \times (0.01)^{1 - \frac{0.01}{t}},$$

$$Y_2 = \frac{1}{100} (0.4)^{\frac{0.01}{t}} \left(\frac{t}{t-0.01}\right) \times (0.01)^{1 - \frac{0.01}{t}},$$

$$\begin{aligned}
 X_3 &= \Phi\left(\frac{2500 - (90 + 78t)}{\sqrt{2.5 + 6t^6}}\right) \\
 &\quad - \Phi\left(\frac{2000 - (90 + 78t)}{\sqrt{2.5 + 6t^6}}\right),
 \end{aligned}$$

$$\begin{aligned}
 Y_3 &= 1 - \frac{1}{100} \left[\left(\frac{22}{13}\right)^{\frac{0.01}{t}} + (0.4)^{\frac{0.01}{t}} \right] \\
 &\quad \times \left(\frac{t}{t-0.01}\right) (0.01)^{1 - \frac{0.01}{t}}.
 \end{aligned} \tag{26.22}$$

Figure 26.10 shows the probability that the system is in state 0 versus the time t , where the solid line represents the compound Poisson process $D(t) = \sum_{i=0}^{N(t)} X_i$ with rate $\lambda = 0.04$, and the dotted line represents the compound Poisson process with rate $\lambda = 0.8$. In Fig. 26.10, we observe that the

Fig. 26.11 Probability plot for state F versus time

probability of being in state 0 is close to zero when $t > 100$ for the rate $\lambda = 0.8$.

The probability of being in state F is calculated as:

$$P_t(F) = P[Y_1(t) \leq G_1, Y_2(t) \leq G_2, D(t) > S]$$

$$= KL \left[1 - e^{-\lambda_2 t} \sum_{j=0}^{\infty} \left(\frac{\lambda_2 t}{j!} \right) F_X^{(j)}(200) \right],$$

where $K = \Phi \left(\frac{2500 - (90 + 78t)}{\sqrt{2.5 + 6t^6}} \right)$,

$$L = 1 - \frac{1}{100} (0.4)^{\frac{0.01}{t}} \left(\frac{t}{t - 0.01} \right) \left(0.01^{1 - \frac{0.01}{t}} \right). \tag{26.23}$$

Figure 26.11 shows the probability of being in state F as a function of time t , where the solid line represents the compound Poisson process $D(t) = \sum_{i=0}^{N(t)} X_i$ with rate $\lambda = 0.04$, and the dotted line represents the compound Poisson process with rate $\lambda = 0.8$.

Finally, the system reliability $R(t)$ is given by

$$R(t) = P(\text{system state} \geq 1)$$

$$= \sum_{i=1}^3 P_t(i)$$

$$= X_3 Y_3 e^{-\lambda_2 t} \sum_{j=0}^{\infty} \left(\frac{\lambda_2 t}{j!} \right) F_X^{(j)}(200),$$

where $X_3 = \Phi \left(\frac{2000 - (90 + 78t)}{\sqrt{2.5 + 6t^6}} \right)$

$$\times \left\{ 1 - \frac{1}{100} \left[(0.4)^{\frac{0.01}{t}} + \left(\frac{22}{13} \right)^{\frac{0.01}{t}} \right] \right\}$$

$$\times \left(\frac{t}{t - 0.01} \left(0.01^{1 - \frac{0.01}{t}} \right) \right) \Bigg\},$$

$$Y_3 = \left[\Phi \left(\frac{2500 - (90 + 78t)}{\sqrt{2.5 + 6t^6}} \right) - \Phi \left(\frac{2000 - (90 + 78t)}{\sqrt{2.5 + 6t^6}} \right) \right]$$

$$\times \left[1 - \frac{1}{100} \left(\frac{t}{t - 0.01} \right) \right]$$

$$\times \left(\frac{22}{13} \right)^{\frac{0.01}{t}} 0.01^{1 - \frac{0.01}{t}}. \tag{26.24}$$

Figure 26.12 shows the system reliability versus time t , where the solid line represents the compound Poisson process with rate $\lambda = 0.04$, and the dotted line represents the compound Poisson process with rate $\lambda = 0.8$. As for the rate $\lambda = 0.8$ we observe that the system will probably fail after a time t of 50. It seems that the random shock process governs the behavior of the reliability function. Therefore, the dotted line quickly approaches the failure caused by the shock damage.

26.5 Repairable Degraded Systems Modeling

26.5.1 Inspection–Maintenance Model Subject to Two Competing Processes

Model Description

Assumptions

The system starts in a new condition. The assumptions are as follows [22]:

1. The system is not continuously monitored, its state can be detected only by inspection, but system failure is self-announcing without inspection.
2. After a PM or CM action, the system will be restored back to an as-good-as-new state.
3. A CM action is more costly than a PM, and a PM costs much more than an inspection. This implies $C_c > C_p > C_i$.
4. The two processes $Y(t)$ and $D(t)$ are independent.
5. Repair time is not negligible.

Although continuous monitoring processes are feasible for some systems, the cost to monitor the process and the labor required would, however, not make it realistic in practice. Therefore, we need to improve the system performance by determining the periodic inspections with maintenance action that will minimize the average total system maintenance

Fig. 26.12 Reliability versus time

cost. Since system deterioration while running leads to system failure, it proves better to assume that the degradation paths are continuous and increasing functions.

Inspection–Maintenance Policy

It is proposed that the system is periodically inspected at times $\{I, 2I, \dots, nI, \dots\}$. We assume that the degradation $(\{Y(t)\}_{t \geq 0})$ and random shock processes $(\{D(t)\}_{t \geq 0})$ are independent. Let T denote the time to failure, defined as

$$T = \inf [t > 0 : Y(t) > G \text{ or } D(t) > S],$$

where G is the critical value for $\{Y(t)\}_{t \geq 0}$ and S is the threshold level for $\{D(t)\}_{t \geq 0}$.

The two threshold values L and G (where G is fixed) effectively divide the system state into three regions, as illustrated in Fig. 26.13. They are: the doing-nothing zone; the PM zone; and the CM zone. The maintenance action will be performed when either of the following situations occurs.

1. The current inspection reveals that the system condition falls into the PM zone, and this state was not found on previous inspection. At inspection time iI , the system falls into the PM zone, which means $\{Y[(i - 1)I] \leq L, D[(i - 1)I] \leq S\} \cap \{L < Y(iI) \leq G, D(iI) \leq S\}$. Then PM action is performed and will take a random time R_1 .
2. When the system fails at T , a CM action is taken immediately and takes time R_2 .

It is assumed that both PM and CM actions are considered to be perfect. Even though both PM and CM actions bring the system back to an as-good-as-new state, they are, physically, not necessarily the same, since a CM has to performed on

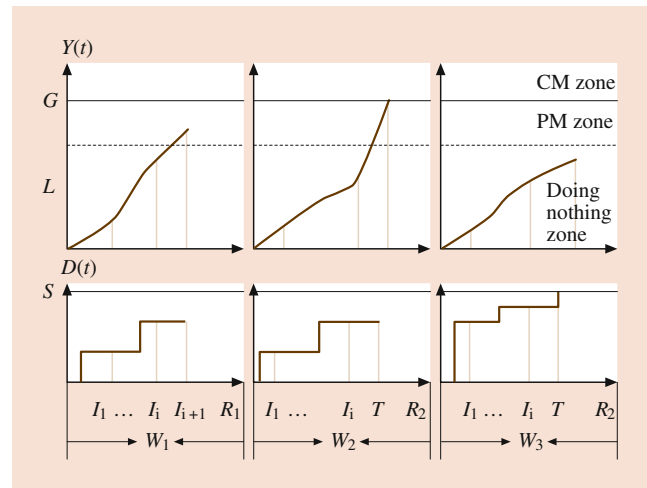

Fig. 26.13 The evolution of the system

a worse system. Hence, CM is likely to be more complex and expensive. Therefore, it is realistic to assume that the repair time is not negligible. This chapter considers that the PM action will take a random amount of time R_1 and that a CM action will take a random amount of time R_2 . After a PM or a CM action is performed, the system is renewed. A new sequence of the inspection would start again, defined in the same way.

Maintenance Cost Modeling

In this section, an explicit expression for the average long-run maintenance cost per unit time is derived. The objectives of the model are to determine the optimal PM threshold L and the optimal inspection time I . From the basics of renewal reward theory, we have

$$\lim_{t \rightarrow \infty} \frac{C(t)}{t} = \frac{E[C_1]}{E[W_1]}.$$

We now model the average total maintenance cost per unit time on a single renewal cycle instead of $\lim_{t \rightarrow \infty} \frac{C(t)}{t}$; then we will analyze $E[C_1]$ and $E[W_1]$.

Expected Maintenance Cost Analysis in a Cycle

The expected total maintenance cost during a cycle $E[C_1]$ is expressed as [22]:

$$E[C_1] = C_i E[N_I] + C_p E[R_1] P_p + C_c E[R_2] P_c. \quad (26.25)$$

During a renewal cycle, activities in terms of costs include: inspection cost, time to repair, and PM or CM actions. The renewal cycle will end by either a PM or a CM action. With a probability of P_p , the cycle will end with a PM action and it will take on average an amount of time $E[R_1]$ to complete a PM action, with a corresponding cost of $C_p E[R_1] P_p$.

Similarly, if a cycle ends with a CM action with probability P_c , it will take on average an amount of time $E[R_2]$ to complete a CM action, with a corresponding cost of $C_c E[R_2] P_c$. In the following, we will perform the analysis of $E[C_1]$.

Calculate $E[N_I]$

Let $E[N_I]$ denote the expected number of inspections during a cycle. $E[N_I]$ can be obtained as:

$$E[N_I] = \sum_{i=1}^{\infty} (i) P(N_I = i). \tag{26.26}$$

Obviously $\sum_{i=1}^{\infty} P(N_I = i) = 1$. There will be a total of i inspections during a cycle if the first PM trigger falls within the time interval $[(i - 1)I, iI]$, or if the system condition is in the doing-nothing zone before time iI and the system fails during the interval $[iI, (i + 1)I]$. In other words, the inspection will stop when the i -th inspection finds that a PM condition is satisfied while this situation was not revealed in the previous inspection, or the system fails during the interval $[iI < T \leq (i + 1)I]$ while the system is in the doing-nothing zone before iI .

Let $P(N_I = i)$ denote the probability that there a total of i inspections occur in a renewal cycle. Then we have

$$\begin{aligned} P(N_I = i) &= P\{Y[(i - 1)I] \leq L, D[(i - 1)I] \leq S\} \\ &\quad \times P[L < Y(iI) \leq G, D(iI) \leq S] \\ &\quad + P[Y(iI) \leq L, D(iI) \leq S] \\ &\quad \times P[iI < T \leq (i + 1)I]. \end{aligned} \tag{26.27}$$

Hence,

$$\begin{aligned} E[N_I] &= \sum_{i=1}^{\infty} i \left\{ P\{Y[(i - 1)I] \leq L, D[(i - 1)I] \leq S\} \right. \\ &\quad \times P[L < Y(iI) \leq G, D(iI) \leq S] \\ &\quad + P[Y(iI) \leq L, D(iI) \leq S] \\ &\quad \left. \times P[iI < T \leq (i + 1)I] \right\}. \end{aligned} \tag{26.28}$$

We now calculate the probabilities $P\{Y[(i - 1)I] \leq L, D[(i - 1)I] \leq S\}$ and $P[L < Y(iI) \leq G, D(iI) \leq S]$ with the following two different expressions for $Y(t)$.

A. Assume $Y(t) = A + Bg(t)$ where $A \sim N(\mu_A, \sigma_A^2)$, $B \sim N(\mu_B, \sigma_B^2)$, and A and B are independent. Given $g(t) = t$. $D(t) = \sum_{i=0}^{N(t)} X_i$ where the X_i are iid and $N(t) \sim$

Poisson(λ). Then

$$\begin{aligned} &P\{Y[(i - 1)I] \leq L, D[(i - 1)I] \leq S\} \\ &= P[A + B(i - 1)I \leq L] \\ &\quad \times P\left\{D[(i - 1)I] = \sum_{i=0}^{N[(i-1)I]} X_i \leq S\right\} \\ &= \Phi\left(\frac{L - (\mu_A + \mu_B(i - 1)I)}{\sqrt{\sigma_A^2 + \sigma_B^2((i - 1)I)^2}}\right) e^{-\lambda(i-1)I} \\ &\quad \times \sum_{j=0}^{\infty} \frac{(\lambda(i - 1)I)^j}{j!} F_X^{(j)}(S) \end{aligned} \tag{26.29}$$

and

$$\begin{aligned} &P[L < Y(iI) \leq G, D(iI) \leq S] \\ &= \left[\Phi\left(\frac{G - (\mu_A + \mu_B iI)}{\sqrt{\sigma_A^2 + \sigma_B^2(iI)^2}}\right) \right. \\ &\quad \left. - \Phi\left(\frac{L - (\mu_A + \mu_B iI)}{\sqrt{\sigma_A^2 + \sigma_B^2(iI)^2}}\right) \right] e^{-\lambda iI} \\ &\quad \times \sum_{j=0}^{\infty} \frac{(\lambda iI)^j}{j!} F_X^{(j)}(S). \end{aligned} \tag{26.30}$$

B. Assume $Y(t) = W \frac{e^{\beta t}}{A + e^{\beta t}}$, where W is a constant, $A \sim U[0, a]$, $a > 0$; $B \sim \text{Exp}(\beta)$, $\beta > 0$, A and B are independent. $D(t) = \sum_{i=0}^{N(t)} X_i$ where the X_i are iid and $N(t) \sim \text{Poisson}(\lambda)$. Then

$$\begin{aligned} &P\{Y[(i - 1)I] \leq L, D[(i - 1)I] \leq S\} \\ &= \left[1 - \frac{1}{a} \left(\frac{1-u_1}{u_1}\right)^{\frac{\beta}{i-1}} \left(\frac{(i-1)I}{(i-1)I-\beta}\right) \times \left(a^{1-\frac{\beta}{(i-1)I}} - 1\right) \right] \\ &\quad \times \sum_{j=0}^{\infty} \frac{[\lambda(i-1)I]^j}{j!} F_X^{(j)}(S), \end{aligned} \tag{26.31}$$

where $u_1 = L/W$. Similarly,

$$\begin{aligned} &P[L < Y(iI) \leq G, D(iI) \leq S] \\ &= \left\{ \frac{1}{a} \left(\frac{iI}{iI-\beta}\right) \times \left(a^{1-\frac{\beta}{iI}}\right) \left[\left(\frac{1-u_3}{u_3}\right)^{\frac{\beta}{iI}} - \left(\frac{1-u_2}{u_2}\right)^{\frac{\beta}{iI}} \right] \right\} e^{-\lambda iI} \\ &\quad \times \sum_{j=0}^{\infty} \frac{(\lambda iI)^j}{j!} F_X^{(j)}(S), \end{aligned} \tag{26.32}$$

where $u_2 = G/W, u_3 = L/W$.

Secondly, we discuss the calculation of $P[iI < T \leq (i + 1)I]$. The definition of T is $T = \inf\{t > 0: Y(t) > G \text{ or } D(t) > S\}$. According to the definition, we derive the expression:

$$\begin{aligned} & P[iI < T \leq (i + 1)I] \\ &= P\{Y(iI) \leq L, Y[(i + 1)I] > G\} \\ &\quad \times P\{D[(i + 1)I] \leq S\} \\ &\quad + P\{Y[(i + 1)I] \leq L\} \\ &\quad \times P\{D(iI) \leq S, D[(i + 1)I] > S\}. \end{aligned} \tag{26.33}$$

In (26.33), since $Y(iI)$ and $Y[(i + 1)I]$ are not independent, we could obtain the joint pdf $f_{Y(iI), Y[(i+1)I]}(y_1, y_2)$ in order to compute $P\{Y(iI) \leq L, Y[(i + 1)I] > G\}$. We consider two different expressions for $Y(t)$. The details are as follows:

A. Assume $Y(t) = A + Bg(t)$ where $A > 0$ and $B > 0$ are two independent random variables, and $g(t)$ is an increasing function of time t . Assume that $A \sim f_A(a), B \sim f_B(b)$. Let

$$\begin{cases} y_1 = a + bg(iI) \\ y_2 = a + bg[(i + 1)I] \end{cases} .$$

After simultaneously solving the above equations in terms of y_1 and y_2 , we obtain:

$$\begin{aligned} a &= \frac{y_1 g[(i + 1)I] - y_2 g(iI)}{g[(i + 1)I] - g(iI)} = h_1(y_1, y_2), \\ b &= \frac{y_2 - y_1}{g[(i + 1)I] - g(iI)} = h_2(y_1, y_2). \end{aligned}$$

The Jacobian J is given by

$$J = \begin{vmatrix} \frac{\partial h_1}{\partial y_1} & \frac{\partial h_1}{\partial y_2} \\ \frac{\partial h_2}{\partial y_1} & \frac{\partial h_2}{\partial y_2} \end{vmatrix} = \left| \frac{1}{g(iI) - g[(i + 1)I]} \right| .$$

Then the random vector $\{Y(iI), Y[(i + 1)I]\}$ has a joint continuous pdf as follows

$$\begin{aligned} & f_{Y(iI), Y[(i+1)I]}(y_1, y_2) \\ &= J | f_A[h_1(y_1, y_2)] f_B[h_2(y_1, y_2)] . \end{aligned} \tag{26.34}$$

B. Assume $Y(t) = \frac{We^{At}}{B + e^{At}}$ where $A > 0$ and $B > 0$ are independent. Assume $A \sim f_A(a), B \sim f_B(b)$. Let

$$\begin{cases} y_1 = \frac{We^{aiI}}{b + e^{aiI}} \\ y_2 = \frac{We^{a(i+1)I}}{b + e^{a(i+1)I}} \end{cases} .$$

The solutions for a and b can be easily found from the above equations in terms of y_1 and y_2 as follows:

$$\begin{cases} a = \frac{\ln\left(\frac{y_2(y_1 - W)}{y_1(y_2 - W)}\right)}{I} = h_1(y_1, y_2) \\ b = -\frac{e^{\frac{\ln\left(\frac{y_2(y_1 - W)}{y_1(y_2 - W)}\right)(i+1)I}}(y_2 - W)}{y_2} = h_2(y_1, y_2) \end{cases} .$$

It can be shown that the random vector $\{Y(iI), Y[(i + 1)I]\}$ has a joint density function given by

$$\begin{aligned} & f_{Y(iI), Y[(i+1)I]}(y_1, y_2) \\ &= |J| f_A[h_1(y_1, y_2)] f_B[h_2(y_1, y_2)], \end{aligned} \tag{26.35}$$

where the Jacobian determinant J is given in Appendix A.

As for the term $P\{D(iI) \leq S, D[(i + 1)I] > S\}$ in (26.30), since $D(t) = \sum_{i=0}^{N(t)} X_i$ is a compound Poisson process, the compound Poisson process has a stationary independent increment property. Therefore, the random variables $D(iI)$ and $D[(i + 1)I] - D(iI)$ are independent. Using the Jacobian transformation, the random vector $\{D(iI), D[(i + 1)I] - D(iI)\}$ is distributed in the same way as vector $\{D(iI), D[(i + 1)I]\}$. Note that $D(iI)$ and $D(I_{i+1})$ are independent, therefore,

$$\begin{aligned} & P\{D(iI) \leq S, D[(i + 1)I] > S\} \\ &= P\{D(iI) \leq S\} P\{D[(i + 1)I] > S\}. \end{aligned} \tag{26.36}$$

Calculate P_p

Note that either a PM or CM action will end a renewal cycle. In other words, these two events are mutually exclusive at the renewal time point. As a consequence, $P_p + P_c = 1$. The probability P_p can be obtained as follows:

$$\begin{aligned} P_p &= P(\text{PM ending a cycle}) \\ &= \sum_{i=1}^{\infty} P\{Y[(i - 1)I] \leq L, L < Y(iI) \leq G\} \\ &\quad \times P\{D(iI) \leq S\}. \end{aligned} \tag{26.37}$$

Analysis of Expected Cycle Length

Since the renewal cycle ends either by a PM action with probability P_p or a CM action with probability P_c , the mean cycle length $E[W_1]$ is calculated as follows:

$$\begin{aligned} E[W_1] &= \sum_{i=1}^{\infty} E[(iI + R_1) I_{\text{PM occurs in } [(i-1)I, iI]}] \\ &\quad + E[(T + R_2) 1_{\text{CM occurs}}] \\ &= \left\{ \sum_{i=1}^{\infty} iP \{Y[(i - 1)I] \leq L, D[(i - 1)I] \leq S\} \right. \\ &\quad \left. P[L < Y(iI) \leq G, D(iI) \leq S]\right\} \\ &\quad + E[R_1] P_p + (E[T] + E[R_2]) P_c, \end{aligned} \tag{26.38}$$

where $I_{PM \text{ occurs in}[(i-1)I, iI]}$ and $I_{CM \text{ occurs}}$ are the indicator functions.

The mean time to failure, $E[T]$ is given by [22]:

$$\begin{aligned} E[T] &= \int_0^\infty P\{T > t\} dt \\ &= \int_0^\infty P[Y(t) \leq G, D(t) \leq S] dt \\ &= \int_0^\infty P[Y(t) \leq G] \sum_{j=0}^\infty \frac{(\lambda_2 t)^j e^{-\lambda_2 t}}{j!} F_X^{(j)}(S) dt \end{aligned}$$

or, equivalently:

$$E[T] = \sum_{j=0}^\infty \frac{F_X^{(j)}(S)}{j!} \int_0^\infty P[Y(t) \leq G] (\lambda_2 t)^j e^{-\lambda_2 t} dt \quad (26.39)$$

The expression $E[T]$ depends on the probability $P[Y(t) \leq G]$ and cannot always easily be obtained in closed form.

Optimization of the Maintenance Cost Rate Policy

We determine the optimal inspection time I and PM threshold L such that the long-run average maintenance cost rate $EC(L, I)$ is minimized. Mathematically, we wish to minimize the following objective function [22]:

$$\begin{aligned} EC(L, I) &= \frac{\sum_{i=1}^\infty iP_1P_2}{\{\sum_{i=1}^\infty I_iP_1P_2\} + E[R_1]P_p + E[R_2]P_c} \\ &+ \frac{\sum_{i=1}^\infty iV_i\{P_3P_4 + P_5P_6\}}{\{\sum_{i=1}^\infty I_iP_1P_2\} + E[R_1]P_p + E[R_2]P_c} \\ &+ \frac{C_pE[R_1]\sum_{i=1}^\infty P_1P_2}{\{\sum_{i=1}^\infty I_iP_1P_2\} + E[R_1]P_p + E[R_2]P_c} \\ &+ \frac{C_pE[R_2]\{1 - \sum_{i=1}^\infty P_1P_2\}}{\{\sum_{i=1}^\infty I_iP_1P_2\} + E[R_1]P_p + E[R_2]P_c}, \end{aligned} \quad (26.40)$$

where $I_{i-1} = (i - 1)I$, $I_i = iI$, $I_{i+1} = (i + 1)I$ and $V_i = P[Y(iI) \leq L, D(iI) \leq S]$, $P_1: P[Y(I_{i-1}) \leq L, D(I_{i-1}) \leq S]$, $P_2: P[L < Y(I_i) \leq G, D(I_i) \leq S]$, $P_3: P[Y(I_i) \leq L, Y(I_{i+1}) > G]$, $P_4: P[D(I_{i+1}) \leq S]$, $P_5: P[Y(I_{i+1}) \leq L]$, $P_6: P[D(I_i) \leq S, D(I_{i+1}) > S]$.

This complex objective function is a nonlinear optimization problem, and it is hard to obtain closed-form optimal solutions for L and I . Nelder and Mead [23] introduced a downhill simplex method that does not require the calculation of derivatives. A simplex is the most elementary geometrical scheme that can be formed in n dimensions and has $(n + 1)$ vertices. A brief summary of the steps of the method is: each iteration generates a new vertex for the simplex. If the new point is better than at least one of the existing vertices, it then

replaces the worst vertex. The search direction is generated through reflection, expansion, and contraction operations.

A step-by-step algorithm proposed by Li and Pham [21] based on the Nelder–Mead downhill simplex method is summarized as follows:

- Step 1: choose $(n + 1)$ distinct vertices as an initial set $\{Z^{(1)}, \dots, Z^{(n+1)}\}$. Then calculate the function value $f(Z)$ for $i = 1, 2, \dots, (n + 1)$, where $f(Z) = EC(I, L)$. Put the values $f(Z)$ in an increasing order where $f(Z^{(1)}) = \min [EC(I, L)]$ and $f(Z^{(n+1)}) = \max [EC(I, L)]$. Set $k = 0$.
- Step 2: compute the best- n centroid $X^{(k)} = \frac{1}{n} \sum_{i=1}^n Z^{(i)}$.
- Step 3: use the centroid $X^{(k)}$ in Step 2 to compute the away-from-worst move direction

$$\Delta X^{(k+1)} = X^{(k)} - Z^{(n+1)}.$$

- Step 4: set $\lambda = 1$ and compute $f(X^{(k)} + \lambda \Delta X^{(k+1)})$. If $f(X^{(k)} + \lambda \Delta X^{(k+1)}) \leq f(Z^{(1)})$ then go to Step 5. Otherwise, if $f(X^{(k)} + \lambda \Delta X^{(k+1)}) \geq f(Z^{(n)})$ then go to Step 6. Otherwise, fix $\lambda = 1$ and go to Step 8.
- Step 5: Set $\lambda = 2$ and compute $f(X^{(k)} + 2\Delta X^{(k+1)})$. If $f(X^{(k)} + 2\Delta X^{(k+1)}) \leq f(X^{(k)} + \Delta X^{(k+1)})$ then set $\lambda = 2$. Otherwise, set $\lambda = 1$. Then go to Step 8.
- Step 6: If $f(X^{(k)} + \lambda \Delta X^{(k+1)}) \leq f(Z^{(n+1)})$ then set $\lambda = 1/2$. Compute $f(X^{(k)} + \frac{1}{2} \Delta X^{(k+1)})$. If $f(X^{(k)} + \frac{1}{2} \Delta X^{(k+1)}) \leq f(Z^{(n+1)})$ then set $\lambda = 1/2$ and go to Step 8. Otherwise, set $\lambda = -1/2$ and, if $f(X^{(k)} + \frac{1}{2} \Delta X^{(k+1)}) \leq f(Z^{(n+1)})$, then set $\lambda = -1/2$ and go to Step 8. Otherwise, go to Step 7.
- Step 7: shrink the current solution set toward the best $Z^{(1)}$ by $Z^{(i)} = \frac{1}{2} (Z^{(1)} + Z^{(i)})$, $i = 2, \dots, n + 1$. Compute the new $f(Z^{(2)}), \dots, f(Z^{(n+1)})$, let $k = k + 1$, and return to Step 2.
- Step 8: Replace the worst $Z^{(n+1)}$ by $X^{(k)} + \lambda \Delta X^{(k+1)}$. If $\sqrt{\frac{1}{n+1} \sum_{i=1}^{n+1} [f(Z^{(i)}) - \bar{f}]^2} < 0.5$, where \bar{f} is an average value, then STOP. Otherwise, let $k = k + 1$ and return to Step 2. (It should be noted that the criterion in Step 8 is not unique but will depend on how soon you would like the algorithm to stop when the function values at the vertices are close. Here we do this when the difference between the maximum and the minimum values of f is less than 0.5.)

A Numerical Example

Here we present an example to illustrate the results and the step-by-step application procedure.

Assume that the degradation process is described by $Y(t) = A + Bg(t)$, where A and B are independent and follow a uniform distribution with parameter interval $[0,4]$ and an exponential distribution with parameter 0.3, i.e., $A \sim U(0, 4)$ and $B \sim \text{Exp}(-0.3t)$, respectively, and $g(t) = \sqrt{t}e^{0.005t}$.

Table 26.1 Optimal values I and L

k	$Z^{(1)}$	$Z^{(2)}$	$Z^{(3)}$	Search result
0	(25,20) EC(I, L) = 564.3	(20,18) EC(I, L) = 631.1	(15,10) EC(I, L) = 773.6	(37.5, 38) EC(I, L) = 440.7
1	(37.5,38) EC(I, L) = 440.7	(25,20) EC(I, L) = 564.3	(20,18) EC(I, L) = 631.1	(42.5,40) EC(I, L) = 481.2
2	(37.5,38) EC(I, L) = 440.7	(42.5,40) EC(I, L) = 481.2	(25,20) EC(I, L) = 564.3	(32.5,29) EC(I, L) = 482.2
3	(37.5,38) EC(I, L) = 440.7	(42.5,40) EC(I, L) = 481.2	(32.5,29) EC(I, L) = 482.2	(32.5,33.5) EC(I, L) = 448.9
4	(37.5,38) EC(I, L) = 440.7	(32.5,33.5) EC(I, L) = 448.9	(42.5,40) EC(I, L) = 481.2	(38.75,37.125) EC(I, L) = 441.0
5	(37.5,38) EC(I, L) = 440.7	(38.75,37.125) EC(I, L) = 441.0	(32.5,33.5) EC(I, L) = 448.9	(35.3125,35.25) EC(I, L) = 441.1
6	(37.5,38) EC(I^*, L^*) = 440.7	(38.75,37.125) EC(I, L) = 441.0	(35.3125,35.25) EC(I, L) = 441.4	Stop

Assume that the random shock damage is described by $D(t) = \sum_{i=1}^{N(t)} X_i$, where X_i follows an exponential distribution, i.e., $X_i \sim \text{Exp}(-0.04t)$ and $N(t) \sim \text{Poisson}(0.1)$. Also $G = 50, S = 100, C_i = 900/\text{inspection}, C_c = 5600/\text{CM}, C_p = 3000/\text{PM}, R_1 \sim \text{Exp}(-0.1t)$, and $R_2 \sim \text{Exp}(-0.04t)$. We now determine both the values of I and L so that the average total cost per unit time $EC(I, L)$ is minimized. Following are step-by-step procedure [22]:

- Step 1: since there are two decision variables I and L , we need $(n + 1) = 3$ initial distinct vertices, which are $Z^{(1)} = (25, 20), Z^{(2)} = (20, 18)$, and $Z^{(3)} = (15, 10)$. Set $k = 0$. We calculate the value of $f(Z^{(i)})$ corresponding to each vertex and sort them in increasing order of $EC(I, L)$.
- Step 2: calculate the centroid: $X^{(0)} = (Z^{(1)} + Z^{(1)})/2 = (22.5, 19)$.
- Step 3: generate the search direction: $\Delta X = X^{(0)} - Z^{(2)} = (7.5, 9)$.
- Step 4: set $\lambda = 1$, which will produce a new minimal $EC(30, 28) = 501.76$ that leads us to try an expansion with $\lambda = 2$, that is $(37.5, 38)$.
- Step 5: set $\lambda = 2$. Similarly, calculate $f(Z)$, which leads to $EC(37.5, 38) = 440.7$. Go to Step 8. This result turns out to be a better solution, hence $(15, 10)$ is replaced by $(37.5, 38)$.

The iteration continues and stops at $k = 6$ (Table 26.1) since $\sqrt{\frac{1}{3} \sum_{i=1}^3 [EC(Z^{(i)}) - \overline{EC(I, L)}]^2} < 0.5$, where $\overline{EC(I, L)}$ is the average value.

Table 26.1 illustrates the process of the Nelder–Mead algorithm. In Table 26.1, $Z^{(i)} = (I, L)$. From Table 26.1, we observe that a set of the optimal values is

$$I^* = 37.5, \quad L^* = 38$$

and the corresponding cost value is $EC^*(I, L) = 440.7$.

Table 26.2 The effect of L on P_c for $I = 37.5$

L	P_c
33	0.465
35	0.505
37	0.654
39	0.759

Fig. 26.14 P_c versus L

Table 26.2 illustrates the various values of L on P_c for given $I = 37.5$. From Table 26.2, we observe that the probability P_c increases as L increases. In other words, a larger value for L will put the system at high risk of failure.

Figure 26.14 shows the relationship between L and P_c for different I values, such as $I = 35, I = 37.5$, and $I = 40$. From Fig. 26.14, we observe that P_c is an increasing function of L . This means a higher preventive-maintenance threshold is more likely to result in a failure.

Figure 26.15 depicts the effect of the first inspection time on P_p for various L values such as $L = 33, L = 35, L = 37$, and

Fig. 26.15 The effect of the inspection sequence on P_p for given L

$L = 39$. Shorter inspection times will cause more-frequent inspection and, as a result, will increase the probability of a PM. From Fig. 26.15, we also observe that, for smaller L values ($L = 33$ and $L = 35$), the curve decreases slightly as I increases; while, for larger values of L such as $L = 37$ and $L = 39$, the curve has a larger decrease as I increases. We also observe that the curve is more sensitive to the value of L , especially when L is large.

In summary, we observe that, on one hand, a lower value of L will result in frequent PM action and prevents full usage of the residual life of the systems. Frequent PM actions might reduce the chance of high deterioration and failures, but will also be costly. On the other hand, a higher L value will keep the system working in a higher-risk condition. Also, frequent inspections will reduce the probability of failure, while incurring additional cost.

26.5.2 Inspection–Maintenance Model for Degraded Systems with Three Competing Processes

General Inspection–Maintenance Description

This section considers systems with inspection-based maintenance subject to three failure processes that are competing for the life of such systems: two of these are degradation processes called degradation process i (measured by $Y_i(t)$ for $i = 1, 2$) and the third is a random shock process measured by the function $D(t)$ [21].

We assume that the three processes are independent and whichever process occurs first will cause the system to fail, where the failure of the system is defined as when $Y_1(t) > G_1$, $Y_2(t) > G_2$ or $D(t) > S$. The state of the system can only be revealed through inspection.

Assumptions

1. System failure is only detected by inspection. Inspections are assumed to be instantaneous, perfect, and nondestructive. Since the system is not continuously monitored, if the system fails it will remain failed until the next inspection, which causes a loss of C_m per unit time. In this case, a maintenance action is begun instantaneously at the inspection time.
2. After a maintenance action, either PM or CM, the system state will start as good as new.
3. A CM action will cost more than a PM action. Similarly, a PM action will cost much more than an inspection itself. This implies that $C_c > C_p > C_i$.
4. The three nondecreasing processes $Y_1(t)$, $Y_2(t)$, and $D(t)$ are independent.
5. No continuous monitoring is performed on the system.
6. The time for a CM or PM action is negligible.

We consider a system subject to three competing processes; two of them are continuous, gradual degradation processes with different characteristics, and the third is a random shock process. Applications of such systems can be found in the Space Shuttle computer complex due to critical mission phases such as boost, reentry, and landing and in electric generator power systems due to the loss of commercial power systems. More related applications can be found in [13].

Although a continuous monitoring process is feasible for some systems, the cost of monitoring the process and the labor required would not make it realistic in practice. Therefore the criteria we consider here is to improve the system performance by performing periodic inspections, with a maintenance action if necessary, to minimize the total system maintenance cost.

Inspection–Maintenance Policy

The length of the inspection will be reduced as the system ages. In other words, the intervals between successive inspections become shorter as the system ages. A geometric sequence is applied in this study to develop the inter-inspection sequence. The inspection time is constructed as $I_n = \sum_{j=1}^n \alpha^{j-1} I_1$, where $0 < \alpha \leq 1$ and I_1 is the first inspection time. We define $U_n = I_n - I_{n-1} = \alpha^{n-1} I_1$ as the inter-inspection interval and $(U_i)_{i \in N}$ as a decreasing geometric sequence. According to the state detected at the inspection I_n , $n = 1, \dots$, one of the following actions will happen [21]:

1. If both degradation values are below their PM thresholds and the shock damage value is less than its threshold, in other words $[Y_1(I_n) \leq L_1, Y_2(I_n) \leq L_2] \cap [D(I_n) \leq S]$, then the system is still in a good condition. In this case, we do

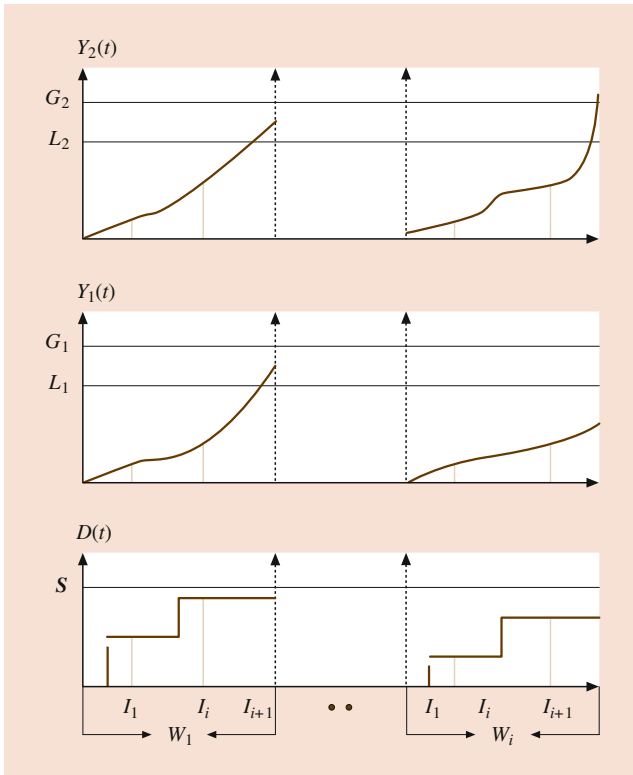

Fig. 26.16 The evolution of the system condition

nothing but determine the next inspection at $I_{n+1} = I_n + U_n$, where U_n is the inter-inspection time between the n -th and the $n + 1$ -th inspection interval.

2. If a degradation process falls into the PM zone [$L_i < Y_i(I_n) \leq G_i, i = 1, 2$] and the other two processes are less than their corresponding critical thresholds, then the system calls for a PM action and it is instantaneously performed accordingly.
3. If any of the process values exceed their corresponding critical thresholds [$Y_i(t) > G_i, i = 1, 2$, or $D(t) > S$], then the system calls for a CM action and it is instantaneously performed. In this case, the system has failed and a CM is performed on the system.

A new sequence of inspection begins, defined in the same way, and the system maintenance follows the same decision rules outlined above. Figure 26.16 shows the evolution of the system, where $Y_1(t)$ and $Y_2(t)$ represent the degradation processes 1 and 2, respectively, and $D(t)$ represents a cumulative shock damage. $(W_i)_{i \in \mathbb{N}}$ is a renewal sequence. Figure 26.17 shows the maintenance zone projected onto the $Y_1(t), Y_2(t)$ planes; G_i and L_i are the CM and PM critical thresholds for $Y_1(t)$, and $Y_2(t)$ respectively.

Fig. 26.17 Maintenance zone projected onto $Y_1(t), Y_2(t)$

Maintenance Cost Analysis

The expected total maintenance cost per cycle, $E[C_1]$, is given as:

$$E[C_1] = C_i E[N_I] + C_p P_p + C_c P_c + C_m E[\zeta], \quad (26.41)$$

where C_i is the cost associated with each inspection, C_p is the cost associated with a PM action, and C_c is the CM action cost. Since failure is not self-announcing and it can occur at any given instant time T within the inspection time interval $[I_i, I_{i+1}]$, the system will remain idle during the interval $[T, I_{i+1}]$. The cost coefficient C_m is defined as the penalty cost per unit time associated with such an event.

Calculation

1. Let $P(N_I = i + 1)$ be the probability that there are a total of $(i + 1)$ inspections in the cycle. The expected number of inspections during a cycle, $E[N_I]$, is

$$E[N_I] = \sum_{i=0}^{\infty} (i + 1) P_{i+1}, \quad (26.42)$$

where $P_{i+1} = P(N_I = i + 1)$. Note that

$$P_{i+1} = P(N_I = i + 1) = \bigcup_{j=1}^{17} P(E_j^{(i+1)}),$$

where $E_j^{(i+1)} (j = 1, \dots, 17)$ denotes the renewal cycle that ends at the j -th possible time I_{i+1} . The details of all $E_j^{(i+1)}$, where the $E_j^{(i+1)}$ are mutually disjointed events for $j = 1, \dots, 18$ are listed in Appendix B.

There are a total of 18 system state combinations revealed at any given interval $(I_i, I_{i+1}]$ where there is only one state event, $E_{18}^{(i+1)}$ (Appendix B) representing that the system is in a good condition and that no maintenance

action will be required. Any other remaining state events will trigger either a PM or a CM action at time I_{i+1} .

After some simplifications, we have

$$P_{i+1} = P[Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S] \\ - P[Y_1(I_{i+1}) \leq L_1, Y_2(I_{i+1}) \leq L_2, D(I_{i+1}) \leq S]. \quad (26.43)$$

Therefore,

$$E[N_1] = \sum_{i=0}^{\infty} (i+1) \{P[Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, \\ D(I_i) \leq S] - P[Y_1(I_{i+1}) \leq L_1, Y_2(I_{i+1}) \leq L_2, \\ D(I_{i+1}) \leq S]\}.$$

2. There will be either a PM or CM action to end a renewal cycle. It is obvious that the two events (PM and CM) are mutually exclusive at the renewal time point: $P_p + P_c = 1$. We now calculate P_p as follows:

$$P_p = P(\text{the cycle ends due to a PM action}) \\ = \sum_{i=0}^{\infty} \sum_{j=1}^3 P[E_j^{(i+1)}].$$

After some simplifications, we obtain

$$P_p = \sum_{i=0}^{\infty} \left\{ P[Y_1(I_i) \leq L_1, L_1 < Y_1(I_{i+1}) \leq G_1] \right. \\ \times P[Y_2(I_i) \leq L_2, Y_2(I_{i+1}) \leq G_2] \\ \times P[D(I_{i+1})] + P[Y_1(I_{i+1}) \leq L_1] \\ \times P[Y_2(I_i) \leq L_2, L_1 < Y_2(I_{i+1}) \leq G_2] \\ \left. \times P[D(I_{i+1})] \right\} \quad (26.44)$$

and $P_c = 1 - P_p$. We can obtain the joint probability density function $f_Y(I_i, Y(I_{i+1}))$ of $Y(I_i)$ and $Y(I_{i+1})$ by computing $P[Y_1(I_i) \leq L_1, Y_1(I_{i+1}) \leq G_1]$ and $P[Y_2(I_i) \leq L_2, Y_2(I_{i+1}) \leq G_2]$.

3. Let T denote the time to failure. That is $T = \inf [t: Y_1(t) > G_1, Y_2(t) > G_2 \text{ or } D(t) > S]$. If $I_i < T \leq I_{i+1}$, the unit will be idle during the interval $[T, I_{i+1}]$. Let $E[\zeta]$ denote the average idle time between the failure occurrence epoch and its inspection during the cycle. Then $E[\xi]$ is calculated as follows:

$$E[\xi] = \sum_{i=0}^{\infty} E[(I_{i+1} - T) 1_{I_i < T \leq I_{i+1}}] \\ = \sum_{j=0}^{\infty} R_j \int_{I_i}^{I_{i+1}} (I_{i+1} - t) dF_T(t), \quad (26.45)$$

where

$$R_j = \left\{ P[Y_1(I_i) \leq L_1, L_1 < Y_1(I_{i+1}) \leq G_1] \right. \\ \times P[Y_2(I_i) \leq L_2, L_1 < Y_1(I_{i+1})] \\ + P[Y_2(I_i) \leq L_2] \\ \times P[Y_1(I_i) \leq L_1, Y_1(I_{i+1}) > G_1] \\ + P[Y_1(I_{i+1}) \leq L_1] \\ \left. \times P[Y_2(I_i) \leq L_2] \right\} P[D(I_i) \leq S]$$

$$F(t) = P[Y_1(t) > G_1, Y_2(t) \leq G_2, D(I_i) \leq S] \\ + P[Y_1(t) \leq G_1, Y_2(t) > G_2, D(I_i) \leq S] \\ + P[Y_1(t) \leq G_1, Y_2(t) \leq G_2, D(I_i) > S]$$

and $1_{I_i < T \leq I_{i+1}}$ is an indicator function.

Expected Cycle Length

The expected cycle length $E[W_1]$ is given as follows:

$$E[W_1] = E[E[W_1|N_1]] \\ = \sum_{i=0}^{\infty} E[W_1|N_1 = i] P(N_1 = i) \\ = \sum_{i=0}^{\infty} I_{i+1} P_{i+1}, \quad (26.46)$$

where P_{i+1} is given in (26.43).

Therefore, the average long-run maintenance cost rate function $EC(L_1, L_2, I_1)$ is a function of the inspection times $\{I_1, \dots, I_i, \dots\}$ and the PM critical threshold values (L_1, L_2) through the functions $P_p, P_c, E[N_1], E[\zeta]$, and $E[W_1]$. The average long-run maintenance cost rate is, in other words, $EC(L_1, L_2, I_1) = \frac{E[C_1]}{E[W_1]}$, and can be obtained by computing the two functions given in (26.41) and (26.46).

Optimization of the Maintenance Cost Rate

The geometric inspection sequence $\{I_1, \dots, I_i, \dots\}$, where $I_n = \sum_{j=1}^n \alpha^{j-1} I_1$, depends on I_1 for given α . In this section, we develop a step-by-step algorithm based on the Nelder–Mead downhill simplex method to obtain the optimum decision variables (I_1, L_1, L_2) such that the long-run average maintenance cost rate $EC(L_1, L_2, I_1)$ is minimized.

Mathematically, the optimization problem of the cost rate function can be formulated as follows [21]:

Optimization Problem

Find I_1, L_1 and $L_2 (0 < L_1 \leq G_1, 0 < L_2 \leq G_2)$ such that

EC (L_1, L_2, I_1)

$$\begin{aligned}
 &= \frac{C_i \sum_{i=0}^{\infty} (i+1) \left\{ P \left[Y_1 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq L_1, Y_2 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq L_2, D \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq S \right] - P \left[Y_1 \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq L_1, Y_2 \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq L_2, D \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq S \right] \right\}}{\sum_{i=0}^{\infty} \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \left\{ P \left[Y_1 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq L_1, Y_2 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq L_2, D \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq S \right] - P \left[Y_1 \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq L_1, Y_2 \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq L_2, D \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq S \right] \right\}} \\
 &+ \frac{C_p \sum_{i=0}^{\infty} \left\{ P \left[Y_1 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq L_1, Y_2 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq G_2 \right] P \left[Y_2 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq L_2, Y_2 \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq G_2 \right] P \left[D \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq S \right] \right\}}{\sum_{i=0}^{\infty} \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \left\{ P \left[Y_1 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq L_1, Y_2 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq L_2, D \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq S \right] - P \left[Y_1 \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq L_1, Y_2 \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq L_2, D \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq S \right] \right\}} \\
 &+ \frac{C_c (1 - \sum_{i=0}^{\infty} \left\{ P \left[Y_1 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq L_1, Y_2 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq G_2 \right] P \left[Y_2 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq L_2, Y_2 \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq G_2 \right] P \left[D \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq S \right] \right\}}{\sum_{i=0}^{\infty} \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \left\{ P \left[Y_1 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq L_1, Y_2 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq L_2, D \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq S \right] - P \left[Y_1 \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq L_1, Y_2 \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq L_2, D \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq S \right] \right\}} \\
 &+ \frac{C_m \sum_{i=0}^{\infty} \left\{ (R_{1i} + R_{2i} + R_{3i}) P \left[D \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq S \right] \int_{\sum_{j=1}^i \alpha^{j-1} I_1}^{\sum_{j=1}^{i+1} \alpha^{j-1} I_1} \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 - t \right) dF_T(t) \right\}}{\sum_{i=0}^{\infty} \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \left\{ P \left[Y_1 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq L_1, Y_2 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq L_2, D \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq S \right] - P \left[Y_1 \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq L_1, Y_2 \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq L_2, D \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq S \right] \right\}}
 \end{aligned}$$

is minimum, where

$$\begin{aligned}
 R_{1i} &= P \left[Y_1 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq L_1, L_1 < Y_1 \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \leq G_1 \right] \times P \left[Y_2 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq L_2, L_1 < Y_1 \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \right], \\
 R_{2i} &= P \left[Y_1 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq L_1, G_1 < Y_1 \left(\sum_{j=1}^{i+1} \alpha^{j-1} I_1 \right) \right] \times P \left[Y_2 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq L_2 \right], \\
 R_{3i} &= P \left[Y_1 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq L_1 \right] \times P \left[Y_2 \left(\sum_{j=1}^i \alpha^{j-1} I_1 \right) \leq L_2 \right].
 \end{aligned}$$

This optimization function is a complex nonlinear function, the optimum solution of which is difficult to find. The Nelder–Mead downhill simplex method (discussed in Sect. 26.5.1) is the most popular direct-search method for obtaining the optimum solution of an unconstrained nonlinear function and does not require the calculation of derivatives.

Numerical Examples

This section illustrates the results in the Sect. 26.5.2. Assume that degradation process 1 is described as the function $Y_1(t) = \frac{We^{B_1 t}}{A_1 + e^{B_1 t}}$, where the random variables A_1 and B_1 are independent and follow a uniform distribution with parameter interval [0,40], and exponential distribution with parameter 1, respectively. In short, $A_1 \sim U[0, 40]$ and $B_1 \sim \text{Exp}(1)$. Similarly, assume that degradation process 2 is modeled as $Y_2(t) = A_2 + B_2 g(t)$ where $A_2 \sim U[0, 2]$, $B_2 \sim \text{Exp}(0.2)$ and $g(t) = \sqrt{t} e^{0.01t}$. Assume that the random shock is represented by the function $D(t) = \sum_{i=0}^{N_2(t)} X_i$, where $X_i \sim \text{Exp}(0.04)$ and $N(t) \sim \text{Poisson}(0.1)$. Also $G_1 = 300$, $G_2 = 70$, and $S = 100$. Assume that the cost parameters are as

follows: $C_c = 560$ units/CM, $C_p = 400$ units/PM, $C_i = 100$ units/inspection, $C_m = 500$ units/unit time and $\alpha = 0.97$. The inspection sequence $\{I_1, \dots, I_n, \dots\}$ is constructed with $I_n = \sum_{j=1}^n \alpha^{j-1} I_1$. We want to determine the values of I_1 and (L_1, L_2) so that the average long-run maintenance cost rate per unit time is minimized. Following are the steps using our proposed algorithm in Sect. 26.5.1:

- Step 1: There are three decision variables, say L_1, L_2 , and I_1 , so we need four distinct vertices as an initial set of values: $Z^{(1)} = (270, 56, 76)$, $Z^{(1)} = (280, 60, 72)$, $Z^{(2)} = (290, 52, 66)$, and $Z^{(3)} = (300, 50, 57)$. Set $k = 0$.

We now calculate the function value $f(Z)$ corresponding to each vertex and put them in increasing order of the objective value $EC(L_1, L_2, I_1)$ from smallest to highest.

- Step 2: Compute the centroid: $X^{(0)} = \frac{1}{3} (Z^{(1)} + Z^{(2)} + Z^{(3)}) = -(-20, 6, 14.3)$.

Table 26.3 Nelder–Mead algorithm results

k	$Z^{(1)} = (L_1, L_2, I_1)$	$Z^{(2)}$	$Z^{(3)}$	$Z^{(4)}$	Search result
0	(270,56,76)	(280,60,72)	(290,52,66)	(300,50,57)	$\lambda = 2$
	$\frac{E[C_1]}{E[W_1]} = 300.7$	$\frac{E[C_1]}{E[W_1]} = 332.2$	$\frac{E[C_1]}{E[W_1]} = 360.4$	$\frac{E[C_1]}{E[W_1]} = 388.2$	$\frac{E[C_1]}{E[W_1]} = 247.9$
1	(240,60,99.9)	(270,56,76)	(280,60,72)	(290,52,66)	$\lambda = 1$
	$\frac{E[C_1]}{E[W_1]} = 247.9$	$\frac{E[C_1]}{E[W_1]} = 300.7$	$\frac{E[C_1]}{E[W_1]} = 332.2$	$\frac{E[C_1]}{E[W_1]} = 360.4$	$\frac{E[C_1]}{E[W_1]} = 248.0$
2	(236,60,99.2)	(240,60,99.9)	(270,56,76)	(280,60,72)	$\lambda = 2$
	$\frac{E[C_1]}{E[W_1]} = 247.9$	$\frac{E[C_1]}{E[W_1]} = 248.0$	$\frac{E[C_1]}{E[W_1]} = 300.7$	$\frac{E[C_1]}{E[W_1]} = 332.2$	$\frac{E[C_1]}{E[W_1]} = 246.7$
3	(187,56,131)	(236,60,99.2)	(240,60,99.9)	(270,56,76)	$\lambda = 1$
	$\frac{E[C_1]}{E[W_1]} = 246.7$	$\frac{E[C_1]}{E[W_1]} = 247.9$	$\frac{E[C_1]}{E[W_1]} = 248.0$	$\frac{E[C_1]}{E[W_1]} = 300.7$	$\frac{E[C_1]}{E[W_1]} = 245.9$
4	(172,60,144)	(187,56,131)	(236,60,99.2)	(240,60,99.9)	Stop
	$\frac{E[C_1]}{E[W_1]} = 245.9$	$\frac{E[C_1]}{E[W_1]} = 246.7$	$\frac{E[C_1]}{E[W_1]} = 247.9$	$\frac{E[C_1]}{E[W_1]} = 248.0$	

- Step 3: Search for the away-from-worst direction: $\Delta X = X^{(0)} - Z^{(4)} = (-20, 6, 14.3)$.
- Step 4: Set $\lambda = 1$, which will generate a new minimal $EC(260, 60, 85.6) = 291.9$ that leads to an expansion with $\lambda = 2$ that is $(240, 60, 99.9)$.
- Step 5: Set $\lambda = 2$. Similarly, compute $f(Z)$, which leads to 247.9. Go to Step 8.

This result turned out to be a better solution, hence $(300, 50, 57)$ is replaced by $(240, 60, 99.9)$.

The iteration continues and stops at $k = 4$ (see Table 26.3) since

$$\sqrt{\frac{1}{4} \sum_{i=1}^4 [EC(Z^{(i)}) - \overline{EC(L_1, L_2, I_1)}]^2} = 0.449 < 0.5,$$

where $\overline{EC(L_1, L_2, I_1)}$ is the average value.

From Table 26.3, we obtain the optimal solution for (L_1, L_2, I_1) as: $(L_1^* = 172, L_2^* = 60, I_1^* = 144)$ and the corresponding average long-run maintenance cost rate is $EC(L_1^*, L_2^*, I_1^*) = 245.9$. Figure 26.18 depicts the average long-run maintenance cost-rate curve $EC(L_1, L_2, I_1)$ as a function of the inspection time interval I_1 for $L_1 = 172$ and $L_2 = 60$.

Table 26.4 presents a sensitivity analysis in terms of the probability that the cycle will end due to a PM action, P_p , for various values of (L_1, L_2) for $\alpha = 0.97$ and $I_1 = 144$. From Table 26.4, we observe that the probability P_p slightly increases as both L_1 and L_2 decrease. This in fact shows that one would perform more PMs than CMs when L_1 and L_2 both become smaller.

Fig. 26.18 The average maintenance cost $EC(L_1, L_2, I_1)$ versus I_1

Table 26.4 The effect of (L_1, L_2) on P_p for a given inspection sequence

L_1	L_2	P_p
200	60	0.5910
190	58	0.5928
180	56	0.5936
170	54	0.5948
160	52	0.5950
150	50	0.5968

Similarly, Table 26.5 presents the probability that the cycle will end due to a PM action, P_p , for various values of I_1 given $L_1 = 172, L_2 = 60$, and $\alpha = 0.97$. From Table 26.5, we observe that the probability P_p decreases as I_1 increases.

Table 26.5 The effect of the inspection sequence on P_p for fixed PM values

I_1	P_p
110	0.642
120	0.610
130	0.578
140	0.510
150	0.480
160	0.430

Fig. 26.19 The probability P_p versus I_1 for various pairs (L_1, L_2)

In other words, the maintenance cycle will be more likely to end due to corrective rather than preventive maintenance if one delays inspection. This result can help maintenance managers or inspectors to allocate resources and time.

Figure 26.19 shows the results for the probability that the cycle ends due to PM versus the inspection interval time I_1 for given values of the threshold PM levels (L_1, L_2) . It is interesting to observe from Fig. 26.19 that the results are about the same for the two combinations of $(L_1 = 172, L_2 = 60)$ and $(L_1 = 200, L_2 = 50)$.

26.6 Complex Systems with Dependent Competing Risks and Random Shocks Using Copulas

In this subsection, we discuss briefly some dependent competing risk models for systems subject to multiple degradation processes and random shocks especially using time-varying copulas. Assuming independence between degradation processes may underestimate the entire system reliability [24]. There exist two types of the dependent

configurations that should be taken into consideration: (i) the dependent relationship between degradation processes and random shocks, and (ii) the dependent relationship among various degradation processes.

Taking a human heart as an example, at the age of early 40s, the efficiency of the heart delivering blood to the body will begin to be greatly reduced because of the gradual loss of elasticity of blood vessels. As a result, the arteries may harden or become blocked. Also, many factors can contribute as a shock to the human body, such as non-normal living environment and illness. Diabetes can damage many parts of the human body, such as the heart, kidneys, and blood vessels. Therefore, the human body is a complex system with correlated multiple organs and subsystems that contribute to the proper functioning of the physical mechanism [24].

Finkelstein [25] introduced a generalized Strehler-Mildvan model to estimate the first passage time of the survival function for the system subject to cumulative damage due to biological aging, and sudden killing events. Van Noortwijk et al. [26] put forward a novel approach to combine two stochastic processes of deteriorating resistance and fluctuating load for the reliability analysis of a structural component. Ye et al. [27] proposed a degradation model to capture the two failure mechanisms of degradation and shocks using the Brown-Proshan model under the condition that only failure times and failure modes are recorded without the observable information of shock magnitude and degradation amount. Wang and Pham [28] studied a multi-objective imperfect preventive maintenance policy for complex systems subjected to the dependent competing risks of degradation wear and random shocks, by simultaneously maximizing the system asymptotic availability and minimizing the system cost rate. Sari et al. [29] studied a bivariate degradation model with constant stress to accommodate the dependency between more degradation measures distributed with different marginal functions.

Considerable attention has been paid in the early 2000s to the dependence behavior between random variables modeled by copulas which allows to link the univariate marginal distributions to obtain a joint probability of the events, Cossette et al. [30] studied the discounted penalty function for a generalized Farlie-Bumbel-Morgenstern copula model in the presence of the associations between the claim sizes and inter-claim time in a compound Poisson risk model. Lo and Wilke [31] develop a new copula graphic estimator applied to a model with multiple dependent competing risks, and apply the model to the data set of unemployment duration from Germany. In the work by Miladinovic and Tsokos [32], a modified Gumbel failure model is used to study the system failure time and Bayesian reliability estimates.

The copula method is a flexible, powerful technique to build multivariate distributions which is widely used in various applications including economics, finance, and actuarial science. Kaishev et al. [33] developed a dependent multiple-degradation model to examine the dependencies among causes of death to analyze the impact of complete or partial elimination of causes of death on the survival function from competing risks using copulas. Wang and Pham [24] studied an important classical dependent competing risk model by combining time-scaled covariate factors governed by random shocks into the degradation paths using a copula method. They employed the copula method to build a more flexible dependent competing model for continuously degraded complex systems in which the dependent configuration between random shocks and various degradation processes are linked by time-scaled covariate copula methods. A detail of modeling the dependent competing risks with multiple degradation processes and random shocks of complex systems can be found in [24].

Bedford and Alkali [34] studied a competing risk and opportunistic informative maintenance modeling involving censoring through opportunistic maintenance. Recent studies in the areas of competing risk and dependent failures of systems with various applications can be founded in Liu [35] on the system maintenance modeling for competing risk processes with inter-arrival shocks; in Fang et al. [36] using copula; Palayangoda and Ng [37] considering semiparametric and nonparametric; Donev and Hoffmann [38] on the road transportation research in the presence of data censoring and dependent competing risks; and Austin and Fine [39] and Noordzij et al. [40] about the survival competing risks in medical applications .

26.7 Conclusions and Perspectives

In this chapter, we present reliability and maintenance models for degraded systems with multiple competing failure processes. For mathematical modeling, it is always necessary to make some assumptions in order to make the model applicable in practice. For reliability and maintenance

modeling, assumptions have often played an important role in determining the structure and complexity of the models.

The results of the maintenance models in this chapter can be used to help practitioners and inspectors as well as marketing managers to allocate resources and for the promotion strategies for new products. It would be of interest for future research to implement these results by collecting data and observing product system degradations in practice. Other research problems worth exploring in the future are as follows [22].

1. The objective function discussed in this chapter is to minimize the expected long-run maintenance cost. In practice, costs associated with inspections, preventive maintenance, corrective maintenance, and downtime are sometimes difficult to obtain, even when used in practice. For some critical systems, the overriding goal is to ensure that the system should be available when needed; availability is, therefore, of primary interest, and cost is secondary.

To achieve a high level of availability for a specified inspection rate, it is worth to determine the optimum number of inspections with respect to imperfect repairs, such as minimal and opportunistic schemes, that maximizes the system availability. The time required for imperfect repairs and for replacement policies are random.

2. This chapter assumed that at any time there is unlimited supply of systems available for replacement. In reality, this assumption might not be true due to budget allocation and other constraints. In this case, a random lead time for delivering the new system when needed should be considered. It is essential and practical to analyze the effect of this random lead time on availability. When incorporating random lead time, the expected downtime will increase; therefore, system availability will decrease.

Appendix A

Jacobian Determinant

Below is a 2×2 *Jacobian* determinant

$$J = \frac{y_1 (y_2 - W) \left(\frac{y_2}{y_1(y_2 - W)} - \frac{y_2(y_1 - W)}{y_1(y_2 - W)} \right) [-d(y_1, y_2) - d_1(y_1, y_2) + d_2(y_1, y_2)]}{y_2 (y_1 - W) (I_{i+1} - I_i)} + d_3(y_1, y_2),$$

where

$$d(y_1, y_2) = \frac{\left[\left(\frac{y_1 - W}{y_1(y_2 - W)} - \frac{y_2(y_1 - W)}{y_1(y_2 - W)^2} \right) y_1(y_2 - W)^2 I_{i+1} e^{\left(\frac{\ln\left(\frac{y_2(y_1 - W)}{y_1(y_2 - W)}\right)_{i+1}}{i+1-i} \right)} \right]}{y_2^2 (y_1 - W) (I_{i+1} - I_i)}, y_1 \neq W, y_2 \neq W,$$

$$d_1(y_1, y_2) = \frac{e^{\left(\frac{\ln\left(\frac{y_2(y_1 - W)}{y_1(y_2 - W)}\right)_{i+1}}{i+1-i} \right)}}{y_2}, y_2 \neq W,$$

$$d_2(y_1, y_2) = \frac{e^{\left(\frac{\ln\left(\frac{y_2(y_1 - W)}{y_1(y_2 - W)}\right)_{i+1}}{i+1-i} \right)} (y_2 - W)}{y_2^2}, y_2 \neq W,$$

$$d_2(y_1, y_2) = \frac{d_{31}(y_1, y_2) d_{32}(y_1, y_2)}{y_2^3 (y_1 - W)^2 (I_{i+1} - I_i)^2}, y_1 \neq W,$$

$$d_{31}(y_1, y_2) = \left(\frac{y_1 - W}{y_1(y_2 - W)} - \frac{y_2(y_1 - W)}{y_1(y_2 - W)^2} \right) y_1^2 (y_2 - W)^3, y_2 \neq W,$$

$$d_{32}(y_1, y_2) = \left(\frac{y_2}{y_1(y_2 - W)} - \frac{y_2(y_1 - W)}{y_1^2(y_2 - W)} \right) I_{i+1} e^{\left(\frac{\ln\left(\frac{y_2(y_1 - W)}{y_1(y_2 - W)}\right)_{i+1}}{i+1-i} \right)}, y_2 \neq W.$$

Appendix B

A list of all 18 events:

$$E_1^{(i+1)} = [Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S] \cap [L_1 < Y_1(I_{i+1}) \leq G_1, L_2 < Y_2(I_{i+1}) \leq G_2, D(I_{i+1}) \leq S]$$

$$E_2^{(i+1)} = [Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S] \cap [L_1 < Y_1(I_{i+1}) \leq G_1, Y_2(I_{i+1}) \leq L_2, D(I_{i+1}) \leq S]$$

$$E_3^{(i+1)} = [Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S] \cap [Y_1(I_{i+1}) \leq L_1, L_2 < Y_2(I_{i+1}) \leq G_2, D(I_{i+1}) \leq S]$$

$$E_4^{(i+1)} = [Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S] \cap [L_1 < Y_1(I_{i+1}) \leq G_1, Y_2(I_{i+1}) > G_2, D(I_{i+1}) \leq S]$$

$$E_5^{(i+1)} = [Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S] \cap [L_1 < Y_1(I_{i+1}) \leq G_1, L_2 < Y_2(I_{i+1}) \leq G_2, D(I_{i+1}) > S]$$

$$E_6^{(i+1)} = [Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S] \cap [L_1 < Y_1(I_{i+1}) \leq G_1, Y_2(I_{i+1}) > G_2, D(I_{i+1}) > S]$$

$$E_7^{(i+1)} = [Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S] \cap [Y_1(I_{i+1}) > G_1, L_2 > Y_2(I_{i+1}), D(I_{i+1}) \leq S]$$

$$E_8^{(i+1)} = [Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S] \cap [Y_1(I_{i+1}) > G_1, L_2 < Y_2(I_{i+1}) \leq G_2, D(I_{i+1}) \leq S]$$

$$E_9^{(i+1)} = [Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S] \cap [Y_1(I_{i+1}) > G_1, L_2 > Y_2(I_{i+1}), D(I_{i+1}) > S]$$

$$E_{10}^{(i+1)} = [Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S] \cap [Y_1(I_{i+1}) > G_1, L_2 < Y_2(I_{i+1}) \leq G_2, D(I_{i+1}) > S]$$

$$E_{11}^{(i+1)} = [Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S] \cap [Y_1(I_{i+1}) > G_1, Y_2(I_{i+1}) > G_2, D(I_{i+1}) \leq S]$$

$$E_{12}^{(i+1)} = [Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S] \cap [Y_1(I_{i+1}) > G_1, Y_2(I_{i+1}) > G_2, D(I_{i+1}) > S]$$

$$E_{13}^{(i+1)} = [Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S] \cap [L_1 < Y_1(I_{i+1}) \leq G_1, L_2 > Y_2(I_{i+1}), D(I_{i+1}) > S]$$

$$E_{14}^{(i+1)} = [Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S] \cap [L_1 > Y_1(I_{i+1}), L_2 > Y_2(I_{i+1}), D(I_{i+1}) \leq S]$$

$$E_{15}^{(i+1)} = [Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S] \cap [L_1 > Y_1(I_{i+1}), L_2 > Y_2(I_{i+1}), D(I_{i+1}) > S]$$

$$E_{16}^{(i+1)} = [Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S] \cap [L_1 > Y_1(I_{i+1}), L_2 < Y_2(I_{i+1}) \leq G_2, D(I_{i+1}) > S]$$

$$E_{17}^{(i+1)} = [Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S] \cap [L_1 > Y_1(I_{i+1}), Y_2(I_{i+1}) > G_2, D(I_{i+1}) \leq S]$$

$$E_{18}^{(i+1)} = [Y_1(I_i) \leq L_1, Y_2(I_i) \leq L_2, D(I_i) \leq S] \cap [Y_1(I_{i+1}) \leq L_1, Y_2(I_{i+1}) \leq L_2, D(I_{i+1}) \leq S]$$

modeling and condition-based maintenance decision rule. Then, dynamic maintenance policies are described in two different contexts: for groupings of maintenance actions and for reducing uncertainty in modeling. Finally, a particular case of dynamic preventive maintenance model is described in detail for a system with continuous degradation and unknown degradation parameters. It is based on the inverse Gaussian process with a nonperiodic inspection policy and includes parameters update.

Predictive maintenance · Condition-based maintenance · Adaptive maintenance · Dynamic maintenance · Deterioration · Stochastic process · Inverse Gaussian · Bayesian update

Abstract

Digital technologies improve the information collected on systems and allow the development of condition-based maintenance policies and models using the remaining useful life. Accordingly, maintenance policies have evolved from a simple time-based to a more complex and competitive predictive approach. However, considering a dynamic maintenance decision framework with a self-adaptive decision rule has not been thoroughly addressed. This chapter deals with continuously deteriorating systems and focuses on dynamic maintenance policies, i.e., policies using real-time information to update the decision rule and handle the model's uncertainty. The first part presents popular stochastic processes for degradation

27.1 Introduction

Many structures or systems can be restored to working condition through maintenance actions that range from minimal repair, allowing the restart of the system, to total replacement. Depending on the equipment's operating costs or availability, it may be worthwhile to anticipate the failure and intervene while the system is still operating. Maintenance modeling addresses the overall planning of monitoring and maintenance actions throughout the equipment's useful life cycle. Possible actions can be envisaged, for example, as in [1] with an immediate online response to a detection of an unexpected sudden change in the system's operating mode. However, decision-making must be more broadly integrated into an overall supervision system.

Choosing a maintenance policy allows the maintenance decision-maker responding judiciously to questions such as "what has to be done?" and "when has it to be done?". The decision can be supported and improved by information retrieved "online."

Maintenance actions can be classified into two main categories concerning failure time. Preventive maintenance actions are programmed to prevent or delay a failure, and corrective maintenance actions occur in response to, and therefore due to, a system failure.

The development of a maintenance strategy for repairable systems requires the adoption of decision rules allowing jointly and, if possible, on the one hand, to choose the type of maintenance action to be implemented among those that are permitted, on the other hand, to plan the different actions over time. The choice and optimization of a maintenance policy require the ability to assess a given strategy's impact on the system's performance under consideration. The effects of policy need to be quantified. Performance evaluation requires developing models that represent the behavior of the maintained system and allow its characterization. All in all, it is necessary to combine:

- A representation of the system's behavior from a "new" state to failure;
- A model of the rule for monitoring and maintenance planning;
- A criterion for evaluating the performance of the maintained system.

In the last 50 years, many models have been developed and enriched under various assumptions. They allow considering different aspects of maintenance issues for systems with stochastic failure or degradation. Detailed summaries exist from different perspectives and can be found, for example, in [2–13]. Note that the models' different classifications can be proposed depending on the item which is primarily considered.

First, let us consider the system description. Based on the system modeling characteristics, it is possible to distinguish mono-component and multi-component representations. The primary representation is for single individuals or complex systems which can be considered as a whole, i.e., without describing their inner reliability structure. The next one proposes a description of the system as an assembly of parts or subsystems which can be modeled individually. For the latter, different forms of interactions between the components can be highlighted depending on the system's main characteristics under study. Consequently, different classes can be adopted. For instance, links developed for the system reliability structure (series, parallel, k out of n), or types of dependency between the components (economic, stochastic, or structural).

In parallel, the system's behavior or its components up to failure can be described in different ways. It can be based either directly on lifetimes' characterization or represent the evolution of observable conditions from "new" state to "failed" state. Direct lifetime modeling for a component

can be seen as a "two-states" representation of the system's condition ("working" and "failed"). In that case, the relevant indicator is the failure rate, which describes aging and can evolve more or less complicatedly. Moreover, modeling a system's degradation or wear evolution leads to a discrete (countable) or continuous state space with underlying stochastic processes.

Moreover, if the main classification viewpoint is guided by maintenance, models existing in the literature can be associated with the type of maintenance action (inspection, replacement, repair) and its efficiency (minimal, imperfect repair, intervention degrading the system), or with the class of decision rule (time-based rule, age-based rule, condition-based rule).

Finally, policies can be differentiated according to their assessment criteria (cost, reliability, or availability) and the considered time horizon (finite or infinite). In addition to the previous categories, one could also consider classifications depending on the methodology used to develop the cost model, whether it is based on, e.g., renewal theory or Markov decision processes. The characteristics of the information available online about the system to be maintained can also be considered.

This chapter concentrates on maintenance modeling for gradually deteriorating systems and which deterioration can be modeled continuously in time. Consequently, the degradation modeling framework will focus on continuous-time stochastic processes. The most commonly used stochastic processes in degradation modeling for prognosis and maintenance are the Wiener process, gamma process, and inverse Gaussian process. The last two processes allow describing the monotone degradation phenomenon. The gamma process has been widely considered in maintenance modeling; e.g., [14–17] to mention a few. The inverse Gaussian process has been considered more recently in this concept; see, for example, [18–20]. The Wiener process allows us to focus on the maintenance of non-monotone degradation behaviors; see, for example, [21–23], and [24].

Predictive and condition-based maintenance policies include all preventive policies for which maintenance decisions are taken based on observations of the system's current state. Decisions can possibly include future use conditions. When properly implemented, the performance of these classes of policies exceeds that of conventional static policies that do not exploit any information from online monitoring [25–27]. In this context, the main objective is to enable the appropriate use of all system monitoring information available in real-time to enhance maintenance decision-making effectiveness.

In this chapter, attention is paid mainly to the dynamic decision framework. There is no formal and precise definition of dynamic maintenance policies. It can be related to a wide range of configurations. We will consider that the dynamic maintenance decision framework refers to decision rules with

an embedded online self-modification process updated from real-time information. A dynamic maintenance policy must include updating the decision rule parameters or structure or modifying some model elements as new information becomes available. The mentioned information can be related to the system by itself (degradation level, state of other components in case of multi-component systems, ...), or some external influencing factors (covariates related to the environment, hypotheses on the system's future mission, ...). A classical condition-based maintenance policy with fixed decision variables will not be hereafter considered dynamic. Even if decisions are made based on the current observed degradation level, the decision rule by itself is set from the beginning and does not include any adaptive process.

The first part of the chapter is devoted to general definitions and notations about continuous-time degradation processes and usual maintenance decision rules. Then descriptions of the two main configurations and frameworks related to dynamic maintenance policies with gradual deterioration are given. One of the configurations corresponds to imperfect knowledge of the degradation process due to a noninformative database, identification of some random effect, or specific expert opinion. The other one is devoted to systems described as multi-component systems with possible interactions and influence of the environment.

The second part focuses on one specific case of maintenance policy that precisely illustrates the framework and adaptive process of a dynamic maintenance policy for a system described by a scalar degradation indicator. The information collected online by inspections is used to dynamically improve the maintenance decision rule and update it in real-time.

27.2 Gradual Deterioration and Predictive Maintenance

27.2.1 Stochastic Processes

In the following, the process $\{X_t\}_{t \geq 0}$ represents the evolution of the degradation indicator over time. The following is not an exhaustive presentation of the stochastic processes considered for maintenance modeling. It focuses on the ones verifying the following properties:

1. $X_0 = 0$ almost surely; i.e., the system, component or structure is considered as "new" on the date of commissioning;
2. Non-overlapping increments are statistically independent; i.e., for any partition $0 \leq t_0 < t_1 < \dots < t_n < \infty$ the increments $X_{t_1} - X_{t_0}, X_{t_2} - X_{t_1}, \dots, X_{t_n} - X_{t_{n-1}}$ represent n mutually independent random variables;

3. The increments are stationary; i.e., $\forall t, s \geq 0, X_{t+s} - X_t$ depends only on the length s of the interval, but not on its position on the time axis.

Remark that as a consequence of items 2 and 3, the distribution of $X_{t+s} - X_t$ is infinitely divisible. It means that for all integer $n > 0$ it is the sum of n independent variables with the same distribution as $X_{t+s/n} - X_t$. Therefore, appropriate infinitely divisible distributions are good candidates deriving stochastic processes. Here, we focus on continuous-state stochastic processes to model degradation. The relevance of utilizing a stochastic process for degradation modeling depends on several requirements, such as:

- Having clear physical explanations,
- Being easy to understand and use,
- Having good mathematical properties,
- Being adequate for easy incorporation of prior information and agile in dealing with covariates and random effects.

A limit value is typically considered to describe system failure in conjunction with degradation modeling. It will be referred to as L in the following. The failure time is then the first passage time of this limit. It should be noted that reaching this threshold does not necessarily correspond to a hard failure. It can be considered an exit from the acceptable use area to represent the system's inability to meet the requirements. By this definition, the system lifetime corresponds to the hitting time defined as:

$$\sigma_L = \inf\{t > 0 : X_t \geq L\}. \quad (27.1)$$

The first passage time distribution plays an essential role in reliability and maintenance. However, the remaining useful life(RUL) distribution is needed, especially in deteriorating systems. Given the current information about the system's condition at time t_k , it is related to the time duration the system can still work before failure. That means the RUL R_k of the system at t_k is defined as:

$$R_k = \inf\{r > 0 : X_{t_k+r} \geq L | X_{t_k} = x < L\}. \quad (27.2)$$

In other words, the RUL R_k is related to the first passage time σ_{L-x} by the process $\{X_t\}_{t \geq 0}$. In Eq. (27.2), x is the measured degradation level at time t_k . The important point to note here is that the information about the system is supposed to be perfect when available, which means that the system's measured degradation value is exact.

Focusing on continuous degradation modeling, three stochastic processes are widely used. Two of them correspond to nondecreasing degradation indicators and

can be easily used to model various strictly increasing degradation processes like fatigue, corrosion, and crack propagation. In contrast, the other process's distinct feature is the modeling of degradation measures, which are not necessarily monotone. The next paragraphs are devoted to short introductions of Wiener, gamma, and inverse Gaussian processes and their essential functions.

Wiener Process

The Wiener process has normally distributed increments, that is, $X_{t+s} - X_t$, for $s, t \geq 0$ has a normal distribution with drift parameter μs and diffusion parameter $\sigma^2 s$. Then, the pdf of such increment is:

$$f_{\mu s, \sigma^2 s}^W(x) = \frac{1}{\sqrt{2\pi\sigma^2 s}} \exp\left\{-\frac{(x - \mu s)^2}{2\sigma^2 s}\right\}.$$

With this consideration, the mean and variance of X_s are:

$$\mathbb{E}(X_s) = \mu s \text{ and } \mathbb{V}(X_s) = \sigma^2 s.$$

Whitmore and Seshadri [28] derived the first passage time distribution with a Heuristic method. They showed that the cumulative probability function for the first passage time T is:

$$\begin{aligned} \mathbb{P}(\sigma_L \leq s) &= \mathbb{P}\left(\max_{0 \leq t \leq s} X(t) \geq L\right) \\ &= \int_L^\infty p(x)\{1 + Q(x)\} dx \\ &= \Phi\left[\frac{\mu s - L}{\sqrt{\sigma^2 s}}\right] \\ &\quad + \exp\left(\frac{2\mu L}{\sigma^2}\right) \Phi\left[-\frac{\mu s + L}{\sqrt{\sigma^2 s}}\right]. \end{aligned} \quad (27.3)$$

Here Φ denotes the cumulative distribution function of a standard normal distribution and the functions $p(x)$ and $Q(x)$ are, respectively:

$$p(x) = (2\pi\sigma^2 s)^{-1/2} \exp\left\{-\frac{(x - \mu s)^2}{2\sigma^2 s}\right\},$$

and

$$Q(x) = \exp\{-2\mu(x - L)/\sigma^2\}.$$

Taking the derivative of (27.3) with respect to s , one obtains, after simplification,

$$f_{\sigma_L}^W(s) = \frac{L}{\sqrt{2\pi\sigma^2 s^3}} \exp\left\{-\frac{(L - \mu s)^2}{2\sigma^2 s}\right\}.$$

Reparameterizing $\lambda = L^2/\sigma^2$ and $\eta = L/\mu$, leads to the usual form of the first passage time distribution for the Wiener process. It follows an inverse Gaussian distribution. Similarly, the pdf of the RUL at time t_k can be written as:

$$f_{R_k}^W(r) = \frac{L - x_k}{\sqrt{2\pi\sigma^2 r^3}} \exp\left\{-\frac{(L - x_k - \mu r)^2}{2\sigma^2 r}\right\}.$$

Gamma Process

The gamma process is such that the degradation increment $X_{t+s} - X_t$, for $s, t \geq 0$ has a gamma distribution with shape parameter αs and scale parameter β where $\alpha, \beta > 0$. The probability density function is:

$$f_{\alpha s, \beta}^G(x) = \frac{1}{\Gamma(\alpha s)} \frac{x^{\alpha s - 1}}{\beta^{\alpha s}} \exp\left(-\frac{x}{\beta}\right) \mathbb{I}_{\{x \geq 0\}}, \quad (27.4)$$

where $\Gamma(x)$ is the gamma function, i.e.,

$$\Gamma(x) = \int_0^{+\infty} u^{x-1} e^{-u} du,$$

and $\mathbb{I}_{\{A\}}$ is equal to 1 if A is true, 0, otherwise.

The mean and variance of one increment over time s are, respectively, given by:

$$\mathbb{E}(X_s) = \alpha s \beta \text{ and } \mathbb{V}(X_s) = \alpha s \beta^2. \quad (27.5)$$

The homogeneous gamma process has been widely considered for degradation modeling, residual lifetime or reliability assessment, and maintenance modeling [17].

Let, respectively, $F_{\sigma_L}^G(s) = \mathbb{P}(\sigma_L \leq s)$ and $f_{\sigma_L}^G(s)$ denote the cumulative distribution and probability density functions of σ_L when the degradation process is a gamma process. Then:

$$\begin{aligned} \mathbb{P}(\sigma_L > s) &= \mathbb{P}(X_s < L) \\ &= \int_0^L f_{\alpha s, \beta}^G(y) dy \\ &= \int_0^L \frac{1}{\Gamma(\alpha s)} \frac{y^{\alpha s - 1}}{\beta^{\alpha s}} \exp\left(-\frac{y}{\beta}\right) dy \\ &= \frac{1}{\Gamma(\alpha s)} \int_0^{L/\beta} x^{\alpha s - 1} e^{-x} dx. \end{aligned}$$

The cumulative distribution of σ_L can be expressed as:

$$F_{\sigma_L}^G(s) = \mathbb{P}(\sigma_L \leq s) = \frac{\Gamma(\alpha s, L/\beta)}{\Gamma(\alpha s)}, \quad (27.6)$$

where $\Gamma(\alpha, x)$ is the incomplete gamma function, i.e.:

$$\Gamma(\alpha, x) = \int_x^{+\infty} u^{\alpha-1} e^{-u} du.$$

Then, the corresponding pdf is :

$$f_{\sigma_L}^G(s) = \frac{\alpha}{\Gamma(\alpha s)} \int_{L/\beta}^{+\infty} \left(\log(x) - \frac{\Gamma'(\alpha s)}{\Gamma(\alpha s)} \right) x^{\alpha s-1} e^{-x} dx,$$

which is difficult to compute in practice. Usually, a simpler approximate distribution is used for computation. The approximated pdf of the first passage time for the gamma process is [29]:

$$f_{\sigma_L}^G(s) \approx \frac{L}{\beta \sqrt{2\pi \alpha s^3}} \exp \left\{ -\frac{\alpha \left(s - \frac{L}{\alpha \beta} \right)^2}{2s} \right\}.$$

Therefore, the pdf of RUL at time t_k can simply be approximated by:

$$f_{R_k}^G(r) \approx \frac{L - x_k}{\beta \sqrt{2\pi \alpha r^3}} \exp \left\{ -\frac{\alpha \left(r - \frac{L - x_k}{\alpha \beta} \right)^2}{2r} \right\}.$$

Inverse-Gaussian Process

According to this process, the degradation increment $X_{t+s} - X_t$ for $s > 0$, $t \geq 0$ follows an inverse Gaussian distribution (or Wald distribution) with mean parameter s/δ and shape parameter λs^2 . The related pdf and cdf are defined for $x > 0$ as follows:

$$f_{s/\delta, \lambda s^2}^{IG}(x) = \sqrt{\frac{\lambda s^2}{2\pi x^3}} \exp \left\{ -\frac{\lambda}{2x} (\delta x - s)^2 \right\}$$

and

$$F_{s/\delta, \lambda s^2}^{IG}(x) = \Phi \left(\sqrt{\frac{\lambda}{x}} (s - \delta x) \right) - \exp(2s\delta\lambda) \Phi \left(-\sqrt{\frac{\lambda}{x}} (s + \delta x) \right),$$

where $\delta, \lambda > 0$ and Φ is the cdf of the standard normal distribution. The mean and variance of the increment over time s are:

$$\mathbb{E}(X_s) = \frac{s}{\delta} \text{ and } \mathbb{V}(X_s) = \frac{s}{\delta^3 \lambda}. \quad (27.7)$$

The inverse Gaussian process has been considered more recently for degradation modeling [30, 31].

The cumulative distribution function of σ_L when the the degradation process is an inverse Gaussian process can be written as:

$$F_{\sigma_L}^{IG}(s) = \mathbb{P}(\sigma_L \leq s) = \Phi \left(\sqrt{\frac{\lambda}{L}} (s - \delta L) \right) - \exp(2s\delta\lambda) \Phi \left(-\sqrt{\frac{\lambda}{L}} (s + \delta L) \right).$$

By derivation with respect to s , the pdf is:

$$f_{\sigma_L}^{IG}(s) = 2\sqrt{\frac{\lambda}{L}} \Phi \left(\sqrt{\frac{\lambda}{L}} (s - \delta L) \right) - 2\delta\lambda \exp(2s\delta\lambda) \Phi \left(-\sqrt{\frac{\lambda}{L}} (s + \delta L) \right).$$

Accordingly, the RUL has the following cdf:

$$F_{R_k}^{IG}(r) = \Phi \left(\sqrt{\frac{\lambda}{L - x_k}} (r - \delta(L - x_k)) \right) - \exp(2r\delta\lambda) \Phi \left(-\sqrt{\frac{\lambda}{L - x_k}} (r + \delta(L - x_k)) \right). \quad (27.8)$$

27

27.2.2 Maintenance and Inspection Decision Rules

It is necessary to choose a specific structure of decision rule for continuous deterioration models. Most the existing works propose parametric structures based on control limit decision rules. The aim is to decide whether a maintenance action must be performed or not and define the next inspection time. All such decisions must be made given the current measured degradation level.

For this aim, let $\{T_n\}_{n \in \mathbb{N}}$ with $T_0 = 0$, denote the sequence of inspection times such that:

$$T_{n+1} = T_n + \Delta T_n.$$

Inspections can be planned either periodically or aperiodically. In the periodic inspection planning, the system is inspected at each T unit of time. That means $\Delta T_n = T$, for all n . In this case, the constant T is a decision variable and must be optimized. Periodic inspection planning is easy to implement in practice, but some concerns may arise, especially in deteriorating systems. As a matter of fact, the probability of failure increases with time or usage as the degradation level increases. Consequently, when a system is new, there is no need to have numerous inspections; as it ages, more frequent inspections are needed. Hence, in some cases, the maintenance cost will be high in the case of periodic inspections.

Aperiodic inspection planning is related to the current state of the system. It is self-adaptive and takes into account the most recent information about the system state. This alternative has become more popular for gradually deteriorating systems, see for example [21, 32–34]. Nonperiodic inspection scheduling leads to better results than periodic one as the latter can often be considered a limit case of aperiodic planning.

To implement aperiodic inspection planning, a decreasing function of system state, m , can be used to set the time between two inspections, i.e.,

$$\Delta T_n = m(X_{T_n}).$$

The general idea is to decrease the time between successive inspections as the degradation level increases. References [32, 35] used a special linear case of such function. Characteristics of this linear function were considered as decision variables to optimize. Utilizing the remaining useful life function is also another appropriate option [36, 37]. In this case:

$$\Delta T_n = \tau_p(X_{T_n}),$$

where

$$\tau_p(X_{T_n}) = \{\Delta t : \mathbb{P}(X_{T_n+\Delta t} \geq L | X_{T_n}) = p\}. \quad (27.9)$$

In other words, $\tau_p(X_{T_n})$ is the p -quantile of the remaining useful life distribution. Here, p is a decision variable. It is worthy to note that RUL-based inspection planning provides a reliability (safety) level equal to $(1 - p)$.

Along with inspection scheduling, maintenance actions must be arranged. To this aim, fixed thresholds are considered on the degradation level for preventive repairs or replacements. That means the systems with degradation higher than a specified level are highly risky, hence better to be replaced preventively. Replacements can alternatively be triggered as soon as the interval between two successive inspections is less than a given threshold. It is also reasonable because, as already mentioned, only the systems with a higher chance of failure need frequent inspections. In all these cases, the thresholds are decision variables that have to be optimized.

For more details about maintenance actions based on a threshold of degradation level, let $X_{T_n^-}$ ($n \in \mathbb{N}$) refer to the degradation level at the corresponding inspection time before potential maintenance action. Classically, with a preventive threshold M , the structure of the decision rule for perfect maintenance is as follows:

- If $X_{T_n^-} \geq L$, the system has failed and is correctively replaced. The next inspection is planed at time $T_n^- + m(0)$.

- If $M \leq X_{T_n^-} < L$, the system has not yet failed but is considered as “close to failure.” As a consequence, preventive action is taken immediately. The next inspection is planed at time $T_n^- + m(0)$.
- If $X_{T_n^-} < M$, the system is still properly functioning, and there is no need for replacement. The system is left as it is. The next inspection is planed at time $T_n^- + m(X_{T_n^-})$.

In this consideration, $m(\cdot)$ can equivalently be replaced by $\tau_p(\cdot)$. The decision-maker must determine the decision variables to optimize a given assessment criterion, usually the global maintenance cost. Decision variables are typically M and parameters of the function m or τ_p . In the case of discrete degradation modeling, i.e., with discrete state space, it may be possible to find the optimal decision structure, e.g., with Markov decision theory.

Note that, in imperfect maintenance actions, the structure of the decision rule is not so straightforward and requires additional elements and parameters. For instance, selection between imperfect preventive repair and perfect preventive replacement can be based on two preventive thresholds M_1 and M_2 with $0 < M_1 < M_2 < L$. Imperfect action takes place as the system state at inspection time is between M_1 and M_2 . Perfect ones are needed when the system state is higher than M_2 and less than L ; see, for example, [38]. Describing the gain of imperfect intervention with a specified distribution and defining appropriate characteristics for this distribution is also done in [39].

27.3 Framework of Dynamic Maintenance Policy

A dynamic maintenance policy is a maintenance policy that implements online modifications of an initial inspection/maintenance planning from new monitoring information. It adapts itself to the level of information which is available at a given time. The framework of dynamic maintenance covers a vast range of configurations. New information can be related directly to the maintained system, its environment or future usage. Two different cases are considered hereafter, which can lead to the development of dynamic maintenance policies. The first one focuses on multi-unit or multicomponent systems with dependencies between components. In that case, the dynamic characteristic is directly related to the grouping of maintenance actions, which requires successive updates for future action planning. The terminology “dynamic maintenance” has initially been introduced in this context. The second case deals with maintenance problems when the degradation phenomenon is not fully characterized. More precisely, a degradation model is chosen, but its parameters are unknown. In that case, successive inspections have to be considered online to

improve the maintenance model dynamically in real time. These two cases are described more precisely in the next two sections.

27.3.1 Grouping and Opportunistic Maintenance

Complex deteriorating systems or subsystems can be considered as a whole and characterized by a unique degradation indicator. Nevertheless, such systems may be composed of components, some of which deteriorate individually. The interaction between these components and their related degradation leads to the system's overall deterioration. Different specific information is collected if these components can be inspected and monitored separately. Therefore, it is interesting to consider a multivariate model that describes possible dependencies between components or the effect of specific missions on certain parts of the system. A dynamic decision framework can improve maintenance decision-making for such multi-component systems or fleets of units, especially when the timing of interventions needs to be managed rationally.

This section focuses on how dynamic maintenance can be implemented for multicomponent systems to handle short-term information obtained online. It is interesting for such systems to take advantage of dependencies between components, leading to maintenance opportunities. Different classifications of dependencies can be found in the literature. From the extended scheme proposed in [40], four different types of dependencies exist in contributions on condition-based maintenance policies: structural dependency, stochastic dependency, resource dependency, and economic dependency. Briefly, structural dependency can be related to the system reliability block diagram or some technical dependence when the maintenance of one component requires replacing other components. Stochastic dependency describes the relationship between the degradation of different components due to, e.g., load sharing, common causes of failure, or when the failure of one component modifies others' deterioration. Resource dependency deals with restrictions due to limited resources for maintenance, whether in spare parts, logistics, tools, maintenance workers, or budget. Finally, the system is subject to negative or positive economic dependencies when maintaining several components together is respectively more expensive or less expensive than maintaining them separately.

Dynamic maintenance grouping strategies have been developed mainly for economic dependencies in the context of continuously deteriorating multicomponent systems. More precisely, most of the models consider setup costs as follows. When maintenance is triggered, a system-dependent cost or setup cost S is incurred systematically. It is counted

only once, regardless of the number of components to be maintained simultaneously. In addition, let c_i be the individual maintenance cost of component i . Hence if all the components from the subset of components E_m are maintained simultaneously, it incurs the total maintenance cost $S + \sum_{i \in E_m} c_i$ at that time. Nonsimultaneous maintenance actions would lead to a cost equal to $\sum_{i \in E_m} (S + c_i)$. Due to the possibility of grouping maintenance activities, relevant groupings can reduce maintenance costs over a given planning horizon. The failure of a critical component can be considered an opportunity for additional preventive maintenance actions. Short-term additional information can be obtained in real time. For example, it can be linked to changes in the system's operational environment. This type of information is interesting to dynamically improve groupings on a rolling short-term horizon [41].

The seminal work on dynamic maintenance policy for grouping maintenance is developed in [42], which deals with the lifetime modeling of components. It does not consider continuously deteriorating systems but allows us to define the "dynamic" characteristic of maintenance policy. This characteristic is related to the availability of information and the choice to take it into account "online" with possible modifications of the decision rule's structure or decision variables' updates. Specifically, the authors in [42] consider an iterative procedure that characterizes dynamic rules as described in Fig. 27.1.

First, long-term tentative maintenance planning is defined, which consists of individual maintenance planning for each activity or component. It is based on long-run maintenance costs and stationary states. For each component, a penalty cost function is jointly derived to assess the drawback due to shifting the execution time of maintenance actions from the tentative planning. At a given time t , current information about the system state and the planned future solicitation is introduced. That step is considered on a short-term time horizon and allows us to shift the tentatively planned times obtained from the first step. Based on the penalty cost function, an optimal grouping structure is derived on the short-term horizon and iteratively updated when it is needed. The reiteration of this procedure at different successive times corresponds to the "rolling-horizon step." As already mentioned, the work in [42] does not consider gradual deterioration but rather lifetime modeling. It is devoted to series systems, and an algorithm based on dynamic programming technics is proposed for optimal grouping. The information about the system state available online is related to replacement and repair times of components and their usage rates. In [42], the latter can be updated. It illustrates the possibilities of their approach. Short-term knowledge about the future tasks planned for the system is also included when it is available. The "dynamic" property of the maintenance decision rule is related explicitly to the maintenance groupings' successive

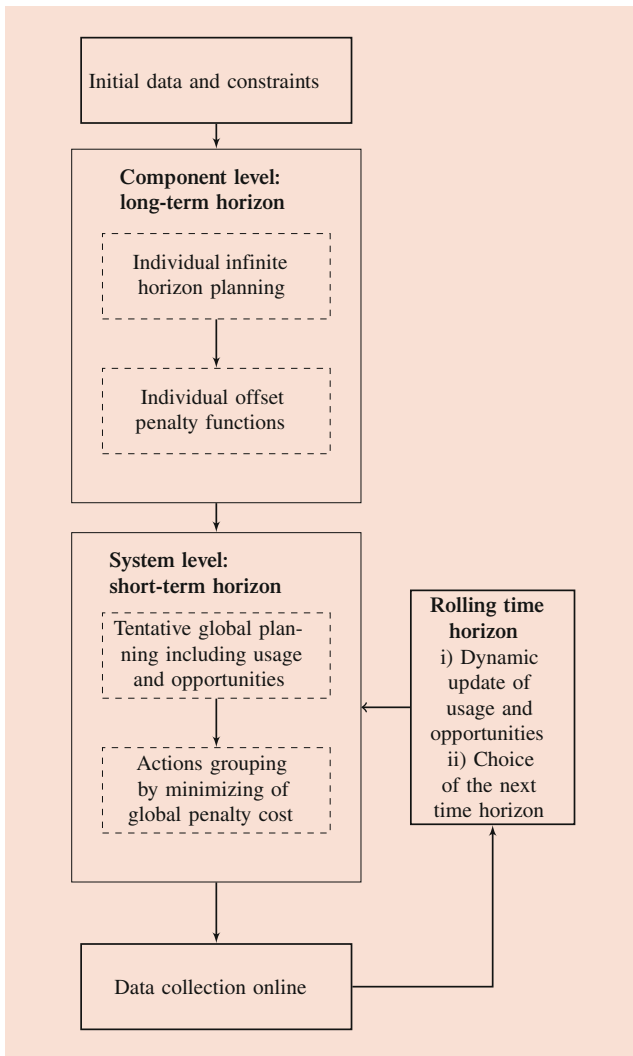

Fig. 27.1 The dynamic process for multiunit systems

updates. Other work has been subsequently published following the same idea; we refer to [43] to see a more complex structure for multicomponent systems. It is worthy to note that the optimal grouping strategy can be obtained via a Genetic algorithm.

Let's now consider systems that gradually deteriorate with time or usage. In such cases, information about the degradation level can be obtained by inspections or continuous monitoring. Condition-based or predictive maintenance policies can be implemented, and dynamic procedures may be derived. To illustrate and give more details about these dynamic policies, we focus hereafter on the works of Bouvard et al. [44], and Van Horenbeek and Pintelon [45]. It highlights the main characteristics of the dynamic maintenance framework for multicomponent deteriorating systems.

Consider a system with n components that deteriorate gradually. Each component is characterized by its degradation indicator $X_i(t)$ obtained by synthesizing

information from several sensors or directly representing a physical variable. In the mentioned papers, [44] and [45], the degradation processes are modeled classically with homogeneous gamma processes described in Sect. 27.2.1. Information about the degradation level of each component can be obtained at inspection times. Component i is considered failed when its degradation level crosses a failure threshold L_i , which may be a constant as in [44] or a random variable depending on operating load, operating environment, etc, as in [45]. In that case, information about the value of L_i can be obtained on a given time horizon. Each component can be preventively or correctively maintained, and the structure of the costs is as described previously: the system-dependent or set-up cost S is incurred once at each maintenance time. With the same notations as in [44, 45], the total maintenance cost on a finite planning horizon including m maintenance times referred as t_i , $i = 1, \dots, m$ and ending at time t_m can be written in a very general way as:

$$C(t_m) = mS + \sum_{i=1}^m \sum_{j \in G_i} (c_{j,p} \mathbb{I}_{X_j(t_i) \leq L_j} + c_{j,c} \mathbb{I}_{X_j(t_i) > L_j}),$$

where G_i is a subset of $\{1, \dots, n\}$, which refers to the numbers of the components maintained at time t_i . $c_{i,p}$ and $c_{i,c}$ are, respectively, preventive and corrective maintenance cost for component i . \mathbb{I}_A is equal to 1 if A is true, 0 otherwise. The main issue is then determining the groups G_i and the dates of intervention on the considered period to minimize $C(t_m)$.

The dynamic maintenance policy aims to optimally define the maintenance times and determine the associated groups of components to be maintained simultaneously. The proposed algorithms in [44, 45] follow the same procedure as in [42]. Each component is firstly considered individually. A provisional individual schedule is derived based on a classical maintenance policy for single unit systems, and it is optimized in order to minimize the long-run cost rate. This cost is evaluated by taking into account updated monitoring information. If new information becomes available and if necessary, the long-run cost rate expression can be updated.

Advanced continuous condition-based or predictive maintenance policies for single-unit systems could be considered for individual tentative planning. However, these decision rules use the last observed level of degradation to determine online the next time between inspections and the decision about the maintenance date. This real-time adaptive process makes the aggregation step difficult. Consequently, an age-based maintenance policy is chosen by the authors in [44] and [45] for the sake of simplicity. According to such a policy and considering each component individually, the component i is replaced at failure time or age θ_i^* [7]. In this case, the long-run cost rate can be expressed analytically from

the conditional reliability of components. The associated asymptotic cost rate can be obtained from renewal theory for component i as:

$$\begin{aligned} C_i^\infty(\theta) &= \lim_{t \rightarrow \infty} \frac{C_i(t, \theta)}{t} = \frac{E[C_i(T_i^r, \theta)]}{E[T_i^r]} \\ &= \frac{c_{i,p} + (c_{i,c} - c_{i,p})F_i(\theta)}{\int_0^\theta (1 - F_i(u))du}, \end{aligned} \quad (27.10)$$

where $C_i(t, \theta)$ is the cumulative maintenance cost up to time t and T_i^r represents the first replacement time, i.e., the length of the first renewal cycle. Moreover, F_i is the cumulative distribution function of the failure time of component i denoted by σ_{L_i} . That means:

$$F_i(\theta) = \mathbb{P}(\sigma_{L_i} \leq \theta) = \mathbb{P}(X_i(\theta) \geq L_i).$$

With notations from Sect. 27.2.1, it can be rewritten:

$$F_i(\theta) = G_{\sigma_{L_i}}^G(\theta) = \frac{\Gamma(\alpha_i \theta, L_i / \beta)}{\Gamma(\alpha_i \theta)}.$$

Aforementioned, the policy's optimal decision variable is the limit age of replacement θ_i^* , which minimizes $C_i^\infty(\theta)$. Authors in [44] and [45] made calculations with a discretized degradation process in order to assess such optimal decision variables. The cumulative distribution function of the failure time for the initial gamma process is converted into a discretized reliability function that is easier to handle numerically. Let the step of this discretization be hereafter denoted as δt . According to this discretization, $t_k = k\delta t$ and the conditional reliability over one time step δt given that the component's current age is t_k is:

$$\begin{aligned} R_{i,k} &= R(t_{k+1} | \sigma_{L_i} > t_k) \\ &= \mathbb{P}(\sigma_{L_i} > t_k + \delta t | \sigma_{L_i} > t_k), \end{aligned}$$

and by definition, it comes:

$$\begin{aligned} R_{i,k} &= \frac{\mathbb{P}(\sigma_{L_i} > t_{k+1})}{\mathbb{P}(\sigma_{L_i} > t_k)} \\ &= \frac{1 - F_i(t_{k+1})}{1 - F_i(t_k)}. \end{aligned}$$

The values of $R_{i,k}$ can then be obtained as a discretization of the failure probability distribution $F_i(\cdot)$, which is obtained by Monte-Carlo simulation in [45] (with random failure limit L_i). Then, the maintenance cost rate can be rewritten as:

$$C_i^\infty(\theta) \simeq \frac{c_{i,p} + (c_{i,c} - c_{i,p}) \left(1 - \prod_{k=0}^{l-1} R_{i,k}\right)}{1 + \sum_{p=2}^l \prod_{k=0}^{p-2} R_{i,k}}, \quad (27.11)$$

with $\theta = l\delta t$. Maintenance downtimes can also be introduced additionally in the previous expression.

Note that up-to-date information, i.e., the current degradation level of the component, only influences short-term predictions and planning. On a long-term basis, the stationary state or mean behavior is considered. Nevertheless, it is possible to consider the last measured degradation level of the component jointly with the expression of the long-run cost rate. Let the observed degradation level of component i at time t_0 be denoted by $X_i(t_0) = x_{i,0}$. It is possible to consider the cost expression from Eqs. (27.10) or (27.11) by replacing L_i with $L_i - x_{i,0}$ in the expressions above. It is equivalent to considering cycles where the initial state is $x_{i,0}$ instead of 0. Let $\theta_{i,0}^*$ be the value of θ , which minimizes this cost. The next preventive replacement given the degradation level $x_{i,0}$ at time t_0 can be scheduled at time $t_0 + \theta_{i,0}^*$.

As an illustration, let's focus on the expression of cost in continuous case specified by Eq. (27.10). Given the current degradation level of the component i at time t , the maintenance cost function can be written as a function of the conditional cumulative distribution function F_i , i.e.:

$$C_i^\infty(\theta | X_i(t) = x_{i,t}) = g(F_i(\theta | X_i(t) = x_{i,t})),$$

where g is a known function depending on maintenance unit costs and:

$$\begin{aligned} F_i(\theta | X_i(t) = x_{i,t}) &= 1 - R_{i,t}(\theta | X_i(t) = x_{i,t}) \\ &= \mathbb{P}(X_i(t + \theta) \geq L | X_i(t) = x_{i,t}), \end{aligned}$$

where $R_{i,t}(\theta | X_i(t) = x_{i,t})$ is the conditional reliability of component i at time θ with last inspection at time t . It can be obtained from the expression of the hitting time, as defined in Sect. 27.2.1. At time t , two different versions of the cost are considered as criteria to be minimized for the determination of the age of preventive maintenance:

- the criterium of short-term optimal maintenance time for component i takes into account the last monitoring information. It means that at inspection time t , this criterium is the cost:

$$C_i^{ST}(\tau) = C_i^\infty(\tau | X_i(t) = x_{i,t}).$$

It can also include short-term prognosis information about future missions;

- the criterium of long-term optimal maintenance time for component i is based on the maintained component's stationary behavior. It is obtained considering the component is new at time t , i.e., the cost is

$$C_i^{LT}(\tau) = C_i^\infty(\tau | X_i(t) = 0).$$

In the case of imperfect maintenance, the expectation over the degradation level of component i just after maintenance is considered. It requires the knowledge of the corresponding degradation level distribution.

The value $\tau_{i,1}^*$ which minimizes $C_i^{ST}(\tau)$ gives the time interval before the next tentative maintenance time. For the following maintenance times the value $\tau_{i,+}^*$ which minimizes $C_i^{LT}(\tau)$ is considered. In other words, the k -th planned maintenance time for component i takes place at time $t + \tau_{i,1} + (k-1)\tau_{i,+}$ in the absence of failure. Downtime due to maintenance duration can be considered but is neglected here. In both cases, the cost expression comes from a formulation over an infinite horizon and uses renewal properties. The dynamic decision-making process leads to using it only on a limited time horizon and then updating it.

A strategy for maintenance groupings must be defined to exploit economic dependencies represented by setup costs. For this purpose, a penalty cost function is defined along with the initial individual tentative planning. It allows evaluation of how the cost is affected by shifting maintenance activities from the previous tentative planning for each component. Two cases are considered by including or not the knowledge about $X_i(t)$, in accordance with the way short-term and long-term optimal maintenance times have been determined previously. In case of failure of component i at time t , the penalty function is infinite if the replacement is delayed and null if it is moved forward. Let G_j denote a group of components to be maintained at the same time. Assume the maintenance of the group takes place at time t_g . The penalty cost associated with this group is denoted by $H_{G_j}(t_g)$, which is the sum of short-term penalty costs of all components from G_j . The optimal maintenance time $t_{G_j}^*$ for group G_j is the one minimizing H_{G_j} . When the maintenance time is determined for the group, it is possible to evaluate the savings obtained if the maintenance of all the elements of the group G_j is simultaneously executed at time $t_{G_j}^*$. It is given by:

$$Q_{G_j}(t_{G_j}^*) = (|G_j| - 1)S - H_{G_j}(t_{G_j}^*),$$

where $|G_j|$ is the number of elements in G_j and S is the setup cost.

Maintenance groupings are considered on a given planning horizon HP, i.e., considering all the tentative planned maintenance actions within this time horizon. The length of the planning horizon can be determined in different ways. For example, it is defined as:

- HP = $\max_{i \in \{1, \dots, n\}} \{\tau_{i,1}\}$ in [44];
- HP = $\max_{i \in \{1, \dots, n\}} \{\tau_{i,1} + \tau_{i,+}; \epsilon_i\}$ where ϵ_i is the time between two successive inspections of component i in [45].

Information about production planning or intended short-term use could be considered. The planning horizon is chosen to include maintenance actions on all the components and has to be short enough to allow optimal groupings. The set of optimal groups G_j over horizon HP is determined heuristically based on the grouping algorithm from [42]. According to the dynamic framework, a rolling-horizon approach is considered. The planning horizon is modified whenever new monitoring information is obtained, and the groups are updated accordingly. In summary, the problem complexity in grouping strategies is mainly due to the number of components and the juxtaposition of multiple degradation processes. The degradation models and individual inspection and maintenance policies are chosen as simply as possible. They are supposed to be perfectly known. The next section deals with another difficulty, not related to the system structure but to the degradation model itself. The different case of a single subsystem or component is considered but with a degradation model which is not entirely known. It leads to additional uncertainty, which can be handled with the help of monitoring information.

27.3.2 Uncertainty in Degradation Models

The problem of determining the optimal maintenance strategy for deteriorating systems has been studied extensively. Almost all of these studies assume that the degradation process and its parameters are known with certainty, although this is usually not the case in practice. Based on the situation, uncertainty can be considered in the model in different ways. A common approach is to assume a specific degradation process and consider the related parameters as unknown [46, 47]. This assumption is helpful when a flexible degradation process is chosen, which can be appropriate in various cases.

With the consideration mentioned earlier, the parameter estimation must be regarded. The parameters can be estimated either by gathering data and then using the frequentist perspective or using the Bayesian approach. In the latter case, the expert judgment or the previous information about the system can be considered for prior distribution. The more information is in hand; the more informative the prior distribution will be. Otherwise, noninformative priors can be assumed. Here, we refer to some examples of such estimations. Paroissin [48] provided recursive estimators based on the moments of the gamma process. As the author mentioned, this online estimation method could be applied jointly with a condition-based maintenance policy. Kallen and van Noortwijk [46] employed the Bayes method to estimate the unknown degradation parameters. Iterative Bayesian updates of degradation parameters can be found in [49–51]. Liu et al. [52] considered a maintenance model taking account of both

degradation and aging. Their model updates the degradation processes' parameters at each inspection with maximum a posteriori (MAP) estimation when a new observation is in hand.

Attempts to analyze the influence of Bayesian updates on maintenance decision-making have been made in [47,53,54]. Flage et al. [53] gave a general description of aperiodic condition-based maintenance by focusing on safety constraints. Papers [47,54] also deal with a dynamic and adaptive predictive maintenance policy for degradation processes with unknown parameters. The authors introduced a heuristic way to assess the long-run maintenance cost in [47], while [54] includes the simulation-based version of the research. Adaptive preventive maintenance policies in lifetime modeling with Bayes' theorem can also be found in [55,56].

The uncertainty in the parameters can also happen due to a sudden change in the environment. Fouladirad and Grall [57] and Fouladirad et al. [58] studied the case in which the degradation rate is subject to sudden changes. Fouladirad and Grall [59,60] investigated the situation that after such an abrupt change in the system degradation rate, the new parameters are unknown.

The change in degradation rate can also be related to imperfect actions for a system as preventive maintenance. Generally, two main effects have been considered for imperfect maintenance actions: (i) restoring the system to a state between good-as-new and bad-as-old and (ii) changing, or in severe cases, accelerating the degradation rate. Therefore, the degradation rate after imperfect maintenance action may be different and unknown. The second effect, which usually is referred to as imperfect maintenance's negative effect, must be regarded carefully. To deal with this problem, Zhang et al. [61] employed the random improvement factor model when a Wiener process governs the underlying degradation. They considered that the degradation rate after a repair would be $bv(t)$ with $0 < b < 1$, while the degradation rate before the repair is $v(t)$. The random variable b is called the degradation-rate-reduction factor and has a specific distribution. Considering this, each imperfect maintenance action has a different degree of impact on the rate of deterioration. They used the quasi-Monte Carlo method to estimate the fixed model parameters. Then the impact of each maintenance action is dynamically estimated with filtering techniques. Zhao et al. [62] also employed the random improvement factor to model the system's condition after an imperfect repair. Consider that an imperfect repair takes place at time T_i which is driven by the remaining useful lifetime information, then:

$$X_i^+ = a_i X_i,$$

where $0 < a_i < 1$, and X_i, X_i^+ are, respectively, the condition of system before and after the maintenance action at time T_i . Another work related to this issue is Shen et al. [63].

They considered that after j -th imperfect maintenance action the threshold of failure L will be substituted by $(1 - \delta^j)L$ where $0 < \delta < 1$. The reason for such a description is that after an imperfect maintenance action, the condition of a system will not be better than its condition at previous maintenance. Hence, the system will fail sooner. To mention other works in which the system's state gets worse by increasing the number of imperfect maintenance, we may refer to Huynh [64,65]. Do et al. [36] and Chen et al. [39] considered the gamma process and tried to model the negative effect of imperfect maintenance by defining additive random models for the rate of the degradation procedure. Assume that the shape parameter of degradation process before and after j -th imperfect maintenance are, respectively, v_{j-1} and v_j . To describe the effect of j -th imperfect maintenance on the system deterioration speed, Do et al. [36] suggested

$$v_j = v_{j-1} + \varepsilon_j,$$

where ε_j follows an exponential distribution. While, Chen et al. [39] proposed:

$$v_j = \rho v_{j-1} + \text{error},$$

where $\rho > 1$ and the error term represents the effect of the difference between the environment before and after the maintenance action.

Another source of uncertainty may be due to heterogeneity. Many papers assume that the parameters are fixed for all units across the population in maintenance or degradation modeling. This assumption is not usually correct since units' degradation characteristics can be identical due to different environments and usage. Utilizing a random effect model can help take account of heterogeneities commonly observed among a product population. As an example of such consideration in maintenance policies, we can refer to Chen et al. [18]. They have chosen an inverse Gaussian process for modeling degradation and assumed the inverse of the degradation rate has a truncated normal distribution. Hence different products may deteriorate at various speeds. They also supposed the chosen distribution for random effect can be updated when more degradation observations are available.

The dynamic maintenance framework is of great interest in the case of uncertainty in degradation models and the grouping of maintenance actions. It allows taking advantage of real-time monitoring data to improve decision-making according to the general framework described above. The following section will detail more precisely an example of a dynamic maintenance framework introduced in [47]. It is specifically developed for a deteriorating system with unknown deterioration parameters. This system can be monitored only by inspections. The maintenance decision rule

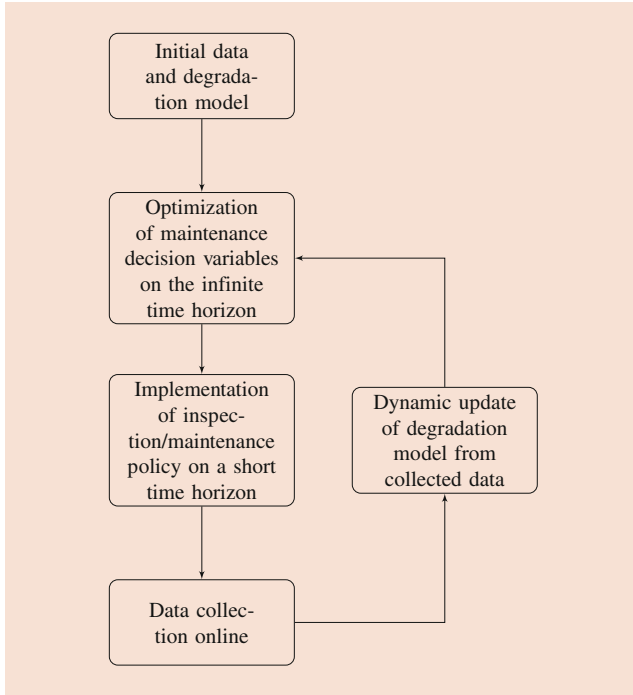

Fig. 27.2 The dynamic process of the model update from monitoring data

belongs to the class of condition-based predictive policies, which allows the optimization of aperiodic inspection times as well as system replacements or perfect repairs. According to the dynamic process described in Sect. 27.3.1, the general scheme is based on alternating long-run cost rate optimization for a given planning horizon and successive updates using the information collected online as described in Fig. 27.2.

27.4 Dynamic Policy with Parameter Updates

27.4.1 Unknown Degradation Parameters and Update

Degradation Process

As it is already mentioned in Sect. 27.3.2, the assumption of having a specified degradation process with an unknown parameter is appropriate when the degradation process is flexible enough to fit a various range of degradation data. As Wang and Xu [30] showed, the inverse Gaussian (IG) process is a suitable model to handle such a situation. On the other hand, the IG process has a close relationship with normal distribution; hence Bayesian inference can be convenient. For these reasons, this section will focus on the IG process while describing dynamic condition-based maintenance with Bayesian updates. More precisely, the system degradation

behavior will be modeled by an IG process, as described in Sect. 27.2.1.

If degradation parameters are unknown, expert opinion and other information about degradation can be used to choose a prior distribution for parameters. This prior distribution can be updated in the Bayesian framework when new information arises. For the sake of simplicity and the ease of calculations, conjugate priors will be considered preferably. With the same notations as in Sect. 27.2.1, two unknown parameters of the IG process are respectively denoted by δ and λ . Focusing on conjugate priors, the joint prior distribution of (δ, λ) is given by $f(\delta, \lambda) = f_1(\delta|\lambda)f_2(\lambda)$ where λ is gamma distributed with shape and scale parameters α and β such that $\mathbb{E}[\lambda] = \alpha\beta$ and $\mathbb{V}[\lambda] = \alpha\beta^2$, i.e.,

$$f_2(\lambda) = \frac{\lambda^{\alpha-1}}{\Gamma(\alpha)\beta^\alpha} \exp\{-\lambda/\beta\}, \quad (27.12)$$

and given λ , δ is normally distributed with mean ξ and variance σ^2/λ , i.e.:

$$f_1(\delta|\lambda) = \sqrt{\frac{\lambda}{2\pi\sigma^2}} \exp\left\{-\frac{\lambda(\delta - \xi)^2}{2\sigma^2}\right\}. \quad (27.13)$$

The hyper-parameters of the degradation model, α , β , ξ and σ , can be updated with new information.

Remaining Useful Lifetime

In the rest of this chapter, when the inspection times and associated degradation level are noted, respectively, t_k and x_k , the notation $R_k = R_{t_k}$ will be used for the RUL R_{t_k} as defined in (27.2).

As mentioned in Sect. 27.2.1, a failure occurs once degradation exceeds the threshold L . The system lifetime σ_L and the RUL R_k are defined, respectively, by Eqs. (27.1) and (27.2). RUL's cdf is given by:

$$F_{R_k}(r|X_t = x_t) = \int_0^\infty \int_{-\infty}^{+\infty} F_{R|\delta,\lambda}^{IG}(r|\delta, \lambda, x_t) f_1(\delta|\lambda) f_2(\lambda) d\delta d\lambda,$$

where $F_{R|\delta,\lambda}^{IG}(r|\delta, \lambda, x_t)$ is RUL cdf in case of IG degradation process with known parameters, as given in Eq. (27.8). Reference [66] proposed developments leading to:

$$\begin{aligned} F_{R_k}(r|X_t = x_k) &= 1 - \frac{\sqrt{\beta}}{2\pi} \frac{\Gamma(\alpha + 1/2)r}{\Gamma(\alpha)} \\ &\times \int_0^{L-x_t} z^{-3/2} (\sigma^2 z + 1)^{-1/2} \\ &\times \left(1 + \frac{\beta(\xi z - r)^2}{2z(\sigma^2 z + 1)}\right)^{-(\alpha+1/2)} dz. \end{aligned} \quad (27.14)$$

which can also be rewritten as a function of the standard t -distribution.

Bayesian Update

Consider that the system degradation level has been measured at $k+1$ successive times $t_0, \dots, t_k, k \in \mathbb{N}$. The observed data are

$$\text{Data} = \{(t_0, x_0), (t_1, x_1), \dots, (t_k, x_k)\}.$$

Let $\Delta x_i = x_i - x_{i-1}$ and $\Delta t_i = t_i - t_{i-1}$ denote the observed degradation increments and the corresponding time intervals, for $i \in \{1, \dots, k\}$. Then, the likelihood function of degradation parameters, δ and λ , is:

$$L(\delta, \lambda | \text{Data}) \propto \lambda^{\frac{k}{2}} \exp \left\{ -\frac{\lambda}{2} \sum_{i=1}^k \frac{(\Delta x_i \delta - \Delta t_i)^2}{\Delta x_i} \right\}, \quad (27.15)$$

and given the observed data, the joint posterior distribution of (δ, λ) is such that:

$$f(\delta, \lambda | \text{Data}) \propto L(\delta, \lambda | \text{Data}) f_1(\delta | \lambda) f_2(\lambda).$$

From Eqs. (27.12), (27.13) and (27.15) it can be shown that (see for example [47]):

$$f(\delta, \lambda | \text{Data}) = f_1(\delta | \lambda, \text{Data}) f_2(\lambda | \text{Data}),$$

where

$$f_1(\delta | \lambda, \text{Data}) = \sqrt{\frac{\lambda}{2\pi\sigma^{*2}}} \exp \left\{ -\frac{\lambda(\delta - \xi^*)^2}{2\sigma^{*2}} \right\},$$

$$f_2(\lambda | \text{Data}) = \frac{\lambda^{\alpha^*-1}}{\Gamma(\alpha^*) \beta^{*\alpha^*}} \exp \left\{ -\lambda/\beta^* \right\}.$$

The posterior distributions of $\delta | \lambda$ and λ are respectively the normal and gamma distributions. The updated values of hyper-parameters are:

$$\xi^* = B/A, \quad \sigma^* = A^{-1/2}, \quad (27.16)$$

$$\alpha^* = \alpha + k/2 \quad \beta^* = (1/\beta + 1/D)^{-1} \quad (27.17)$$

with

$$A = \sum_{i=1}^k \Delta x_i + \frac{1}{\sigma^2} \quad B = \sum_{i=1}^k \Delta t_i + \frac{\xi}{\sigma^2}$$

$$C = \sum_{i=1}^k \frac{(\Delta t_i)^2}{\Delta x_i} + \frac{\xi^2}{\sigma^2} \quad D = \frac{1}{2} \left(C - \frac{B^2}{A} \right).$$

The Bayesian procedure can update the joint probability law of δ and λ using new observations. The hyper-parameters are modified sequentially. After i -th update, they will be written in the following as $\alpha^{(i)}, \beta^{(i)}, \xi^{(i)}$ and $\sigma^{(i)}$ and the corresponding prior distribution will be $f^{(i)}(\delta, \lambda) = f_1^{(i)}(\delta | \lambda) f_2^{(i)}(\lambda)$. The values of hyper-parameters related to initial prior are $\alpha^{(0)}, \beta^{(0)}, \xi^{(0)}$ and $\sigma^{(0)}$.

27.4.2 Maintenance and Inspections Decision Rule

Let's consider a predictive maintenance policy with aperiodic inspection planning. Such a policy allows adapting the time between inspections to the current degradation level of the maintained system. When the system is inspected, the next inspection time can be determined. As a predictive policy, it is based on the system's RUL described in Sect. 27.2.2. Let $\{T_n\}_{n \in \mathbb{N}}$ denote the sequence of inspection times, with $T_0 = 0$. Consider:

$$T_{n+1} = T_n + \tau_p(X_{T_n}),$$

where $\tau_p(X_{T_n})$ is defined from Eq. (27.9) as the p -quantile of the remaining useful life distribution given in Eq. (27.14), i.e.,

$$\tau_p(X_{T_n}) = \{\Delta t : F_{R_k}(\Delta t | X_{T_n} = x_n) = p\}. \quad (27.18)$$

Figures 27.3 and 27.4 show respectively the pdf and cdf of the system's RUL at inspection times between two replacements. The simulated sample path has been generated with the decision variable $p = 0.045$. It ends when the degradation level is greater than $M = 6.44$. As explained previously, the times between successive inspections are defined, and the degradation model is with unknown parameters with the same model as in Sect. 27.4.1. The degradation parameters' distributions are such that $\mathbb{E}[\lambda] = 1$, $\mathbb{V}[\lambda] = 0.1$, $\mathbb{E}[\delta] = 1$ and $\mathbb{V}[\delta] = 0.07$.

According to Sect. 27.2.2, T_n^- for $n \in \mathbb{N}$ refers to the inspection time just before possible maintenance action. The decision rule at each inspection time is as follows:

- If $X_{T_n^-} \geq L$, the system has failed and is correctively replaced.
- If $M \leq X_{T_n^-} < L$, the system has not yet failed but is considered as "close to failure". As a consequence, preventive action is taking place immediately.
- If $X_{T_n^-} < M$, the system is still properly functioning, and there is no need for replacement. The system is left as it is.

As preventive and corrective replacements are supposed to be perfect, the system degradation level after maintenance is 0. In other words, it is "as good as new." More precisely:

Fig. 27.3 The pdf of the system’s RUL at successive inspection times for a cycle path with $(T_1, X_{T_1}) = (3.5, 2.47)$, $(T_2, X_{T_2}) = (5.8, 3.9)$ and $(T_3, X_{T_3}) = (7.5, 5.54)$

Fig. 27.4 The cdf of the system’s RUL at successive inspection times for a cycle (same path as in Fig. 27.3)

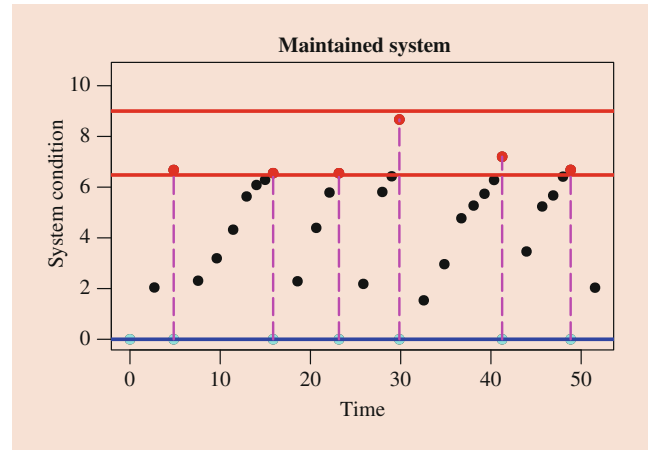

Fig. 27.5 The degradation path for a maintained system with unknown degradation parameters such that $\mathbb{E}[\delta] = 1$, $\mathbb{V}[\delta] = 0.5$, $\mathbb{E}[\lambda] = 1$ and $\mathbb{V}[\lambda] = 0.5$. Decision variables are $p = 0.09$, and $M = 6.48$

Fig. 27.6 The degradation path for a maintained system with known degradation parameters, $\delta = 1$ and $\lambda = 1$. Decision variables are $p = 0.035$ and $M = 6.46$

$$\begin{aligned} \text{If } X_{T_n} \geq L & \quad \text{then } X_{T_n} = 0 \\ \text{If } M \leq X_{T_n} < L & \quad \text{then } X_{T_n} = 0 \\ \text{If } 0 \leq X_{T_n} < M & \quad \text{then } X_{T_n} = X_{T_n} \end{aligned}$$

For more illustration, Figs. 27.5 and 27.6 represent the evolution of the degradation level of a component that is maintained according to the previous maintenance decision rule. For Fig. 27.5, the degradation parameters are unknown and described as in Sect. 27.4.1. Figure 27.6 is with known degradation parameters. As expected, lifetime modeling hence the inspection planning is more accurate when parameters are known. It can be seen that the mean number of inspections in a renewal cycle is higher in case of uncertainty on degradation parameters.

Finally, the considered decision rule has two decision variables: p and M . The decision-maker must determine these two variables to optimize a given assessment criterion. Classically, the economic criterion is considered, as defined in the next section. Note that in Figs. 27.5 and 27.6, optimal decision variables are considered. They have been optimized by minimization of the maintenance costs with the same unit costs.

27.4.3 Maintenance Cost

The inspections are planned sequentially, and each inspection incurs a unit cost denoted by C_i . Preventive and corrective actions are performed with respective costs C_p and C_c such that $C_c > C_p$. Failures are not self-announcing; hence, they can only be diagnosed and isolated at inspection times. Consequently, an additional cost at a rate of C_d is incurred from the failure time until the next replacement time. It is hereafter referred to as the unavailability cost rate. Let $C(t)$ define the cumulative maintenance cost up to time t . Considering that $N_i(t)$, $N_p(t)$ and $N_c(t)$ are, respectively, the numbers of inspections, preventive replacements, and corrective replacements in $[0, t]$, it comes:

$$C(t) = C_i N_i(t) + C_p N_p(t) + C_c N_c(t) + C_d d(t), \quad (27.19)$$

where $d(t)$ is the total time passed in a failed state in $[0, t]$.

As in the usual framework for dynamic maintenance, a long-run cost rate is considered to propose a tentative planning or decision rule settings for inspections and maintenance actions. It is intended to be applied on a rolling horizon basis and modified dynamically based on information obtained in real-time. The baseline objective cost function is then the long-term expected maintenance cost per time unit, which is defined by:

$$\begin{aligned} EC_\infty &= \lim_{t \rightarrow \infty} \frac{E[C(t)]}{t} \\ &= \lim_{t \rightarrow \infty} \frac{1}{t} E \left[\sum_{n \in \mathbb{N}} \mathbb{I}_{\{T_n < t\}} (1 + \mathbb{I}_{\{M \leq X_{T_n} < L\}} \right. \\ &\quad \left. + \mathbb{I}_{\{X_{T_n} \geq L\}}) + \int_0^t \mathbb{I}_{\{X_s \geq L\}} ds \right]. \end{aligned}$$

Note that mathematical derivation of such a criterion may take advantage of renewal theory. Notably, in the presence of perfect repair or replacement, the stochastic process describing the maintained system is regenerative. Renewal property allows rewriting the long-run average cost per time unit as the ratio of the expected cost on the first renewal cycle over this cycle's expected length. In other words:

$$EC_\infty = \frac{E[C(S_1)]}{E(S_1)}. \quad (27.20)$$

where S_1 is the first regeneration time, i.e., the time of first preventive or corrective replacement.

The decision variables for the maintenance policy are p and M . Tentative values can be obtained by minimization of the maintenance cost EC_∞ . The optimal decision variables, p^* and M^* , are such that:

$$\begin{aligned} EC_\infty(p^*, M^*) &\leq EC_\infty(p, M), \\ \forall (p, M) &\in [0, 1] \times [0, L], \end{aligned}$$

For an aperiodic maintenance policy with a gradual deterioration process, analytical expressions of EC_∞ cannot be derived easily from Eq. (27.20) because of the complexity of scenarios that can arise. The next section will focus on using of Markov renewal properties to overcome this difficulty.

27.4.4 Decision Variables Based on Long-Term Assessment

In this section, the maintained system's evolution is characterized to derive an expression for the long-run expected maintenance cost. As the degradation parameters are unknown, the calculation has to be done based on the available information at the time of calculation. As explained in Sect. 27.4.1, the prior distribution of δ and λ contains all this information.

Semi-regenerative Process and Cost Rate

The process $\{X_t\}_{t \geq 0}$ is a regenerative process, with regeneration times being the dates of replacement. Let's consider the discrete-time stochastic process describing the system state at inspection times and after maintenance action, if any. It is hereafter denoted $\{Y_n\}_{n \in \mathbb{N}}$ with $Y_n = X_{T_n}$. The embedded process $\{Y_n, T_n\}_{n \in \mathbb{N}}$ is a Markov renewal process, and the process $\{X_t\}_{t \geq 0}$ is a semi-regenerative process with semi-regeneration times being the inspection times. Due to the maintenance policy with perfect replacements, the embedded Markov chain $\{Y_n\}_{n \in \mathbb{N}}$ has $\{0\}$ as the regeneration set. Such a Markov chain is called Harris recurrent (or just Harris chain) in [67]. A stationary measure π can be defined, and it is unique up to a multiplicative constant; see [67] (pages 200-201). Then it comes (see [35]):

$$EC_\infty = \lim_{t \rightarrow \infty} \frac{E[C(t)]}{t} = \frac{E_\pi[C(T_1)]}{E_\pi[T_1]},$$

where T_1 is the first inspection time and \mathbb{E}_π refers to the expectation with respect to the stationary probability distribution π .

Note that the previous equality holds since the process $C(t)$ is such that:

- $C(t)$ is positive;
- $C(0) = 0$;
- $C(t)$ is given by $C(t) = \Psi_t(X_u, 0 \leq u \leq t)$ and is such that for $0 \leq s \leq t$, $C(t) - C(s) = \Psi_{t-s}(X_u, s \leq u \leq t)$ which is true for a cumulative cost.

With the classical renewal property, the expression of the maintenance cost EC_∞ can be obtained from the analysis of the system behavior on a regenerative cycle, i.e., between two replacements. The semi-regenerative property allows deriving EC_∞ from the analysis on a semi-regenerative cycle, i.e., between two successive inspections, which is simpler. As a prerequisite, this approach requires the knowledge of the stationary probability distribution π . It is derived from the transition probability density function of $\{Y_n\}_{n \in \mathbb{N}}$ which is developed in next paragraphs.

Degradation at Inspection Times

For all $n \in \mathbb{N}$, Y_n describes the system degradation level at n -th inspection time and after maintenance action if necessary. Thus, the process $\{Y_n\}_{n \in \mathbb{N}}$ takes values in $[0, M)$. In the following, $Y_n^- = X_{T_n^-}$ will denote the system degradation level at inspection time T_n^- , i.e., just before maintenance action.

First, consider the case that the two degradation parameters, δ and λ , are given. From Markovian properties and given the current state x with $x < M$, the probability of transition from state $Y_n = x$ at time T_n to state $Y_{n+1} = y$ at time T_{n+1} is given according to the maintenance decision rule. Two scenarios can arise if $Y_{n+1}^- \geq M$ the degradation level overpasses the maintenance threshold, and the system or component is replaced, i.e., $Y_{n+1} = 0$; if $Y_{n+1}^- < M$, only the next inspection is scheduled and $Y_{n+1} = Y_{n+1}^-$. It comes:

$$\begin{aligned} \Pr(Y_{n+1} = 0 | Y_n = x, \delta, \lambda) &= \bar{F}_{\tau_p(x)/\delta, \lambda \tau_p^2(x)}(M - x) \\ &\quad \text{(case } y = 0) \\ \Pr(Y_{n+1} \leq y | Y_n = x, \delta, \lambda) &= F_{\tau_p(x)/\delta, \lambda \tau_p^2(x)}(y - x) \\ &\quad \text{(case } x \leq y < M) \end{aligned}$$

with

$$\begin{aligned} &F_{\tau_p(x)/\delta, \lambda \tau_p^2(x)}(y - x) \\ &= \Pr(X_{t+\tau_p(x)} - X_t \leq y - x | X_t = x) \\ &= \int_0^{y-x} f_{\tau_p(x)/\delta, \lambda \tau_p^2(x)}(u) du \end{aligned}$$

and

$$\bar{F}_{\tau_p(x)/\delta, \lambda \tau_p^2(x)}(M - x) = 1 - F_{\tau_p(x)/\delta, \lambda \tau_p^2(x)}(M - x).$$

Consequently, the transition probability distribution function of $\{Y_n\}_{n \in \mathbb{N}}$ can be written as:

$$\begin{aligned} \Pr(dy|x, \delta, \lambda) &= \bar{F}_{\tau_p(x)/\delta, \lambda \tau_p^2(x)}(M - x) \delta_0(dy) \\ &\quad + f_{\tau_p(x)/\delta, \lambda \tau_p^2(x)}(y - x) \mathbb{I}_{\{x \leq y < M\}} dy, \end{aligned} \quad (27.21)$$

where δ_0 denotes the Dirac delta function.

As explained previously, the first part of the right-hand side in Eq. (27.21) is associated with replacements when the degradation level is higher than M at inspection time just before maintenance. The second part describes a classical degradation increment from x to y for $x \leq y$ and when $y < M$.

In the case of unknown degradation parameters, the transition probability density function of $\{Y_n\}_{n \in \mathbb{N}}$ is obtained from the transition pdf knowing the degradation parameters by:

$$\begin{aligned} \Pr(dy|x) &= \int_0^\infty \int_{-\infty}^{+\infty} \Pr(dy|x, \delta, \lambda) \\ &\quad f_1(\delta|\lambda) f_2(\lambda) d\delta d\lambda. \end{aligned} \quad (27.22)$$

Replacing $\Pr(dy|x, \delta, \lambda)$ by its expression from Eq.(27.21) leads to:

$$\begin{aligned} \Pr(dy|x) &= \bar{G}_{\tau_p(x)}(M - x) \delta_0(dy) \\ &\quad + g_{\tau_p(x)}(y - x) \mathbb{I}_{\{x \leq y < M\}} dy, \end{aligned} \quad (27.23)$$

where

$$\begin{aligned} g_{\tau_p(x)}(z) &= \sqrt{\frac{\beta}{2\pi}} \frac{\Gamma(\alpha + 1/2) \tau_p(x)}{\Gamma(\alpha)} z^{-3/2} \\ &\quad \times (\sigma^2 z + 1)^{-1/2} \left(1 + \frac{\beta(\xi z - \tau_p(x))^2}{2z(\sigma^2 z + 1)} \right)^{-(\alpha+1/2)}, \end{aligned}$$

and

$$\bar{G}_{\tau_p(x)}(z) = \int_z^\infty g_{\tau_p(x)}(u) du.$$

Stationary Law

The unique stationary probability distribution π of the Markov chain $\{Y_n\}_{n \in \mathbb{N}}$ has the same structure as $\Pr(dy|x)$ with a mass and a density part, i.e.:

$$\pi(dx) = \tilde{a}_1 \delta_0(dx) + \tilde{a}_2 b(x) dx. \quad (27.24)$$

Besides, the stationary law is a solution of the stationary equation:

$$\pi(dy) = \int_{[0,M]} \Pr(dy|x)\pi(dx). \quad (27.25)$$

Let replace, respectively, $\Pr(dy|x)$ and $\pi(\cdot)$ in (27.25) by their expressions from Eqs. (27.23) and (27.24). The density part of the resulting equation can be written for $y < M$:

$$\tilde{a}_2 b(y) = \tilde{a}_1 g_{\tau_p(0)}(y) + \tilde{a}_2 \int_0^y g_{\tau_p(x)}(y-x)b(x)dx. \quad (27.26)$$

and as $\int_{[0,M]} \pi(dx) = 1$, it can be shown that $\tilde{a}_1 = 1 - \tilde{a}_2$. If $B(y)$ is defined for any $y \in [0, M]$ by:

$$B(y) = \frac{1 - \tilde{a}_1}{\tilde{a}_1} b(y), \quad (27.27)$$

Equation (27.26) can be rewritten:

$$B(y) = g_{\tau_p(0)}(y) + \int_0^y B(x)g_{\tau_p(x)}(y-x)dx. \quad (27.28)$$

The resulting equation is the Volterra equation of the second kind. Then, $B(\cdot)$ can be obtained numerically through classical numerical schemes; see, for example, [68]. Finally, from $\int_{[0,M]} \pi(dx) = 1$ and the expression of $\pi(dx)$ in Eq. (27.24), it comes:

$$\frac{1}{\tilde{a}_1} = 1 + \int_{[0,M]} B(x)dx,$$

hence

$$\tilde{a}_1 = \frac{1}{1 + \int_0^M B(x)dx}. \quad (27.29)$$

As an illustration, Fig. 27.7 shows the density functions of the stationary probability distribution π obtained for four different configurations of degradation parameters. The failure threshold is $L = 9$ and the decision variables are set to $p = 0.036$ and $M = 6.45$ for all cases. Configurations considered in Fig. 27.7 are of two types:

- (i) The case of known degradation parameters with $\lambda = 1$ and $\delta = 1 (= 1/\mu)$, and
- (ii) For unknown parameters, three different prior distributions are considered, as given in Table 27.1.

The probability density functions of priors given in Table 27.1 are depicted, respectively, in Figs. 27.8, 27.9 and 27.10. The expected values of δ and λ are identical for the three cases and equal to the values considered for known parameters.

Figure 27.7 shows, for fixed decision variables, that the probability of observing a low degradation level (less than 3) at inspection times decreases when the uncertainty of degradation parameters decreases.

Fig. 27.7 Stationary probability distributions for known and unknown degradation parameters with $L = 9$, $p = 0.036$, and $M = 6.45$

Table 27.1 Configurations for prior distribution considered on Fig. 27.7

	Case 1	Case 2	Case 3
$E[\lambda]$	1	1	1
$V[\lambda]$	0.5	0.2	0.1
$E[\delta]$	1	1	1
$V[\delta]$	0.5	0.2	0.07

Fig. 27.8 Prior distributions of degradation parameters: Case 1

Long-Run Cost Rate

Finally, the long-term expected maintenance cost of the system per unit of time can be assessed by expectation with respect to π as:

$$EC_\infty = \lim_{t \rightarrow \infty} \frac{E[C(t)]}{t} = \frac{E_\pi[C(T_1)]}{E_\pi[T_1]}, \quad (27.30)$$

Fig. 27.9 Prior distributions of degradation parameters: Case 2

Fig. 27.10 Prior distributions of degradation parameters: Case 3

where $C(t)$ is defined in Eq. (27.19). Obviously, $E_{\pi}[N_i(T_1)] = 1$. The other expectations are given by:

$$E_{\pi}(N_p(T_1)) = P_{\pi}(M \leq X_{T_1^-} < L) = \int_0^M [\bar{G}_{\tau_p(x)}(M - x) - \bar{G}_{\tau_p(x)}(L - x)] \pi(dx),$$

$$E_{\pi}(N_c(T_1)) = P_{\pi}(X_{T_1^-} \geq L) = \int_0^M \bar{G}_{\tau_p(x)}(L - x) \pi(dx),$$

$$E_{\pi}(d(T_1)) = \int_0^M \left[\int_0^{\tau_p(x)} \bar{G}_s(L - x) ds \right] \pi(dx),$$

and finally:

$$E_{\pi}(T_1) = \int_0^M \tau_p(x) \pi(dx).$$

These integrals can be calculated using standard numerical integration techniques like the trapezoidal rule or Simpson's rule.

27.4.5 Dynamic Policy

The long-run expected maintenance cost for a given level of information about degradation parameters is developed in the previous section. It is then possible to optimize the decision variables p and M with respect to that cost. This section describes the dynamic procedure to adjust the maintenance decision rule parameters according to updated information. In the dynamic framework, decision parameters are derived from maintenance costs assessed on a long-term horizon. They are considered on a short-term rolling horizon. New information obtained on that short-term horizon is included and helps to update the expression of long-term maintenance cost hence the values of decision parameters for the next planning horizon. The planning horizon hereafter is the length of a renewal cycle, i.e., the time to the next perfect repair or replacement.

Algorithm

Let $\Theta^{(i)} = (\alpha^{(i)}, \beta^{(i)}, \xi^{(i)}, \sigma^{(i)})$ denote the values of hyper-parameters after i -th update, starting from the initial prior for $i = 0$. The function $f^{(i)}(\delta, \lambda)$ is the joint prior distribution of (δ, λ) obtained with values $\Theta^{(i)}$ of hyperparameters. The algorithm for maintenance decision-making is as follows:

Step 0: Initialization. Set $i = 0, k = 0, X_k = 0$, and $T_k = 0$. Choose the initial values of the hyper-parameters $\Theta^{(0)}$.

Step 1: Optimize the value of decision variables for the renewal cycle i by minimizing the cost rate given in Eq. (27.30). The long-run cost rate optimization requires assessments of the stationary law $\pi^{(i)}$, which is obtained from Eq. (27.24) with hyper-parameters $\Theta^{(i)}$.

Step 2: Clean up the memory of degradation increments. Apply the aperiodic maintenance policy for the current cycle:

- **2.1:** Evaluate $\Delta T_k = \tau_p(X_{T_k})$ according to the RUL distribution with $\Theta^{(i)}$, see Eq. (27.14).
- **2.2:** Inspect the system at time $T_{k+1} = T_k + \Delta T_k$.
- **2.3:** If $X_{k+1} < M$, then memorize the degradation increment $\Delta X_{k+1} = X_{T_{k+1}} - X_{T_k}$ and the corresponding time interval ΔT_k . Set $k = k + 1$, and go back to sub-step 2.1.
 Else if $X_{k+1} \geq M$ then let $X_{k+1} = 0$ (i.e., maintain the system) and set $k = k + 1$.

Step 3: Update the degradation model from observations during the last cycle, i.e., find the new values of hyper-parameters $\Theta^{(i+1)}$ from all the degradation increments which are in memory, see Eq. (27.16). Set $i = i + 1$ and go to step 1.

Fig. 27.11 Level curves of long-run cost rate with $\mathbb{E}[\delta] = 1.1$, $\mathbb{V}[\delta] = 1.1$, $\mathbb{E}[\lambda] = 1$ and $\mathbb{V}[\lambda] = 1$

Fig. 27.13 Level curves of long-run cost rate for case 3 from Table 27.1

Fig. 27.12 Level curves of long-run cost rate for case 1 from Table 27.1

As stated above, each step of the dynamic process requires the minimization of the long-run cost rate for hyper-parameters current values. No analytical expression is available for optimal values. The long-run cost rate must have a unique minimum to ensure that such optimal values can be determined without ambiguity. Numerous numerical experiments have been carried out for a wide range of hyper-parameters. They all show convex shapes for the cost as a function of decision variables. For illustration purposes, three examples of cost rate functions are given in Figs. 27.11, 27.12, and 27.13 for different sets of hyper-parameters with decreasing variance for degradation

parameters δ and λ as happening during the dynamic process. The variance of δ is successively 1.1, 0.5 and 0.07 and these values for λ are, respectively, 1, 0.5, and 0.1.

Due to observed convexity, classical nonlinear optimization algorithms can be used for numerical optimization. The downhill simplex method proposed in [69], also known as Nelder-Mead method, has been considered for optimization in this chapter. This method requires a significant number of successive numerical evaluations of the cost function during the optimization process. As a consequence, it is not very efficient in terms of computing speed. However, it does not require derivatives evaluations and can be robust [68].

Behavior of the Dynamic Policy

A numerical study and analysis of such a dynamic maintenance policy can be found in [47], as well as its comparison with other policies. It shows the relevance of dynamic strategies that are based on long-term cost rates with updates from monitoring information. Figures 27.14 and 27.15 give examples of inspection times and related degradation levels for two levels of information based on cases 1 and 3 considered previously. It can be seen that as the uncertainty about degradation parameters decreases, from case 1 to case 3, the number of inspections in a renewal cycle decreases.

Figure 27.16 is an example of the mean evolution of two decision variables, p and M , after successive updates. It is based on the simulation of 50 paths from time $t = 0$ to 100. The main modifications of the values take place in the first quarter of the sequence. The information collected online leads to significant updates and substantial effects on the evolution of parameters p and M .

27.5 Conclusion

This chapter is related to dynamic condition-based and predictive maintenance modeling. It focuses on the case of continuous degradation and aims to describe a dynamic decision-making framework’s characteristics. Classical stochastic processes for continuous degradation modeling are firstly recalled with their main indicators for failure

Fig. 27.16 Example of dynamic evolution of decision variables

prediction. The most common structure of the maintenance decision rule is also given. The context resulting in a need for a dynamic approach is then described in two main directions. The first one is related to maintenance grouping in multicomponent systems, with opportunistic maintenance and (economic) dependencies. The second one deals with uncertainty in degradation description or behavior. Information collected in real time is used to update the planning or improve the degradation model and the maintenance decision rule. The general framework of dynamic decision-making is described with successive cycles on a finite time-rolling horizon. On each cycle, the starting point for maintenance and inspection planning is based on long-term system behavior. A long-term cost rate is optimized to determine tentative planning for each component or the decision rule variables. In the case of maintenance grouping, this planning may be modified with a short-term criterion. The availability of new information leads to an update of the maintenance model and the beginning of a new cycle. Finally, a specific case related to gradual degradation modeling with unknown parameters is described precisely as an example of dynamic condition-based predictive maintenance.

Abstract

Many serious accidents have happened as systems have become large scale and complex, and moreover, advanced nations have almost finished infrastructures and rushed into a maintenance period. Maintenance would be more important than production and construction for environment consideration and the protection of natural resources. A variety of maintenance policies have been established to prevent failures for objective systems in reliability theory. It has been well-known that high system reliability can be achieved through redundancy. Alternatively, several maintenance policies are planned simultaneously, such as bivariate, trivariate, and multivariate policies with multiple maintenance plans. This chapter takes up age and periodic replacements that are the most standard maintenance policy, shows their optimal policies, and proposes redundant replacement policies with time T and n kinds of replacements. The results obtained in this chapter would be applied to maintenances for redundant systems, imperfect repair, and several failure nodes.

28.1 Introduction

Performance degradation and replacement strategy for manufacturing systems are commonly encountered in practice. Replacements done after failure and before failure are called corrective replacement and preventive replacement, respectively [1]. Age and periodic replacement policies have been modelled extensively in maintenance engineering. Age replacement is a time-based policy in which an operating unit is replaced by a new one or is perfectly repaired and becomes

like new at failures [2, p. 69]. On the other hand, when the unit undergoes imperfect repair at failures, this is called imperfect maintenance [2, p. 171], and its age becomes younger at repair. Especially, When the unit has the same age before repair at failures, this is called minimal repair [1, p. 96], [2, p. 95] and is commonly used with complex systems such as computers and airplanes. Such two replacement policies have been generally taken up for most reliability models theoretically and practically in maintenance engineering.

It has also been well-known that high system reliability can be achieved through redundancy, e.g., parallel systems with n units in parallel structures [3]. When several replacement policies are planned simultaneously as alternatives, they can be considered as redundancies with each other, such as bivariate policies of replacement first and last [4], trivariate policies of replacement middle [5], and general policies with multiple replacement plans [6].

In this chapter, we name the replacements with redundancies as redundant replacement policies and survey the recent redundant policies that are based on the approaches of whichever occurs first and last, overtime approach for replacement delay, and triggering policies at middle times. From such a viewpoint, we firstly give the single age replacement policies that are planned at time T , at cycle N of working times, and at the first completion of working cycles over time T , respectively [7]. For a large and complex system, which consists of many kinds of units, minimal repairs that cost less are always taken into considerations at failures [1]. Next, we use the cumulative hazard function $H(t)$ to count the number of minimal repairs and survey periodic replacement policies that are planned at time T , at number K of failures, at cycle N of working times, and at the first failure or the first completion of working cycles over time T , respectively.

When a bivariate replacement policy is planned, it has been shown that the policies based on the approaches of whichever occurs first and last [4] become good alternatives from the points of cost and maintainability. For example, replacement first could be done for high system reliability but could not complete the necessary working cycles, while replacement last could let the system operate for a longer time and avoid operational interruptions to complete the running working cycles. On the other hand, when the system is running some successive jobs without stops, it is better to perform replacement policies after several jobs are completed even though the replacement time has arrived [7]. Replacement policies scheduled at the first completion of some working cycle over a planned time T were summarized [8]. That is, replacement scheduled at continuous times could be modified to be done at discrete applications. For the above viewpoint, we combine the above respective single replacement policies for bivariate replacement policies, such that the unit is replaced at time T or at cycle N , whichever occurs first and last, and the unit is replaced at cycle N or at the first

completion of working cycles over time T . When minimal repair is taken into considerations, the number K of failures is modeled for the periodic policies of replacement first and last and replacement overtime first and last [9]. In addition, we begin to plan replacement time T once the K th failure has occurred and plan failure number K once time T has arrived, as the extensions of the above overtime replacement.

When a trivariate replacement policy is planned, i.e., time T , cycle N of working times, and number K of failures are planned simultaneously, we survey the models of replacement first and last, and meanwhile, replacement middle in which the policy is only available at middle times rather than the first or last times [5]. The modified replacement first and last for trivariate policies also contains some cases when replacement is done at middle times. Finally, redundant replacement policies, which means replacement planned at time T , have n redundant policies that can be done at n random times [6]. Age and periodic replacement policies, using the approaches of first and last, are surveyed. For each policy, we give the models of the expected cost rates, and their optimal replacement solutions are obtained analytically and discussed numerically.

Throughout this chapter, it is assumed that the failure time of the unit has a failure distribution $F(t)$, its density function $f(t) \equiv dF(t)/dt$, i.e., $F(t) = \int_0^t f(u)du$ for $t \geq 0$, and its finite mean $\mu \equiv \int_0^\infty \bar{F}(t)dt$, where $\bar{F}(t) \equiv 1 - F(t)$. Furthermore, it is assumed that the failure function is $h(t) \equiv f(t)/\bar{F}(t)$, which increases strictly with t from $h(0) = 0$ to $h(\infty) = \infty$, and the cumulative hazard function is $H(t) \equiv \int_0^t h(u)du$, i.e., $h(t) = dH(t)/dt$ and $F(t) = 1 - e^{-H(t)}$. Generally, we use the following notations throughout this chapter for the simplicity of equations: $\bar{\Phi}(t) \equiv 1 - \Phi(t)$, $\lim_{t \rightarrow 0} \Phi(t) \equiv \Phi(0)$ and $\lim_{t \rightarrow \infty} \Phi(t) \equiv \Phi(\infty)$ for a general function $\Phi(t)$.

When failures occur at a nonhomogeneous Poisson process with hazard rate $H(t)$, the probability that k failures occur in $[0, t]$ is $p_k(t) \equiv [H(t)^k/k!]e^{-H(t)}$ ($k = 0, 1, 2, \dots$), and $P_K(t) \equiv \sum_{k=K}^\infty p_k(t)$ ($K = 0, 1, 2, \dots$), $\bar{P}_K(t) \equiv 1 - P_K(t) = \sum_{k=0}^{K-1} p_k(t)$, where note that $P_K(0) = 0$, $P_K(\infty) = 1$, $P_0(t) = 1$, and $\lim_{K \rightarrow \infty} P_K(t) = 0$. Furthermore, we have the following relations: For $0 < t < \infty$ and $K = 0, 1, 2, \dots$,

$$\begin{aligned}
 P_{K+1}(t) &= \int_0^t p_K(u)h(u)du, \\
 \bar{P}_{K+1}(t) &= \int_t^\infty p_K(u)h(u)du, \\
 \int_0^\infty p_K(t)h(t)dt &= 1, \\
 \int_0^\infty H(t)dP_K(t) &= \int_0^\infty \bar{P}_K(t)h(t)dt \\
 &= \sum_{k=0}^{K-1} \int_0^\infty p_k(t)h(t)dt = K,
 \end{aligned}$$

and letting $N(t)$ be the expected number of failures during $[0, t]$,

$$E\{N(t)\} = \sum_{k=1}^{\infty} k p_k(t) = \sum_{k=1}^{\infty} \bar{P}_k(t) = H(t).$$

In addition, when the unit operates for successive jobs without stops, the working cycles Y_j ($j = 1, 2, \dots$) are independent random variables with an identical distribution $G(t) \equiv \Pr\{Y_j \leq t\}$ with finite mean $1/\theta \equiv \int_0^{\infty} \bar{G}(t) dt$, where $Y_0 \equiv 0$. Furthermore, denote $G^{(j)}(t)$ ($j = 0, 1, 2, \dots$) as the j -fold Stieltjes convolution of $G(t)$ with itself, where $G^{(0)}(t) \equiv 1$ for $t \geq 0$.

28.2 Single Policy

28.2.1 Age Replacement

We introduce the age replacement policies in which the unit is replaced at failure, time T , or cycle N . The expected cost rates are obtained, and optimal policies which minimize them are theoretically shown.

(1) Time T

Suppose that the unit is replaced at a planned time T ($0 < T \leq \infty$) or at failure, whichever occurs first, which is called *standard age replacement*. Then, the expected cost rate is [1, p. 88], [2, p. 72]

$$C(T) = \frac{c_T + (c_F - c_T)F(T)}{\int_0^T \bar{F}(t) dt}, \tag{28.1}$$

where c_T = replacement cost at time T and c_F = replacement cost at failure with $c_F > c_T$. We find optimal T^* to minimize $C(T)$. Differentiating $C(T)$ with respect to T and setting it equal to zero,

$$h(T) \int_0^T \bar{F}(t) dt - F(T) = \frac{c_T}{c_F - c_T}, \tag{28.2}$$

whose left-hand side increases strictly with T from 0 to ∞ . Thus, there exists a finite and unique T^* ($0 < T^* < \infty$) which satisfies (28.2), and the resulting cost rate is

$$C(T^*) = (c_F - c_T)h(T^*). \tag{28.3}$$

(2) Cycle N

Suppose that the unit is replaced at cycle N ($N = 1, 2, \dots$) of working times or at failure, whichever occurs first, which is called *random replacement*. Then, the expected cost rate is [7, p. 44]

$$C(N) = \frac{c_N + (c_F - c_N) \int_0^{\infty} [1 - G^{(N)}(t)] dF(t)}{\int_0^{\infty} [1 - G^{(N)}(t)] \bar{F}(t) dt}, \tag{28.4}$$

where c_N = replacement cost at cycle N with $c_N < c_F$. We find optimal N^* to minimize $C(N)$. Forming $C(N + 1) - C(N) \geq 0$,

$$Q(N) \int_0^{\infty} [1 - G^{(N)}(t)] \bar{F}(t) dt - \int_0^{\infty} [1 - G^{(N)}(t)] dF(t) \geq \frac{c_N}{c_F - c_N}, \tag{28.5}$$

where

$$Q(N) \equiv \frac{\int_0^{\infty} [G^{(N)}(t) - G^{(N+1)}(t)] dF(t)}{\int_0^{\infty} [G^{(N)}(t) - G^{(N+1)}(t)] \bar{F}(t) dt}.$$

Thus, if $Q(N)$ increases strictly with N to $h(\infty)$, then there exists a finite and unique minimum N^* ($1 \leq N^* < \infty$) which satisfies (28.5).

In particular, when $G(t) = 1 - e^{-\theta t}$, i.e., $G^{(j)}(t) = \sum_{i=j}^{\infty} [(\theta t)^i / i!] e^{-\theta t}$ ($j = 0, 1, 2, \dots$), (28.5) becomes

$$Q(N) \int_0^{\infty} [1 - G^{(N)}(t)] \bar{F}(t) dt - \int_0^{\infty} [1 - G^{(N)}(t)] dF(t) \geq \frac{c_N}{c_F - c_N}, \tag{28.6}$$

where

$$Q(N) \equiv \frac{\int_0^{\infty} (\theta t)^N e^{-\theta t} dF(t)}{\int_0^{\infty} (\theta t)^N e^{-\theta t} \bar{F}(t) dt},$$

which increases strictly with N to $h(\infty)$ from Appendix 2. Thus, noting that the left-hand side of (28.6) increases strictly with N to ∞ , there exists a finite and unique minimum N^* ($1 \leq N^* < \infty$) which satisfies (28.6).

(3) Overtime T

Suppose that the unit is replaced at the first completion of working cycles over time T ($0 \leq T < \infty$) or at failure, whichever occurs first, which is called *age replacement overtime*. Then, the expected cost rate is [7, p. 35], [8, p. 7]

$$C_O(T) = \frac{c_O + (c_F - c_O) \left(F(T) + \sum_{j=0}^{\infty} \int_0^T \left\{ \int_{T-t}^{\infty} [F(t+u) F(T)] dG(u) \right\} dG^{(j)}(t) \right)}{\int_0^T \bar{F}(t) dt + \sum_{j=0}^{\infty} \int_0^T \left[\int_{T-t}^{\infty} \bar{G}(u) \bar{F}(t+u) du \right] \times dG^{(j)}(t)}, \tag{28.7}$$

where c_O = replacement cost over time T with $c_O < c_F$.

In particular, when $G(t) = 1 - e^{-\theta t}$, (28.7) becomes

$$C_O(T) = \frac{c_O + (c_F - c_O) [F(T) + \int_T^{\infty} e^{-\theta(t-T)} dF(t)]}{\int_0^T \bar{F}(t) dt + \int_T^{\infty} e^{-\theta(t-T)} \bar{F}(t) dt}. \tag{28.8}$$

We find optimal T_O^* to minimize $C_O(T)$. Differentiating $C_O(T)$ with respect to T and setting it equal to zero,

$$\tilde{Q}_O(T) \int_0^T \bar{F}(t) dt - F(T) = \frac{c_O}{c_F - c_O}, \tag{28.9}$$

where

$$\tilde{Q}_O(T) \equiv \frac{\int_T^\infty e^{-\theta t} dF(t)}{\int_T^\infty e^{-\theta t} \bar{F}(t) dt},$$

which increases strictly with T to $h(\infty)$ from Appendix 1. Thus, noting that the left-hand side of (28.9) increases strictly with T from 0 to ∞ , there exists a finite and unique T_O^* ($0 < T_O^* < \infty$) which satisfies (28.9), and the resulting cost rate is

$$\begin{aligned} C_O(T_O^*) &= (c_F - c_O) \tilde{Q}_O(T_O^*) \\ &= \frac{c_F - (c_F - c_O) \bar{F}(T_O^*)}{\int_0^{T_O^*} \bar{F}(t) dt}, \end{aligned} \tag{28.10}$$

which agrees with (28.1) when $c_O = c_T$ and $T_O^* = T$. In addition, when $c_O = c_T$, comparing (28.9) with (28.2), $T_O^* < T^*$ because $\tilde{Q}_O(T) > h(T)$. Therefore, from (28.10), $C_O(T_O^*) > C(T^*)$, i.e., age replacement is better than replacement overtime when both replacement costs are the same.

28.2.2 Periodic Replacement

An operating unit undergoes minimal repair at each failure, and the failure rate remains undisturbed by any repair of failures between replacements. Then, we introduce the standard periodic replacement policies in which the unit is replaced at time T , failure K , and cycle N . The results obtained in this section could be applied easily to imperfect maintenance policies [2, p. 175].

(1) Time T

Suppose that the unit is replaced at a planned time T ($0 < T < \infty$) which is called *standard periodic replacement*. Then, the expected cost rate is [1, p. 97], [2, p. 102]

$$C(T) = \frac{c_T + c_M H(T)}{T}, \tag{28.11}$$

where c_T = replacement cost at time T and c_M = cost of minimal repair at each failure. We find optimal T^* to minimize $C(T)$. Differentiating $C(T)$ with respect to T and setting it equal to zero,

$$Th(T) - H(T) = \frac{c_T}{c_M}, \tag{28.12}$$

whose left-hand side increases strictly with T from 0 to ∞ . Thus, there exists a finite and unique T^* ($0 < T^* < \infty$) which satisfies (28.12), and the resulting cost rate is

$$C(T^*) = c_M h(T^*). \tag{28.13}$$

(2) Failure K

Suppose that the unit is replaced at a number K ($K = 1, 2, \dots$) of failures. Then, the expected cost rate is [2, p. 104]

$$C(K) = \frac{c_K + c_M K}{\int_0^\infty \bar{P}_K(t) dt}, \tag{28.14}$$

where c_K = replacement cost at failure K . We find optimal K^* to minimize $C(K)$. Forming $C(K + 1) - C(K) \geq 0$,

$$\frac{1}{\int_0^\infty \bar{P}_K(t) dt} - K \geq \frac{c_K}{c_M}, \tag{28.15}$$

whose left-hand increases strictly with K to ∞ . Thus, there exists a finite and unique minimum K^* ($1 \leq K^* < \infty$) which satisfies (28.15).

(3) Cycle N

Suppose that the unit is replaced at cycle N ($N = 1, 2, \dots$) of working times. Then, the expected cost rate is [7, p. 76]

$$C(N) = \frac{c_N + c_M \int_0^\infty [1 - G^{(N)}(t)] h(t) dt}{N/\theta}, \tag{28.16}$$

where c_N = replacement cost at cycle N . We find optimal N^* to minimize $C(N)$. Forming $C(N + 1) - C(N) \geq 0$,

$$\frac{NH(N)}{\theta} - \int_0^\infty [1 - G^{(N)}(t)] h(t) dt \geq \frac{c_N}{c_M}, \tag{28.17}$$

where

$$H(N) \equiv \theta \int_0^\infty [G^{(N)}(t) - G^{(N+1)}(t)] h(t) dt.$$

Thus, if $H(N)$ increases strictly with N to $h(\infty)$, then noting that the left-hand side of (28.17) increases strictly with N to ∞ , there exists a finite and unique minimum N^* ($1 \leq N^* < \infty$) which satisfies (28.17).

In particular, when $G(t) = 1 - e^{-\theta t}$, (28.17) becomes

$$\frac{NH(N)}{\theta} - \int_0^\infty [1 - G^{(N)}(t)] h(t) dt \geq \frac{c_N}{c_M}, \tag{28.18}$$

where

$$H(N) \equiv \int_0^\infty \frac{\theta(\theta t)^N}{N!} e^{-\theta t} h(t) dt,$$

which increases strictly with N to $h(\infty)$ from Appendix 3. Thus, there exists a finite and unique minimum N^* ($1 \leq N^* < \infty$) which satisfies (28.18).

(4) Overtime T

Suppose that the unit is replaced at the first failure over time T , which is called *periodic replacement overtime*. Then, the expected cost rate is [8, p. 47]

$$C_{OK}(T) = \frac{c_{OK} + c_M[H(T) + 1]}{T + \int_T^\infty e^{-H(t)+H(T)}dt}, \quad (28.19)$$

where c_{OK} = replacement cost at the first failure over time T . We find optimal T_{OK}^* to minimize $C_{OK}(T)$. Differentiating $C_{OK}(T)$ with respect to T and setting it equal to zero,

$$TQ(T) - H(T) = \frac{c_{OK}}{c_M}, \quad (28.20)$$

where

$$Q(T) \equiv \frac{1}{\int_T^\infty e^{-H(t)+H(T)}dt} = \frac{\bar{F}(T)}{\int_T^\infty \bar{F}(t)dt},$$

which increases strictly with T from $1/\mu$ to $h(\infty)$ from Appendix 1. Thus, noting that the left-hand side of (28.20) increases strictly with T from 0 to ∞ , there exists a finite and unique T_{OK}^* ($0 < T_{OK}^* < \infty$) which satisfies (28.20), and the resulting cost rate is

$$C_{OK}(T_{OK}^*) = c_{OK}Q(T_{OK}^*) = \frac{c_{OK} + c_M H(T_{OK}^*)}{T_{OK}^*}, \quad (28.21)$$

which agrees with (28.11) when $c_{OK} = c_T$ and $T_{OK}^* = T$. In addition, when $c_{OK} = c_T$, comparing (28.20) with (28.12), $T_{OK}^* < T^*$, because $Q(T) > h(T)$. Therefore, from (28.21), $C_{OK}(T_{OK}^*) > C(T^*)$, i.e., periodic replacement is better than replacement overtime when both replacement costs are the same.

Next, suppose that the unit is replaced at the first completion of working cycles over time T . Then, the expected cost rate is [8, p. 39]

$$C_{ON}(T) = \frac{c_{ON} + c_M \sum_{j=0}^\infty \int_0^T [\int_0^\infty \bar{G}(u)h(t+u)du]dG^{(j)}(t)}{(1/\theta) \sum_{j=0}^\infty G^{(j)}(T)}, \quad (28.22)$$

where c_{ON} = replacement cost at the first cycle over time T . We find optimal T_{ON}^* to minimize $C_{ON}(T)$. Differentiating $C_{ON}(T)$ with respect to T and setting it equal to zero,

$$\int_0^\infty \bar{G}(t)h(T+t)dt \sum_{j=0}^\infty G^{(j)}(T) - \sum_{j=0}^\infty \int_0^T \left[\int_0^\infty \bar{G}(u)h(t+u)du \right]dG^{(j)}(t) = \frac{c_{ON}}{c_M}, \quad (28.23)$$

whose left-hand side increases strictly with T from 0 to ∞ . Thus, there exists a finite and unique T_{ON}^* ($0 < T_{ON}^* < \infty$) which satisfies (28.23).

In particular, when $G(t) = 1 - e^{-\theta t}$, (28.23) becomes

$$T \int_0^\infty \theta e^{-\theta t}h(T+t)dt - H(T) = \frac{c_{ON}}{c_M}, \quad (28.24)$$

whose left-hand side increases strictly with T from 0 to ∞ . Thus, there exists a finite and unique T_{ON}^* ($0 < T_{ON}^* < \infty$) which satisfies (28.24), and the resulting cost rate is

$$C_{ON}(T_{ON}^*) = c_M \int_0^\infty \theta e^{-\theta t}h(T_{ON}^*+t)dt = \frac{c_{ON} + c_M H(T_{ON}^*)}{T_{ON}^*}, \quad (28.25)$$

which agrees with (28.11) when $c_{ON} = c_T$ and $T_{ON}^* = T$. In addition, when $c_{ON} = c_T$, comparing (28.24) with (28.12), $T_{ON}^* < T^*$, because $\int_0^\infty \theta e^{-\theta t}h(T+t)dt > h(T)$. Therefore, from (28.25), $C_{ON}(T_{ON}^*) > C(T^*)$, i.e., periodic replacement is better than replacement overtime when both replacement costs are the same. However, if replacement cost at overtime would be smaller than that at time T , then replacement overtime might be better than periodic replacement.

28.3 Two Policies

28.3.1 Age Replacement

Combining age replacements with time T and cycle N in Sect. 28.2.1, we introduce the following four policies:

(1) Replacement First

Suppose that the unit is replaced preventively at time T ($0 < T \leq \infty$) or at cycle N ($N = 1, 2, \dots$), whichever occurs first. Then, the expected cost rate is [7, p. 43]

$$C_F(T, N) = \frac{c_T + (c_F - c_T) \int_0^T [1 - G^{(N)}(t)]dF(t) + (c_N - c_T) \int_0^T \bar{F}(t)dG^{(N)}(t)}{\int_0^T [1 - G^{(N)}(t)]\bar{F}(t)dt}. \quad (28.26)$$

Note that $C_F(T, \infty) = C(T)$ in (28.1) and $C_F(\infty, N) = C(N)$ in (28.4).

When $c_T = c_N$, we find optimal T_F^* and N_F^* to minimize $C_F(T, N)$. Differentiating $C_F(T, N)$ with respect to T and setting it equal to zero,

$$h(T) \int_0^T [1 - G^{(N)}(t)]\bar{F}(t)dt - \int_0^T [1 - G^{(N)}(t)]dF(t) = \frac{c_T}{c_F - c_T}, \quad (28.27)$$

whose left-hand side increases strictly with T from 0 to ∞ . Thus, there exists a finite and unique T_F^* ($0 < T_F^* < \infty$) which satisfies (28.27) for any N , and the resulting cost rate is

$$C_F(T_F^*, N) = (c_F - c_T)h(T_F^*). \quad (28.28)$$

Furthermore, noting that the left-hand side of (28.27) increases with N to that of (28.2), T_F^* decreases with N to T^* given in (28.2), and $T_F^* \geq T^*$.

Forming $C_F(T, N + 1) - C_F(T, N) \geq 0$,

$$Q(T, N) \int_0^T [1 - G^{(N)}(t)]\bar{F}(t)dt - \int_0^T [1 - G^{(N)}(t)]dF(t) \geq \frac{c_T}{c_F - c_T}, \quad (28.29)$$

where

$$Q(T, N) \equiv \frac{\int_0^T [G^{(N)}(t) - G^{(N+1)}(t)]dF(t)}{\int_0^T [G^{(N)}(t) - G^{(N+1)}(t)]\bar{F}(t)dt},$$

and $Q(T, N) < h(T)$. Substituting (28.27) for (28.29),

$$Q(T, N) \geq h(T),$$

which does not hold for any T , i.e., $C_F(T, N + 1) < C_F(T, N)$ and $N_F^* = \infty$. Therefore, the optimal policy which minimizes $C_F(T, N)$ is $N_F^* = \infty$ and $T_F^* = T^*$ given in (28.2).

In particular, when $G(t) = 1 - e^{-\theta t}$,

$$Q(T, N) = \frac{\int_0^T (\theta t)^N e^{-\theta t} dF(t)}{\int_0^T (\theta t)^N e^{-\theta t} \bar{F}(t) dt},$$

which increases strictly with T to $Q(N)$ in (28.6) and increases strictly with N to $h(T)$ from Appendix 2. Thus, the left-hand side of (28.29) increases strictly with N to that of (28.2). Therefore, if $T \leq T^*$, then $N_F^* = \infty$, and conversely, if $T > T^*$, then there exists a finite and unique minimum N_F^* ($1 \leq N_F^* < \infty$) which satisfies (28.29). In addition, because the left-hand side of (28.29) increases with T to that of (28.6), N_F^* decreases with T to N^* given in (28.6), and $N_F^* \geq N^*$.

(2) Replacement Last

Suppose that the unit is replaced preventively at time T ($0 \leq T < \infty$) or at cycle N ($N = 0, 1, 2, \dots$), whichever occurs last. Then, the expected cost rate is [7, p. 47]

$$C_L(T, N) = \frac{c_T + (c_F - c_T) \left\{ F(T) + \int_T^\infty [1 - G^{(N)}(t)] dF(t) \right\} + (c_N - c_T) \int_T^\infty \bar{F}(t) dG^{(N)}(t)}{\int_0^T \bar{F}(t) dt + \int_T^\infty [1 - G^{(N)}(t)] \bar{F}(t) dt}, \quad (28.30)$$

which agrees with (28.1) when $N = 0$ and (28.4) when $T = 0$.

When $c_T = c_N$, we find optimal T_L^* and N_L^* to minimize $C_L(T, N)$. Differentiating $C_L(T, N)$ with respect to T and setting it equal to zero,

$$h(T) \left\{ \int_0^T \bar{F}(t) dt + \int_T^\infty [1 - G^{(N)}(t)] \bar{F}(t) dt \right\} - F(T) - \int_T^\infty [1 - G^{(N)}(t)] dF(t) = \frac{c_T}{c_F - c_T}, \quad (28.31)$$

whose left-hand side increases strictly to ∞ . Thus, there exists a finite and unique T_L^* ($0 \leq T_L^* < \infty$) which satisfies (28.31) for any N , and the resulting cost rate is

$$C_L(T_L^*, N) = (c_F - c_T)h(T_L^*). \quad (28.32)$$

Furthermore, noting that the left-hand side of (28.31) decreases with N from that of (28.2), T_L^* increases with N from T^* given in (28.2), and $T_L^* \geq T^*$.

Forming $C_L(T, N + 1) - C_L(T, N) \geq 0$,

$$\tilde{Q}(T, N) \left\{ \int_0^T \bar{F}(t) dt + \int_T^\infty [1 - G^{(N)}(t)] \bar{F}(t) dt \right\} - F(T) - \int_T^\infty [1 - G^{(N)}(t)] dF(t) \geq \frac{c_T}{c_F - c_T}, \quad (28.33)$$

where

$$\tilde{Q}(T, N) = \frac{\int_T^\infty [G^{(N)}(t) - G^{(N+1)}(t)] dF(t)}{\int_T^\infty [G^{(N)}(t) - G^{(N+1)}(t)] \bar{F}(t) dt},$$

and $\tilde{Q}(T, N) > h(T)$. Substituting (28.31) for (28.33),

$$\tilde{Q}(T, N) \geq h(T),$$

which always holds for any T , i.e., $C_L(T, N + 1) \geq C_L(T, N)$. Therefore, the optimal policy which minimizes $C_L(T, N)$ is $N_L^* = 0$ and $T_L^* = T^*$ given in (28.2).

In particular, when $G(t) = 1 - e^{-\theta t}$,

$$\tilde{Q}(T, N) = \frac{\int_T^\infty (\theta t)^N e^{-\theta t} dF(t)}{\int_T^\infty (\theta t)^N e^{-\theta t} \bar{F}(t) dt},$$

which increases strictly with T from $Q(N)$ to $h(\infty)$ and increases strictly with N from $\tilde{Q}_0(T)$ to $h(\infty)$ from Appendix 2. Thus, the left-hand side of (28.33) increases strictly with N from

$$\tilde{Q}_0(T) \int_0^T \bar{F}(t) dt - F(T) > h(T) \int_0^T \bar{F}(t) dt - F(T),$$

which agrees with (28.2). Therefore, if $T \geq T^*$, then $N_L^* = 0$, and conversely, if $T < T^*$, then there exists a finite and unique minimum N_L^* ($0 \leq N_L^* < \infty$) which satisfies (28.33). In addition, the left-hand side of (28.33) increases with T from that of (28.6), N_L^* decreases with T from N^* given in (28.6), and $N_L^* \leq N^*$.

Therefore, from the above results, if $T > T^*$, replacement first is better than replacement last, if $T = T^*$, then age replacement is better than replacement first and last, and if $T < T^*$, replacement last is better than replacement first.

Finally, compare replacement first and replacement last for given N . From (28.27) and (28.31), denoting

$$\begin{aligned}
 L_1(T; N) &\equiv \\
 &h(T) \left\{ \int_0^T \bar{F}(t)dt + \int_T^\infty [1 - G^{(N)}(t)]\bar{F}(t)dt \right\} \\
 &\quad - F(T) - \int_T^\infty [1 - G^{(N)}(t)]dF(t) \\
 &\quad - h(T) \int_0^T [1 - G^{(N)}(t)]\bar{F}(t)dt \\
 &\quad + \int_0^T [1 - G^{(N)}(t)]dF(t) \\
 &= \int_0^T G^{(N)}(t)\bar{F}(t)[h(T) - h(t)]dt \\
 &\quad - \int_T^\infty [1 - G^{(N)}(t)]\bar{F}(t)[h(t) - h(T)]dt,
 \end{aligned}$$

we have

$$\begin{aligned}
 L_1(0; N) &= - \int_0^\infty [1 - G^{(N)}(t)]dF(t) < 0, \\
 L_1(\infty) &= \infty, \\
 L_1'(T; N) &= h'(T) \left\{ \int_0^T G^{(N)}(t)\bar{F}(t)dt \right. \\
 &\quad \left. + \int_T^\infty [1 - G^{(N)}(t)]\bar{F}(t)dt \right\} > 0.
 \end{aligned}$$

Thus, there exists a finite and unique T_A ($0 < T_A < \infty$) which satisfies $L_1(T; N) = 0$. In addition, noting that $L_1(T; N)$ decreases with N , T_A increases with N from T^* given in (28.2) to ∞ . We set that

$$\begin{aligned}
 L(T_A) &\equiv h(T_A) \int_0^{T_A} [1 - G^{(N)}(t)]\bar{F}(t)dt \\
 &\quad - \int_0^{T_A} [1 - G^{(N)}(t)]dF(t).
 \end{aligned}$$

Then, it is shown from (28.27) and (28.31) that if $L(T_A) \geq c_T/(c_F - c_T)$, i.e., $c_F/c_T \geq 1 + 1/L(T_A)$, then $T_F^* \leq T_L^*$, and from (28.28) and (28.32), replacement first is better than replacement last. Conversely, if $L(T_A) < c_T/(c_F - c_T)$, then $T_F^* > T_L^*$, and replacement last is better than replacement first. This means that if the ratio of c_T/c_F is greater than $L(T_A)/[1 + L(T_A)]$, i.e., replacement cost c_F is nearly equal to cost c_T , replacement last is better than replacement first.

On the other hand, noting that $L_1(T, N)$ decreases with N from

$$L_1(T; 0) = \int_0^T \bar{F}(t)[h(T) - h(t)]dt > 0,$$

to

$$L_1(T; \infty) = - \int_T^\infty \bar{F}(t)[h(t) - h(T)]dt < 0,$$

there exists a finite and unique maximum N_A ($0 \leq N_A < \infty$) which satisfies $L_1(T, N) > 0$. Thus, if $N \geq N_A$, then $L_1(T, N) \leq 0$, i.e., $T_F^* \leq T_L^*$ and replacement first is better than replacement last. Conversely, if $N < N_A$, then $L_1(T, N) > 0$, i.e., $T_F^* > T_L^*$ and replacement last is better than replacement first.

From the above results, if c_F and N are small, replacement last is better than replacement first, and vice versa.

(3) Replacement Overtime First

Suppose that the unit is replaced preventively at cycle N ($N = 1, 2, \dots$) before time T or at the first completion of working cycles over time T ($0 \leq T < \infty$), whichever occurs first. Then, the expected cost rate is [8, p. 9]

$$\begin{aligned}
 C_{OF}(T, N) &= \\
 &\frac{c_O + (c_N - c_O) \int_0^T \bar{F}(t)dG^{(N)}(t) + (c_F - c_O) \left(\int_0^T [1 - G^{(N)}(t)]dF(t) + \sum_{j=0}^{N-1} \int_0^T \left\{ \int_{T-t}^\infty [F(t+u) - F(T)]dG^{(j)}(u) \right\} \times dG^{(j)}(t) \right)}{\int_0^T [1 - G^{(N)}(t)]\bar{F}(t)dt + \sum_{j=0}^{N-1} \int_0^T \left[\int_{T-t}^\infty \bar{G}(u)\bar{F}(t+u)du \right]dG^{(j)}(t)},
 \end{aligned} \tag{28.34}$$

which agrees with (28.4) when $T = \infty$ and (28.7) when $N = \infty$.

When $c_O = c_N$ and $G(t) = 1 - e^{-\theta t}$, the expected cost rate is

$$\begin{aligned}
 C_{OF}(T, N) &= \\
 &\frac{c_O + (c_F - c_O) \left\{ \int_0^T [1 - G^{(N)}(t)]dF(t) + [1 - G^{(N)}(T)] \int_T^\infty e^{-\theta(t-T)}dF(t) \right\}}{\int_0^T [1 - G^{(N)}(t)]\bar{F}(t)dt + [1 - G^{(N)}(T)] \int_T^\infty e^{-\theta(t-T)}\bar{F}(t)dt}.
 \end{aligned} \tag{28.35}$$

We find optimal T_{OF}^* and N_{OF}^* to minimize $C_{OF}(T, N)$. Differentiating $C_{OF}(T, N)$ with respect to T and setting it equal to zero,

$$\begin{aligned} &\tilde{Q}_O(T) \int_0^T [1 - G^{(N)}(t)] \bar{F}(t) dt \\ &- \int_0^T [1 - G^{(N)}(t)] dF(t) = \frac{c_O}{c_F - c_O}, \end{aligned} \quad (28.36)$$

whose left-hand side increases strictly with T from 0 to ∞ . Thus, there exists a finite and unique T_{OF}^* ($0 < T_{OF}^* < \infty$) which satisfies (28.36) for any N , and the resulting cost rate is

$$\begin{aligned} C_{OF}(T_{OF}^*) &= (c_F - c_O) \tilde{Q}_O(T_{OF}^*) \\ &= \frac{c_O + (c_F - c_O) \int_0^{T_{OF}^*} [1 - G^{(N)}(t)] dF(t)}{\int_0^{T_{OF}^*} [1 - G^{(N)}(t)] \bar{F}(t) dt}, \end{aligned} \quad (28.37)$$

which agrees with (28.26) when $c_O = c_T = c_N$ and $T_{OF}^* = T$. Furthermore, noting that the left-hand side of (28.36) increases strictly with N to that of (28.9), T_{OF}^* decreases with N to T_O^* given in (28.9), and $T_{OF}^* \geq T_O^*$.

Forming $C_{OF}(T, N + 1) - C_{OF}(T, N) \geq 0$,

$$\begin{aligned} &Q_1(T, N - 1) \left\{ [1 - G^{(N)}(T)] \int_T^\infty e^{-\theta(t-T)} \bar{F}(t) dt \right. \\ &+ \left. \int_0^T [1 - G^{(N)}(t)] \bar{F}(t) dt \right\} \\ &- [1 - G^{(N)}(T)] \int_T^\infty e^{-\theta(t-T)} dF(t) \\ &- \int_0^T [1 - G^{(N)}(t)] dF(t) \geq \frac{c_O}{c_F - c_O}, \end{aligned} \quad (28.38)$$

where

$$Q_1(T, N) \equiv \frac{\int_0^T (\theta t)^N \left[\int_t^\infty e^{-\theta u} dF(u) \right] dt}{\int_0^T (\theta t)^N \left[\int_t^\infty e^{-\theta u} \bar{F}(u) du \right] dt},$$

which increases strictly with T to $Q_1(\infty, N) = Q(N + 1)$, and increases strictly with N to $\tilde{Q}_O(T)$, and $Q_1(T, N) < \tilde{Q}_O(T)$ from Appendix 4. Substituting (28.36) for (28.38),

$$\begin{aligned} &Q_1(T, N - 1) \left\{ [1 - G^{(N)}(T)] \int_T^\infty e^{-\theta(t-T)} \bar{F}(t) dt \right. \\ &+ \left. \int_0^T [1 - G^{(N)}(t)] \bar{F}(t) dt \right\} \\ &- [1 - G^{(N)}(T)] \int_T^\infty e^{-\theta(t-T)} dF(t) \\ &\geq \tilde{Q}_O(T) \int_0^T [1 - G^{(N)}(t)] \bar{F}(t) dt, \end{aligned}$$

which does not hold for any T , i.e., $C_{OF}(T, N + 1) \leq C_{OF}(T, N)$. Therefore, the optimal policy which minimizes $C_{OF}(T, N)$ is $N_{OF}^* = \infty$ and $T_{OF}^* = T_O^*$ given in (28.9).

Furthermore, note that the left-hand side of (28.38) increases strictly with N to that of (28.9). Therefore, if $T \leq T_O^*$, then $N_{OF}^* = \infty$, and conversely, if $T > T_O^*$, then there exists a finite and unique minimum N_{OF}^* ($1 \leq N_{OF}^* < \infty$) which satisfies (28.38). In addition, because the left-hand side of (28.38) increases with T to

$$\begin{aligned} &Q_1(\infty, N - 1) \int_0^\infty [1 - G^{(N)}(t)] \bar{F}(t) dt \\ &- \int_0^\infty [1 - G^{(N)}(t)] dF(t) < \\ &Q(N) \int_0^\infty [1 - G^{(N)}(t)] \bar{F}(t) dt \\ &- \int_0^\infty [1 - G^{(N)}(t)] dF(t), \end{aligned}$$

which agrees with (28.6), N_{OF}^* decreases with T to N^* given in (28.6), and $N_{OF}^* \geq N^*$.

(4) Replacement Overtime Last

Suppose that the unit is preventively at cycle N ($N = 0, 1, 2, \dots$) or at the first completion of working cycles over time T ($0 \leq T < \infty$), whichever occurs last. Then, the expected cost rate is [8, p. 13]

$$\begin{aligned} C_{OL}(T, N) &= \\ &\frac{c_O + (c_N - c_O) \int_T^\infty \bar{F}(t) dG^{(N)}(t) + (c_F - c_O) (F(T) + \int_T^\infty [F(t) - F(T)] dG^{(N)}(t) + \sum_{j=N}^\infty \int_0^T \{ \int_{T-t}^\infty [F(t+u) - F(T)] dG^{(j)}(u) \} dG^{(j)}(t))}{\int_0^T \bar{F}(t) dt + \int_T^\infty [1 - G^{(N)}(t)] \bar{F}(t) dt + \sum_{j=N}^\infty \int_0^T [\int_{T-t}^\infty \bar{G}(u) \bar{F}(t+u) du] dG^{(j)}(t)}, \end{aligned} \quad (28.39)$$

which agrees with (28.4) when $T = 0$ and (28.7) when $N = 0$, and note that $C_{OL}(T, 0) = C_{OL}(T, 1)$.

When $c_O = c_N$ and $G(t) = 1 - e^{-\theta t}$, the expected cost rate is

$$\begin{aligned} C_{OL}(T, N) &= \\ &\frac{c_O + (c_F - c_O) \{ F(T) + \int_T^\infty [1 - G^{(N)}(t)] dF(t) + G^{(N)}(T) \int_T^\infty e^{-\theta(t-T)} dF(t) \}}{\int_0^T \bar{F}(t) dt + \int_T^\infty [1 - G^{(N)}(t)] \bar{F}(t) dt + G^{(N)}(T) \int_T^\infty e^{-\theta(t-T)} \bar{F}(t) dt}. \end{aligned} \quad (28.40)$$

We find optimal T_{OL}^* and N_{OL}^* to minimize $C_{OL}(T, N)$. Differentiating $C_{OL}(T, N)$ with respect to T and setting it equal to zero,

$$\begin{aligned} & \tilde{Q}_O(T) \int_T^\infty [1 - G^{(N)}(t)] \bar{F}(t) dt \\ & - \int_T^\infty [1 - G^{(N)}(t)] dF(t) \\ & + \tilde{Q}_O(T) \int_0^T \bar{F}(t) dt - F(T) = \frac{c_O}{c_F - c_O}, \quad (28.41) \end{aligned}$$

$$\begin{aligned} & + \tilde{Q}_1(T, N - 1) \int_0^T \bar{F}(t) dt \\ & \geq \tilde{Q}_O(T) \int_T^\infty [1 - G^{(N)}(t)] \bar{F}(t) dt \\ & + \tilde{Q}_O(T) \int_0^T \bar{F}(t) dt, \end{aligned}$$

whose left-hand side increases strictly with T to ∞ . Thus, there exists a finite and unique T_{OL}^* ($0 < T_{OL}^* < \infty$) which satisfies (28.41) for any N , and the resulting cost rate is

$$\begin{aligned} C_{OL}(T_{OL}^*, N) &= (c_F - c_O) \tilde{Q}_O(T_{OL}^*) = \\ & \frac{c_O + (c_F - c_O) \{ F(T_{OL}^*) + \int_{T_{OL}^*}^\infty [1 - G^{(N)}(t)] dF(t) \}}{\int_0^{T_{OL}^*} \bar{F}(t) dt + \int_{T_{OL}^*}^\infty [1 - G^{(N)}(t)] \bar{F}(t) dt}, \quad (28.42) \end{aligned}$$

which agrees with (28.30) when $c_O = c_T = c_N$ and $T_{OL}^* = T$. Furthermore, noting that the left-hand side of (28.41) decreases with N from that of (28.9), T_{OL}^* increases with N from T_O^* given in (28.9), and $T_{OL}^* \geq T_O^*$.

Forming $C_{OL}(T, N + 1) - C_{OL}(T, N) \geq 0$,

$$\begin{aligned} & \tilde{Q}_1(T, N - 1) \left\{ \int_T^\infty [1 - G^{(N)}(t)] \bar{F}(t) dt \right. \\ & \left. + G^{(N)}(T) \int_T^\infty e^{-\theta(t-T)} \bar{F}(t) dt \right\} \\ & - \int_T^\infty [1 - G^{(N)}(t)] dF(t) \\ & - G^{(N)}(T) \int_T^\infty e^{-\theta(t-T)} dF(t) \\ & + \tilde{Q}_1(T, N - 1) \int_0^T \bar{F}(t) dt - F(T) \geq \frac{c_O}{c_F - c_O}, \quad (28.43) \end{aligned}$$

where

$$\tilde{Q}_1(T, N) \equiv \frac{\int_T^\infty (\theta t)^N \left[\int_t^\infty e^{-\theta u} dF(u) \right] dt}{\int_T^\infty (\theta t)^N \left[\int_t^\infty e^{-\theta u} \bar{F}(u) du \right] dt},$$

which increases strictly with T from $Q(N + 1)$ to $h(\infty)$ and increases strictly with N from $\tilde{Q}_1(T, 0)$ to $h(\infty)$, and $\tilde{Q}_1(T, N) > \tilde{Q}_O(T) > Q_1(T, N)$ from Appendix 4. Substituting (28.41) for (28.43),

$$\begin{aligned} & \tilde{Q}_1(T, N - 1) \left\{ \int_T^\infty [1 - G^{(N)}(t)] \bar{F}(t) dt \right. \\ & \left. + G^{(N)}(T) \int_T^\infty e^{-\theta(t-T)} \bar{F}(t) dt \right\} \\ & - G^{(N)}(T) \int_T^\infty e^{-\theta(t-T)} dF(t) \end{aligned}$$

which always holds for any T , i.e., $C_{OL}(T, N + 1) \geq C_{OL}(T, N)$. Therefore, the optimal policy which minimizes $C_{OL}(T, N)$ is $N_{OL}^* = 0$ or 1 and $T_{OL}^* = T_O^*$ given in (28.9).

Furthermore, note that the left-hand side of (28.43) increases strictly with N from more than that of (28.9). Therefore, if $T \geq T_O^*$, then $N_{OL}^* = 1$ and conversely, if $T < T_O^*$, then there exists a finite and unique minimum N_{OL}^* ($1 \leq N_{OL}^* < \infty$) which satisfies (28.43). In addition, because the left-hand side of (28.43) decreases with T from

$$Q(N) \int_0^\infty [1 - G^{(N)}(t)] \bar{F}(t) dt - \int_0^\infty [1 - G^{(N)}(t)] dF(t),$$

which agrees with (28.6), N_{OL}^* increases with T from N^* given in (28.6), and $N_{OL}^* \geq N^*$.

Therefore, from the above results, if $T > T_O^*$, replacement overtime first is better than overtime last, if $T = T_O^*$, then replacement overtime is better than overtime first and last, and if $T < T_O^*$, replacement overtime last is better than overtime first.

Finally, compare replacement overtime first and last for given N ($N \geq 1$) when $G(t) = 1 - e^{-\theta t}$. From (28.36) and (28.41), denoting

$$\begin{aligned} L_2(T, N) &\equiv \int_0^T G^{(N)}(t) \bar{F}(t) [\tilde{Q}_O(T) - h(t)] dt \\ &- \int_T^\infty [1 - G^{(N)}(t)] \bar{F}(t) [h(t) - \tilde{Q}_O(T)] dt, \quad (28.44) \end{aligned}$$

we have

$$\begin{aligned} L_2(0, N) &= \\ & - \int_0^\infty [1 - G^{(N)}(t)] \bar{F}(t) [h(t) - \tilde{Q}_O(0)] dt < 0, \end{aligned}$$

$$L_2(\infty) = \infty,$$

$$\begin{aligned} L_2(T, N) &= \frac{e^{-\theta T} \bar{F}(T) [\tilde{Q}_O(T) - h(T)]}{\int_T^\infty e^{-\theta t} \bar{F}(t) dt} \\ &\times \left\{ \int_0^T G^{(N)}(t) \bar{F}(t) dt + \int_T^\infty [1 - G^{(N)}(t)] \bar{F}(t) dt \right\} \\ &+ \bar{F}(T) [\tilde{Q}_O(T) - h(T)] > 0. \end{aligned}$$

Thus, there exists a finite and unique T_{OA} ($0 < T_{OA} < \infty$) which satisfies $L_2(T, N) \equiv 0$. In addition, noting that $L_2(T, N)$ decreases with N , T_{OA} increases with N from T_O^* . We set that

$$L(T_{OA}) \equiv \int_0^{T_{OA}} [1 - G^{(N)}(t)] \bar{F}(t) [\tilde{Q}_O(T_{OA}) - h(t)] dt.$$

Then, it is shown from (28.36) and (28.41) that if $L(T_{OA}) > c_O/(c_F - c_O)$, i.e., $c_F/c_O \geq 1 + 1/L(T_{OA})$, then $T_{OF}^* \leq T_{OL}^*$, and from (28.37) and (28.42), replacement overtime first is better than overtime last. Conversely, if $L(T_{OA}) < c_O/(c_F - c_O)$, then $T_{OF}^* > T_{OL}^*$, and replacement overtime last is better than overtime first. This means that if the ratio of c_O/c_F is greater than $L(T_{OA})/[1 + L(T_{OA})]$, i.e., replacement cost c_F is nearly equal to cost c_O , replacement overtime last is better than overtime first.

On the other hand, noting that $L_2(T, N)$ decreases with N from

$$L_2(T; 0) = \int_0^T \bar{F}(t) [\tilde{Q}_O(T) - h(t)] dt > 0,$$

to

$$L_2(T; \infty) = - \int_T^\infty \bar{F}(t) [h(t) - \tilde{Q}_O(T)] dt < 0,$$

there exists a finite and unique maximum N_{OA} ($0 \leq N_{OA} < \infty$) which satisfies $L_2(T, N) > 0$. Thus, if $N \geq N_{OA}$, then $L_2(T, N) \leq 0$, i.e., $T_{OF}^* \leq T_{OL}^*$, and replacement overtime first is better than overtime last. Conversely, if $N < N_{OA}$, then $L_2(T, N) > 0$, i.e., $T_{OF}^* > T_{OL}^*$, and replacement overtime last is better than overtime first. From the above results, if c_F and N are small, replacement overtime last is better than overtime first and vice versa.

28.3.2 Periodic Replacement

Combining replacements with time T , failure K , and cycle N in Sect. 28.2.2, we introduce the following twelve policies:

(1) Replacement First with Time T and Failure K

Suppose that the unit is replaced at time T ($0 < T \leq \infty$) or at failure K ($K = 1, 2, \dots$), whichever occurs first. Then, the expected cost rate is [9]

$$C_F(T, K) = \frac{c_T + (c_K - c_T)P_K(T) + c_M \int_0^T \bar{P}_K(t)h(t)dt}{\int_0^T \bar{P}_K(t)dt}, \quad (28.45)$$

which agrees with (28.11) when $K = \infty$ and (28.14) when $T = \infty$.

When $c_T = c_K$, we find optimal T_F^* and K_F^* to minimize $C_F(T, K)$. Differentiating $C_F(T, K)$ with respect to T and setting it equal to zero,

$$h(T) \int_0^T \bar{P}_K(t)dt - \int_0^T \bar{P}_K(t)h(t)dt = \frac{c_T}{c_M}, \quad (28.46)$$

whose left-hand side increases strictly with T from 0 to ∞ . Thus, there exists a finite and unique T_F^* ($0 < T_F^* < \infty$) which satisfies (28.46) for any K , and the resulting cost rate is

$$C_F(T_F^*, K) = c_M h(T_F^*). \quad (28.47)$$

Furthermore, noting that the left-hand side of (28.46) increases with K to that of (28.12), T_F^* decreases with K to T^* given in (28.12), and $T_F^* \geq T^*$.

Forming $C_F(T, K+1) - C_F(T, K) \geq 0$,

$$H(T, K) \int_0^T \bar{P}_K(t)dt - \int_0^T \bar{P}_K(t)h(t)dt \geq \frac{c_T}{c_M}, \quad (28.48)$$

where

$$H(T, K) \equiv \frac{\int_0^T p_K(t)h(t)dt}{\int_0^T p_K(t)dt},$$

which increases strictly with T to $H(\infty, K) = 1/\int_0^\infty p_K(t)dt$ and increases strictly with K to $h(T)$, and $H(T, K) < h(T)$ from Appendix 5. Substituting (28.46) for (28.48),

$$H(T, K) \geq h(T),$$

which does not hold for any T , i.e., $C_F(T, K+1) < C_F(T, K)$. Therefore, the optimal policy which minimizes $C_F(T, K)$ is $K_F^* = \infty$ and $T_F^* = T^*$ given in (28.12).

Furthermore, noting that the left-hand side of (28.48) increases strictly with K to that of (28.12), if $T \leq T^*$, then $K_F^* = \infty$, and if $T > T^*$, then there exists a finite and unique minimum K_F^* ($1 \leq K_F^* < \infty$) which satisfies (28.48). In addition, because the left-hand side of (28.48) increases with T to that of (28.15), K_F^* decreases with T to K^* given in (28.15), and $K_F^* \geq K^*$.

(2) Replacement Last with Time T and Failure K

Suppose that the unit is replaced at time T ($0 \leq T < \infty$) or at failure K ($K = 0, 1, 2, \dots$), whichever occurs last. Then, the expected cost rate is [9]

$$C_L(T, K) = \frac{c_T + (c_K - c_T)\bar{P}_K(T) + c_M \left[H(T) + \int_T^\infty \bar{P}_K(t)h(t)dt \right]}{T + \int_T^\infty \bar{P}_K(t)dt}, \quad (28.49)$$

which agrees with (28.11) when $K = 0$ and (28.14) when $T = 0$.

When $c_T = c_K$, we find optimal T_L^* and K_L^* to minimize $C_L(T, K)$. Differentiating $C_L(T, K)$ with respect to T and setting it equal to zero,

$$h(T) \left[T + \int_T^\infty \bar{P}_K(t) dt \right] - H(T) - \int_T^\infty \bar{P}_K(t) h(t) dt = \frac{c_T}{c_M}, \tag{28.50}$$

whose left-hand side increases strictly with T to ∞ . Thus, there exists a finite and unique T_L^* ($0 < T_L^* < \infty$) which satisfies (28.50) for any K , and the resulting cost rate is

$$C_L(T_L^*, K) = c_M h(T_L^*). \tag{28.51}$$

Furthermore, noting that the left-hand side of (28.50) increases strictly with K from that of (28.12), T_L^* decreases with K from T^* given in (28.12), and $T_L^* \leq T^*$.

Forming $C_L(T, K + 1) - C_L(T, K) \geq 0$,

$$\tilde{H}(T, K) \left[T + \int_T^\infty \bar{P}_K(t) dt \right] - H(T) - \int_T^\infty \bar{P}_K(t) h(t) dt \geq \frac{c_T}{c_M}, \tag{28.52}$$

where

$$\tilde{H}(T, K) \equiv \frac{\int_T^\infty p_K(t) h(t) dt}{\int_T^\infty p_K(t) dt},$$

which increases strictly with T from $1 / \int_0^\infty p_K(t) dt$ to $h(\infty)$ and increases strictly with K from $\tilde{H}(T, 0) = Q(T)$ in (28.20) to $h(\infty)$, and $\tilde{H}(T, K) > h(T)$ from Appendix 5. Substituting (28.50) for (28.52),

$$\tilde{H}(T, K) \geq h(T),$$

which always holds for any T , i.e., $C_L(T, K + 1) > C_L(T, K)$. Therefore, the optimal policy which minimizes $C_L(T, K)$ is $K_L^* = 0$ and $T_L^* = T^*$ given in (28.12).

Furthermore, noting that the left-hand side of (28.52) increases strictly with K from

$$TQ(T) - H(T) > Th(T) - H(T),$$

which agrees with that of (28.12), if $T \geq T^*$, then $K_L^* = 0$, and if $T < T^*$, then there exists a finite and unique minimum K_L^* ($0 \leq K_L^* < \infty$) which satisfies (28.52). In addition, because the left-hand side of (28.52) increases with T from that of (28.15), K_L^* decreases with T from K^* given in (28.15), and $K_L^* \leq K^*$.

Comparing replacement first and last with T and K , if $T < T^*$, then replacement last is better than replacement first, if $T = T^*$, then replacement with time T^* is better than replacement first and last, and if $T > T^*$, then replacement first is better than replacement last.

(3) Replacement First with Time T and Cycle N

Suppose that the unit is replaced at time T ($0 < T \leq \infty$) or at cycle N ($N = 1, 2, \dots$), whichever occurs first. Then, the expected cost rate is [7, p. 76]

$$C_F(T, N) = \frac{c_T + (c_N - c_T)G^{(N)}(T) + c_M \int_0^T [1 - G^{(N)}(t)]h(t) dt}{\int_0^T [1 - G^{(N)}(t)] dt}, \tag{28.53}$$

which agrees with (28.11) when $N = \infty$ and (28.16) when $T = \infty$.

When $c_T = c_N$ and $G(t) = 1 - e^{-\theta t}$, we find optimal T_F^* and N_F^* to minimize $C_F(T, N)$. Differentiating $C_F(T, N)$ with respect to T and setting it equal to zero,

$$h(T) \int_0^T [1 - G^{(N)}(t)] dt - \int_0^T [1 - G^{(N)}(t)]h(t) dt = \frac{c_T}{c_M}, \tag{28.54}$$

whose left-hand side increases strictly with T from 0 to ∞ . Thus, there exists a finite and unique T_F^* ($0 < T_F^* < \infty$) which satisfies (28.54) for any N , and the resulting cost rate is

$$C_F(T_F^*, N) = c_M h(T_F^*). \tag{28.55}$$

Furthermore, noting that the left-hand side of (28.54) increases strictly with N to that of (28.12), T_F^* decreases with N to T^* given in (28.12), and $T_F^* \geq T^*$.

Forming $C_F(T, N + 1) - C_F(T, N) \geq 0$,

$$H(T, N) \int_0^T [1 - G^{(N)}(t)] dt - \int_0^T [1 - G^{(N)}(t)]h(t) dt \geq \frac{c_T}{c_M}, \tag{28.56}$$

where

$$H(T, N) \equiv \frac{\int_0^T (\theta t)^N e^{-\theta t} h(t) dt}{\int_0^T (\theta t)^N e^{-\theta t} dt},$$

which increases strictly with T to $H(N)$ and increases strictly with N to $h(T)$, and $H(T, N) < h(T)$ from Appendix 3. Substituting (28.54) for (28.56),

$$H(T, N) \geq h(T),$$

which does not hold for any T . Therefore, the optimal policy which minimizes $C_F(T, N)$ is $N_F^* = \infty$ and $T_F^* = T^*$ given in (28.12).

Furthermore, noting that the left-hand side of (28.56) increases strictly with N to that of (28.12), if $T \leq T^*$, then $N_F^* = \infty$, and if $T > T^*$, then there exists a finite and unique minimum N_F^* ($1 \leq N_F^* < \infty$) which satisfies (28.56). In addition, because the left-hand side of (28.56) increases with T to that of (28.18), N_F^* decreases with T to N^* given in (28.18), and $N_F^* \geq N^*$.

(4) Replacement Last with Time T and Cycle N

Suppose that the unit is replaced at time T ($0 \leq T < \infty$) or at cycle N ($N = 0, 1, 2, \dots$), whichever occurs last. Then, the expected cost rate is [7, p. 79]

$$C_L(T, N) = \frac{c_T + (c_N - c_T)[1 - G^{(N)}(T)] + c_M \{H(T) + \int_T^\infty [1 - G^{(N)}(t)]h(t)dt\}}{T + \int_T^\infty [1 - G^{(N)}(t)]dt}, \quad (28.57)$$

which agrees with (28.11) when $N = 0$ and (28.16) when $T = 0$,

When $c_T = c_N$ and $G(t) = 1 - e^{-\theta t}$, we find optimal T_L^* and N_L^* to minimize $C_L(T, N)$. Differentiating $C_L(T, N)$ with respect to T and setting it equal to zero,

$$h(T) \left\{ T + \int_T^\infty [1 - G^{(N)}(t)]dt \right\} - H(T) - \int_T^\infty [1 - G^{(N)}(t)]h(t)dt = \frac{c_T}{c_M}, \quad (28.58)$$

whose left-hand side increases strictly with T to ∞ . Thus, there exists a finite and unique T_L^* ($0 < T_L^* < \infty$) which satisfies (28.58) for any N , and the resulting cost rate is

$$C_L(T_L^*, N) = c_M h(T_L^*). \quad (28.59)$$

Furthermore, noting that the left-hand side of (28.58) decreases strictly with N from that of (28.12), T_L^* increases with N from T^* given in (28.12), and $T_L^* \leq T^*$.

Forming $C_L(T, N + 1) - C_L(T, N) \geq 0$,

$$\tilde{H}(T, N) \left\{ T + \int_T^\infty [1 - G^{(N)}(t)]dt \right\} - H(T) - \int_T^\infty [1 - G^{(N)}(t)]h(t)dt \geq \frac{c_T}{c_M}, \quad (28.60)$$

where

$$\tilde{H}(T, N) \equiv \frac{\int_T^\infty (\theta t)^N e^{-\theta t} h(t) dt}{\int_T^\infty (\theta t)^N e^{-\theta t} dt},$$

which increases strictly with T from $H(N)$ in (28.18) to $h(\infty)$ and increases strictly with N from $\int_0^\infty \theta e^{-\theta t} h(T + t) dt$ to $h(\infty)$, and $\tilde{H}(T, N) > h(T)$ from Appendix 3. Substituting (28.58) for (28.60),

$$\tilde{H}(T, N) \geq h(T),$$

which always holds for any T , i.e., $C_L(T, N + 1) \geq C_L(T, N)$. Therefore, the optimal policy which minimizes $C_L(T, N)$ is $N_L^* = 0$ and $T_L^* = T^*$ given in (28.12).

Furthermore, noting that the left-hand side of (28.60) increases strictly with N from

$$T \int_0^\infty \theta e^{-\theta t} h(T + t) dt - H(T) > Th(T) - H(T),$$

which agrees with that of (28.12), if $T \geq T^*$, then $N_L^* = 0$, and if $T < T^*$, then there exists a finite and unique minimum N_L^* ($0 \leq N_L^* < \infty$) which satisfies (28.60). In addition, because the left-hand side of (28.60) increases with T from that of (28.18), N_L^* decreases with T from N^* given in (28.18), and $N_L^* \leq N^*$.

Comparing replacement first and last with T and N , if $T < T^*$, then replacement last is better than replacement first, if $T = T^*$, then replacement with time T^* is better than replacement first and last, and if $T > T^*$, then replacement first is better than replacement last.

(5) Replacement Overtime First with Time T and Failure K

Suppose that the unit is replaced at failure K ($K = 1, 2, \dots$) before time T or at the first failure over time T ($0 \leq T < \infty$), whichever occurs first. Then, the expected cost rate is [8, p. 47]

$$C_{OF}(T, K) = \frac{c_{OK} + (c_K - c_{OK})P_K(T) + c_M [\bar{P}_K(T) + \int_0^T \bar{P}_K(t)h(t)dt]}{\int_0^T \bar{P}_K(t)dt + \bar{P}_K(T) \int_T^\infty e^{-H(t)+H(T)} dt}, \quad (28.61)$$

which agrees with (28.14) when $T = \infty$ and (28.19) when $K = \infty$.

When $c_K = c_{OK}$, we find optimal T_{OF}^* and K_{OF}^* to minimize $C_{OF}(T, K)$. Differentiating $C_{OF}(T, K)$ with respect to T and setting it equal to zero,

$$Q(T) \int_0^T \bar{P}_K(t)dt - \int_0^T \bar{P}_K(t)h(t)dt = \frac{c_{OK}}{c_M}, \quad (28.62)$$

whose left-hand side increases strictly with T from 0 to ∞ . Thus, there exists a finite and unique T_{OF}^* ($0 < T_{OF}^* < \infty$) which satisfies (28.62) for any K , and the resulting cost rate is

$$C_{OF}(T_{OF}^*, K) = c_M Q(T_{OF}^*) = \frac{c_{OK} + c_M \int_0^{T_{OK}^*} \bar{P}_K(t) h(t) dt}{\int_0^{T_{OF}^*} \bar{P}_K(t) dt}, \quad (28.63)$$

which agrees with (28.45) when $c_K = c_{OK} = c_T$ and $T_{OF}^* = T$. Comparing (28.62) with (28.46), $T_{OF}^* < T_F^*$ because $Q(T) > h(T)$, and from (28.63), when $c_K = c_{OK}$, replacement first is better than replacement overtime first. Furthermore, noting that the left-hand side of (28.62) increases strictly with K to that of (28.20), T_{OF}^* decreases with K to T_{OK}^* given in (28.20), and $T_{OF}^* \geq T_{OK}^*$.

Forming $C_{OF}(T, K + 1) - C_{OF}(T, K) \geq 0$,

$$H_1(T, K) \left[\int_0^T \bar{P}_K(t) dt + \bar{P}_K(T) \int_T^\infty e^{-H(t)+H(T)} dt \right] - \bar{P}_K(T) - \int_0^T \bar{P}_K(t) h(t) dt \geq \frac{c_M}{c_{OK}}, \quad (28.64)$$

where

$$H_1(T, K) \equiv \frac{P_K(T)}{\int_0^T [\int_t^\infty e^{-H(u)+H(t)} du] dP_K(t)},$$

which increases strictly with T to $1/\int_0^\infty p_K(t) dt$ and increases strictly with K to $Q(T)$, and $H_1(T, K) < Q(T)$ from Appendix 6. Substituting (28.62) for (28.64),

$$H_1(T, K) \geq Q(T),$$

which does not hold for any T , i.e., $C_{OF}(T, K + 1) < C_{OF}(T, K)$. Therefore, the optimal policy which minimizes $C_{OF}(T, K)$ is $K_{OF}^* = \infty$ and $T_{OF}^* = T_{OK}^*$ given in (28.20).

Furthermore, noting that the left-hand side of (28.64) increases with K to that of (28.20), if $T \leq T_{OK}^*$, then $K_{OF}^* = \infty$, and if $T > T_{OK}^*$, then there exists a finite and unique minimum K_{OF}^* ($1 \leq K_{OF}^* < \infty$) which satisfies (28.64). In addition, because the left-hand side of (28.64) increases with T to that of (28.15), K_{OF}^* decreases with T to K^* given in (28.15), and $K_{OF}^* \geq K^*$.

(6) Replacement Overtime Last with Time T and Failure K

Suppose that the unit is replaced at failure K ($K = 0, 1, 2, \dots$) after time T ($0 \leq T < \infty$) or at the first failure over time T , whichever occurs last. Then, the expected cost rate is [8, p. 50]

$$C_{OL}(T, K) = \frac{c_{OK} + (c_K - c_{OK}) \bar{P}_K(T) + c_M \left[H(T) + P_K(T) + \int_T^\infty \bar{P}_K(t) h(t) dt \right]}{T + \int_T^\infty \bar{P}_K(t) dt + P_K(T) \int_T^\infty e^{-H(t)+H(T)} dt}, \quad (28.65)$$

which agrees with (28.14) when $T = 0$ and (28.19) when $K = 0$, and $C_{OL}(T, 0) = C_{OL}(T, 1)$ when $c_K = c_{OK}$.

When $c_K = c_{OK}$, we find optimal T_{OL}^* and K_{OL}^* to minimize $C_{OL}(T, K)$. Differentiating $C_{OL}(T, K)$ with respect to T and setting it equal to zero,

$$Q(T) \left[T + \int_T^\infty \bar{P}_K(t) dt \right] - H(T) - \int_T^\infty \bar{P}_K(t) h(t) dt = \frac{c_{OK}}{c_M}, \quad (28.66)$$

whose left-hand side increases strictly with T to ∞ . Thus, there exists a finite and unique minimum T_{OL}^* ($0 < T_{OL}^* < \infty$) which satisfies (28.66) for any K , and the resulting cost rate is

$$C_{OL}(T_{OL}^*) = c_M Q(T_{OL}^*) = \frac{c_{OK} + c_M \left[H(T_{OL}^*) + \int_{T_{OL}^*}^\infty \bar{P}_K(t) h(t) dt \right]}{T_{OL}^* + \int_{T_{OL}^*}^\infty \bar{P}_K(t) dt}, \quad (28.67)$$

which agrees with (28.49) when $T_{OL}^* = T$ and $c_K = c_{OK} = c_T$. Comparing (28.66) with (28.50), $T_{OL}^* < T_L^*$ because $Q(T) > h(T)$, and from (28.67), when $c_K = c_{OK}$, replacement last is better than replacement overtime last. Furthermore, noting that the left-hand side of (28.66) increases strictly with K from (28.20), T_{OL}^* decreases with K from T_{OK}^* given in (28.20), and $T_{OL}^* \leq T_{OK}^* \leq T_{OF}^*$.

Forming $C_{OL}(T, K + 1) - C_{OL}(T, K) \geq 0$,

$$\tilde{H}_1(T, K) \left[T + \int_T^\infty \bar{P}_K(t) dt + P_K(T) \int_T^\infty e^{-H(t)+H(T)} dt \right] - H(T) - P_K(T) - \int_T^\infty \bar{P}_K(t) h(t) dt = \frac{c_{OK}}{c_M}, \quad (28.68)$$

where

$$\tilde{H}_1(T, K) \equiv \frac{\bar{P}_K(T)}{\int_T^\infty [\int_t^\infty e^{-H(u)+H(t)} du] dP_K(t)},$$

which increases strictly with T from $1/\int_0^\infty p_K(t) dt$ to $h(\infty)$ and increases strictly with K from $\tilde{H}_1(T, 1)$ to $h(\infty)$, and $\tilde{H}_1(T, K) > Q(T)$ from Appendix 6. Substituting (28.66) for (28.68),

$$\tilde{H}_1(T, K) \geq Q(T),$$

which always holds for any T , i.e., $C_{OL}(T, K + 1) \geq C_{OL}(T, K)$. Therefore, the optimal policy which minimizes $C_{OL}(T, K)$ is $K_{OL}^* = 0$ or 1 and $T_{OL}^* = T_{OK}^*$ given in (28.20).

Furthermore, noting that the left-hand side of (28.68) increases strictly with K from

$$\begin{aligned} \tilde{H}_1(T, 1) & \left[T + \int_T^\infty e^{-H(t)+H(T)} dt \right] - H(T) - 1 \\ & > TQ(T) - H(T), \end{aligned}$$

which agrees with that of (28.20), if $T \geq T_{OK}^*$, then $K_{OL}^* = 0$, and if $T < T_{OK}^*$, then there exists a finite and unique minimum K_{OL}^* ($1 \leq K_{OL}^* < \infty$) which satisfies (28.68). In addition, because the left-hand side of (28.68) increases with T from that of (28.15), K_{OL}^* decreases with T from K^* given in (28.15), and $K_{OL}^* \leq K^* \leq K_{OF}^*$.

Comparing replacement overtime first and last with T and K , if $T < T_{OK}^*$, then replacement overtime last is better than overtime first, if $T = T_{OK}^*$, then replacement overtime with T_{OK}^* is better than overtime first and last, and if $T > T_{OK}^*$, then replacement overtime first is better than overtime last.

(7) Replacement Overtime First with Time T and Cycle N

Suppose that the unit is replaced at cycle N ($N = 1, 2, \dots$) before time T or at the first cycle over time T ($0 \leq T \leq \infty$), whichever occurs first. Then, the expected cost rate is [8, p. 42]

$$\begin{aligned} C_{OF}(T, N) = & \frac{c_{ON} + (c_N - c_{ON})G^{(N)}(T) + c_M \left\{ \int_0^T [1 - G^{(N)}(t)]h(t)dt + \sum_{j=0}^{N-1} \int_0^T \int_{T-t}^T \bar{G}(u)h(t+u)du \right\} dG^{(j)}(t)}{\int_0^T [1 - G^{(N)}(t)]dt + \sum_{j=0}^{N-1} \int_0^T \int_{T-t}^\infty \bar{G}(u)du dG^{(j)}(t)}, \end{aligned} \quad (28.69)$$

which agrees with (28.16) when $T = \infty$ and (28.22) when $N = \infty$.

When $c_N = c_{ON}$ and $G(t) = 1 - e^{-\theta t}$, (28.69) is

$$\begin{aligned} C_{OF}(T, N) = & \frac{c_{ON} + c_M \left\{ \int_0^T [1 - G^{(N)}(t)]h(t)dt + [1 - G^{(N)}(T)] \int_0^\infty e^{-\theta t} h(T+t)dt \right\}}{\int_0^T [1 - G^{(N)}(t)]dt + (1/\theta)[1 - G^{(N)}(T)]}. \end{aligned} \quad (28.70)$$

We find optimal T_{OF}^* and N_{OF}^* to minimize $C_{OF}(T, N)$. Differentiating $C_{OF}(T, N)$ with respect to T and setting it equal to zero,

$$\begin{aligned} & \int_0^\infty \theta e^{-\theta t} h(T+t)dt \int_0^T [1 - G^{(N)}(t)]dt \\ & - \int_0^T [1 - G^{(N)}(t)]h(t)dt = \frac{c_{ON}}{c_M}, \end{aligned} \quad (28.71)$$

whose left-hand side increases strictly with T from 0 to ∞ . Thus, there exists a finite and unique T_{OF}^* ($0 < T_{OF}^* < \infty$) which satisfies (28.71) for any N , and the resulting cost rate is

$$\begin{aligned} C_{OF}(T_{OF}^*, N) & = c_M \int_0^\infty \theta e^{-\theta t} h(T_{OF}^* + t)dt \\ & = \frac{c_{ON} + c_M \int_0^{T_{OF}^*} [1 - G^{(N)}(t)]h(t)dt}{\int_0^{T_{OF}^*} [1 - G^{(N)}(t)]dt}, \end{aligned} \quad (28.72)$$

which agrees with (28.53) when $c_N = c_{ON} = c_T$ and $T_{OF}^* = T$. Comparing (28.71) with (28.54), $T_{OF}^* < T_F^*$ because $\int_0^\infty \theta e^{-\theta t} h(T+t)dt > h(T)$, and from (28.72), when $c_N = c_{ON}$, replacement first is better than replacement overtime first. Furthermore, noting that the left-hand side of (28.71) increases strictly with N to that of (28.24), T_{OF}^* decreases with N to T_{ON}^* given in (28.24), and $T_{OF}^* \geq T_{ON}^*$.

Forming $C_{OF}(T, N + 1) - C_{OF}(T, N) \geq 0$,

$$\begin{aligned} & \frac{H_1(T, N)}{\theta} \sum_{j=0}^{N-1} G^{(j)}(T) - \int_0^T [1 - G^{(N)}(t)]h(t)dt \\ & - [1 - G^{(N)}(T)] \int_0^\infty e^{-\theta t} h(T+t)dt \geq \frac{c_{ON}}{c_M}, \end{aligned} \quad (28.73)$$

where

$$H_1(T, N) \equiv \frac{\int_0^T \int_0^\infty \theta e^{-\theta u} h(t+u)du dG^{(N)}(t)}{G^{(N)}(T)},$$

which increases strictly with T to $H(N)$ and increases strictly with N to $\int_0^\infty \theta e^{-\theta t} h(T+t)dt$, and $H_1(T, N) < \int_0^\infty \theta e^{-\theta t} h(T+t)dt$ from Appendix 7. Substituting (28.71) for (28.73),

$$H_1(T, N) \geq \int_0^\infty \theta e^{-\theta t} h(T+t)dt,$$

which does not hold for any T . Therefore, the optimal policy which minimizes $C_{OF}(T, N)$ is $N_{OF}^* = \infty$ and $T_{OF}^* = T_{ON}^*$ given in (28.24).

Furthermore, noting that the left-hand side of (28.73) increases strictly with N to that of (28.24), if $T \leq T_{ON}^*$, then $N_{OF}^* = \infty$, and if $T > T_{ON}^*$, then there exists a finite and unique minimum N_{OF}^* ($1 \leq N_{OF}^* < \infty$) which satisfies (28.73) and approaches to N^* given in (28.5) as $T \rightarrow \infty$.

(8) Replacement Overtime Last with Time T and Cycle N

Suppose that the unit is replaced at cycle N ($N = 0, 1, 2, \dots$) or at the first cycle over time T ($0 \leq T < \infty$), whichever occurs last. Then, the expected cost rate is [8, p. 44]

$$C_{OL}(T, N) = \frac{c_{ON} + (c_N - c_{ON})[1 - G^{(N)}(T)] + c_M \left\{ \int_0^\infty [1 - G^{(N)}(t)]h(t)dt + \sum_{j=N}^\infty \int_0^T \int_0^\infty \bar{G}(u)h(t+u)du \right\} dG^{(j)}(t)}{(1/\theta)[N + \sum_{j=N}^\infty G^{(j)}(T)]}, \quad (28.74)$$

which agrees with (28.16) when $T = 0$ and (28.22) when $N = 0$, and $C_{OL}(T, 0) = C_{OL}(T, 1)$ when $c_N = c_{ON}$.

When $c_N = c_{ON}$ and $G(t) = 1 - e^{-\theta t}$, (28.74) is

$$C_{OL}(T, N) = \frac{c_{ON} + c_M \left\{ H(T) + \int_T^\infty [1 - G^{(N)}(t)]h(t)dt + G^{(N)}(T) \int_0^\infty e^{-\theta t} h(T+t)dt \right\}}{(1/\theta)[N + \sum_{j=N}^\infty G^{(j)}(T)]}. \quad (28.75)$$

We find optimal T_{OL}^* and N_{OL}^* to minimize $C_{OL}(T, N)$. Differentiating $C_{OL}(T, N)$ with respect to T and setting it equal to zero,

$$\int_0^\infty e^{-\theta t} h(T+t)dt \left[N + \sum_{j=N+1}^\infty G^{(j)}(T) \right] - H(T) - \int_T^\infty [1 - G^{(N)}(t)]h(t)dt = \frac{c_{ON}}{c_M}, \quad (28.76)$$

whose left-hand side increases strictly with T to ∞ . Thus, there exists a finite and unique T_{OL}^* ($0 < T_{OL}^* < \infty$) which satisfies (28.76) for any N , and the resulting cost rate is

$$C_{OL}(T_{OL}^*, N) = c_M \int_0^\infty \theta e^{-\theta t} h(T_{OL}^* + t)dt = \frac{c_{ON} + c_M \left\{ H(T_{OL}^*) + \int_{T_{OL}^*}^\infty [1 - G^{(N)}(t)]h(t)dt \right\}}{(1/\theta)[N + \sum_{j=N+1}^\infty G^{(j)}(T_{OL}^*)]}, \quad (28.77)$$

which agrees with (28.57) when $T_{OL}^* = T$ and $c_N = c_{ON} = c_T$. Comparing (28.76) with (28.58), $T_{OL}^* < T_L^*$ because $\int_0^\infty \theta e^{-\theta t} h(T+t)dt > h(T)$, and from (28.77), when $c_N = c_{ON}$, replacement last is better than replacement overtime last. Furthermore, noting that the left-hand side of (28.76) increases strictly with N from (28.24), T_{OL}^* decreases with N from T_{ON}^* given in (28.24), and $T_{OL}^* \leq T_{ON}^* \leq T_{OF}^*$.

Forming $C_{OL}(T, N+1) - C_{OL}(T, N) \geq 0$,

$$\frac{\tilde{H}_1(T, N)}{\theta} \left[N + \sum_{j=N+1}^\infty G^{(j)}(T) \right] - H(T) - \int_T^\infty [1 - G^{(N)}(t)]h(t)dt \geq \frac{c_{ON}}{c_M}, \quad (28.78)$$

where

$$\tilde{H}_1(T, N) \equiv \frac{\int_T^\infty \left[\int_0^\infty \theta e^{-\theta u} h(t+u)du \right] dG^{(N)}(t)}{1 - G^{(N)}(T)},$$

which increases strictly with T from $H(N)$ to $h(\infty)$ and increases strictly with N from $\tilde{H}_1(T, 1)$ to $h(\infty)$, and $\tilde{H}_1(T, N) > \int_0^\infty \theta e^{-\theta t} h(T+t)dt$ from Appendix 7. Substituting (28.76) for (28.78),

$$\tilde{H}_1(T, N) \geq \int_0^\infty \theta e^{-\theta t} h(T+t)dt,$$

which always holds for any T . Therefore, the optimal policy which minimizes $C_{OL}(T, N)$ is $N_{OL}^* = 0$ or 1 and $T_{OL}^* = T_{ON}^*$ given in (28.24).

Furthermore, noting that the left-hand side of (28.78) increases strictly with N from

$$\frac{\tilde{H}_1(T, 1)}{\theta} [\theta T + e^{-\theta T}] - H(T) - \int_T^\infty e^{-\theta t} h(t)dt > T \int_0^\infty \theta e^{-\theta t} h(T+t)dt - H(T),$$

which agrees with (28.24), if $T \geq T_{ON}^*$, then $N_{OL}^* = 0$, and if $T < T_{ON}^*$, then there exists a finite and unique minimum N_{OL}^* ($1 \leq N_{OL}^* < \infty$) which satisfies (28.78). In addition, because the left-hand side of (28.78) increases strictly with T from

$$N \int_0^\infty \frac{\theta(\theta t)^N}{N!} e^{-\theta t} h(t)dt - \int_0^\infty [1 - G^{(N)}(t)]h(t)dt,$$

which agrees with that of (28.18), N_{OL}^* decreases with T from N^* , and $N_{OL}^* \leq N^*$.

Comparing replacement overtime first and last with T and N , if $T < T_{ON}^*$, then replacement overtime last is better than overtime first, if $T = T_{ON}^*$, then replacement overtime with T_{ON}^* is better than replacement overtime first and last, and if $T > T_{ON}^*$, then replacement overtime first is better than overtime last.

(9) Replacement First with Failure K and Cycle N

Suppose that the unit is replaced at failure K ($K = 1, 2, \dots$) or at cycle N ($N = 1, 2, \dots$), whichever occurs first. Then, the expected cost rate is [10]

$$C_F(K, N) = \frac{c_K - (c_K - c_N) \int_0^\infty \bar{P}_K(t) dG^{(N)}(t) + c_M \int_0^\infty [1 - G^{(N)}(t)] \bar{P}_K(t) h(t) dt}{\int_0^\infty [1 - G^{(N)}(t)] \bar{P}_K(t) dt}, \quad (28.79)$$

which agrees with (28.14) when $N = \infty$ and (28.16) when $K = \infty$.

We find optimal K_F^* and N_F^* to minimize $C_F(K, N)$ when $c_K = c_N$ and $G(t) = 1 - e^{-\theta t}$. Then, (28.79) is

$$C_F(K, N) = \frac{c_K + c_M \int_0^\infty [1 - G^{(N)}(t)] \bar{P}_K(t) h(t) dt}{\int_0^\infty [1 - G^{(N)}(t)] \bar{P}_K(t) dt}. \quad (28.80)$$

Forming $C_F(K + 1, N) - C_F(K, N) \geq 0$,

$$H_1(K, N) \int_0^\infty [1 - G^{(N)}(t)] \bar{P}_K(t) dt - \int_0^\infty [1 - G^{(N)}(t)] \bar{P}_K(t) h(t) dt \geq \frac{c_K}{c_M}, \quad (28.81)$$

where

$$H_1(K, N) \equiv \frac{\int_0^\infty [1 - G^{(N)}(t)] p_K(t) h(t) dt}{\int_0^\infty [1 - G^{(N)}(t)] p_K(t) dt},$$

which increases strictly with K to $h(\infty)$ and increases strictly with N to $1 / \int_0^\infty p_K(t) dt$ from Appendix 8. Thus, because the left-hand side of (28.81) increases strictly with K to ∞ , there exists a finite and unique minimum K_F^* ($1 \leq K_F^* < \infty$) which satisfies (28.81) for any N . In addition, noting that the left-hand side of (28.81) goes to that of (28.15) as $N \rightarrow \infty$, K_F^* approaches to K^* given in (28.15) as $N \rightarrow \infty$.

Forming $C_F(K, N + 1) - C_F(K, N) \geq 0$,

$$H_2(K, N) \int_0^\infty [1 - G^{(N)}(t)] \bar{P}_K(t) dt - \int_0^\infty [1 - G^{(N)}(t)] \bar{P}_K(t) h(t) dt \geq \frac{c_N}{c_M}, \quad (28.82)$$

where

$$H_2(K, N) \equiv \frac{\int_0^\infty (\theta t)^N e^{-\theta t} \bar{P}_K(t) h(t) dt}{\int_0^\infty (\theta t)^N e^{-\theta t} \bar{P}_K(t) dt},$$

which increases strictly with N to $h(\infty)$ and increases strictly with K to $H(N)$ from Appendix 9. Thus, because the left-hand side of (28.82) increases strictly with N to ∞ , there exists a finite and unique minimum N_F^* ($1 \leq N_F^* < \infty$) which satisfies (28.82) for any K . In addition, noting that the

left-hand side of (28.82) goes to that of (28.18) as $K \rightarrow \infty$, N_F^* approaches to N^* given in (28.18) as $K \rightarrow \infty$.

(10) Replacement Last with Failure K and Cycle N

Suppose that the unit is replaced at failure K ($K = 0, 1, 2, \dots$) or at cycle N ($N = 0, 1, 2, \dots$), whichever occurs last. Then, the expected cost rate is [10]

$$C_L(K, N) = \frac{c_K - (c_K - c_N) \int_0^\infty P_K(t) dG^{(N)}(t) + c_M \int_0^\infty [1 - G^{(N)}(t)] P_K(t) h(t) dt}{\int_0^\infty [1 - G^{(N)}(t)] P_K(t) dt}, \quad (28.83)$$

which agrees with (28.14) when $N = 0$ and (28.16) when $K = 0$.

We find optimal K_L^* and N_L^* to minimize $C_L(K, N)$ when $c_K = c_N$ and $G(t) = 1 - e^{-\theta t}$. Then, (28.83) is

$$C_L(K, N) = \frac{c_K + c_M \int_0^\infty [1 - G^{(N)}(t)] P_K(t) h(t) dt}{\int_0^\infty [1 - G^{(N)}(t)] P_K(t) dt}. \quad (28.84)$$

Forming $C_L(K + 1, N) - C_L(K, N) \geq 0$,

$$H_3(K, N) \int_0^\infty [1 - G^{(N)}(t)] P_K(t) dt - \int_0^\infty [1 - G^{(N)}(t)] P_K(t) h(t) dt \geq \frac{c_K}{c_M}, \quad (28.85)$$

where

$$H_3(K, N) \equiv \frac{\int_0^\infty G^{(N)}(t) p_K(t) h(t) dt}{\int_0^\infty G^{(N)}(t) p_K(t) dt},$$

which increases strictly with K to $h(\infty)$ and increases strictly with N from $1 / \int_0^\infty p_K(t) dt$ to $h(\infty)$ from Appendix 9. Thus, because the left-hand side of (28.85) increases strictly with K to ∞ , there exists a finite and unique K_L^* ($0 \leq K_L^* < \infty$) which satisfies (28.85) for any N . In addition, noting that the left-hand side of (28.85) agrees with that of (28.15) when $N = 0$, $K_L^* = K^*$ given in (28.15) when $N = 0$.

Forming $C_L(K, N + 1) - C_L(K, N) \geq 0$,

$$H_4(K, N) \int_0^\infty [1 - G^{(N)}(t)] P_K(t) dt - \int_0^\infty [1 - G^{(N)}(t)] P_K(t) h(t) dt \geq \frac{c_K}{c_M}, \quad (28.86)$$

where

$$H_4(K, N) \equiv \frac{\int_0^\infty (\theta t)^N e^{-\theta t} P_K(t) h(t) dt}{\int_0^\infty (\theta t)^N e^{-\theta t} P_K(t) dt},$$

which increases with N to $h(\infty)$ and increases strictly with K from $H(N)$ to $h(\infty)$ from Appendix 9. Thus, because the left-hand side of (28.86) increases strictly with N to ∞ , there exists a finite and unique minimum N_L^* ($0 \leq N_L^* < \infty$) which satisfies (28.86) for any K . In addition, noting that the left-hand side of (28.86) agrees with that of (28.18) when $K = 0$, $N_L^* = N^*$ given in (28.18) when $K = 0$.

As modified policies of periodic replacements with two variables, we consider the following two policies:

(11) Modified Replacement with Time T after Failure K

Suppose that the unit is replaced at time T ($0 \leq T < \infty$) after K th ($K = 0, 1, 2, \dots$) failure. Then, the mean time to replacement is

$$\int_0^\infty (t + T)dP_K(t) = T + \int_0^\infty \bar{P}_K(t)dt,$$

and the expected number of failures until replacement is

$$\begin{aligned} & \int_0^\infty [K + H(T + t) - H(t)]dP_K(t) \\ &= \int_0^\infty H(T + t)dP_K(t) = \int_0^\infty h(T + t)\bar{P}_K(t)dt. \end{aligned}$$

Thus, the expected cost rate is

$$C_{M1}(T, K) = \frac{c_T + c_M \int_0^\infty H(T + t)dP_K(t)}{T + \int_0^\infty \bar{P}_K(t)dt}, \quad (28.87)$$

which agrees with (28.11) when $K = 0$ and (28.14) when $T = 0$.

We find optimal T_{M1}^* and K_{M1}^* to minimize $C_{M1}(T, K)$. Differentiating $C_{M1}(T, K)$ with respect to T and setting it equal to zero,

$$\begin{aligned} & \int_0^\infty h(T + t)dP_K(t) \left[T + \int_0^\infty \bar{P}_K(t)dt \right] \\ & - \int_0^\infty H(T + t)dP_K(t) = \frac{c_T}{c_M}, \end{aligned} \quad (28.88)$$

whose left-hand side increases strictly with T to ∞ . Thus, there exists a finite and unique T_{M1}^* ($0 \leq T_{M1}^* < \infty$) which satisfies (28.88) for any K , and the resulting cost rate is

$$C_{M1}(T_{M1}^*) = c_M \int_0^\infty h(T_{M1}^* + t)dP_K(t). \quad (28.89)$$

In addition, noting that the left-hand side of (28.88) increases strictly with K from that of (28.12) to ∞ , T_{M1}^* decreases with K from T^* given in (28.12), and $T_{M1}^* \leq T^*$.

Forming $C_{M1}(T, K + 1) - C_{M1}(T, K) \geq 0$,

$$\begin{aligned} & H_{M1}(T, K) \left[T + \int_0^\infty \bar{P}_K(t)dt \right] \\ & - \int_0^\infty H(T + t)dP_K(t) \geq \frac{c_T}{c_M}, \end{aligned} \quad (28.90)$$

where

$$H_{M1}(T, K) \equiv \frac{\int_0^\infty h(T + t)p_K(t)dt}{\int_0^\infty p_K(t)dt},$$

which increases strictly with T from $1/\int_0^\infty p_K(t)dt$ to $h(\infty)$ and increases strictly with K to $h(\infty)$ from Appendix 10. Thus, because the left-hand side of (28.90) increases strictly with K to ∞ , there exists a finite and unique minimum K_{M1}^* ($0 \leq K_{M1}^* < \infty$) which satisfies (28.90) for any T . Noting that the left-hand side of (28.90) increases strictly with T from that of (28.15), K_{M1}^* decreases with T from K^* given in (28.15), and $K_{M1}^* \leq K^*$.

(12) Modified Replacement with Failure K after Time T

Suppose that the unit is replaced at failure K ($K = 0, 1, 2, \dots$) after time T ($0 \leq T < \infty$). Then, the mean time to replacement is

$$T + \int_T^\infty (t - T)dP_K(t, T) = T + \int_T^\infty \bar{P}_K(t, T)dt,$$

where for $T \leq t < \infty$,

$$p_K(t, T) \equiv \frac{[H(t) - H(T)]^K}{K!} e^{-[H(t) - H(T)]},$$

$$P_K(t, T) \equiv \sum_{j=K}^\infty p_j(t, T) \quad (K = 0, 1, 2, \dots),$$

and the expected number of failures until replacement is

$$H(T) + K.$$

Thus, the expected cost rate is

$$C_{M2}(T, K) = \frac{c_K + c_M[H(T) + K]}{T + \int_T^\infty \bar{P}_K(t, T)dt}, \quad (28.91)$$

which agrees with (28.11) when $K = 0$, (28.14) when $T = 0$, and (28.19) when $K = 1$.

We find optimal T_{M2}^* and K_{M2}^* to minimize $C_{M2}(T, K)$. Differentiating $C_{M2}(T, K)$ with respect to T and setting it equal to zero,

$$H_{M2}(T, K - 1) \left[T + \int_T^\infty \bar{P}_K(t, T) dt \right] - H(T) - K = \frac{c_K}{c_M}, \tag{28.92}$$

where

$$H_{M2}(T, K) \equiv \begin{cases} \frac{1}{\int_T^\infty p_K(t, T) dt} & (K = 0, 1, 2, \dots), \\ h(T) & (K = -1), \end{cases}$$

which increases strictly with K from $h(T)$ to $h(\infty)$ and increases strictly with T from $1/\int_0^\infty p_K(t) dt$ to $h(\infty)$ from Appendix 11. Thus, because the left-hand side of (28.92) increases strictly with T to ∞ , there exists a finite and unique T_{M2}^* ($0 \leq T_{M2}^* < \infty$) which satisfies (28.92) for any K , and the resulting cost rate is

$$C_{M2}(T_{M2}^*, K) = c_M H_{M2}(T_{M2}^*, K - 1). \tag{28.93}$$

In addition, noting that the left-hand side of (28.92) increases strictly with K from that of (28.12), T_{M2}^* decreases with K from T^* given in (28.12), and $T_{M2}^* \leq T^*$.

Forming $C_{M2}(T, K + 1) - C_{M2}(T, K) \geq 0$,

$$H_{M2}(T, K) \left[T + \int_T^\infty \bar{P}_K(t, T) dt \right] - H(T) - K \geq \frac{c_K}{c_M}. \tag{28.94}$$

Substituting (28.92) for (28.94),

$$H_{M2}(T, K) \geq H_{M2}(T, K - 1),$$

which always holds for any T . Thus, the optimal policy which minimizes $C_{M2}(T, K)$ is $K_{M2}^* = 0$ and $T_{M2}^* = T^*$ given in (28.12).

Therefore, because the left-hand side of (28.94) increases strictly with K from that of (28.12), if $T \geq T^*$, then $K_{M2}^* = 0$, and if $T < T^*$, then there exists a finite and unique minimum K_{M2}^* ($1 \leq K_{M2}^* < \infty$) which satisfies (28.94). In addition, noting that the left-hand side of (28.94) increases with T from that of (28.15), K_{M2}^* decreases with T from K^* given in (28.15), and $K_{M2}^* \leq K^*$.

28.4 Three Policies

Combining periodic replacement with time T , failure K , and cycle N , we consider five replacement policies. The expected cost rates are obtained, and when the replacement costs c_T , c_N , and c_K are equal, optimal policies are discussed. Using these results, we could derive optimal policies for different replacement costs.

28.4.1 Replacement First and Last

Suppose that the unit is replaced at time T ($0 < T \leq \infty$), at failure K ($K = 1, 2, \dots$) or at cycle N ($N = 1, 2, \dots$), whichever occurs first. Then, the expected cost rate is [8, p. 87]

$$C_F(T, K, N) = \frac{c_T + (c_N - c_T) \int_0^T \bar{P}_K(t) dG^{(N)}(t) + (c_K - c_T) \int_0^T [1 - G^{(N)}(t)] dP_K(t) + c_M \int_0^T [1 - G^{(N)}(t)] \bar{P}_K(t) h(t) dt}{\int_0^T [1 - G^{(N)}(t)] \bar{P}_K(t) dt}. \tag{28.95}$$

Clearly, $C_F(T, \infty, \infty) = C(T)$ in (28.11), $C_F(\infty, K, \infty) = C(K)$ in (28.14), $C_F(\infty, \infty, N) = C(N)$ in (28.16), $C_F(T, K, \infty) = C_F(T, K)$ in (28.45), $C_F(T, \infty, N) = C_F(T, N)$ in (28.53), and $C_F(\infty, K, N) = C_F(K, N)$ in (28.79).

Differentiating $C_F(T, K, N)$ with respect to T when $c_T = c_K = c_N$ and setting it equal to zero,

$$h(T) \int_0^T [1 - G^{(N)}(t)] \bar{P}_K(t) dt - \int_0^T [1 - G^{(N)}(t)] \bar{P}_K(t) h(t) dt = \frac{c_T}{c_M}, \tag{28.96}$$

whose left-hand side increases strictly with T from 0 to ∞ . Thus, there exists a finite and unique T_F^* ($0 < T_F^* < \infty$) which satisfies (28.96) for any K and N , and the resulting cost rate is

$$C_F(T_F^*, K, N) = c_M h(T_F^*). \tag{28.97}$$

Noting that the left-hand side of (28.96) increases with K and N , T_F^* decreases with K and N , and T_F^* goes to T^* as $K \rightarrow \infty$ and $N \rightarrow \infty$.

Furthermore, by making similar discussions in Sect. 28.3, the optimal policy to minimize $C_F(T, K, N)$ is $K_F^* = N_F^* = \infty$ and $T_F^* = T^*$ given in (28.12).

Next, suppose that the unit is replaced at time T ($0 \leq T < \infty$), at failure K ($K = 0, 1, 2, \dots$) or at cycle N ($N = 0, 1, 2, \dots$), whichever occurs last. Then, the expected cost rate is [8, p. 88]

$$C_L(T, K, N) = \frac{c_T + (c_N - c_T) \int_T^\infty P_K(t) dG^{(N)}(t) + (c_K - c_T) \int_T^\infty G^{(N)}(t) dP_K(t) + c_M \{ H(T) + \int_T^\infty [1 - G^{(N)}(t)] P_K(t) h(t) dt \}}{T + \int_T^\infty [1 - G^{(N)}(t)] P_K(t) dt}. \tag{28.98}$$

Clearly, $C_L(T, 0, 0) = C(T)$ in (28.11), $C_L(0, K, 0) = C(K)$ in (28.14), $C_L(0, 0, N) = C(N)$ in (28.16), $C_L(T, K, 0) = C_L(T, K)$ in (28.49), $C_L(T, 0, N) = C_L(T, N)$ in (28.57), and $C_L(0, K, N) = C_L(K, N)$ in (28.83).

Differentiating $C_L(T, K, N)$ with respect to T when $c_T = c_K = c_N$ and setting it equal to zero,

$$h(T) \left\{ T + \int_T^\infty [1 - G^{(N)}(t)P_K(t)]dt \right\} - H(T) - \int_T^\infty [1 - G^{(N)}(t)P_K(t)]h(t)dt = \frac{c_T}{c_M}, \quad (28.99)$$

whose left-hand side increases strictly with T to ∞ . Thus, there exists a finite and unique T_L^* ($0 < T_L^* < \infty$) which satisfies (28.99) for any K and N , and the resulting cost rate is

$$C_L(T_L^*) = c_M h(T_L^*). \quad (28.100)$$

Noting that the left-hand side of (28.99) decreases with K and N , T_L^* increases with K and N , and $T_L^* = T^*$ given in (28.12) when $K = N = 0$.

Furthermore, by making similar discussions in Sect. 28.3, the optimal policy to minimize $C_L(T, K, N)$ is $K_L^* = N_L^* = 0$ and $T_L^* = T^*$ given in (28.12).

28.4.2 Replacement Middle

Suppose that the unit is replaced at time T ($0 \leq T < \infty$), at cycle K ($K = 0, 1, 2, \dots$) or at cycle N ($N = 0, 1, 2, \dots$), whichever occurs middle. That is, when t_K and t_N are denoted by the respective occurrence times of failure K and cycle N , the unit is replaced at time T for $\{t_N < T < t_K\}$ or $\{t_K < T < t_N\}$, at failure K for $\{T < t_K < N\}$ or $\{N < t_K < T\}$, and at cycle N for $\{T < t_N < t_K\}$ or $\{t_K < t_N < T\}$. Then, the expected cost rate is [5, 8, p. 90]

$$C_M(T, K, N) = \frac{c_T + (c_N - c_T) \left[\int_T^\infty \bar{P}_K(t) dG^{(N)}(t) + \int_0^T P_K(t) dG^{(N)}(t) \right] + (c_K - c_T) \left\{ \int_T^\infty [1 - G^{(N)}(t)] dP_K(t) + \int_0^T G^{(N)}(t) dP_K(t) \right\} + c_M \left\{ \int_0^T [1 - G^{(N)}(t)P_K(t)]h(t)dt + \int_T^\infty [1 - G^{(N)}(t)]\bar{P}_K(t)h(t)dt \right\}}{\int_0^T [1 - G^{(N)}(t)P_K(t)]dt + \int_T^\infty [1 - G^{(N)}(t)]\bar{P}_K(t)dt}. \quad (28.101)$$

Clearly,

$$\begin{aligned} C_M(0, K, N) &= C_F(\infty, K, N), \\ C_M(\infty, K, N) &= C_L(0, K, N), \\ C_M(T, 0, N) &= C_F(T, \infty, N), \\ C_M(T, \infty, N) &= C_L(T, 0, N), \\ C_M(T, K, 0) &= C_F(T, K, \infty), \\ C_M(T, K, \infty) &= C_L(T, K, 0). \end{aligned}$$

Differentiating $C_M(T, K, N)$ with respect to T when $c_T = c_K = c_N$ and setting it equal to zero,

$$h(T) \left\{ \int_0^T [1 - G^{(N)}(t)P_K(t)]dt + \int_T^\infty [1 - G^{(N)}(t)]\bar{P}_K(t)dt \right\} - \int_0^T [1 - G^{(N)}(t)P_K(t)]h(t)dt - \int_T^\infty [1 - G^{(N)}(t)]\bar{P}_K(t)h(t)dt = \frac{c_M}{c_T}, \quad (28.102)$$

whose left-hand side increases strictly with T to ∞ . Thus, there exists a finite and unique T_M^* ($0 < T_M^* < \infty$) which satisfies (28.102) for any K and N , and the resulting cost rate is

$$C_M(T_M^*, K, N) = c_M h(T_M^*). \quad (28.103)$$

28.4.3 Modified Replacement First and Last

Suppose that the unit is replaced at time T ($0 < T \leq \infty$) or at $\text{Max}\{t_K, t_N\}$ ($K, N = 1, 2, \dots$), whichever occurs first. Then, the probability that the unit is replaced at time T is

$$1 - G^{(N)}(T)P_K(T),$$

the probability that it is replaced at failure K is

$$\int_0^T G^{(N)}(t) dP_K(t),$$

and the probability that it is replaced at cycle N is

$$\int_0^T P_K(t) dG^{(N)}(t).$$

Thus, the mean time to replacement is

$$\begin{aligned} T[1 - G^{(N)}(T)P_K(T)] + \int_0^T tP_K(t) dG^{(N)}(t) + \int_0^T tG^{(N)}(t) dP_K(t) \\ = \int_0^T [1 - G^{(N)}(t)P_K(t)]dt, \end{aligned}$$

and the expected number of failures until replacement is

$$\begin{aligned} H(T)[1 - G^{(N)}(T)P_K(T)] + \int_0^T H(t)P_K(t) dG^{(N)}(t) + \int_0^T H(t)G^{(N)}(t) dP_K(t) \\ = \int_0^T [1 - G^{(N)}(t)P_K(t)]h(t)dt. \end{aligned}$$

Thus, the expected cost rate is

$$C_{MF}(T, K, N) = \frac{c_T + (c_K - c_T) \int_0^T G^{(N)}(t) dP_K(t) + (c_N - c_T) \int_0^T P_K(t) dG^{(N)}(t) + c_M \int_0^T [1 - G^{(N)}(t) P_K(t)] h(t) dt}{\int_0^T [1 - G^{(N)}(t) P_K(t)] dt}. \quad (28.104)$$

Clearly,

$$\begin{aligned} C_{MF}(\infty, K, N) &= C_L(0, K, N) = C_M(\infty, K, N), \\ C_{MF}(T, 0, N) &= C_F(T, \infty, N) = C_M(T, 0, N), \\ C_{MF}(T, K, 0) &= C_F(T, K, \infty) = C_M(T, K, 0). \end{aligned}$$

Differentiating $C_{MF}(T, K, N)$ with respect to T when $c_T = c_K = c_N$ and setting it equal to zero,

$$h(T) \int_0^T [1 - G^{(N)}(t) P_K(t)] dt - \int_0^T [1 - G^{(N)}(t) P_K(t)] h(t) dt = \frac{c_T}{c_M}, \quad (28.105)$$

whose left-hand side increases strictly with T from 0 to ∞ . Thus, there exists a finite and unique T_{MF}^* ($0 < T_{MF}^* < \infty$) which satisfies (28.105) for any K and N , and the resulting cost rate is

$$C_{MF}(T_{MF}^*, K, N) = c_M h(T_{MF}^*). \quad (28.106)$$

Next, suppose that the unit is replaced at time T ($0 \leq T < \infty$) or at $\text{Min}\{t_K, t_N\}$ ($K, N = 0, 1, 2, \dots$), whichever occurs last. Then, the probability that the unit is replaced at time T is

$$P_K(T) + G^{(N)}(T) \bar{P}_K(T),$$

the probability that it is replaced at failure K is

$$\int_T^\infty [1 - G^{(N)}(t)] dP_K(t),$$

and the probability that it is replaced at cycle N is

$$\int_T^\infty \bar{P}_K(t) dG^{(N)}(t).$$

Thus, the mean time to replacement is

$$T[P_K(T) + G^{(N)}(T) \bar{P}_K(T)] + \int_T^\infty t[1 - G^{(N)}(t)] dP_K(t)$$

$$\begin{aligned} &+ \int_T^\infty t \bar{P}_K(t) dG^{(N)}(t) \\ &= T + \int_T^\infty \{1 - [1 - G^{(N)}(t)] \bar{P}_K(t)\} dt, \end{aligned}$$

and the expected number of failures until replacement is

$$\begin{aligned} &H(T)[P_K(T) + G^{(N)}(T) \bar{P}_K(T)] \\ &+ \int_T^\infty H(t)[1 - G^{(N)}(t)] dP_K(t) \\ &+ \int_T^\infty H(t) \bar{P}_K(t) dG^{(N)}(t) \\ &= H(T) + \int_T^\infty \{1 - [1 - G^{(N)}(t)] \bar{P}_K(t)\} h(t) dt. \end{aligned}$$

Thus, the expected cost rate is

$$C_{ML}(T, K, N) = \frac{c_T + (c_K - c_T) \int_T^\infty [1 - G^{(N)}(t)] dP_K(t) + (c_N - c_T) \int_T^\infty \bar{P}_K(t) dG^{(N)}(t) + c_M \left(H(T) + \int_T^\infty \{1 - [1 - G^{(N)}(t)] \bar{P}_K(t)\} h(t) dt \right)}{T + \int_T^\infty \{1 - [1 - G^{(N)}(t)] \bar{P}_K(t)\} dt}. \quad (28.107)$$

Clearly,

$$\begin{aligned} C_{ML}(0, K, N) &= C_L(0, K, N) = C_M(\infty, K, N), \\ C_{ML}(T, \infty, N) &= C_F(T, \infty, N) = C_M(T, 0, N), \\ C_{ML}(T, K, \infty) &= C_F(T, K, \infty) = C_M(T, K, 0). \end{aligned}$$

Differentiating $C_{ML}(T, K, N)$ with respect to T when $c_T = c_K = c_N$ and setting it equal to zero,

$$\begin{aligned} &h(T) \left(T + \int_T^\infty \{1 - [1 - G^{(N)}(t)] \bar{P}_K(t)\} dt \right) \\ &- H(T) - \int_T^\infty \{1 - [1 - G^{(N)}(t)] \bar{P}_K(t)\} h(t) dt \\ &= \frac{c_T}{c_M}, \end{aligned} \quad (28.108)$$

whose left-hand side increases strictly with T to ∞ . Thus, there exists a finite and unique T_{ML}^* ($0 < T_{ML}^* < \infty$) which satisfies (28.108) for any K and N , and the resulting cost rate is

$$C_{ML}(T_{ML}^*) = c_M h(T_{ML}^*). \quad (28.109)$$

28.5 Redundant Replacement Policies

We have introduced the age and periodic replacements with one, two, and three policies. Using these results, we can extend them to the following replacements with time T and n number of policies, which is called *redundant replacement*

policy: Assume that the unit is replaced at time T ($0 \leq T \leq \infty$) or random times Y_1, Y_2, \dots, Y_n ($n = 1, 2, \dots$), where Y_j is independent with each other and has a general distribution $G_j(t) \equiv \Pr\{Y_j \leq t\}$ with finite mean $1/\theta_j$ ($0 < \theta_j < \infty$) [6, 8, p. 100].

28.5.1 Age Replacement

(1) Replacement First

Suppose that the unit is replaced preventively at time T ($0 < T \leq \infty$) or at time Y_1, Y_2, \dots, Y_n ($n = 1, 2, \dots$), whichever occurs first. Then, by setting $Z_m = \text{Min}\{T, Y_1, \dots, Y_n\}$, Z_m has a distribution

$$G_F(t) \equiv \Pr\{Z_m \leq t\} = \begin{cases} 1 - \prod_{j=1}^n \bar{G}_j(t) & \text{for } t < T, \\ 1 & \text{for } t \geq T. \end{cases}$$

The probability that the unit is replaced at time T is

$$\bar{F}(T) \prod_{j=1}^n \bar{G}_j(T),$$

the probability that it is replaced at time Y_j is

$$\int_0^T \bar{F}(t) \left[\prod_{i=1, i \neq j}^n \bar{G}_i(t) \right] dG_j(t) \quad (j = 1, 2, \dots, n),$$

and the probability that it is replaced at failure is

$$\int_0^T \left[\prod_{j=1}^n \bar{G}_j(t) \right] dF(t).$$

Thus, the mean time to replacement is

$$\begin{aligned} T\bar{F}(T) \left[\prod_{j=1}^n \bar{G}_j(T) \right] \\ + \sum_{j=1}^n \int_0^T t\bar{F}(t) \left[\prod_{i=1, i \neq j}^n \bar{G}_i(t) \right] dG_j(t) \\ + \int_0^T t \left[\prod_{j=1}^n \bar{G}_j(t) \right] dF(t) = \int_0^T \bar{F}(t) \left[\prod_{j=1}^n \bar{G}_j(t) \right] dt. \end{aligned}$$

Therefore, the expected cost rate is

$$C_F(T) = \frac{c_T + \sum_{j=1}^n (c_j - c_T) \int_0^T \bar{F}(t) \times \left[\prod_{i=1, i \neq j}^n \bar{G}_i(t) \right] dG_j(t) + (c_F - c_T) \int_0^T \left[\prod_{j=1}^n \bar{G}_j(t) \right] dF(t)}{\int_0^T \bar{F}(t) \left[\prod_{j=1}^n \bar{G}_j(t) \right] dt}, \quad (28.110)$$

where $c_j =$ replacement cost at time Y_j ($j = 1, 2, \dots, n$) and $c_F > c_j$.

We find optimal T_F^* to minimize $C_F(T)$ when $c_j = c_T$. Differentiating $C_F(T)$ with respect to T and setting it equal to zero,

$$h(T) \int_0^T \bar{F}(t) \left[\prod_{j=1}^n \bar{G}_j(t) \right] dt - \int_0^T \left[\prod_{j=1}^n \bar{G}_j(t) \right] dF(t) = \frac{c_T}{c_F - c_T}, \quad (28.111)$$

whose left-hand side increases strictly with T from 0 to ∞ . Thus, there exists a finite and unique T_F^* ($0 < T_F^* < \infty$) which satisfies (28.111), and the resulting cost rate is

$$C_F(T_F^*) = (c_F - c_T)h(T_F^*). \quad (28.112)$$

In addition, because the left-hand side of (28.111) decreases with n , T_F^* increases with n .

(2) Replacement Last

Suppose that the unit is replaced preventively at time T ($0 \leq T < \infty$) or at time Y_1, Y_2, \dots, Y_n ($n = 1, 2, \dots$), whichever occurs last. Thus, by setting $Z_M \equiv \text{Max}\{T, Y_1, \dots, Y_n\}$, Z_M has a distribution

$$G_L(t) \equiv \Pr\{Z_M \leq t\} = \begin{cases} 0 & \text{for } t < T, \\ \prod_{j=1}^n G_j(t) & \text{for } t \geq T. \end{cases}$$

The probability that the unit is replaced at time T is

$$\bar{F}(T) \prod_{j=1}^n G_j(T),$$

the probability that it is replaced at time Y_j is

$$\int_T^\infty \bar{F}(t) \left[\prod_{i=1, i \neq j}^n G_i(t) \right] dG_j(t) \quad (j = 1, 2, \dots, n),$$

and the probability that it is replaced at failure is

$$F(T) + \int_T^\infty \left[1 - \prod_{j=1}^n G_j(t) \right] dF(t).$$

Thus, the mean time to replacement is

$$\begin{aligned} & T\bar{F}(T) \prod_{j=1}^n G_j(T) \\ & + \sum_{j=1}^n \int_T^\infty t\bar{F}(t) \left[\prod_{i=1, i \neq j}^n G_i(t) \right] dG_j(t) \\ & + \int_0^T t dF(t) + \int_T^\infty t \left[1 - \prod_{j=1}^n G_j(t) \right] dF(t) \\ & = \int_0^T \bar{F}(t) dt + \int_T^\infty \bar{F}(t) \left[1 - \prod_{j=1}^n G_j(t) \right] dt. \end{aligned}$$

Therefore, the expected cost rate is

$$\begin{aligned} C_L(T) = & \\ & \frac{c_T + \sum_{j=1}^n (c_j - c_T) \int_T^\infty \bar{F}(t) \times \left[\prod_{i=1, i \neq j}^n G_i(t) \right] dG_j(t) + (c_F - c_T) \left\{ F(T) + \int_T^\infty \left[1 - \prod_{j=1}^n G_j(t) \right] dF(t) \right\}}{\int_0^T \bar{F}(t) dt + \int_T^\infty \bar{F}(t) \left[1 - \prod_{j=1}^n G_j(t) \right] dt}. \end{aligned} \quad (28.113)$$

We find optimal T_L^* to minimize $C_L(T)$ when $c_j = c_T$. Differentiating $C_L(T)$ with respect to T and setting it equal to zero,

$$\begin{aligned} & h(T) \left\{ \int_0^T \bar{F}(t) dt + \int_T^\infty \bar{F}(t) \left[1 - \prod_{j=1}^n G_j(t) \right] dt \right\} \\ & - F(T) - \int_T^\infty \left[1 - \prod_{j=1}^n G_j(t) \right] dF(t) = \frac{c_T}{c_F - c_T}, \end{aligned} \quad (28.114)$$

whose left-hand side increases strictly with T to ∞ . Thus, there exists a finite and unique T_L^* ($0 < T_L^* < \infty$) which satisfies (28.114), and the resulting cost rate is

$$C_L(T_L^*) = (c_F - c_T)h(T_L^*). \quad (28.115)$$

In addition, because the left-hand side of (28.114) decreases with n , T_L^* increases with n .

28.5.2 Periodic Replacement

(1) Replacement First

Suppose that the unit is replaced at time T ($0 < T \leq \infty$) or at time Y_1, Y_2, \dots, Y_n ($n = 1, 2, \dots$), whichever occurs first. Then, the probability that the unit is replaced at time T is

$$\prod_{j=1}^n \bar{G}_j(T),$$

and the probability that it is replaced at time Y_j is

$$\int_0^T \left[\prod_{i=1, i \neq j}^n \bar{G}_i(t) \right] dG_j(t) \quad (j = 1, 2, \dots, n).$$

Thus, the mean time to replacement is

$$\begin{aligned} & T \prod_{j=1}^n \bar{G}_j(T) + \sum_{j=1}^n \int_0^T t \left[\prod_{i=1, i \neq j}^n \bar{G}_i(t) \right] dG_j(t) \\ & = \int_0^T \left[\prod_{j=1}^n \bar{G}_j(t) \right] dt, \end{aligned}$$

and the expected number of failures is

$$\begin{aligned} & H(T) \prod_{j=1}^n \bar{G}_j(T) \\ & + \sum_{j=1}^n \int_0^T H(t) \left[\prod_{i=j, i \neq j}^n \bar{G}_i(t) \right] dG_j(t) \\ & = \int_0^T \left[\prod_{j=1}^n \bar{G}_j(t) \right] h(t) dt. \end{aligned}$$

Therefore, the expected cost rate is

$$\begin{aligned} C_F(T) = & \\ & \frac{c_T + \sum_{j=1}^n (c_j - c_T) \int_0^T \left[\prod_{i=1, i \neq j}^n \bar{G}_i(t) \right] dG_j(t) + c_M \int_0^T \left[\prod_{j=1}^n \bar{G}_j(t) \right] h(t) dt}{\int_0^T \left[\prod_{j=1}^n \bar{G}_j(t) \right] dt}. \end{aligned} \quad (28.116)$$

We find optimal T_F^* to minimize $C_F(T)$ when $c_j = c_T$. Differentiating $C_F(T)$ with respect to T and setting it equal to zero,

$$\begin{aligned} & h(T) \int_0^T \left[\prod_{j=1}^n \bar{G}_j(t) \right] dt - \int_0^T \left[\prod_{j=1}^n \bar{G}_j(t) \right] h(t) dt \\ & = \frac{c_T}{c_M}, \end{aligned} \quad (28.117)$$

whose left-hand side increases strictly with T from 0 to ∞ . Thus, there exists a finite and unique minimum T_F^* ($0 < T_F^* < \infty$) which satisfies (28.117), and the resulting cost rate is

$$C_F(T_F^*) = c_M h(T_F^*).$$

In addition, because the left-hand side of (28.117) decreases with n , T_F^* increases with n .

(2) Replacement Last

Suppose that the unit is replaced at time T ($0 \leq T < \infty$) or at time Y_1, Y_2, \dots, Y_n ($n = 1, 2, \dots$), whichever occurs last. Then, the probability that the unit is replaced at time T is

$$\prod_{j=1}^n G_j(T),$$

and the probability that it is replaced at time Y_j is

$$\int_T^\infty \left[\prod_{i=1, i \neq j}^n G_i(t) \right] dG_j(t) \quad (j = 1, 2, \dots, n).$$

Thus, the mean time to replacement is

$$\begin{aligned} T \prod_{j=1}^n G_j(T) + \sum_{j=1}^n \int_T^\infty t \left[\prod_{i=1, i \neq j}^n G_i(t) \right] dG_j(t) \\ = T + \int_T^\infty \left[1 - \prod_{j=1}^n G_j(t) \right] dt, \end{aligned}$$

and the expected number of failures until replacement is

$$\begin{aligned} H(T) \prod_{j=1}^n G_j(T) + \sum_{j=1}^n \int_T^\infty H(t) \left[\prod_{i=1, i \neq j}^n G_i(t) \right] dG_j(t) \\ = H(T) + \int_T^\infty \left[1 - \prod_{j=1}^n G_j(t) \right] h(t) dt. \end{aligned}$$

Therefore, the expected cost rate is

$$\begin{aligned} C_L(T) = \\ \frac{c_T + \sum_{j=1}^n (c_j - c_T) \int_T^\infty \left[\prod_{i=1, i \neq j}^n G_i(t) \right] dG_j(t) + c_M \{ H(T) + \int_T^\infty [1 - \prod_{j=1}^n G_j(t)] h(t) dt \}}{T + \int_T^\infty [1 - \prod_{j=1}^n G_j(t)] dt}. \end{aligned} \quad (28.118)$$

We find optimal T_L^* to minimize $C_L(T)$. Differentiating $C_L(T)$ with respect to T and setting it equal to zero,

$$\begin{aligned} h(T) \left\{ T + \int_T^\infty \left[1 - \prod_{j=1}^n G_j(t) \right] dt \right\} - H(T) \\ - \int_T^\infty \left[1 - \prod_{j=1}^n G_j(t) \right] h(t) dt = \frac{c_T}{c_M}, \end{aligned} \quad (28.119)$$

whose left-hand side increases strictly with T to ∞ . Thus, there exists a finite and unique T_L^* ($0 < T_L^* < \infty$) which satisfies (28.118), and the resulting cost rate is

$$C_L(T_L^*) = c_M h(T_L^*). \quad (28.120)$$

In addition, because the left-hand side of (28.119) increases with n , T_L^* decreases with n .

Appendix 1

It is assumed that the failure rate $h(t) \equiv f(t)/\bar{F}(t)$ increases strictly with t from $h(0)$ to $h(\infty)$, and for $N = 0, 1, 2, \dots$ and $K = 0, 1, 2, \dots$

$$\begin{aligned} g^{(N+1)}(t) &= \frac{\theta(\theta t)^N}{N!} e^{-\theta t}, \\ G^{(N)}(t) &= \int_0^t g^{(N)}(u) du = \sum_{j=N}^\infty \frac{(\theta t)^j}{j!} e^{-\theta t}, \\ p_K(t) &= \frac{H(t)^K}{K!} e^{-H(t)}, \\ P_K(t) &= \sum_{j=K}^\infty p_j(t) = \sum_{j=K}^\infty \frac{H(t)^j}{j!} e^{-H(t)}. \end{aligned}$$

When $F(t) = 1 - e^{-H(t)}$, for $0 < T < \infty$,

$$\begin{aligned} Q(T) &= \frac{\bar{F}(T)}{\int_T^\infty \bar{F}(t) dt}, \quad Q_O(T) = \frac{\int_0^T e^{-\theta t} dF(t)}{\int_0^T e^{-\theta t} \bar{F}(t) dt}, \\ \tilde{Q}_O(T) &= \frac{\int_T^\infty e^{-\theta t} dF(t)}{\int_T^\infty e^{-\theta t} \bar{F}(t) dt}, \end{aligned}$$

all of which increase strictly with T , and for $0 < T < \infty$,

$$\begin{aligned} Q(\infty) &= \tilde{Q}_O(\infty) = h(\infty), \\ Q_O(T) &< h(T) < \tilde{Q}_O(T) < Q(T). \end{aligned}$$

Appendix 2

1. For $N = 0, 1, 2, \dots$ and $0 < T \leq \infty$,

$$Q(T, N) \equiv \frac{\int_0^T (\theta t)^N e^{-\theta t} dF(t)}{\int_0^T (\theta t)^N e^{-\theta t} \bar{F}(t) dt}$$

increases strictly with T from $h(0)$ to $Q(N) \equiv \int_0^\infty (\theta t)^N e^{-\theta t} dF(t) / \int_0^\infty (\theta t)^N e^{-\theta t} \bar{F}(t) dt$ and increases strictly with N from $Q_O(T)$ to $h(T)$.

2. For $N = 0, 1, 2, \dots$ and $0 \leq T < \infty$,

$$\tilde{Q}(T, N) \equiv \frac{\int_T^\infty (\theta t)^N e^{-\theta t} dF(t)}{\int_T^\infty (\theta t)^N e^{-\theta t} \bar{F}(t) dt}$$

increases strictly with T from $Q(N)$ to $h(\infty)$ and increases strictly with N from $\tilde{Q}_O(T)$ to $h(\infty)$.

Proof. Note that

$$\begin{aligned} Q(0, N) &= h(0), & Q(\infty, N) &= Q(N), \\ Q(T, 0) &= Q_0(T), & Q(T, \infty) &= h(T), \\ \tilde{Q}(0, N) &= Q(N), & \tilde{Q}(\infty, N) &= h(\infty), \\ \tilde{Q}(T, 0) &= \tilde{Q}_0(T), & \tilde{Q}(T, \infty) &= h(\infty). \end{aligned}$$

Differentiating $Q(T, N)$ with respect to T ,

$$(\theta T)^N e^{-\theta T} \bar{F}(T) \int_0^T (\theta t)^N e^{-\theta t} [h(T) - h(t)] dt > 0,$$

which follows that $Q(T, N)$ increases strictly with T from $h(0)$ to $Q(N)$ for any N . Forming $Q(T, N + 1) - Q(T, N)$ and denoting

$$\begin{aligned} L_1(T) &\equiv \\ &\int_0^T (\theta t)^{N+1} e^{-\theta t} dF(t) \int_0^T (\theta t)^N e^{-\theta t} \bar{F}(t) dt \\ &\quad - \int_0^T (\theta t)^N e^{-\theta t} dF(t) \int_0^T (\theta t)^{N+1} e^{-\theta t} \bar{F}(t) dt, \end{aligned}$$

we have $L_1(0) = 0$ and

$$\begin{aligned} L'_1(T) &= (\theta T)^N e^{-\theta T} \bar{F}(T) \\ &\quad \times \int_0^T (\theta t)^N e^{-\theta t} \bar{F}(t) (\theta T - \theta t) [h(T) - h(t)] dt > 0, \end{aligned}$$

which follows that $Q(T, N)$ increases strictly with N from $Q_0(T)$ to $h(T)$ for any T .

Using the similar method, we can easily prove 2. Therefore, taking $T \rightarrow \infty$, $Q(N)$ increases strictly with N to $h(\infty)$, and for $0 < T, N < \infty$,

$$\begin{aligned} Q(T, N) &< h(T) < \tilde{Q}_0(T) < \tilde{Q}(T, N), \\ Q(T, N) &< Q(N) < \tilde{Q}(T, N). \end{aligned}$$

Appendix 3

1. For $N = 0, 1, 2, \dots$ and $0 < T \leq \infty$,

$$H(T, N) \equiv \frac{\int_0^T (\theta t)^N e^{-\theta t} h(t) dt}{\int_0^T (\theta t)^N e^{-\theta t} dt}$$

increases strictly with T from $h(0)$ to $H(N) \equiv \int_0^\infty [\theta(\theta t)^N / N!] e^{-\theta t} h(t) dt$ and increases strictly with N from $H(T, 0) = \int_0^T \theta e^{-\theta t} h(t) dt / (1 - e^{-\theta T})$ to $h(T)$.

2. For $N = 0, 1, 2, \dots$ and $0 \leq T < \infty$,

$$\tilde{H}(T, N) \equiv \frac{\int_T^\infty (\theta t)^N e^{-\theta t} h(t) dt}{\int_T^\infty (\theta t)^N e^{-\theta t} dt}$$

increases strictly with T from $H(N)$ to $h(\infty)$ and increases strictly with N from $\int_0^\infty \theta e^{-\theta t} h(T + t) dt$ to $h(\infty)$.

Proof. Note that

$$\begin{aligned} H(0, N) &= h(0), & H(\infty, N) &= H(N), \\ H(T, 0) &= \frac{\int_0^T \theta e^{-\theta t} h(t) dt}{1 - e^{-\theta T}}, & H(T, \infty) &= h(T), \\ \tilde{H}(0, N) &= H(N), & \tilde{H}(\infty, N) &= h(\infty), \\ \tilde{H}(T, 0) &= \int_0^\infty \theta e^{-\theta t} h(T + t) dt, & \tilde{H}(T, \infty) &= h(\infty). \end{aligned}$$

Using the similar method in Appendix 1, we can prove 1 and 2. Therefore, for $0 < T, N < \infty$,

$$\begin{aligned} H(T, N) &< h(T) < \tilde{H}(T, N), \\ H(T, N) &< H(N) < \tilde{H}(T, N), \end{aligned}$$

and $H(N)$ increases strictly with N from $\int_0^\infty \theta e^{-\theta t} h(t) dt$ to $h(\infty)$.

Appendix 4

1. For $N = 0, 1, 2, \dots$ and $0 < T \leq \infty$,

$$Q_1(T, N) \equiv \frac{\int_0^T (\theta t)^N [\int_t^\infty e^{-\theta u} dF(u)] dt}{\int_0^T (\theta t)^N [\int_t^\infty e^{-\theta u} \bar{F}(u) du] dt}$$

increases strictly with T from $\tilde{Q}_0(0) = \int_0^\infty e^{-\theta t} dF(t) / \int_0^\infty e^{-\theta t} \bar{F}(t) dt$ to $Q(N + 1)$ and increases strictly with N from $Q_1(T, 0)$ to $\tilde{Q}_0(T)$.

2. For $N = 0, 1, 2, \dots$ and $0 \leq T < \infty$,

$$\tilde{Q}_1(T, N) \equiv \frac{\int_T^\infty (\theta t)^N [\int_t^\infty e^{-\theta u} dF(u)] dt}{\int_T^\infty (\theta t)^N [\int_t^\infty e^{-\theta u} \bar{F}(u) du] dt}$$

increases strictly with T from $Q(N + 1)$ to $h(\infty)$ and increases strictly with N from $\tilde{Q}_1(T, 0)$ to $h(\infty)$.

Proof. Note that

$$Q_1(0, N) = \frac{\int_0^\infty e^{-\theta t} dF(t)}{\int_0^\infty e^{-\theta t} \bar{F}(t) dt} = \tilde{Q}_0(0),$$

$$\begin{aligned} Q_1(\infty, N) &= Q(N + 1), & Q_1(T, \infty) &= \tilde{Q}_O(T), \\ \tilde{Q}_1(0, N) &= Q(N + 1), & \tilde{Q}_1(\infty, N) &= h(\infty), \\ \tilde{Q}_1(T, \infty) &= h(\infty). \end{aligned}$$

Differentiating $Q_1(T, N)$ with respect to T ,

$$\begin{aligned} &(\theta T)^N \int_T^\infty e^{-\theta t} \bar{F}(t) dt \int_0^T (\theta t)^N \\ &\times \left[\int_t^\infty e^{-\theta u} \bar{F}(u) du \right] [\tilde{Q}_O(T) - \tilde{Q}_O(t)] dt > 0, \end{aligned}$$

which follows that $Q_1(T, N)$ increases strictly with T from $\tilde{Q}_O(0)$ to $Q(N + 1)$ for any N . Forming $Q_1(T, N + 1) - Q_1(T, N)$ and denoting

$$\begin{aligned} L_3(T) &= \int_0^T (\theta t)^{N+1} \left[\int_t^\infty e^{-\theta u} dF(u) \right] dt \\ &\times \int_0^T (\theta t)^N \left[\int_t^\infty e^{-\theta u} \bar{F}(u) du \right] dt \\ &- \int_0^T (\theta t)^N \left[\int_t^\infty e^{-\theta u} dF(u) \right] dt \\ &\times \int_0^T (\theta t)^{N+1} \left[\int_t^\infty e^{-\theta u} \bar{F}(u) du \right] dt, \end{aligned}$$

we have $L_3(0) = 0$ and

$$\begin{aligned} L'_3(T) &= (\theta T)^N \left[\int_T^\infty e^{-\theta t} \bar{F}(t) dt \right] \\ &\times \int_0^T (\theta t)^N \left[\int_t^\infty e^{-\theta u} \bar{F}(u) du \right] \\ &\times (\theta T - \theta t) [\tilde{Q}_O(T) - \tilde{Q}_O(t)] dt > 0, \end{aligned}$$

which follows that $Q_1(T, N)$ increases strictly with N from $Q_1(T, 0)$ to $\tilde{Q}_O(T)$ for any T .

Using the similar method, we can prove 2, and for $0 < T, N < \infty$,

$$\begin{aligned} Q_1(T, N) &< \tilde{Q}_O(T) < \tilde{Q}_1(T, N), \\ Q_1(T, N) &< Q(N + 1) < \tilde{Q}_1(T, N). \end{aligned}$$

Appendix 5

1. For $K = 0, 1, 2, \dots$ and $0 < T \leq \infty$,

$$H(T, K) \equiv \frac{\int_0^T p_K(t) h(t) dt}{\int_0^T p_K(t) dt}$$

increases strictly with T from $h(0)$ to $H(\infty, K) = 1 / \int_0^\infty p_K(t) dt$ and increases strictly with K from $F(T) / \int_0^T \bar{F}(t) dt$ to $h(T)$.

2. For $K = 0, 1, 2, \dots$ and $0 \leq T < \infty$,

$$\tilde{H}(T, K) \equiv \frac{\int_T^\infty p_K(t) h(t) dt}{\int_T^\infty p_K(t) dt}$$

increases strictly with T from $1 / \int_0^\infty p_K(t) dt$ to $h(\infty)$ and increases strictly with K from $Q(T)$ to $h(\infty)$.

Proof. Note that

$$\begin{aligned} H(0, K) &= h(0), & H(\infty, K) &= \frac{1}{\int_0^\infty p_K(t) dt}, \\ H(T, 0) &= \frac{F(T)}{\int_0^T \bar{F}(t) dt}, & H(T, \infty) &= h(T), \\ \tilde{H}(0, K) &= \frac{1}{\int_0^\infty p_K(t) dt}, & \tilde{H}(\infty, K) &= h(\infty), \\ \tilde{H}(T, 0) &= Q(T), & \tilde{H}(T, \infty) &= h(\infty). \end{aligned}$$

Differentiating $H(T, K)$ with respect to T

$$p_K(T) \int_0^T p_K(t) [h(T) - h(t)] dt > 0,$$

which follows that $H(T, K)$ increases strictly with T from $h(0)$ to $1 / \int_0^\infty p_K(t) dt$ for any K . Forming $H(T, K + 1) - H(T, K)$ and denoting

$$\begin{aligned} L_4(T) &\equiv \int_0^T p_{K+1}(t) h(t) dt \int_0^T p_K(t) dt \\ &- \int_0^T p_K(t) h(t) dt \int_0^T p_{K+1}(t) dt, \end{aligned}$$

we have $L_4(0) = 0$ and

$$\begin{aligned} L'_4(T) &= \frac{p_K(T) h(T)}{(K + 1)} \\ &\times \int_0^T p_K(t) [H(T) - H(t)] [h(T) - h(t)] dt > 0, \end{aligned}$$

which follows that $H(T, K)$ increases strictly with K from $F(T) / \int_0^T \bar{F}(t) dt$ to $h(T)$ for any T .

Using the similar method, we can prove 2. Therefore, for $0 \leq K < \infty$ and $0 < T < \infty$,

$$\begin{aligned} H(T, K) &< h(T) < \tilde{H}(T, K), \\ H(T, K) &< \frac{1}{\int_0^\infty p_K(t) dt} < \tilde{H}(T, K), \end{aligned}$$

and $1 / \int_0^\infty p_K(t) dt$ increases strictly with K from $1 / \int_0^\infty p_0(t) dt = 1 / \mu$ to $h(\infty)$.

Appendix 6

1. For $K = 0, 1, 2, \dots$ and $0 < T \leq \infty$,

$$H_1(T, K) \equiv \frac{P_K(T)}{\int_0^T [\int_t^\infty e^{-H(u)+H(t)} du] dP_K(t)}$$

increases strictly with T from $1/\mu$ to $1/\int_0^\infty p_K(t)dt$ and increases strictly with K from $1/\mu$ to $Q(T)$.

2. For $K = 1, 2, \dots$ and $0 \leq T < \infty$,

$$\tilde{H}_1(T, K) \equiv \frac{\bar{P}_K(T)}{\int_T^\infty [\int_t^\infty e^{-H(u)+H(t)} du] dP_K(t)}$$

increases strictly with T from $1/\int_0^\infty p_K(t)dt$ to $h(\infty)$ and increases strictly with K from $\tilde{H}_1(T, 1)$ to $h(\infty)$.

Proof. Note that

$$\begin{aligned} H_1(0, K) &= \frac{1}{\mu}, \\ H_1(\infty, K) &= \frac{1}{\int_0^\infty [\int_t^\infty e^{-H(u)+H(t)} du] dP_K(t)} \\ &= \frac{1}{\int_0^\infty p_K(t)dt}, \\ H_1(T, \infty) &= \frac{\bar{F}(T)}{\int_T^\infty \bar{F}(T)dt} = Q(T), \\ \tilde{H}_1(0, K) &= \frac{1}{\int_0^\infty p_K(t)dt}, \\ \tilde{H}_1(\infty, K) &= h(\infty), \quad \tilde{H}_1(T, \infty) = h(\infty). \end{aligned}$$

Using the similar method in Appendix 4, we can prove 1 and 2. Therefore, for $0 < T, K < \infty$,

$$\begin{aligned} H_1(T, K) &< Q(T) < \tilde{H}_1(T, K), \\ \frac{1}{\mu} &< H_1(T, K) < \frac{1}{\int_0^\infty p_K(t)dt} < \tilde{H}_1(T, K). \end{aligned}$$

Appendix 7

1. For $N = 0, 1, 2, \dots$ and $0 < T \leq \infty$,

$$H_1(T, N) \equiv \frac{\int_0^T [\int_0^\infty \theta e^{-\theta u} h(t+u) du] dG^{(N)}(t)}{G^{(N)}(T)}$$

increases strictly with T from $\int_0^\infty \theta e^{-\theta t} h(t)dt$ to $H(N)$ and increases strictly with N from $\int_0^\infty \theta e^{-\theta t} h(t)dt$ to $\int_0^\infty \theta e^{-\theta t} h(T+t)dt$.

2. For $N = 1, 2, \dots$ and $0 \leq T < \infty$,

$$\begin{aligned} \tilde{H}_1(T, N) &\equiv \\ &\frac{\int_T^\infty [\int_0^\infty \theta e^{-\theta u} h(t+u) du] dG^{(N)}(t)}{1 - G^{(N)}(T)} \end{aligned}$$

increases strictly with T from $H(N)$ to $h(\infty)$ and increases strictly with N from $\tilde{H}_1(T, 1)$ to $h(\infty)$.

Proof. Note that

$$\begin{aligned} H_1(0, N) &= \int_0^\infty \theta e^{-\theta t} h(t)dt, \\ H_1(\infty, N) &= \int_0^\infty \left[\int_0^\infty \theta e^{-\theta u} h(t+u) du \right] dG^{(N)}(t) \\ &= H(N), \\ H_1(T, 0) &= \int_0^\infty \theta e^{-\theta t} h(t)dt, \\ H_1(T, \infty) &= \int_0^\infty e^{-\theta t} h(T+t)dt, \\ \tilde{H}_1(0, N) &= H(N), \quad \tilde{H}_1(\infty, N) = h(\infty), \\ \tilde{H}_1(T, \infty) &= h(\infty). \end{aligned}$$

Differentiating $H_1(T, N)$ with respect to T ,

$$\begin{aligned} g^{(N)}(T) \int_0^T \left[\int_0^\infty \theta e^{-\theta u} h(T+u) du \right. \\ \left. - \int_0^\infty \theta e^{-\theta u} h(t+u) du \right] dG^{(N)}(t) > 0, \end{aligned}$$

which follows that $H_1(T, N)$ increases strictly with T from $\int_0^\infty \theta e^{-\theta t} h(t)dt$ to $H(N)$ for any N . Forming $H_1(T, N+1) - H_1(T, N)$ and denoting

$$\begin{aligned} L_5(T) &\equiv \\ &G^{(N)}(T) \int_0^T \left[\int_0^\infty \theta e^{-\theta u} h(t+u) du \right] dG^{(N+1)}(t) \\ &- G^{(N+1)}(T) \int_0^T \left[\int_0^\infty \theta e^{-\theta u} h(t+u) du \right] dG^{(N)}(t), \end{aligned}$$

we have $L_5(0) = 0$ and

$$\begin{aligned} L_5'(T) &= g^{(N)}(T) \int_0^T \left[\int_0^\infty \theta e^{-\theta u} h(T+u) du \right. \\ &\left. - \int_0^\infty \theta e^{-\theta u} h(t+u) du \right] (\theta T - \theta t) dG^{(N)}(t) > 0, \end{aligned}$$

which follows that $H_1(T, N)$ increases strictly with N from $H_1(T, 1)$ to $\int_0^\infty \theta e^{-\theta t} h(T+t)dt$ for any T .

Using the similar method, we can easily prove 2. Therefore, for $0 < T, N < \infty$,

$$H_1(T, N) < \int_0^\infty \theta e^{-\theta t} h(T+t) dt < \tilde{H}_1(T, N),$$

$$H_1(T, N) < H(N) < \tilde{H}_1(T, N).$$

Appendix 8

1. For $N = 1, 2, \dots$ and $K = 0, 1, 2, \dots$,

$$H_1(K, N) \equiv \frac{\int_0^\infty [1 - G^{(N)}(t)] p_K(t) h(t) dt}{\int_0^\infty [1 - G^{(N)}(t)] p_K(t) dt}$$

increases strictly with K from $H(0, N)$ to $h(\infty)$ and increases strictly with N from $H(K, 1)$ to $1 / \int_0^\infty p_K(t) dt$.

2. For $N = 0, 1, 2, \dots$ and $K = 1, 2, \dots$,

$$H_2(K, N) \equiv \frac{\int_0^\infty (\theta t)^N e^{-\theta t} \bar{P}_K(t) h(t) dt}{\int_0^\infty (\theta t)^N e^{-\theta t} \bar{P}_K(t) dt}$$

increases strictly with K from $H_2(1, N)$ to $H(N)$ and increases strictly with N from $H_2(K, 0)$ to $h(\infty)$.

Proof. Denoting that for $0 < T \leq \infty$,

$$H_1(T; K, N) \equiv \frac{\int_0^T [1 - G^{(N)}(t)] p_K(t) h(t) dt}{\int_0^T [1 - G^{(N)}(t)] p_K(t) dt},$$

we have

$$\lim_{K \rightarrow \infty} H_1(T; K, N) = h(T),$$

$$\lim_{N \rightarrow \infty} H(T; K, N) = \frac{\int_0^T p_K(t) h(t) dt}{\int_0^T p_K(t) dt} = H(T, K).$$

Furthermore, using the similar methods in Appendixes 3 and 5, $H_1(T; K, N)$ increases strictly with K and increases strictly with N . Thus, $H_1(T; K, N)$ increases strictly with K to $h(T)$ and increases strictly with N to $H(T, K)$ for any T . Taking $T \rightarrow \infty$, $H_1(K, N)$ increases strictly with K to $h(\infty)$ for any N and increases strictly with N to $1 / \int_0^\infty p_K(t) dt$ for any N .

Using the similar method, we can prove 2.

Appendix 9

1. For $N = 0, 1, 2, \dots$ and $K = 0, 1, 2, \dots$,

$$H_3(K, N) \equiv \frac{\int_0^\infty G^{(N)}(t) p_K(t) h(t) dt}{\int_0^\infty G^{(N)}(t) p_K(t) dt}$$

increases strictly with K from $H_3(0, N)$ to $h(\infty)$ and increases strictly with N from $1 / \int_0^\infty p_K(t) dt$ to $h(\infty)$.

2. For $N = 0, 1, 2, \dots$ and $K = 0, 1, 2, \dots$,

$$H_4(K, N) \equiv \frac{\int_0^\infty (\theta t)^N e^{-\theta t} P_K(t) h(t) dt}{\int_0^\infty (\theta t)^N e^{-\theta t} P_K(t) dt}$$

increases strictly with K from $H(N)$ to $h(\infty)$ and increases strictly with N from $H_4(K, 0)$ to $h(\infty)$. Therefore, for $0 < K, N < \infty$,

$$H_1(K, N) < \frac{1}{\int_0^\infty p_K(t) dt} < H_3(K, N),$$

$$H_2(K, N) < H(N) < H_4(K, N).$$

Proof. Using the similar method in Appendix 8, we can prove 1 and 2.

Appendix 10

For $K = 0, 1, 2, \dots$ and $0 \leq T \leq \infty$,

$$H_{M1}(T, K) \equiv \frac{\int_0^\infty h(T+t) p_K(t) dt}{\int_0^\infty p_K(t) dt}$$

increases strictly with T from $1 / \int_0^\infty p_K(t) dt$ to $h(\infty)$ and increases strictly with K from $H_{M1}(T, 0)$ to $h(\infty)$.

Proof. It can be clearly shown that $H_{M1}(T, K)$ increases strictly with T from $1 / \int_0^\infty p_K(t) dt$ to $h(\infty)$ for any K . Next, denoting that for $0 < T_1 < \infty$,

$$H(T_1, T, K) \equiv \frac{\int_0^{T_1} h(T+t) p_K(t) dt}{\int_0^{T_1} p_K(t) dt},$$

we have $\lim_{K \rightarrow \infty} H(T_1, T, K) = h(T + T_1)$. Forming $H(T_1, T, K + 1) - H(T_1, T, K)$ and denoting

$$L_6(T_1) \equiv \int_0^{T_1} h(T+t) p_{K+1}(t) dt \int_0^{T_1} p_K(t) dt$$

$$- \int_0^{T_1} h(T+t) p_K(t) dt \int_0^{T_1} p_{K+1}(t) dt,$$

we have $L_6(0) = 0$ and

$$L'_6(T_1) = \frac{p_K(T_1)}{K+1} \int_0^{T_1} p_K(t)[H(T_1) - H(t)] \times [h(T+T_1) - h(T+t)]dt > 0,$$

which follows that $H(T_1, T, K)$ increases strictly with K to $h(T+T_1)$ for any T_1 . Taking $T_1 \rightarrow \infty$, $H_{M1}(T, K)$ increases strictly with K to $h(\infty)$ for any T , and $H_{M1}(T, K) \geq h(T)$ and $H_{M1}(T, K) \geq 1/\int_0^\infty p_K(t)dt$.

Appendix 11

For $K = 0, 1, 2, \dots$ and $0 \leq T < \infty$,

$$H_{M2}(T, K) \equiv \frac{1}{\int_T^\infty p_K(t, T)dt}$$

increases strictly with T from $1/\int_0^\infty p_K(t)dt$ to $h(\infty)$ and increases strictly with K from $Q(T)$ to $h(\infty)$.

Proof. Note first that

$$H_{M2}(T, K) = \frac{\int_T^\infty [H(t) - H(T)]^K e^{-H(t)} h(t) dt}{\int_T^\infty [H(t) - H(T)]^K e^{-H(t)} dt},$$

because

$$\int_T^\infty [H(t) - H(T)]^K e^{-H(t)} h(t) dt = K! e^{-H(T)}.$$

Next, note that

$$H_{M2}(0, K) = \frac{1}{\int_0^\infty p_K(t)dt}, \quad H_{M2}(\infty, K) = h(\infty),$$

$$H_{M2}(T, 0) = Q(T), \quad H_{M2}(T, \infty) = h(\infty).$$

Differentiating $H_{M2}(T, K)$ with respect to T ,

$$Kh(T) \left\{ \int_T^\infty [H(t) - H(T)]^K dF(t) \times \int_T^\infty [H(u) - H(T)]^{K-1} \bar{F}(u) du - \int_T^\infty [H(t) - H(T)]^{K-1} dF(t) \times \int_T^\infty [H(u) - H(T)]^K \bar{F}(u) du \right\} = Kh(T) \int_T^\infty [H(t) - H(T)]^{K-1} \bar{F}(t) dt$$

$$\times \int_T^t [H(u) - H(T)]^{K-1} \bar{F}(u) \times [h(t) - h(u)][H(t) - H(u)] du > 0,$$

because

$$\int_T^\infty [H(t) - H(T)]^K dF(t) \times \left\{ \int_T^t [H(u) - H(T)]^{K-1} \bar{F}(u) du + \int_t^\infty [H(u) - H(T)]^{K-1} \bar{F}(u) du \right\} = \int_T^\infty [H(t) - H(T)]^K dF(t) \times \int_T^t [H(u) - H(T)]^{K-1} \bar{F}(u) du + \int_T^\infty [H(t) - H(T)]^{K-1} \bar{F}(t) dt \times \int_T^t [H(u) - H(T)]^K dF(u),$$

which follows that $H_{M2}(T, K)$ increases strictly with T from $1/\int_0^\infty p_K(t)dt$ to $h(\infty)$ for any K . Forming $H_{M2}(T, K+1) - H_{M2}(T, K)$, and denoting

$$L_7(T) \equiv \int_T^\infty [H(t) - H(T)]^{K+1} dF(t) \times \int_T^\infty [H(u) - H(T)]^K \bar{F}(u) du - \int_T^\infty [H(t) - H(T)]^K dF(t) \times \int_T^\infty [H(u) - H(T)]^{K+1} \bar{F}(u) du,$$

we have $L_7(\infty) = 0$ and $L'_7(T) < 0$ which follows that $H_{M2}(T, K)$ increases strictly with K from $Q(T)$ to $h(\infty)$ for any T , and $H_{M2}(T, K) \geq 1/\int_0^\infty p_K(t)dt$, $H_{M2}(T, K) \geq Q(T)$.

29.1 Introduction

A confidence distribution (CD) refers to a sample-dependent distribution function that can represent confidence intervals (regions) of all levels for a parameter of interest [74, 90]. Instead of the usual point estimator or confidence interval, CD is a distribution estimator of a parameter of interest with a pure frequentist interpretation. The development of the CD can be traced back to, for example, [16, 28, 47, 66]. However, its associated inference schemes and applications have not received much attention until the recent surge of interest in the research of CD and its applications [25, 46, 52, 53, 72–74, 77, 78, 82, 90, 91, 94]. All of these developments of CDs, along with a modern definition and interpretation, provide a powerful inferential tool for statistical inference.

One of the main contributions of CD is its applications on fusion learning [12, 15, 40, 51–53, 72, 75, 77, 81, 91, 92]. Combining CDs from independent studies naturally preserves more information from the individual studies than a traditional approach of combining only point estimators. A unified framework of combining CDs for fusion learning generally includes three steps: (1) using a CD to summarize relevant information or obtain an inference result from each study, (2) combining information from different sources or studies by combining these CDs, and (3) making inference via the combined CD. This approach has sound theoretical support and has been applied to many practical situations with much success.

On a different note, the fiducial distribution may be considered as one special type of CD, which provides a

Abstract

This chapter introduces to readers the new concept and methodology of confidence distribution and the modern-day distributional inference in statistics. This discussion should be of interest to people who would like to go into the depth of the statistical inference methodology and to utilize distribution estimators in practice. We also include in the discussion the topic of generalized fiducial inference, a special type of modern distributional inference, and relate it to the concept of confidence distribution. Several real data examples are also provided for practitioners. We hope that the selected content covers the greater part of the developments on this subject.

systematic way to obtain a CD. The origin of fiducial inference can be traced back to R.A. Fisher [28] who introduced the concept of a fiducial distribution for one parameter and proposed the use of this fiducial distribution to avoid the problems related to the choice of a prior distribution. Since the mid-2000s, there has been a renewed interest in modifications of fiducial inference [2, 7, 8, 22, 24, 30, 31, 33–37, 41, 56, 57, 59–63, 68, 73, 74, 79, 85, 87, 90, 93, 96].

We briefly overview these modern approaches which extend Fisher's original fiducial argument. We then focus on a recent development termed generalized fiducial inference and its applications [14, 17, 37, 41, 42, 44, 49, 50, 65, 86, 88, 89] that greatly expand the applicability of fiducial ideas. We demonstrate this recipe on several examples of varying complexity. The statistical procedures derived by the generalized fiducial inference often have very good performance from both theoretical and numerical points of view.

29.2 Confidence Distribution

29.2.1 The Concept of CD

This section will mainly focus on the concept of CD. The CD can be viewed as a distribution estimator, which can be utilized for constructing statistical procedures such as point estimates, confidence intervals, hypothesis tests, etc. The basic notion of CDs is related to the fiducial distribution of [28]; however, it is a pure frequentist concept. Some have suggested to view CD as the frequentist analog of Bayesian posterior distribution [e.g., 73, 74]. More broadly, if the credible intervals or regions obtained from a Bayesian posterior match with frequentist intervals or regions (either exactly or asymptotically), then the Bayesian posterior can be viewed as CD, and thus Bayesian approach is also a way to obtain CD [90].

Suppose X_1, X_2, \dots, X_n are independent and identically distributed and \mathcal{X} is the sample space corresponding to the dataset (X_1, X_2, \dots, X_n) . Let θ be a scalar parameter of interest and Θ be the parameter space. The following formal definitions of CD and asymptotic CD are proposed in [72, 77].

Definition 29.2.1 (CD and Asymptotic CD) A function $H_n(\cdot) = H_n(x, \cdot)$ on $\mathcal{X} \times \Theta \rightarrow [0, 1]$ is called a CD for a parameter, if (1) for each given $x \in \mathcal{X}$, $H_n(\cdot)$ is a (continuous) cumulative distribution function on Θ and (2) at the true parameter value $\theta = \theta_0$, $H_n(\theta_0) \equiv H_n(x, \theta_0)$, as a function of the sample x , follows the uniform distribution $U(0, 1)$. In addition, the function $H_n(\cdot)$ is called an asymptotic CD if condition (2) is replaced by (2') at the true parameter $\theta = \theta_0$, $H_n(\theta_0) \xrightarrow{d} U(0, 1)$ as $n \rightarrow \infty$.

From a nontechnical point of view, a CD is a function of both the parameter and the sample which satisfies two conditions. The first condition basically states that for any fixed sample, a CD is a distribution function on the parameter space. The second condition essentially requires that the corresponding inference derived by a CD has desired frequentist properties. Section 29.2.2 will further discuss how to use the second condition to extract information from a CD to make inference.

Birnbaum [9] introduced the concept of confidence curve as "an omnibus technique for estimation and testing statistical hypotheses," which was independent of the development of CD. From a CD $H_n(\theta)$, the confidence curve can be written as

$$CV_n(\theta) = 2 \min\{H_n(\theta), 1 - H_n(\theta)\}.$$

Indeed, confidence curve is an alternative expression of CD and it is a very useful graphical tool for visualizing CDs. On a plot of $CV_n(\theta)$ versus θ , a line across the y -axis of the significance level α , for any $0 < \alpha < 1$, intersects with the confidence curve at two points, and these two points correspond to an $1 - \alpha$ level, equal-tailed, two-sided confidence interval for θ . In addition, the maximum of a confidence curve is the median of the CD which is the recommended point estimator.

We present below five illustrating examples of CDs. More examples refer to [74, 77, 90].

Example 29.2.1 Suppose the data $X_i \sim N(\mu, 1)$, $i = 1, \dots, n$, with unknown μ . Let \bar{x}_n denote the sample mean. Then $N(\bar{x}_n, 1/n)$ is a CD for μ , and it can be represented in the following three forms: (i) confidence distribution (cumulate distribution form), $H_n(\mu) = \Phi(\sqrt{n}(\mu - \bar{x}_n))$; (ii) confidence density (density form), $h_n(\mu) = \frac{1}{\sqrt{2\pi/n}} \exp\{-\frac{n}{2}(\mu - \bar{x}_n)^2\}$; and (iii) confidence curve, $CV_n(\mu) = 2 \min\{\Phi(\sqrt{n}(\mu - \bar{x}_n)), 1 - \Phi(\sqrt{n}(\mu - \bar{x}_n))\}$. See Fig. 29.1 for an illustration. The data are generated from $N(0.3, 1)$ with sample size 100.

Example 29.2.2 ([77]) Suppose the data $X_i \sim N(\mu, \sigma^2)$, $i = 1, \dots, n$, with both unknown μ and σ . A CD for μ is $H_n(\mu) = F_{t_{n-1}}(\frac{\sqrt{n}(\mu - \bar{x}_n)}{s_n})$, where s_n is the sample standard deviation and $F_{t_{n-1}}(\cdot)$ is the cumulative distribution function of student t distribution with parameter $n - 1$. A CD for σ^2 is $H_n(\sigma^2) = 1 - F_{\chi_{n-1}^2}(\frac{(n-1)s_n^2}{\sigma^2})$, where $F_{\chi_{n-1}^2}(\cdot)$ is the cumulative distribution function of the χ_{n-1}^2 -distribution.

Example 29.2.3 ([77]) Let $\hat{\theta}$ be a consistent estimator of θ . For bootstrap, the distribution of $\hat{\theta}^* - \theta$ is estimated by the bootstrap distribution $\hat{\theta}^* - \hat{\theta}$, where $\hat{\theta}^*$ is the estimator of θ computed on a bootstrap sample [26]. An asymptotic CD for θ is given by $H_n(\theta) = 1 - \Pr(\hat{\theta}^* - \hat{\theta} \leq \hat{\theta} - \theta) =$

Fig. 29.1 Confidence distribution presented in Example 29.2.1 in the forms of density function, cumulative distribution function, and confidence curve

$\Pr(\hat{\theta}^* \geq 2\hat{\theta} - \theta)$. In addition, when the limiting distribution of normalized $\hat{\theta}$ is symmetric, the raw bootstrap distribution $H_n(\theta) = 1 - \Pr(\hat{\theta} - \hat{\theta}^* \leq \hat{\theta} - \theta) = \Pr(\hat{\theta}^* \leq \theta)$ is also an asymptotic CD.

Example 29.2.4 Suppose we are interested in the location parameter θ of a continuous distribution. When the distribution F is symmetric, i.e., $F(\theta - y) = 1 - F(\theta + y)$, θ is the median. The Wilcoxon rank test for $H_0 : \theta = t, H_1 : \theta \neq t$ is based on the summation of signed ranks of $Y_i - t$, i.e., the test statistic $W = \sum_{i=1}^n Z_i R_i$, where R_i is the rank of $|Y_i - t|$ and Z_i is an indicator variable with 1 if $Y_i - t > 0$ and -1 otherwise. Denote by $p(t)$ the p -value associated with the Wilcoxon rank test for $H_0 : \theta = t, H_1 : \theta \neq t$. When t varies in $(-\infty, \infty)$, the p -value $p(t)$ is referred to as a p -value function. We can prove that the p -value function $p(t)$ is an asymptotic CD [90]. Figure 29.2 provides illustrations of the asymptotic CD density $p'(t)$, the asymptotic CD function $p(t)$, and the asymptotic CV $2 \min\{p(t), 1 - p(t)\}$ for two sample sizes. The data are generated from $N(0, 1)$ with sample sizes $n = 10$ and 100 , respectively.

Example 29.2.5 ([78]) Suppose that there is an independent and identically distributed sample of size n from a semi-parametric model involving multiple parameters. Let $l_n(\theta)$ be the log profile likelihood function and $\mathcal{J}_n(\theta) = -\dot{l}_n(\theta)$ be the observed Fisher information for a scalar parameter of interest θ . Under certain mild assumptions, Theorem 4.1 of [78] proves that, for any given θ ,

$$G_n(\theta) = H_n(\theta) + o_p(1), \text{ where } G_n(\theta) = \frac{\int_{-\infty}^{\theta} \exp\{l_n(x)\} dx}{\int_{-\infty}^{\infty} \exp\{l_n(x)\} dx},$$

$$H_n(\theta) = \Phi\left(\frac{\theta - \hat{\theta}}{\sqrt{\mathcal{J}_n(\hat{\theta})/n}}\right), \hat{\theta} = \arg \max_{\theta} l_n(\theta).$$

Because at the true parameter value $\theta = \theta_0, H_n(\theta_0)$ converges to $U(0, 1)$ as $n \rightarrow \infty$, it follows that $G_n(\theta_0)$ converges to $U(0, 1)$. Thus, $G_n(\theta)$ is an asymptotic CD. From this observation, we see that CD-based inference may subsume a likelihood inference in some occasions.

If the sample X is from a discrete distribution, we can typically invoke a large sample theory to obtain an asymptotic CD to ensure the asymptotic frequentist coverage property, when the sample size is large. However, when the sample size is limited, we sometimes may want to examine the difference between the “distribution estimator” and the $U(0, 1)$ distribution to get a sense of under and over coverage. To expand the concept of CD to cover the cases of discrete distributions with finite sample sizes, we introduce below the notions of lower and upper CDs. The lower and upper CDs provide us inference statements that are associated with under and over coverages at every significant level.

Definition 29.2.2 (Upper and Lower CDs) A function $H_n^+(\cdot) = H_n^+(x, \cdot)$ on $\mathcal{X} \times \Theta \rightarrow [0, 1]$ is said to be an upper CD for a parameter, if (i) for each given $x \in \mathcal{X}$, $H_n(\cdot)$ is a monotonic increasing function on Θ with values ranging within $(0, 1)$ and (ii) at the true parameter value $\theta = \theta_0, H_n^+(\theta_0) \equiv H_n^+(x, \theta_0)$, as a function of the sample x , is stochastically less than or equal to a uniformly distributed random variable $U \sim U(0, 1)$, i.e.,

$$\Pr(H_n^+(X, \theta_0) \leq t) \geq t. \tag{29.1}$$

Correspondingly, a lower CD $H_n^-(\cdot) = H_n^-(x, \cdot)$ for parameter θ can be defined but with (29.1) replaced by $\Pr(H_n^-(X, \theta_0) \leq t) \leq t$ for all $t \in (0, 1)$.

More generally, we also refer to $H_n^+(\cdot)$ and $H_n^-(\cdot)$ as the upper and lower CD, respectively, even when the monotonic

Fig. 29.2 Confidence distributions presented in Example 29.2.4 in the forms of density function, cumulative distribution function, and confidence curve. The top row is for sample size $n = 10$ and the bottom row is $n = 100$

condition (i) is removed. Note that, due to the stochastic dominance inequalities in the definition, we have, for any $\alpha \in (0, 1)$,

$$\Pr(\theta_0 \in \{\theta : H_n^+(X, \theta) \leq \alpha\}) \geq \alpha \text{ and } \Pr(\theta_0 \in \{\theta : H_n^-(X, \theta) \leq \alpha\}) \leq \alpha.$$

Thus, a level- $(1 - \alpha)$ confident interval (or set) $\{\theta : H_n^+(X, \theta) \leq 1 - \alpha\}$ or $\{\theta : H_n^-(X, \theta) \geq \alpha\}$ has guaranteed the coverage rate of $(1 - \alpha)100\%$, regardless of whether we have the monotonic condition in (i). After we remove the monotonic condition in (i), $H_n^+(\cdot)$ and $H_n^-(\cdot)$ may not be a distribution function, and the “nest-ness property” of confidence intervals/sets may also be lost. Here, the “nest-ness property” refers to “a level- $(1 - \alpha)$ confidence set $C_{1-\alpha}$ is not necessarily inside its corresponding level- $(1 - \alpha')$ confidence set $C_{1-\alpha'}$, when $1 - \alpha < 1 - \alpha'$.”

To conclude this section, we present an example of lower and upper CDs.

Example 29.2.6 ([40]) Suppose sample X is from Binomial (n, p_0) with observation x . Let $H_n(p, x) = \Pr(X > x) = \sum_{x < k \leq n} \binom{n}{k} p^k (1 - p)^{n-k}$. We can show that $P(H_n(p_0, X) \leq t) \geq t$ and $P(H_n(p_0, X - 1) \leq t) \leq t$. Thus, $H^+(p, x) =$

$H_n(p, x)$ and $H_n^-(p, x) = H_n(p, x - 1)$ are lower and upper CDs for the success rate p_0 . The half-corrected CD [25,37,72] is

$$\frac{H_n^-(p, x) + H_n^+(p, x)}{2} = \sum_{x < k \leq n_i} \binom{n}{k} p^k (1 - p)^{n-k} + \frac{1}{2} \binom{n}{x} p^x (1 - p)^{n-x}.$$

29.2.2 CD-Based Inference

Analogous to the Bayesian posterior, a CD contains a wealth of information for constructing any type of frequentist inference. We illustrate three aspects of making inference based on a given CD. Figure 29.3 from [90] provides a graphical illustration of the point estimation, confidence interval, and hypothesis testing. More specifically:

Point Estimation The natural choices of point estimators of the parameter θ given a CD $H_n(\cdot)$ include (i) the median $\tilde{\theta}_n = H_n(1/2)$, (ii) the mean $\bar{\theta}_n = \int_{\theta \in \Theta} \theta dH_n(\theta)$, and (iii) the mode $\hat{\theta}_n = \arg \max_{\theta \in \Theta} h_n(\theta)$, where $h_n(\theta) = dH_n(\theta)/d\theta$

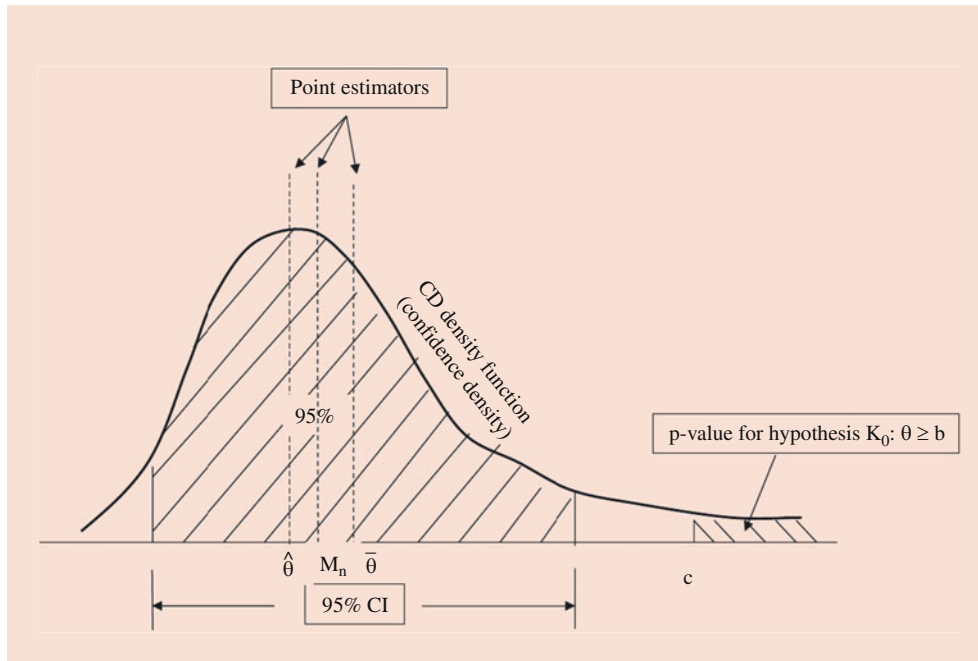

Fig. 29.3 A graphical illustration of CD-based inference [90]

is the confidence density function. Under some moderate conditions, these three point estimators are consistent [77, 90, 91].

To further understand these three types of estimators, the median $\tilde{\theta}_n$ is an unbiased estimator with $\Pr_{\theta_0}(\tilde{\theta}_n \leq \theta_0) = \Pr_{\theta_0}(1/2 \leq H_n(\theta_0)) = 1/2$. The mean $\bar{\theta}_n$ can be viewed as a frequentist analog of Bayesian estimator under the squared loss function. The mode $\hat{\theta}_n$ matches with the maximum likelihood estimator if the confidence density is from a normalized likelihood function [90].

Confidence Interval As discussed in Sect. 29.2.1, in a confidence curve, a line across the y-axis of the significance level α intersects with the confidence curve at two points, and these two points correspond to an $1 - \alpha$ level, equal-tailed, two-sided confidence interval for θ , i.e., $(H_n^{-1}(\alpha/2), H_n^{-1}(1 - \alpha/2))$. Furthermore, $(-\infty, H_n^{-1}(1 - \alpha)]$ and $[H_n^{-1}(\alpha), \infty)$ are one-sided $1 - \alpha$ level confidence intervals for the parameter θ .

Hypothesis Testing From a CD, one can obtain p -values for various hypothesis testing problems. The natural thinking is to measure the support that $H_n(\cdot)$ lends to a null hypothesis [29]. Xie and Singh [90] summarized making inference for hypothesis testing from a CD in the following theorem.

Theorem 29.2.1 (i) For the one-sided test $K_0 : \theta \in C$ versus $K_1 : \theta \in C^c$, where c denotes the complementary set and C is an interval of the type of $C_l = (-\infty, b]$ or $C_u = [b, \infty)$, we have $\sup_{\theta \in C} \Pr_{\theta}(p(C) \leq \alpha) = \alpha$, and $p(C) = H_n(C)$ is the corresponding p -value of the test. (ii)

For the singleton test $K_0 : \theta = b$ versus $K_1 : \theta \neq b$, we have $\Pr_{\theta=b}(2 \min\{p(C_l), p(C_u)\} \leq \alpha) = \alpha$, and $2 \min\{p(C_l), p(C_u)\} = 2 \min\{H_n(b), 1 - H_n(b)\}$ is the p -value of the corresponding test.

Example 29.2.7 ([90]) Consider Example 29.2.2 again. A CD for θ is $H_n = F_{t_{n-1}}(\frac{\sqrt{n}(\mu - \bar{x}_n)}{s_n})$. For a one-sided test $K_0 : \mu \leq b$ versus $K_1 : \mu > b$, its support on the null set $C = (-\infty, b]$ is

$$p(C) = p((-\infty, b]) = H_n(b) = F_{t_{n-1}}(\frac{\sqrt{n}(b - \bar{x}_n)}{s_n}).$$

This is the same p -value using the one-sided t-test. For a two-sided test $K_0 : \theta = b$ versus $K_1 : \theta \neq b$, the null set $C = \{b\}$. We would like to measure the supports of two alternative sets $p(C_l^c)$ and $p(C_u^c)$. The rejection region is defined as $\{x : 2 \max\{p(C_l^c), p(C_u^c)\} \geq 1 - \alpha\}$, i.e.,

$$\{x : 2 \min\{p(C_l), p(C_u)\} \leq \alpha\} = \{x : 2 \min\{H_n(b), 1 - H_n(b)\} \leq \alpha\}. \tag{29.2}$$

Under K_0 with $\theta = b$, $2 \min\{p(C_l), p(C_u)\} = 2 \min\{H_n(b), 1 - H_n(b)\} \sim U(0, 1)$ by the definition of a CD. Thus,

$$\Pr_{\theta=b}(2 \min\{p(C_l), p(C_u)\} \leq \alpha) = \Pr_{\theta=b}(2 \min\{H_n(b), 1 - H_n(b)\} \leq \alpha) = \alpha$$

and the reject region (29.2) corresponds to a level α test. Again, the p -value $2 \min\{p(C_l), p(C_u)\}$ is the standard p -value from a two-sided t-test.

29.2.3 Combination of CDs for Fusion Learning

One of the important applications of CD development is on fusion learning, which synthesizes information from disparate sources with deep implications for meta-analysis [12, 15, 40, 51–53, 72, 75, 77, 81, 91, 92]. Fusion learning aims to combine inference results obtained from different data sources to achieve a more efficient overall inference result. CD-based fusion learning applies even when inference results are derived from different tests or different paradigms, i.e., Bayesian, fiducial, and frequentist (BFF).

The combination of CD can be considered as a unified framework for fusion learning. Suppose there are k independent studies that are dedicated to estimate a common parameter of interest θ . We assume that we have a CD $H^i(\cdot)$ for θ for the sample x_i of the i -th study. Singh et al. [77] proposed a general recipe for combining these k independent CDs:

$$H^c(\theta) \equiv G_c\{g_c(H^1(\theta), \dots, H^k(\theta))\}, \quad (29.3)$$

where g_c is a given continuous function on $[0, 1]$ which is nondecreasing in each coordinate, the function G_c is determined by the monotonic function g_c with $G_c(t) = \Pr(g_c(U_1, \dots, U_k) \leq t)$, and U_1, \dots, U_k are independent uniform random variables. The function $H_c(\cdot)$ contains information from all k samples and is referred to as a combined CD for the parameter θ . Furthermore, the CD obtained by Eq. (29.3) does not require any information regarding how the input CDs are obtained.

A special class of the general combining framework (29.3) plays a prominent role in unifying many modern meta-analysis approaches. The choice of the function g_c for this special class is

$$g_c(u_1, \dots, u_k) = w_1 F^{-1}(u_1) + \dots + w_k F^{-1}(u_k), \quad (29.4)$$

where $F(\cdot)$ is a given cumulative distribution function and $w_i \geq 0$ with at least one $w_i \neq 0$ are generic weights for the combination rule. Generally, there are two types of weights: fixed weights to improve the efficiency of combination and adaptive weights based on data.

As shown in [91], it is remarkable that by choosing different g_c functions, all the classic approaches of combining p -values including Fisher, Normal (Stouffer), Min (Tippett), Max, and Sum methods [55] and all the five model-based meta-analysis estimators described in [67] including the maximum likelihood method and Bayesian approach under fixed-effects model, method of moment estimators, restricted maximum likelihood method, and Bayesian estimator with a normal prior under random-effects model, can all be obtained through a CD combination framework. Furthermore, it was shown in [94] that Mantel-Haenszel and Peto methods as well

as Tian et al.'s method of combining confidence intervals [81] for meta-analysis of 2×2 tables can also all be obtained through a CD combination framework. An R-package "gmeta" developed by [95] implements the CD combining framework for fusion learning including classical p -value combination methods from [55], meta-analysis estimators with both fixed-effects and random-effects models, and many other approaches.

Fusion learning under the framework of combining CD provides an extensive and powerful tool for synthesizing information from diverse data sources. This approach has sound theoretical support and has been applied to many practical situations including robust fusion learning [91], exact fusion learning for discrete data [52, 81], fusion learning for heterogeneous studies [53], nonparametric fusion learning [15, 51], split-conquer-combine approach [12], individualized fusion learning (i -fusion) [75], etc. We refer to [13] for more detailed discussions.

29.2.4 Multivariate CDs

A simultaneous CD for vector parameters can sometimes be difficult to define [72], especially on how to define a multivariate CD in the exact sense in some non-Gaussian settings to ensure that their marginal distributions are CDs for the corresponding single parameter. We consider the Behrens-Fisher problem of testing for the equality of means from two multivariate normal distributions when the covariance matrices are unknown and possibly not equal. A joint CD of the two population means (μ_1, μ_2) has a joint density of the form

$$f_1 \left(\frac{\mu_1 - \bar{x}_1}{s_1/\sqrt{n_1}} \right) f_2 \left(\frac{\mu_2 - \bar{x}_2}{s_2/\sqrt{n_2}} \right) / (s_1 s_2 \sqrt{n_1 n_2}),$$

where f_i is the density function for the student t -distribution with $n_i - 1$ degrees of freedom, $i = 1, 2$. The marginal distribution of $\mu_1 - \mu_2$ is only an asymptotic CD but not a CD in the exact sense.

The good news in the multidimensional case is that under asymptotic settings or wherever bootstrap theory applies, one can still work with multivariate CDs [90]. When no analytic confidence curve for the parameter vector θ of interest is available, the product method of [4] can be used if confidence curves are available for each component of the vector [72]. Additionally, if we only consider center-outward confidence regions instead of all Borel sets in the $p \times 1$ parameter space, the central-CDs considered in [78] and the confidence net considered in [71] offer coherent notions of multivariate CDs in the exact sense [90].

There are many approaches to obtain CDs. One way is normalizing a likelihood function curve with respect to its

parameters so that the area underneath the curve is one. The normalized likelihood function is typically a density function. For instance, under some mild conditions, Fraser and McDunnough [32] show that this normalized likelihood function is the normal density function of an asymptotic CD. Other ways like bootstrap distributions and p -value functions also often provide valid CDs. Finally, CDs and fiducial distributions have been always linked since their inception. The class of fiducial inference provides another systematic way to obtain CDs and we will further discuss fiducial inference in the next section.

29.3 Fiducial Inference

CD can be somehow viewed as “the Neymanian interpretation of Fisher’s fiducial distributions” [74]. From the definition of CD and fiducial distribution, we may consider the fiducial distribution as one special type of CD, though the CD looks at the problem of obtaining an inferentially meaningful distribution on the parameter space from a pure frequentist point of view [90]. Nevertheless, fiducial inference provides a systematic way to obtain a CD, and its development provides a rich class of literature for CD inference. We briefly review fiducial inference and its recent developments in this section.

29.3.1 Fiducial Inference

R.A. Fisher introduced the idea of fiducial probability and fiducial inference [28] as a potential replacement of the Bayesian posterior distribution. Although he discussed fiducial inference in several subsequent papers, there appears to be no rigorous definition of a fiducial distribution for a vector parameter. The basic idea of the fiducial argument is switching the role of data and parameters to introduce the distribution on the parameter space. This obtained distribution then summarizes our knowledge about the unknown parameter. Since the mid-2000s, there has been a renewed interest in modern modifications of fiducial inference. The common approaches for these modifications rely on a definition of inferentially meaningful probability statements about subsets of the parameter space without introducing any prior information.

These modern approaches include generalized fiducial inference [37, 41], Dempster-Shafer theory [22, 24], and inferential models [56, 61]. Objective Bayesian inference, which aims at finding nonsubjective model-based priors, can also be seen as addressing the same question. Examples of recent breakthroughs related to reference prior and model selection are [2, 7, 8]. Another related approach is based on higher-order likelihood expansions and implied data-dependent

priors [30, 31, 33–36]. There are many more references that interested readers can find in [41].

29.3.2 Generalized Fiducial Distribution

Generalized fiducial inference, motivated by [83, 84], has been at the forefront of the modern fiducial revival. Generalized fiducial inference defines a data-dependent measure on the parameter space by using an inverse of a deterministic data generating equation without the use of Bayes theorem.

Motivated by Fisher’s fiducial argument, generalized fiducial inference begins with expressing the relationship between the data Y and the parameters θ as

$$Y = G(U, \theta), \quad (29.5)$$

where $G(\cdot, \cdot)$ is a deterministic function termed as the data generating equation and U is the random component of this data generating equation whose distribution is independent of parameters and completely known.

The data Y are created by generating a random variable U and plugging it into the data generating equation (29.5). For example, a single observation from $N(\mu, 1)$ distribution can be written as $Y = \mu + U$, where $\theta = \mu$ and U is $N(0, 1)$ random variable.

Fisher’s original fiducial argument only addresses the simple case where the data generating equation (29.5) can be inverted and the inverse $Q_y(u) = \theta$ exists for any observed y and for any arbitrary u . One can define the fiducial distribution for θ as the distribution of $Q_y(U^*)$ where U^* is an independent copy of U . Equivalently, a sample from the fiducial distribution of θ can be obtained by first generating U_i^* , and then let $\theta_i^* = Q_y(U_i^*)$, $i = 1, \dots, n$. Point estimation and confidence intervals for θ can be obtained based on this sample. In the $N(\mu, 1)$ example, $Q_y(u) = y - u$ and the fiducial distribution is therefore the distribution of $y - U^* \sim N(y, 1)$.

In the case of no θ satisfying Eq. (29.5), Hannig [37] proposed to use the distribution of U conditional on the event $\{u : y = G(u, \theta), \text{ for some } \theta\}$. Hannig et al. [41] generalized this approach and proposed an attractive definition of generalized fiducial distribution (GFD) through a weak limit.

Definition 29.3.1 A probability measure on the parameter space Θ is called a GFD if it can be obtained as a weak limit

$$\lim_{\epsilon \rightarrow 0} \left[\arg \min_{\theta^*} \|y - G(U^*, \theta^*)\| \mid \min_{\theta^*} \|y - G(U^*, \theta^*)\| \leq \epsilon \right]. \quad (29.6)$$

Hannig et al. [41] pointed out a close relationship between GFD and approximate Bayesian computations (ABC) [3].

In an idealized ABC, one first generates an observation θ^* from the prior, then generates a new sample using a data generating equation $y^* = G(U^*, \theta^*)$, and compares the generated data with the observed data y . If the observed and generated datasets are close, i.e., $\|y - y^*\| \leq \epsilon$, the generated θ^* is accepted; otherwise it is rejected and the procedure is repeated. On the other hand, as for GFD, one first generates U^* , finds a best fitting $\theta^* = \arg \min_{\theta^*} \|y - G(U^*, \theta^*)\|$, computes $y^* = G(U^*, \theta^*)$, again accepts θ^* if $\|y - y^*\| \leq \epsilon$, and rejects otherwise. In either approach an artificial dataset $y^* = G(U^*, \theta^*)$ is generated and compared to the observed data. The main difference is that the Bayes posterior simulates the parameter θ^* from the prior, while GFD uses the best-fitting parameter.

Fiducial distributions often have good frequentist properties, and corresponding fiducial confidence intervals often give asymptotically correct coverage [37, 41]. In addition, fiducial distribution is a data-dependent measure on the parameter space and thereby a CD. Xie and Singh [90] described the relation between the concepts of CD and fiducial distributions using an analogy in point estimation: A CD is analogous to a consistent estimator and a fiducial distribution is analogous to a maximum likelihood estimator. In the context of point estimation, a consistent estimator does not have to be a maximum likelihood estimator. But under some regularity conditions, the maximum likelihood estimator typically provides a standard procedure to obtain a consistent estimator. In the context of distribution estimator, a CD does not have to be a fiducial distribution. However, under suitable conditions, a fiducial distribution often has good frequentist properties and thus a CD.

29.3.3 A User-Friendly Formula for GFD

While Definition (29.6) for GFD is conceptually and mathematically appealing, it is not clear how to compute the limit in most of practical situations. The following theorem proposed by [41] provides a computational tool.

Theorem 29.3.1 *Under certain assumptions, the limiting distribution in (29.6) has a density*

$$r(\theta|y) = \frac{f(y, \theta)J(y, \theta)}{\int_{\Theta} f(y, \theta')J(y, \theta') d\theta'}, \tag{29.7}$$

where $f(y, \theta)$ is the likelihood and the function

$$J(y, \theta) = D \left(\frac{d}{d\theta} G(u, \theta) \Big|_{u=G^{-1}(y, \theta)} \right). \tag{29.8}$$

If (i) $n = p$, then $D(A) = |\det A|$. Otherwise the function $D(A)$ depends on the norm used; (ii) the l_∞

norm gives $D(A) = \sum_{i=(i_1, \dots, i_p)} |\det(A)_i|$;¹ (iii) under an additional assumption stated in [41], the l_2 norm gives $D(A) = (\det A^\top A)^{1/2}$.

Hannig et al. [41] recommended using (ii) for practitioners. A nice property of GFD is that GFD is invariant under smooth re-parameterizations. This property follows directly from (29.6), since for an appropriate selection of minimizers and any one-to-one function $\theta = \phi(\eta)$,

$$\phi \left(\arg \min_{\eta^*} \|y - G(U^*, \phi(\eta^*))\| \right) = \arg \min_{\theta^*} \|y - G(U^*, \theta^*)\|.$$

Note that GFD could change with transformations of the data generating equation. Assume that the observed dataset has been transformed by a one-to-one smooth transformation $Z = T(Y)$. By the chain rule, the GFD based on this new data generating equation and observed data $z = T(y)$ is the density (29.7) with the Jacobian function

$$J_T(z, \theta) = D \left(\frac{d}{dy} T(y) \cdot \frac{d}{d\theta} G(u, \theta) \Big|_{u=G^{-1}(y, \theta)} \right), \tag{29.9}$$

where for simplicity we write y instead of $T^{-1}(z)$.

29.3.4 Examples of GFD

In this section we will consider two examples, linear regression and uniform distribution. In the first case, the GFD is the same as Bayes posterior with respect to the independence Jeffreys prior, while in the second case, the GFD is not a Bayes posterior with respect to any prior (that is not data dependent).

Linear Regression [41] We consider a generalized fiducial approach to regression problem. We express linear regression via the data generating equation,

$$Y = G(U, \theta) = X\beta + \sigma U,$$

where Y is the dependent variables, X is the design matrix, $\theta = (\beta, \sigma)$ are the unknown parameters, and U is a random vector with known density $f(u)$ independent of θ and X . Note that $\frac{d}{d\theta} G(U, \theta) = (X, U)$ and $U = (y - X\beta)/\sigma$; the Jacobian in (29.9) using the l_∞ norm simplifies to

¹In (ii) the sum spans over $\binom{n}{p}$ of p -tuples of indexes $i = (1 \leq i_1 < \dots < i_p \leq n)$. For any $n \times p$ matrix A , the sub-matrix $(A)_i$ is the $p \times p$ matrix containing the rows $i = (i_1, \dots, i_p)$ of A .

$$J_\infty(y, \theta) = \sigma^{-1} \sum_{\substack{i=(1, \dots, i_p) \\ 1 \leq i_1 < \dots < i_p \leq n}} |\det(X, Y)_i|,$$

and the density of GFD is

$$r(\beta, \sigma | y) \propto \sigma^{-n-1} f((Y - X\beta)/\sigma).$$

The fiducial solution is the same as the Bayesian solution using Jeffreys prior [5]. Furthermore, by a simple calculation, the Jacobian with l_2 norm differs from $J_\infty(y, \theta)$ only by a constant; the GFD remains unchanged.

GFD in Irregular Models [41] We consider an irregular model $U(a(\theta) - b(\theta), a(\theta) + b(\theta))$. The reference prior for

this model has been shown complex in Theorem 8 from [7]. Considering GFD approach, we first express the observed data by the following data generating equation:

$$Y_i = a(\theta) + b(\theta)U_i, \quad U_i \stackrel{i.i.d.}{\sim} U(-1, 1).$$

By simple algebra,

$$\frac{d}{d\theta} G(u, \theta) = a'(\theta) + b'(\theta)U \text{ with } U = b^{-1}(\theta)(Y - a(\theta)).$$

If $a'(\theta) > |b'(\theta)|$, (29.8) simplifies to

$$J_1(y, \theta) = n[a'(\theta) - a(\theta)\{\log b(\theta)\}' + \bar{y}_n\{\log b(\theta)\}'],$$

and the GFD is

$$r_1(\theta|y) \propto \frac{a'(\theta) - a(\theta)\{\log b(\theta)\}' + \bar{y}_n\{\log b(\theta)\}'}{b(\theta)^n} I_{\{a(\theta)-b(\theta) < y_{(1)} \ \& \ a(\theta)+b(\theta) > y_{(n)}\}}.$$

Consider an alternative fiducial solution, which constructs the GFD based on the minimal sufficient and ancillary statistics $Z = \{h_1(Y_{(1)}), h_2(Y_{(n)}), (Y - Y_{(1)})/(Y_{(n)} - Y_{(1)})\}^T$, where

$Y_{(1)}, Y_{(n)}$ are order statistics, $h_1^{-1}(\theta) = EY_{(1)} = a(\theta) - b(\theta)(n - 1)/(n + 1)$ and $h_2^{-1}(\theta) = EY_{(n)} = a(\theta) + b(\theta)(n - 1)/(n + 1)$. By a simple calculation,

$$J_2(y, \theta) = (w_1 + w_2) \left[a'(\theta) - a(\theta)\{\log b(\theta)\}' + \frac{w_1 y_{(1)} + w_2 y_{(n)}}{w_1 + w_2} \{\log b(\theta)\}' \right],$$

$$r_2(\theta|y) \propto \frac{I_{\{a(\theta)-b(\theta) < y_{(1)} \ \& \ a(\theta)+b(\theta) > y_{(n)}\}}}{[(w_1 + w_2)[a'(\theta) - a(\theta)\{\log b(\theta)\}'] + (w_1 y_{(1)} + w_2 y_{(n)})\{\log b(\theta)\}']^{-1} b(\theta)^n},$$

where $w_1 = h_1'(y_{(1)})$ and $w_2 = h_2'(y_{(n)})$.

Hannig et al. [41] performed extensive simulation studies for a particular case $U(\theta, \theta^2)$ comparing GFD to the Bayesian posteriors with the reference prior $\pi(\theta) = \frac{(2\theta-1)}{\theta(\theta-1)} e^{\psi(\frac{2\theta}{\theta-1})}$ [7]² and flat prior $\pi(\theta) = 1$. The simple GFD, the alternative GFD, and the reference prior Bayes posterior maintain nominal coverage for all parameter settings. However, the flat prior Bayes posterior does not have a satisfactory coverage, with the worst departures from nominal coverage for small sample size and large parameter θ .

Nonparametric Fiducial Inference with Right-Censored Data [17] Let failure times X_i ($i = 1, \dots, n$) follow the true distribution function F_0 and censoring times C_i ($i = 1, \dots, n$) have the distribution function R_0 . We treat the situation when failure and censoring times are independent and unknown.

Suppose we observe right-censored data $\{y_i, \delta_i\}$ ($i = 1, \dots, n$), where $y_i = x_i \wedge c_i$ is the minimum of x_i and c_i , $\delta_i = I\{x_i \leq c_i\}$ denotes censoring indicator.

Consider the following data generating equation:

$$Y_i = F^{-1}(U_i) \wedge R^{-1}(V_i), \quad \Delta_i = I\{F^{-1}(U_i) \leq R^{-1}(V_i)\}$$

$$(i = 1, \dots, n),$$

where U_i, V_i are independent and identically distributed $U(0, 1)$.

For a failure event $\delta_i = 1$, we have full information about failure time x_i , i.e., $x_i = y_i$, and partial information about censoring time c_i , i.e., $c_i \geq y_i$. Thus,

$$F^{-1}(u_i) = y_i \iff F(y_i) \geq u_i, F(y_i - \epsilon) < u_i \text{ for any } \epsilon > 0.$$

For a censored event $\delta_i = 0$, we only know partial information about x_i , i.e., $x_i > y_i$, and full information on c_i , i.e., $c_i = y_i$. Similarly,

² $\psi(x)$ is the digamma function defined by $\psi(z) = \frac{d}{dz} \log(\Gamma(z))$ for $z > 0$, where Γ is gamma function.

$$F^{-1}(u_i) > y_i \iff F(y_i) < u_i,$$

$$R^{-1}(v_i) = y_i \iff R(y_i) \geq v_i, R(y_i - \epsilon) < v_i \text{ for any } \epsilon > 0.$$

The complete inverse map of the data generating equation is

$$Q^F(y, \delta, u) = \left\{ F : \begin{cases} F(y_i) \geq u_i, F(y_i - \epsilon) < u_i \text{ for any } \epsilon > 0 & \text{for all } i \text{ such that } \delta_i = 1 \\ F(y_j) < u_j & \text{for all } j \text{ such that } \delta_j = 0 \end{cases} \right\}, \tag{29.11}$$

$$Q^{F,R}(y, \delta, u, v) = \bigcap_i Q_{\delta_i}^{F,R}(y_i, u_i, v_i) = Q^F(y, \delta, u) \times Q^R(y, \delta, v), \tag{29.10}$$

where

and $Q^R(y, \delta, v)$ is analogous.

Let (U^*, V^*) be an independent copy of (U, V) . Because the inverse (29.10) separates into a Cartesian product, and of the fact that U^* and V^* are independent, the marginal fiducial distribution for the failure distribution function F is

$$Q^F(y, \delta, U^*) \mid \{Q^F(y, \delta, U^*) \neq \emptyset\}.$$

Figure 29.4 from [17] demonstrates the survival function representation of $Q^F(y, \delta, u)$, as defined in Eq. (29.11), for one dataset with $n = 8$ observations of X following $Weibull(20, 10)$ censored by Z following $Exp(20)$. Each of the panels corresponds to a different value of u , where each u is a realization of U^* . Any survival function lying between the upper red and the lower black fiducial survival functions corresponds to an element of the closure of $Q^F(y, \delta, u)$. The technical details of sampling refer to Algorithm 1 in [17]. The corresponding fiducial-based confidence intervals proposed in [17] maintain coverage in situations where asymptotic methods often have substantial coverage problems. Furthermore, as also shown in [17], the average length of their log-interpolation fiducial confidence intervals is often shorter than the length of confidence intervals for competing methods that maintain coverage. As pointed by [80], it would also be interesting to consider other choices of fiducial samples such as monotonic spline interpolation.

GFDs for Discrete Distributions [41] Let Y be a random variable with distribution function $F(y|\theta)$. Assume there is \mathcal{Y} so that $P_\theta(Y \in \mathcal{Y}) = 1$ for all θ , and for each fixed $y \in \mathcal{Y}$, the distribution function is either a nonincreasing function of θ , spanning the whole interval $(0, 1)$, or a constant equal to 1; the left limit $F(y_-|\theta)$ is also either a nonincreasing function of θ spanning the whole interval $(0, 1)$ or a constant equal to 0.

Define $F^-(a|\theta) = \inf\{y : F(y|\theta) \geq a\}$. It is well known [11] that if $U \sim U(0,1)$, $Y = F^-(U|\theta)$ has the correct distribution and we use this association as a data generating equation. It follows that both $Q_y^+(u) = \sup\{\theta : F(y|\theta) = u\}$ and $Q_y^-(u) = \inf\{\theta : F(y_-|\theta) = u\}$ exist and satisfy $F(y|Q_y^+(u)) = u$ and $F(y_-|Q_y^-(u)) = u$. Consequently,

$$P(Q_y^+(u) \leq t) = 1 - F(y|t) \text{ and}$$

$$P(Q_y^-(u) \leq t) = 1 - F(y_-|t).$$

Note that for all $u \in (0, 1)$, the function $F^-(u|\theta)$ is nonincreasing in θ and the closure of the inverse image $\bar{Q}_y(u) = \{Q_y^-(u), Q_y^+(u)\}$. The half-corrected GFD has distribution function

$$R(\theta|y) = 1 - \frac{F(y|\theta) + F(y_-|\theta)}{2}.$$

If either of the distribution functions is constant, we interpret it as a point mass at the appropriate boundary of the parameter space. Analogous argument shows that if the distribution function and its left limit were nondecreasing in θ , the half-corrected GFD would have distribution function

$$R(\theta|y) = \frac{F(y|\theta) + F(y_-|\theta)}{2}.$$

Hannig et al. [41] provide a list of the half-corrected GFDs for three well-known discrete distributions. Let $Beta(0, n + 1)$ and $Beta(x + 1, 0)$ denote the degenerate distributions on 0 and 1, respectively. Let $\Gamma(0, 1)$ denote the degenerate distribution on 0:

- $X \sim \text{Binomial}(m, p)$ with m known. GFD is the mixture of $Beta(x + 1, m - x)$ and $Beta(x, m - x + 1)$ distributions [37].
- $X \sim \text{Poisson}(\lambda)$. GFD is the mixture of $\Gamma(x + 1, 1)$ and $\Gamma(x, 1)$ distributions [22].
- $X \sim \text{Negative Binomial}(r, p)$ with r known. GFD is the mixture of $Beta(r, x - r + 1)$ and $Beta(r, x - r)$ distributions [38].

Model Selection via GFD [41] Hannig and Lee [39] introduced model selection into the generalized fiducial inference paradigm in the context of wavelet regression. Two important ingredients are needed for fiducial model selection: (1) include the choice of model as one of the parameters; (2) include penalization in the data generating equation.

Consider a finite collection of models \mathcal{M} . The data generating equation is

Fig. 29.4 Two realizations of fiducial curves for a sample of size 8 from *Weibull*(20, 10) censored by *Exp*(20) [17]. Here fiducial curves refer to Monte Carlo samples S_i^L , S_i^U , and S_i^I ($i = 1, 2$) from the GFD. The red and black curves are corresponding realizations of the upper

and lower fiducial survival functions. The green curve is the log-linear interpolation type of survival functions. The circle points denote failure observations. The triangle points denote censored observations. The dashed blue curve is the true survival function of *Weibull*(20, 10)

$$Y = G(M, \theta_M, U), \quad M \in \mathcal{M}, \theta_M \in \Theta_M, \quad (29.12)$$

where Y is the observation, M is the model considered, θ_M includes the parameters associated with model M , and U is a random vector of with fully known distribution independent of any parameters. Hannig and Lee [39] proposed a novel way of adding a penalty into the fiducial model selection. In particular, for each model M , they proposed to augment the data generating equation (29.12) by

$$0 = P_k, \quad k = 1, \dots, \min(|M|, n), \quad (29.13)$$

where P_k are independent and identically distributed continuous random variables independent of U with $f_P(0) = q$ and q is a constant determined by the penalty. Hannig and Lee [39] recommended using $q = n^{-1/2}$ as the default penalty. Note that the number of additional equations is the same as the number of unknown parameters in the model. As we never actually observe the outcomes of the extra data generating equations, we will select their values as $p_i = 0$.

For the augmented data generating equation, we have the following theorem from [41]. The quantity $r(M|y)$ can be used for inference in the usual way. For example, fiducial factor, the ratio $r(M_1|y)/r(M_2|y)$, can be used in the same way as a Bayes factor, as discussed in [6] in the context of Bayesian model selection.

Theorem 29.3.2 ([41]) *Suppose $|M| \leq n$ and certain assumptions hold; the marginal generalized fiducial probability of model M is*

$$r(M|y) = \frac{q^{|M|} \int_{\Theta_M} f_M(y, \theta_M) J_M(y, \theta_M) d\theta_M}{\sum_{M' \in \mathcal{M}} q^{|M'|} \int_{\Theta_{M'}} f_{M'}(y, \theta_{M'}) J_{M'}(y, \theta_{M'}) d\theta_{M'}}, \quad (29.14)$$

where $f_M(y, \theta_M)$ is the likelihood and $J_M(y, \theta_M)$ is the Jacobian function computed using (29.9) for each fixed model M .

For more details on the use of fiducial model selection, see [39] and [43].

29.4 Applications and Numerical Examples

29.4.1 CD-Based Inference

Two-Parameter Exponential Distribution Inference procedures based on the two-parameter exponential model, $Exp(\mu, \sigma)$, are extensively used in several areas of statistical practice, including survival and reliability analysis. The probability distribution function and cumulative distribution function of a random variable $X \sim Exp(\mu, \sigma)$ are given, respectively, by

$$f(x) = \frac{1}{\sigma} \exp\left\{-\frac{x-\mu}{\sigma}\right\},$$

$$F(x) = \begin{cases} 1 - \exp\left\{-\frac{x-\mu}{\sigma}\right\} & \text{if } x > \mu, \\ 0 & \text{if } x \leq \mu, \end{cases}$$

and survival function (also known as reliability function) is $S(x) = 1 - F(x)$. The inference problem of interest is to obtain confidence intervals (sets) of μ, σ and $S(t)$ at a given $t > 0$.

Let $X_{(1)}, \dots, X_{(k)}$ be the k ($k > 1$) smallest observations among X_1, \dots, X_n . Then the maximum likelihood estimator of μ and σ are

$$\hat{\mu} = X_{(1)}, \quad \text{and} \quad \hat{\sigma} = \frac{1}{k} \left\{ \sum_{i=1}^k X_{(i)} + (n-k)X_{(k)} - nX_{(1)} \right\}.$$

It turns out that $\hat{\mu}$ and $\hat{\sigma}$ are independent and they follow the distributions

$$U = 2n(\hat{\mu} - \mu)/\sigma \sim \chi^2(2), \quad V = 2k\hat{\sigma}/\sigma \sim \chi^2(2k - 2), \tag{29.15}$$

respectively. Here $\chi^2(m)$ is the chi-square distribution with degree of freedom m . We provide below a simple CD-based method to answer the inference problem of interest.

From Eq. (29.15), we have

$$\frac{n(\hat{\mu} - \mu)}{k\hat{\sigma}} = \frac{U/2}{V/(2k - 2)} \sim F(2, 2k - 2),$$

where $F(a, b)$ is the F -distribution with degrees of freedom a and b . By the pivot-based CD construction method [78, p134], a CD for μ is $H_1(\mu) = 1 - F_{F(2, 2k-2)}(\frac{n(\hat{\mu}-\mu)}{k\hat{\sigma}})$, where $F_{F(2, 2k-2)}$ is the cumulative distribution function of $F(2, 2k - 2)$ -distribution. Similarly, a CD for σ is $H_2(\sigma) = 1 - F_{\chi^2(2k-2)}(\frac{2k\hat{\sigma}}{\sigma})$, where $F_{\chi^2(2k-2)}$ is the cumulative distribution function of $\chi^2(2k - 2)$ -distribution. Inferential statements regarding μ and σ , including confidence intervals and testing results, can be obtained from these two CDs. Coverage rates and test errors obtained from these two CDs are exact.

We can also consider the inference for (μ, σ) jointly. Here, we introduce a simulation-based approach. Let $U^* \sim \chi^2(2)$ and $V^* \sim \chi^2(2k - 2)$ be two independently simulated random numbers. Define

$$\xi^* = \hat{\mu} - \frac{k\hat{\sigma}}{n} \frac{U^*}{V^*} \quad \text{and} \quad \zeta^* = \frac{2k\hat{\sigma}}{V^*}.$$

Then, $\xi^* | (\hat{\mu}, \hat{\sigma}) \sim H_1(\mu)$ and $\zeta^* | (\hat{\mu}, \hat{\sigma}) \sim H_2(\sigma)$, and they are called *CD random variables* [90]. Furthermore, the underlying joint distribution of (ξ^*, ζ^*) , given $(\hat{\mu}, \hat{\sigma})$, is a joint CD function $H_3(\mu, \sigma)$ of (μ, σ) . If we simulate a large number of, say M , copies of (U^*, V^*) , then we can get M copies of (ξ^*, ζ^*) . In order to make inference statements about (μ, σ) , we can treat these M copies of $(\xi_1^*, \zeta_1^*), \dots, (\xi_M^*, \zeta_M^*)$ as if they were M copies of bootstrap estimators in bootstrap inference or as if they were M copies of random samples from the posterior distribution of (μ, σ) in a Bayesian inference.

Additionally, we can also use the M copies of CD random variables $(\xi_1^*, \zeta_1^*), \dots, (\xi_M^*, \zeta_M^*)$ to obtain a pointwise confidence band for $S(t), t > 0$. For each given $t > 0$, we compute $\kappa_j^*(t) = \exp\{-(t - \xi_j^*)/\zeta_j^*\}$, for $j = 1, \dots, M$. Then $[\kappa_{[\alpha M]}^*(t), +\infty)$ and $[\kappa_{[\frac{\alpha}{2} M]}^*(t), \kappa_{[\frac{1-\alpha}{2} M]}^*(t)]$ are the one-sided and two-sided level- α confidence intervals of $S(t)$, respectively, where $\kappa_{[qM]}^*(t)$ is the q -th quantile of $\kappa_1^*(t), \dots, \kappa_M^*(t)$. Now by varying t , $[\kappa_{[\alpha M]}^*(t), +\infty)$ forms a level- α lower confidence band, and $[\kappa_{[\frac{\alpha}{2} M]}^*(t), \kappa_{[\frac{1-\alpha}{2} M]}^*(t)]$ forms a level- α confidence band for the survival function $S(t)$.

We can show that this set of exact confidence bands derived from the CD method matches with those obtained in [69] using Tsui and Weerahandi's generalized inference approach [83], but the CD approach is very simple and more direct. Roy and Mathew [69] illustrated the 95% lower limit $\tilde{S}(t)$ for time ranging from 150 to 2000 in Figure 1 of [69] using a real data example with 19 observations taken from [45]. The data deal with mileages for military personnel carriers that failed in service. Figure 29.5 is a similar plot for the confidence band, using our CD approach with $M = 1000$.

Data [45]:

162, 200, 271, 320, 393, 508, 539, 629, 706, 777, 884, 1008, 1101, 1182, 1463, 1603, 1984, 2355, 2880

Bivariate Normal Correlation Suppose we have the following bivariate normal distribution:

$$N\left(\begin{pmatrix} \mu_1 \\ \mu_2 \end{pmatrix}, \begin{pmatrix} \sigma_1^2 & \rho\sigma_1\sigma_2 \\ \rho\sigma_1\sigma_2 & \sigma_2^2 \end{pmatrix}\right),$$

Fig. 29.5 Point estimate (solid line) and 95% confidence band (dashed line) of CD-based inference

and let ρ denote the correlation coefficient. One could use the asymptotic pivot, Fisher's Z [27, 78],

$$\frac{1}{2} \log \frac{1+r}{1-r} - \frac{1}{2} \log \frac{1+\rho}{1-\rho},$$

where r is the sample correlation. The limiting distribution of the above pivot is $N(0, \frac{1}{n-3})$. Therefore, the asymptotic CD is

$$H_n(\rho) = 1 - \Phi \left(\sqrt{n-3} \left[\frac{1}{2} \log \frac{1+r}{1-r} - \frac{1}{2} \log \frac{1+\rho}{1-\rho} \right] \right), \quad -1 \leq \theta \leq 1.$$

Figure 29.6 presents the CD of correlation coefficient ρ for a simulated dataset with $n = 50, \mu_1 = \mu_2 = 1, \sigma_1 = \sigma_2 = 1, \rho = 0.5$.

In addition to the above two examples, there also are recent developments of CDs on causal inference; see more applications in [54].

Fig. 29.6 CD of the correlation coefficient ρ

29.4.2 Nonparametric GFD-Based Inference

[17] proposed a fiducial approach to testing reliability function with an infinite dimensional parameter. Their approach does not assume a parametric distribution and is robust to model mis-specification. In [17], they considered a clinical trial of chemotherapy against chemotherapy combined with radiotherapy in the treatment of locally unresectable gastric cancer conducted by the Gastrointestinal Tumor Study Group [70]. In this trial, 45 patients were randomized to each of the 2 groups and followed for several years. The censoring percentage is 13.3% for the combined therapy group, and 4.4% for the chemotherapy group. We are interested in testing whether the two treatment groups have the same survival functions.

The Kaplan-Meier curves for these two datasets are presented in Fig. 29.7a. We notice that the two hazards appear to be crossing, which could pose a problem for some log-rank

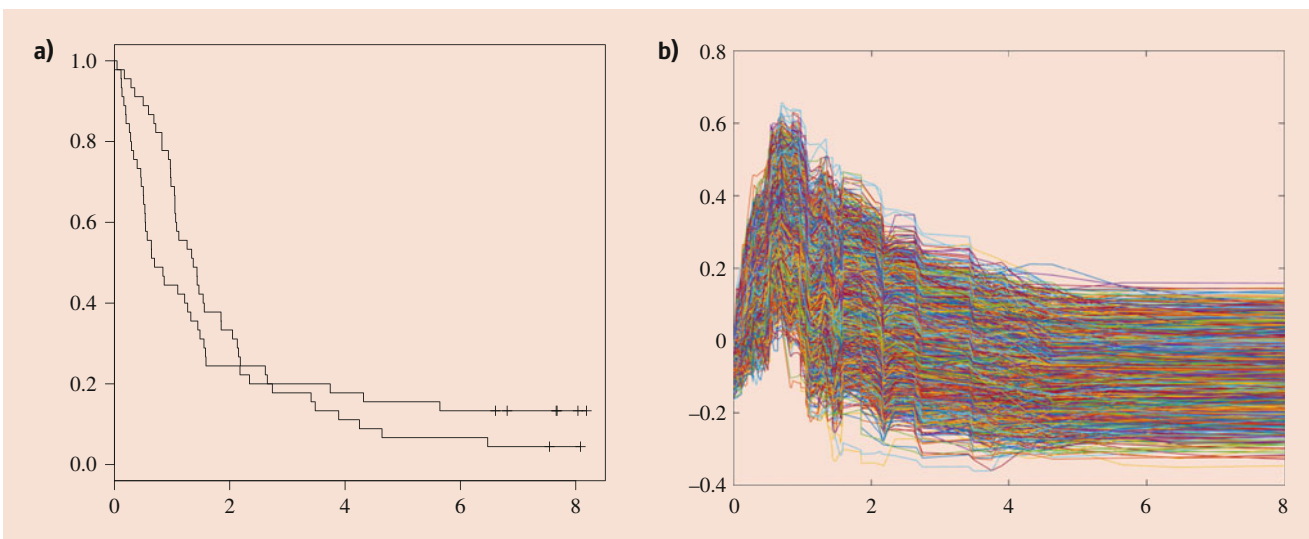

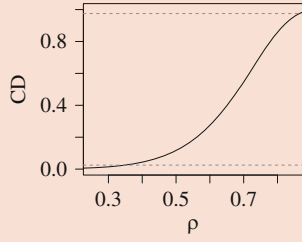

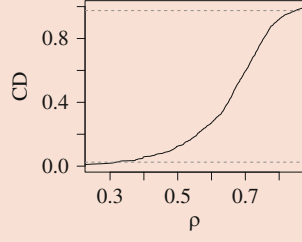

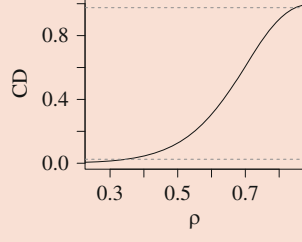

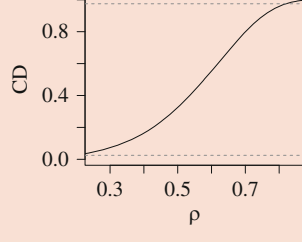

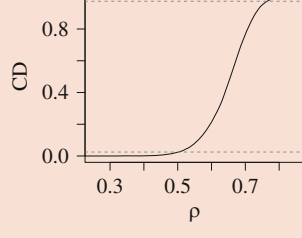

Fig. 29.7 (a) Kaplan-Meier estimators for two treatment groups [17]. (b) Difference of two sample fiducial distributions

tests. In this instance, the fiducial approach gives a small p-value 0.002. The p-values of other types of log-rank tests are reported in [17]. To explain why their proposed fiducial approach works good, they plot the sample of the difference of two fiducial distributions in Fig. 29.7b. If these two datasets are from the same distribution, 0 should be well within the sample curves. However, from Fig. 29.7b, we could see that the majority of curves are very far away from 0 on the interval [0.5, 1]. This gives strong evidence that the group

with combined therapy has significantly worse early survival outcomes.

In [17], they choose to use the sup-norm in the definition of the curvewise confidence intervals and tests. It could be possible to make the procedure more powerful by using a different (possibly weighted) norm [64]. Similarly, it might also be possible to use the choice of norm motivated by inferential models [18, 58, 61]. Besides the above example, there also are recent developments of non-

Table 29.1 Inference on correlation coefficient: combining independent bivariate normal studies

29.4.3 Combining Information from Multiple CDs

We use simple cluster of differentiation 4 (cd-4) count data considered in [23] to demonstrate combining information from CDs. Twenty HIV-positive subjects received an experimental antiviral drug. The cd-4 counts in hundreds were recorded for each subject at baseline and after 1 year of treatment.

We obtained the summary statistics and simulated four independent datasets from the following bivariate normal distribution:

$$N\left(\begin{pmatrix} \mu_1 \\ \mu_2 \end{pmatrix}, \begin{pmatrix} \sigma_1^2 & \rho\sigma_1\sigma_2 \\ \rho\sigma_1\sigma_2 & \sigma_2^2 \end{pmatrix}\right),$$

where $\mu_1 = 3.288$, $\mu_2 = 4.093$, $\sigma_1^2 = 0.657$, $\sigma_2^2 = 1.346$, and $\rho = 0.723$.

Suppose each study makes its own inference conclusion individually. Each dataset was analyzed by Fisher’s Z method [27, 76], the bias-corrected and accelerated (BC_a) bootstrap [10, 21, 23], the profile likelihood approach [48], and Bayesian with uniform prior [1], respectively. One natural question we would like to ask is if we can combine the inferences from four independent studies, given that ρ is the same in all studies. The answer is yes. As introduced in Section 29.2.3, combination of CDs is a powerful inferential tool. We fused studies by combining p -values (Stouffer) [55, 95].

The results of the analysis are summarized in Table 29.1. As we can see from the table, four methods in different studies provide more or less similar results, and the combined interval is much shorter than any of the four individual intervals. In order to study the performance of the combination of CDs in this situation, we present a simulation study with 200 replications. Table 29.2 shows the

Table 29.2 Combination of four independent bivariate normal studies via CDs

Methods	Coverage	Mean length (sd) of 95% CIs
Fisher’s Z method	0.948	0.484 (0.140)
Bootstrap BC_a	0.936	0.464 (0.156)
Profile likelihood	0.918	0.436 (0.131)
Bayes (uniform prior)	0.964	0.522 (0.128)
Combination	0.954	0.226 (0.041)

coverage and average length of 95% CIs. We see that not only the combined approach maintains the desired coverage but also the length of CIs is roughly half of the lengths of CIs from individual studies. This result is as expected, since theoretically each study provides a $n^{-1/2}$ -CIs and the sample size of combined data is $4n$ so we expect to obtain $(4n)^{-1/2}$ -CI.

Data [23]:

Baseline: 2.12, 4.35, 3.39, 2.51, 4.04, 5.10, 3.77, 3.35, 4.10, 3.35, 4.15, 3.56, 3.39, 1.88, 2.56, 2.96, 2.49, 3.03, 2.66, 3.00
 One year: 2.47, 4.61, 5.26, 3.02, 6.36, 5.93, 3.93, 4.09, 4.88, 3.81, 4.74, 3.29, 5.55, 2.82, 4.23, 3.23, 2.56, 4.31, 4.37, 2.40

Abstract

Ordinary logistic regression (OLR) models the probability of a binary outcome. A logistic regression tree (LRT) is a machine learning method that partitions the data and fits an OLR model in each partition. This chapter motivates LRT by highlighting the challenges of OLR with respect to model selection, interpretation, and visualization on a completely observed dataset. Being nonparametric, a LRT model typically has higher prediction accuracy than OLR for large datasets. Further, by sharing model complexity between the tree structure and the OLR node models, the latter can be made simple for easier interpretation and visualization.

OLR is more challenging if there are missing values in the predictor variables, because imputation must be carried out first. The second part of the chapter reviews the GUIDE method of constructing LRT models. A strength of GUIDE is its ability to deal with large numbers of variables and without the need to impute missing values. This is demonstrated on a vehicle crash-test dataset for which imputation is difficult due to missing values and other problems.

Classification and regression trees · Imputation · Logistic regression · Machine learning · Missing data · Visualization

30.1 Introduction

Ordinary logistic regression (OLR) is a technique for modeling the probability of a binary outcome in terms of one or more predictor variables. Consider, for example, a dataset on tree damage during a severe thunderstorm over 477,000 acres of the Boundary Waters Canoe Area Wilderness in northeastern Minnesota in July 4, 1999 (R package `alr4` [1]). Observations from 3666 trees were collected, including for each tree, whether it was blown down ($Y = 1$) or not ($Y = 0$), its trunk diameter D in centimeters, its species S , and the local intensity L of the storm, as measured by the fraction of damaged trees in its vicinity.

Let $p = P(Y = 1)$ denote the probability that a tree is blown down. OLR approximates the logit function $\text{logit}(p) = \log(p/(1-p))$ as a function of the predictor variables linear in any unknown parameters. A *simple linear* OLR model has the form $\text{logit}(p) = \log(p/(1-p)) = \beta_0 + \beta_1 X$, where X is the only predictor variable. Solving for p yields the p -function

$$p = \frac{\exp(\beta_0 + \beta_1 X)}{1 + \exp(\beta_0 + \beta_1 X)} = \frac{1}{1 + \exp(-\beta_0 - \beta_1 X)}$$

In general, if there are k predictor variables, X_1, \dots, X_k , a *multiple linear* OLR model has the form $\text{logit}(p) = \beta_0 + \sum_{j=1}^k \beta_j X_j$. The parameters $\beta_0, \beta_1, \dots, \beta_k$ are typically estimated by maximizing the likelihood function. Let n denote the sample size, and let $(x_{i1}, \dots, x_{ik}, y_i)$ denote the values of (X_1, \dots, X_k, Y) for the i th observation ($i = 1, \dots, n$). Treating each y_i as the outcome of an independent Bernoulli random variable with success probability p_i , the likelihood function is

$$\prod_{i=1}^n p_i^{y_i} (1 - p_i)^{1-y_i} = \frac{\exp\{\sum_i y_i(\beta_0 + \sum_j \beta_j x_{ij})\}}{\prod_i \{1 + \exp(\beta_0 + \sum_j \beta_j x_{ij})\}}$$

The maximum likelihood estimates are the values of $(\beta_0, \beta_1, \dots, \beta_k)$ that maximize this function.

30.2 Fitting OLR Models

Fitting a simple linear OLR model to the tree damage data using L yields

$$\text{logit}(p) = -1.999 + 4.407L \tag{30.1}$$

with estimated p -function shown in Fig. 30.1. The equation implies that the stronger the local storm intensity, the higher the chance that a tree is blown down. The boxplots in Fig. 30.2 show that the distributions of D are skewed. To reduce the skewness, Cook and Weisberg [2] transformed D to $\log(D)$ and obtained the model

$$\text{logit}(p) = -4.792 + 1.749 \log(D) \tag{30.2}$$

which suggests that larger trees are less likely to survive the thunderstorm than narrower ones. If both $\log(D)$ and L are used, the model becomes

$$\text{logit}(p) = -6.677 + 1.763 \log(D) + 4.42L. \tag{30.3}$$

The relative stability of the coefficients of L and $\log(D)$ in Eqs. (30.1)–(30.3) is due to the weak correlation of 0.168 between the two variables. If the interaction $L \log(D)$ is included, the model changes to

$$\text{logit}(p) = -4.341 + 0.891 \log(D) - 1.482L + 2.235L \log(D) \tag{30.4}$$

and the coefficients of $\log(D)$ and L are changed more dramatically.

So far, species S has been excluded from the models. As in linear regression, a categorical variable having m distinct values may be represented by $(m - 1)$ indicator variables, U_1, \dots, U_{m-1} , each taking value 0 or 1. The variables for species are shown in Table 30.1, which uses the “set-to-zero constraint” that sets all the indicator variables to 0 for the first species (aspen). A model that assumes the same slope coefficients for all species but that gives each a different intercept term is

$$\begin{aligned} \text{logit}(p) = & -5.997 + 1.581 \log(D) + 4.629L \\ & - 2.243U_1 + 0.0002U_2 + 0.167U_3 - 2.077U_4 \\ & + 1.040U_5 - 1.724U_6 - 1.796U_7 \\ & - 0.003U_8. \end{aligned} \tag{30.5}$$

RP (red pine)	0	0	0	0	0	0	0	1

How well do models (30.1)–(30.5) fit the data? One popular way to assess fit is by means of significance tests based on the residual deviance and its degrees of freedom (df)—see, e.g., [3, p. 96] for the definitions. The residual deviance is analogous to the residual sum of squares in linear regression. For model (30.5), the residual deviance is 3259 with 3655 df. We can evaluate the fit of this model by comparing its residual deviance against that of a larger one, such as the 27-parameter model

$$\begin{aligned} \text{logit}(p) &= \beta_0 + \beta_1 \log(D) + \beta_2 L + \sum_{j=1}^8 \gamma_j U_j \\ &+ \sum_{j=1}^8 \beta_{1j} U_j \log(D) + \sum_{j=1}^8 \beta_{2j} U_j L \end{aligned} \quad (30.6)$$

that allows the coefficients of $\log(D)$ and L to vary with species. It has a residual deviance of 3163 with 3639 df. If model (30.5) fits the data well, the difference between its residual deviance and that of model (30.6) is approximately distributed as a chi-squared random variable with df equal to the difference in df of the two models. The difference in deviance is $3259 - 3163 = 96$, which is improbably large for a chi-squared random variable with $3655 - 3639 = 16$ df.

Rejection of model (30.5) does not necessarily imply that model (30.6) is satisfactory. To find out, it may be compared with a larger one, such as the 28-parameter model

$$\begin{aligned} \text{logit}(p) &= \beta_0 + \beta_1 \log(D) + \beta_2 L + \beta_3 L \log(D) + \sum_{j=1}^8 \gamma_j U_j \\ &+ \sum_{j=1}^8 \beta_{1j} U_j \log(D) + \sum_{j=1}^8 \beta_{2j} U_j L \end{aligned} \quad (30.7)$$

that includes an interaction between L and $\log(D)$. This has a residual deviance of 3121 with 3638 df. Therefore model (30.6) is rejected because its residual deviance differs from that of (30.7) by 42 but their dfs differ only by 1. With this procedure, each of models (30.1) through (30.6) is rejected when compared against the next larger model in the sequence.

Another way to select a model employs a function such as AIC, which is residual deviance plus two times the number of estimated parameters. AIC tries to balance deviance against model complexity (see, e.g., [4, p. 234]), but it tends to overfit the data. That is, AIC often chooses a large model. In this dataset, if we apply AIC to the set of all models up to third order, it chooses the largest, namely, the three-factor interaction model

$$\begin{aligned} \text{logit}(p) &= \beta_0 + \beta_1 \log(D) + \beta_2 L + \sum_{j=1}^8 \gamma_j U_j \\ &+ \beta_3 L \log(D) + \sum_{j=1}^8 \beta_{1j} U_j \log(D) \\ &+ \sum_{j=1}^8 \beta_{2j} U_j L + \sum_{j=1}^8 \delta_j U_j L \log(D) \end{aligned} \quad (30.8)$$

which has 36 parameters.

Fig. 30.3 Estimated probability of blowdown for seven species, excluding balsam fir (BF) and black spruce (BS), according to model (30.9)

Models (30.7) and (30.8) are hard to graph. Plotting the estimated p -function as in Fig. 30.1 is impossible if a model has more than one predictor variable. This problem is exacerbated by the tendency of model complexity increasing with increase in sample size and number of predictors. Interpretation of the estimated coefficients is futile then, as they often change from one model to another, due to multicollinearity among the terms. For example, the coefficient for L is 4.424, -1.482 , and 4.629 in models (30.3), (30.4), and (30.5), respectively.

To deal with this problem, [2] used a “partial one-dimensional model” (POD) that employs a linear function of $\log(D)$ and L as predictor variable. They found that if the observations for balsam fir (BF) and black spruce (BS) are excluded, the model $\text{logit}(p) = \beta_0 + Z + \sum_j \gamma_j U_j$, with $Z = 0.78 \log(D) + 4.1L$, fits the remaining data quite well. Now the estimated p -function can be plotted as shown in Fig. 30.3, but the graph is not as simple to interpret as that in Fig. 30.1 because Z is a linear combination of two variables. To include species BF and BS, [2] settled on the larger model

$$\begin{aligned} \text{logit}(p) &= \beta_0 + Z + \sum_{j=1}^9 \gamma_j U_j + (\theta_1 I_{\text{BF}} + \theta_2 I_{\text{BS}}) \log(D) \\ &+ (\phi_1 I_{\text{BF}} + \phi_2 I_{\text{BS}}) L \end{aligned} \quad (30.9)$$

which contains separate coefficients (θ_j, ϕ_j) for BF and BS. Here $I_{(\cdot)}$ denotes the indicator function, i.e., $I_A = 1$ if species is A, and $I_A = 0$ otherwise. The model cannot be displayed graphically for species BF and BS because it is a function of three predictor variables.

30.3 Logistic Regression Trees

A logistic regression tree (LRT) model is a machine learning solution that simultaneously retains the graphical advantage of simple models and the prediction accuracy of more complex ones. It recursively partitions the dataset and fits a simple or multiple linear OLR model in each partition. As a result, the partitions can be displayed as a decision tree [5] such as Fig. 30.4, which shows a *simple linear* LRT model fitted to the tree damage data by the GUIDE algorithm [6, 7]. A terminal node represents a partition, and an OLR model with a single linear predictor is fitted in each one. Beside each intermediate node is a condition stating that an observation goes to the left subnode if and only if the condition is satisfied. Below each terminal node are the sample size (in italics), the proportion of blown down trees, and the name of the best linear predictor variable. The split at the root node (labeled “1”) sends observations to node 2 if and only if S is A, BS, JP, or RP. (Node labels employ the convention that a node with label k has left and right child nodes labeled $2k$ and $2k + 1$, respectively.) Node 5, consisting of the JP and RP species, has the highest proportion of blown down trees at 0.82. Node 9, which consists of species A and BS trees with diameters greater than 9.75 cm, has the second highest proportion of 0.67. Variable L is the best linear predictor in all terminal nodes except nodes 13 and 15, where D is the best linear predictor. The main advantage in using one linear predictor in each node is that the fitted p -functions can be displayed graphically, as shown in Fig. 30.5. It is not necessary to transform D to $\log(D)$ in the LRT.

The LRT model in Fig. 30.4 may be considered a different kind of POD model from that proposed in [2]. Whereas the

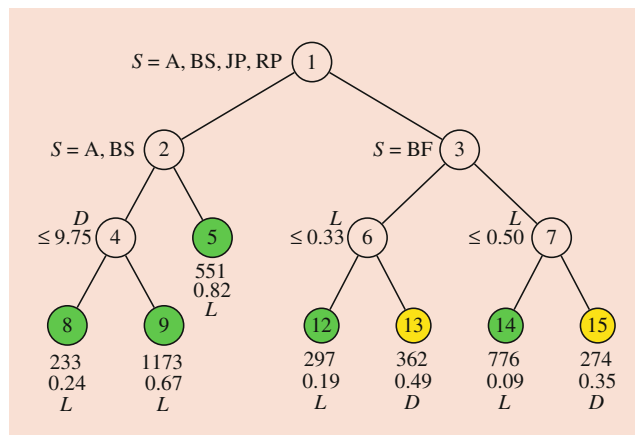

Fig. 30.4 GUIDE simple linear LRT model for $P(\text{blowdown})$. At each split, an observation goes to the left branch if and only if the condition is satisfied. Sample size (in italics), proportion of blowdowns, and name of regressor variable are printed beneath each terminal node. Green and yellow terminal nodes have L and D , respectively, as best linear predictor

word “partial” in POD refers to model (30.9) being one-dimensional if restricted to certain parts of the data (species in this example), it refers to partitions of the predictor space in a LRT. In addition, whereas “one-dimensional” refers to Z being a linear combination of $\log(D)$ and L in (30.9), the OLR predictor in each node of a LRT is trivially one-dimensional because it is an original variable.

GUIDE is a classification and regression tree algorithm with origins in the FACT [8], SUPPORT [9], QUEST [10], CRUISE [11, 12], and LOTUS [13] methods; see [14]. All of them split a dataset recursively, choosing a single X variable to split each node. If X is an ordinal variable, the split typically has the form $s = \{X \leq c\}$, where c is a constant. If X is a categorical variable, the split has the form $s = \{X \in \omega\}$, where ω is a subset of the values taken by X . For linear regression trees, algorithms such as AID [15], CART [16], and M5 [17] choose s to minimize the total sum of squared residuals of the regression models fitted to the two data subsets formed by s . Though seemingly innocuous, this approach is flawed as it is biased toward choosing X variables that allow more splits. To see this, suppose that X is an ordinal variable having m distinct values. Then there are $(m-1)$ ways to split the data along the X axis, with each split $s = \{X \leq c\}$ being such that c is the midpoint between two consecutively ordered distinct values of X . This creates a *selection bias* toward X variables with large values of m . In the current example, variable L has 709 unique values but D has only 87. Hence L has eight times as many opportunities as D to split the data. The bias is worse if there are high-level categorical variables, because a categorical variable having m categorical values permits $(2^{m-1} - 1)$ splits of the form $s = \{X \in \omega\}$. For example, variable S permits $(2^{9-1} - 1) = 255$ splits, which is almost three times as many splits as D allows. The earliest warning on the potential for the bias to produce misleading conclusions seems to be [18].

GUIDE avoids the bias by using a two-step approach to split selection. First, it uses significance tests to select the X variable. Then it searches for c or ω for X . For linear regression trees, this is achieved by fitting a linear model to the data in the node and using a contingency table chi-squared test of the association between grouped values of each predictor variable and the signs of the residuals. If X is ordinal, the groups are intervals between certain order statistics. If X is categorical, the groups are the categorical levels. Then the X variable having the smallest chi-squared p -value is selected. Repeating this procedure recursively produces a large binary tree that is pruned to minimize a cross-validation estimate of prediction mean squared error [16].

Let $\hat{p}(x)$ denote the estimated value of $p(x) = P(Y = 1 | X = x)$. The preceding split variable selection method needs modification for logistic regression, because the residual $y - \hat{p}(x)$ is positive if $y = 1$ and negative if $y = 0$, irrespective of the value of $\hat{p}(x)$. Consequently, the residual

Fig. 30.5 Estimated p -functions in terminal nodes of the tree in Fig. 30.4

signs provide no information on the adequacy of $\hat{p}(x)$. A first attempt at a solution was proposed in [19], where the residuals $y - \hat{p}(x)$ are replaced with “pseudo-residuals” $\bar{p}(x) - \hat{p}(x)$, with $\bar{p}(x)$ being a weighted average of the y values in a neighborhood of x . Its weaknesses are sensitivity to choice of weights and neighborhoods and difficulty in specifying the neighborhoods if the dimension of the predictor space is large or if there are missing values. LOTUS uses a trend-adjusted chi-squared test [20, 21] that effectively replaces $\bar{p}(x)$ with a linear estimate.

For logistic regression, GUIDE uses the average from an ensemble of least-squares GUIDE regression trees (called a “GUIDE forest”) to form the pseudo-residuals for variable selection. The main steps are as follows:

1. Fit a least-squares GUIDE forest [22] to the data to obtain a preliminary estimate $\bar{p}(x)$ of $p(x)$ for each observed x . (Random forest [23] cannot substitute for GUIDE forest if the data contain missing values.)
2. Beginning with the root node, carry out the following steps on the data in each node, stopping only if the number of observations is below a pre-specified threshold or if all the values of the predictor variables or the Y values are constant:
 - (a) For each X variable to be used in fitting an OLR model in the node, temporarily impute its missing values with its node sample mean.
 - (b) Fit a simple or multiple linear OLR model to the imputed data in the node. If a simple linear OLR model is desired, fit one to each linear predictor variable in turn, and choose the one with smallest residual deviance.

Let $\hat{p}(x)$ denote the estimated value of $p(x)$ from the fitted model.

- (c) Revert the imputed values in step (2a) to their original missing state.
- (d) For each ordinal X variable, let $q_1 \leq q_2 \leq q_3$ denote its sample quartiles at the node, and define the categorical variable $V = \sum_{j=1}^3 I(X > q_j)$. If X is a categorical variable, define $V = X$. Add an extra “missing” category to V if X has missing values.
- (e) Form a contingency table for each X variable using the signs of $\bar{p}(x) - \hat{p}(x)$ as rows and the values of V as columns. Find the chi-squared statistic χ_v^2 for the test of independence between rows and columns.
- (f) Let $G_v(x)$ denote the distribution function of a chi-squared variable with v df, and let $\epsilon = 2 \times 10^{-6}$. Convert each χ_v^2 to its equivalent one-df χ_1^2 value as follows:
 - i. If $\epsilon < G_v(\chi_v^2) < 1 - \epsilon$, define $\chi_1^2 = G_1^{-1}(G_v(\chi_v^2))$.
 - ii. Otherwise, to avoid dealing with very small or large p-values, use the following dual application of the Wilson-Hilferty approximation [24]. Define

$$W_1 = \left\{ \sqrt{2\chi_v^2} - \sqrt{2v-1} + 1 \right\}^2 / 2$$

$$W_2 = \max \left(0, \left[\frac{7}{9} + \sqrt{v} \left\{ \left(\frac{\chi_v^2}{v} \right)^{1/3} - 1 + \frac{2}{9v} \right\}^3 \right] \right).$$

Approximate the one-df chi-squared value with

$$\chi_1^2 = \begin{cases} W_2 & \text{if } \chi_v^2 < v + 10\sqrt{2v} \\ (W_1 + W_2)/2 & \text{if } \chi_v^2 \geq v + 10\sqrt{2v} \text{ and } \\ & W_2 < \chi_v^2 \\ W_1 & \text{otherwise.} \end{cases}$$

An earlier one-step approximation is used in [7]. Tables 30.2 and 30.3 show the contingency tables and corresponding chi-squared statistics for Species, Intensity, and Diameter at the root node of the tree in Fig. 30.4.

- (g) Let X^* be the variable with the largest value of χ_1^2 , and let NA denote the missing value code:
 - i. If X^* is ordinal, let s be a split of the form $\{X^* = \text{NA}\}$, $\{X^* \leq c\} \cup \{X^* = \text{NA}\}$, or $\{X^* \leq c\} \cap \{X^* \neq \text{NA}\}$.
 - ii. If X^* is categorical, let s be a split of the form $\{X^* \in \omega\}$, where ω is a proper subset of the values (including NA) of X^* .
 - (h) For each split s , apply steps (2a) and (2b) to the data in the left and right subnodes induced by s , and let $d_L(s)$ and $d_R(s)$ be their respective residual deviances.
 - (i) Select the split s that minimizes $d_L(s) + d_R(s)$.
3. After splitting stops, prune the tree with the CART cost-complexity method [16] to obtain a nested sequence of subtrees.
 4. Use the CART cross-validation method to estimate the prediction deviance of each subtree.
 5. Select the smallest subtree whose estimated prediction deviance is within a half standard error of the minimum.

Figure 30.6 shows the LOTUS tree for the current data. MOB [25] is another algorithm that can construct a LRT, but for simple linear LRT models, it requires the linear predictor to be pre-specified and to be the same in all terminal nodes. Figure 30.7 shows the MOB tree with L as the common

linear predictor. Figure 30.8 compares the values of $\hat{p}(x)$ from a GUIDE forest of 500 trees, model (30.9) and the simple linear GUIDE, LOTUS, and MOB LRT models. Although there are clear differences in the values of $\hat{p}(x)$ between GUIDE, LOTUS, and MOB, they seem to compare similarly against (30.9) and GUIDE forest. Figure 30.9 shows the corresponding results where LOTUS fits the multiple linear LRT model $\text{logit}(p) = \beta_0 + \beta_1 D + \beta_2 L$ and GUIDE and MOB fit $\text{logit}(p) = \beta_0 + \beta_1 D + \beta_2 L + \sum_{j=1}^8 \gamma_j U_j$ in each terminal node. (LOTUS does not convert categorical variables to indicator variables to serve as regressors.) The correlations among the $\hat{p}(x)$ values are much higher.

30.4 Missing Values and Cyclic Variables

The US National Highway Traffic Safety Administration has been evaluating vehicle safety by performing crash tests with dummy occupants since 1972 ([ftp://www.nhtsa.dot.gov/ges](http://www.nhtsa.dot.gov/ges)).

Fig. 30.8 Comparison of fitted values \hat{p} of Cook-Weisberg model (30.9) and GUIDE forest versus simple linear LRT models

We use data from 3310 crash tests where the test dummy is in the driver's seat to show how GUIDE deals with missing values and cyclic variables. Each test gives the severity of head injury (HIC) sustained by the dummy and the values of about 100 variables describing the vehicle, test environment, and the test dummy. The response variable is $Y = 1$ if $HIC > 1000$ (threshold for severe head injury) and $Y = 0$ otherwise. About half of the predictor variables are ordinal, six are cyclic, and the rest are categorical.

Three features in the data make model building particularly challenging. The first is missing data. Missing values in categorical variables are not problematic, as they can be assigned a "missing" category. Missing values in other variables, however, need to be imputed before application of OLR. This can be extraordinarily difficult if there are many missing values and the missingness patterns are complex [22, 26]. All ordinal and cyclic variables here have missing values. Table 30.4 gives the names and numbers of missing values of some of them (see [27] for the others). For example, IMPANG, the angle between the axis of a vehicle and the

axis of another vehicle or barrier, is undefined for a rollover crash test, where there is no barrier and only one vehicle is involved. In such cases, the value of IMPANG is recorded as missing and imputing it with a number is inappropriate. The situation is worse for variable CARANG, which has 991 missing values. Given that the crash tests are carefully monitored and have been performed for years, it is unlikely for so many observations to be missing by chance.

For split selection, GUIDE sends all missing values in the selected ordinal or cyclic variable either to the left or to the right subnode, depending on which split gives a smaller sum of residual deviances in the two subnodes. Hence no imputation is carried out in this step. To fit an OLR model to a node, GUIDE imputes missing values in the selected predictor variable with its node mean.

A second challenging feature is the presence of cyclic variables that are angles with periods of 360 degrees. These variables are traditionally transformed to sines and cosines, but splits on one of them at a time are not as meaningful as splits on the angles themselves. The problem is more

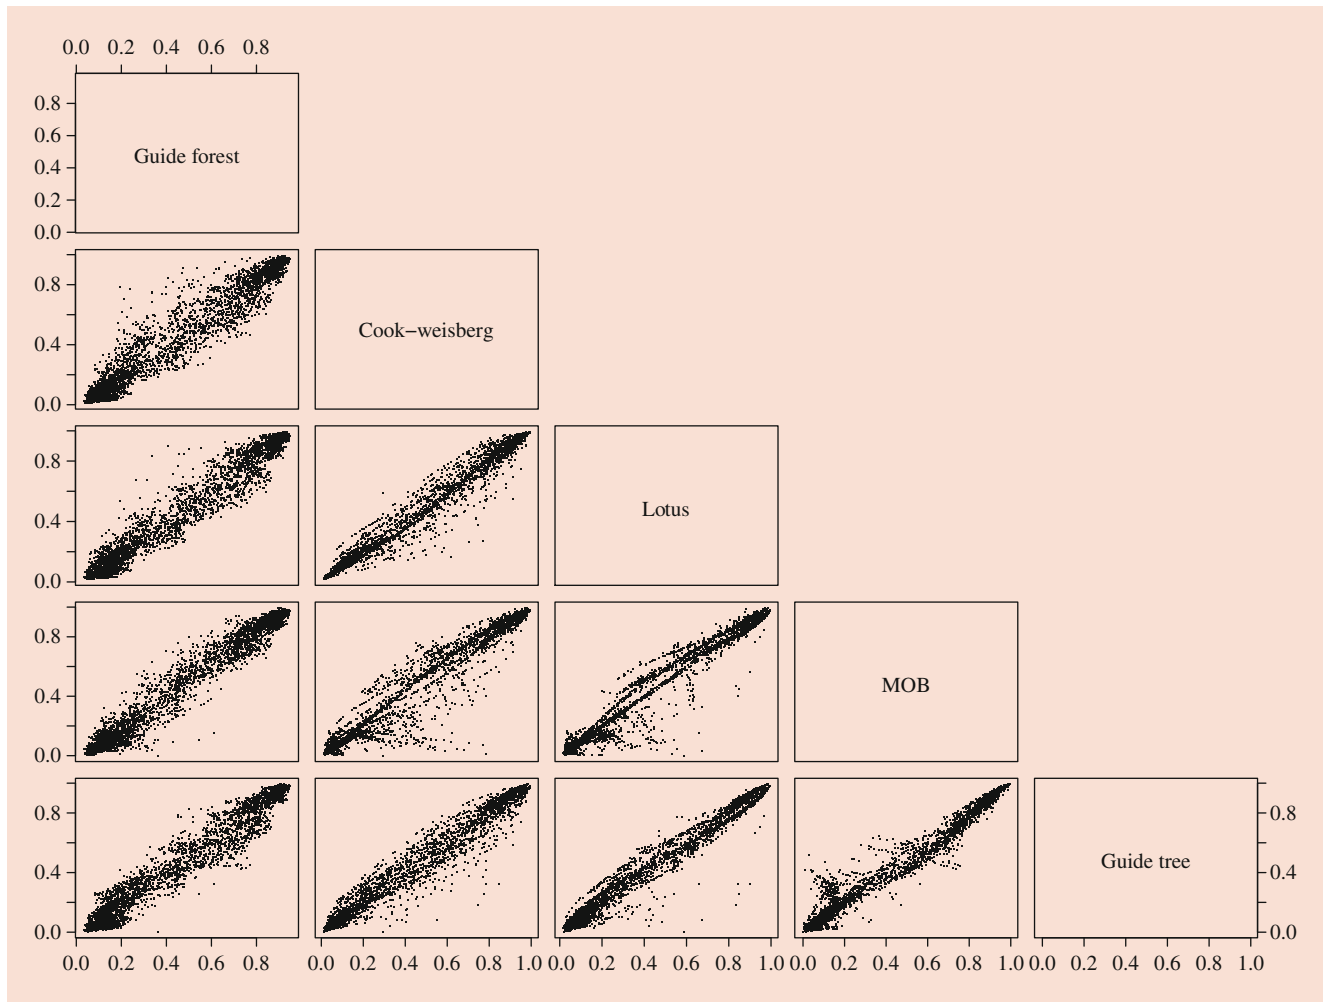

Fig. 30.9 Comparison of fitted values \hat{p} of Cook-Weisberg model (30.9) and GUIDE forest versus multiple linear LRT models

Table 30.4 Definitions and numbers of missing values of some predictor variables in the crash-test data

Variable	Description	Missing
BARRIG	Rigid or deformable barrier	1
BARSHP	Barrier shape (21 types)	0
BX2	Rear surface of vehicle to front of engine	288
BX5	Rear surface of vehicle to upper leading edge of left door	288
CARANG	Angle between surface of rollover test cart and ground	991
COLMEC	Steering column collapse mechanism (9 types)	248
ENGDSP	Engine displacement	24
IMPANG	Angle between axis of vehicle 2 and axis of vehicle 1 or barrier (0 degree is perpendicular to barrier)	4
CLSSPD	Closing speed: relative velocity of approach of two centers of gravity before contact	2
VEHSPD	Resultant speed of vehicle before impact	1
VEHTWT	Vehicle test weight	4
VEHWID	Vehicle width	90
WHLBAS	Vehicle or impactor's wheelbase	30
YEAR	Vehicle model year	4

difficult if the variable has missing values. Should we impute the angles and then compute the sines and cosines of the imputed values, or should we impute the sines and cosines

directly? GUIDE avoids imputation entirely by restricting cyclic variables to split the nodes. If a cyclic variable is selected, the split takes the form of a sector “ $X \in [\theta_1, \theta_2]$,”

where θ_1 and θ_2 are angles, and missing values are sent to the left or right subnode in the same fashion as noncyclic variables.

The third challenging feature is that, apparently by design, high-speed crash tests are more often carried out on deformable barriers and low-speed tests more often on rigid

barriers. This is evident from the boxplots of CLSSPD by BARRIG in Fig. 30.10, where half of the tests with deformable barriers are above closing speeds of 60 km/h, but less than one quarter of those with rigid barriers are above 60 km/h. Presumably, crashes into rigid barriers are not performed at high speeds because the outcomes are predictable, but this confounds the effects of CLSSPD and BARRIG in an OLR model.

We say that X is an “s” variable if it can be used to *split* the nodes and an “f” variable if it can be used to *fit* OLR models in the nodes. To limit the amount of imputation in this example, we restrict ordinal variables with more than 20 percent missing values to serve as s variables only. Cyclic and categorical variables are also restricted to splitting nodes.

Figure 30.11 shows the LRT where a simple linear OLR model is fitted in each node. The root node is split on COLMEC, which is steering wheel collapse mechanism. Observations with COLMEC equal to BWU (behind wheel unit), EMB (embedded ball), EXA (extruded absorber), NON (none), or OTH (other) go to node 2. Otherwise, if COLMEC is CON (convoluted tube), CYL (cylindrical mesh tube), NAP (not applicable), UNK (unknown), or missing, observations go to node 3. At node 2, observations go to node 4 if $BX2 \leq 3496.5$ or missing (the asterisk beside the inequality sign in the figure indicates that missing values go to the left node). At node 3,

Fig. 30.10 Boxplots of closing speed by barrier rigidity for the crash-test data, with box width proportional to square root of sample size

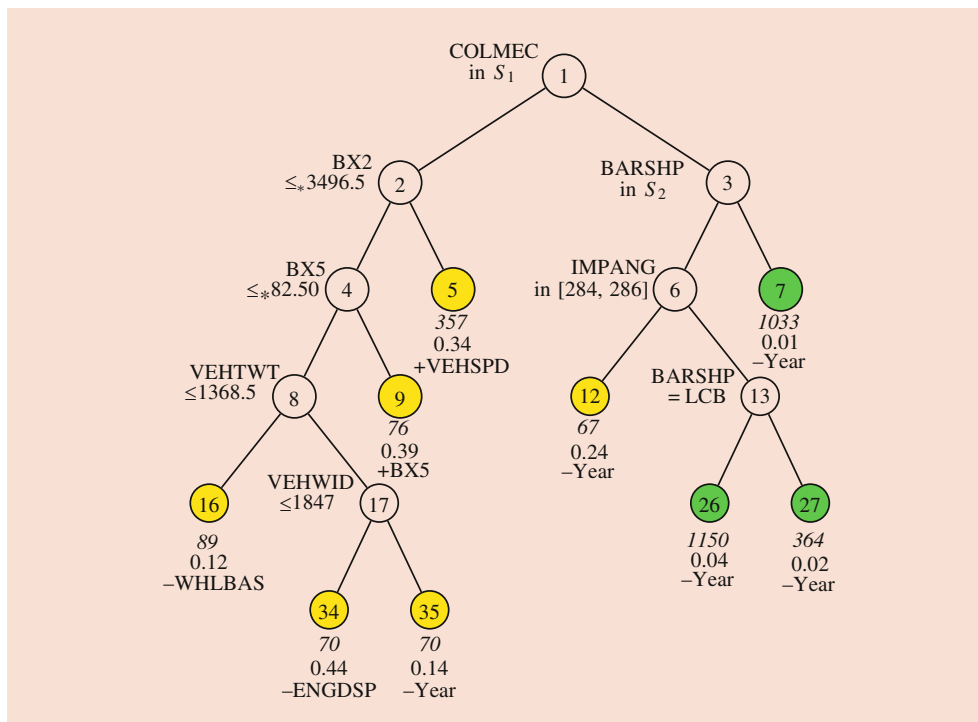

Fig. 30.11 GUIDE piecewise simple linear LRT for crash-test data. At each split, an observation goes to the left branch if and only if the condition is satisfied. The symbol “ \leq_* ” stands for “ \leq or missing.” Set $S_1 = \{BWU, EMB, EXA, NON, OTH\}$. Set $S_2 = \{LCB, POL, US2, US3\}$.

Sample size (*in italics*), proportion of cases with $Y = 1$, and sign and name of regressor variable printed below nodes. Terminal nodes with proportions of $Y = 1$ above and below value of 0.08 at root node are colored yellow and green, respectively

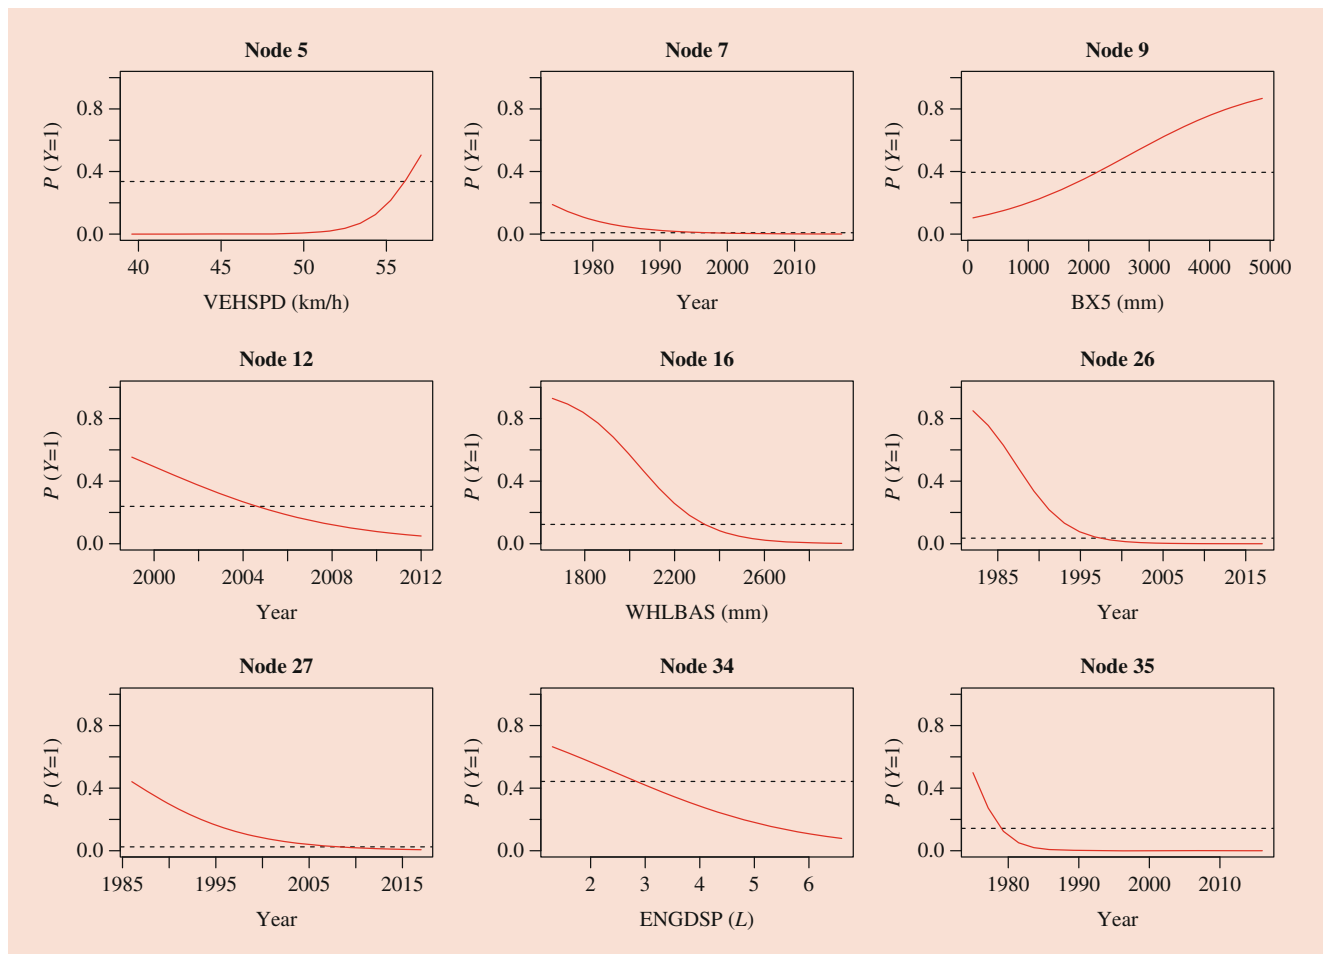

Fig. 30.12 Fitted logistic regression curves in terminal nodes of Fig. 30.11; horizontal dotted lines indicate proportion of severe injury in the node

observations go to node 6 if BARSHP is LCB (load cell barrier), POL (pole), US2, or US3 (different barrier types). Node 6 is split on impact angle IMPANG, where 0 degree indicates impact is head-on. If an observation has IMPANG between 284 and 286 degrees inclusive (i.e., Driver side), it goes to node 12. The 2-degree range may seem narrow, but there are 67 observations in the node, suggesting that the tests were by design. Below each terminal node are the sample size (in *italics*), proportion of $Y = 1$, and the selected OLR predictor variable, with the sign of its estimated coefficient.

The tree shows that nodes 5, 9, and 34 have the highest proportions of severe head injury, at 34, 39, and 44%, respectively. Vehicles in these nodes have certain steering wheel collapse mechanisms, and they tend to be longer ($BX2 > 3496.5$ or $BX5 > 82.5$) or are heavy ($VEHTWT > 1368.5$) and narrow ($VEHWID \leq 1846$). Figure 30.12 shows the fitted logistic regression curves in the terminal nodes. The proportion of tests with severe head injury is indicated by a dotted line in each plot.

30.5 Conclusion

Logistic regression is a technique for estimating the probability of an event in terms of the values of one or more predictor variables. If there are missing values among the predictor variables, they need to be imputed first. Otherwise, the observations or variables containing the missing values would need to be deleted. Neither solution is attractive. In practice, finding a logistic regression model with good prediction accuracy is seldom automatic; it usually requires trial-and-error selection of variables, choice of transformations, and estimation of the accuracy of numerous models. Even when a model with good estimated accuracy is found, interpretation of the regression coefficients is not straightforward if there are two or more predictor variables.

A logistic regression tree is a piecewise logistic regression model, with the pieces obtained by recursively partitioning the space of predictor variables. Consequently, if there

is no over-fitting, it may be expected to possess higher prediction accuracy than a one-piece logistic regression model. Recursive partitioning has two advantages over a search of all partitions: it is computationally efficient and it allows the partitions to be displayed as a decision tree. At a minimum, a logistic regression tree can serve as an informal goodness of fit test of whether a one-piece logistic model is adequate for the whole sample. A nontrivial pruned tree would indicate that a one-piece logistic model has lower prediction accuracy, possibly due to unaccounted interactions or nonlinearities among the variables. Ideally, an effective tree-growing and pruning algorithm would automatically account for the overlooked effects, making it unnecessary to specify interaction and higher-order terms. It would also allow the models in the terminal nodes to be as simple as desired (such as fitting a single linear predictor in each node).

Tree pruning is very important for prediction accuracy. Many methods adopt the AIC-type approach of selecting the tree that minimizes the sum of the residual deviance and a multiple, K , of the number of terminal nodes. There being no value of K that works for all datasets [16], the advantage of this approach is mainly computational speed. Our experience indicates that it is inferior to a pruning approach that uses cross-validation to estimate prediction accuracy.

Despite a binary decision tree being intuitive to interpret, a poor split selection method can yield misleading conclusions. A common cause is selection bias. The greedy approach used by CART and many other algorithms is known to prefer variables that permit more splits of the data. Consequently, it is hard to know if a variable is chosen due to its predictive power or because it has more ways to partition the data. LOTUS and GUIDE avoid the bias by selecting variables with chi-squared tests. At the time of completion of this article, GUIDE is the only tree algorithm that can deal with cyclic variables and with two or more missing value codes [22]. The GUIDE software and manual may be obtained from www.stat.wisc.edu/~loh/guide.html.

Abstract

This chapter reviews diagnostic and robust procedures for detecting outliers and other interesting observations in linear regression. First, we present statistics for detecting single outliers and influential observations and show their limitations for multiple outliers in high-leverage situations. Second, we discuss diagnostic procedures designed to avoid masking by finding first a clean subset for estimating the parameters and then increasing its size by

incorporating, one by one, new homogeneous observations until a heterogeneous observation is found. We also discuss procedures based on sensitive observations for detecting high-leverage outliers in large data sets using the eigenvectors of a sensitivity matrix. We briefly review robust estimation methods and its relationship with diagnostic procedures. Next, we consider large high-dimensional data sets where the application of iterative procedures can be slow and show that the joint use of simple univariate statistics, as predictive residuals, Cook’s distances, and Peña’s sensitivity statistic, can be a useful diagnostic tool. We also comment on other recent procedures based on regularization and sparse estimation and conclude with a brief analysis of the relationship of outlier detection and cluster analysis. A real data and a simulated example are presented to illustrate the procedures presented in the chapter.

Cook’s distance · Influential observations · Influence matrix · Leverage · Masking · Predictive residuals · Sensitivity matrix · Robust estimation

31.1 Introduction

Data often contains outliers or atypical observations. Outliers are points which are heterogeneous with the rest, due to large measurement errors, different experimental conditions, or unexpected variability. Detecting these observations is important: first, because they can lead to new discoveries and, second, because they can modify completely the conclusions we draw from the data. For instance, penicillin was found because Pasteur instead of ignoring an outlier tried to understand the reason of an atypical effect. As Box [1] has emphasized: “Every operating system supplies information

D. Peña (✉)
 Department of Statistics, Universidad Carlos III de Madrid, Madrid, Spain
 e-mail: daniel.pena@uc3m.es

on how it can be improved and if we use this information it can be a source of continuous improvement.” A way in which this relevant information may appear is in outlying observations that, in many engineering processes, can show the way to improve the process. For instance, in a production process, a large value in one of the variables we monitor may be due, among other causes, to (1) a large value of one of the input control variables, (2) an unexpected interaction among the input variables, and (3) a large measurement error due to some defect in the measurement instrument. In the first case, the outlying observations may provide no new information about the performance of the process; in the second case, may lead to a potentially useful discovery; and in the third one, to an improvement of the process control.

Detection of outliers has a long tradition in engineering statistics, see Chapter 1 of Hampel et al. [2], and now it has a growing importance in the big data environment. Many communications and controlling devices are automatically collecting large data sets with many observations and variables using wireless sensor networks. Sensor nodes sometime fail to record the data correctly, due to depletion of batteries or environmental influence, and congestion in communication may lead to packet loss. These failures will produce outliers, and their identification is very important when building regression models as otherwise we may fail to explain the relationship between the variables in the data set. An alternative way to deal with the problem of contaminated data is to use robust methods that avoid large outliers effects on the estimation of the parameters, and this approach will be also briefly discussed.

This chapter defines outliers, influential and sensitive observations in regression models, and presents diagnostic methods to detect them. Outliers are observations that are very different from its forecast, or interpolation, with the rest of the available data. Note that this implies that an outlier is defined with respect to a model, or in general a rule to forecast the observations, and, therefore, an observation can be an outlier given a model and a common point under another. Influential observations are those which have a strong influence on the estimation of the model parameters. Again, as outliers, they are model dependent. These observations are obtained by looking at the standardized change they produce in the parameter vector or in the vector of forecasts. Influence is a global analysis. A third type of interesting points in the sample is sensitive observations which are those points that suffer an unusual influence from the rest of the sample. Sensitivity is more a local concept, it shows how each observation is affected by the rest, and it is computed by deleting each sample point in turn and looking at the change that these modifications produce in the forecast of a single point. We will see that influence and sensitivity are important concepts for understanding the effect of data in building a regression model and in finding groups of outliers.

Many procedures are available to identify a single outlier or an isolated influential point in linear regression. The books of Belsley et al. [3], Hawkins [4], Cook and Weisberg [5], Atkinson [6], Chatterjee and Hadi [7], Barnett and Lewis [8], Atkinson and Riani [9], and Carroll [10] present good analyses of this problem. To identify outliers and to measure influence, each point can be deleted, as proposed by Cook [11] and Belsley et al. [3], or its weight decreased, as in the local influence analysis introduced by Cook [12]. See Suárez Rancel and González Sierra [13] and Hartless et al. [14] for a review of local influence in regression and many references. A related way to analyze influence has been proposed by Critchley et al. [15] by an extension of the influence-curve methodology.

The detection of influential subsets, or multiple outliers, is more difficult due to the masking and swamping problems. Masking occurs when one outlier is not detected because of the presence of others; swamping happens when a non-outlier is wrongly identified due to the effect of some hidden outliers, see Lawrance [16]. Several procedures have been proposed for dealing with multiple outliers; see Hawkins et al. [17], Gray and Ling [18], Marasinghe [19], Kianifard and Swallow [20,21], Hadi and Simonoff [22,23], Atkinson [24], and Swallow and Kianifard [25]. A different analysis for detecting groups of outliers by looking at the eigenvectors of an influence matrix, or even better those of a sensitivity matrix, is presented by Peña and Yohai [26,27].

We briefly discuss in this chapter the relationship between these diagnostic procedures and robust regression methods. See Huber [28] and Hampel et al. [2] for good discussions of the complementary role of diagnosis and robustness and for robust estimation in regression and the books by Rousseeuw and Leroy [29] and Maronna et al. [30] for robust regression estimates. This problem has also received attention in the Bayesian literature since the seminal article of Box and Tiao [31]. See Peña and Guttman [32], Berger et al. [33], Justel and Peña [34], and Hans [35] for a Bayesian approach to this problem and references.

The chapter is organized as follows. In Sect. 31.2 we present the regression model and the notation we will use in this chapter and define the main measures which will be introduced for outlier analysis. Section 31.3 reviews procedures for detecting single outliers and influential observations in regression. In Sect. 31.4 we discuss the multiple outlier problem and two types of diagnostic procedures: first, those based on an initial clean subset and, second, those based on eigenvalue analysis of some diagnostic matrices. Section 31.5 briefly discusses robust estimation and its connection to diagnostic methods. Section 31.6 presents some fast procedures to find outliers in large data sets. In particular we introduce a simple statistic proposed by Peña [36] as a diagnostic tool for large data set that avoids the masking problem. Section 31.7 includes two ex-

amples, one simulated and the other with real data, to illustrate some of the diagnostic methods presented for detecting groups of outliers. Section 31.8 summarizes some concluding remarks.

31.2 Residuals and Leverage in the Regression Model

We assume that we have observed a sample of size n of a random variable $\mathbf{y} = (y_1, \dots, y_n)'$ and a set of $p - 1$ explanatory variables which are linearly related by

$$y_i = \mathbf{x}_i' \boldsymbol{\beta} + u_i, \quad (31.1)$$

where the u_i are the measurement errors, which will be independent normal zero mean random variables with variance σ^2 and $\mathbf{u} = (u_1, \dots, u_n)'$. The $\mathbf{x}_i = (1, x_{2i}, \dots, x_{pi})'$ s are numerical vectors in R^p , and we will denote by \mathbf{X} the $n \times p$ matrix of rank p whose i -th row is \mathbf{x}_i' . The usual criterion to estimate the parameters $\boldsymbol{\beta}$ is to minimize

$$\sum_{i=1}^n (y_i - \mathbf{x}_i' \boldsymbol{\beta})^2 \quad (31.2)$$

that is the least squares (LS) criterion that is optimal for normally distributed data. The LS estimate of $\boldsymbol{\beta}$ is obtained by projecting the vector \mathbf{y} on the space generated by the columns of \mathbf{X} , which leads to

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y},$$

and the vector of fitted values, $\hat{\mathbf{y}} = (\hat{y}_1, \dots, \hat{y}_n)'$, is given by

$$\hat{\mathbf{y}} = \mathbf{X}\hat{\boldsymbol{\beta}} = \mathbf{H}\mathbf{y}, \quad (31.3)$$

where $\mathbf{H} = \mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'$ is the idempotent projection matrix. The vector orthogonal to the space generated by the \mathbf{X} variables is the residual vector, $\mathbf{e} = (e_1, \dots, e_n)'$, which is defined by

$$\mathbf{e} = \mathbf{y} - \hat{\mathbf{y}} = \mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}} = (\mathbf{I} - \mathbf{H})\mathbf{y}, \quad (31.4)$$

and we will let $\hat{\sigma}_R^2 = \mathbf{e}'\mathbf{e}/(n - p)$ be the estimated residual variance.

From (31.4), inserting $\mathbf{X}\boldsymbol{\beta} + \mathbf{u}$ instead of \mathbf{y} and using $\mathbf{H}\mathbf{X} = \mathbf{X}$, we obtain the relationship between the residuals and the measurement errors, $\mathbf{e} = (\mathbf{I} - \mathbf{H})\mathbf{u}$. Thus, each residual is a linear combination of the measurement errors. Letting $h_{ij} = \mathbf{x}_i'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_j$ be the elements of the matrix, \mathbf{H} , we have

$$e_i = u_i - \sum_{j=1}^n h_{ij}u_j \quad (31.5)$$

and, if the second term is small, the residual e_i will be close to the measurement error, u_i . The variance of this second term is

$$\text{var}\left(\sum_{j=1}^n h_{ij}u_j\right) = \sigma^2 \sum_{j=1}^n h_{ij}^2 = \sigma^2 h_{ii}$$

and if h_{ii} , the diagonal term of \mathbf{H} , is large, the difference between the residual and the measurement error can be large. The values h_{ii} are called the leverage of the observation and measure the discrepancy of each observation \mathbf{x}_i with respect to the mean of the explanatory variables. It can be shown (see, for instance, [11] p. 12) that

$$h_{ii} = \mathbf{x}_i'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_i = \frac{1}{n} \left(1 + (\tilde{\mathbf{x}}_i - \bar{\mathbf{x}})' \mathbf{S}_{xx}^{-1} (\tilde{\mathbf{x}}_i - \bar{\mathbf{x}})\right)$$

where $\tilde{\mathbf{x}}_i = (x_{2i}, \dots, x_{pi})$ does not include the constant term, $\bar{\mathbf{x}}$ is the vector of means of the $p - 1$ explanatory variables, and \mathbf{S}_{xx} is their covariance matrix. Note that if the explanatory variables were uncorrelated, h_{ii} would be the sum of the standardized distances to the means, $((x_{ij} - \bar{x}_j)/s_j)^2$. As $\sum_{i=1}^n h_{ii} = \text{tr}(\mathbf{H}) = p$, the average value of the leverage is $\bar{h} = \sum h_{ii}/n = p/n$, and it can be shown that $1/n \leq h_{ii} \leq 1$. From (31.5) we conclude that the residual will be close to the measurement error for those observations close to the center of the explanatory data, where $h_{ii} \simeq 1/n$, but will be very different for the extreme points where $h_{ii} \simeq 1$. The residual covariance matrix is

$$\text{Var}(\mathbf{e}) = E[\mathbf{e}\mathbf{e}'] = E((\mathbf{I} - \mathbf{H})\mathbf{u}\mathbf{u}'(\mathbf{I} - \mathbf{H})) = \sigma^2(\mathbf{I} - \mathbf{H}) \quad (31.6)$$

and $\text{Var}(e_i) = \sigma^2(1 - h_{ii})$, which will be large when $h_{ii} \simeq 1/n$ and close to zero if $h_{ii} \simeq 1$. As the mean of the residuals is zero if the variance of e_i is very small, this implies that its value will be close to zero, whatever the value of u_i is.

To avoid residuals with different variances, the standardized residuals are defined as

$$r_i = \frac{e_i}{\hat{\sigma}_R \sqrt{1 - h_{ii}}} \quad (31.7)$$

which will have variance equal to one. A third type of useful residuals are the predictive, deleted, or out-of-sample residuals, defined by $e_{(i)} = y_i - \hat{y}_{i(i)}$, where $\hat{y}_{i(i)}$ is computed in a sample with the i th observation deleted. It can be shown that

$$e_{(i)} = \frac{e_i}{(1 - h_{ii})} \quad (31.8)$$

and the variance of these predictive residuals is $\sigma^2/(1 - h_{ii})$. If we estimate σ^2 by $\hat{\sigma}_{(i)R}^2$, the residual variance in a regression which does not include the i th observation, the standardization of the predictive residual leads to the studentized residual, defined by

$$\hat{t}_i = \frac{e_i}{\hat{s}_{R(i)}\sqrt{1-h_{ii}}} \quad (31.9)$$

which has a student t distribution with $n-p-1$ degrees of freedom. An alternative useful expression of these residuals is based on $h_{ii(i)} = \mathbf{x}'_i (\mathbf{X}_{(i)}\mathbf{X}_{(i)})^{-1} \mathbf{x}_i = h_{ii}/(1-h_{ii})$, where $\mathbf{X}_{(i)}$ is the $(n-1) \times p$ matrix without the row \mathbf{x}'_i , and therefore, we have the alternative expression

$$\hat{t}_i = \frac{e^{(i)}}{\hat{s}_{R(i)}\sqrt{1+h_{ii(i)}}}. \quad (31.10)$$

31.3 Diagnosis for a Single Outlier

31.3.1 Outliers

If one observation, y_h , does not follow the regression model, either because its expected value is not $\mathbf{x}'_h\boldsymbol{\beta}$ or its conditional variance is not σ^2 , we will say that this observation is an outlier. The discrepancy is usually translated to the residual. For instance, if the h th observation has not been generated by the linear model $y_h = \mathbf{x}'_h\boldsymbol{\beta} + u_h$, but by a different model, $g(\mathbf{x}'_h) + u_h$, then

$$e_h = g(\mathbf{x}'_h) - \mathbf{x}'_h\hat{\boldsymbol{\beta}} + u_h$$

and the h th point will be an outlier if the deviation $|g(\mathbf{x}'_h) - \mathbf{x}'_h\hat{\boldsymbol{\beta}}|$ is much larger than $|\mathbf{x}'_h(\boldsymbol{\beta} - \hat{\boldsymbol{\beta}})|$. Suppose, in order to simplify, that $g(\mathbf{x}'_h) = \mathbf{x}'_h\boldsymbol{\alpha}$, that is, the data are also generated by a linear model but with different parameter values. Then, even if $\boldsymbol{\alpha}$ is very different from $\boldsymbol{\beta}$, the size of $|\mathbf{x}'_h(\boldsymbol{\alpha} - \hat{\boldsymbol{\beta}})|$ depends on \mathbf{x}'_h , and the discrepancy between the parameter values would be easier to detect when $|\mathbf{x}'_h|$ is large than when it is small. When the observation is an outlier because its measurement error comes from a different distribution, for instance, one with variance $k\sigma^2$, instead of σ^2 , where $k > 1$, we expect that $|u_h|$ will be larger than the rest of the measurement errors. It is intuitive, and it has been formally shown [33] that we cannot differentiate between a change in the mean and a change in the variance of a distribution by using just one observation; also models which assume a change in the variance are equivalent to those which assume shifts in the mean of the observations. Thus, a simple model for a single outlier at time h th is to consider the mean shift model

$$y_h = \mathbf{x}'_h\boldsymbol{\beta} + w + u_h \quad (31.11)$$

where w is the size of the outlier and u_h is $N(0, \sigma^2)$. In general, the size of a possible outlier at every point is estimated by the parameter w in the model

$$y_i = \mathbf{x}'_i\boldsymbol{\alpha} + wI_i^{(h)} + u_i, \quad i = 1, \dots, n \quad (31.12)$$

where $I_i^{(h)}$ is a dummy variable given by $I_i^{(h)} = 1$, when $i = h$, and $I_i^{(h)} = 0$ otherwise. We can test for outliers by fitting this model for $h = 1, \dots, n$ and checking if the estimated coefficient \hat{w}_h is significant. It is easy to show that:

- (1) $\hat{\boldsymbol{\alpha}}_h = (\mathbf{X}'_{(h)}\mathbf{X}_{(h)})^{-1} \mathbf{X}'_{(h)}\mathbf{y}_{(h)} = \hat{\boldsymbol{\beta}}_{(h)}$, the regression parameters in the model with the dummy variable at point h th are estimated by deleting the case (y_h, \mathbf{x}_h) affected by the dummy variable and applying to the rest of the observations the usual procedure;
- (2) $\hat{w}_h = y_h - \mathbf{x}'_h\hat{\boldsymbol{\alpha}}_h$, and, therefore, the estimated residual at the h th point is zero, as $e_h = y_h - \mathbf{x}'_h\hat{\boldsymbol{\alpha}}_h - \hat{w}_h = 0$.
- (3) The t statistic to check if the parameter \hat{w}_h is significant is equal to the studentized residual, t_h , as defined in (31.9).

Assuming that only one observation is an outlier, the test is made by comparing the standardized residual to the maximum of a t distribution with $n-p-2$ degrees of freedom. Often, for moderate n , a point is considered as an outlier if its studentized residual is larger than 3.5.

31.3.2 Influential Observations

An intuitive way to measure the effect of an observation on the vector of estimated parameters, or in the vector of forecasts, is to delete this observation from the sample and see how its deletion affects these vectors. A measure of the influence of the i th observation on the parameter estimate is given by

$$D(i) = \frac{(\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(i)})\mathbf{X}'\mathbf{X}(\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(i)})}{p\hat{s}_{R}^2}, \quad (31.13)$$

which, as the covariance of $\hat{\boldsymbol{\beta}}$ is $\hat{s}_{R}^2(\mathbf{X}'\mathbf{X})^{-1}$, measures the change between $\hat{\boldsymbol{\beta}}$ and $\hat{\boldsymbol{\beta}}_{(i)}$ with relation to the covariance matrix of $\hat{\boldsymbol{\beta}}$, standardized by the dimension of the vector p . This measure was introduced by Cook [11]. Of course, other standardizations are possible, Belsley et al. [3] proposed using instead of \hat{s}_{R}^2 , the variance of the regression model when the i th observation is deleted, $\hat{s}_{(i)R}^2$, and Diaz-García and Gonzalez-Farias [37] have suggested standardizing the vector $(\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(i)})$ by its variance, instead of using the variance of $\hat{\boldsymbol{\beta}}$. See Cook, Peña and Weisberg [38] for a comparison of some of these possible standardizations.

Equation (31.13) can also be written as the standardized change in the vector of forecast:

$$D_i = \frac{(\hat{\mathbf{y}} - \hat{\mathbf{y}}_{(i)})' (\hat{\mathbf{y}} - \hat{\mathbf{y}}_{(i)})}{p \hat{s}_R^2} \tag{31.14}$$

where $\hat{\mathbf{y}}_{(i)} = \mathbf{X} \hat{\boldsymbol{\beta}}_{(i)} = (\hat{y}_{1(i)}, \dots, \hat{y}_{n(i)})'$. Note that from (31.3) we have that $\text{var}(\hat{y}_i) = \sigma^2 h_{ii}$ and as the average value of h_{ii} is p/n , (31.14) is standardized by this average value and by the dimension, n , of the vector. A third way to measure the influence of the i th point is to compare \hat{y}_i with $\hat{y}_{(i)}$, where $\hat{y}_{(i)} = \mathbf{x}_i' \hat{\boldsymbol{\beta}}_{(i)}$. With the usual standardization by the variance, we have

$$D_i = \frac{(\hat{y}_i - \hat{y}_{(i)})^2}{p \hat{s}_R^2 h_{ii}} \tag{31.15}$$

and using the relation between the inverse of $\mathbf{X}'\mathbf{X}$ and $\mathbf{X}'_{(i)}\mathbf{X}_{(i)}$, we obtain

$$\boldsymbol{\beta} - \hat{\boldsymbol{\beta}}_{(i)} = (\mathbf{X}'\mathbf{X})^{-1} \mathbf{x}_i \frac{e_i}{1 - h_{ii}} \tag{31.16}$$

inserting this in (31.13), it is easy to see that (31.15) is equivalent to (31.13) and (31.14). Also, as from (31.16) we have that

$$\hat{\mathbf{y}} - \hat{\mathbf{y}}_{(i)} = \mathbf{h}_i \frac{e_i}{1 - h_{ii}} \tag{31.17}$$

where \mathbf{h}_i is the i th column of the \mathbf{H} matrix. Using this expression in (31.14), we obtain a convenient way to compute Cook's statistic:

$$D_i = \frac{r_i^2 h_{ii}}{p(1 - h_{ii})} \tag{31.18}$$

where r_i is the standardized residual given by (31.7). For large n , the expected value of D_i can be approximated by

$$E(D_i) \simeq \frac{h_{ii}}{p(1 - h_{ii})}, \tag{31.19}$$

and it will be very different for observations with different leverage.

Cook proposed judging the values of D_i by an $F(p; n - p; 1 - \alpha)$, where F is the distribution used in building a confidence region for the $\boldsymbol{\beta}$ parameters. Thus, we may identify points as influential when they are able to move the estimate out of the confidence region for a fixed value of α and declare as influential those observations which verify $D_i \geq F(p; n - p; 1 - \alpha)$. This solution is not satisfactory for large sample size because it is difficult that any observation is deemed as influential. Muller and Mok [39] have obtained the distribution of the D_i for normal explanatory variables, but this distribution is complicated.

Cook [12] proposed a procedure for the assessment of the influence on a vector of parameters $\boldsymbol{\theta}$ of minor perturbations of a statistical model. This approach is very flexible and can be used to see the effect of small perturbations which would not normally be detected by deletion of one observation. He suggested introducing a $n \times p$ vector $\boldsymbol{\omega}$ of case weights and

using the likelihood displacement $(L(\hat{\boldsymbol{\theta}}) - L(\hat{\boldsymbol{\theta}}_\omega))$, where $\hat{\boldsymbol{\theta}}$ is the maximum likelihood (ML) estimator of $\boldsymbol{\theta}$ and $\hat{\boldsymbol{\theta}}_\omega$ the ML when the case weight ω is introduced. Then, he showed that the directions of greatest local change in the likelihood displacement for the linear regression model are given by the eigenvectors linked to the largest eigenvalues of the curvature matrix, $\mathbf{L} = \mathbf{EHE}$, where \mathbf{E} is the vector of residuals. Later, we will see the relation of this approach to some procedures for multiple outlier detection.

31.3.3 The Relationship Between Outliers and Influential Observations

An outlier may or may not be an influential observation, and an influential observation may or may not be an outlier. To illustrate this point, consider the data in Table 31.1. We will use these data to build four data sets. The first one includes cases 1 to 9 repeated three times and has sample size $n = 27$. The other three sets are formed by adding a new observation to this data set. The set (a) is built by adding case 28(a), the set (b) by adding case 28(b), and the set (c) by adding case 28(c). Table 31.2 shows some statistics of these four data sets where (0) refers to the set of 27 observations and (a), (b), and (c) to the sets of 28 observations, as defined before. The table gives the values of the estimated parameters, their t statistics under parenthesis, the residual standard deviation, the leverage of the added point, the standardized residual for the added point, and the value of Cook's statistics.

In set (a) observation 28 is clearly an outlier with a value of the standardized residual of 4.68, but it is not influential, as $D_{28(a)} = 0.92$ which is a small value. In case (b) the 28th point is not an outlier as $r_{28(b)} = 1.77$ is not significant, but

Table 31.1 Three sets of data which differ in one observation

Case	1	2	3	4	5	6	7	8	9	(a)	(b)	(c)
\mathbf{x}_1	-2	0	2	-4	3	1	-3	-1	4	0	-3	-3
\mathbf{x}_2	6, 5	7, 3	8, 3	6, 0	8, 8	8, 0	5, 9	6, 9	9, 5	7, 2	9, 7	7, 3
\mathbf{y}	-1, 5	0, 5	1, 6	-3, 9	3, 5	0, 8	-2, 7	-1, 3	4, 1	5	-1, 5	4

Table 31.2 Some statistics for the three regression fitted to the data in Table 31.1

	$\hat{\beta}_0$	$\hat{\beta}_2$	$\hat{\beta}_1$	\hat{s}_R	h_{28}	r_{28}	D_{28}
(0)	2.38 (0.82)	-0.30 (0.78)	1.12 (6.24)	0.348	-	-	-
(a)	13.1 (1.7)	-1.72 (-1.66)	1.77 (3.69)	0.96	0.11	4.68	0.92
(b)	-2.74 (-2.9)	0.38 (3.08)	0.80 (13.87)	0.36	0.91	1.77	11.1
(c)	-25.4 (-5.41)	3.43 (5.49)	-0.624 (2.22)	0.91	0.65	4.63	13.5

it is very influential as is indicated by the large D_{28} value. Finally, in set (c) the observation is both an outlier, $r_{28} = 4.63$, and very influential, $D_{28} = 13.5$.

Note that if the leverage is small $h_{ii} \simeq 1/n$, $h_{ii}/(1-h_{ii}) \simeq (n-1)^{-1}$, and by (31.18)

$$D_i = \frac{r_i^2}{p} \left(\frac{1}{n-1} \right)$$

then if n is large, the observation cannot be influential, whatever the value of r_i^2 . On the other hand, high-leverage observations with h_{ii} close to one will have a ratio $h_{ii}/(1-h_{ii})$ arbitrarily large and, even if r_i^2 is small, will be influential

31.4 Diagnosis for Groups of Outliers

The procedures that we have presented in the previous section are designed for a single outlier. We can extend these ideas to multiple outliers as follows. Let I be an index set corresponding to a subset of r data points. The checking of this subset can be done by introducing dummy variables, as in the univariate case. Assuming normality, the F test for the hypothesis that the coefficients of the dummy variables are zero is given by

$$F_{r,(n-p-r)} = \frac{\mathbf{e}'_I(\mathbf{I} - \mathbf{H}_I)^{-1}\mathbf{e}_I}{r\hat{s}_{(r)R}^2}$$

where \mathbf{e}_I is the vector of least squares residuals; \mathbf{H}_I the $r \times r$ submatrix of \mathbf{H} , corresponding to the set of observations included in I ; and $\hat{s}_{(r)R}^2$ the residual variance of the regression with the set I deleted. Cook and Weisberg [5] proposed to measure the joint influence of the data points with index in I by deleting the set I and computing, as in the single outlier case,

$$D_I = \frac{(\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(I)})\mathbf{X}'\mathbf{X}(\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(I)})}{p\hat{s}_R^2}$$

which can also be written, as a generalization of (31.18), by $D_I = (\mathbf{e}'_I(\mathbf{I} - \mathbf{H}_I)^{-1}\mathbf{H}_I(\mathbf{I} - \mathbf{H}_I)^{-1}\mathbf{e}_I)/p\hat{s}_R^2$. Note that a large value of D_I may be due to a single influential observation included in the set I , but it can also be due to the sum of small individual effects of a set of observations that are masking each other. However, in the first case, this single observation will be easily identified. Also, a subset of individually highly influential points, whose effect is to cancel each other out, will lead to a small value of D_I , but, again in this case, the individual effects will be easy to identify. However, to build this measure, we should compute all the set of I in the n data, and this task will be impossible to do for large I and n .

The procedures for finding multiple outliers in regression can be divided into three main groups. The first one is based on robust estimation that will be discussed in Sect. 31.5. The

main idea is to compute an estimate that is not affected by the outliers and then find the outliers as those cases with large residuals with respect to the robust fit. A second class of procedures uses also robust ideas to build an initial clean subset and then combine least squares estimates in clean subsets and diagnosis ideas for outlier detection. Three procedures in this spirit will be presented next, and they can be very effective when p and n are not large. For large data sets with many predictors and high-leverage observations, robust estimates can be very difficult to compute, and procedures based on the clean set idea may not work well, because of the difficulty in selecting the initial subset. The third type of procedures is based on the eigen-structure analysis of some diagnostic matrices and is specially useful for large data sets.

31.4.1 Methods Based on an Initial Clean Set

Kianifard and Swallow [20, 21] proposed to build a “clean” set of observations and check the rest of the data with respect to this set. If the observation closest to the clean set is not an outlier, then increase the “clean” set by one observation, and continue checking points until no new observation can be incorporated into the basic set. The key step in this procedure is to find the initial subset because if it contains outliers, all the procedure breaks down. These authors proposed using either the predictive or standardized residuals or a measure of influence as D_i .

A similar procedure was proposed by Hadi and Simonoff [22, 23]. They recommend building the initial subset using as robust estimate the least median of squares estimate (LMS) that will be presented in Sect. 31.5. The clean set is built by computing this robust estimate and then uses the $h = \lceil \frac{n+p+1}{2} \rceil$ observations with the smallest residuals with respect to this robust fit to form the initial “clean” set, which we call M . The procedure continues by fitting a regression model by least squares to this clean set, M . Calling $\hat{\boldsymbol{\beta}}_M$ the LS estimated parameters and $\hat{\sigma}_M$ the residual standard deviation, a set of in-sample and out-of-sample residuals is obtained as follows:

$$d_i = \frac{|y_i - \mathbf{x}'_i\hat{\boldsymbol{\beta}}_M|}{\hat{\sigma}_M\sqrt{1 - \mathbf{x}'_i(\mathbf{X}'_M\mathbf{X}_M)^{-1}\mathbf{x}_i}}, \quad \text{if } i \in M$$

$$d_i = \frac{|y_i - \mathbf{x}'_i\hat{\boldsymbol{\beta}}_M|}{\hat{\sigma}_M\sqrt{1 + \mathbf{x}'_i(\mathbf{X}'_M\mathbf{X}_M)^{-1}\mathbf{x}_i}}, \quad \text{if } i \notin M$$

That is, d_i represents the standardized residual (31.7) for the data in set M and the predictive residual (31.10) for observations outside this set. Then, all the observations are arranged in increasing order according to d_i . Let s be the size of the set M (which is h in the first iteration, but will be changing as explained below). If $d_{(s+1)}$ is smaller than some critical value, a new set of size $s+1$ is built with the

$s + 1$ observations with smallest d values. If $d_{(s+1)}$ is larger than some critical value, all observations out of the set M are declared as outliers, and the procedure stops. If $n = s + 1$, we stop and declare no outliers in the data. These authors proposed using as critical values those of the t distribution adjusted by Bonferroni, that is, $t(\frac{\alpha}{2(s+1)}, s - p)$.

Atkinson [24, 40] proposed a similar approach called the forward search. His idea is again to combine a robust estimate with diagnostic analysis. He computes also the LMS estimate but instead of generating a large set of candidates by random sample, he generates a set of candidate values of $\hat{\boldsymbol{\beta}}$ fitting by least squares subsamples of size $p, p + 1, \dots, n$. The procedure is as follows. We start generating a random sample of size p , let I_p the indices of the observations selected. Then, we compute the parameters $\hat{\boldsymbol{\beta}}(p)$ by LE and the residual for all the cases, $\mathbf{e} = \mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}(p)$. The residuals are corrected by

$$\begin{aligned} u_i^2 &= e_i^2, & i \in I \\ u_i^2 &= e_i^2 / (1 + h_{ii}), & i \notin I \end{aligned} \quad (31.20)$$

and these residuals, u_i^2 , are ordered and the smallest $p + 1$ are selected. With this new sample of size $m = p + 1$, the process is repeated, that is, the parameters are computed by LE and the residuals to this fit for the n points are obtained. The corrected residuals (31.20) are computed and the process is continued. In this way we obtain a set of estimates, $\hat{\boldsymbol{\beta}}(m)$, $m = p, \dots, n$, the corresponding residuals; $\mathbf{e}(m) = \mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}(m)$; and the robust scales (31.27), $s(\boldsymbol{\beta}(m))$. The value selected is the $\hat{\boldsymbol{\beta}}(m)$ which minimizes the robust scale. This process is a complete forward search, and several forward searches are done starting by different random samples. The residuals are then identified by using this LMS estimate

computed from several forward searches. An improvement of this procedure was proposed by Atkinson and Riani [9], which separates clearly the estimation of the clean subset and the forward search. The initial estimate is computed as proposed by LMS, by taking many random samples of size p . Then, the forward search is applied but stressing the use of diagnostic statistics for monitoring the performance of the procedure. Finally, Swallow and Kianifard [25] suggest also a similar procedure which uses a robust estimate of the scale and determines the cutoff values for the testing from simulations.

These procedures work when both p and n are not large and the proportion of outliers is moderate, as shown in the simulated comparison by Wisnowski et al. [41]. However, they do not work as well in large data sets with high contamination. The LMS estimates rely on having at least a sample of size p without outliers, and we need an unfeasible number of samples to have a large probability of this event when p and n are large (see [27]). This good initial estimate is the key for the procedures of the clean set. In the next section, we will present more effective procedures for large data sets.

31.4.2 Methods Based on Eigenvectors of the Influence and Sensitivity Matrix

The matrix of forecast changes was defined by Peña and Yohai [26] by looking at the vectors of changes in the forecast vector when each observation is deleted. Calling as before \hat{y}_i to the forecast of the i th observation and $\hat{y}_{i(j)}$ to the forecast when the parameters are computed deleting the j th observations, this matrix of forecast changes is given by

$$\mathbf{T} = \begin{bmatrix} \hat{y}_1 - \hat{y}_{1(1)} & \hat{y}_1 - \hat{y}_{1(2)} & \cdots & \hat{y}_1 - \hat{y}_{1(n-1)} & \hat{y}_1 - \hat{y}_{1(n)} \\ \hat{y}_2 - \hat{y}_{2(1)} & \hat{y}_2 - \hat{y}_{2(2)} & \cdots & \hat{y}_2 - \hat{y}_{2(n-1)} & \hat{y}_2 - \hat{y}_{2(n)} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ \hat{y}_{n-1} - \hat{y}_{n-1(1)} & \hat{y}_{n-1} - \hat{y}_{n-1(2)} & \cdots & \hat{y}_{n-1} - \hat{y}_{n-1(n-1)} & \hat{y}_{n-1} - \hat{y}_{n-1(n)} \\ \hat{y}_n - \hat{y}_{n(1)} & \hat{y}_n - \hat{y}_{n(2)} & \cdots & \hat{y}_n - \hat{y}_{n(n-1)} & \hat{y}_n - \hat{y}_{n(n)} \end{bmatrix}$$

The columns of this matrix are the vectors $\mathbf{t}_i = \hat{\mathbf{y}} - \hat{\mathbf{y}}_{(i)}$, and the Cook's statistic (31.14) is their standardized norm. These vectors can also be written as $\mathbf{t}_i = \mathbf{e}_{(i)} - \mathbf{e}$, where $\mathbf{e}_{(i)}$ is the vector of residuals when observation i th is deleted. Therefore, \mathbf{T} can also be considered the matrix of residual changes. Peña and Yohai [26] define the $n \times n$ influence matrix \mathbf{M} as

$$\mathbf{M} = \frac{1}{ps_R^2} \mathbf{T}'\mathbf{T}.$$

The matrix \mathbf{T} has columns $\mathbf{X}(\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(i)})$, and using (31.16) it is easy to see that the ij -th element of \mathbf{M} is

$$m_{ij} = \frac{e_i e_j h_{ij}}{(1 - h_{ii})(1 - h_{jj})ps_R^2} = \frac{e_{i(i)} e_{j(j)} h_{ij}}{ps_R^2}.$$

and \mathbf{M} can be written as

$$\mathbf{M} = \frac{1}{ps_R^2} \mathbf{W}\mathbf{H}\mathbf{W} \quad (31.21)$$

where \mathbf{W} is the diagonal matrix of predictive residuals (31.8). Assuming that all the residuals are different from zero, from (4) the rank of \mathbf{M} is equal to p , the rank of \mathbf{H} . Observe that the diagonal elements of \mathbf{M} are the Cook's statistics.

Let $r_{ij} = m_{ij}/m_{ii}^{1/2}m_{jj}^{1/2}$ be the uncentered correlation coefficient between \mathbf{t}_i and \mathbf{t}_j . Let us show that the eigenvectors of the matrix \mathbf{M} will be able to indicate groups of influential observations. Suppose that there are k groups of influential observations I_1, \dots, I_k , such that:

- (i) If $i, j \in I_h$, then $|r_{ij}| = 1$. This means that the effects on the least squares fit produced by the deletion of two points in the same set I_h have correlation 1 or -1 .
- (ii) If $i \in I_j$ and $l \in I_h$ with $j \neq h$, then $r_{il} = 0$. This means that the effects produced on the least squares fit by observations i and j belonging to different sets are uncorrelated.
- (iii) If i does not belong to any I_h , then $m_{ij} = 0$ for all j . This means that data points outside these groups have no influence on the fit.

Now, according to (i) we can split each set I_h in I_h^1 and I_h^2 such that: (1) If $i, j \in I_h^q$, then $r_{ij} = 1$. (2) If $i \in I_h^1$ and $j \in I_h^2$, then $r_{ij} = -1$. Let $\mathbf{v}_1 = (v_{11}, \dots, v_{1n})', \dots, \mathbf{v}_k = (v_{k1}, \dots, v_{kn})'$ be defined by $v_{hj} = m_{ij}^{1/2}$ if $j \in I_h^1$, $v_{hj} = -m_{ij}^{1/2}$ if $j \in I_h^2$, and $v_{hj} = 0$ if $j \notin I_h$. Then, if (i)–(iii) hold, by (6) the matrix \mathbf{M} is

$$\mathbf{M} = \sum_{i=1}^k \mathbf{v}_i \mathbf{v}_i'$$

and since the \mathbf{v}_i 's are orthogonal, the eigenvectors of \mathbf{M} are $\mathbf{v}_1, \dots, \mathbf{v}_k$, and the corresponding eigenvalues $\lambda_1, \dots, \lambda_k$ are given by

$$\lambda_h = \sum_{i \in I_h} m_{ii}.$$

It is clear that when the matrix \mathbf{M} satisfies (i)–(iii), the only sets I with large C_I are I_h^q , $1 \leq h \leq k$, $q = 1, 2$, and these sets may be found by looking at the eigenvectors associated with non-null eigenvalues of \mathbf{M} . Note that (6) can also be written as

$$r_{ij} = \text{sign}(e_i)\text{sign}(e_j)h_{ij}/(h_{ii}h_{jj})^{1/2}$$

which means that, in the extreme case that we have presented, the \mathbf{H} matrix and the signs of the residuals are able, by themselves, to identify the set of points that are associated with masking. For real data sets, (i)–(iii) do not hold exactly. However, the masking effect is typically due to the presence of blocks of influential observations in the sample having similar or opposite effects. These blocks are likely to produce a matrix \mathbf{M} with a structure close to the one described on (i)–(iii). In fact, two influential observations i, j producing similar effects should have r_{ij} close to 1 and close to -1 when they have opposed effects. Influential observations with non-correlated effects have $|r_{ij}|$ close to 0. The same

will happen with non-influential observations. Therefore, the eigenvectors will have approximately the structure described above, and the null components will be replaced by small values. This suggests finding the eigenvectors corresponding to the p non-null eigenvalues of the influence matrix \mathbf{M} , considering the eigenvectors corresponding to large eigenvalues, and defining the sets I_j^1 and I_j^2 by those components with large positive and negative weights, respectively.

The influence matrix \mathbf{M} may be considered a generalization of Cook's local influence matrix $\mathbf{L} = \mathbf{EHE}$ (see Cook [12]). It replaces the matrix of residuals \mathbf{E} by the matrix of standardized residuals \mathbf{W} . If there are no high-leverage observations and the h_{ii} are similar for all points, both matrices will also be similar and will have similar eigenvectors. However, when the observations have very different leverage, the directions corresponding to the eigenvectors of the matrix \mathbf{M} give more weight to the influence of the high-leverage observations, which are precisely those more likely to produce masking effects.

An alternative way to analyze the information contained in the matrix of forecast changes, \mathbf{T} , is to look at its rows instead of at its columns. The rows of \mathbf{T} indicate the sensitivity of each point, that is, how the forecast of a given point is affected by all the other points in the sample. In fact the rows of this matrix

$$\mathbf{s}_i = (\widehat{y}_i - \widehat{y}_{i(1)}, \dots, \widehat{y}_i - \widehat{y}_{i(n)})'$$

describe how the forecast of the i th observation is affected by deleting any of the observations in the sample. From (31.17) we can write

$$\mathbf{s}_i = (h_{i1}e_1/(1 - h_{11}), \dots, h_{in}e_n/(1 - h_{nn})) = \mathbf{W}\mathbf{h}_i, \tag{31.22}$$

where \mathbf{W} is the diagonal matrix con elements $e_i/(1 - h_{ii})$ and \mathbf{h}_i is the i th column of \mathbf{H} . Peña and Yohai [27] define the sensitivity matrix as the covariance matrix of the sensitivity vectors of the sample points by

$$\mathbf{P} = \frac{1}{p\widehat{s}_R^2} \begin{bmatrix} \mathbf{s}'_1 \mathbf{s}_1 & \dots & \mathbf{s}'_1 \mathbf{s}_n \\ \dots & \dots & \dots \\ \mathbf{s}'_n \mathbf{s}_1 & \dots & \mathbf{s}'_n \mathbf{s}_n \end{bmatrix}.$$

with elements

$$p_{ij} = \frac{1}{p\widehat{s}_R^2} \mathbf{h}'_i \mathbf{W}^2 \mathbf{h}_j = \frac{1}{p\widehat{s}_R^2} \sum_{k=1}^n \frac{e_k^2}{(1 - h_{kk})^2} h_{ik} h_{jk},$$

which can be computed by

$$\mathbf{P} = \frac{1}{p\widehat{s}_R^2} \mathbf{H}\mathbf{W}^2\mathbf{H}. \tag{31.23}$$

It can be shown that the sensitivity and the influence matrix have both rank p and the same eigenvalues but different eigenvectors. In fact, influence and sensitivity are complementary ways to look at the observations, and the sum of the influence of all the points is equal to the sum of sensitivities. Peña and Yohai [27] have shown that the eigenvectors of the sensitivity matrix are more powerful to identify groups of outliers than those of the influence matrix and have proposed the following iterative procedure for identifying groups of outliers avoiding the masking effect:

Iteration 1: Put $k = 1$, and form a set A_1 that includes $3p + 1$ possible regression LS estimates computed as follows. The first is the standard LS estimate, computed by using all the data points. Then, for each of the p eigenvector \mathbf{z}_i , $1 \leq i \leq p$, of the \mathbf{P} matrix, with elements z_{ij} , $1 \leq j \leq n$, we obtain three other LS estimates: the first is computed dropping the points corresponding to the m largest elements z_{ij} , the second to the m smallest elements, and the third to the largest $|z_{ij}|$. Then define

$$\widehat{\boldsymbol{\beta}}^{(k)} = \arg \min_{\boldsymbol{\beta} \in A_k} S(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})$$

where S is a robust measure of variability of the residuals as the MAD (median of the absolute values of the residuals) and

$$\widehat{\sigma}^{(k)} = \min_{\boldsymbol{\beta} \in A_k} S(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})$$

is the value of this scale.

Iteration k : Suppose that we have selected a value $\widehat{\boldsymbol{\beta}}^{(k)}$. Compute the residuals $e_i^{(k)} = y_i - \mathbf{x}_i' \widehat{\boldsymbol{\beta}}^{(k)}$ for $1 \leq i \leq n$, and all observations with residual larger than

$$\left| e_i^{(k)} \right| > C \widehat{\sigma}^{(k)}$$

are deleted, and the rest of observations are used to a new sensitivity matrix (31.23), and its eigenvectors are used to compute the new set of estimates A_{k+1} . The procedure ends when $\widehat{\boldsymbol{\beta}}^{(k)} = \widehat{\boldsymbol{\beta}}^{(k-1)}$ and the observations deleted in the last iteration formed the set of outliers in the sample.

The values recommended by Peña and Yohai are $m = n/2$ and $C = 2$.

31.5 Robust Regression

An alternative approach to search for outliers is to use estimation methods that are robust to outliers. It is well known that LS is optimal for normal distributed data, but it may be inefficient when the data comes from a heavy tail distribution that can produce outliers. The breakdown point of an estimator is defined as the minimum fraction of outliers in the sample that makes the estimate take any arbitrary

value. For instance, the LS estimate has a breakdown point of $1/n$ because a single outlier may change $\boldsymbol{\beta}$ to any arbitrary value. If instead of LS we use a robust estimate with high breakdown point, b/n , and we have a fraction of outlier smaller than this number, b/n , we can find atypical points as observations with high residuals with respect to the robust model. These robust estimates can be obtained by, instead of finding the parameters that minimize the squared residuals as in (31.2), minimizing another function of the residuals that grows slower than the squares or, even better, that is bounded, so that the maximum effect of an outlier is limited. Robust estimation and diagnostic methods are complementary ways to analyze the problem of data heterogeneity. Diagnostic methods emphasize the need to find the possible outliers, whereas robust methods try to estimate the parameters in such a way that they are not affected by possible outliers. Both approaches complement each other, and the best procedures are often those that use ideas and results coming from both fields.

A general class of robust estimates for regression are M-estimators that minimize

$$M = \sum_{i=1}^n \rho \left(\frac{e_i(\boldsymbol{\beta})}{\widehat{\sigma}} \right) \quad (31.24)$$

where ρ is a nondecreasing bounded function with $\rho(0) = 0$, and $\rho(\infty) = 1$, so that the effect of each residual, $e_i(\boldsymbol{\beta}) = y_i - \mathbf{x}_i' \boldsymbol{\beta}$, is bounded, and $\widehat{\sigma}$ is an initial estimate of σ that makes the M-estimate independent of the scale of the observations. Particular members of this class are the LS estimate obtained, for $\rho(x) = x^2$, and the L_1 estimate, for $\rho(x) = |x|$. Note also that these two estimates do not require an initial value of $\widehat{\sigma}$. For M-estimates the value of $\widehat{\sigma}$ can be obtained by an initial estimate that does not require the scale, as, for instance, minimizing the L_1 distances

$$\sum_{i=1}^n |y_i - \mathbf{x}_i' \widehat{\boldsymbol{\beta}}^L| = \sum_{i=1}^n |e_i^L|$$

that gives an estimate more robust than LS. Then, we can obtain an initial estimate, $\widehat{\sigma}$, by the MAD (median of absolute deviations) of these residuals by

$$\widehat{\sigma} = \frac{1}{0.675} \text{Med}(|e_i^L|, e_i^L \neq 0).$$

The function (31.24) is minimized by an iterative algorithm as follows. Taking the derivative of M in (31.24) with respect to $\boldsymbol{\beta}$, the estimate must verify

$$\sum_{i=1}^n \rho' \left(\frac{e_i(\boldsymbol{\beta})}{\widehat{\sigma}} \right) \mathbf{x}_i = 0 \quad (31.25)$$

where $\rho'(x) = d\rho(x)/dx$. Now we define the weight function

$$\omega(x) = \rho'(x)/x \quad \text{if } \neq 0; \quad \omega(0) = 0$$

and the solution of (31.25) can be written as

$$\sum_{i=1}^n \omega_i(y_i - \mathbf{x}'_i \boldsymbol{\beta}) \mathbf{x}_i = 0$$

where $\omega_i = \omega(e_i(\boldsymbol{\beta})/\hat{\sigma})$; this implies

$$\boldsymbol{\beta} = \left(\sum_{i=1}^n \omega_i \mathbf{x}_i \mathbf{x}'_i \right)^{-1} \left(\sum_{i=1}^n \omega_i y_i \mathbf{x}_i \right) \quad (31.26)$$

that is a weighted LS estimate that gives a weight to each observation that depends on its standardized residual $e_i(\boldsymbol{\beta})/\hat{\sigma}$, so that observations with large residuals will have small weight in the estimation. The function (31.24) is minimized by using some initial $\boldsymbol{\beta}$ value to obtain the residuals and then computing a new value of the estimate by (31.26). This estimate will produce new residuals and new weights, and this procedure is iterated until convergence.

These M-estimates are useful when the samples only have low-leverage outliers but do not work for high-leverage outliers because, as we have seen, the residuals at these points can be very small. A better alternative is the MM-estimates in which the estimation is made in two steps: (1) an initial consistent estimate $\hat{\boldsymbol{\beta}}_0$ is computed that has high breakdown point, although it may be non-efficient, and a robust scale is obtained with this estimate; (2) Eq. (31.24) is minimized by the previous iterative procedure starting with $\hat{\boldsymbol{\beta}}_0$.

A possible initial consistent estimate is the least median of squares (LMS) estimate, proposed by Rousseeuw [42], that is computed by generating many possible values of the parameters, $\boldsymbol{\beta}_1, \dots, \boldsymbol{\beta}_N$ by resampling: many random samples of size p , $(\mathbf{X}_i, \mathbf{y}_i)$ where the matrix \mathbf{X}_i is $p \times p$ and \mathbf{y}_i is $p \times 1$, are generated, and with each sample the LS estimate, $\boldsymbol{\beta}_i = \mathbf{X}_i^{-1} \mathbf{y}_i$, is computed. For each value $\boldsymbol{\beta}_i$ ($i = 1, \dots, N$), the residuals associated are obtained, $\mathbf{e}_i = \mathbf{y} - \mathbf{X} \boldsymbol{\beta}_i$ ($i = 1, \dots, N$), and the median of these residuals is used to form a robust scale

$$s(\boldsymbol{\beta}_i) = \text{median}(e_{1i}^2, \dots, e_{ni}^2). \quad (31.27)$$

The value $\boldsymbol{\beta}_i$ which minimizes this robust scale is the LMS estimate. This LMS estimate, although very robust, is not efficient. A better method is to use as initial estimate the one proposed by Peña and Yohai [27] that we have presented in Sect. 31.4.2, which can be shown has a breakdown point close to 1/2 for high-leverage concentrated outliers and p/n small. See Maronna et al. [30] for a comparison of different estimates in regression.

31.6 Detecting Outliers in Large Data Sets

The previous procedures can be very useful for moderate data sets, but they can be very slow with big data with many variables and observations. In these large data sets, iterative procedures are unfeasible and other methods are required. In this section we will recommend a simple approach and review briefly other possibilities.

A useful approach is to compute a few diagnostic statistics that can identify single and masked outliers. For masked outliers Peña [36] has proposed a single statistic that is able to identify groups of high-leverage outliers, which are the most difficult to identify. This statistic can be obtained through a proper standardization of the diagonal elements of the sensitivity matrix. Peña's P_i statistic is defined as the squared norm of the standardized sensitivity vector \mathbf{s}_i , given by (31.22), that is,

$$P_i = \frac{\mathbf{s}'_i \mathbf{s}_i}{p \widehat{\text{var}}(\hat{y}_i)}, \quad (31.28)$$

and using (31.17) and $\widehat{\text{var}}(\hat{y}_i) = \widehat{s}_R^2 h_{ii}$, this statistic can be written as

$$P_i = \frac{1}{p \widehat{s}_R^2 h_{ii}} \sum_{j=1}^n \frac{h_{ji}^2 e_j^2}{(1 - h_{jj})^2}. \quad (31.29)$$

An alternative way to write P_i is as a linear combination of the sample Cook's distance. From (31.15) and (31.29), we have

$$P_i = \sum_{j=1}^n \rho_{ji}^2 D_j, \quad (31.30)$$

where $\rho_{ij} = (h_{ij}^2/h_{ii}h_{jj})^{1/2} \leq 1$ is the correlation between forecasts \hat{y}_i and \hat{y}_j . Also, using the predictive residuals, $e_{j(j)} = e_j/(1 - h_{jj})$, we have that

$$P_i = \frac{1}{p \widehat{s}_R^2} \sum_{j=1}^n \omega_{ji} e_{j(j)}^2 \quad (31.31)$$

and P_i is a weighted combination of the predictive residuals.

The sensitivity Peña's statistics has three interesting properties. The first one is that in a sample without outliers or high-leverage observations, all the cases have the same expected sensitivity, approximately equal to $1/p$. This is an important advantage over Cook's statistic, which has an expected value that depends heavily on the leverage of the case. The second property is that for large sample sizes with many predictors, the distribution of the S_i statistic will be approximately normal. This again is an important difference from Cook's distance which has a complicated asymptotic distribution (see Muller and Mock [39]). This

normal distribution allows for computing cutoff values for finding outliers. The third property is that when the sample is contaminated by a group of similar outliers with high leverage, the sensitivity statistic will discriminate between the outliers and the good points, and the sensitivity statistic S_i is expected to be smaller for the outliers than for the good data points.

The normality of the distribution of the S_i statistic implies that we can search for outliers by finding observations with large values of $(P_i - E(P_i))/std(P_i)$. As the possible presence of outliers and high-leverage points will affect the distribution of S_i , it is better to use robust estimates as the median and MAD (median of the absolute deviations from the sample median) and consider as heterogeneous observations those which satisfy

$$|P_i - med(P)| \geq 4.5MAD(P) \quad (31.32)$$

where $med(P)$ is the median of the P_i values and $MAD(P) = median |P_i - med(P)|$. For normal data $MAD(P)/.645$ is a robust estimate for the standard deviation, and the previous rule is roughly equivalent to take three standard deviations in the normal case. See Kashif et al. [43] for other applications of this statistic.

An alternative approach is based on using the simple idea of introducing dummy variables at each point in the sample. The basic model will be

$$y_i = \mathbf{x}'_i \boldsymbol{\beta} + \sum_{j=h_1}^{h_2} w_j I_j^{(i)} + u_i, \quad i = 1, \dots, n \quad (31.33)$$

where $I_j^{(i)}$ is a dummy variable such that $I_j^{(i)} = 1$ if $j = i$ and $I_j^{(i)} = 0$ if $j \neq i$, and we allow for the possibility of an outlier at each point $h_1 = 1$ and $h_2 = n$. This model cannot be estimated because it includes $p + n$ parameters, more than the n observations, and Hendry et al. [44] and Hendry and Doornik [45] proposed the following impulse indicator saturation method: (1) Introduce dummy variables in the first half of the observations and estimate model (31.33) with $h_1 = 1$ and $h_2 = n/2$, find observations with significant w_i coefficients, and form with them a set of potential outliers. (2) Estimate model (31.33) with $h_1 = n/2 + 1$ and $h_2 = n$ in the second half of the sample, and include the outliers found in this second half in the set of potential outliers. (3) Estimate a model with dummy variables corresponding to all the observations in the set of potential outliers, and check the new estimated parameters w_i for significance. In order to control for the large number of tests made in this process, the significance level of the t test on the coefficients of the dummy variables is chosen as $\alpha = 1/n$, so that we expect to find $n\alpha = 1$ false outlier in the sample. Johansen and Nielsen [46] have shown that this procedure can be related to M regression estimates.

This method may work well when the groups of outliers occur in patches along some clear dimension, as time. If we have data ordered over time, we expect that groups of outliers will be roughly consecutive and, therefore dividing the sample into two periods of time, they will be analyzed together. Of course, we may not see the effect of a patch of outliers that occur just in the middle of the observed period, because they will be split into the two halves, but we may have an opportunity in the final estimation where dummies from both sides can be included. However, this procedure may not be very useful when there is not a clear way to split the sample and the split is made at random. Then the probability that each group of outliers appear together in one of the two halves at random will be small. We will need to repeat the procedure several times with different random splitting, but this will be unfeasible for large data sets.

A third approach is also based on model (31.33), but instead of splitting the sample, restrictions are added to estimate the parameters. These procedures still require a heavy computational burden and therefore are not suitable for very large data sets, but they are presented here because they are based on sparse analysis that may lead to powerful future procedures for big data. She and Owen [47] proposed to estimate the model assuming sparsity of the coefficients w_i and adding a Lasso penalty function

$$\min \left(\sum_{i=1}^n (y_i - \mathbf{x}'_i \boldsymbol{\beta} + w_i I_i^{(h)})^2 + \sum_{i=1}^n \lambda_i |w_i| \right),$$

and Kong, Bondell, and Wu [48] improve this approach for many variables by adding penalties on the $\boldsymbol{\beta}$ and on the w_i coefficients. Thus, they propose to estimate the model

$$\min \left(\sum_{i=1}^n (y_i - \mathbf{x}'_i \boldsymbol{\beta} + w_i I_i^{(h)})^2 + \lambda_n \sum_{i=1}^n |\beta_i| + \mu_n \sum_{i=1}^n \frac{|w_i|}{|\tilde{w}_i|} \right) \quad (31.34)$$

where \tilde{w}_i are residuals of an initial robust regression fit and λ_n and μ_n are penalty parameters. In order to implement the procedure, we need some initial robust fit, and then (31.34) is minimized by a quadratic programming algorithm.

31.7 Examples

We will show two examples in order to illustrate the previous procedures. The first is a simulated example and the second a well-known data set.

31.7.1 A Simulated Example

As an illustration we will use the simulated data from Table 31.3, which are plotted in Fig. 31.1.

Fig. 31.1 The simulated data from Table 31.3

The three sets of data have in common cases 1 to 8 and differ in cases 9 and 10. In the first set of data, the largest values of the Cook’s statistics are $D_{10} = 0.795, D_1 = 0, 29$, and $D_9 = 0.228$. The most influential observation is the tenth which has a standardized residual $r_{10} = 1.88$; thus there is no evidence that the point is an outlier. However, the first eigenvector of the influence matrix leads to the results shown in Table 31.4. We see that both cases 9 and 10 appear separated from the rest. When they are deleted from the sample and checked against the first eight observations, we obtain the values indicated in Table 31.5, where they are clearly declared as outliers. Thus, in this example the eigenvalues of the influence matrix are able to avoid the masking effect which was clearly present in the univariate statistics.

In case (b) as both outliers have a different sign, they do not produce masking, and both of them are detected by the univariate analysis, $D_9 = 1.889$ and $D_{10} = 1.893$, and the outlier tests are $t_{10} = 5.20$ and $t_9 = -5.24$. The two points are also shown in the extremes of the eigenvalue. Finally in case (c) there is only an outlier which is detected by both the univariate and multivariate analysis.

Table 31.3 A simulated set of data from which three different samples are generated

	1	2	3	4	5	6	7	8	9(a)	10(a)	9(b)	10(b)	9(c)	10(c)
x	1	2	3	4	5	6	7	8	12	12	12	12	12	12
y	2.0	2.9	3.9	5.1	6.2	6.9	7.8	9.1	19	20	19	7	13	7

Table 31.4 Eigenanalysis of the influence matrix for the three samples from Table 31.3. The first two eigenvalues and the first eigenvector are shown

	λ_1	λ_1/λ_2	1	2	3	4	5	6	7	8	9	10
(a)	1.27	2.87	-.17	-.06	-.00	-.00	-.02	-.10	-.22	-.33	.42	.79
(b)	3.78	3.783	.00	-.00	-.00	-.00	-.00	.00	-.00	-.00	-.71	.71
(c)	3.25	32	-.05	-.02	-.00	-.00	-.01	-.02	-.04	-.10	-.50	.85

Table 31.5 Values of the t statistic for testing each point as an outlier

Case	9	10
(a)	27.69	32.28
(b)	31.94	-32.09
(c)	-0.07	-32.09

If we compute the eigenvectors of the sensitivity matrix for these data, we obtain the results presented in Table 31.6. The first eigenvector clearly separates the observations 9 and 10 from the rest. In fact, if we order the coordinates of this vector, we find the largest ratio at $170/22 = 8.5$ which separates cases 9 and 10 from the others.

31.7.2 The Housing Boston Data

We analyze the Boston housing data set which consists of 506 observations on 14 variables, available at <http://lib.stat.cmu.edu/datasets/boston>. This data set was given by Belsley et al. [3] and we have used the same variables they considered: The dependent variable is the logarithm of the median value of owner-occupied homes.

Figure 31.2 shows the diagnostic analysis of this data set. The first row corresponds to the residuals of the regression model. The residuals have been divided by their standard error, and the first plot shows a few points which can be considered as outliers. The plot of the studentized residual is similar and identifies the same points as outliers. The second row gives information about the Cook’s D statistics. There are clearly some points in the middle of the sample which are more influential than the rest, but all the values of the statistic are small and, as we expect a skew distribution, the conclusion is not clear. However, the sensitivity statistics clearly identifies a group of extreme observations which are not homogeneous with the rest. The median of the sensitivity statistic is 0.0762, very close to the expected value $1/p = 1/14 = 0.0714$. The MEDA is 0.0195 and the plot indicates that 45 observations are heterogeneous with respect to the rest. These observations are most of the cases 366–425 and some other isolated points. From Belsley et al. [3], we obtain that cases 357–488 correspond to Boston, whereas the rest correspond to the suburbs. Also, the 45 points indicated by

Table 31.6 Eigenvalues of the sensitivity matrix for data from Table 31.3

	1	2	3	4	5	6	7	8	9	10
v_1	0.502	0.455	0.407	0.360	0.312	0.264	0.217	0.170	-0.020	-0.020
v_2	-0.191	-0.119	-0.046	0.026	0.099	0.172	0.245	0.318	0.610	0.610

Fig. 31.2 Residuals, Cook’s statistics, and sensitivity statistics for the Boston housing data. Right, histogram; left, case plot of the value of the statistic

statistic S_i as outliers all correspond to some central districts of Boston, including downtown, which suggests that the relation among the variables could be different in these districts than in the rest of the sample. In fact, if we fit regression equations to these two groups, we find very different coefficients for the regression coefficients in both groups of data, and in the second group, only five variables are significant. Also, we obtain a large reduction in residual sum of squares (RSE) when fitting different regression equations in the two groups.

Figure 31.3 shows the first eigenvalues of the matrix of influence and sensitivity. Although both eigenvectors indicate the heterogeneity, the one from the matrix of sensitivity is more clear.

The procedure of impulse indicator saturation identifies 54 outliers in the second half of the observations correspond-

ing to the downtown area. In this case the procedure works well because the group of consecutive outliers is in agreement with the sequence of the observations.

31.8 Final Remarks

We have shown different procedures for diagnosis in regression model and have stressed that the detection of groups of outliers in regression in large data sets can be made by the eigenanalysis of the influence and sensitivity matrices. We have also shown that a single statistic of sensitivity is able to reveal masked outliers in large data set. The most challenging problem today is to identify heterogeneity when we do not have a central model which explains more than 50% of the data and some groups of outliers, as it has been

Fig. 31.3 First eigenvalue of the influence and sensitivity matrices

assumed in this chapter, but different regression models in different regions of the parameter space. In this case the robust methods are no longer useful and we need other methods to solve this problem. These situations are very close to cluster analysis, and [10] showed the usefulness of clustering procedures in detecting outliers. In fact, if we apply *k*-means to the housing data analyzed in Sect. 31.7, the two groups of regression are found. Better cluster procedures can be developed by searching directly for clusters around different regression lines; see Peña, Rodríguez, and Tiao [49] and García-Escudero et al. [50, 51] for different approaches to this problem.

Abstract

The purpose of this chapter is to describe and review a variety of statistical issues and methods related to the analysis of microarray data. In the first section, after a brief introduction of the DNA microarray technology in biochemical and genetic research, we provide an overview of four levels of statistical analyses. The subsequent sections present the methods and algorithms in detail.

In the second section, we describe the methods for identifying significantly differentially expressed genes in

different groups. The methods include fold change, different *t*-statistics, empirical Bayesian approach, and significance analysis of microarrays (SAM). We further illustrate SAM using a publicly available colon cancer dataset as an example. We also discuss multiple comparison issues and the use of false discovery rate.

In the third section, we present various algorithms and approaches for studying the relationship among genes, particularly clustering and classification. In clustering analysis, we discuss hierarchical clustering, and *k*-means and probabilistic model-based clustering in detail with examples. We also describe the adjusted Rand index as a measure of agreement between different clustering methods. In classification analysis, we first define some basic concepts related to classification. Then we describe four commonly used classification methods including linear discriminant analysis (LDA), support vector machines (SVM), neural network, and tree-and-forest-based classification. Examples are included to illustrate SVM and tree-and-forest-based classification.

The fourth section is a brief description of the meta-analysis of microarray data in three different settings: meta-analysis of the same biomolecule and same platform microarray data, meta-analysis of the same biomolecule but different platform microarray data, and meta-analysis of different biomolecule microarray data.

We end this chapter with final remarks on future prospects of microarray data analysis.

32.1 Introduction

Since the seminal work on microarray technology of *Schena* et al. [1], microarray data have attracted a great deal of attention, as reflected by the ever-increasing number of publications on this technology in the past decade. The applications of the microarray technology encompass many fields of science from the search for differentially expressed genes [2] to the understanding of regulatory networks [3], DNA sequencing and mutation study [4], single-nucleotide polymorphism (SNP) detection [5], cancer diagnosis [6], and drug discovery [7].

Accompanying the advancement of the microarray technology, analyzing microarray data has arguably become the most active research area of statistics and bioinformatics. Figure 32.1 provides a four-level overview of the analytic process. The first challenge in dealing with the microarray data is to preprocess the data, which involves background subtraction, array normalization, and probe-level data summarization. The purpose of this preprocessing is to remove noise and artifacts in order to enhance and extract hybridization signals. This data preprocessing is also often referred as the low-level analysis [8]. After the data are processed

and cleaned, they are analyzed for different purposes. The focus of this article is on the methods for this postprocessing analysis.

The second-level analysis usually contains two steps: one is to filter *unusual* genes whose expression profiles are suspicious due to noise or are too extreme, and the other is to identify the differentially expressed genes across different samples. The gene filtration process is generally heuristic and specific to known biological contents. Thus, we will not discuss it here. To identify genes that have significantly different expression profiles, the commonly used approaches include the estimation of fold change, Student's *t*-test, the Wilcoxon rank sum test, the penalized *t*-test, empirical Bayes [9], and significance analysis of microarray (SAM, *Tusher* et al. [10]). We will review these methods in Sect. 32.2.

We will review the third-level analysis in Sect. 32.3. This type of analysis is also called high-level analysis [11], and it includes clustering, classification, and pathway analysis. This is usually conducted on a subset of genes that are selected from the second-level analysis. To identify genes that may be correlated to each other, clustering analysis has become particularly popular, and the approaches include hierarchical clustering [12], *k*-means [13], self-organization maps (SOM) [14], principle component analysis (PCA) [15], and probabilistic model-based clustering [16].

To classify tissue samples or diagnose diseases based on gene expression profiles, both classic discriminant analysis and contemporary classification methods have been used and developed. The methods include *k*-nearest neighbors (KNN) [17], linear discriminant analysis (LDA) [18], support vector machine (SVM) [19], artificial neural networks (ANN) [20], classification trees [21], and random and deterministic forests [18]. It is noteworthy that tree- and forest-based approaches can be easily applied to the entire microarray dataset without restricting our attention to a subset of selected genes.

To identify genes that may be on the same pathway of a particular biological process, relevance networks [22], linear differential equation [23], Boolean networks [24], Bayesian networks [25], and the probabilistic rational model (PRM) [26] have been used and developed.

The fourth-level analysis, also referred as meta-analysis, is a relatively new topic for the analysis of microarray data. Because many different types and platforms of microarrays can be designed to address the same (or similar) biological problems, it is useful to compare and synthesize the results from different studies.

Before we introduce specific methods, we should point out that, as a result of high-throughput technology, the unique challenge from analyzing microarray data is the large number of genes (tens of thousands) and relatively small sample sizes (commonly on the order of tens or hundreds). In this article, n denotes the number of genes and m the number of arrays. n is generally much greater than m .

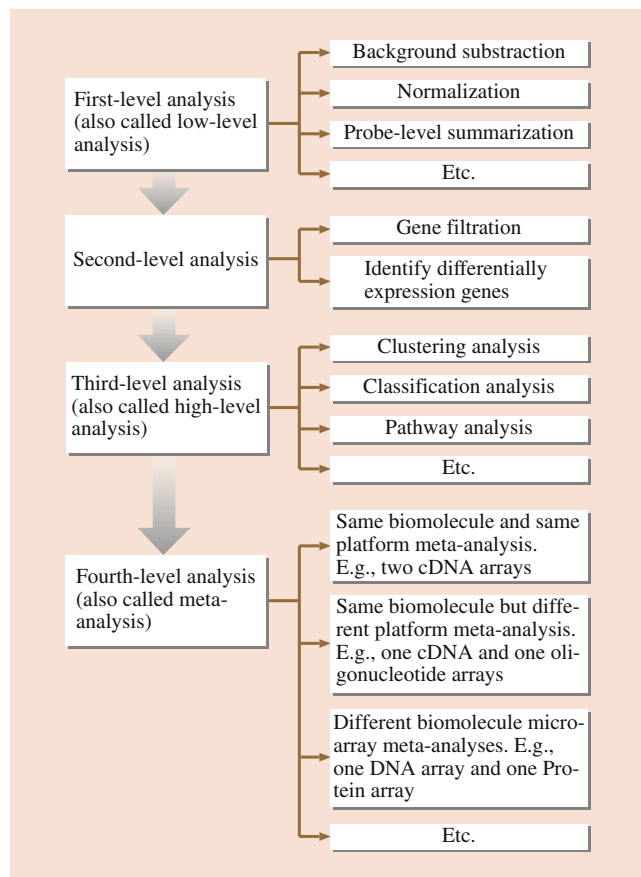

Fig. 32.1 Diagram of the four-level analysis of microarray data

32.2 Second-Level Analysis of Microarray Data

32.2.1 Notation

For a two-channel cDNA microarray data [1], we have a $2n \times m$ matrix of imaging data reflecting the red (cy5) and green (cy3) signals for each of the n genes on m arrays. The log ratio of the red to green signal is usually taken for each gene, and the analysis will be based on an $n \times m$ data matrix.

For one-channel Affymetrix Oligonucleotide Gene-Chip data [27], we have a $2 \sum_{i=1}^n p_i \times m$ matrix of raw image data where p_i is the number of probes for the i -th gene. Note that, for each probeset, Affymetrix uses a pair of perfect match (PM) and mismatch (MM). As for oligonucleotide microarrays, steps (differences, ratios, analysis of variance (ANOVA) models, etc.) can be taken to summarize the PM and MM signals for each gene, and we still have an $n \times m$ data matrix.

A major objective of microarray analysis is to infer significantly differentially expressed genes (abbreviated as SDE genes) across different samples, e.g., m_1 tumor samples versus m_2 normal samples.

Let $Y_{ij,k}$ be the expression level of the i -th gene on the j -th array in the k -th sample. Let $\bar{Y}_{i.,1}$ and $\bar{Y}_{i.,2}$ denote the average expression level of the i -th gene in samples 1 and 2, respectively.

32.2.2 Fold Change

Many studies identify SDE genes in two samples based on simple fold-change thresholds such as a two-fold change in means. Although the choice of a threshold is somewhat arbitrary, fold change is intuitive and biologically meaningful, and serves as an effective preliminary step to eliminate a large portion of genes whose data are of little interest in a particular study.

32.2.3 t -Statistic

As in many clinical studies, the t -statistic provides a simple, extremely useful tool to compare the data from two samples. Let \bar{M} be the mean difference between the expression profiles of a gene in two groups and $\text{se}(\bar{M})$ be the standard error of \bar{M} . The t -statistic, defined as

$$t = \frac{\bar{M}}{\text{sd}(\bar{M})},$$

is useful to test a null hypothesis that the gene is not differentially expressed in the two groups against the alternative hypothesis that the gene is differentially expressed.

Unlike a typical clinical study, in which we have one pair or a very few pairs of hypotheses to test, in microarray analysis we have a pair of hypotheses for every gene of interest. This means that we inevitably deal with the multiple comparison issue. Although this issue is difficult and there is no clear-cut, ideal answer, many reasonable solutions have been proposed.

Efron et al. [9] proposed to inflate $\text{se}(\bar{M})$ by adding a constant that equals the 90-th percentile of the standard errors of all the genes. *Tusher* et al. [10] call such a constant a fudge factor, and propose to estimate it by minimizing the coefficient of variation of the absolute t -values. We will discuss this approach in detail in Sect. 32.2.4. Other approaches have also been proposed; for example, *Smyth* [28] replaces $\text{se}(\bar{M})$ with a Bayesian shrinkage estimator of the standard deviation.

The permutation test is also commonly used to compare the microarrays. Permutations are usually performed at the array level to create a situation similar to the null hypothesis while maintaining the dependence structure among the genes [10]. In every permutation, a t -statistic can be calculated for each gene. Once a large number of permutations are completed, we have an empirical distribution for the t -statistic under the null hypothesis, which then can be used to identify SDE genes.

32.2.4 The Multiple Comparison Issue

As we mentioned earlier, we have to control the type I error rate α while testing a large number of hypotheses simultaneously. There are two commonly used approaches to deal with this issue. One is to control the family-wise error rate (FWER) and the other is to control the false discovery rate (FDR).

The FWER controls the probability of making at least one false positive call at the desired significance level. FWER guarantees that the type I error rate is less than or equal to a specified value for any given set of genes. The most known example of FWER is Bonferroni correction that divides the desired significance level α by total number of hypotheses. If the desired significance level is 0.05 and we compare expression profiles in 10,000 genes, a gene is declared to have significantly different profiles in two groups if the P -value is not greater than $\frac{0.05}{10,000} = 5 \times 10^{-6}$. Another FWER approach is the so-called *Šidák* correction in which the adjusted type I error rate is at $1 - (1 - \alpha)^{\frac{1}{n}}$ [29], which is close to α/n . Clearly, Bonferroni and *Šidák* corrections are sufficient but not necessary conditions [30], and FWER approaches are generally very conservative and set a stringent bar to declare SDE genes.

Because of the conservative nature of the FWER approaches, the FDR concept has flourished since it was proposed by [31]. FDR is defined as the mean of the ratio of the

number, denoted by V , of falsely rejected hypotheses to the total rejected hypotheses, denoted by R , namely,

$$\text{FDR} = E \left(\frac{V}{R} \mid R > 0 \right) \Pr(R > 0),$$

where $\Pr(R > 0)$ is the probability of rejecting at least one hypothesis.

The FDR can be controlled at a given α level through the following steps. First, for n genes, we have n null hypotheses and np values, denoted by p_1, \dots, p_n . Then, we sort the p -values in ascending order such that $p_{(1)} \leq \dots \leq p_{(n)}$. We reject any gene i that satisfies the condition $p(i) \leq \frac{i}{n} \times \frac{\alpha}{p_0}$, where p_0 is the proportion of genes for which the null hypotheses are indeed true. Because p_0 is unknown in practice, the most conservative approach is to replace it with 1. Recently, attempts have been made to estimate p_0 as in Tusher et al.'s SAM, where they used a permutation procedure to estimate p_0 . Similar to the classical p -values, the significance measures for each gene in terms of FDR are called q -values, a name that was introduced by Storey [32, 33].

In addition, the FDR concept has been generalized. For example, Storey and Tibshirani [9] and Storey et al. [32] proposed positive FDR (pFDR), which corrects the error rate only when there are positive findings. For microarray data, many gene profiles are correlated; Troendle [34] proposed an adjusted FDR to address the correlation and demonstrated the benefit in terms of gained power.

32.2.5 Empirical Bayesian Approach

Using microarray data from a breast cancer study, Efron et al. [9, 35] described the empirical Bayesian method. As an initial step, a summary statistic, Z , needs to be defined for every gene to reflect the scientific interest; this can be the t -statistic as described above, a Wilcoxon rank statistic, or another choice. All genes are perceived to belong to either the differentially or nondifferentially expressed group. The density of Z_i is $f_0(z_i)$ if gene i is in the nondifferentially expressed group, and $f_1(z_i)$ otherwise. Without knowing the group, Z_i has the following mixture distribution:

$$p_0 f_0(z_i) + p_1 f_1(z_i),$$

where p_0 is the prior probability that gene i is not differentially expressed, and $p_1 = 1 - p_0$.

Based on Bayes' theorem, the posterior probability that gene i is not differentially expressed given Z_i is

$$p_0(z_i) = p_0 \frac{f_0(z_i)}{f(z_i)}.$$

We can estimate the mixture density $f(z_i)$ by the empirical distribution $\hat{f}(z_i)$ because the genes of interest are naturally a mixture of the two groups. In addition, the null density $f_0(z_i)$ can be estimated through the permutation that artificially generates data under the null hypothesis. In other words, we can derive the posterior probability $p_0(z_i)$.

For a given prior p_0 . The choice of p_0 can be subjective. One conservative possibility is to choose p_0 to be the minimum of $\hat{f}(z_i) / \hat{f}_0(z_i)$ so that the posterior probability $p_1(z_i)$ that gene i is differentially expressed is non-negative. Note that $p_1(z_i) = 1 - p_0(z_i)$. Finally, all genes can be ranked according to $p_1(z_i)$ and highly probably differentially expressed genes can be selected.

Efron et al. [9, 35] did not assume a specific form for $f(z_i)$. In contrast, Lonnstedt and Speed [36] assumed that the data comes from the mixture of normal distributions and used the conjugate priors for the variances and the means. Under those assumptions, they derived the log odds posterior test. Smyth [28] extended the hierarchical model of Lonnstedt and Speed [36] to deal with microarray experiments with more than two sample groups. The method is called the Limma algorithm.

32.2.6 Significance Analysis of Microarray (SAM)

Tusher et al. [10] introduced the SAM algorithm. SAM identifies genes with statistically significant changes in expression by assimilating a set of gene-specific t -tests in which the standard error is adjusted by adding a small positive constant. It performs a random permutation among experiments and declares the significant genes based on a selected threshold. For the given threshold, SAM estimates the FDR by comparing the number of genes significant in the permuted samples with the number of genes significant in the original sample.

SAM can be downloaded from <http://www-stat.stanford.edu/~tibs/SAM/>. Specifically, first, for each gene i , SAM computes a t -like statistic

$$t_i = \frac{r_i}{s_i + s_0},$$

where r_i is the difference between the expression means of gene i in the two groups (expression is on a logarithm scale), s_i is the standard error, and s_0 is the fudge factor to be estimated. Secondly, similarly to the FDR scheme, all t_i values are sorted into the order statistics

$$t_{(1)} \leq t_{(2)} \leq \dots \leq t_{(n)}.$$

To choose the significance threshold, the expression data are permuted in the two groups within each gene B times, and during each permutation, we repeat the first two steps, which leads to a set of order statistics:

$$t_{(1)}^b \leq t_{(2)}^b \leq \dots \leq t_{(n)}^b.$$

After the permutations, we calculate the mean of the order statistics for each gene as follows:

$$\bar{t}_{(i)} = \frac{1}{B} \sum_{b=1}^B t_{(i)}^b.$$

For a given threshold Δ , a gene is considered significant if $|t_{(i)} - \bar{t}_{(i)}| > \Delta$, and the FDR is estimated by the ratio of the number of genes found to be significant in the permutation samples to the number of genes called significant in the original sample.

Example 1: Identification of SDE Genes Using SAM

In this example, we apply SAM to examine a publicly available colon cancer dataset [37]. This dataset contains the expression profiles of 2000 genes using an Affymetrix oligonucleotide array in 22 normal and 40 colon cancer tissues.

Figure 32.2 displays the quantile–quantile plot from SAM. The two dashed lines determine a boundary to call genes SDE depending on the choice of Δ . For example, Δ was chosen as 0.9857 in Fig. 32.2 to control the FDR at about 5%. The white square and triangle points in the figure correspond to the genes that are declared to be significantly overexpressed and underexpressed, respectively. Out of the 490 declared SDE genes (440 overexpressed and 50 underexpressed), 25 genes are expected to be declared falsely.

Fig. 32.2 The quantile–quantile plot from SAM for the colon cancer dataset. Genes are declared significantly changed when their corresponding t -values are outside the two dashed lines. The white square and triangle points correspond to the genes that are significantly overexpressed and underexpressed, respectively

32.3 Third-Level Analysis of Microarray Data

The third-level microarray analysis includes clustering, classification, and pathway analysis. These approaches usually, though not always, follow the second-level microarray analysis because most of them can work effectively on only a small number of genes.

32.3.1 Clustering

Clustering is arguably the most commonly used approach at the third level of analysis [38, 39]. It is an unsupervised learning algorithm from a machine learning viewpoint, because the gene classes are unknown or not used, and need to be *discovered* from the data. Therefore, the goal of clustering analysis is to group genes (or arrays) based on their similarity in the feature space (e.g., expression pattern).

The underlying assumption behind clustering is that genes with similar expression profiles should share some common biological behaviors, e.g., belonging to the same protein complex or gene family [40], having common biological functions [41], being regulated by common transcription factors [3], belonging to the same genetic pathway, or coming from the same origin [39].

After the clusters are formed, a dendrogram or a tree of all genes will be viewed, although the views are not unique, because there is a left-or-right selection at each splitting step. Two popular programs for gene clustering are Eisen et al.’s TreeView program [12] and Li and Wong’s dChip programs [8]. Routines are also available in standard statistical packages such as R, Splus, and SAS.

Distance

In order to group objects (genes or arrays) together, we need to define a measure to quantify the similarity among objects in the feature space. Such a measure of similarity is called a distance. There are several commonly used definitions of distance. Suppose that the expression profiles of two genes are $Y_i = (y_{i1}, y_{i2}, \dots, y_{im})$ and $Y_j = (y_{j1}, y_{j2}, \dots, y_{jm})$.

The Euclidean distance between Y_i and Y_j is

$$d_E(Y_i, Y_j) = \left[\sum_{k=1}^m (y_{ik} - y_{jk})^2 \right]^{\frac{1}{2}}.$$

The city-block distance between Y_i and Y_j is

$$d_C(Y_i, Y_j) = \sum_{k=1}^m |y_{i1} - y_{j1}|.$$

The Pearson correlation distance between Y_i and Y_j is

$$d_R(Y_i, Y_j) = 1 - r_{Y_i Y_j},$$

where $r_{Y_i Y_j}$ is the Pearson correlation coefficient between Y_i and Y_j .

The Spearman correlation distance between Y_i and Y_j uses the rank-based correlation coefficient in which the expression levels are replaced with the ranks.

More definitions can be found in the book by *Draghici* [30]. We should note that the Euclidean and city-block distance look for similar expression numerical values while the Pearson and Spearman distances tend to emphasize similar expression patterns.

The distances defined above measure the gene-wise distance. When clusters are found, we also need to define the distance between two clusters. The four approaches are: single linkage distance (the minimum distance between any gene in one cluster and any gene in the other cluster), complete linkage distance (the maximum distance between any gene in one cluster and any gene in the other cluster), average linkage distance (the average of all pair-wise distances between any gene in one cluster and any gene in the other cluster), and centroid linkage distance (the distance between the centroids of the two clusters).

Clustering Methods

When a distance measure is chosen, there are different ways to execute the clustering process. The clustering methods broadly fall into two categories: hierarchical methods and partitioning methods. Hierarchical methods build up a hierarchy for clusters, from the lowest one (all genes are in one cluster) to the highest one (all genes are in their own clusters), while partitioning methods group the genes into the different clusters based on their expression profiles. Therefore, one does not need to provide the cluster number for hierarchical clustering methods but it is necessary for the partitioning clustering methods.

Hierarchical methods include agglomerative hierarchical methods and divisive hierarchical methods.

The agglomerative hierarchical methods use a bottom-up strategy by treating each individual gene as a cluster at the first step. Then two nearest genes are found and assigned into a cluster where the *nearest* is defined by the distance between these two genes, e.g., for a Pearson distance nearest means the two genes having the largest correlation coefficient. Then an agglomerative hierarchical method assigns a new expression profile for the formed clusters, and repeats these steps until there is only one cluster left.

The divisive hierarchical methods, on the other hand, treat all genes belonging to one cluster at the beginning. Then in each step they choose a partitioning method to divide all genes into a predecided number of clusters, e.g., using k -means to partition genes into two clusters at each single

step. Therefore, the decisive hierarchical clustering methods employ the bottom-down strategy.

The k -means clustering is the simplest and fastest clustering algorithm [42] among the partitioning methods. It has been widely used in many microarray analyses. To form K clusters, the k -means algorithm allocates the observations into different groups in order to minimize the within-group sum of squares

$$\min_{S_k} \left[\sum_{k=1}^K \sum_{i \in S_k} \sum_{j=1}^m (y_{ij} - \bar{y}_{kj})^2 \right],$$

where K is the prespecified cluster number, S_k is the set of objects in the k -th cluster, and \bar{y}_{kj} is the mean of group j in cluster k . In other words, k -means clustering uses the Euclidean distance.

The k -means clusters are formed through iterations as follows: First, k center genes are randomly selected, and every other gene is assigned to the closest center gene. Then, the center is redefined for each cluster to minimize the sum of squares toward the center. In fact, the coordinates of a cluster center are the mean expressions of all the genes in that cluster. After the centers are redefined, all genes are regrouped and the iteration process continues until it converges.

After analyzing a yeast cell cycle expression dataset, *Duan* and *Zhang* [43] noted that it could be particularly useful to use a weighted sum of squares for gene clustering to take into account the loss of synchrony of cells. We refer to *Duan* and *Zhang* [43] for the details.

Another widely used partitioning clustering algorithm is *self-organizing maps* (SOMs) which were developed by *Kohonen* [44]. In essence, SOM clustering is a spatial version of the k -means clustering. For a prespecified grid (i.e., a 6×8 hexagonal grid), SOMs project high-dimensional gene expression data onto a two- or three-dimensional map and place similar genes close to each other. Here, the centroid positions of clusters are related to one another via a spatial topology (e.g., the squared map), and are also iteratively adjusted according to the data.

Both the k -means and SOMs are algorithmic methods and do not have a probabilistic justification. *Probabilistic model-based* clustering (PMC) analysis, on the other hand, assumes that the data is generated by a mixture of underlying probability distributions and uses the maximum likelihood method to estimate parameters that define the number of clusters as well as the clusters. Hence, we do not need to specify the number of clusters. Using the probabilistic model, we can even consider covariates while determining the clustering memberships of the genes. However, the model can quickly become complicated as the number of clusters increases. Thus, we must try to use parsimonious models as

much as possible. Finally, PMC and k -means are also closely related. In fact, k -means can be interpreted as a parsimonious model of simple independent Gaussians [15, 45, 46].

Example 2: Clustering Analysis

In this example, first we perform a hierarchical clustering analysis on the 490 SDE genes from example 1. The clustering analysis is applied in two directions: clustering on samples and clustering on genes. Although we do not present the entire clustering tree here, two major clusters are formed to distinguish tumor and normal samples. For clustering on the genes, there are roughly five major patterns in terms of the gene expressions. One pattern corresponds to the

underexpressed genes and the other four corresponds to the overexpressed genes in the tumor samples versus the normal ones.

For illustration, we selected the first 10 normal arrays and the first 10 cancer arrays, and 20 overexpressed and 20 underexpressed genes randomly from the 490 SDE genes. Figure 32.3 is from the heatmap function in *R*. Though not perfect, two patterns are formed mostly along the line of normal versus tumor tissues. There are roughly five major patterns in terms of expression profiles. Overexpressed and underexpressed genes tend to belong to different clusters. For example, pattern 3 (P3) and pattern 4 (P4) are mainly composed of underexpressed genes,

Fig. 32.3 Hierarchical clustering based on a subset of the colon cancer dataset. Each column corresponds to a sample, and each row a gene. The underexpressed genes were assigned numbers above 440, and the overexpressed genes at or below 440

Table 32.1 The numbers of genes belonging to the intersects of the five k -means clusters and the 13 PMC clusters

k -Means clusters	PMC clusters												
	1	2	3	4	5	6	7	8	9	10	11	12	13
1	0	11	0	0	0	57	35	0	0	0	0	29	0
2	25	8	0	0	62	5	0	0	0	0	0	0	0
3	0	0	2	13	0	0	0	0	23	0	0	0	0
4	0	0	15	0	0	0	0	0	1	31	0	0	41
5	0	2	0	0	0	0	1	65	0	34	24	6	0

while the other three clusters contain mainly overexpressed genes.

Following the hierarchical clustering analysis presented above, we also applied the k -means approach to the 490 SDE genes and set the number of clusters to five. Furthermore, we applied *probabilistic model-based* clustering (PMC) to the same dataset. We examined the BIC (Bayesian information criterion) for different numbers of clusters, and it turned out that the value of BIC reaches its minimum at 13 clusters, which is much more than heuristic choice of five. Table 32.1 displays the numbers of genes belonging to the intersects of the five k -means clusters and the 13 PMC clusters. Each of the five k -means clusters is a union of four or so PMC clusters. In fact, if we choose five PMC clusters, they are very similar to the formation of the five k -means clusters, and we will assess this similarity in the next section.

Measure of Agreement Between Two Sets of Clusters

From both the methodological and biologic points of view, there is a need to compare the clusters from different clustering methods. For example, to evaluate the performance of a new clustering approach, we need to compare the derived clusters with the underlying membership in a simulation study. We may also be interested in comparing clustering results derived from the same mRNA samples but being hybridized and analyzed in two different laboratories.

A commonly used measure of agreement between two sets of clusters is the so-called adjusted Rand index (ARI) [15, 47, 48]. Let us consider the partitions U and V , and let n_{ij} be the number of genes falling in the intersect of the i -th cluster in U and the j -th cluster in V . The ARI is defined as

$$\frac{\sum_{i,j} \binom{n_{ij}}{2} - \left[\sum_i \binom{n_i}{2} \sum_j \binom{n_j}{2} \right] / \binom{n}{2}}{\frac{1}{2} \left[\sum_i \binom{n_i}{2} + \sum_j \binom{n_j}{2} \right] - \left[\sum_i \binom{n_i}{2} \sum_j \binom{n_j}{2} \right] / \binom{n}{2}},$$

where n_i and n_j are the numbers of genes in the i -th cluster of U and the j -th cluster of V , respectively.

We suggested some similarity between the k -means and PMC clusters. In fact, the ARI value between the two sets of clusters is 0.425, and it increases to 0.94 if both methods

use five clusters. This similarity is expected, because PMC and k -means are equivalent if PMC assumes an independent Gaussian covariance structure [15].

32.3.2 Classification

In most microarray experiments, we know the groups on the arrays. For example, some mRNA samples were extracted from tumor cells and the others from normal cells. This is similar to the situation in Sect. 32.2.1. Therefore, it is natural to use this information in analysis and to class cells based on the expression profiles. This is so-called supervised learning.

In Sect. 32.2.1, $Y_{ij,k}$ denotes the expression level of the i -th gene on the j -th array in the k -th sample. Here, we also use $(Y_{ij}, Z = k)$ to reflect the fact that the expression level Y_{ij} of the i -th gene on the j -th array comes from the k -th sample. In other words, the sample group is represented by Z , which is the response or dependent variable in classification.

The essence of classification is to define domains in the feature space spanned by Y_{ij} and to assign a class membership Z to each domain. Classification methods differ in the choice of the shape for the domain and in the algorithm to identify the domain. Some elementary concepts are useful to distinguish these differences. The first one is *linearity*. It refers to a linear combination of the features (expressions of different genes) that forms a hyperplane separating different domains in the feature space. The second term is *separability*. It reflects the extent that the different classes of samples are separable. The third concept is *misclassification*. Often, data are only partially separable, and misclassification is inevitable. In this circumstance, we may need to define a cost function to accommodate different classification errors.

In the machine learning literature, there is also a distinction between the *learning* (i.e., training) and the *test* samples. The learning data are used to train the classification algorithm and the test data are used to test the predictive ability of the trained classification algorithm. In practice, however, we usually have one dataset and have to split the sample into the training and test samples by leaving a portion of data out during the learning process and saving it as the test data. This procedure is called cross-validation. More precisely, for a ν -fold cross-validation, we first divide the data into ν approximately equal subsamples. Then, we use $\nu - 1$ subsamples as the training data to construct a classification rule and the leftover subsample as the test data to validate the classification rule. After rotating every subsample between training and test data, the performance of the classification rule is assessed through the average in the ν runs of validation in the test sample.

In the next subsections, we will review four classification methods that are useful for classifying tissue samples based on gene expression profiles. The methods are linear discrim-

inant analysis (LDA), support vector machines (SVM), artificial neural networks (ANN), and tree-based classification.

LDA

LDA was introduced by Fisher in 1936 for classifying samples by finding a hyperplane that maximizes the between-class variances. Let S_Y be the common sample covariance matrix of all gene expressions, \bar{Y}_1 and \bar{Y}_2 be the average expression levels of the genes in groups 1 and 2, respectively. The solution to LDA is $S_Y^{-1}(\bar{Y}_1 - \bar{Y}_2)$.

SVM

SVM was first proposed by *Boser et al.* [49] and *Cortes and Vapnik* [50]. SVM finds an optimal hyperplane to separate samples and to allow the maximum *separation* between different classes of samples. The margin of the region that separates samples is *supported* by a few vectors, termed support vectors.

In a two-class classification problem, let $Z = 1$ or -1 denote the two classes. If the two classes of samples are separable, we find a hyperplane $\{y : y^T \beta + \beta_0 = 0, \|\beta\| = 1\}$ such that $(y^T \beta + \beta_0)Z \geq C \geq 0$, where C is the margin optimized to allow the maximal space between the two classes of samples.

For nonseparable case, the procedure is much complicated. Some points will inevitably be on the wrong side of the hyperplane. The idea is to introduce a slack variable to reflect how far a sample is on the wrong side, and then look for the hyperplane at the condition of the total misclassification less than a user-selected limit (i.e., bound the sum of slack variables by a constant). We refer to *Vapnik* [51] for the details.

Example 3: Support Vector Machine (SVM)

In this example, we perform a classification analysis on the colon cancer data by SVM. We use M26697 and M63391, the two most significant genes that were identified by SAM from example 1. Specifically, M26697 is the most significant overexpressed gene and M63391 is the most significant underexpressed gene. We used the SVM function in *R* with the cost equal to 100, γ of 1 and tenfold cross-validation, where γ is the coefficient of the radial kernel used to form a hyperplane. Figure 32.4 displays the contour plot of the SVM result. The prediction model correctly classifies 37 cancer and 20 normal samples, but misclassifies three cancer and two normal samples.

Neural Network

The artificial neural network (ANN) is a very popular methodology in machine learning. Also referred to as connectionist architectures, parallel distributed processing, and neuromorphic systems, ANN is an information-processing paradigm with collections of mathematical models that emulate the densely interconnected, parallel

Fig. 32.4 Contour plot of the SVM result using two genes: M26997 and M63391 for the colon cancer data. C represents cancer and N represents normal. The *light-gray area* is the cancer region and the *brown area* is the normal region. *Square points* represent the support vectors and the *triangle points* represent the data points other than support vectors. The *brown* and *white points* belong to the cancer and the normal regions, respectively

structure of the mammalian brain and adaptive biological learning. It is composed of a large number of highly interconnected processing elements that are analogous to neurons and are tied together with weighted connections that are analogous to synapses. Learning typically occurs by example through training, or exposure to a true set of input/output data where the training algorithm iteratively adjusts the connection weights (synapses). These connection weights store the knowledge necessary to solve specific problems.

ANN can be used for feature selection and feature extraction. The former amounts to variable selection and reduction in statistics and the latter is a generation of the statistical techniques such as principal component analysis, factor analysis, and linear discriminant analysis that are intended to identify lower-dimensional data structures such as linear directions. These lower-dimensional structures usually depend on all of the original variables (i.e., features). Thus, ANN is in essence a computationally intensive version of traditional statistical methods such as regression, classification, clustering, and factor analysis. However, ANN is designed in a way that mimics neural networks and is biologically intuitive and appealing in many applications. This is the major reason that we plan to consider ANN

as one of the primary tools to explore the unknown relationship in our data, which is usually referred to as pattern recognition.

The advantage of ANNs lies in their resilience against distortions in the input data and their capability for learning. They are often good at solving problems that are too complex for conventional technologies (e.g., problems that do not have an algorithmic solution, or for which an algorithmic solution is too complex to be found), and are often well suited to problems that people are good at solving, but for which traditional methods are not.

There are multitudes of different types of ANNs. Some of the more popular include the multilayer perceptron, which is generally trained with the backpropagation of error algorithm, learning vector quantization, radial basis functions, Hopfield, and Kohonen, to name a few. Some ANNs are classified as feed-forward while others are recurrent (i.e., implement feedback) depending on how data is processed through the network. Some ANNs employ supervised training while others are referred to as unsupervised or self-organizing.

Figure 32.5 illustrates a conventional three-layer neural network with n features and K classes. For this feed-forward neural network, the inputs are y_1, \dots, y_n which correspond to the gene expression profiles and the outputs are z_1, \dots, z_K , which correspond to the K samples in the microarray data. The middle layer consists of many hidden units (also called neurons) and the number of hidden units can be freely chosen and determine the maximum nonlinearity. Each line in Fig. 32.5 indicates a weight – the edge – in the network. This weight represents how much the two neurons which are connected by it can interact. If the weight is larger, then the two neurons can interact more, that is, a stronger signal can

Fig. 32.5 Architecture of a conventional three-layered feed-forward neural network

pass through the edge. The nature of the interconnections between two neurons can be such that one neuron can either stimulate (a positive weight α) or inhibit (a negative weight α) the other. More precisely, in each hidden unit, we have

$$X_m = \sigma(\alpha_{0m} + \alpha_m^T Y),$$

where σ is called the activation function or neural function and $(\alpha_{0m}, \alpha_m^T)$ are the weights. A common choice for σ is the sigmoid function

$$\sigma(v) = \frac{1}{1 + e^{-v}}.$$

The output function allows a final transformation of the linear combinations of the hidden unit variables

$$f_k(z) = g_k(\beta_{0k} + \beta_k^T X).$$

For a K -class classification, a softmax (logistic) function is usually chosen for the output function

$$g_k(T) = \frac{e^{T_k}}{\sum_{l=1}^K e^{T_l}}.$$

During the training period, we present the perceptron with inputs one at a time and see what output it gives. If the output is wrong, we will tell it that it has made a mistake. It should then change its weights and/or threshold properly to avoid making the same mistake later.

32.3.3 Tree- and Forest-Based Classification

One of the most convenient and intuitive approaches for classification is classification trees [52–54]. Classification trees, and their expansion to forests, are based on the so-called recursive partitioning technique. The basic idea of recursive partitioning is to extract homogeneous strata of the tissue samples through expression profiles depending on the expression levels of a particular gene.

Zhang and Yu [55] reanalyzed the dataset from Hedenfalk et al. [56] to classify breast cancer mutations in either the BRCA1 or BRCA2 gene using gene expression profiles. Hedenfalk et al. [56] collected and analyzed biopsy specimens of primary breast cancer tumors from seven and eight patients with germline mutations of BRCA1 and BRCA2, respectively. In addition, seven patients with sporadic cases of primary breast cancer whose family history was unknown were also identified. They obtained cDNA microarrays from 5361 unique genes, of which 2905 are known genes and 2456

are unknown. Thus, in this dataset, let $Z = 1, 2, 3$ denote BRCA1, BRCA2, and sporadic cases, respectively.

If we use this entire breast cancer dataset to construct a tree, these 22 samples form the initial learning sample, which is called the root node and labeled as node 1 in the tree diagram (Fig. 32.6). The tree structure is determined by recursively selecting a split to divide an upper layer node into two offspring nodes. To do this, we need to evaluate the homogeneity, or the impurity to its opposite, of any node. A common measure of node impurity is the entropy function

$$i_t = - \sum_{k=1}^K P(Z = k | \text{node } t) \log [P(Z = k | \text{node } t)].$$

If node t is the root node, then $P(Z = 1 | \text{node } t) = 7/22$, $P(Z = 2 | \text{node } t) = 8/22$, and $P(Z = 3 | \text{node } t) = 7/22$. Thus, the impurity i_t of the root node can be calculated easily as follows: $i_t = -(7/22) \log(7/22) - (8/22) \log(8/22) - (7/22) \log(7/22) = 1.097$.

How good is the root node? The impurity is zero for a perfect node in which $P(Z = k | \text{Node } t)$ is either 0 or 1, and reaches its worst level when $P(Z = k | \text{node } t) = \frac{1}{3}$ with $i_t = 1.099$. Therefore, the impurity of the root node is near the worst level by design, motivating us to partition the root node into small nodes to reduce the impurity.

The first step of the recursive partitioning process is to divide the root of 32 samples in Fig. 32.6 into two nodes, namely, nodes 2 and 3 in Fig. 32.6. There are many ways of partitioning the root node, because we can take any of the 5361 genes and split the root node according to whether the expression level of this chosen gene is greater than any threshold c . After comparing all possible partitions, we choose the gene and its threshold to keep both i_2 in node 2 and i_3 in node 3 at their lowest possible levels simultaneously. Mathematically, we achieve this goal by minimizing the

weighted impurity $r_2 i_2 + r_3 i_3$, where r_2 and r_3 are the proportions of tissue samples in nodes 2 and 3, respectively. This is precisely how the first split (i.e., whether $ST13 > 0.835$) in Fig. 32.6 is determined.

Once the root is split into nodes 2 and 3, and we can apply the same procedure to potentially split nodes 2 and 3 further. Indeed, the tree in Fig. 32.6 divides the 22 samples into four groups using Heping Zhang’s RTREE (<http://c2s2.yale.edu/software>). Nodes 2 and 3 are divided based on the expression levels of genes ARF3 and LRBA.

Using a variety of analytic techniques including a modified F- and t -test and a mutual information scoring, Hedenfalk et al. [56] selected nine differentially expressed genes to classify BRCA1-mutation-positive and negative tumors and then 11 genes for BRCA2-mutation-positive and negative tumors. Clearly, the tree in Fig. 32.6 uses fewer genes and is a much simpler classification rule.

Although Fig. 32.6 is simple, it does not contain the potentially rich information in the dataset. To improve the reliability of the classification and to accommodate potentially multiple biological pathways, Zhang and Yu [55] and Zhang et al. [57] proposed expanding trees to forests. The large number of genes in microarray makes it an ideal application for these forests.

The most common approach to constructing forests is to perturb the data randomly, form a tree from the perturbed data, and repeat this process to form a series of trees; this is called a random forest. After a forest is formed, we aggregate information from the forest. One such scheme, called bagging (bootstrapping and aggregating), generates a bootstrap sample from the original sample. The final classification is then based on the majority vote of all trees in the forest [58].

It is well known that random forests [18, 58] improve predictive power in classification. After observing the fact that there are typically many trees that are of equally high predictive quality in analyzing genomic data, Zhang et al. [18] proposed a method to construct forests in a deterministic manner. Deterministic forests eliminate the randomness in the random forests and maintain a similar, and sometimes improved, level of precision as the random forests.

The procedure for constructing the deterministic forests is simple. We can search and collect all distinct trees that have a nearly perfect classification or are better than any specified precision. This can be carried out by ranking the trees in deterministic forests. One limitation for the forests (random or deterministic) is that we cannot view all trees in the forests. However, we can examine the frequency of genes as they appear in the forests. Frequent and prominent genes may then be used and analyzed by any method as described above. In other words, forest construction offers a mechanism for data reduction. For the breast cancer data, one of the most

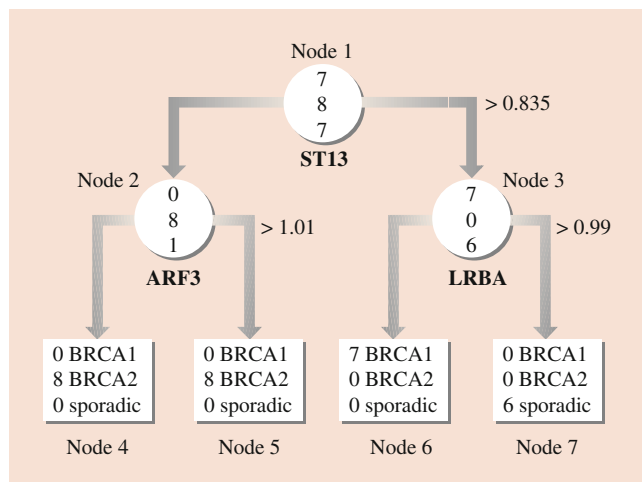

Fig. 32.6 Classification tree for breast cancer data

prominent genes identified in the forests is ERBB2. *Kroll et al.* [59] analyzed the gene expression patterns of four breast cancer cell lines: MCF-7, SK-BR-3, T-47D, and BT-474, and reported unique high levels of expressions in the receptor tyrosine kinase ERBB2.

32.4 Fourth-Level Analysis of Microarray Data

Nowadays, different types and platforms of microarray have been developed to address the same (or similar) biological problems. How to integrate and exchange the information contained in different sources of studies effectively is an important and challenging topic for both biologists and statisticians [60]. The strategy depends on the situation. When all studies of interest were conducted under the same experimental conditions, this is a standard situation for meta-analysis. There are situations where the experiments are similar, but different platforms were measured, such as the integration of one cDNA array-based study and one oligonucleotide array-based study. There are also situations where different biomolecule microarrays were collected, such as the integration of a genomic array study and a proteomic array study.

Integrating a cDNA array and an Affymetrix chip is complicated because genes on a cDNA array may correspond to several genes (or probesets) on the Affymetrix chip based on the Unigene cluster-matching criteria [61]. Instead of matching by genes, matching by the sequence-verified probes may increase the correlation between two studies [62].

Most meta-analyses of microarray data have been performed in a study-by-study manner. For example, *Yauk et al.* [63] use the Pearson coefficient to measure the correlation across studies; *Rhodes et al.* [64] and *Wang et al.* [65] use the estimations from one study as prior knowledge while analyzing other studies; and *Welsh et al.* [66] treat DNA microarrays as a screening tool and then use protein microarrays to identify the biomarker in cancer research. While they are convenient, these strategies are not ideal [64, 67]. Thus, it is imperative and useful to develop better methods to synthesize information from different genomic and proteomic studies [60, 63, 68].

32.5 Final Remarks

The technology of gene and protein chips is advancing rapidly, and the entire human genome can be simultaneously monitored on a single chip. The analytic methodology

is evolving together with the technology development, but is far from satisfactory. This article reviews some of the commonly used methods in analyzing microarrays. Analyzing microarray data is still challenging; some of the important issues include how to interpret the results in the biological context, how to improve the reproducibility of the conclusions, and how to integrate information from related but different studies.

Fenghai Duan was born in Heilongjiang, China. After completing his bachelor's degree in biochemistry at Fudan University in 1995, he received his master's degree in molecular biology from the Institute of Biophysics, Academia Sinica, in 1998. In the year 2000, Duan joined the Ph.D. program in biostatistics at Yale University and worked on his thesis under the supervision of Professor Heping Zhang. Duan's doctoral dissertation was about the analysis of microarray experiments and was awarded the Ph.D. degree in May 2005. Currently, he is an associate professor of biostatistics at Brown University. His research interests are in the development of statistical methods for the analysis of high-dimensional biological data.

Heping Zhang is the Susan Dwight Bliss Professor of Biostatistics, Child Study, and Statistics and Data Science at the Yale University. He is interested in development of statistical methods and software and their applications in biomedical studies, particularly in behavioral science, epidemiology, genetics, psychiatry, and pregnancy outcomes. He publishes extensively on tree- and spline-based methods as well as latent variable models for genetic studies of ordinal traits. He is a fellow of the American Statistical Association and Institute of the Mathematical Statistics, and the editor of the *Journal of the American Statistical Association – Applications and Case Studies*.

Abstract

The first part of this chapter describes the foundation of genetic algorithms. It includes hybrid genetic algorithms, adaptive genetic algorithms, and fuzzy logic controllers. After a short introduction to genetic algorithms, the second part describes combinatorial optimization problems including the knapsack problem, the minimum spanning tree problem, the set-covering problem, the bin-packing problem, and the traveling-salesman problem; these are combinatorial optimization problems which are characterized by a finite number of feasible solutions. The third part describes network design problems. Network design and routing are important issues in the building and expansion of computer networks. In this part, the shortest-path problem, maximum-flow problem, minimum-cost-flow problem, centralized network design, and multistage process planning problem are introduced. These problems are typical network problems and have been studied for a long time. The fourth section describes scheduling problems. Many scheduling problems from

manufacturing industries are quite complex in nature and very difficult to solve by conventional optimization techniques. In this part the flow-shop sequencing problem, job-shop scheduling, the resource-constrained project scheduling problem, and multiprocessor scheduling are introduced. The fifth part introduces the reliability design problem, including simple genetic algorithms for reliability optimization, reliability design with redundant units and alternatives, network reliability design, and tree-based network topology design. The sixth part describes logistic problems including the linear transportation problem, the multiobjective transportation problem, the bicriteria transportation problem with fuzzy coefficients, and supply chain management network design. Finally, the last part describes location and allocation problems including the location-allocation problem, capacitated plant-location problem, and obstacle location-allocation problem.

33.1 Foundations of Genetic Algorithms

Recently, genetic algorithms (GAs) have received considerable attention regarding their potential as an optimization technique for complex problems and have been successfully applied in the area of industrial engineering. The well-known applications include scheduling and sequencing, reliability design, vehicle routing location, transportation, and many others.

There are three major advantages when applying GA to optimization problems:

1. **Adaptability:** GA does not have much mathematical requirements about the optimization problems. Due to the evolutionary nature, GA will search for solutions without regard to the specific inner workings of the problem. GA can handle any kind of objective functions and any kind of constraints, i.e., linear or nonlinear, defined on discrete, continuous, or mixed search spaces.
2. **Robustness:** The use of evolution operators makes GA very effective in performing global search (in probability), while most of conventional heuristics usually perform local search (LS). It has been proved by many studies that GA is more efficient and more robust in locating optimal solution and reducing computational effort than other conventional heuristics.
3. **Flexibility:** GA provides us a great flexibility to hybridize with domain-dependent heuristics to make an efficient implementation for a specific problem.

33.1.1 Basic Genetic Algorithm

Since the 1960s there has been being an increasing interest in imitating living beings to solve such kinds of hard optimization problems. Simulating natural evolutionary processes of human beings results in stochastic optimization techniques called evolutionary algorithms (EAs) that can often outperform conventional optimization methods when applied to difficult real-world problems. EAs mostly involve metaheuristic optimization algorithms such as genetic algorithm (GA) [1], evolutionary programming (EP), evolution strategy (ES), genetic programming (GP), particle swarm optimization (PSO), and ant colony optimization (ACO) [2, 3]. Among them, genetic algorithms are perhaps the most widely known type of evolutionary algorithms used today [4].

Genetic algorithms are stochastic search algorithms based on the mechanism of natural selection and natural genetics. Genetic algorithms, in contrast to conventional search techniques, start with an initial set of random solutions called the population. Each individual in the population is called a chromosome, encoding a solution to the problem at hand. A chromosome is a string of symbols, usually, but not necessarily, a binary bit string. The chromosomes *evolve* through successive iterations, called generations. During each generation, the chromosomes are evaluated, using some measures of fitness [5]. To create the next generation, new chromosomes, called offspring, are formed by either merging two chromosomes from the current generation using a *crossover* operator or modifying a chromosome using a mutation operator.

A new generation is formed by selecting, according to the fitness values, some of the parents and offspring and rejecting others so as to keep the population size constant.

Fitter chromosomes have higher probabilities of being selected. After several generations, the algorithms converge to the best chromosome, which we hope represents the optimum or suboptimal solution to the problem when decoded. Let $P(t)$ and $C(t)$ be population or parents and offspring in the current generation t ; the general structure of GAs (Fig. 33.1) is described as follows:

procedure: Genetic Algorithms (GA)

input: problem data, parameters

output: the best solution

begin

$t \leftarrow 0$;

initialize $P(t)$ by encoding routine;

evaluate $P(t)$ by decoding routine & keep best solution;

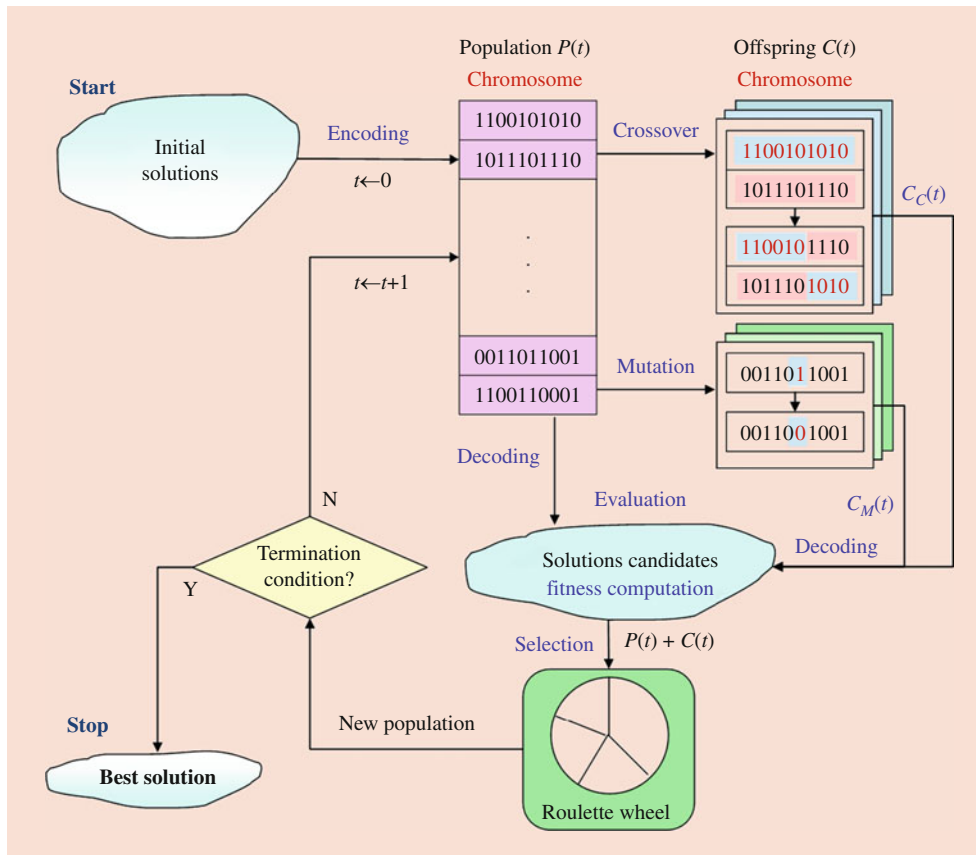

Fig. 33.1 The general structure of genetic algorithms

```

while (not terminating condition) do
  create  $C(t)$  from  $P(t)$  by crossover routine;
  create  $C(t)$  from  $P(t)$  by mutation routine;
  evaluate  $C(t)$  by decoding routine & update the best solution;
  reproduce  $P(t + 1)$  from  $P(t)$  and  $C(t)$  by selection routine;
   $t \leftarrow t + 1$ ;
end

```

output: the best solution;

end;

Crossover is the main genetic operator. It operates on two chromosomes at a time and generates offspring by combining both chromosomes' features. A simple way to achieve crossover would be to choose a random cut-point and generate the offspring by combining the segment of one parent to the left of the cut-point with the segment of the other parent to the right of the cut-point.

Mutation is a background operator, which produces spontaneous random changes in various chromosomes. A simple way to achieve mutation would be to alter one or more genes.

33.1.2 Hybrid Genetic Algorithms

Genetic algorithms (GAs) have proved to be a versatile and effective approach for solving optimization problems. Nevertheless, there are many situations in which the simple GA does not perform particularly well, and various methods have been proposed [5]. One of the most common forms of hybrid genetic algorithms is to incorporate local search (LS) or traditional optimization as an add-on extra to the canonical GA loop of recombination and selection [6–9]. With the hybrid approach, local optimization such as hill climbing is applied to each newly generated offspring to move it to a local optimum before injecting it into the population as shown in Fig. 33.2. Genetic algorithms are used to perform global exploration among the population, while heuristic methods are used to perform local exploitation around chromosomes. Because of the complementary properties of genetic algorithms and conventional heuristics, the hybrid approach often outperforms either method operating alone. Some work has been done to reveal the natural mechanism behind such a hybrid approach, among which is Lamarckian evolution. The hybrid GA can be combined with LS and tuned parameters

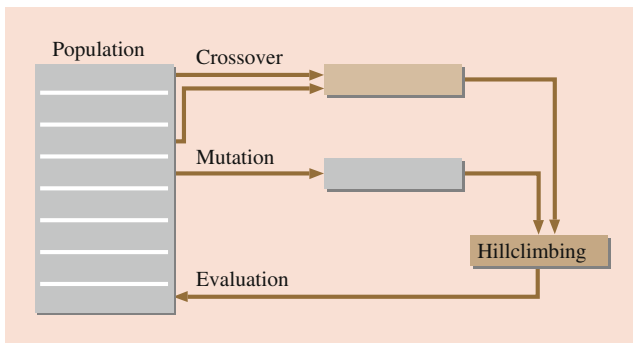

Fig. 33.2 General structure of hybrid genetic algorithms

by FLSI routines. The general structure of hybrid genetic algorithms is described as follows:

procedure: Hybrid Genetic Algorithm (HGA)

input: problem data, paramters

output: the best solution

begin

$t \leftarrow 0$

initialize $P(t)$ by encoding routine;

evaluate $P(t)$ by decoding routine & keep
the best solution;

while (not termination condition) **do**

improve best solution by LS routine;

tune parameters by FLC routine;

reproduce $P(t + 1)$ from $P(t)$ and $C(t)$ by
selection routine;

$t \leftarrow t + 1$;

end

output: the best solution;

end;

33.1.3 Adaptive Genetic Algorithms

There are two basic approaches to applying the genetic algorithms to a given problem: (1) to adapt a problem to the genetic algorithms and (2) to adapt the genetic algorithms to a problem.

Genetic algorithms were first created as a kind of generic and weak method featuring binary encoding and binary genetic operators. This approach requires a modification of the original problem into an appropriate form suitable for the genetic algorithms, as shown in Fig. 33.3.

To overcome such problems, various nonstandard implementations of the genetic algorithm have been created for

Fig. 33.3 Adapt a problem to the genetic algorithms

Fig. 33.4 Adapt the genetic algorithms to a problem

particular problems, which leave the problem unchanged and adapt the genetic algorithms by modifying a chromosome representation of a potential solution and applying appropriate genetic operators, as shown in Fig. 33.4. This approach has been successfully applied in the area of industrial engineering and is becoming the main approach in recent applications of genetic algorithms [4, 10, 11].

33.1.4 Fuzzy Logic Controller (FLC)

Fuzzy logic is much closer in spirit to human thinking and natural language than the traditional logical systems. In essence, the fuzzy logic controller (FLC) provides an algorithm which can convert a linguistic control strategy based on expert knowledge into an automatic control strategy. In particular, this methodology appears very useful when the processes are too complex for analysis by conventional techniques or when the available sources of information are interpreted qualitatively, inexactly, or with uncertainty [7–9].

Lin and Gen reported auto-tuning strategy by using fuzzy logic control for evolutionary algorithms adaptively regulation for taking the balance among the stochastic search and local search probabilities based on the change of the average fitness of parents and offspring in each generation [9].

The pioneering work to extend the fuzzy logic technique to adjust the strategy parameters of genetic algorithms dynamically was carried out by Yun, Lin, and Gen [7–9]. The experts' knowledge is stored in the knowledge base in the form of linguistic control rules. The inference system is the kernel of the controller, which provides an approximate reasoning based on the knowledge base. The generic structure of a fuzzy logic controller is shown in Fig. 33.5.

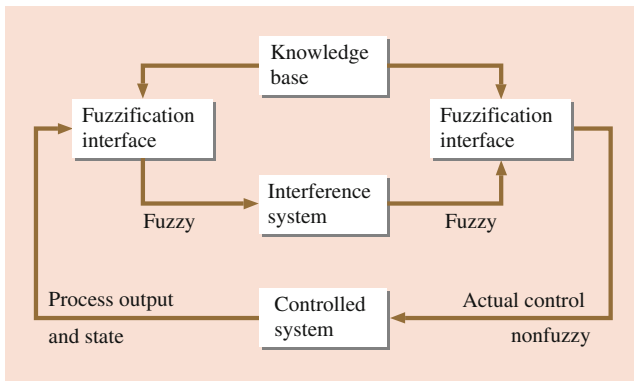

Fig. 33.5 A generic structure of a fuzzy logic controller

33.1.5 Multiobjective Optimization Problems

Many real-world decision-making problems involve multiple and conflicting objectives which need to be tackled while respecting various constraints, leading to overwhelming problem complexity. The multiobjective optimization problem (MOP) has been receiving growing interest from researchers with various backgrounds since early 1960. There are a number of scholars who have made significant contributions to the problem. Among them, Pareto is perhaps one of the most recognized pioneers in the MOP field [4, 12].

Multiobjective optimization problem with q objectives and m constraints will be formulated as follows:

$$\max [z_1 = f_1(\mathbf{x}), z_2 = f_2(\mathbf{x}), \dots, z_q = f_q(\mathbf{x})], \quad (33.1)$$

$$\text{s. t.} \quad g_i(\mathbf{x}) \leq 0, \quad i = 1, 2, \dots, m. \quad (33.2)$$

$$\mathbf{x} \geq \mathbf{0} \quad (33.3)$$

where $\mathbf{x} \in \mathbf{R}^n$ is a vector of n decision variables, $f_j(\mathbf{x})$ is the objective function, and $g_i(\mathbf{x})$ are inequality constraint functions, which form the area of feasible solutions. We usually denote the feasible area in decision space with the set S as follows:

$$S = \{\mathbf{x} \in \mathbf{R}^n \mid g_i(\mathbf{x}) \leq 0, i = 1, \dots, m, \mathbf{x} \geq \mathbf{0}\} \quad (33.4)$$

We sometimes graph the multiple objective problem in both decision space and criterion space. S is used to denote the feasible region in the decision space, and Z is used to denote the feasible region in the criterion space as follows:

$$Z = \{\mathbf{z} \in \mathbf{R}^q \mid z_1 = f_1(\mathbf{x}), \dots, z_q = f_q(\mathbf{x}), \mathbf{x} \in S\} \quad (33.5)$$

where $\mathbf{z} \in \mathbf{R}^q$ is a vector of values of q objective functions. In other words, Z is the set of images of all points in S .

Although S is confined to the nonnegative orthant of \mathbf{R}^n , Z is not necessarily confined to the nonnegative orthant of \mathbf{R}^q .

Definition 1 For a given point $z_0 \in Z$, it is nondominated if and only if there does not exist another point $z \in Z$ such that, for the maximization case,

$$z_k > z_k^0, \text{ for some } k \in \{1, 2, \dots, q\} \text{ and} \quad (33.6)$$

$$z_l \geq z_l^0, \text{ for all } l \neq k \quad (33.7)$$

where z_0 is a dominated point in the criterion space Z .

A point in the decision space is efficient if and only if its image is a nondominated point in the criterion space Z .

Definition 2 For a given point $\mathbf{x}^0 \in S$, it is efficient if and only if there does not exist another point $\mathbf{x} \in S$ such that, for the maximization case,

$$f_k(\mathbf{x}) > f_k(\mathbf{x}^0), \text{ for some } k \in \{1, 2, \dots, q\} \text{ and} \quad (33.8)$$

$$f_l(\mathbf{x}) \geq f_l(\mathbf{x}^0), \text{ for all } l \neq k \quad (33.9)$$

where \mathbf{x}_0 is inefficient.

A point in the decision space is efficient if and only if its image is a nondominated point in the criterion space Z .

A. The Concept of a Pareto Solution

In most existing methods, Pareto solutions are identified at each generation and are only used to calculate fitness values or ranks for each chromosome. The overall structure of the basic multiobjective genetic algorithm (MoGA) is given as follows:

procedure: Multiobjective Genetic Algorithm

input: problem data, paramters

output: the best Pareto optimal solution

begin

$t \leftarrow 0$

initialize $P(t)$ by encoding routine;

calculate each $f_i(\mathbf{P})$ by decoding;

create Pareto frontier $E(\mathbf{P})$ by non-dominated;

evaluate $P(t)$ by fitness assignment function
& keep the best Pareto solution;

while (not termination condition) **do**
 create $C(t)$ from $P(t)$ by crossover routine;
 create $C(t)$ from $P(t)$ by mutation routine;
 calculate each $f_i(C)$ by decoding;
 update Pareto frontier $E(P)$ by non-dominated;
 evaluate $C(t)$ by fitness assignment function and update the best Pareto solution;
 reproduce $P(t+1)$ from $P(t)$ and $C(t)$ by selection routine;
 $t \leftarrow t+1$;
end
output: the best Pareto optimal solution;
end;

B. Fitness Assignment Function

Adaptive-Weight Genetic Algorithm (AWGA: Gen and Cheng 2000): Gen and Cheng proposed an adaptive-weight approach which utilizes some useful information from the current population to readjust weights to obtain a search pressure toward a positive ideal point.

For the examined solutions at each generation, we define two extreme points: the maximum extreme point z^+ and the minimum extreme point z^- in criteria space as follows:

$$z^+ = (z_1^{\max}, z_2^{\max}, \dots, z_q^{\max}), \quad (33.10)$$

$$z^- = (z_1^{\min}, z_2^{\min}, \dots, z_q^{\min}), \quad (33.11)$$

where z_k^{\max} and z_k^{\min} are the maximum value and minimum value for objective k in the current population. Let P denote the set of the current population. For a given individual x , the maximal value and minimal value for each objective are defined as follows:

$$z_k^{\max} = \max\{f_k(x) | x \in P\}, \quad k = 1, 2, \dots, q, \quad (33.12)$$

$$z_k^{\min} = \min\{f_k(x) | x \in P\}, \quad k = 1, 2, \dots, q, \quad (33.13)$$

The hyperparallelogram defined by the two extreme points is a minimal hyperparallelogram containing all current solutions. The two extreme points are renewed at each generation. The maximum extreme point will gradually approximate the positive ideal point. The adaptive weight for objective k is calculated by

$$w_k = \frac{1}{z_k^{\max} - z_k^{\min}}, \quad k = 1, 2, \dots, q. \quad (33.14)$$

For a given individual x , the weighted-sum objective function is given by

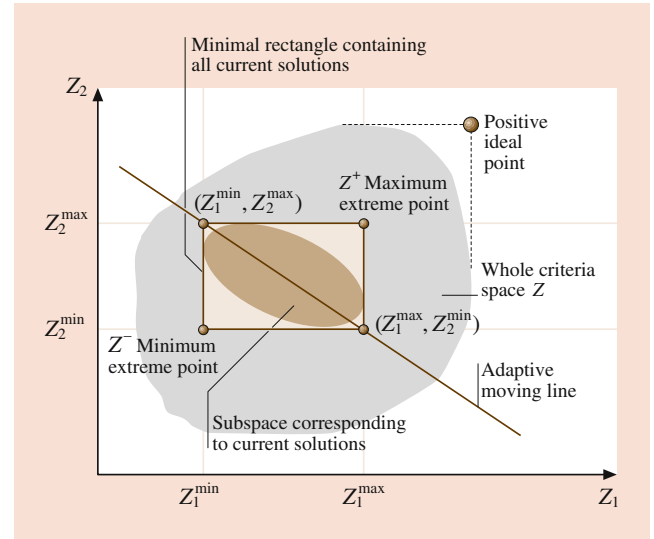

Fig. 33.6 Adaptive weights and adaptive hyperplane

$$eval(x) = \sum_{k=1}^q w_k (z_k - z_k^{\min}) \quad (33.15)$$

$$= \sum_{k=1}^q \frac{z_k - z_k^{\min}}{z_k^{\max} - z_k^{\min}} \quad (33.16)$$

$$= \sum_{k=1}^q \frac{f_k(x) - z_k^{\min}}{z_k^{\max} - z_k^{\min}}. \quad (33.17)$$

As the extreme points are renewed at each generation, the weights are renewed accordingly. Figure 33.6 is a hyperplane defined by the extreme points in the current solutions. It is an adaptive moving line defined by the extreme points (z_1^{\max}, z_2^{\min}) and (z_1^{\min}, z_2^{\max}) as shown Fig. 33.6. The rectangle defined by the extreme points (z_1^{\max}, z_2^{\min}) and (z_1^{\min}, z_2^{\max}) is the minimal rectangle containing all current solutions.

Nondominated Sorting Genetic Algorithm II (NSGA II: Deb 2001) Deb developed a Pareto ranking-based fitness assignment, and it is called NSGA [12]. In each method, the nondominated solutions constituting a nondominated front are assigned the same dummy fitness value. These solutions are shared with their dummy fitness values (phenotypic sharing on the decision vectors) and ignored in the further classification process. Finally, the dummy fitness is set to a value less than the smallest shared fitness value in the current non-dominated front. Then the next front is extracted. The procedure of NSGA II is repeated until all individuals in the population are classified [12].

Strength Pareto Evolutionary Algorithm 2 (SPEA2: Zitzler et al. [13]) Zitzler and Thiele proposed strength Pareto evolutionary algorithm and an extended version SPEA2 [13]

that combines several features of previous MoGA in a unique manner. The fitness assignment procedure is a two-stage process. The individuals in the external nondominated set P' are ranked.

Interactive Adaptive-Weight Genetic Algorithm (i-AWGA: Lin and Gen [9]) Lin and Gen proposed an interactive AWGA, which is an improved adaptive-weight fitness assignment approach with the consideration of the disadvantages of weighted-sum approach and Pareto ranking-based approach [14]. They combined a penalty term to the fitness value for all of dominated solutions. Firstly, we calculate the adaptive weight $w_i = 1/(z_i^{\max} - z_i^{\min})$ for each objective by using AWGA. Afterward, we calculate the penalty term $p(v_k) = 0$, if v_k is nondominated solution in the nondominated set P . Otherwise $p(v_k)=1$ for dominated solution v_k . Lastly, we calculate the fitness value of each chromosome by combining the i-AWGA method:

$$eval(v_k) = \sum_{i=1}^q w_i(z_i^k - z_i^{\min}) + p(v_k), \forall k \in \text{popSize} \quad (33.18)$$

Hybrid Sampling Strategy-Based EA Zhang et al. [15] Zhang et al. proposed a hybrid sampling strategy-based evolutionary algorithm [15, 16]. A Pareto dominating and dominated relationship-based fitness function (PDDR-FF) is proposed to evaluate the individuals. The PDDR-FF of an individual S_i is calculated by the following function:

$$eval(S_i) = q(s_i) + \frac{1}{p(s_i + 1)}, i = 1, 2, \dots, \text{popSize} \quad (33.19)$$

where $p()$ is the number of individuals which can be dominated by the individual S . $q()$ is the number of individuals which can dominate the individual S . The PDDR-FF can set the obvious difference values between the nondominated and dominated individuals. The general structure in the pseudocode of multiobjective hybrid genetic algorithm (Mo-HGA) is designed MoGA with a local search and FLC in HGA.

33.1.6 Genetic Algorithm with Learning

Earlier attention of the interaction between machine learning (ML) and genetic algorithm (GA) was presented by Goldberg and Holland in 1988 [1, 17]. During the search process, the GA can store ample data about the search information, population information, and problem features. Thus, the ML

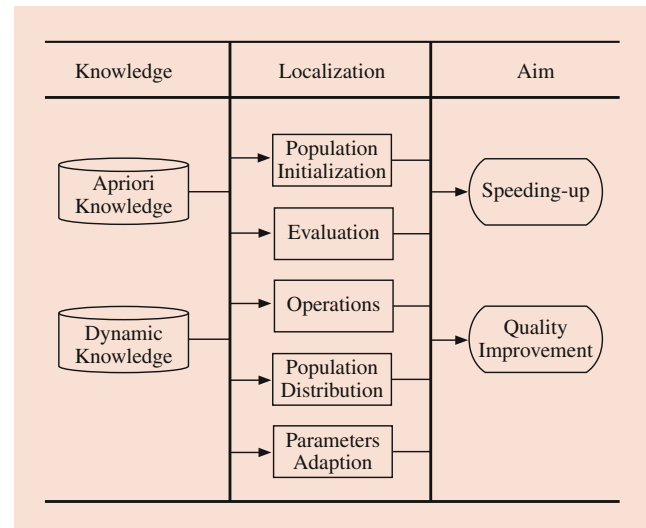

Fig. 33.7 An illustration of the hybridization taxonomy [18]

technique is helpful in analyzing these data for enhancing the search performance of GAs. Recently Lin and Gen surveyed hybrid evolutionary optimization algorithms with learning for various production scheduling problems [18]. In this way, useful information can be extracted to understand the search behavior and to assist with future searches for the global optimum. In many applications, GAs incorporating ML techniques have been proven to be advantageous in both convergence speed and solution quality. Jourdan et al. [19] and Zhang et al. [20] presented surveys of ML technique enhanced GAs.

The ML techniques can be incorporated into different GAs in various ways, and they affect GA also on various aspects. To classify the different ways to hybridization of ML techniques and GAs, Jourdan et al. presented a taxonomy by knowledge type/localization/aim as shown in Fig. 33.7.

Knowledge Type

ML as a knowledge discovery technique is the process of automatically exploring large volumes of data. For enhancing the performance of EAs, two kinds of knowledge can be distinguished:

- (1) A priori knowledge, a previously acquired knowledge, such as problem features and problem data set.
- (2) Dynamic knowledge, a dynamically acquired knowledge which is extracted or discovered during the search, such as search information and population information.

Aim

Another useful information to classify algorithms is to distinguish the aim of the hybridization:

- (1) Speeding-up: The hybridization is used to reduce the computational time, i.e., speed up techniques, by simplification of the fitness, i.e., fitness approximation, or by significantly reducing the search space, e.g., leading the EAs in promising area
- (2) Quality improvement: The hybridization is used to improve the quality of the search by introducing knowledge in EA operations or in other parts of the EAs.

In fact, the insertion of ML techniques often leads to both speeding up the EAs and improving the quality.

Localization

Different EAs have similar framework in implementation and algorithmic characteristics. Michalewicz [5] summarized five basic components of EAs, and a general evolution process of the EAs is shown in Fig. 33.8:

- An evolutionary representation of potential solutions to the problem.
- A way to create a population (an initial set of potential solutions).
- An evaluation function rating solutions in terms of their fitness.
- Evolutionary operators that alter the genetic composition of offspring (crossover, mutation, selection, etc.).
- Parameter values that evolutionary algorithm uses (population size, probabilities of applying evolutionary operators, etc.).

33.2 Combinatorial Optimization Problems

Combinatorial optimization studies problems which are characterized by a finite number of feasible solutions. An impor-

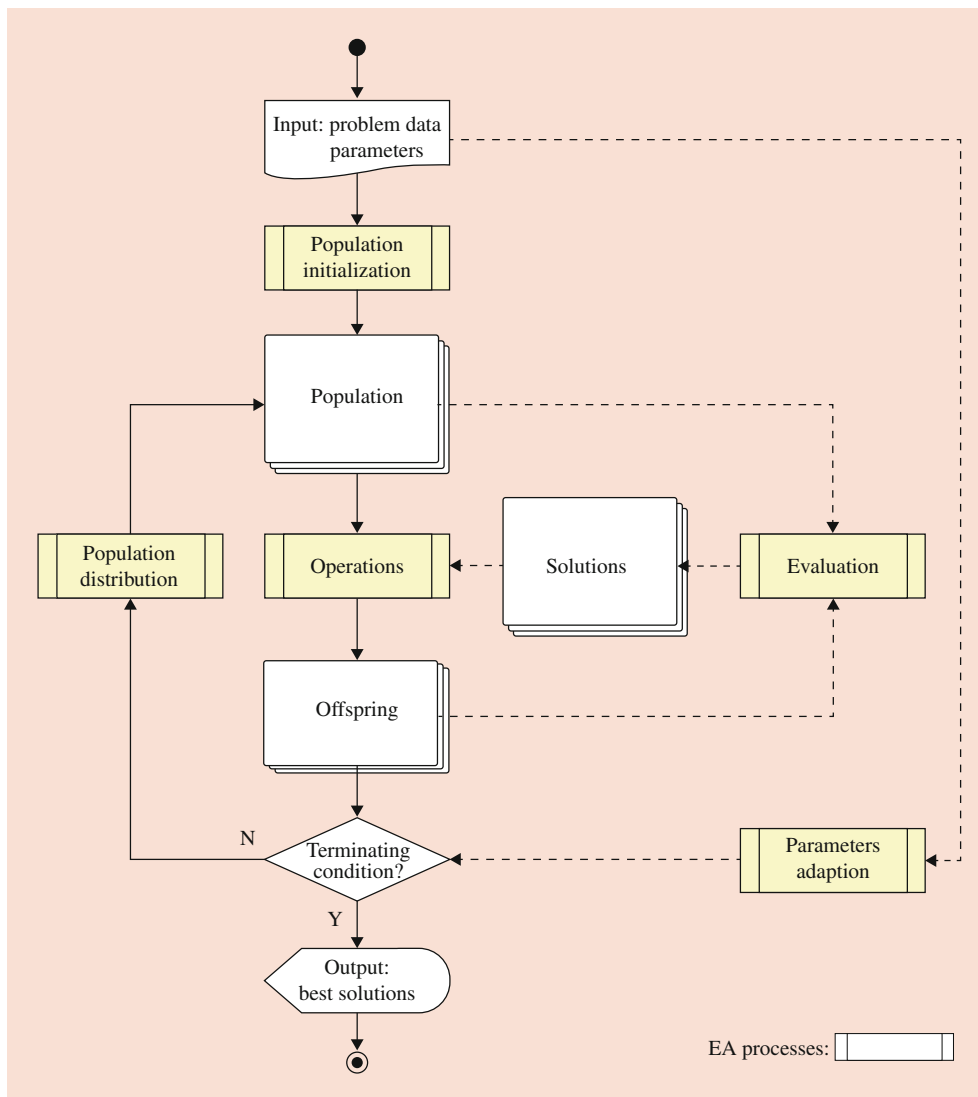

Fig. 33.8 A general evolution process of the EAs [18]

tant and widespread area of application concerns the efficient use of scarce resources to increase productivity.

33.2.1 Knapsack Problem

Suppose that we want to fill up a knapsack by selecting some objects among various objects (generally called items). There are n different items available, and each item j has a weight of w_j and amazing profit of p_j . The knapsack can hold a weight of at most W . The problem is to find an optimal subset of items so as to maximize the total profit subject to the knapsack's weight capacity. The profits, weights, and capacity are positive integers [21].

Let x_j be binary variables given by

$$x_j = \begin{cases} 1 & \text{if item } j \text{ is selected,} \\ 0 & \text{otherwise.} \end{cases} \quad (33.20)$$

The knapsack problem can be mathematically formulated as

$$\max \sum_{j=1}^n p_j x_j, \quad (33.21)$$

$$\text{s. t. } \sum_{j=1}^n w_j x_j \leq W, \quad (33.22)$$

$$x_j = 0 \text{ or } 1 \quad j = 1, 2, \dots, n. \quad (33.23)$$

Binary Representation Approach

The binary string is a natural representation for the knapsack problem, where one means the inclusion and zero the exclusion of one of the n items from the knapsack. For example, a solution for the 10-item problem can be represented as the following bit string:

$$\mathbf{x} = (x_1 x_2 \dots x_{10}) \\ (0 \ 1 \ 0 \ 1 \ 0 \ 0 \ 0 \ 1 \ 0),$$

meaning that items 2, 4, and 9 are selected for inclusion in the knapsack.

33.2.2 Minimum Spanning Tree Model

Consider a connected undirected graph $G = (V, E)$, where $V = \{v_1, v_2, \dots, v_n\}$ is a finite set of vertices representing terminals or telecommunication stations, etc. and $E = \{e_{ij} | e_{ij} = (v_i, v_j), v_i, v_j \in V\}$ is a finite set of edges representing connections between these terminals or stations. Each edge has an associated positive real number denoted by $W = \{w_{ij} | w_{ij} = w(v_i, v_j), w_{ij} > 0, v_i, v_j \in V\}$ representing distance, cost, and

so on. The vertices and edges are sometimes referred to as nodes and links, respectively.

Based on their different backgrounds, many researchers have proposed varieties of spanning tree problems with some constraints on them, such as the spanning tree problem with a degree constraint, the stochastic spanning tree problem, the quadratic spanning tree problem, the multicriteria spanning tree problem, and the spanning tree problem with a constraint on the number of leaves or leaf-constrained spanning tree problem [22, 23].

A spanning tree is a minimal set of edges from E that connects all the vertices in V , and therefore at least one spanning tree can be found in graph G . The minimum spanning tree is just one of the spanning trees whose total weight of all edges is minimal. It can be formulated as

$$\min z(\mathbf{x}) = \sum_{i=1}^{n-1} \sum_{j=2}^n w_{ij} x_{ij}, \quad (33.24)$$

$$\text{s. t. } \sum_{i=1}^{n-1} \sum_{j=2}^n x_{ij} = n - 1; \quad (33.25)$$

$$\sum_{i \in S} \sum_{j \in S} x_{ij} \leq |S| - 1, \quad S \subseteq V \setminus \{1\}, \quad |S| \geq 2, \quad (33.26)$$

$$x_{ij} = 0 \text{ or } 1, \quad i = 1, 2, \dots, n-1, \\ j = 2, 3, \dots, n, \quad (33.27)$$

where

$$x_{ij} = \begin{cases} 1, & \text{if edge } (i, j) \text{ is selected in a spanning tree} \\ 0, & \text{otherwise} \end{cases} \quad (33.28)$$

and T is a set of the spanning trees of graph G .

A. Tree Encodings

For the minimum spanning tree (MST) problem, the method of encoding a tree is critical for the genetic algorithm approach because the solution should be a tree.

If we associate an index k with each edge, i.e., $E = \{e_k\}$, $k = 1, 2, \dots, K$, where k is the number of edges in a graph, a bit string can represent a candidate solution by indicating which edges are used in a spanning tree, as illustrated in Fig. 33.9.

B. Genetic Algorithm Approach

Representation The chromosome representation for a spanning tree should contain, implicitly or explicitly, the degree on each vertex. Among the several tree encodings, only the Prüfer number encoding explicitly contains the information of vertex degree, i.e., that any vertex with degree d will appear

Fig. 33.9 A graph with its edge encoding for a spanning tree

exactly $d-1$ times in the encoding. Thus the Prüfer number encoding is adopted.

Crossover and Mutation Prüfer number encoding can still represent a tree after any crossover or mutation operations. Simply, the one-point crossover operator is used, as illustrated in Fig. 33.10. Mutation is performed as random perturbation within the permissive integer from 1 to n (n is the number of vertices in graph). An example is given in Fig. 33.11.

33.2.3 Set-Covering Model

The problem is to cover the rows of an m -row/ n -column zero-one matrix by a subset of columns at minimal cost. Considering a vector n , x_j is 0–1 variable that takes on the 3 value 1, if item j is selected (with a cost $c_j > 0$). The set-covering problem is then formulated as

$$\min z(\mathbf{x}) = \sum_{j=1}^n c_j x_j, \tag{33.29}$$

$$\text{s. t. } \sum_{j=1}^n a_{ij} x_j \leq 1 \quad i = 1, 2, \dots, m, \tag{33.30}$$

$$x_j \in \{0, 1\}, \quad j = 1, 2, \dots, n. \tag{33.31}$$

Genetic Algorithm Approach

Representation The fitness $f(\mathbf{x})$ of an individual is calculated simply by

$$f(\mathbf{x}) = \sum_{j=1}^n c_j x_j. \tag{33.32}$$

The initial population can be generated randomly.

Fig. 33.10 Illustration of the crossover operation

Fig. 33.11 Illustration of the mutation operation

Genetic Operators Beasley and Chu proposed a generalized fitness-based crossover operator called the fusion operator.

Let P_1 and P_2 be the parent strings. Let f_{P_1} and f_{P_2} be the fitness values of the parent strings P_1 and P_2 , respectively. Let C be the child string. The fusion operator works as follows:

Procedure: Fusion Operator

- Step 1. $i = 1$.
- Step 2. If $P_1[i] = P_2[i]$, then $C[i] \leftarrow P_1[i] = P_2[i]$.
- Step 3. If $P_1[i] \neq P_2[i]$, then
 - (a) $C[i] \leftarrow P_1[i]$ with probability $p = f_{P_2} / (f_{P_1} + f_{P_2})$.
 - (b) $C[i] \leftarrow P_2[i]$ with probability $1-p$
- Step 4. If $i = n$, stop; otherwise, set $i \leftarrow i + 1$ and go to step 1.

33.2.4 Bin-Packing Model

The bin-packing problem consists of placing n objects into a number of bins (at most n bins). Each object has a weight ($w_i > 0$) and each bin has a limited bin capacity ($c_i > 0$). The problem is to find the best assignment of objects to bins such that the total weight of the objects in each bin does not exceed its capacity and the number of bins used is minimized.

Genetic Algorithm Approach

Representation The most straightforward approach is to encode the membership of objects in the solution. For instance,

Fig. 33.12 Representation of membership of objects

the chromosome [1 4 2 3 5 2] would encode a solution where the first object is in bin 1, the second in bin 4, the third in bin 2, the fourth in bin 3, the fifth in bin 5, and the sixth in bin 2. This representation for the bin-packing problem is illustrated in Fig. 33.12.

A mathematical formulation for the bin-packing problem is given as follows [10, 21]:

$$\min z(y) = \sum_{i=1}^n y_i, \tag{33.33}$$

$$\text{s. t. } \sum_{j=1}^n w_j x_{ij} \leq c_i y_i, \quad i \in N = \{1, 2, \dots, n\}, \tag{33.34}$$

$$\sum_{i=1}^n x_{ij} = 1, \quad j \in N \tag{33.35}$$

$$y_i = 0 \text{ or } 1, \quad i \in N \tag{33.36}$$

$$x_{ij} = 0 \text{ or } 1, \quad i, j \in N \tag{33.37}$$

where

$$y_i = \begin{cases} 1, & \text{if bin } i \text{ is used} \\ 0, & \text{otherwise,} \end{cases} \tag{33.38}$$

$$x_{ij} = \begin{cases} 1, & \text{if object } j \text{ is assigned to bin } i \\ 0, & \text{otherwise.} \end{cases} \tag{33.39}$$

Genetic Operators

Procedure: Crossover

- Step 1 Select at random two crossing sites, delimiting the crossing section, in each of the two parents.
- Step 2 Inject the contents of the crossing section of the first parent at the first crossing site of the second parent.
- Step 3 Eliminate all objects now occurring twice from the bins they were members of in the second parent, so that the *old* membership of these objects gives way to the membership specified by the *new* injected bins. Consequently, some of the old groups coming from the second parent are altered.
- Step 4 If necessary, adapt the resulting bins, according to the hard constraints and the cost function to optimize.

Step 5 Apply steps 2–4 to the two parents with their roles permuted to generate the second child.

33.2.5 Traveling-Salesman Model

The traveling-salesman problem (TSP) is one of the most widely studied combinatorial optimization problems. Its statement is deceptively simple: a salesman seeks the shortest tour through *n* cities.

For example, a tour of a nine-city TSP

$$3 - 2 - 5 - 4 - 7 - 1 - 6 - 9 - 8$$

is simply represented as follows:

$$[3 \ 2 \ 5 \ 4 \ 7 \ 1 \ 6 \ 9 \ 8].$$

This representation is also called a path representation or order representation. This representation may lead to illegal tours if the traditional one-point crossover operator is used; therefore many crossover operators have been investigated for it. Another method is the random keys representation. This representation encodes a solution with random numbers from (0,1). These values are used as sort keys to decode the solution.

For example, a chromosome for a nine-city problem may be

$$[0.23 \ 0.82 \ 0.45 \ 0.74 \ 0.87 \ 0.11 \ 0.56 \ 0.69 \ 0.78]$$

where position *i* in the list represents city *i*. The random number in position *i* determines the visiting order of city *i* in a TSP tour. We sort the random keys in ascending order to get the following tour:

$$6 - 1 - 3 - 7 - 8 - 4 - 9 - 2 - 5.$$

Genetic Algorithm Approach *Representation*: Permutation representation is perhaps the most natural representation of a TSP tour, where cities are listed in the order in which they are visited [24, 25].

Crossover Operators

Procedure Partial-Mapped Crossover (PMX) [25].

- Step 1. Select two positions along the string uniformly at random.
- Step 2. Exchange two substrings between parents to produce proto-children.
- Step 3. Determine the mapping relationship between two mapping sections.
- Step 4. Legalize offspring with the mapping relationship.

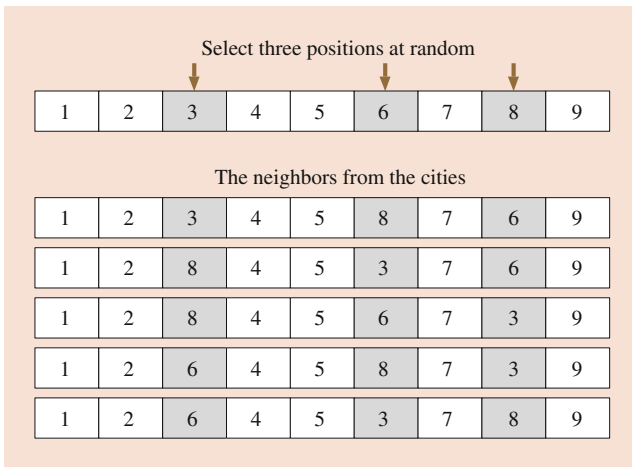

Fig. 33.13 Illustration of the heuristic mutation operator

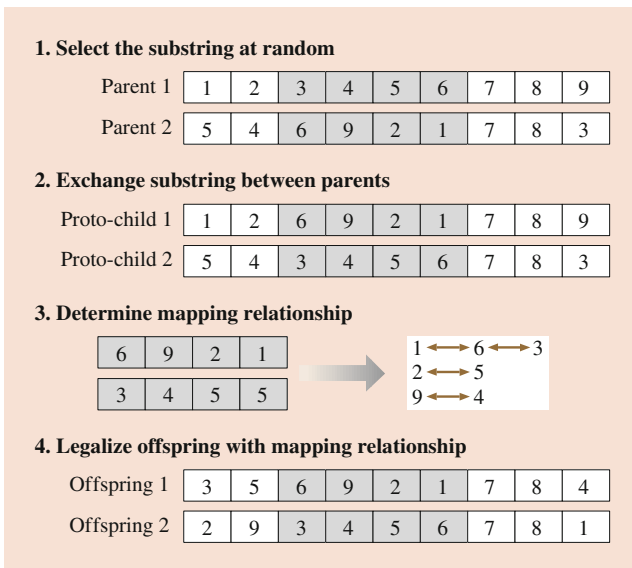

Fig. 33.14 Illustration of the PMX operator

The procedure is illustrated in Fig. 33.13.

Mutation Operators

Procedure : *Heuristic Mutation* [26,27].

- Step 1. Pick n genes at random.
- Step 2. Generate neighbors according to all possible permutation of the selected genes.
- Step 3. Evaluate all neighbors and select the best one as offspring.

The procedure is illustrated in Fig. 33.14.

33.3 Network Design Problems

Network design and routing are one of important issues in the building and expansion of computer networks. Many ideas

Fig. 33.15 Simple undirected graph with six nodes and ten edges

and methods have been proposed and tested in the past two decades. Recently, there is an increasing interest in applying genetic algorithms to problems related to computer network [4,28].

33.3.1 Shortest-Path Model

An undirected graph $G = (V, E)$ comprises a set of nodes $V = \{1, 2, \dots, n\}$ and a set of edges $E \in V \times V$ connecting nodes in V .

Corresponding to each edge, there are two nonnegative numbers c_{ij}^1 and c_{ij}^2 representing the cost and distance, or other items of interest, from node i to node j is a sequence of edges $(i, l), (l, m), \dots, (k, j)$ from E in which no node appears more than once. A path can also be equivalently represented as a sequence of nodes (i, l, m, \dots, k, j) . For the example given in Fig. 33.15, $(1,4), (4,3), (3,5), (5,6)$ is a path from node 1 to node 6. The node representation is $(1, 4, 3, 5, 6)$.

Let 1 denote the initial node and n denote the end node of the path. Let x_{ij} be an indicator variable defined as follows:

$$x_{ij} = \begin{cases} 1, & \text{if edge } (i, j) \text{ is included in the path} \\ 0, & \text{otherwise.} \end{cases} \tag{33.40}$$

Genetic Algorithm Approach

Priority-Based Encoding [14,29–32] The position of a gene is used to represent a node, and the value is used to represent the priority of the node for constructing a path among the candidates. The encoding method is denoted by priority-based encoding. The path corresponding to a given chromosome is generated by a sequential node appending procedure, beginning from the specified node 1 and terminating at the specified node n . The bicriteria shortest-path problem can be formulated as follows:

$$\min z_1(\mathbf{x}) = \sum_i \sum_j c_{ij}^1 x_{ij}, \tag{33.41}$$

Fig. 33.16 Simple undirected graph with 10 nodes and 16 edges

Position: node ID	1	2	3	4	5	6	7	8	9	10
Value: priority	7	3	4	6	2	5	8	10	1	9

Fig. 33.17 Example of priority-based encoding

$$\min z_2(\mathbf{x}) = \sum_i \sum_j c_{ij}^2 x_{ij}, \quad (33.42)$$

$$\text{s. t. } \sum_j x_{ij} \leq 2, \forall i \in V, \quad (33.43)$$

$$\sum_j x_{ij} \geq x_{ik}, \forall (i, k) \in E, \forall i \in V \setminus \{1, n\} \quad (33.44)$$

$$\sum_j x_{1j} = \sum_j x_{jn} = 1, \forall i, j \in V, \quad (33.45)$$

$$x_{ij} = x_{ji}, \quad \forall (i, j) \in E, \quad (33.46)$$

$$0 \leq x_{ij} \leq 1, \quad \forall (i, j) \in E \quad (33.47)$$

Consider the undirected graph shown in Fig. 33.16. Suppose we are going to find a path from node 1 to node 10. An encoding of the instance is given in Fig. 33.17. At the beginning, we try to find a node for the position next to node 1. Nodes 2 and 3 are eligible for the position, which can be easily fixed according to the adjacency relation among nodes. The priorities of them are 3 and 4, respectively. Node 3 has the highest priority and is put into the path. The possible nodes next to node 3 are nodes 2, 5, and 6. Because node 6 has the largest priority value, it is put into the path. Then we form the set of nodes available for the next position and select the one with the highest priority among them. These steps are repeated until we obtain a complete path (1, 3, 6, 7, 8, 10).

For an n -node problem, let Ω be a set containing integer exclusively from the set Ω , that is, $\Omega = \{1, 2, \dots, n\}$; let p_i denote the priority for node i , which is a random integer exclusively from the set Ω . Priorities p_i of all nodes satisfy the following conditions:

$$p_i \neq p_j, \quad p_i, p_j \in \Omega, \quad i \neq j, i, j \neq 1, 2, \dots, n \quad (33.48)$$

Fig. 33.18 Position-based crossover operator

Fig. 33.19 Swap mutation operator

Then the priority-based encoding can be formally defined as

$$[p_1 \ p_2 \ \dots \ p_n]$$

Genetic Operators

Here the position-based crossover operator proposed by Syswerda is adopted. It can be viewed as a kind of uniform crossover operator for integer permutation representation together with a pairing procedure, as shown in Fig. 33.18. Essentially, it takes some genes from one parent at random and fills the vacuum position with genes from the other parent using a left-to-right scan. The swap mutation operator is used here, which simply selects two positions at random and swaps their contents as shown in Fig. 33.19.

33.3.2 Maximum-Flow Model

There have been many applications of the maximum-flow problem (MXF) in the real world. One of them is to determine the maximum flow through a pipeline network. Assume that oil should be shipped from the refinery (the source) to a storage facility (the sink) along arcs of the network. Each arc has a capacity which limits the amount of flow along that arc. Here, we want to determine the largest possible.

This is a flow that can be sent from the refinery to the storage facility with the restriction that no arc (pipe) capacity can be exceeded. MXF has also been applied to some other applications such as the problem of selecting sites for an electronic message-transmission system and dynamic flows in material-handling systems [14, 32, 33]. A mathematical formulation for the bin-packing problem is given by

$$\max f \quad (33.49)$$

$$\text{s. t. } \sum_{j=1}^n x_{ij} - \sum_{k=1}^m x_{ki} = \begin{cases} f, & \text{if } i = 1 \\ 0, & \text{if } i = 2, 3, \dots, m-1 \\ -f, & \text{if } i = m \end{cases} \quad (33.50)$$

$$0 \leq x_{ij} \leq u_{ij}, \quad i, j = 1, 2, \dots, m \quad (33.51)$$

where f is the amount of flow in the network from node 1 to node m and u_{ij} is arc capacities.

Genetic Algorithm Approach

The priority-based encoding method is used to represent the chromosome. The chromosome here is represented by m -digit numbers that are generated randomly. Each number represents the priority of the node.

Crossover As the first step in the crossover operation, we generate random numbers γ_k in the range $[0, 1]$ ($k = 1, 2, \dots, popSize$). Next, we select the chromosomes v_k to which the crossover operation will be applied. If $\gamma_k < p_C$, then the crossover operation will be applied to chromosome v_k .

Mutation Similarly, the first step in the mutation operation is to generate a random γ_r in the range $[0, 1]$, ($r = 1, 2, \dots, popSize$).

If $\gamma_r < p_M$, then the chromosome v_k ($l = (r/m + 1)$) is chosen for the mutation operation.

33.3.3 Minimum-Cost-Flow Model

The minimum-cost-flow (MCF) problem is known as a useful type of network optimization problem. It consists of finding the minimum-cost flows in the networks. For this problem, we are given a directed network $G = (X, A)$ in which each arc connecting nodes i and j in the network is associated with a cost c_{ij} and a capacity u_{ij} . A feasible solution to the MCF problem should satisfy two constraints. First, the flow through each arc should satisfy the capacity constraint. Second, the conservation of flow in all nodes should also be preserved. The conservation of flows here means that the flow into a node must equal the flow out of the node. The common objective is to determine the feasible network flow that minimizes the total cost.

A mathematical formulation for the bin-packing problem is given by

$$\min z = \sum_{i=1}^m \sum_{j=1}^m c_{ij} x_{ij}, \quad (33.52)$$

$$\text{s. t. } \sum_{j=1}^m x_{ij} - \sum_{k=1}^m x_{ki} = b_i, \quad i = 1, \dots, m, \quad (33.53)$$

$$x_{ij} \geq 0, \quad i, j = 1, \dots, m, \quad (33.54)$$

where x_{ij} is the flow through an arc and c_{ij} is the unit shipping cost along the arc. Equation (33.53) is called the flow conservation or Kirchhoff equation and indicates that flow may be neither created nor destroyed in the network. Genetic Algorithm Approach

Representation The chromosome here is represented by m -digit numbers generated randomly. Each number represents the priority of the node respectively.

Crossover The crossover is done by selecting two chromosome randomly. We use the partially matched crossover (PMX) method for the crossover operation.

Mutation Mutation here is done by selecting a chromosome at random. Two bit positions of the chromosome are exchanged.

33.3.4 Centralized Network Design

Consider a complete, undirected graph $G = (V, E)$; let $V = \{1, 2, \dots, n\}$ be the set of nodes representing terminals. Denote the central site or root node as node 1, and let $E = \{(i, j) | i, j \in V\}$ be the set of edges representing all possible telecommunication wiring. For a subset of nodes $S (\subseteq V)$, define $E(S) = \{(i, j) | i, j \in S\}$ as the edges whose endpoints are both in S . Define the following binary decision variables for all edges $(i, j) \in E$:

$$x_{ij} = \begin{cases} 1, & \text{if edge } (i, j) \text{ is selected} \\ 0, & \text{otherwise.} \end{cases} \quad (33.55)$$

Let c_{ij} be the fixed cost with respect to edge (i, j) in the solution, and suppose that d_i represents the demand at each node $i \in V$, where by convention the demand of the root node is $d_1 = 0$. Let $d(S)$, $S \subseteq V$ denote the sum of the demands of nodes of S . The subtree capacity is denoted with k . The centralized network design problem can be formulated as follows:

$$\min z = \sum_{i=1}^{n-1} \sum_{j=2}^n c_{ij} x_{ij}, \quad (33.56)$$

$$s. t. \sum_{i=1}^{n-1} \sum_{j=2}^n x_{ij} = 2(n - 1), \quad (33.57)$$

$$\sum_{i \in S} \sum_{j \in S} x_{ij} \leq 2[|S| - \lambda(S)]$$

$$S \subseteq V \setminus \{1\}, |S| \geq 2, \quad (33.58)$$

$$\sum_{i \in U} \sum_{j \in U} x_{ij} \leq 2(|U| - 1), U \subset V,$$

$$|U| \geq 2, \{1\} \in U, \quad (33.59)$$

$$x_{ij} = 0 \text{ or } 1, i = 1, 2, \dots, n - 1, \\ j = 2, 3, \dots, n, \quad (33.60)$$

Equality (33.57) is true of all spanning trees: a tree with n nodes must have $n - 1$ edges. Inequality (33.58) is a standard inequality for spanning trees: if more than $|U| - 1$ edges connect the nodes of a subset U , then the set U must contain a cycle. The parameter $\lambda(S)$ refers to the bin-packing number of set S , namely, the number of bins of size k needed to pack the nodes of items of size d_i for all $i \in S$. These constraints are similar to those for inequality (33.59), except that they reflect the capacity constraint: if the set S does not contain the root node, then the nodes of S must be contained in at least $\lambda(S)$ different subtrees of the root.

In Fig. 33.20, node ID is the node number based on the depth-first search (DFS), and the degree at node ID is the number of connecting nodes.

Genetic Algorithm Approach

To solve the centralized network design problem by using a genetic algorithm, a tree-based permutation encoding method is adopted to encode the candidate solutions, as illustrated in Fig. 33.20.

33.3.5 Multistage Process Planning Model

The multistage process planning (MPP) system usually consists of a series of machining operations, such as turning, drilling, grinding, finishing, and so on, to transform a part into its final shape or product. The whole process can be divided into several stages. At each stage, there are a set of similar manufacturing operations. The MPP problem is to find the optimal process planning among all possible alternatives given certain criteria such as minimum cost, minimum time, and maximum quality or under several of these criteria.

For an n -stage MPP problem, let s_k be some state at stage k , $D_k(s_k)$ be the set of possible states to be chosen at stage k , and $k = 1, 2, \dots, n$, x_k be the decision variable to determine which state to choose at stage k ; obviously $x_k \in D_k(s_k)$, $k = 1, 2, \dots, n$. Then the MPP problem can be formulated as follows:

Fig. 33.20 Rooted tree and its tree-based permutation

Fig. 33.21 Mutation with neighborhood search

$$\min_{x_k \in D_k(s_k), k=1,2,\dots,n} V(x_1, x_2, \dots, x_n) = \sum_{k=1}^n v_k(s_k, x_k). \quad (33.61)$$

where $v_k(s_k, x_k)$ represents the criterion to determine x_k under state s_k at stage k , usually defined as a real number such as cost, time, or distance.

Genetic Algorithm Approach

Representation The MPP solution can be concisely encoded in a state permutation format by concatenating all the set states of stages. This state permutation encoding has a one-to-one mapping for the MPP problem. The probability of randomly producing a process planning is definitely 1. It is also easy to decode and evaluate. As to the initial population for an n -stage MPP problem, each individual is a permutation with $n - 1$ integers, whereas the integers are generated randomly with the number of all possible states in the corresponding stage.

Genetic Operation: In Zhou and Gen’s method, only the mutation operation was adopted because it is easy to hybrid the neighborhood search technique to produce more adapted offspring[10]. This hybrid mutation operation provides a great chance to evolve to the optimal solution.

Figure 33.21 shows an example for this mutation operation with a neighborhood search technique supposing that

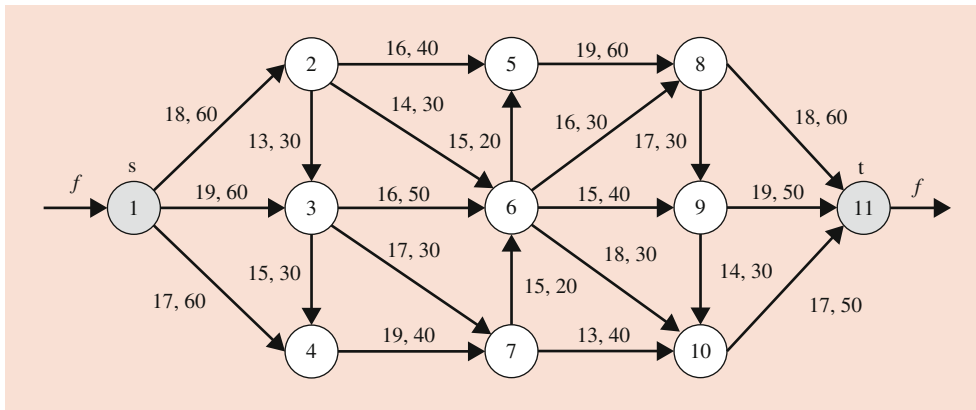

Fig. 33.22 A simple network with 11 nodes and 22 edges

the gene is at stage 3 and the number of possible states to be chosen is 4.

33.3.6 Bicriteria MXF/MCF Model

The bicriteria network design (BND) problem is known as NP-hard; it is not simply an extension from single objective to two objectives. Considering the characteristic of priority-based encoding method, we applied a new crossover operator called as weight mapping crossover (WMX), and insertion mutation operator is adopted [34].

Mathematical Formulation

Consider a directed network $G = (N, A)$, consisting of a finite set of nodes $N = \{1, 2, \dots, n\}$ and a set of directed arcs $A = \{(i, j), (k, l), \dots, (s, t)\}$ joining pairs of nodes in N . Arc (i, j) is said to be incident with nodes i and j and is directed from node i to node j . We shall assume that the network has n nodes and m arcs. Figure 33.22 presents a simple network with 11 nodes and 22 arcs.

The decision variables in the BND problem are the maximum possible flow z_1 with minimum cost z_2 from source node 1 to sink node n . Mathematically, this problem is formulated as follows (where summations are taken over existing arcs):

$$\max z_1 = f \tag{33.62}$$

$$\min z_2 = \sum_{i=1}^n \sum_{j=1}^n c_{ij}x_{ij} \tag{33.63}$$

$$\text{s. t. } \sum_{j=1}^n x_{ij} - \sum_{k=1}^n x_{ki} = \begin{cases} f & (i = 1) \\ 0 & (i = 2, 3, \dots, n - 1) \\ -f & (i = n) \end{cases} \tag{33.64}$$

Locus :	1	2	3	4	5	6	7	8	9	10	11
Node ID :	11	1	10	3	8	9	5	7	4	2	6

Fig. 33.23 An example of priority-based chromosome

$$0 \leq x_{ij} \leq u_{ij} \quad \forall (i, j) \tag{33.65}$$

$$x_{ij} = 0 \text{ or } 1 \quad \forall i, j \tag{33.66}$$

The first objective function (33.62) is maximizing the total flow, and second objective function (33.63) is minimizing the total cost. Constraints (33.64) are called the flow conservation or Kirchhoff equations and indicate that the flow may be neither created nor destroyed in the network. In the conservation equations, sum of x_{jk} represents the total flow out of node j , while sum of x_{ij} indicates the total flow into node j . These equations require that the net flow out of node j should equal f . If $f < 0$, then there should be more flow into j than out of j .

Genetic Representation

In this problem, we consider a priority-based encoding method with special decoding for various network design problems. Cheng and Gen proposed priority-based genetic algorithm (priGA) firstly for solving resource-constrained project scheduling problem (rcPSP) [27]. The priority-based encoding method is an indirect approach. As it is known, a gene in a chromosome is characterized by two factors: locus, i.e., the position of gene located within the structure of chromosome, and allele, i.e., the value the gene takes. An example of priority-based encoding is shown in Fig. 33.23. For designing the decoding method, we first design a one-path growth procedure that obtains a path base on the generated chromosome with given network. We then design an overall-path growth procedure that removes the used flow from each arc and deletes the arcs whose capacity is 0. Table 33.1 shows two examples of the solution of bDN with various paths.

Table 33.1 Examples of the solutions with various paths

Solution	# of paths K	Path $P(\cdot)$	Total flow z_1	Total cost z_2
1	3	(1-3-6-5-8-11), (1-3-6-8-11), (1-3-7-6-9-11)	60	4660
2	8	(1-3-6-5-8-11), (1-3-6-8-11), (1-3-7-6-9-11), (1-4-7-6-9-11), (1-4-7-10-11), (1-2-5-8-11), (1-2-5-8-9-11), (1-2-6-9-10-11)	160	12450

Genetic Operators

For priority-based representation as a permutation representation, several crossover operators have been proposed, such as partial-mapped crossover (PMX), order crossover (OX), cycle crossover (CX), position-based crossover (PX), heuristic crossover, etc. [4]. In this BND model, we propose a weight mapping crossover (WMX); it can be viewed as an extension of one-cut-point crossover for permutation representation. At one-cut-point crossover, two chromosomes (parents) would choose a random cut-point and generate the offspring by using a segment of its own parent to the left of the cut-point and then remap the right segment based on the weight of other parent of the right segment. An example of the WMX is given in Fig. 33.24. For the mutation, we examine several kinds of mutation operators, and effectiveness of insertion mutation is the best one for priority-based representation. For the selection, it is mainly used to adjust genetic search in favor of a wide exploration of the search space when solving BND problems by the weighted-sum approach. We adopted roulette wheel selection that is the best selection type as supplementary to the weighted-sum approach.

In the BND model, we propose a fitness assignment approach by an interactive adaptive-weight GA (i-AWGA), which is an improved adaptive-weight fitness assignment approach with the consideration of the disadvantages of weighted-sum approach and Pareto ranking-based approach. We combine a penalty term to the fitness value for all of dominated solutions. Calculate the adaptive weight $w_1 = 1/(f_1^{\max} - f_1^{\min})$ for objective 1 and the adaptive weight $w_2 = 1/(f_2^{\max} - f_2^{\min})$ for objective 2. Afterward, calculate the penalty term $p(v_k) = 0$, if v_k is nondominated solution in the nondominated set P . Otherwise $p(v_k) = 1$ for dominated solution v_k . Last, calculate the fitness value of each chromosome by combining the method as follows, and we adopted roulette wheel selection as supplementary to the i-AWGA fitness assignment approach based on the following equation:

$$eval(v_k) = w_1(f_1^k - f_1^{\min}) + w_2(f_2^k - f_2^{\min}) + p(v_k), \quad \forall k \in popSize \tag{33.67}$$

Performance Measures

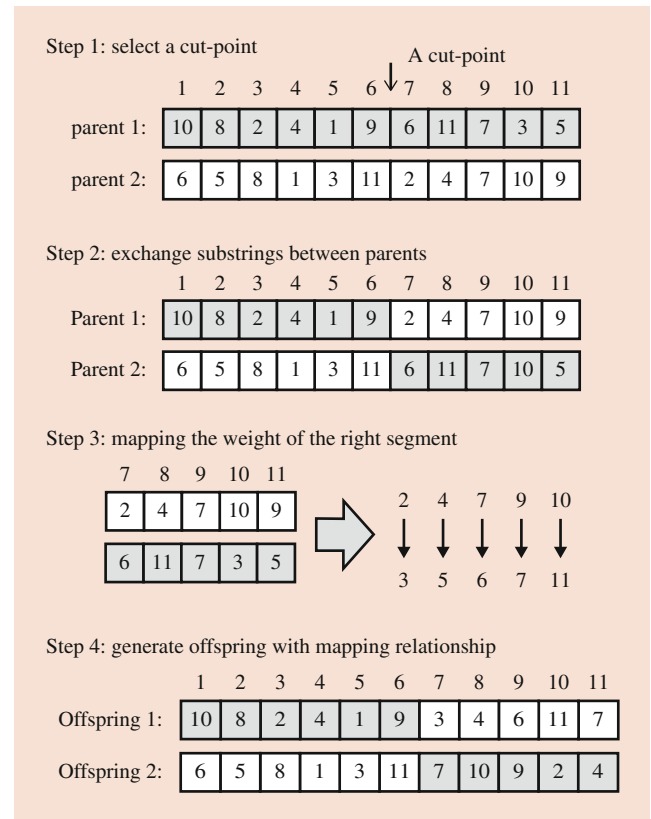

Fig. 33.24 An example of WMX

In order to evaluate the results of each test for the bicriteria network design problem, we are using the performance measures: average of the best solutions (ABS), percent deviation (PD) from optimal solution, and standard deviation (SD). We also give a statistical analysis by ANOVA and give examples of Pareto frontier, convergence patterns for the problems:

- (1) The number of obtained solutions $|S_j|$.
- (2) The ratio of nondominated solutions $R_{NDS}(S_j)$: A straightforward performance measure of the S_j with respect to the J solution sets is the ratio of solutions in S_j that are not dominated by any other solutions in S . The $R_{NDS}(S_j)$ measure can be written as follows:

Table 33.2 Fitness assignment approaches for the 25/49 test problem

# of eval. solut.	S _j				R _{NDS} (S _j)				D1 _R (S _j)			
	spEA	nsGAll	rwGA	i-awGA	spEA	nsGAll	rwGA	i-awGA	spEA	nsGAll	rwGA	i-awGA
50	41.20	43.60	42.60	44.00	0.35	0.33	0.34	0.33	181.69	180.64	168.73	168.96
500	49.80	56.60	51.60	57.50	0.47	0.50	0.42	0.46	104.77	114.62	119.53	103.13
2000	62.90	62.90	55.30	64.70	0.61	0.65	0.51	0.65	74.76	81.24	95.70	76.41
5000	67.80	68.40	60.70	69.40	0.73	0.72	0.64	0.73	62.97	62.77	80.68	62.33

Table 33.3 Comparison results using the three performance measures

Test problems (# of nodes/ # of arcs)	S _j		R _{NDS} (S _j)		D1 _R	
	pri-awGA	mo-hGA	pri-awGA	mo-hGA	pri-awGA	mo-hGA
25/49	60	58	0.379	0.483	1.945	0.727
25/56	67	60	0.516	0.597	1.647	1.207

$$R_{NDS}(S_j) = \frac{|S_j\{x \in S_j | \exists r \in S^* : r < x\}|}{|S_j|} \quad (33.68)$$

(3) The distance D1_R measure can be written as follows:

$$D1_R = \frac{1}{|S^*|} \sum_{r \in S^*} \min\{d_{rx} | x_t \in S_j\} \quad (33.69)$$

where S* is a reference solution set for evaluation of the solution set S_j and d_{rx} is the distance between a current solution x and a reference solution r.

$$d_{rx} = \sqrt{(f_1(r) - f_1(x))^2 + (f_2(r) - f_2(x))^2} \quad (33.70)$$

Experimental Result

We compare i-AWGA with SPEA, NSGA II, and rwGA through computational experiments under the same stopping condition (i.e., evaluation of 5000 solutions). Each algorithm was applied to each test problem 10 times and gives the average results of the three performance measures. In Table 33.2, better results of |S_j| and D1_R were obtained by the i-AWGA than other fitness assignment approach. As shown in Table 33.3, the Mo-HGA got the shortest distance D1_R and also gives better performance than pri-AWGA by R_{NDS}(S_j) measure. However, Mo-HGA did not effectively combine the number of obtained solutions |S_j|. We show the Pareto optimal solutions obtained from pri-AWGA and Mo-HGA with the test problem comprised of 25 nodes and 49 arcs in Fig. 33.25.

33.4 Scheduling Problem

Scheduling problems exist almost everywhere in real-world situations, especially in the industrial engineering world. Many scheduling problems from manufacturing industries are quite complex in nature and very difficult to solve by conventional optimization techniques [35].

33.4.1 Flow-Shop Sequencing Model

The flow-shop sequencing problem is generally described as follows: there are *m* machines and *n* jobs, each job consists of *m* operations, and each operation requires a different machine. *n* jobs have to be processed in the same sequence on *m* machines. The processing time of job *i* on machine *j* is given by *t_{ij}* (*i* = 1, ..., *n*; *j* = 1, ..., *m*). The objective is to find the sequence of jobs minimizing the maximum-flow time, which is called makespan.

Heuristics for general *m*-machine problems: i.e., genetic algorithms have been successfully applied to solve flow-shop problems. We describe Gen, Tsujimura, and Kubota's approach [36].

Representation Because the flow-shop problem is essentially a permutation schedule problem [4, 37, 38], we can use the permutation of jobs as the representation scheme of chromosome, which is the natural representation for a sequencing problem. For example, let the *k*-th chromosome be

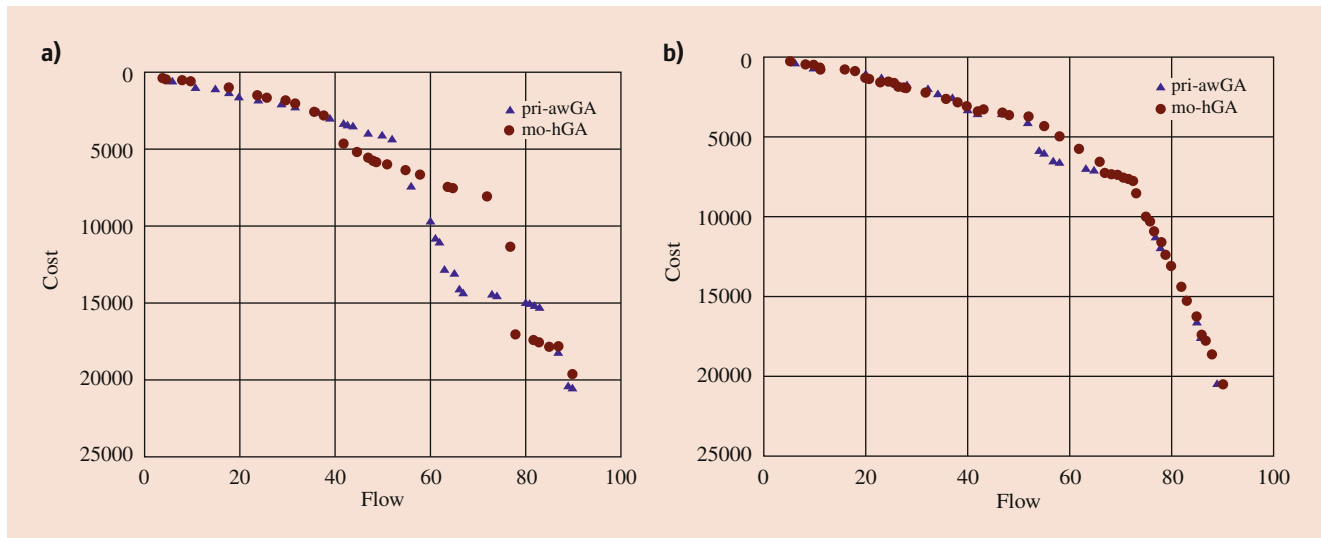

Fig. 33.25 Pareto optimal solutions by pro-AWGA and Mo-HGA with the 25/49 test problem. (a) The result is obtained at generation $gen = 50$. (b) The result is obtained at generation $gen = 100$

Fig. 33.26 Swap mutation

$$v_k = [3\ 2\ 4\ 1]$$

meaning that the jobs sequence is j_3, j_2, j_4, j_1 .

Crossover and Mutation Here, Goldberg’s PMX is used. Mutation is designed to perform random exchange; that is, it selects two genes randomly in a chromosome and exchanges their positions. An example is given in Fig. 33.26.

33.4.2 Job-Shop Scheduling Model

In the job-shop scheduling problem (JSP), we are given a set of jobs and a set of machines. Each machine can handle at most one job at a time. Each job consists of a chain of operations, each of which needs to be processed during an uninterrupted time period of a given length on a given machine. The purpose is to find a schedule, that is, an allocation of the operations to time intervals on the machines, which has a minimum duration required to complete all jobs [36,39,40].

Adapted Genetic Operators

During the past two decades, various crossover operators have been proposed for literal permutation encodings, such

as partial-mapped crossover (PMX), order crossover (OX), cycle crossover (CX), etc.

PMX is explained in the previous section.

Order Crossover (OX): Order crossover was proposed by Davis. OX has the following major steps [4, 25]:

- Step 1. Select a substring from one parent at random.
- Step 2. Produce a proto-child by copying the substring into the corresponding positions as they are in the parent.
- Step 3. Delete all the symbols from the second parent that are already in the substring. The resulted sequence contains the symbols the proto-child needs.
- Step 4. Place the symbols into the unfixed positions of the proto-child from left to right according to the order of the sequence to produce an offspring.

Cycle Crossover (CX): Cycle crossover was proposed by Oliver et al. CX works as follows:

- Step 1 Find the cycle which is defined by the corresponding positions of symbols between parents.
- Step 2 Copy the symbols in the cycle to a child with the corresponding positions of one parent.
- Step 3 Determine the remaining symbols for the child by deleting those symbols which are already in the cycle from the other parent.
- Step 4 Fill the child with the remaining symbols.

Mutation: It is relatively easy to make some mutation operators for the permutation representation. During the last decade, several mutation operators have been proposed for permutation representation, such as inversion, insertion, displacement, reciprocal exchange mutation, and shift mutation.

Inversion mutation selects two positions within a chromosome at random and then inverts the substring between these two positions. *Insertion mutation* selects a gene at random and inserts it in a random position.

33.4.3 Flexible Job-Shop Scheduling Model

Flexible job-shop scheduling problem (FJSP) is an extension of the traditional job-shop scheduling problem, which provides a closer approximation to real scheduling problems [41–44]. In the job-shop scheduling problem (JSP), there are n jobs that must be processed on a group of m machines. Each job i consists of a sequence of n_i operations ($o_{i1}, o_{i2}, \dots, o_{in_i}$), where o_{ik} (the k -th operation of job i) must be processed without interruption on a predefined machine m_{ik} for p_{ik} time units. The operations $o_{i1}, o_{i2}, \dots, o_{in_i}$ must be processed one after another in the given order, and each machine can process at most one operation at a time.

The first objective function accounts for makespan, Eq. (33.71) combining with Eq. (33.72) giving a physical meaning to the FJSP, referring to reducing total processing time and dispatching the operations averagely for each machine.

Mathematical Model of FJSP

$$\min c_M = \max_{1 \leq i \leq n} \{c_{in_i}\} \tag{33.71}$$

$$\min w_M = \max_{1 \leq j \leq m} \left\{ \sum_{i=1}^n \sum_{k=1}^{n_i} t_{ikj} x_{ikj} \right\} \tag{33.72}$$

$$\min w_T = \sum_{i=1}^n \sum_{k=1}^{n_i} \sum_{j=1}^m t_{ikj} x_{ikj} \tag{33.73}$$

$$\text{s. t. } c_{ik} - c_{i(k-1)} \geq t_{ikj} x_{ikj}, \quad k = 2, \dots, n_i; \quad \forall i, j \tag{33.74}$$

$$[(c_{hg} - c_{ik} - t_{hgi})x_{hgi}x_{ikj} \geq 0] \vee [(c_{ik} - c_{hg} - t_{ikj})x_{hgi}x_{ikj} \geq 0], \quad \forall (i, k), (h, g), j \tag{33.75}$$

$$\sum_{j \in A_{ik}} x_{ikj} = 1, \quad \forall i, k \tag{33.76}$$

$$x_{ikj} \in \{0, 1\}, \quad \forall i, k, j \tag{33.77}$$

$$c_{ik} > 0, \quad \forall i, k \tag{33.78}$$

function Eq. (33.73) is to minimize the total workload. Considering both equations, our objective is to balance the workloads of all machines. Inequality (33.74) describes the operation precedence constraints. Inequality (33.75) is a disjunctive constraint, where one or the other constraint must be observed.

It represents that the operation o_{hg} should not be started before the completion of operation o_{ik} or that the operation

o_{hg} must be completed before the starting of operation o_{ik} , if they are assigned on the same machine j . Shortly, the execution of operation o_{ik} cannot be overlapped in time with the execution of operation o_{hg} , which describes the operation precedence constraints. Equation (33.76) states that one machine must be selected from a set of available machines for each operation. Equations (33.77–33.78) are variable restrictions on decision variables [45, 46].

Multistage Operation-Based GA

For saving CPU time on several representations, a multistage operation-based GA approach has been proposed [47]. The two-vector multistage operation-based genetic algorithm (MoGA) for the FJSP is as follows:

Phase 1: Creating an operation sequence

- Step 1.1: Generate a random priority to each operation in the model using priority-based encoding procedure for the vector v_1 .
- Step 1.2: Decode a feasible operation sequence that satisfies the precedence constraints of FJSP by the priority-based decoding procedure.

Phase 2: Assigning operations to machines

- Step 2.1: Input the operation sequence found in step 1.2.
- Step 2.2: Generate a permutation encoding for machine assignment of each operation (second vector v_2).

Phase 3: Designing a schedule

- Step 3.1: Create a schedule S using operation sequence and machine assignments.
- Step 3.2: Draw a Gantt chart for the schedule.

For introducing the multistage operation-based GA for solving a simple example of the FJSP model, we first prepare the data set including three jobs operated on four machines in Table 33.4.

Table 33.4 Data set of a three-job four-machine problem

		M_1	M_2	M_3	M_4
J_1	O_{11}	1	3	4	1
	O_{12}	3	8	2	1
	O_{13}	3	5	4	7
J_2	O_{21}	4	1	1	4
	O_{22}	2	3	9	3
	O_{23}	9	1	2	2
J_3	O_{31}	8	6	3	5
	O_{32}	4	5	8	1

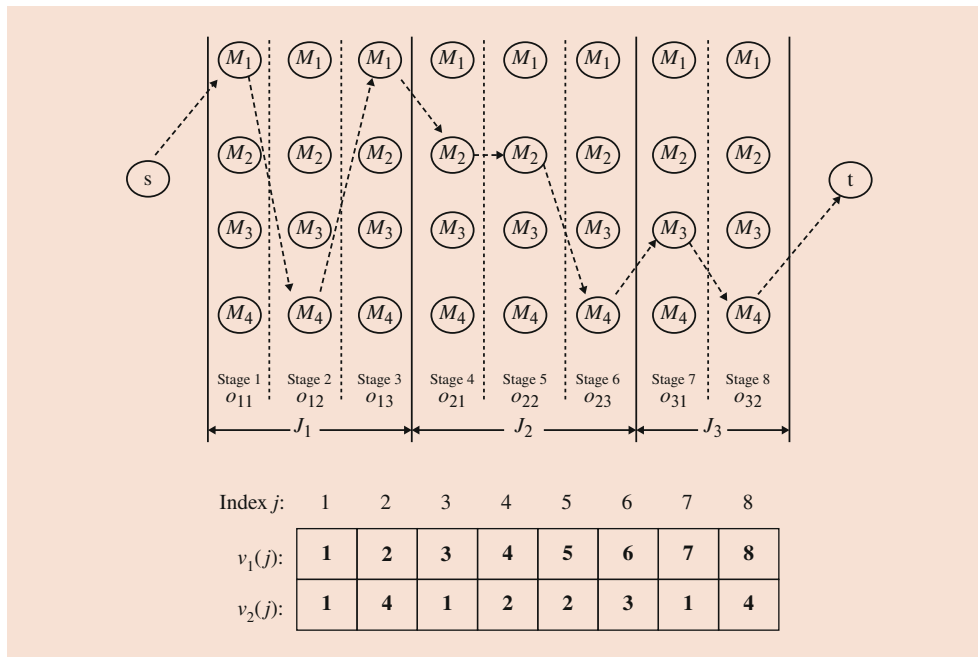

Fig. 33.27 Multistage operation-based representation of simple FJSP example

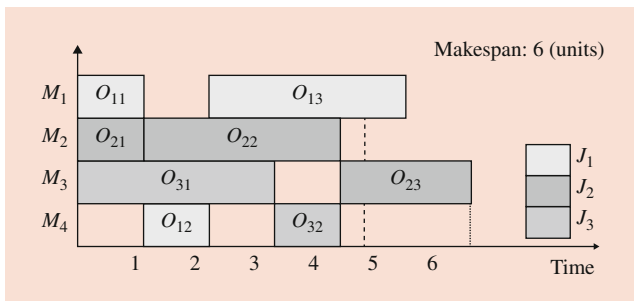

Fig. 33.28 Gantt chart for simple FJSP example

For the multistage operation-based representation of the simple FJSP example shown in Table 33.4, we denote each operation as one stage and each machine as one state; the problem can be formulated into an eight-stage, four-state problem; and also connected by the dashed arcs, a feasible schedule can be obtained as Fig. 33.27.

After Phases 1 and 2 of the multistage operation-based GA, we can create a schedule S using operation sequence and machine assignments as follows:

$$\begin{aligned}
 S &= \{(o_{11}, M_1), (o_{12}, M_4), (o_{13}, M_1), (o_{21}, M_2), \\
 & \quad (o_{22}, M_2), (o_{23}, M_1), (o_{31}, M_3), (o_{32}, M_4)\} \\
 &= \{(o_{11}, M_1 : 0 - 1), (o_{11}, M_4 : 1 - 2), (o_{11}, M_1 : \\
 & \quad 2 - 5), (o_{11}, M_2 : 0 - 1), (o_{11}, M_2 : 1 - 4), (o_{11}, \\
 & \quad M_1 : 4 - 6), (o_{11}, M_3 : 1 - 3), (o_{11}, M_4 : 3 - 4)\}
 \end{aligned}$$

From this schedule S , we can draw the Gantt chart as shown in Fig. 33.28.

The main advantages of the two-vector representation are that each possible chromosome always represents a feasible solution candidate and that the coding space is smaller than that of permutation representation. For the detailed solving process of the FJSP such as the priority-based decoding and neighborhood search method using critical path, we can refer to Section 5.3 Flexible Job-Shop Scheduling Model in [48–51].

Fitness Function

The three considered objective functions do not conflict with one another as seriously as in most other multiobjective optimization problems, because a small makespan (c_M) requires a small maximal workload (w_M) and a small maximal workload implies a small total workload (w_T). During evaluation, the fitness of a solution is calculated by synthesizing the three objectives into a weighted sum. We have to normalize the objective values on the three criteria before they are summed since they are of different scales. Let $c_M(\mathbf{v})$ be the makespan of the chromosome. The scaled makespan ($c'_M(\mathbf{v})$) of a solution \mathbf{v} is as follows:

$$c'_M(\mathbf{v}) = \begin{cases} \frac{c_M(\mathbf{v}) - c_M^{\min}}{c_M^{\max} - c_M^{\min}}, & \text{if } c_M^{\max} \neq c_M^{\min}, \text{ for all } \mathbf{v} \\ 0.5 & \text{otherwise,} \end{cases} \tag{33.79}$$

where

$$c_M^{\min} = \min_{1 \leq l \leq p} \{c_M(\mathbf{v})\} \quad (33.80)$$

$$c_M^{\max} = \max_{1 \leq l \leq p} \{c_M(\mathbf{v})\} \quad (33.81)$$

After scaling, the three objectives all take values from the range of [0, 1]. In order to guide the genetic and local search to the most promising area, makespan is given a very large weight since the other two objectives heavily depend on it. Additionally, it is typically the most important criterion in practical production environments. For the FJSP problem, a number of solutions with different maximal workloads or total workloads may have the same makespan. From this point of view, we firstly find the solutions with the minimum makespan and then minimize the maximal workload and the total workload in the presence of the minimum makespan. The fitness of a solution \mathbf{v} then is

$$eval(\mathbf{v}) = \alpha_1 \cdot c'_M(\mathbf{v}) + \alpha_2 \cdot w'_M(\mathbf{v}) + \alpha_3 \cdot w'_T(\mathbf{v})$$

$$\text{where, } \alpha_1 > \alpha_2 > \alpha_3 > 0 \text{ and } \alpha_1 + \alpha_2 + \alpha_3 = 1. \quad (33.82)$$

33.4.4 Resource-Constrained Project Scheduling Model

The problem of scheduling activities under resource and precedence restrictions with the objective of minimizing the project duration is referred to as the resource-constrained project scheduling problem in the literature [27, 52].

The problem can be stated mathematically as follows:

$$\min t_n, \quad (33.83)$$

$$\text{s. t. } t_j - t_i \geq d_i, \quad \forall j \in S_i, \quad (33.84)$$

$$\sum_{t_i \in A_{ik}} r_{ik} \leq b_k, \quad k = 1, 2, \dots, m, \quad (33.85)$$

$$t_i \geq 0, \quad i = 2, \dots, n, \quad (33.86)$$

where t_i is the starting time of activity i , d_i the duration (processing time) of activity i , S_i the set of successors of activity i , r_{ik} the amount of resource k required by activity i , b_k the total availability of resource k , A_{ik} the set of activities in process at time t_i , and m the number of different resource types. Activities 1 and n_4 are dummy activities which mark the beginning and end of the project. The objective is to minimize the total project duration.

A. Priority-Based Encoding

For this problem, priority-based encoding is used; it is explained in the previous section.

Fig. 33.29 Swap mutation operator

B. Genetic Operators

Position-Based Crossover: The position-based crossover operator is used. This crossover is explained in the previous section.

Swap Mutation: The swap mutation operator was used here, which simply selects two positions at random and swaps their contents, as shown in Fig. 33.29.

33.4.5 Multiprocessor Scheduling Model

The multiprocessor scheduling is to assign n tasks to m processors in such a way that precedence constraints are maintained and to determine the start and finish times of each task with the objective of minimizing the completion time. There is a paper which deals with real-time tasks [4, 53]. However, here we introduce an algorithm concerned with general tasks. The mathematical formulation of the problem is given as

$$\min[\max_j(x_j y_{ij})] \quad (33.87)$$

$$\text{s. t. } x_k - x_j \geq P_k, T_j < T_k, \quad (33.88)$$

$$\sum_{j=1}^n p_j y_{ij}, \quad j = 1, \dots, n, \quad (33.89)$$

$$\sum_{j=1}^m y_{ij} = 1, \quad j = 1, \dots, n, \quad (33.90)$$

$$y_{ij} = 0 \text{ or } 1, \quad i = 1, \dots, n, j = 1, \dots, n, \quad (33.91)$$

where

$$x_{ij} = \begin{cases} 1, & \text{if task } T_j \text{ is assigned to processor } P_i \\ 0, & \text{otherwise.} \end{cases} \quad (33.92)$$

and where $t_{\max} = \max_i(t_i)$, x_j is the completion time of task T_j , p_j is the processing time of task T_j , t_i is the time required to process all tasks assigned to process P_i , and $<$ represents a precedence relation; a precedence relation between tasks, $T_j < T_k$, means that T_k precedes T_j .

Genetic Algorithm for MSP

For the chromosome representation scheme and genetic operations, we adopt the concept of the height function, which considers precedence relations among the tasks in the implementation of a genetic algorithm.

Height Function To facilitate the generation of the schedule and the construction of the genetic operators, we define the *height* of each task in the task graph as

$$\text{height}(T_i) = \begin{cases} 0, & \text{if } \text{pre}(T_i) = \phi \\ 1 + \max_{T_k \in \text{pre}(T_i)} [\text{height}(T_k)], & \text{otherwise.} \end{cases} \quad (33.93)$$

$$\begin{aligned} \text{height}'(T_j) &= \text{rand} \in \{\max[\text{height}(T_i)] + 1\}, \\ \min[\text{height}'(T_k)] &\text{ over all } T_i \in \text{pre}(T_j) \text{ and} \\ T_k &\in \text{suc}(T_j) \end{aligned} \quad (33.94)$$

where $\text{pre}(T_j)$ is the set of predecessors of T_j and $\text{suc}(T_j)$ is the set of successors of T_j .

Representation The chromosome representation used here is based on the schedule of the tasks in each processor. The representation of the schedule for genetic algorithms must accommodate the precedence relations between the computational tasks.

Genetic Operators The function of the genetic operators is to create new search nodes based on the current population of search nodes. New search nodes are typically constructed by combining or rearranging parts of the old search nodes.

Operation 1: Operation 1 is performed in the following steps:

Step 1 Generate a random number c from the range $[1, \max(\text{height}')]]$.

Step 2 Place the cut-point at each processor in such a way that the tasks' height' before the cut-point is less than c and more than or equal to c after the cut-point.

Step 3 Exchange the second partial schedules.

Operation 2: Operation 2 is performed in the following steps:

Step 1 Generate a random number c from the range $[1, \max(\text{height}')]]$

Step 2 At each processor, pick all tasks whose height' is c .

Step 3 Replace the position of all tasks randomly.

33.4.6 Assembly Line Balancing

An *assembly line* (AL) is a manufacturing process consisting of various tasks in which interchangeable parts are added to a product in a sequential manner at a station to produce a finished product. Most of the works related to the ALs concentrate on the *assembly – line balancing* (ALB). The ALB model deals with the allocation of the tasks among stations so that the precedence relations are not violated and a given objective function is optimized [54,55].

Based on the model structure, ALB models can be classified into two groups. The first group [55] includes single-model *assembly line balancing* (smALB), multi-model *assembly line balancing* (muALB), and mixed-model *assembly line balancing* (mALB); the second group includes *simple assembly linebalancing* (sALB) and general *assembly line balancing* (gALB) [56–60].

Mathematical Model

For formulating a mathematical programming model, firstly we define the following utilization and average utilization of the station, respectively:

$$u_i = \frac{1}{\max_{1 \leq i \leq m} \{t(S_i)\}} t(S_i) \quad (33.95)$$

$$\bar{u} = \frac{1}{m} \sum_{i=1}^m u_i \quad (33.96)$$

The mathematical model for the simple assembly line balancing (sALB) Type 1 can be stated as the 0-1 as follows:

$$\max E = \frac{1}{m c_T} \sum_{j \in S_i} t_j x_{ij} \quad (33.97)$$

$$\min m = \sum_{i=1}^M \max_{1 \leq j \leq x} \{x_{ij}\} \quad (33.98)$$

$$\min V = \sqrt{\frac{1}{m} \sum_{i=1}^m (u_i - \bar{u})^2} \quad (33.99)$$

$$\text{s. t. } \sum_{i=1}^M x_{ij} = 1, \forall j \quad (33.100)$$

$$\sum_{i=1}^M i x_{ik} \leq \sum_{i=1}^M i x_{ij}, \forall j, \forall k \in \text{pre}(j) \quad (33.101)$$

$$t(S_j) = \sum_{j \in S_i} t_j = \sum_{j=1}^M t_j x_{ij} \leq c_T, \forall i \quad (33.102)$$

$$x_{ij} = 0 \text{ or } 1, \quad \forall i, j. \quad (33.103)$$

M: maximum number of stations available ($n \leq M$). In this mathematical model, the first objective Eq. (33.101) is to maximize the line efficiency. The second objective Eq. (33.102) is to minimize the number of stations actually employed. The third objective Eq. (33.103) is to minimize the variation of workload. The constraints given in Eqs. (33.104–33.106) are used to formulate the general feasibility of the problem. The constraint (33.104) states that each task must be assigned to one and only one station. The inequality (33.105) represents the precedence constraints, and it states that the direct predecessor of task j must be assigned to a station which is in front of or the same as the station that task j is assigned in. This constraint stresses that if a task is assigned to a station, then the predecessor of this task must be already assigned to a station. The inequality (33.106) denotes that the available time at each station should be less than or equal to the given cycle time. Constraint (33.107) represents the usual integrity restriction.

Priority-Based GA

In this section, we will introduce a priority-based genetic algorithm (priGA) for solving the multiobjective sALB Type 1 model. The priGA approach was originally developed by Gen and Cheng [10] in order to handle the problem of creating encoding while treating the precedence constraints efficiently. For applying a priority-based genetic representation for the sALB model, there are three main phases:

Phase 1: Creating a task sequence

- Step 1.1: Generate a random priority to each task in the model using encoding procedure.
- Step 1.2: Decode a feasible task sequence T_S that satisfies the precedence constraints.

Phase 2: Assigning tasks to stations

- Step 2.1: Input the task sequence found in T_S
- Step 2.2: Obtain a feasible solution set according to this task sequence.

Phase 3: Designing a schedule

- Step 3.1: Create a schedule S using station assignments found in step 2.2.
- Step 3.2: Draw a Gantt chart for this schedule.

Table 33.5 presents the data set for an example sALB model, which contains 12 tasks. Using this data set, the precedence graph in Fig. 33.30 is constructed.

The precedence graph contains 12 nodes for tasks, node weights for task processing times, and arcs for orderings. Phase 1: Creating a Task Sequence

By using the priority-based encoding, the position of a gene was used to represent a task node, and the value of the gene was used to represent the priority of the task node

Table 33.5 Data set of the sALB model

Task j	Sue(j)	Task time t_j
1	{2,4}	5
2	{3}	3
3	{6}	4
4	{5}	3
5	{6}	6

7	{8}	2
8	{12}	6
9	{12}	1
10	{11}	4
11	{12}	4
12	{}	7

Fig. 33.30 Precedence graph of the sALB model

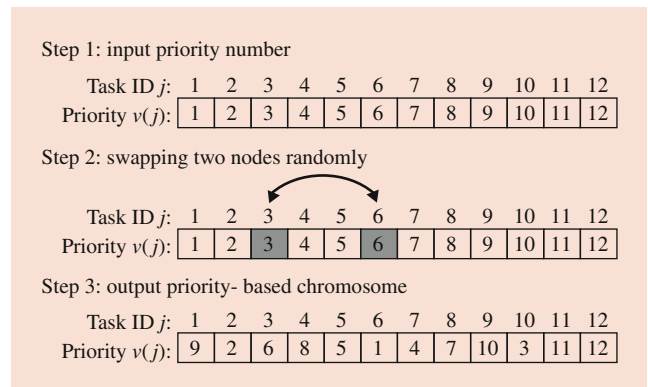

Fig. 33.31 Illustration of an example priority-based encoding

for constructing a schedule among candidates. This encoding method verifies any permutation-type representations, so that most of the existing genetic operators can be easily applied. Figure 33.31 illustrates the process of this encoding procedure on a chromosome.

Then the next possible nodes are 2 and 5. They have priority of 2 and 5, respectively, and then we put 5 into task sequence T_S . Finally, we repeat these steps until we obtain a complete schedule $T_S = \{1, 4, 5, 2, 3, 6, 9, 7, 8, 10, 11, 12\}$. Phase 2: Assigning Tasks to Stations

Fig. 33.32 Gantt chart for the sALB model (one unit of product)

In this phase, the assignments of task to stations are formed using the task sequence found in step 1.2. For the illustration of this decoding procedure, the task sequence $T_S = \{1, 4, 5, 2, 3, 6, 9, 7, 8, 10, 11, 12\}$ found in step 1.2 is used. Table 33.6 presents the trace table for the decoding procedure. In the example, we obtained a feasible line balance with cycle time 10 time units and 6 stations represented by the station loads $S_1 = 1, 4, S_2 = 2, 5, S_3 = 3, 6, 9, S_4 = 7, 8, S_5 = 10, 11, S_6 = 12$. While no idle time occurs in station 3, stations 1, 2, 4, 5, and 6 show idle times of 2, 1, 2, 2, and 3 time units, respectively.

Phase 3: Designing a Schedule

For creating a schedule S , we can use the station assignment found in Step 2.2. Using the trace table for the decoding procedure, the schedule can be constructed as follows:

Schedule $S = \{(j, S_i, t_j)\}$:

$$\begin{aligned}
 S = & \{(1, S_1, t_1), (4, S_1, t_4), (5, S_2, t_5), (2, S_2, t_2), \\
 & (3, S_1, t_3), (6, S_1, t_8), (9, S_1, t_9), (7, S_1, t_7), \\
 & (8, S_1, t_8), (10, S_1, t_{10}), (6, S_1, t_8), (9, S_1, t_9), \\
 & (7, S_1, t_7), (8, S_1, t_8), (10, S_1, t_{10}), (11, S_1, t_{11}), \\
 & (12, S_1, t_{12})\} \\
 = & \{(1, S_1, 0 - 5), (4, S_1, 5 - 8), (5, S_1, 8 - 14), \\
 & (2, S_1, 14 - 17), (3, S_1, 17 - 21), (6, S_1, 21 - 26), \\
 & (9, S_1, 26 - 27), (7, S_1, 27 - 29), (8, S_1, 29 - 35), \\
 & (10, S_1, 35 - 39), (11, S_1, 39 - 43), \\
 & (12, S_1, 43 - 50)\}
 \end{aligned}$$

By using the schedule S , we can draw a Gantt chart as shown in Fig. 33.32 which illustrates a feasible schedule for one unit of product. However, since a single type of product is produced on a simple assembly line system, the minimization of the makespan becomes an important production management issue.

Table 33.6 Trace table for task to station assignment decoding procedure

j	\bar{s}	$v(j)$	$j^*(t_j)$	$S_j = \{ \}; t(S_j) (c_T - t(S_j))$
0	{1}	$v(1)=9$	1(5)	$S_j = \{1\}; 5 (5)$
1	{2,4}	$v(2)=2, v(4)=8$	4(3)	$S_j = \{1,4\}; 8 (2)$
4	{2,5}	$v(2)=2, v(5)=5$	5(6)	$S_2 = \{5\}; 6 (4)$
5	{2}	$v(3)=6$	2(3)	$S_2 = \{5,2\}; 9 (1)$
2	{3}	$v(3)=6$	3(4)	$S_3 = \{3\}; 4 (6)$
3	{6}	$v(6)=1$	6(5)	$S_3 = \{6\}; 9 (1)$
6	{7,9,10}	$v(7)=4, v(9)=10, v(10)=3$	9(1)	$S_3 = \{3,6,9\}; 10 (0)$
9	{7,10}	$v(7)=4, v(10)=3$	7(2)	$S_4 = \{7\}; 2 (8)$
7	{8,10}	$v(8)=7, v(10)=3$	8(6)	$S_4 = \{7,8\}; 8 (2)$
8	{10}	$v(10)=3$	10(4)	$S_5 = \{10\}; 4 (6)$
10	{11}	$v(11)=11$	11(4)	$S_5 = \{10,11\}; 8 (2)$
11	{12}	$v(12)=12$	12(7)	$S_6 = \{12\}; 7 (3)$

This time, Fig. 33.33 shows a Gantt chart for three units of product in which the makespan is 70 time units for three units of products.

In this study, adaptive-weight approach that utilizes some useful information from the current population to readjust weights for obtaining a search pressure toward a positive ideal point I is used. Two objective functions, i.e., maximization of line efficiency (Eq. 42.97) and minimization of variation of workload (Eq. 42.99), are used in this study:

$$\begin{aligned}
 eval(v_k) &= w_1(f_1(v_k) - z_1^{min}) + w_3(f_3(v_k) - z_3^{min}) \\
 &= w_1 \left\{ \frac{1}{mc_T} \sum_{j=1}^n t_j - z_1^{min} \right\} + w_3 \\
 &\quad \left\{ 1 - \sqrt{\frac{1}{m} \sum_{i=1}^m (u_i - \bar{u})^2} - z_3^{min} \right\} \\
 k &= 1, \dots, popSize
 \end{aligned} \tag{33.104}$$

33.5 Reliability Design Problem

Reliability optimization appeared in the late 1940s and was first applied to communication and transportation systems. Much of the early work was confined to the analysis of certain performance aspects of systems. One goal of the reliability engineer is to find the best way to increase system reliability.

Fig. 33.33 Gantt chart for the sALB model (three units of product)

The reliability of a system can be defined as the probability that the system has operated successfully over a specified interval of time under stated conditions [61].

33.5.1 Genetic Algorithm for Reliability Optimization

The problem is to maximize the system reliability subject to three nonlinear constraints with parallel redundant units in subsystems that are subject to A failures, which occur when the entire subsystem is subjected to the failure condition. It can be mathematically stated as follows:

$$\max R(\mathbf{m}) = \prod_{i=1}^3 \{1 - [1 - (1 - q_{iu})^{m_i+1}] - \sum_{n=2}^4 (q_{iu})^{m_i+1}\}, \quad (33.105)$$

$$\text{s. t. } G_1(\mathbf{m}) = (m_1 + 3)^2 + (m_2)^2 + (m_3)^2 \leq 51, \quad (33.106)$$

$$G_2(\mathbf{m}) = 20 \sum_{i=1}^3 [m_i + \exp(-m_i)] \geq 120 \quad (33.107)$$

$$G_3(\mathbf{m}) = 20 \sum_{i=1}^3 [m_i \exp(-m_i/4)] \geq 65 \quad (33.108)$$

$$1 \leq m_1 \leq 4, \quad 1 \leq m_2, m_3 \leq 7 \quad (33.109)$$

$$m_i \geq 0; \text{ Integer, } i = 1, 2, 3 \quad (33.110)$$

Table 33.7 Failure modes and probabilities in each

Subsystem i	Failure modes $s_i = 4, h_i = 1$	Failure probability q_{iu}
1	O	0.01
	A	0.05
	A	0.10
	A	0.18
2	O	0.08
	A	0.02
	A	0.15
	A	0.12
3	O	0.04
	A	0.05
	A	0.20
	A	0.10

where $\mathbf{m} = (m_1 \ m_2 \ m_3)$. The subsystems are subject to four failure modes ($s_i = 4$) with one O failure ($h_i = 1$) and three A failures, for $i = 1, 2, 3$. For each subsystem the failure probability is shown in Table 33.7.

Genetic Algorithm Approach

Representation: The integer value of each variable m_i is represented as a binary string. The length of subsystem the string depends on the upper bound u_i of the redundant units. For instance, when the upper bound u_i equals 4, we need three binary bits to represent m_i .

In this example, the upper bounds of the redundant units in each subsystem are $u_1 = 4, u_2 = 7, \text{ and } u_3 = 7$, so each decision variable m_i needs three binary bits. This means that a total of nine bits are required. If $m_1 = 2, m_2 = 3, \text{ and } m_3 = 3$, we have the following chromosome:

$$\begin{aligned} \mathbf{v} &= [x_{33} \ x_{32} \ x_{31} \ x_{23} \ x_{22} \ x_{21} \ x_{13} \ x_{12} \ x_{11}] \\ &= [0 \ 1 \ 1 \ 0 \ 1 \ 1 \ 0 \ 1 \ 0] \end{aligned}$$

where x_{ij} is the symbol for the j -th binary bit of variable m_i .
Crossover: One-cut-point crossover is used here.
Mutation: Mutation is performed on a bit-by-bit basis.

33.5.2 Reliability Design with Redundant Unit and Alternatives

Gen, Yokota, Ida, and Taguchi further extended their work to the reliability optimization problem by considering both redundant units and alternative design [30, 61, 62, 75]. The example used here was firstly given by Fyffe et al. as follows:

$$\max R(\mathbf{m}, \boldsymbol{\alpha}) = \prod_{i=1}^{14} \{1 - [1 - R_i(\alpha_i)]^{m_i}\}, \quad (33.111)$$

$$\text{s. t. } G_1(\mathbf{m}, \boldsymbol{\alpha}) = \sum_{i=1}^{14} c_i(\alpha_i)m_i \leq 130, \quad (33.112)$$

$$G_2(\mathbf{m}, \boldsymbol{\alpha}) = \sum_{i=1}^{14} w_i(\alpha_i)m_i \leq 170, \quad (33.113)$$

$$1 \leq m_i \leq u_i, \quad \forall i, \quad (33.114)$$

$$1 \leq \alpha_i \leq \beta_i, \quad \forall i, \quad (33.115)$$

$$m_i, \alpha_i \geq 0; \quad \text{Integer, } \forall i, \quad (33.116)$$

where α_i represents the design alternative available for the i -th subsystem, m_i represents the identical units used in redundancy for the i -th subsystem, u_i is the upper bound of the redundant units for the i -th subsystem, and β_i is the upper bound of alternative design for the i -th subsystem.

Genetic Algorithm Approach

Representation The representation can be written as follows:

$$\mathbf{v} = [(\alpha_{k1}, m_{k1}) (\alpha_{k2}, m_{k2}) \dots (\alpha_{k14}, m_{k14})]$$

where α_{ki} is a design alternative, m_{ki} is a redundant unit, and the subscript k is the index of chromosome.

Crossover The uniform crossover operator given by Syswerda is used here, which has been shown to be superior to traditional crossover strategies for combinatorial problem. Uniform crossover firstly generates a random crossover mask and then exchanges relative genes between parents according to the mask. A crossover mask is simply a binary string with the same size of chromosome.

33.5.3 Network Reliability Design

A communication network can be represented by an undirected graph $G = (V, E)$, in which the nodes V and edges E represent computer sites and communication cables, respectively. The optimal design of network can be represented as follows [63]:

$$\min z(\mathbf{x}) \times 1 = \sum_{i=1}^{n-1} \sum_{j=i+1}^n c_{ij}x_{ij} \quad (33.117)$$

$$\text{s. t. } R(\mathbf{x}) \geq R_{\min} \quad (33.118)$$

Genetic Algorithm Approach

Representation: A genetic algorithm lends itself to this problem because each network design x is easily formed into a binary string which can be used as a chromosome for genetic algorithms. Each element of the chromosome represents a possible edge in the network design problem, so there are $n(n-1)/2$ string components in each candidate architecture Z .

Crossover: The one-cut-point crossover operation is used.

Mutation: The bit-flip mutation operation is employed, performed on a bit-by-bit basis.

33.5.4 Tree-Based Network Design

Consider a local-area network (LAN) that connects m users (stations). Also, we assume the $n \times m$ service center topology matrix \mathbf{x}_1 , which represents the connection between service centers. An element x_{1ij} is represented as

$$x_{1ij} = \begin{cases} 1, & \text{if the center } i \text{ and } j \text{ are connected} \\ 0, & \text{otherwise.} \end{cases} \quad (33.119)$$

Assume that the LAN is partitioned into n segments (service centers or clusters). The users are distributed over those n service centers. The $n \times m$ clustering matrix \mathbf{X}_2 specifies which user belongs to which center. Thus

$$x_{2ij} = \begin{cases} 1, & \text{if user } j \text{ belongs to center } i \\ 0, & \text{otherwise.} \end{cases} \quad (33.120)$$

A user can only belong to one center; thus, $\forall j = 1, 2, \dots, m, \sum_{i=1}^n x_{2ij} = 1$. We define an $n \times (n+m)$ matrix \mathbf{X} called the spanning tree matrix $(\mathbf{X}_1 \ \mathbf{X}_2)$. The bicriteria LAN topology design problem can be formulated as the following nonlinear 0-1 programming model [23, 64], where $R(\mathbf{X})$

is the network reliability and w_{1ij} is the weight of the link between the centers i and j :

$$\max R(\mathbf{x}) \tag{33.121}$$

$$\min \sum_{i=1}^{n-1} \sum_{j=i+1}^n w_{1ij}x_{1ij} + \sum_{i=1}^n \sum_{j=1}^m w_{2ij}x_{2ij} \tag{33.122}$$

$$\text{s. t. } \sum_{j=1}^m x_{1ij} \leq g_i, \quad i = 1, 2, \dots, m \tag{33.123}$$

$$\sum_{i=1}^n x_{2ij} = 1, \quad j = 1, 2, \dots, m, \tag{33.124}$$

w_{2ij} is the weight of the link between the center i and the user j , and g_i is the maximum number that can connect to the center i .

Genetic Algorithm Approach

Representation: We can easily construct an encoding as follows:

Procedure: Encoding of Prüfer Number

- Step 1 Let node i be the smallest labeled leaf node in a labeled tree T
- Step 2 Let j be the first digit in the encoding as the node j incident to node i is uniquely determined. The encoding is built by appending digits from left to right.
- Step 3 Remove node i and the link from i to j ; thus we have a tree with $k - 1$ nodes.
- Step 4 Repeat the above steps until one link is left. We produce a Prüfer number or an encoding with $k - 2$ digits between 1 and k inclusive.

Crossover: Uniform crossover is used. This type of crossover is accomplished by selecting two parent solutions and randomly taking a component from one parent to form the corresponding component of the offspring (Fig. 33.34).

Mutation: Swap mutation is used, as explained in the previous section.

Fig. 33.34 Uniform crossover operator

33.6 Logistics Network Problems

The transportation problem is a basic model in the logistics networks. Many scholars have since refined and extended the basic transportation model to include not only the determination of optimum transportation patterns but also the analysis of production scheduling problems, transshipment problems, and assignment problems.

33.6.1 Linear Transportation Model

The linear transportation problem (LTP) involves the shipment of some homogeneous commodity from various origins or sources of supply to a set of destinations, each demanding specified levels of the commodity. The usual objective function is to minimize the total transportation cost or total weighted distance or to maximize the total profit contribution from the allocation. Given m origins and n destinations, the transportation problem can be formulated as a linear programming model[4, 5]:

$$\min z \sum_{i=1}^m \sum_{j=1}^n c_{ij}x_{ij}, \tag{33.125}$$

$$\text{s. t. } \sum_{j=1}^n x_{ij} \leq a_i, \quad i = 1, 2, \dots, m, \tag{33.126}$$

$$\sum_{i=1}^m x_{ij} \geq b_j, \quad j = 1, 2, \dots, n, \tag{33.127}$$

$$x_{ij} \geq 0, \quad \text{for all } i \text{ and } j \tag{33.128}$$

where x_{ij} is the amount of units shipped from origin i to destination j , c_{ij} is the cost of shipping one unit from source i to destination j , a_i is the number of units available at origin i , and b_j is the number of units demanded at destination j .

Genetic Algorithm Approach

Representation. Perhaps the matrix is the most natural representation of a solution for the transportation problem. The allocation matrix for the transportation problem can be written as follows:

$$X_p = \begin{pmatrix} x_{11} & x_{12} & \dots & x_{1n} \\ x_{21} & x_{22} & \dots & x_{2n} \\ \dots & \dots & \dots & \dots \\ x_{m1} & x_{m2} & \dots & x_{nm} \end{pmatrix} \tag{33.129}$$

where X_p denotes the p -th chromosome and x_{ij} is the corresponding decision variable.

Crossover Assume that two matrices $X_1 = (x_{ij}^1)$ and $X_2 = (x_{ij}^2)$ are selected as parents for the crossover operation. The crossover is performed in the following three main steps:

- Step 1 Create two temporary matrices $D = (d_{ij})$ and $R = (r_{ij})$ as follows: $d_{ij} = [(x_{ij}^1 + x_{ij}^2)/2]$ and $r_{ij} = [(x_{ij}^1 + x_{ij}^2)/2]$ mode 2.
- Step 2 Divide matrix R into two matrices $R^1 = (r_{ij}^1)$ and $R^2 = (r_{ij}^2)$ such that $R = R^1 + R^2$
- Step 3 Then we produce two offspring of X_1' and X_2' as follows: $X_1' = D + R^1$ and $X_2' = D + R^2$

Mutation The mutation is performed in following three main steps:

- Step 1 Make a submatrix from the parent matrix. Randomly select i_1, \dots, i_p rows and j_1, \dots, j_q columns to create a $(p * q)$ submatrix $Y = (y_{ij})$, where i_1, \dots, i_p is a proper subset of $1, 2, \dots, m$, i_1, \dots, i_p and $2 \leq p \leq m$, j_1, \dots, j_q is a proper subset of $1, 2, \dots, n$ and $2 \leq q \leq n$, and y_{ij} takes the value of the element in the crossing position of selected row i and column j in the parent matrix.
- Step 2 Reallocate commodity for the submatrix. The available amount of commodity a_i^y and the demands b_j^y for the submatrix are determined as follows:

$$a_i^y = \sum_{j \in \{j_1, \dots, j_q\}} y_{ij}, i = i_1, i_2, \dots, i_p, \quad (33.130)$$

$$b_j^y = \sum_{i \in \{i_1, \dots, i_p\}} y_{ij}, j = j_1, j_2, \dots, j_q, \quad (33.131)$$

- Step 3 Replace appropriate element of the parent matrix by new elements from the reallocated submatrix Y .

Spanning Tree-Based Approach Transportation problems (TP) as a special type of network problem have a special data structure characterized as a transportation graph in their solutions. The spanning tree-based GA incorporating this data structure of TP was proposed by Gen and Li. This GA utilized the Prüfer number encoding based on a spanning tree, which is adopted because it is capable of representing all possible trees. Using the Prüfer number representation, the memory only requires $m + n - 2$ entries for a chromosome in the TP. Transportation problems have separable sets of nodes for plants and warehouses. From this point, Gen and Cheng designed the criterion for feasibility of the chromosome. The proposed spanning tree-based GA can find the optimal or near-optimal solution for transportation problems in the solution space [10, 61, 64].

33.6.2 Multiobjective Transportation

In the transportation problem, multiple objectives are required in practical situations, such as minimizing transportation cost, minimizing the average shipping time to priority customers, maximizing production using a given process, minimizing fuel consumption, and so on. The traditional multiobjective transportation problem (moTP) with m plants and n warehouses can be formulated as

$$\min z_q = \sum_{i=1}^m \sum_{j=1}^n c_{ij}^q x_{ij}, \quad q = 1, 2, \dots, Q, \quad (33.132)$$

$$\text{s. t. } \sum_{j=1}^n x_{ij} \leq a_i, \quad i = 1, 2, \dots, m, \quad (33.133)$$

$$\sum_{i=1}^m x_{ij} \geq b_j, \quad j = 1, 2, \dots, n, \quad (33.134)$$

$$x_{ij} \geq 0, \quad \forall i, j, \quad (33.135)$$

where q means the q -th objective function.

Spanning Tree-Based GA for Multiobjective TP

The Pareto optimal solutions are usually characterized as the solutions of the multiobjective programming problem [37, 65].

33.6.3 Bicriteria Transportation Model with Fuzzy Coefficients

Consider the following two objectives: minimizing total transportation cost and minimizing total delivery time. Let \tilde{c}_{ij}^1 be the fuzzy data representing the transportation cost of shipping one unit from plant i to warehouse j , \tilde{c}_{ij}^2 be the fuzzy data representing the delivery time of shipping one unit of the product from plant i to warehouse j , a_i be the number of units available at plant i , and b_j be the number of units demanded at warehouse j . This problem with m plants and n warehouses can be formulated as

$$\min \tilde{z}_1 = \sum_{i=1}^m \sum_{j=1}^n \tilde{c}_{ij}^1 x_{ij}, \quad (33.136)$$

$$\min \tilde{z}_2 = \sum_{i=1}^m \sum_{j=1}^n \tilde{c}_{ij}^2 x_{ij}, \quad (33.137)$$

$$\text{s. t. } \sum_{j=1}^n x_{ij} \leq a_i, \quad i = 1, 2, \dots, m, \quad (33.138)$$

$$\sum_{j=1}^n x_{ij} \geq b_j, \quad j = 1, 2, \dots, n, \quad (33.139)$$

$$x_{ij} \geq 0, \quad \forall i, j, \quad (33.140)$$

where P and W are upper limits on total number of plants or DCs that can be opened. where x_{ij} is the unknown quantity to be transported from plant i to warehouse j .

Genetic Algorithm Approach

The proposed genetic algorithm approach is based on spanning tree. In multicriteria optimization, we are interested in finding Pareto solutions. When the coefficients of objectives are represented with fuzzy numbers, the objective values become fuzzy numbers. Since a fuzzy number represents many possible real numbers, it is not easy to compare solutions to determine which is the Pareto solution. Fuzzy ranking techniques can help us to compare fuzzy numbers. In this approach, Pareto solutions are determined based on the ranked values of fuzzy objective functions, and genetic algorithms are used to search for Pareto solutions.

Representation The spanning tree encoding, the Prüfer number, is used to represent the candidate solution. The criterion for the solution’s feasibility designed in the proposed spanning tree-based GA is also employed.

Crossover For simplicity one-point crossover is used.

Mutation Inversion mutation and displacement mutation are used.

33.6.4 Multistage Logistics Model

Logistics network design is one of the most important fields of *supply chain management* (SCM). SCM describes the discipline of optimizing the delivery of goods, services, and information from supplier to customer. Typical SCM goals include transportation network design, plant/DC location, production schedule streamlining, and efforts to improve order response time. Logistics network design is one of the most important fields of SCM. It offers great potential to reduce costs and to improve service quality. There are now expanded multistage logistics models for applications to real-world cases so the supply chain network (SCN) design problem is referred to as three-stage, i.e., suppliers, plants, DCs, and customers [65–69]. The design task involves the decision of choosing to open a facility (plant or DCs) or not and the distribution network design to satisfy the customer demand at minimum cost. The three-stage logistics network model is formulated as a 0-1 mixed-integer programming as follows:

$$\begin{aligned} \min & \sum_i \sum_j s_{ij}x_{ij} + \sum_j \sum_k f_{jk}y_{jk} \\ & + \sum_k \sum_l u_{kl}z_{kl} + \sum_j f_j w_j + \sum_k g_k z_k \end{aligned} \quad (33.141)$$

$$\text{s. t. } \sum_j x_{ij} \leq a_i, \forall i \quad (33.142)$$

$$\sum_k y_{jk} \leq b_j w_j, \forall j \quad (33.143)$$

$$\sum_j w_j \leq P \quad (33.144)$$

$$\sum_l z_{kl} \leq c_k z_k, \forall k \quad (33.145)$$

$$\sum_k z_k \leq W, \quad (33.146)$$

$$\sum_k z_{kl} \geq d_l, \forall l \quad (33.147)$$

$$w_j, z_k = (0, 1), \forall j, k, \quad (33.148)$$

$$x_{ij}, y_{jk}, z_{kl} \geq 0, \forall i, j, k, l, \quad (33.149)$$

where P and W are upper limits on total number of plants or DCs that can be opened.

Transportation Tree Representation

For a two-stage transportation problem (tsTP) as a simple example of multistage logistics model, a chromosome consists of priorities for sources and depots to obtain a transportation tree. Its length is equal to the total number of sources ($|K|$) and depots ($|J|$), i.e., $|K| + |J|$.

For a given chromosome, the transportation tree is generated by a sequential arc appending procedure between sources and depots. At each step, only one arc is added to the tree by selecting a source (depot) with the highest priority and connecting it to a depot (source) with the minimum cost. Figure 33.35 represents a transportation tree with three sources and four depots, its cost matrix, and the corresponding priority-based encoding.

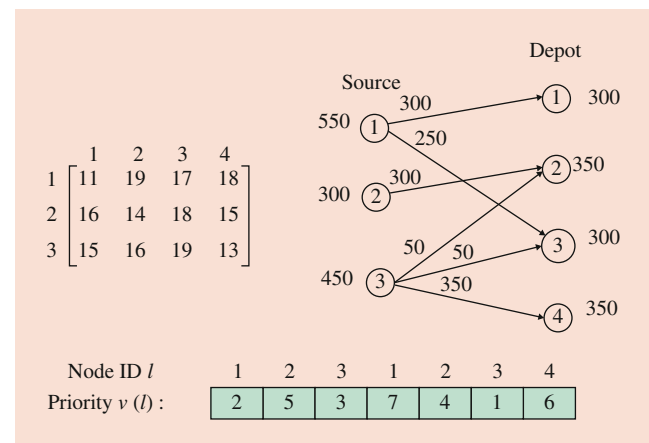

Fig. 33.35 A sample of transportation tree and its encoding

Table 33.8 Trace table of decoding procedure

Iteration	$v(k+j)$	a	b	k	j	g_{kj}
0	[2 5 3 7 4 1 6]	(550, 300, 450)	(300, 350, 300, 350)	1	1	300
1	[2 5 3 0 4 1 6]	(250, 300, 450)	(0, 350, 300, 350)	3	4	350
2	[2 5 3 0 4 1 0]	(250, 300, 100)	(0, 350, 300, 0)	2	2	300
3	[2 0 3 0 4 1 0]	(250, 0, 100)	(0, 50, 300, 0)	3	2	50
4	[2 0 3 0 0 1 0]	(250, 0, 50)	(0, 0, 300, 0)	3	3	50
5	[2 0 0 0 0 1 0]	(250, 0, 0)	(0, 0, 250, 0)	1	3	250
6	[0 0 0 0 0 0 0]	(0, 0, 0)	(0, 0, 0, 0)			

The decoding process by the priority-based encoding is given in Table 33.8. As shown in the trace table, at the first step of the decoding procedure, an arc between Depot 1 and Source 1 is added to the transportation tree since Depot 1 has the highest priority in the chromosome and the lowest cost between Source 1 and Depot 1. After determining the amount of shipment that is $g_{11} = \min\{550, 300\} = 300$, capacity of source and demand of depot are updated as $a_1 = 550 - 300 = 250$ and $b_1 = 300 - 300 = 0$, respectively. Since $b_1 = 0$, the priority of Depot 1 is set to 0, and Depot 4 with the next highest priority is selected.

After adding arc between Depot 4 and Source 3, the amount of shipment between them is determined and their capacity and demand are updated as explained above, and this process repeats until demands of all depots are met.

For the priority-based encoding and decoding algorithms for any transportation tree, we can refer to Section 3.4 Multi-stage Logistics Models in [4].

As shown in Fig. 33.36, we consider a simple example that has three feasible plants, four feasible DCs, and five customers.

As shown in Fig. 33.36, we consider a simple example that has three feasible plants, four feasible DCs, and five customers. When the upper limit of opened DCs is taken as three, the first part of chromosome consists of seven digits, and the second part consists of nine digits. The total capacity of DCs which will be opened has to satisfy the total demand of customers. Considering this property, we first decode the second part of chromosome. In this phase, transportation tree on the second stage and decision related with which DCs will be opened are obtained simultaneously. After that the transportation tree on the first stage is obtained by considering DCs which were opened in the second stage of the decoding procedure. In the second stage, it is possible to obtain a transportation tree that doesn't satisfy the upper limit of opened DCs, since connection between source and depot is realized considering minimum cost.

Genetic Operation

In this multistage logistics model, we adopt the weight mapping crossover (WMX). Similar to crossover, mutation is done to prevent the premature convergence, and it explores new solution space. However, unlike crossover, mutation is usually done by modifying a gene within a chromosome. We also investigated the effects of two different mutation operators on the performance of GA. Insert and swap mutations were used for this purpose. For the selection, we adopt the *roulette wheel selection* (RWS). This is to determine selection probability or survival probability for each chromosome proportional to the fitness value. For the numerical experiments of the various sizes of test problems, refer to Section 3.4 Multi-stage Logistics Models in [4].

33.6.5 SCM Network Design

Supply chain management (SCM) is to choose the subset of plants and distribution centers to be opened and to design the distribution network strategy that can satisfy all capacities and demand requirements imposed by customers with minimum cost. We formulate the problem by using the following mixed-integer linear programming (MILP) model:

$$\min \sum_i \sum_j s_{ij}x_{ij} + \sum_j \sum_k t_{jk}y_{jk} + \sum_k \sum_l u_{kl}x_{kl} + \sum_j f_j x_j + \sum_k g_k x_k \quad (33.150)$$

$$\text{s. t. } \sum_j x_{ij} \leq a_i, \quad \forall i \quad (33.151)$$

$$\sum_k y_{jk} \leq b_j w_j, \quad \forall j \quad (33.152)$$

$$\sum_j w_j \leq P, \quad (33.153)$$

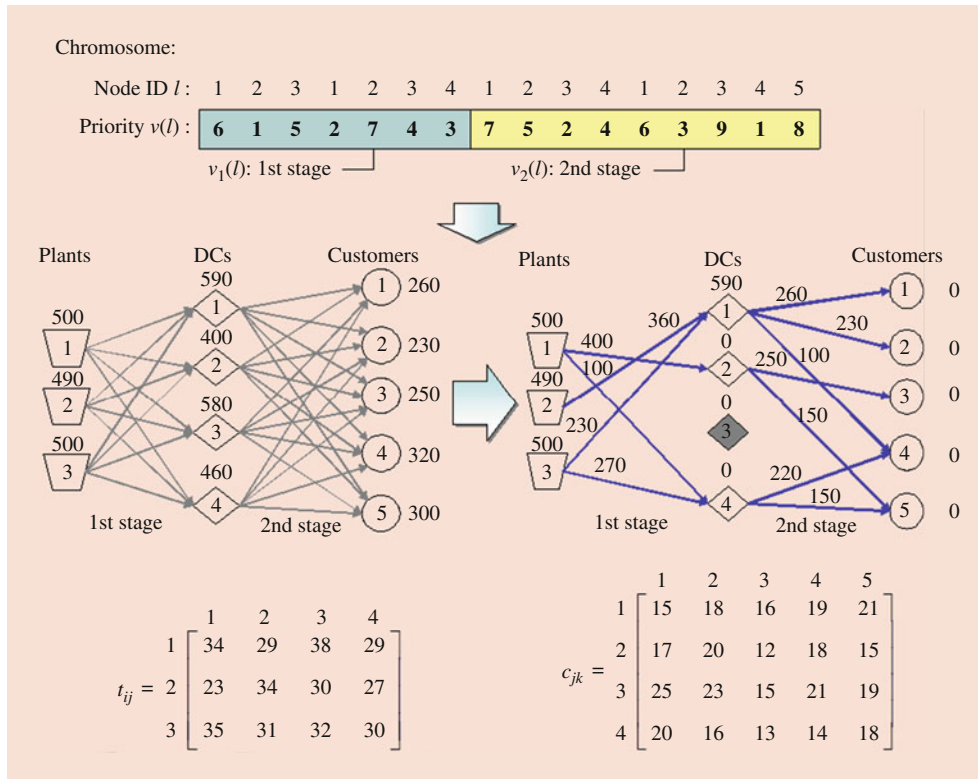

Fig. 33.36 An illustration of chromosome, transportation trees, and transportation costs for each stage on tsTP

$$\sum_l z_{kl} \leq c_k u_k, \forall k \quad (33.154)$$

$$\sum_k u_k \leq W, \quad (33.155)$$

$$\sum_k z_{kl} \geq d_l, \forall l \quad (33.156)$$

$$w_j, u_k = \{0, 1\}, \forall j, k \quad (33.157)$$

$$x_{ij}, y_{jk}, z_{kl} \geq 0, \forall i, j, k, l \quad (33.158)$$

distribution center k , and z_{kl} is the amount shipped from distribution center k to customer l . w_j and u_k are defined as

$$w_j = \begin{cases} 1, & \text{if production takes place at plant } j \\ 0, & \text{otherwise.} \end{cases} \quad (33.159)$$

$$u_k = \begin{cases} 1, & \text{if distribution center } k \text{ is opened} \\ 0, & \text{otherwise.} \end{cases} \quad (33.160)$$

where I is the number of suppliers, J is the number of plants, K is the number of distribution centers, L is the number of customers, a_i is the capacity of supplier i , b_j is the capacity of plant j , c_k is the capacity of distribution center k , d_l is the demand of customer l , s_{ij} is the unit cost of production in plant j using material from supplier i , t_{jk} is the unit cost of transportation from plant j to the distribution center k , u_{kl} is the unit cost of transportation from distribution k to customer l , f_j is the fixed cost for operating plant j , g_k is the fixed cost for operating distribution center k , W is an upper limit on the total number of distribution centers that can be opened, and P is an upper limit on the total number of plants that can be opened.

Here, x_{ij} is the quantity produced at plant j using raw material from supplier i , y_{jk} is the amount shipped from plant j to

Crossover: The crossover is done by exchanging the information of two parents to provide a powerful exploration capability. We employ a one-cut-point crossover operation, which randomly selects one cut-point and exchanges the right parts of the two parents to generate offspring.

Mutation: Modifying one or more of the gene values of an existing individual, mutation creates a new individual to increase the variability of the population. We use inversion and displacement mutation operations.

33.6.6 Reverse Logistics Model

Beyond the current interest in supply chain management, recent attention has been given to extending the traditional forward supply chain to incorporate a reverse logistic element

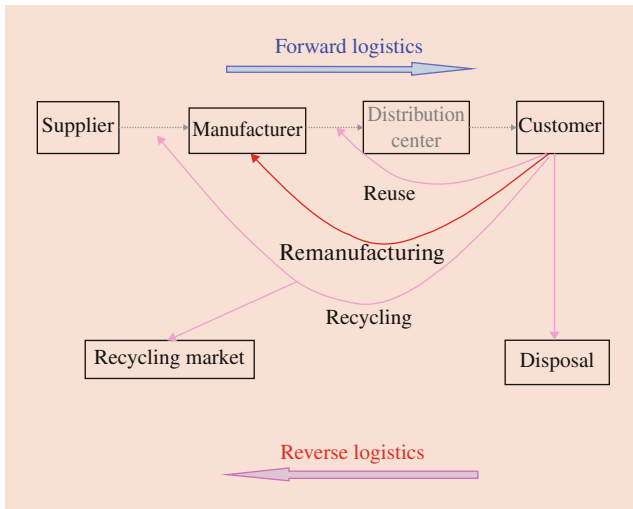

Fig. 33.37 Logistics flow of forward and reverse

owing to liberalized return policies, environmental concern, and a growing emphasis on customer service and parts reuse. Implementation of reverse logistics especially in product returns would allow not only for savings in inventory carrying cost, transportation cost, and waste disposal cost due to returned products but also for the improvement of customer loyalty and future sales.

As shown in Fig. 33.37, the reverse logistics problem (or closed-loop recycling problem) can be formulated as a multistage logistics network model.

First, recovered products from customers are transported to disassembly center, in the first stage. Then disassembled parts are transported to processing center, in the second stage. Last, in the third stage, processed parts are transported to manufacturer. In the third stage, if the quantity of provided parts from processing center is not enough for requirement of manufacturer, then manufacturer must buy parts from suppliers. In case of opposition, then exceeded capacities are distributed in order of recycling and disposal. The illustrative of the multistage reverse logistics network model is shown in Fig. 33.38. For a mathematical model of the multistage reverse logistics network formulated as a 0-1 mixed programming and genetic algorithm based on the priority encoding method, refer to [4, 70]. Recently reported is the multistage reverse logistics network design for product resale by adaptive genetic algorithm [35, 66–69].

Lee et al. [71] proposed a multiobjective hybrid genetic algorithm for minimizing the total cost and delivery tardiness in a reverse logistics designing problem. Guo et al. [72, 73] reported the case study of lead battery in Shanghai for the dynamic joint construction and optimal strategy of multiobjective multi-period multistage government-enterprise reverse logistics network.

33.7 Location and Allocation Problems

Location-allocation problems arise in many practical settings. The classical single location-allocation problem is to find the single location which minimizes the summed distance from some number of fixed points, representing customers with known locations.

33.7.1 Location-Allocation Model

There are m facilities to be located, and n customers with known locations are to be allocated to the variable facilities. Each customer has the requirement $q_j, j = 1, 2, \dots, n$, and each facility has the capacity $b_i, i = 1, 2, \dots, m$. We need to find the locations of facilities and allocations of customers to facilities so that the total summed distance among the customers and their serving facilities is minimized (Fig. 33.39). This problem is formulated mathematically as [24, 74]

$$\min \sum_{i=1}^m \sum_{j=1}^n \sqrt{(x_i - u_j)^2 + (y_i - v_j)^2} z_{ij} \quad (33.161)$$

$$\text{s. t. } \sum_{j=1}^n q_j \cdot z_{ij} \leq b_i, \quad i = 1, 2, \dots, m, \quad (33.162)$$

$$\sum_{i=1}^m z_{ij} = 1, \quad j = 1, 2, \dots, n, \quad (33.163)$$

$$z_{ij} = 0 \text{ or } 1, \quad i = 1, 2, \dots, m, \quad j = 1, 2, \dots, n, \quad (33.164)$$

where

$$(u_j, v_j) = \text{location of customer } j, \quad j = 1, 2, \dots, n, \quad (33.165)$$

$$(x_i, y_i) = \text{location of facility } i,$$

decision variables $i = 1, 2, \dots, m$

$z_{ij} = 0 - 1$ decision variable,

$$z_{ij} = \begin{cases} 1, & \text{customer } j \text{ is served by facility } i \\ 0, & \text{otherwise.} \end{cases} \quad (33.166)$$

A. Genetic Algorithm Approach

Representation: Since location variables are continuous, the float-value chromosome representation is used. A chromosome is given as follows:

$$c^k = [(x_1^k, y_1^k)(x_2^k, y_2^k) \dots (x_m^k, y_m^k)]$$

Fig. 33.38 Multistage reverse logistics network model

where (x_i^k, y_i^k) is the location of the i -th facility in the k -th chromosome, $i = 1, 2, \dots, m$.

Crossover: Two mating strategies are used: one is free mating, which selects two parents at random; another is dominating mating, which uses the fittest individual as a fixed parent and randomly selects another parent from the population pool. These two strategies are used alternatively in the evolutionary process. Suppose two parents with the following chromosomes are selected to produce a child:

$$c^{k1} = [(x_1^{k1}, y_1^{k1})(x_2^{k1}, y_2^{k1}) \dots (x_m^{k1}, y_m^{k1})]$$

$$c^{k2} = [(x_1^{k2}, y_1^{k2})(x_2^{k2}, y_2^{k2}) \dots (x_m^{k2}, y_m^{k2})]$$

Only one child is allowed to be produced:

$$c = [(x_1, y_1)(x_2, y_2) \dots (x_m, y_m)]$$

$$x_i = r_i \cdot x_i^{k1} + (1 - r_i)x_i^{k2},$$

$$y_i = r_i \cdot y_i^{k1} + (1 - r_i)y_i^{k2}, \quad (33.167)$$

Mutation: Suppose the candidate chromosome to be mutated is as follows:

$$c^k = [(x_1^k, y_1^k)(x_2^k, y_2^k) \dots (x_m^k, y_m^k)]$$

then the chromosome of the child produced by subtle mutation $c = [x_1, y_1, x_2, y_2, \dots, x_m, y_m]$ is as follows:

$$x_i = x_i^k + \text{random value in } [-\varepsilon, \varepsilon],$$

$$y_i = y_i^k + \text{random value in } [-\varepsilon, \varepsilon], \quad (33.168)$$

Fig. 33.39 Location-allocation problem

B. Numerical Example

Cooper and Rosing’s examples are used to test the effectiveness of this method. Cooper carefully constructed the front half data which contains three natural groups, and Rosing increased the number of customers with random points. These examples provide a good benchmark to test the effectiveness of the proposed method because their global optimal solutions have already been found.

These examples include 30 customers whose location coordinates are shown in Table 33.9. There is a common location-allocation problem where the requirements of the customers are treated as equal and the capacities of the facilities are assumed to be unlimited.

33.7.2 Capacitated Plant Location Model

The capacitated plant location problem (cPLP) is referred to as a fixed-charge problem to determine the locations of plants

Table 33.9 Coordinates of Cooper and Rosing’s example

Order number	X	Y	Order number	X	Y
1	5	9	16	53	8
2	5	24	17	1	34
3	5	48	18	33	8
4	13	4	19	3	26
5	12	19	20	17	9
6	13	39	21	53	20
7	28	37	22	24	17
8	21	45	23	40	22
9	25	50	24	22	41
10	31	9	25	7	13
11	39	2	26	5	17
12	39	16	27	39	3
13	45	22	28	50	50
14	41	30	29	16	40
15	49	31	30	22	45

with minimal total cost, including production, shipping costs, and fixed costs where the plants are located. In this case, m sources (or facility locations) produce a single commodity for n customers, each with demand of $b_j (j = 1, \dots, n)$ units. If a particular source i is opened (or facility is built), it has a fixed cost $d_i \geq 0$ and a production capacity $a_i \geq 0$ associated with it. There is also a positive cost c_{ij} for shipping a unit from source i to customer j . The problem is to determine the locations of the plants so that capacities are not exceeded and demands are met, all at a minimal total cost. The cPLP is a mixed-integer program, as shown in the following:

$$\min z(x) = \sum_{i=1}^m \sum_{j=1}^n c_{ij}x_{ij} + \sum_{i=1}^m d_i y_i \quad (33.169)$$

$$\text{s. t. } \sum_{i=1}^m x_{ij} = b_j, \quad j = 1, 2, \dots, n \quad (33.170)$$

$$\sum_{j=1}^n x_{ij} \leq a_i y_i, \quad i = 1, 2, \dots, m \quad (33.171)$$

$$x_{ij} \geq 0, \quad \forall i, j \quad (33.172)$$

$$y_i = 0 \text{ or } 1, \quad i = 1, 2, \dots, m, \quad (33.173)$$

The variables are x_{ij} and y_i , which represent the amount shipped from plant i to warehouse j and whether a plant is open (or located) ($y_i = 1$) or closed ($y_i = 0$), respectively.

Spanning Tree-Based GA for Plant Location Problems

The spanning tree-based GA for the capacitated plant location problem is the same as that of the fixed-charge

transportation problem except there is a different evaluation function in the evolutionary process[61].

33.7.3 Obstacle Location-Allocation Model

There are n customers with known locations and m facilities to be built to supply some kind of services to all customers, for example, supplying materials or energy. There are also p obstacles representing some forbidden areas. The formulation of the mathematical model is based on the following assumptions:

- Customer j has service demand $q_j, j = 1, 2, \dots, n$,
- Facility i has service capacity $b_i, i = 1, 2, \dots, m$,
- Each customer should be served by only one facility,
- New facilities should not be built within any obstacle,
- Connecting paths between facilities and customers should not be allowed to pass through any of the obstacles.

The problem is to choose the best locations for facilities so that the sum of distances between customers and their serving facilities is minimal, as illustrated in Fig. 33.40. The obstacle location-allocation problem can be formulated as follows:

$$\min f(D, z) = \sum_{i=1}^m \sum_{j=1}^n t(D_i, C_j) \cdot z_{ij} \quad (33.174)$$

$$\text{s. t. } \sum_{j=1}^m z_{ij} = 1, \quad i = 1, 2, \dots, m \quad (33.175)$$

$$\sum_{i=1}^m d_j z_{ij} = b_j, \quad j = 1, 2, \dots, n \quad (33.176)$$

$$D_i = (x_i, y_i) \notin Q_k, \quad i = 1, 2, \dots, m, \quad (33.177)$$

$$k = 1, 2, \dots, q,$$

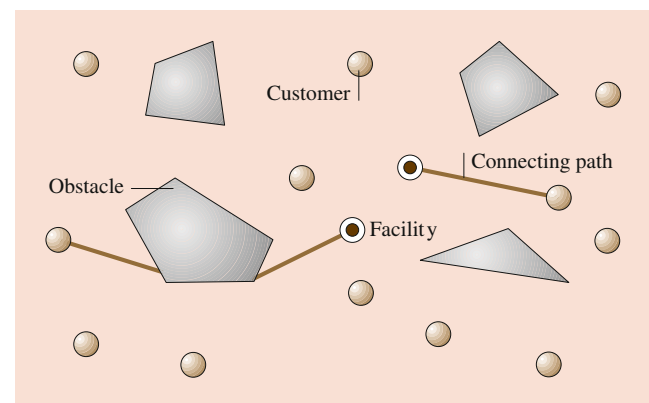

Fig. 33.40 Obstacle location-allocation problem

$$(x_i, y_i) \in R_T, i = 1, 2, \dots, m, \tag{33.178}$$

$$x_i, y_i \in R_T, i = 1, 2, \dots, m, \tag{33.179}$$

$$z_{ij} = 1 \text{ or } 0, i = 1, 2, \dots, m, j = 1, 2, \dots, n, \tag{33.180}$$

where $C_j = (u_j, v_j)$ is the location of the j -th customer, $D_i = (x_i, y_i)$ is the decision variable, the location of the j -th distribution center DC_i should not fall within any of the obstacles, $t(D_i, C_j)$ is the shortest connecting path from the set of possible paths between the distribution center DC_i and the customer C_j which avoids all obstacles, R_T is the total area considered for the location and allocation problem, and z_{ij} is a 0–1 decision variable; $z_{ij} = 1$ indicates that the j -th customer is served by DC_i , $z_{ij} = 0$ otherwise.

Hybrid Evolutionary Method

Since there are obstacles, the locations of the chromosome produced by initialization, crossover, and mutation procedure may become infeasible. Generally, there are three kinds of methods to treat infeasible chromosomes as shown in Table 33.10. The first is to discard it, but according to the experience of other researchers, this method may lead to very low efficiency. The second is to add a penalty to infeasible chromosomes. The third is to repair the infeasible chromosome according to the characteristics of the specified problem.

33.7.4 LAP with Multi-facility Service

LAP Model with Multiple facility Service The sugarcane loading with multi-facility problem is identified as a location-allocation problem (LAP) for multi-facility services in sugarcane supply system. The m loading stations are considered as candidate facilities. They are selected to satisfy n sugarcane

fields (C_i) each of which contains a_i tons of sugarcane, $i = 1, 2, \dots, n$. We assume that the capacity of a facility is specified or known. The several k types of facility services (L_{jk}) are assigned for each loading station (F_j). This model is formulated as a 0–1 mixed-integer programming (0-1 MIP) model for locating a number of loading stations among a finite set of potential sites and assigning the several types of facility services to each loading station and allocating sugarcane between these loading stations and growers’ fields.

Based on the characteristics of the LAP, the mathematical model will be constructed as follows: The objective function is to minimize the total cost in any period (week or month) within 1 crop year in which the first term is the transportation cost from a field to a loading station. The second term is the transportation cost from the loading station to a sugar mill. The third term is the fixed cost of each loading station. Finally, the fourth and fifth terms are the operation cost of loading sugarcane to a truck or trailer and the fixed cost of each transloader, respectively:

$$f(\mathbf{x}, \mathbf{y}, \mathbf{z}) = \sum_{i=1}^n \sum_{j=1}^m h d_{ij} x_{ij} + \sum_{j=1}^m h l_{jM} y_j + \sum_{j=1}^m e_j y_j + \sum_{j=1}^m \sum_{k=1}^p o_k z_{jk} + \sum_{j=1}^m \sum_{k=1}^p f_k z_{jk} \tag{33.181}$$

Seven constraints are formulated as follows:

$$g_j(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^n a_i x_{ij} \leq B_j y_j, j = 1, 2, \dots, m \tag{33.182}$$

$$g_{m+i}(\mathbf{x}) = \sum_{j=1}^m x_{ij} = 1, j = 1, 2, \dots, m \tag{33.183}$$

Table 33.10 Comparison results of Cooper and Rosing’s example

Fig. 33.41 Illustration of a representation chromosome

$$g_{m+n+1}(\mathbf{y}) = \sum_{j=1}^m y_j \leq M \tag{33.184}$$

$$g_{m+n+1+j}(\mathbf{z}) = \sum_{i=1}^n a_i x_{ij} \leq \sum_{k=1}^p b_k z_{jk}, \quad j = 1, 2, \dots, m \tag{33.185}$$

$$x_{ij} = 0 \text{ or } 1, \quad i = 1, 2, \dots, n \quad i = 1, 2, \dots, m \tag{33.186}$$

$$y_j = 0 \text{ or } 1, \quad j = 1, 2, \dots, n \tag{33.187}$$

$$z_{jk} \geq 0 \text{ Integer}, \quad j = 1, 2, \dots, m, \quad k = 1, 2, \dots, p \tag{33.188}$$

Constraints (33.182) ensure that the service capacity of each loading station shall not exceed its capacity. Constraints (33.183) ensure that every field shall be served by only one loading station. Constraints (33.183) reflect that total number of opened loading stations shall not exceed the total number of candidate loading stations. Constraints (33.185) ensure that the total quantity of sugarcane can be served by each loading station. Constraints (33.186–33.188) are variable restrictions for the decision variables to be found.

Designing Representation and Feasibility of Chromosome For designing a natural representation of LAP for multi-facility services, an effective chromosome representation was built by employing three parts of chromosomes in the encoding method. The design of the chromosome and its parameters is by necessity specific to the problem to be solved, and each chromosome in the population consists of three parts as shown in the example in Fig. 33.41:

- (1) Facility location (or loading station’s location; $F_j, j = 1, 2, \dots, m$): 0–1 chromosome.
- (2) Customer allocation (or sugarcane allocation; $C_i, i = 1, 2, \dots, n$): Heuristics-based chromosome.
- (3) Facility service assignment (or transloader assignment; $L_k, k = 1, 2, \dots, p$): Integer-based chromosome.

The procedure of initialization based on heuristics is given as follows:

- Step 1 Calculate the distance between each sugarcane field and each loading station.
- Step 2 Find the minimum distance between each sugarcane field and loading stations.
- Step 3 Assign all sugarcane fields to the nearest loading stations with adequate available capacity. If not, then the sugarcane field will be assigned to the loading station which is the second nearest to the field and so on.

Genetic Operations

Crossover Generally, crossover generates offspring that combines both parents’ features by exchanging the information of each. Based on the characteristics of the chromosome, we apply displacement crossover.

Check-and-Repair Problem Constraints for Offspring

Although GAs are powerful and popular optimization tools because of their simplicity and ease of implementation, they do not incorporate constraint-handling features. Hence, they may encounter difficulties when applied for solving highly constrained problems. This is because the search operators of GAs (i.e., crossover and mutation) are blind to constraints [74] which can result in infeasible offspring. Therefore, a proper constraint-handling method is required to maintain the applicability of GAs with the solutions satisfying the constraints.

Mutation This operator produces random changes in a chromosome of a population generation. By using swapping mutation operators with one or more genes are swapped by randomly selecting two genes within a chromosome and exchanging their positions with one another.

For designing a hybrid genetic algorithm, fuzzy logic controller (FLC) is combined to automatically tune crossover and mutation parameters by Yun and Gen [7, 8] who reported a case study of a sugar industry in northeastern Thailand in which there are 14 sugar mills out of a total 47 sugar mills in the entire country. The case study’s sugar mill produces

approximately 23,000 tons of sugarcane per day over an area of 4.68×10^4 [ha] in eight provinces, and for the detailed contents, refer to [74].

Some of these problems admit nonconvex objective functions. On the other hand, DCA (difference of convex functions algorithm) has proven its strength in tackling a large class of smooth or nonsmooth, nonconvex optimization problems called DC programming. The key advantages of DCA come from its simplicity and flexibility that allows it to treat large-scale problems arising in various contexts. This chapter concerns methods incorporating ideas of stochastic optimization in an online manner into DCA framework to create new algorithms called online stochastic DCA. The first section introduces the chapter. The second section accounts for deterministic DC programming and DCA. The third section briefly reviews stochastic optimization. The fourth section is dedicated to stochastic DC programming and DCA, where we propose two online stochastic DCA schemes for solving a class of stochastic DC programs. The last section concludes the chapter with discussions about promising aspects of the topic.

DC programming · DCA · Stochastic DC programming · Online stochastic DCA · Conditional expectation

Abstract

In the context of big data analysis, stochastic optimization algorithms are widely used as effective tools to handle data complexity and data uncertainty. These algorithms usually aim to solve problems modeled as stochastic programs.

34.1 Introduction

In many real-life problems, uncertainty appears naturally due to the insufficiency of our knowledge. The unknown quantity in which we are interested is modeled as a random variable or a random vector called Z . Suppose that we have to make a decision called w prior to knowing Z . When a realization z of Z becomes known, depending on the decision which was made, we have to pay a cost of $f(w, z)$. The optimization problem involved consists of finding the optimal decision w minimizing the cost $f(w, z)$. Since the realization z is unknown before the decision is made, one reasonable approach is minimizing the cost on average, i.e., the expected cost (the

expected loss) considered is $F(\mathbf{w}) = E(f(\mathbf{w}, \mathbf{Z}))$. Furthermore, if we have a piece of information \mathcal{P} about \mathbf{Z} , the loss should be updated as $F_{\mathcal{P}}(\mathbf{w}) = E(f(\mathbf{w}, \mathbf{Z})|\mathcal{P})$. Obviously, if \mathcal{P} is independent to \mathbf{Z} , its information is useless, and we then recover $E(f(\mathbf{w}, \mathbf{Z})|\mathcal{P}) = E(f(\mathbf{w}, \mathbf{Z}))$. In contrast, when \mathcal{P} gives enough information to determine \mathbf{Z} , a realization z of \mathbf{Z} becomes known, and the following relation holds:

$$E(f(\mathbf{w}, \mathbf{Z})|\mathcal{P}) = f(\mathbf{w}, z).$$

Solving stochastic programming problems is a challenging task because the underlying distribution of \mathbf{Z} is usually unknown. If sampling independently from the distribution of \mathbf{Z} is possible, one can solve the empirical loss instead. However, the empirical loss is well-approximated to the expected loss only if the sample size is large enough. Hence, solving directly the empirical loss could be very expensive. The main idea of stochastic optimization in an online manner consists of using one or several samples at a time, combining with information of the previous iteration to create a new optimization problem. The new problem is simpler than the original problem with the empirical loss, so it is more likely easier to solve. On top of that, stochastic optimization is the most applicable regarding sequential data since it gives elegant ways to integrate new information into the previous solution.

In order to model accurately real-world problems, stochastic programming framework usually takes into account nonconvexity. When it relates to nonconvexity, things become complicated and they require novel robust tools. However, even in deterministic nonconvex programming, finding effective algorithms that ensure both the quality of solutions and the scalability for large-scale problems is a great challenge. In this deterministic context, it is well-known that most nonconvex nonsmooth problems encountered in real life fall into the framework of DC programming. In nonconvex programming, DCA is one of the rare algorithms that allow to solve problems in a large-scale setting. This renowned method is used by researchers and practitioners worldwide and is usually proven to be state-of-the-art comparing with other related standard methods [1–3].

Despite of its efficiency and scalability in deterministic nonconvex optimization, traditional DCA finds it difficult to apply directly to solve stochastic programming problems due to the lack of knowledge of the distribution. For this reason, it is natural to develop stochastic versions of DCA.

In this chapter, we propose two stochastic DCA schemes for solving a class of stochastic DC problems. Our main idea is quite simple; we replace some deterministic quantities in the DCA by their corresponding stochastic approximations. The stochastic approximations are constructed in an online manner since we are interested in sequential data coming from the distribution of \mathbf{Z} . Our algorithms, on the one hand,

confront nonconvexity. On the other hand, they handle the stochastic nature of the problems.

34.2 Deterministic DC Programming and DCA

It goes, without saying, that in applied mathematics and computer science, nonconvex (differentiable or nondifferentiable) programming have experienced over the past two decades dramatic developments in the world. The explanation for this explosion is quite simple: on the one hand, the variational optimization approaches are flexible and efficient alongside the classical ones, which know their limits on qualities of numerical solutions and sizes of tackled problems; and on the other hand, modern convex analysis and convex optimization widely studied since the early 1960s (at the time being, one can say that available theoretical and algorithmic tools might allow to formulate/reformulate suitable convex programs and to design efficient related solution algorithms) are forced to a logical and natural extension to nonconvexity/nondifferentiability. As most real-world optimization problems are nonconvex and in many areas of industrial, economic, and financial applications, current requirements lead to replacements of older convex models by nonconvex ones, more complex (especially for large-scale problems) but more reliable (because they represent more accurately the nature of considered problems), and especially more economical and competitive.

The absence of convexity is a source of difficulties of all kinds, namely, the distinction between the local and global minima and the nonexistence of verifiable characterizations of global solutions, etc. Passing from convex to nonconvex programming causes all the computational complexity. If one word is used to differentiate between easy and hard problems, convexity is probably the watershed (dixit Rockafellar). Finding a global solution of nonconvex programs is the holy grail of the optimization community.

Really realistic and pragmatic extension of convex analysis, convex programming to nonconvex analysis, nonconvex programming, should be sufficiently large to cover most real-world nonconvex programs, but not too much broad in order to use the powerful arsenal of convex analysis/programming.

We hear more and more often speaking of *trading convexity for scalability* and *the blessings and the curses of dimensionality* in areas such as data mining and machine learning, transport and logistic, communication networks, computational biology, finance and economy, image science, etc., to name but a few, and those now grouped into the discipline called data science, where we have to deal with very large nonconvex programs. Consequently, one should rather look for inexpensive, scalable, and efficient local approaches for the large-scale setting.

Idea (philosophy/principle):

If there is a problem you can't solve, then there is an easier problem you can solve: find it. (George Polya)

1. How to approximate a DC function by a convex function to get a convex program.
2. What to do with a solution \mathbf{x}^* of such a convex program.
3. How to iterate the process.

Reply to these three questions implies the construction of DCA which consists in iteratively generating a sequence $\{\mathbf{x}^k\}$ of solutions of successive convex subprograms. For standard DC programs (i.e., with only convex constraints), one can state local/global optimality conditions by using just basic modern convex analysis (convex analysis by Rockafellar, 1970 [4]), more precisely fundamental properties of conjugate and subdifferential of convex functions.

DC programming and DCA, which constitute the backbone of nonconvex programming, are introduced in 1985 by Pham Dinh Tao in the preliminary state, as a quite natural and logical extension of his previous works on concave programming at the early 1970s, and extensively developed by Le Thi Hoai An and Pham Dinh Tao since 1994 to become now classic and increasingly popular. Being a descent method without line search, DCA, which is one of rare effective algorithms in nonsmooth nonconvex programming, has proven its strength in this framework, especially in a large-scale setting. Regardless of its local behavior, DCA finds itself quite often reaching a global solution if the initial point is good enough. The DC structures of the objective and constraint functions are exploited by DCA in a suitable way which allows us to make use of powerful tools in convex optimization. In fact, solving a DC program using DCA amounts to solving successively convex optimization problems. That is, at each iteration, the method minimizes a convex surrogate of the objective. By its way of incorporating convex optimization in each iteration, DCA can be considered as a natural extension of convex optimization to DC programming. Moreover, with suitable DC decomposition of the objective, DCA can recover most of existing algorithms in nonconvex programming.

With the main strength coming from its deep mathematical foundation, simplicity and flexibility, DCA has found its applications in numerous areas of applied sciences. We list here some areas using DCA (with just a few citations): data mining and machine learning [5–7], finance [8, 9], transport logistics [10, 11], image processing [12, 13], computer vision [14], cryptology [15], computational chemistry and biology [16, 17], game theory [18], telecommunications [19], multiobjective programming [20], inverse problems and ill-posed problems [21], mathematical programming with equilibrium constraints [22, 23], etc. The reader can see the list of reference in [1, 2].

34.2.1 Preliminaries

This subsection recalls some basic notions from convex analysis and nonsmooth analysis [4, 24, 25] to make preparations for giving the theory of DC programming and DCA.

The space $X := \mathbb{R}^n$ is equipped with the canonical inner product $\langle \cdot, \cdot \rangle$. Its dual space Y is identified with X itself. The effective domain of a function $f : X \rightarrow \mathbb{R} \cup \{+\infty\}$, denoted by $\text{dom} f$, is

$$\text{dom} f := \{\mathbf{x} \in X : f(\mathbf{x}) < +\infty\}.$$

It is called proper if $\text{dom} f \neq \emptyset$. Let C be a nonempty and convex set contained in $\text{dom} f$. By definition, f is convex on C if the following inequality holds for all $\mathbf{x}, \mathbf{u} \in C, \lambda \in [0, 1]$:

$$f(\lambda \mathbf{x} + (1 - \lambda)\mathbf{u}) \leq \lambda f(\mathbf{x}) + (1 - \lambda)f(\mathbf{u}).$$

Let $\rho \geq 0$; f is called ρ -convex on C if $f - \frac{\rho}{2}\|\cdot\|^2$ is convex on C . The modulus of strong convexity of f on C , denoted by $\rho(f, C)$ or $\rho(f)$ if $C = \text{dom} f$, is defined by

$$\rho(f, C) := \sup\{\rho \geq 0 : f - (\rho/2)\|\cdot\|^2 \text{ is convex on } C\}.$$

Obviously, ρ -convexity implies convexity. The function f is called strongly convex on C if $\rho(f, C) > 0$. Let $\mathbf{x} \in \text{dom} f$; a vector $\mathbf{z} \in X$ is called a subgradient of f at \mathbf{x} if

$$\forall \mathbf{y} \in X, f(\mathbf{y}) - f(\mathbf{x}) \geq \langle \mathbf{z}, \mathbf{y} - \mathbf{x} \rangle.$$

The whole set of subgradients of f at \mathbf{x} , denoted by $\partial f(\mathbf{x})$, is called the subdifferential of f at \mathbf{x} . In general, $\partial f(\mathbf{x})$ can be empty. We say that f is subdifferentiable at \mathbf{x} if $\partial f(\mathbf{x}) \neq \emptyset$.

The set $A \subset X$ is called an affine space if

$$\forall t \in \mathbb{R}, \forall \mathbf{x}, \mathbf{y} \in A : \mathbf{x} + t(\mathbf{y} - \mathbf{x}) \in A.$$

Let $C \subset X$; the affine hull of C , denoted by $\text{aff}(C)$, is the smallest affine space containing C .

The relative interior of a convex set C , denoted by $\text{ri} C$, is defined as follows:

$$\text{ri} C := \{\mathbf{x} \in \text{aff}(C) \mid \exists \epsilon > 0, B(\mathbf{x}, \epsilon) \cap \text{aff}(C) \subset C\},$$

where $B(\mathbf{x}, \epsilon)$ is the open ball with the center \mathbf{x} and the radius ϵ .

We next recall two concepts of subdifferential, namely, Fréchet subdifferential and Clarke subdifferential.

Let $f : X \rightarrow \mathbb{R} \cup \{+\infty\}$ be a proper function; the Fréchet subdifferential of f at $\mathbf{x} \in \text{dom} f$, denoted by $\partial^F f(\mathbf{x})$, is defined as follows:

$$\partial^F f(\mathbf{x}) = \left\{ \mathbf{y} \in Y : \liminf_{\mathbf{h} \rightarrow 0} \frac{f(\mathbf{x} + \mathbf{h}) - f(\mathbf{x}) - \langle \mathbf{y}, \mathbf{h} \rangle}{\|\mathbf{h}\|} \geq 0 \right\}. \quad (P_{dc}) \quad \alpha := \inf \{f(\mathbf{x}) := g(\mathbf{x}) - h(\mathbf{x}) : \mathbf{x} \in X\}$$

For $\mathbf{x} \notin \text{dom } f$, we set $\partial^F f(\mathbf{x}) = \emptyset$. If f is a convex function, then $\partial^F f$ coincides with the subdifferential ∂f . A point $\mathbf{x}_0 \in X$ is called a (Fréchet) *critical* (or *stationary*) point for the function f , if $0 \in \partial^F f(\mathbf{x}_0)$.

If f is locally Lipschitz at $\mathbf{x} \in X$, then the Clarke directional derivative $f^C(\mathbf{x}; \cdot)$ at \mathbf{x} along a direction $\mathbf{d} \in X$ is defined by

$$f^C(\mathbf{x}; \mathbf{d}) := \lim_{(t, \mathbf{u}) \rightarrow (0^+, \mathbf{x})} \frac{f(\mathbf{u} + t\mathbf{d}) - f(\mathbf{u})}{t}.$$

The Clarke subdifferential set of f at \mathbf{x} is defined as

$$\partial^C f(\mathbf{x}) := \{\mathbf{y} \in Y : \langle \mathbf{y}, \mathbf{d} \rangle \leq f^C(\mathbf{x}; \mathbf{d}), \forall \mathbf{d} \in X\}.$$

If f is continuously differentiable at \mathbf{x} , $\partial^C f(\mathbf{x})$ coincides with the Fréchet derivative of f at \mathbf{x} , $\{\nabla f(\mathbf{x})\}$. When f is a convex function, then $\partial^C f$ coincides with the subdifferential ∂f . The two basic operators to manipulate the Clarke subdifferential are presented as follows:

$$\partial^C(-f)(\mathbf{x}) = -\partial^C f(\mathbf{x}),$$

$$\partial^C(f + g)(\mathbf{x}) \subset \partial^C f(\mathbf{x}) + \partial^C g(\mathbf{x}),$$

where f, g are locally Lipschitz at a given $\mathbf{x} \in X$. The equality in the latter inclusion holds if f is continuously differentiable at \mathbf{x} . For a DC function f , i.e., $f := g - h$, where g and h are convex functions, one has

$$\partial^F f(\mathbf{x}) \subset \partial g(\mathbf{x}) - \partial h(\mathbf{x}),$$

wherever h is continuous at \mathbf{x} . Especially, if h is differentiable at \mathbf{x} , then the equality holds:

$$\partial^F f(\mathbf{x}) = \partial g(\mathbf{x}) - \nabla h(\mathbf{x}).$$

34.2.2 DC Programming and DCA: Basic Results

Let $\Gamma_0(X)$ denote the convex cone of all lower semicontinuous proper convex functions on X . The vector space of DC functions is denoted by

$$DC(X) := \Gamma_0(X) - \Gamma_0(X).$$

The richness of this class of DC functions allows it to contain most objective functions arising in real-life problems.

The standard DC program takes the form

with $g, h \in \Gamma_0(X)$. Such a function f is called DC on X , $g - h$ is DC decomposition, while g and h are DC components of f . One can, without loss of generality, assume that g and h are strongly convex based on the fact that we can replace g and h by $g + \frac{\rho}{2}\|\cdot\|^2$ and $h + \frac{\rho}{2}\|\cdot\|^2$ with $\rho > 0$. It also implies that a DC function f has infinitely many DC decompositions. Since DCA works on each DC component of f , the DC decomposition highly affects the practical performance of DCA including quality of computed solutions, computational efficiency and scalability, etc.

Note that a DC program with closed convex constraint $\mathbf{x} \in C$ can be equivalently written as a standard DC program by adding the indicator function χ_C to the first component g :

$$\begin{aligned} \inf \{f(\mathbf{x}) := g(\mathbf{x}) - h(\mathbf{x}) : \mathbf{x} \in C\} \\ = \inf \{\chi_C(\mathbf{x}) + g(\mathbf{x}) - h(\mathbf{x}) : \mathbf{x} \in X\}. \end{aligned}$$

Under the convention $+\infty - (+\infty) = +\infty$, the finiteness of the optimal value α implies

$$\text{dom } f = \text{dom}(g + \chi_C) = \text{dom } g \cap \text{dom } \chi_C = C \subset \text{dom } h.$$

The dual DC program (D_{dc}) of (P_{dc}) is

$$(D_{dc}) \quad \alpha = \inf \{h^*(\mathbf{y}) - g^*(\mathbf{y}) : \mathbf{y} \in Y\}.$$

Here g^* and h^* are the conjugate functions of g and h , respectively, i.e.,

$$g^*(\mathbf{y}) := \sup \{\langle \mathbf{x}, \mathbf{y} \rangle - g(\mathbf{x}) : \mathbf{x} \in X\}.$$

Critical and Strongly Critical Points of $g - h$

A point \mathbf{x}^* is a critical point of (P_{dc}) (or $f = g - h$), iff $\partial g(\mathbf{x}^*) \cap \partial h(\mathbf{x}^*) \neq \emptyset$, or equivalently $0 \in \partial g(\mathbf{x}^*) - \partial h(\mathbf{x}^*)$, while it is called strongly critical point of (P_{dc}) (or $f = g - h$), iff $\emptyset \neq \partial h(\mathbf{x}^*) \subset \partial g(\mathbf{x}^*)$. The sets of critical (resp. strongly critical) points of $g - h$ are denoted by \mathcal{P}_c (resp. \mathcal{P}_{sc}), and \mathcal{P}_l is the set of local minimizers of $g - h$. Likewise, replacing (P_{dc}) by (D_{dc}) gives the similar notations for $h^* - g^*$.

Due to the symmetry between the primal DC program and the dual DC program, the following necessary local optimality conditions for the primal problem can be deduced to the dual problem without difficulty [3, 26, 27].

The notion of DC criticality has a close connection to Clarke/Fréchet stationarity that is presented in the following.

The point \mathbf{x}^* is called Clarke/Fréchet stationary if $0 \in \partial^C f(\mathbf{x}^*)$ (resp. $0 \in \partial^F f(\mathbf{x}^*)$). On the other hand, under technical assumptions, the following inclusions hold:

$$\partial^C f(\mathbf{x}) \subset [\partial g(\mathbf{x}) - \partial h(\mathbf{x})],$$

$$\partial^F f(\mathbf{x}) \subset [\partial g(\mathbf{x}) - \partial h(\mathbf{x})].$$

As a consequence, Clarke stationarity of \mathbf{x}^* or its Fréchet stationarity implies *DC criticality* of \mathbf{x}^* . Equivalence between them depends on conditions that make these inclusions become equalities.

DC Strong Criticality and d-Stationarity

As mentioned, DC criticality and strong criticality depend on DC decomposition of DC objective function $f = g - h$. Since a DC function has infinitely many DC decompositions, it is natural and important to find relations between DC criticality and some stationarity concepts that depend only on f . Therefore, we present the commonly used directional stationarity and point out its link with DC criticality.

Some useful results of these different criticalities are presented as follows [4, 28].

Let $\varphi : X \rightarrow \mathbb{R} \cup \{+\infty\}$ be a proper function on X and $\mathbf{x} \in \text{dom } \varphi$. The directional derivative $\varphi'(\mathbf{x}; \cdot)$ of φ at \mathbf{x} along a direction $\mathbf{u} \in X$ is defined by

$$\varphi'(\mathbf{x}; \mathbf{u}) := \lim_{t \downarrow 0} \frac{\varphi(\mathbf{x} + t\mathbf{u}) - \varphi(\mathbf{x})}{t}.$$

If φ is convex, then it becomes

$$\varphi'(\mathbf{x}; \mathbf{u}) := \inf_{t > 0} \frac{\varphi(\mathbf{x} + t\mathbf{u}) - \varphi(\mathbf{x})}{t}.$$

Assume that the function $\varphi : X \rightarrow \mathbb{R} \cup \{+\infty\}$ is proper convex on X ; then for $\mathbf{x} \in \text{dom } \varphi$,

(a) $\varphi'(\mathbf{x}; \cdot)$ is convex positively homogeneous.

(b) $\mathbf{y} \in \partial\varphi(\mathbf{x})$ if and only if $\varphi'(\mathbf{x}; \mathbf{u}) \geq \langle \mathbf{u}, \mathbf{y} \rangle$ for every $\mathbf{u} \in X$, i.e.,

$$\varphi'(\mathbf{x}; \mathbf{u}) \geq \sup\{\langle \mathbf{u}, \mathbf{y} \rangle : \mathbf{y} \in \partial\varphi(\mathbf{x})\} = \chi_{\partial\varphi(\mathbf{x})}^*(\mathbf{u}).$$

In fact, the closure of $\varphi'(\mathbf{x}; \mathbf{u})$ as a convex function of \mathbf{u} is the support function of the closed convex set $\partial\varphi(\mathbf{x})$

$$\text{cl}(\varphi'(\mathbf{x}; \mathbf{u})) = \chi_{\partial\varphi(\mathbf{x})}^*(\mathbf{u}).$$

Moreover, if $\mathbf{x} \in \text{ri}(\text{dom } \varphi)$, then $\partial\varphi(\mathbf{x})$ is nonempty, and $\varphi'(\mathbf{x}; \mathbf{u})$ is semicontinuous and proper on X as a function of \mathbf{u} such that

$$\varphi'(\mathbf{x}; \mathbf{u}) = \sup\{\langle \mathbf{u}, \mathbf{y} \rangle : \mathbf{y} \in \partial\varphi(\mathbf{x})\} = \chi_{\partial\varphi(\mathbf{x})}^*(\mathbf{u}).$$

Let C be a nonempty closed convex set in X . Then, for $\mathbf{x} \in C$,

$$\partial\chi_C(\mathbf{x}) = \{\mathbf{y} \in Y : \langle \mathbf{u} - \mathbf{x}, \mathbf{y} \rangle \leq 0 \forall \mathbf{u} \in C\} = N(C, \mathbf{x}),$$

where $N(C, \mathbf{x})$ is the (closed convex) normal cone to C at \mathbf{x} .

(c) Let C_1 and C_2 be two closed convex sets in X . Then,

$$C_1 \subset C_2 \Leftrightarrow \chi_{C_1}^* \leq \chi_{C_2}^*.$$

The d-Stationarity of a Proper Function

A vector $\mathbf{x} \in \text{dom } \varphi$ is *d-stationary* of φ , iff $\varphi'(\mathbf{x}; \mathbf{u}) \geq 0$ for every $\mathbf{u} \in X$. The following theorem presents the key relations between d-stationarity and strong criticality. The proof follows directly from the mentioned properties a), b), and c).

Theorem 34.1 *Let $f := g - h$ be the DC objective function of the primal DC program (P_{dc}) with $g, h \in \Gamma_0(X)$ and its optimal value α being finite (implying $\text{dom } f = \text{dom } g \subset \text{dom } h$). Then, the following properties hold:*

- (1) $f'(\mathbf{x}; \mathbf{u}) = g'(\mathbf{x}; \mathbf{u}) - h'(\mathbf{x}; \mathbf{u})$ for all $\mathbf{u} \in X$.
- (2) *The vector $\mathbf{x} \in \text{dom } f$ is d-stationary of f (or for (P_{dc})) if and only if $g'(\mathbf{x}; \mathbf{u}) \geq h'(\mathbf{x}; \mathbf{u})$ for all $\mathbf{u} \in X$. Hence for $\mathbf{x} \in \text{dom } f$, if both equalities $g'(\mathbf{x}; \mathbf{u}) = \chi_{\partial g(\mathbf{x})}^*(\mathbf{u})$ and $h'(\mathbf{x}; \mathbf{u}) = \chi_{\partial h(\mathbf{x})}^*(\mathbf{u})$ hold for all $\mathbf{u} \in X$, then there is an identity between the d-stationarity of \mathbf{x} and the strong criticality of \mathbf{x} .*
- (3) *If $\mathbf{x} \in \text{ri}(\text{dom } g) \cap \text{ri}(\text{dom } h)$, then the d-stationarity of \mathbf{x} is equivalent to the strong criticality of \mathbf{x} .*
- (4) *If $\mathbf{x} \in \text{ri}(\text{dom } g)$, then the d-stationarity of \mathbf{x} implies the strong criticality of \mathbf{x} .*
- (5) *If $\mathbf{x} \in \text{ri}(\text{dom } h)$, then the strong criticality of \mathbf{x} implies the d-stationarity of \mathbf{x} .*
- (6) *If the affine hulls of $\text{dom } g$ and of $\text{dom } h$ are identical, then $\text{ri}(\text{dom } g) \subset \text{ri}(\text{dom } h)$, and for $\mathbf{x} \in \text{ri}(\text{dom } g)$, the d-stationarity of \mathbf{x} is equivalent to the strong criticality of \mathbf{x} .*

Duality and Local Optimality Conditions in DC Programming

The following theorem and its corollaries give some important results about DC programming including its duality, (strict) local optimality, and the transportation of local minimizer between primal and dual DC problems [1–3, 26, 27]. These results are useful to understand and analyze DCA.

Theorem 34.2 *Let \mathbf{x}^* be a critical point of $g - h$ and $\mathbf{y}^* \in \partial g(\mathbf{x}^*) \cap \partial h(\mathbf{x}^*)$. Let U be a neighborhood of \mathbf{x}^* such that $(U \cap \text{dom } g) \subset \text{dom } \partial h$. If for any $\mathbf{x} \in U \cap \text{dom } g$ there is $\mathbf{y} \in \partial h(\mathbf{x})$ such that*

$$h^*(\mathbf{y}) - g^*(\mathbf{y}) \geq h^*(\mathbf{y}^*) - g^*(\mathbf{y}^*),$$

then \mathbf{x}^ is a local minimizer of $g - h$. More precisely,*

$$g(\mathbf{x}) - h(\mathbf{x}) \geq g(\mathbf{x}^*) - h(\mathbf{x}^*), \quad \forall \mathbf{x} \in U \cap \text{dom } g.$$

Corollary 34.1 (Sufficient Local Optimality) *Let \mathbf{x}^* be a point that admits a neighborhood U such that $\partial h(\mathbf{x}) \cap \partial g(\mathbf{x}^*) \neq \emptyset, \forall \mathbf{x} \in U \cap \text{dom } g$. Then, \mathbf{x}^* is a local minimizer of $g - h$. More precisely,*

$$g(\mathbf{x}) - h(\mathbf{x}) \geq g(\mathbf{x}^*) - h(\mathbf{x}^*), \quad \forall \mathbf{x} \in U \cap \text{dom } g.$$

Corollary 34.2 (Sufficient Strict Local Optimality) *If $\mathbf{x}^* \in \text{int}(\text{dom } h)$ verifies $\partial h(\mathbf{x}^*) \subset \text{int}(\partial g(\mathbf{x}^*))$, then \mathbf{x}^* is a strict local minimizer of $g - h$.*

Corollary 34.3 (DC Duality Transportation of a Local Minimizer) *Let $\mathbf{x}^* \in \text{dom } \partial h$ be a local minimizer of $g - h$, and let $\mathbf{y}^* \in \partial h(\mathbf{x}^*)$ (i.e., $\partial h(\mathbf{x}^*)$ is nonempty and \mathbf{x}^* admits a neighborhood U such that*

$$g(\mathbf{x}) - h(\mathbf{x}) \geq g(\mathbf{x}^*) - h(\mathbf{x}^*), \quad \forall \mathbf{x} \in U \cap \text{dom } g.$$

If

$$\mathbf{y}^* \in \text{int}(\text{dom } g^*) \text{ and } \partial g^*(\mathbf{y}^*) \subset U \quad (34.1)$$

((34.1) holds if g^* is differentiable at \mathbf{y}^*), then \mathbf{y}^* is a local minimizer of $h^* - g^*$.

DCA and Its Convergence Properties

Philosophy of DCA: As a convex analysis approach to DC programming, the main idea of DCA is quite simple: at the iteration k , the second DC component h is approximated by its affine minorization at \mathbf{x}^k ,

$$h_k(\mathbf{x}) := h(\mathbf{x}^k) + \langle \mathbf{x} - \mathbf{x}^k, \mathbf{y}^k \rangle$$

with $\mathbf{y}^k \in \partial h(\mathbf{x}^k)$. The resulting function is convex and DCA minimizes it to get the next point \mathbf{x}^{k+1} .

Basic DCA scheme.

Initialization: Let $\mathbf{x}^0 \in \text{dom } \partial h$.

For $k = 0, 1, 2 \dots$

Step 1: Compute $\mathbf{y}^k \in \partial h(\mathbf{x}^k)$.

Step 2: Compute

$$\mathbf{x}^{k+1} \in \arg \min \{g(\mathbf{x}) - h_k(\mathbf{x}) : \mathbf{x} \in X\} (P_k).$$

Step 3: If $f(\mathbf{x}^{k+1}) = f(\mathbf{x}^k)$, then stop: \mathbf{x}^k and \mathbf{x}^{k+1} are critical points of (P_{dc}) .

Despite of its simple idea, DCA is a powerful method which enjoys some nice properties mainly coming from local optimality conditions and duality in DC programming.

The following theorem recalls some major results on DCA's convergence [3, 26, 27].

Theorem 34.3 *The DCA is a descent method without line search, but with global convergence, which enjoys the following properties (C and D are two convex sets in X , containing the sequences $\{\mathbf{x}^k\}$ and $\{\mathbf{y}^k\}$, respectively):*

- (1) *The sequences $\{g(\mathbf{x}^k) - h(\mathbf{x}^k)\}$ and $\{h^*(\mathbf{y}^k) - g^*(\mathbf{y}^k)\}$ are decreasing and convergent to the same limit, and*
 - *$g(\mathbf{x}^{k+1}) - h(\mathbf{x}^{k+1}) = g(\mathbf{x}^k) - h(\mathbf{x}^k)$ iff $[\rho(g, C) + \rho(h, C)]\|\mathbf{x}^{k+1} - \mathbf{x}^k\| = 0, \mathbf{y}^k \in \partial g(\mathbf{x}^k) \cap \partial h(\mathbf{x}^k)$, and $\mathbf{y}^k \in \partial g(\mathbf{x}^{k+1}) \cap \partial h(\mathbf{x}^{k+1})$. Moreover if g or h is strictly convex on C , then $\mathbf{x}^k = \mathbf{x}^{k+1}$. In such a case, the DCA terminates at the k^{th} iteration (finite convergence of DCA).*
 - *$h^*(\mathbf{y}^{k+1}) - g^*(\mathbf{y}^{k+1}) = h^*(\mathbf{y}^k) - g^*(\mathbf{y}^k)$ iff $\mathbf{x}^{k+1} \in \partial g^*(\mathbf{y}^k) \cap \partial h^*(\mathbf{y}^k), \mathbf{x}^{k+1} \in \partial g^*(\mathbf{y}^{k+1}) \cap \partial h^*(\mathbf{y}^{k+1})$, and $[\rho(g^*, D) + \rho(h^*, D)]\|\mathbf{y}^{k+1} - \mathbf{y}^k\| = 0$. Moreover if g^* or h^* is strictly convex on D , then $\mathbf{y}^{k+1} = \mathbf{y}^k$. In such a case, the DCA terminates at the k^{th} iteration (finite convergence of DCA).*
- (2) *If $\rho(g, C) + \rho(h, C) > 0$ (resp. $\rho(g^*, D) + \rho(h^*, D) > 0$), then the series $\{\|\mathbf{x}^{k+1} - \mathbf{x}^k\|^2\}$ and $\{\|\mathbf{y}^{k+1} - \mathbf{y}^k\|^2\}$ are convergent.*
- (3) *If the optimal value α of the problem (P_{dc}) is finite, let \mathbf{x}^* be a limit point of $\{\mathbf{x}^k\}$, then*

$$\frac{\rho(g, C) + \rho(h, C)}{2} \sum_{l=0}^{k-1} \|\mathbf{x}^{l+1} - \mathbf{x}^l\|^2 \leq f(\mathbf{x}^0) - f(\mathbf{x}^*).$$

As a consequence,

$$\begin{aligned} & \frac{k}{2} (\rho(g, C) + \rho(h, C)) \times \min \{ \|\mathbf{x}^l - \mathbf{x}^{l+1}\|^2 : l = \overline{0, k-1} \} \\ & \leq f(\mathbf{x}^0) - f(\mathbf{x}^*). \end{aligned}$$

If $\rho(g, C) + \rho(h, C) > 0$, then

$$\min \{ \|\mathbf{x}^l - \mathbf{x}^{l+1}\| : l = \overline{0, k-1} \} \leq \left(\frac{2(f(\mathbf{x}^0) - f(\mathbf{x}^*))}{k(\rho(g, C) + \rho(h, C))} \right)^{\frac{1}{2}},$$

and consequently, the sequence

$$\{\eta^k\} := \left\{ \min \{ \|\mathbf{x}^l - \mathbf{x}^{l+1}\| : l = \overline{0, k-1} \} \right\}_k$$

converges to 0 with the convergence rate $O(k^{-1/2})$, where k is the number of iterations. This implies that in order to achieve $\eta^k \leq \epsilon$, we must run $O(\epsilon^{-2})$ iterations of DCA.

- (4) *If the optimal value α of the problem (P_{dc}) is finite, let \mathbf{x}^* be a limit point of $\{\mathbf{x}^k\}$, then*

$$\min \{ f(\mathbf{x}^l) - f(\mathbf{x}^{l+1}) : l = \overline{0, k-1} \} \leq \frac{f(\mathbf{x}^0) - f(\mathbf{x}^*)}{k}.$$

Consequently, the sequence

$$\{\mu^k\} := \left\{ \min \{f(\mathbf{x}^l) - f(\mathbf{x}^{l+1}) : l = \overline{0, k-1}\} \right\}_k$$

converges to 0 with the convergence rate $O(k^{-1})$, where k is the number of iterations. This implies that in order to achieve $\mu^k \leq \epsilon$, we must run $O(\epsilon^{-1})$ iterations of DCA.

- (5) If the optimal value α of problem (P_{dc}) is finite and the sequences $\{\mathbf{x}^k\}$ and $\{\mathbf{y}^k\}$ are bounded, then every limit point $\tilde{\mathbf{x}}$ (resp. $\tilde{\mathbf{y}}$) of the sequence $\{\mathbf{x}^k\}$ (resp. $\{\mathbf{y}^k\}$) is a critical point of $g - h$ (resp. $h^* - g^*$).
- (6) For polyhedral DC program (i.e., a DC program in which at least one of the functions g and h is polyhedral), the sequences $\{\mathbf{x}^k\}$ and $\{\mathbf{y}^k\}$ contain finitely many iterates, and hence they have finite convergence (i.e., after a finite number of iterations).

In general, establishing the convergence rate for the whole sequence $\{\mathbf{x}^k\}$ generated by DCA is a challenging task. Thus, Theorem 34.3(5) only ensures that the sequence $\{\mathbf{x}^k\}$ admits a subsequence converging to the a critical point of $g - h$. It is worth noting that, if $\rho(g, C) + \rho(h, C) > 0$, Theorem 34.3(3) implies that the series

$$\sum_{k=0}^{\infty} \|\mathbf{x}^k - \mathbf{x}^{k+1}\|^2$$

is convergent. On the other hand, if the series

$$\sum_{k=0}^{\infty} \|\mathbf{x}^k - \mathbf{x}^{k+1}\| \quad (34.2)$$

is convergent, $\{\mathbf{x}^k\}$ is a Cauchy sequence and, as a consequence, it is convergent. In [29], the authors studied the convergence of (34.2) with the help of Łojasiewicz subgradient inequality for DC programs with subanalytic data. The main results of [29] are summarized as follows with the convergence rates provided.

DCA with Subanalytic Data

Firstly, let us recall some notions of subanalytic sets and functions with their basic properties [30–32].

Definition 34.1

- (1) A subset C of X is said to be semianalytic iff for each point of X , there exists a neighborhood V such that $C \cap V$ is of the following form:

$$C \cap V = \bigcup_{i=1}^p \bigcap_{j=1}^q \{\mathbf{x} \in V : f_{ij}(\mathbf{x}) = 0, g_{ij}(\mathbf{x}) > 0\},$$

where $f_{ij}, g_{ij} : V \rightarrow \mathbb{R}$ ($1 \leq i \leq p, 1 \leq j \leq q$) are real-analytic functions.

- (2) A subset C of X is called subanalytic iff for each point of X , there exists a neighborhood V such that

$$C \cap V = \{\mathbf{x} \in X : \exists \mathbf{y} \in \mathbb{R}^m, (\mathbf{x}, \mathbf{y}) \in D\},$$

where D is a bounded semianalytic subset of $X \times \mathbb{R}^m$ with $m \geq 1$.

- (3) A function $f : X \rightarrow \mathbb{R} \cup \{+\infty\}$ is said to be subanalytic iff its graph $\text{gph} f$ is a subanalytic subset of $X \times \mathbb{R}$.

The class of subanalytic sets (resp. functions) contains all analytic sets (resp. functions). The class of subanalytic sets are closed under locally finite union and intersection, complement and under the natural projection. The distance function to a subanalytic set is a subanalytic function; the sum or difference of the continuous subanalytic functions is also subanalytic. We refer the reader to [31, 33, 34] for further properties.

The subanalyticity of the conjugate of subanalytic function is stated as follows.

Proposition 34.1 *If $f : X \rightarrow \mathbb{R} \cup \{+\infty\}$ is a lower semicontinuous subanalytic strongly convex function, then its conjugate f^* is a $C^{1,1}$ (the class of functions whose derivative is Lipschitz) subanalytic convex function.*

Let us recall next the Łojasiewicz subgradient inequality established by Bolte-Daniliidis-Lewis [35].

Theorem 34.4 (Theorem 3.1 [35]) *Let $f : X \rightarrow \mathbb{R} \cup \{+\infty\}$ be a subanalytic function such that its domain $\text{dom} f$ is closed and $f|_{\text{dom} f}$ is continuous, and let \mathbf{x}_0 be a Fréchet critical point of f . Then, there exist $\theta \in [0, 1)$, $L > 0$ and a neighborhood V of \mathbf{x}_0 such that the following inequality holds:*

$$|f(\mathbf{x}) - f(\mathbf{x}_0)|^\theta \leq L \|\mathbf{x}^*\| \quad \forall \mathbf{x} \in V, \mathbf{x}^* \in \partial^F f(\mathbf{x}),$$

where a convention $0^0 = 1$ is used.

The number θ is called a Łojasiewicz exponent of the function f at the critical point \mathbf{x}_0 . We now have all elements necessary to establish the convergence results of DCA with subanalytic data. The following theorem is about the convergence of the sequences $\{\mathbf{x}^k\}$ and $\{\mathbf{y}^k\}$.

Theorem 34.5 *Let us consider DC problem (P_{dc}) with $\alpha \in \mathbb{R}$. Suppose that the sequences $\{\mathbf{x}^k\}$ and $\{\mathbf{y}^k\}$ are defined by the DCA.*

- (1) Suppose that the DC function $f := g - h$ is subanalytic such that $\text{dom} f$ is closed; $f|_{\text{dom} f}$ is continuous; and around every critical point of (P_{dc}) , either g or h is differentiable with locally Lipschitz derivative. Assume that $\rho := \rho(g) + \rho(h) > 0$, where $\rho(g)$ and $\rho(h)$ are modulus of the strong convexity of g and h , respectively. If either the sequence $\{\mathbf{x}^k\}$ or $\{\mathbf{y}^k\}$ is bounded, then $\{\mathbf{x}^k\}$ and $\{\mathbf{y}^k\}$ are convergent to critical points of (P_{dc}) and (D_{dc}) , respectively.
- (2) Similarly, the dual problem has the counterpart: suppose that $h^* - g^*$ is subanalytic such that $\text{dom}(h^* - g^*)$ is closed, $(h^* - g^*)|_{\text{dom}(h^* - g^*)}$ is continuous, and around critical point of (D_{dc}) , either g^* or h^* is differentiable with locally Lipschitz derivative. If $\rho(g^*) + \rho(h^*) > 0$ ($\rho(g^*)$ and $\rho(h^*)$ are modulus of the strong convexity of g^* and h^* , respectively) and either the sequence $\{\mathbf{x}^k\}$ or $\{\mathbf{y}^k\}$ is bounded, then $\{\mathbf{x}^k\}$ and $\{\mathbf{y}^k\}$ are convergent to critical points of (P_{dc}) and (D_{dc}) , respectively.

Corollary 34.4 Suppose that $g - h$ and $h^* - g^*$ are subanalytic functions with closed domain such that $(g - h)|_{\text{dom}(g-h)}$ and $(h^* - g^*)|_{\text{dom}(h^*-g^*)}$ are continuous. Assume that $\rho(g) + \rho(h) > 0$ as well as $\rho(g^*) + \rho(h^*) > 0$. If either the sequence $\{\mathbf{x}^k\}$ or $\{\mathbf{y}^k\}$ is bounded, then these sequences converge to critical points of (P_{dc}) and (D_{dc}) , respectively.

We next state a theorem about the convergence rate of $\{\mathbf{x}^k\}$ to its limit point \mathbf{x}^∞ .

Theorem 34.6 Suppose that the assumptions of Theorem 34.5(1) are satisfied. Let \mathbf{x}^∞ be the limit point of $\{\mathbf{x}^k\}$ at which the Łojasiewicz exponent $\theta \in [0, 1)$ of the function f is given. Then, there exist constants $\tau_1, \tau_2 > 0$ such that, for all $k \in \mathbb{N}$,

$$\|\mathbf{x}^k - \mathbf{x}^\infty\| \leq \sum_{j=k}^{\infty} \|\mathbf{x}^j - \mathbf{x}^{j+1}\| \leq \tau_1 \|\mathbf{x}^k - \mathbf{x}^{k-1}\| + \tau_2 \|\mathbf{x}^k - \mathbf{x}^{k-1}\|^{\frac{1-\theta}{\theta}}.$$

As a result, one has:

- If $\theta \in (1/2, 1)$, then $\|\mathbf{x}^k - \mathbf{x}^\infty\| \leq ck^{\frac{1-\theta}{1-2\theta}}$ for some $c > 0$.
- If $\theta \in (0, 1/2]$, then $\|\mathbf{x}^k - \mathbf{x}^\infty\| \leq cq^k$ for some $c > 0$ and $q \in (0, 1)$.
- If $\theta = 0$, then $\{\mathbf{x}^k\}$ is convergent in a finite number of steps.

Recent Developments and Open Problems in DC Programming and DCA

So far DCA seems to be the sole existing algorithm in nonsmooth nonconvex programming; the method is surely expected to continue to thrive. We summarize here some recent developments and open problems in DC programming and DCA:

1. Finding reformulations and DC decompositions well adapted to DC programs.
2. Exact penalty with/without error bounds in general DC programs, i.e., DC programs with DC constraints.
3. Using Nesterov smoothing techniques applied to generated convex subprograms for accelerating DCA, similar to the fast iterative shrinkage-thresholding algorithm.
4. Using proximal approaches techniques for both regularization and decomposition and improving DCA's convergence speed.
5. Using line search –standard DCA's step size being equal to 1– for the DC objective function in DCA.
6. Estimating DCA's convergence rate for special classes of DC programs.
7. DCA's global convergence for special DC programs, for example, DC programs with subanalytic data using the Łojasiewicz inequality for nonsmooth subanalytic functions.
8. Strategy for choosing initial points, taking into account specific structures of DC programs.
9. Composite functions techniques in DC programming and DCA.
10. Finding convex minorants of DC functions for computing lower bounds of optimal values.
11. Does DCA generate all existing algorithms for convex programming?

34.2.3 Links Between DCA and Standard Convex/Nonconvex Programming Approaches

This subsection discusses the links between DCA and majorization-minimization (MM), the successive convex approximation (SCA) approaches. Furthermore, some convex/nonconvex programming approaches are shown as special versions of DCA.

DCA Versus the MM and SCA Approaches

The general principle behind the MM was first introduced in the early work [36] by Ortega and Rheinboldt, followed by the work of de Leeuw [37]. Hunter and Lange named the method MM for the first time in [38]. The MM, like DCA, is a philosophy rather than a specific algorithm. Specifically, for solving the minimization problem

$$\min\{f(\mathbf{x}) : \mathbf{x} \in \mathcal{X} \subset \mathbb{R}^n\},$$

the MM constructs a majorization function ϑ over $\mathcal{X} \times \mathcal{X}$ such that

$$f(\mathbf{x}) \leq \vartheta(\mathbf{x}, \mathbf{y}), \forall \mathbf{x}, \mathbf{y} \in \mathcal{X}$$

and

$$f(x) = \vartheta(x, x), \forall x \in \mathcal{X}.$$

At the iteration k , the MM updates

$$\mathbf{x}^{k+1} \in \arg \min \{ \vartheta(\mathbf{x}, \mathbf{x}^k) : \mathbf{x} \in \mathcal{X} \}.$$

In the literature, there are four typical approaches used to construct the surrogate: Jensen's inequality, convexity inequality, Cauchy-Schwartz inequality, and inequality of arithmetic and geometric means. When ϑ is convex, the MM, more recently, is also referred to as SCA. The idea of the MM is quite general, and it leaves us with a challenging task which is how to choose the appropriate surrogate. Working directly on the objective function f is also a source of difficulty of the MM. When it comes to DC programming context, DCA gives the simplest and the most closed convex surrogate function of f that benefits us in many aspects.

Regardless of its generality, most related works using the MM/SCA method in the literature can be recovered as versions of DCA based on latent DC structures of the problems. To demonstrate this statement, we consider here several ways to choose the convex surrogate in SCA.

Linear Upper Bounds of Concave Functions

When f is concave differentiable, the following affine function is often used as the surrogate of f :

$$\vartheta(\mathbf{x}, \mathbf{x}^k) = f(\mathbf{x}^k) + \langle \nabla f(\mathbf{x}^k), \mathbf{x} - \mathbf{x}^k \rangle,$$

and the SCA solve the following program to get \mathbf{x}^{k+1} :

$$\min \{ f(\mathbf{x}^k) + \langle \nabla f(\mathbf{x}^k), \mathbf{x} - \mathbf{x}^k \rangle : \mathbf{x} \in \mathcal{X} \}.$$

Obviously, this algorithm is DCA for the following DC program:

$$\min \{ g(\mathbf{x}) - h(\mathbf{x}) : \mathbf{x} \in \mathcal{X} \},$$

where $g(\mathbf{x}) = 0$, $h(\mathbf{x}) = -f(\mathbf{x})$ that are both convex.

Quadratic Upper Bounds of Smooth Functions

When f is twice differentiable, the following upper bound is usually employed:

$$\vartheta(\mathbf{x}, \mathbf{x}^k) = f(\mathbf{x}^k) + \langle \nabla f(\mathbf{x}^k), \mathbf{x} - \mathbf{x}^k \rangle + \frac{1}{2}(\mathbf{x} - \mathbf{x}^k)^T \mathbf{H}(\mathbf{x} - \mathbf{x}^k),$$

where \mathbf{H} is a positive semidefinite matrix such that $\mathbf{H} - \nabla^2 f(\mathbf{x})$ is also positive semidefinite.

This algorithm is a version of DCA applied to the following DC function:

$$f(\mathbf{x}) = \frac{1}{2} \mathbf{x}^T \mathbf{H} \mathbf{x} - \left(\frac{1}{2} \mathbf{x}^T \mathbf{H} \mathbf{x} - f(\mathbf{x}) \right).$$

34.2.4 Proximal Upper Bounds of Convex Functions

The proximal upper bound of f ,

$$\vartheta(\mathbf{x}, \mathbf{x}^k) = f(\mathbf{x}) + \frac{\rho}{2} \|\mathbf{x} - \mathbf{x}^k\|^2,$$

is frequently used to gain the strong convexity of f . The corresponding SCA algorithm is known as the proximal point algorithm in convex programming. This algorithm, in the more specific setting, will be shown below as a version of DCA.

Proximal Point Algorithm for Convex Programming Is a DCA Version

Let $f \in \Gamma_0(X)$ and C be a nonempty closed convex set in X . Consider the following convex program:

$$\alpha = \inf \{ f(\mathbf{x}) : \mathbf{x} \in C \},$$

or equivalently,

$$\alpha = \inf \{ \chi_C(\mathbf{x}) + f(\mathbf{x}) : \mathbf{x} \in X \}.$$

This convex program can be considered as a DC program by the following DC decomposition:

$$\left(\chi_C(\mathbf{x}) + \frac{1}{2} \lambda \|\mathbf{x}\|^2 + f(\mathbf{x}) \right) - \frac{1}{2} \lambda \|\mathbf{x}\|^2,$$

where $\lambda > 0$.

The DCA iterates

$$\mathbf{x}^{k+1} \in \arg \min \left\{ f(\mathbf{x}) + \frac{1}{2} \lambda \|\mathbf{x}\|^2 - \langle \mathbf{x}, \lambda \mathbf{x}^k \rangle \right\},$$

and we recover the proximal point algorithm.

Goldstein-Levitin-Polyak Projection Algorithm Is a DCA Version

Let λ be a positive number such that the function $h(\mathbf{x}) = \frac{1}{2} \lambda \|\mathbf{x}\|^2 - f(\mathbf{x})$ is convex, and let $g(\mathbf{x}) = \chi_C(\mathbf{x}) + \frac{1}{2} \lambda \|\mathbf{x}\|^2$. Hence g, h are DC components of $\chi_C + f$ and the DCA takes steps

$$\mathbf{y}^k = \lambda \mathbf{x}^k - \boldsymbol{\eta}^k, \boldsymbol{\eta}^k \in \partial f(\mathbf{x}^k);$$

$$\mathbf{x}^{k+1} = P_C \left(\mathbf{x}^k - \frac{1}{\lambda} \boldsymbol{\eta}^k \right).$$

This is exactly the Goldstein-Levitin-Polyak projection algorithm [39].

Iterative Shrinkage-Thresholding Algorithm Is a DCA Version

Iterative shrinkage-thresholding algorithm was first introduced in [40] and later developed in [21, 41]. The most general case considered [21] is

$$\min_{\mathbf{x}} \{f(\mathbf{x}) = g_1(\mathbf{x}) + g_2(\mathbf{x})\},$$

where g_1, g_2 are convex and g_2 is differentiable with L -Lipschitz gradient. ISTA proposed in [21] iteratively computes \mathbf{x}^{k+1} by solving

$$\min_{\mathbf{x}} \left\{ g_1(\mathbf{x}) + \frac{L}{2} \|\mathbf{x} - \left(\mathbf{x}^k - \frac{1}{L} \nabla g_2(\mathbf{x}^k) \right)\|^2 \right\}.$$

It is observed that this algorithm is a version of DCA with the following DC decomposition:

$$f(\mathbf{x}) = \left(g_1(\mathbf{x}) + \frac{L}{2} \|\mathbf{x}\|^2 \right) - \left(\frac{L}{2} \|\mathbf{x}\|^2 - g_2(\mathbf{x}) \right).$$

When the Lipschitz constant L is unknown, the iterative shrinkage-thresholding algorithm with backtracking step size may be employed. Likewise, this algorithm is a version of DCA with successive DC decomposition.

The EM Algorithm for Exponential Families Is a Version of DCA

In statistics and data science, the EM (expectation maximization) algorithm is a popular tool for statistical estimation with incomplete data. The algorithm was named in 1977 in the work by Arthur Dempster et al. [42], where they pointed out that the method had already been proposed many times in special circumstances by earlier authors. In fact, EM is an MM-type algorithm where the surrogate is constructed by Jensen's inequality. When the likelihood function is an exponential family, the EM algorithm is a version of DCA. Specifically, we consider the following form of the likelihood:

$$\mathcal{P}(\mathbf{x}, \mathbf{v}, \mathbf{w}|\boldsymbol{\theta}) = \frac{1}{Z(\mathbf{x}|\boldsymbol{\theta})} \exp \left(\sum_{i=1}^D \boldsymbol{\theta}_i m_i(\mathbf{x}, \mathbf{v}, \mathbf{w}) \right),$$

where \mathbf{x} is a vector observation, \mathbf{v} is a visible state, \mathbf{w} is a hidden variable, $m_i(\mathbf{x}, \mathbf{v}, \mathbf{w})$ is some real or binary function, and

$$Z(\mathbf{x}|\boldsymbol{\theta}) = \sum_{\mathbf{v}, \mathbf{w}} \exp \left(\sum_{i=1}^D \boldsymbol{\theta}_i m_i(\mathbf{x}, \mathbf{v}, \mathbf{w}) \right)$$

is the normalization term.

Given the data set X , the parameter $\boldsymbol{\theta}$ is chosen to maximize the log-likelihood function:

$$\mathcal{L}(\boldsymbol{\theta}) = \sum_{\mathbf{x} \in X} \log \sum_{\mathbf{w}} \mathcal{P}(\mathbf{x}, \mathbf{v}, \mathbf{w}|\boldsymbol{\theta}).$$

The EM algorithm for maximizing $\mathcal{L}(\boldsymbol{\theta})$ consists of two steps described as follows:

- E-step: Determine the lower bound $Q(\boldsymbol{\theta}, \boldsymbol{\theta}^k)$ of $\mathcal{L}(\boldsymbol{\theta})$ by

$$\begin{aligned} \mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\theta}^k) &= \sum_{\mathbf{x}} \sum_{\mathbf{w}} \mathcal{P}(\mathbf{w}|\mathbf{x}, \mathbf{v}; \boldsymbol{\theta}^k) \log \mathcal{P}(\mathbf{x}, \mathbf{v}, \mathbf{w}|\boldsymbol{\theta}) \\ &\quad - \sum_{\mathbf{x}} \sum_{\mathbf{w}} \mathcal{P}(\mathbf{w}|\mathbf{x}, \mathbf{v}; \boldsymbol{\theta}^k) \log \mathcal{P}(\mathbf{w}|\mathbf{x}, \mathbf{v}; \boldsymbol{\theta}^k), \end{aligned}$$

where

$$\mathcal{P}(\mathbf{w}|\mathbf{x}, \mathbf{v}; \boldsymbol{\theta}^k) = \frac{\exp \left(\sum_{i=1}^D \boldsymbol{\theta}_i^k m_i(\mathbf{x}, \mathbf{v}, \mathbf{w}) \right)}{\sum_{\mathbf{w}'} \exp \left(\sum_{i=1}^D \boldsymbol{\theta}_i^k m_i(\mathbf{x}, \mathbf{v}, \mathbf{w}') \right)}.$$

- M-step: Compute $\boldsymbol{\theta}^{k+1}$ by maximizing $Q(\boldsymbol{\theta}, \boldsymbol{\theta}^k)$.

It can be shown that this EM algorithm is DCA for minimizing $-\mathcal{L}(\boldsymbol{\theta})$ with the DC decomposition $-\mathcal{L}(\boldsymbol{\theta}) = g - h$, where

$$\begin{aligned} g(\boldsymbol{\theta}) &= \sum_{\mathbf{x} \in X} \log \sum_{\mathbf{v}, \mathbf{w}} \exp \left(\sum_{i=1}^D \boldsymbol{\theta}_i m_i(\mathbf{x}, \mathbf{v}, \mathbf{w}) \right), \\ h(\boldsymbol{\theta}) &= \sum_{\mathbf{x} \in X} \log \sum_{\mathbf{w}} \exp \left(\sum_{i=1}^D \boldsymbol{\theta}_i m_i(\mathbf{x}, \mathbf{v}, \mathbf{w}) \right). \end{aligned}$$

The Concave-Convex Procedure Is an Instance of DCA in Smooth Optimization

The concave-convex procedure was first proposed in 2003 [43], where the authors assumed that the objective function f is twice differentiable with the DC decomposition

$$f(\mathbf{x}) = f_{\text{vex}}(\mathbf{x}) + f_{\text{cav}}(\mathbf{x}),$$

and the feasible set C is defined by linear constraints. Under these assumptions, the concave-convex procedure takes steps

$$\mathbf{x}^{k+1} \in \arg \min \{f_{\text{vex}}(\mathbf{x}) + \langle \mathbf{x}, \nabla f_{\text{cav}}(\mathbf{x}^k) \rangle : \mathbf{x} \in C\}.$$

Different from other mentioned algorithms where the DC structure of the problems is somehow hidden, the concave-convex procedure is easily recognized as nothing but the DCA.

34.3 Stochastic Optimization in the Literature

Although deterministic programming is able to cover a large class of optimization problems in our real world, such a modeling framework would find it difficult to cope with the presence of randomness. The randomness appears unavoidably since many real-world systems are very complicated, for instance, one input can lead to many possible outcomes, relations between parameters are unclear, or data is uncertain. In these cases, stochastic programming would be a better choice to fit the system. Sometimes, one can nevertheless simplify the problems to make them deterministic in order to use powerful tools of deterministic optimization. However, stochastic programming is more suitable for representing the true nature of the problems and preserving as much as possible the information we are given. In the context of stochastic programming, objective and constraints can be uncertain in various forms such as expectation, conditional expectation, probability, etc. Therefore, we are quite flexible to manipulate the models to describe reasonably our real-life problems. We refer the reader to [44] for some important problems such as the new vendor problem, portfolio selection problem, supply chain network design problem, multiproduct assembly problem, etc. These problems could be one-stage, two-stage, or multistage, with or without chance constraints.

In addition, when solving deterministic programming problems by using multistage algorithms, there is an error ϵ_k at each step. This error is unknown in general, so it can be viewed as a random quantity. Hence, the randomness again appears even in the deterministic programming context [45–51].

It is noteworthy that, among the general class of stochastic optimization algorithms, there is a special class of algorithms whose stochastic approximations are constructed by new fresh samples from the interested distribution. That is to say, the update rules of these stochastic algorithms are performed by using streaming data coming from a certain (possibly unknown) distribution. In this chapter, we refer to these kinds of stochastic algorithms as *online stochastic*.

In the literature of stochastic optimization, it can be traced back to the pioneering work by Robbins and Monro [52], where the authors designed a (nonstationary) Markov chain for solving stochastically the equation

$$M(x) = a,$$

where M is unknown by nature. The Markov chain is constructed in a way that, under some assumptions, it converges in probability to a unique solution θ of the above equation.

The idea of this chapter has inspired many researchers to adopt this method for various challenging problems, especially for those that arise in optimization. It has been followed

by many stochastic methods for solving deterministic or stochastic programs.

Stochastic optimization, in a same way as deterministic optimization, has been developed highly in convex or strongly convex programming. Here we present some of these algorithms.

The stochastic subgradient method for minimizing a function F ,

$$\mathbf{w}^{k+1} \leftarrow \mathbf{w}^k - \alpha_k (\mathbf{y}^k + \boldsymbol{\xi}_k),$$

where $\mathbf{y}^k \in \partial F(\mathbf{w}^k)$ and $\boldsymbol{\xi}_k$ is some random noise satisfying certain conditions. This method generalizes stochastic gradient descent. The explicit form and computational advantages of these two algorithms make them the objects of many works and applications [53–58]. Besides, some variants of these methods which pay attention to second-order information but still remain robust for large-scale setting are studied [59–67]. These works mainly focus on smooth programming since the methods require second-order information. Furthermore, the problems can be convex or nonconvex, but convexity is more favorable. These algorithms are based on the classical quasi-Newton method combining with stochastic approximation idea. Broadly, these algorithms take steps

$$\mathbf{w}^{k+1} \leftarrow \mathbf{w}^k - \alpha_k \mathbf{H}_k \times (\mathbf{y}^k + \boldsymbol{\xi}_k),$$

where $\mathbf{y}^k + \boldsymbol{\xi}_k$ is some stochastic quantity approximating to $\nabla F(\mathbf{w}^k)$ and \mathbf{H}_k is an appropriate deterministic or stochastic matrix approximating to the inverse of the Hessian matrix $\nabla^2 F(\mathbf{w}^k)$.

When it comes to large-sum problem, it is worth noting that the sum of deterministic functions can be rewritten in the expectation form as follows:

$$F(\mathbf{w}) = \frac{1}{n} \sum_{i=1}^n f_i(\mathbf{w}) = E(f_I(\mathbf{w})),$$

where I is a uniform random variable over the set $\{1, 2, \dots, n\}$.

This kind of function has been of great concern. It appears frequently in various contexts of applied mathematics. Regarding its special structure, many stochastic methods have been developed to handle this class of problems. We name some well-known algorithms in this context. Roux et al. [68] proposed an algorithm called stochastic average gradient that can be viewed as a stochastic version of incremental average gradient [69]. Stochastic average gradient needs to store n gradients of the previous iteration. After drawing a random index I_k from $\{1, 2, \dots, n\}$, the algorithm updates

$$\mathbf{w}^k \leftarrow \mathbf{w}^{k-1} - \frac{\alpha_k}{n} \sum_{i=1}^n \mathbf{y}_i^k,$$

with

$$y_i^k = \begin{cases} f_i'(\mathbf{w}^{k-1}) & \text{if } i = I_k \\ y_i^{k-1} & \text{otherwise.} \end{cases}$$

Ghadimi and Lan [70] proposed an algorithm named the accelerated stochastic approximation. The algorithm is inspired by accelerated algorithm of Nesterov [71]. The idea is replacing the gradients in Nesterov's algorithm by stochastic gradients or subgradients.

To name more works in the similar stochastic approximation manner, we refer to stochastic dual coordinate ascent and its proximal versions [72–74], stochastic variance reduced gradient and its proximal variants [75–77], stochastic mirror descent [78–80], etc.

In nonconvex programming, Mairal [81] designed a stochastic version, called MISO, of the basic majorization-minimization scheme by exploiting the structure of the objective. At the iteration k , instead of choosing a surrogate g_k for F near \mathbf{w}^{k-1} , the algorithm constructs a surrogate g_k^l for one random element f_l . The surrogate g_k^l is then combined with information of the previous iteration to construct a stochastic surrogate for F near \mathbf{w}^{k-1} . The minimization process is then applied to this stochastic surrogate to get \mathbf{w}^k .

Recently, a new class of stochastic model-based algorithms has been developed for stochastic composite function

$$F(\mathbf{w}) = E(h(c(\mathbf{w}, \mathbf{Z}), \mathbf{Z})) = \int_{\mathcal{S}} h(c(\mathbf{w}, s), s) dP(s),$$

where the function $\mathbf{w} \mapsto h(\mathbf{w}, s)$ is closed convex and the function $\mathbf{w} \mapsto c(\mathbf{w}, s)$ is continuous for each $s \in \mathcal{S}$.

The minimization problem corresponding to this objective is a special case of stochastic weakly convex optimization [82, 83]:

$$\underset{\mathbf{w} \in X}{\text{minimize}} F(\mathbf{w}) + \varphi(\mathbf{w}) = E(f(\mathbf{w}, \mathbf{Z})) + \varphi(\mathbf{w}),$$

where $X \subset \mathbb{R}^d$ is a closed convex set, φ is a closed convex function, and $f(\cdot, s)$ is weakly convex for each s in \mathcal{S} .

The model-based strategy computes \mathbf{w}^{k+1} by solving the following problem:

$$\underset{\mathbf{y} \in X}{\text{minimize}} \left\{ f_{\mathbf{w}^k}(\mathbf{y}, \mathbf{Z}_k) + \varphi(\mathbf{y}) + \frac{1}{2\alpha_k} \|\mathbf{y} - \mathbf{w}^k\|^2 \right\},$$

where $\mathbf{Z}_k \sim \mathbf{Z}$, $\alpha_k > 0$ is a step size and $f_{\mathbf{w}^k}(\cdot, s)$ is an approximation, or a model, of $f(\cdot, s)$ at \mathbf{w}^k .

With different choices of the model $f_{\mathbf{w}^k}(\cdot, s)$, the mentioned stochastic model-based algorithm can recover many classical stochastic algorithms including stochastic subgradient method, stochastic prox-linear method, stochastic proximal point method, and guarded stochastic proximal point method [82].

Regarding the outperformance of DCA in deterministic nonconvex programming, it is natural to develop stochastic versions for DCA. This idea is the subject of some recent works. However, such kinds of works remain to be rare. Le Thi et al. [84] proposed a stochastic DCA scheme for the large sum of nonconvex functions problem:

$$F(\mathbf{w}) = \frac{1}{n} \sum_{i=1}^n f_i(\mathbf{w}) + \lambda p(\mathbf{w}),$$

where p is DC, $p = \tilde{g} - \tilde{h}$, and f_i is differentiable with L -Lipschitz gradient. The problem can be reformulated as the following stochastic programming problem:

$$\underset{\mathbf{w}}{\text{minimize}} \{F(\mathbf{w}) = G(\mathbf{w}) - H(\mathbf{w})\}, \quad (34.3)$$

where $H(\mathbf{w}) = E(h_I(\mathbf{w}))$ and I is a uniform random variable over $\{1, 2, \dots, n\}$. The proposed algorithm modifies the traditional DCA by approximating stochastically the subgradient $\partial H(\mathbf{w})$.

Le Thi et al. [85] developed the idea of [84] to encounter directly the general nonconvex large-sum problem

$$F(\mathbf{w}) = G(\mathbf{w}) - \frac{1}{n} \sum_{i=1}^n h_i(\mathbf{w}).$$

It is observed that this problem can be written in the form of (34.3).

The authors introduced two stochastic DCA schemes for solving this problem. The first scheme replaces deterministic subgradient $\partial H(\mathbf{w})$ by its stochastic estimator and proceeds the same as traditional DCA, while the second scheme only requires to compute inexactly stochastic estimator of $\partial H(\mathbf{w})$ and solve inexactly subproblems.

Le Thi et al. [86] introduced seven stochastic DCA schemes for minimizing directly the expected loss with the general underlying distribution \mathbf{Z} :

$$F(\mathbf{w}) = E(g(\mathbf{w}, \mathbf{Z})) - E(h(\mathbf{w}, \mathbf{Z})) + r(\mathbf{w}).$$

Roughly speaking, g, h, r are satisfied some assumptions and F is DC. The mentioned seven algorithms consist of many forms such as approximating both ∂H and G or approximating only ∂H , the ways of updating stochastic subgradients, adding proximal terms to subproblems or not, etc.

Nitanda and Suzuki [87] gave a proximal stochastic DCA scheme for DC program $g(\mathbf{w}) - h(\mathbf{w})$ by using an unbiased estimator $v_h(\mathbf{w})$ for $\nabla h(\mathbf{w})$, where h is assumed to be differentiable. After that, the algorithm solves inexactly the following proximal convex program to get \mathbf{w}^{k+1} :

$$\begin{aligned} & \underset{\mathbf{w} \in \mathbb{R}^d}{\text{minimize}} \left\{ \phi_k(\mathbf{w}) = g(\mathbf{w}) + \frac{1}{2} \|\mathbf{w} - \mathbf{w}^k\|_{\mathbf{H}_k}^2 \right. \\ & \left. - (h(\mathbf{w}^k) + \langle v_h(\mathbf{w}^k), \mathbf{w} - \mathbf{w}^k \rangle) \right\}, \end{aligned}$$

where \mathbf{H}_k is a positive definite matrix and the norm $\|\cdot\|_{\mathbf{H}_k}$ is Mahalanobis norm with respect to \mathbf{H}_k .

Similar ideas were adopted by Xu et al. [88].

Liu et al. [89] proposed an online stochastic DCA scheme called RCS algorithm for solving a special class of two-stage stochastic programs with a linearly bi-parameterized recourse function defined by a convex quadratic program. Broadly, the authors approximated both components G and ∇H by new samples and added the proximal term $\frac{1}{2\gamma} \|\mathbf{w} - \mathbf{w}^k\|^2$ to subproblems. The RCS algorithm was then analyzed in the context of the mentioned two-stage stochastic programs. Under some assumptions, every limit point of the sequence generated by RCS algorithm is a generalized critical point, or a d-stationary point of the problem.

It is worth noting that, in the context of nonconvex optimization, some stochastic algorithms are based on DCA, but the authors are not aware of this fact. For example, Allen-Zhu et al. [90] proposed a stochastic variance reduction algorithm for a sum of nonconvex functions with L -Lipschitz continuous gradient (L -smooth). As a variance reduction method, the proposed algorithm consists of two loops. The inner loop takes steps

$$\mathbf{w}_s^{k+1} \leftarrow \mathbf{w}_s^k - \eta (\nabla f_i(\mathbf{w}_s^k) - \nabla f_i(\mathbf{w}_s^0) + \nabla f(\mathbf{w}_s^0)),$$

where s is the index of the outer loop, i is a uniformly random choice in $\{1, 2, \dots, n\}$, and $\eta \leq 1/L$ is a learning rate.

We can see that, with the L -smooth property, f becomes DC with the following decomposition:

$$f(\mathbf{w}) = \frac{1}{2\eta} \|\mathbf{w}\|^2 - \left(\frac{1}{2\eta} \|\mathbf{w}\|^2 - f(\mathbf{w}) \right),$$

where $\eta \leq 1/L$.

The DCA iterates

$$\mathbf{w}^{k+1} \leftarrow \mathbf{w}^k - \eta \nabla f(\mathbf{w}^k).$$

It is observed that the update term in the Allen-Zhu's algorithm can be viewed as a stochastic approximation of $\nabla f(\mathbf{w}_s^k)$, so this algorithm can be referred to as a stochastic version of DCA.

In this chapter, we design two stochastic versions of DCA in an online manner. Our setting is quite general in terms of the distribution of \mathbf{Z} which does not need to be discrete. The concave part of our DC decomposition does not need to be differentiable. The first scheme stochastically approximates a subgradient of H across iterations. Furthermore, our second

online stochastic algorithm approximates stochastically not only the subgradient ∂H but also the convex part G , which let us be able to handle situations where the distribution of \mathbf{Z} is unknown. However, unlike algorithms mentioned in [87, 88], our algorithms require to solve exactly subproblems for guaranteeing the almost sure convergence in our analysis. Our algorithms are distinct from [86] by the ways of approximating subgradients.

34.4 Stochastic DC Programming and DCA

This section introduces a class of stochastic DC programs and proposes two stochastic DCA schemes for solving this class. Our stochastic DCA schemes are designed in an online manner, so we name them *online stochastic DCA*.

From now on, the reader may be aware that most of the statements are understood as almost sure (a.s), i.e., they are true with probability 1.

34.4.1 A Class of Stochastic DC Programs

This section introduces a class of stochastic DC programs that we study in this chapter.

Let (Ω, \mathcal{M}, P) be a complete probability space and \mathbf{Z} be a random vector, $\mathbf{Z} : \Omega \rightarrow \mathbb{R}^n$.

Let $\Xi = \text{supp}(P_{\mathbf{Z}})$ be a support of the probability measure $P_{\mathbf{Z}}$, where $P_{\mathbf{Z}}$, the probability measure on \mathbb{R}^n , is the distribution of \mathbf{Z} .

By definition, a point $\mathbf{x} \in \mathbb{R}^n$ is in $\text{supp}(P_{\mathbf{Z}})$ if $P_{\mathbf{Z}}(N_{\mathbf{x}}) > 0$ for every neighborhood $N_{\mathbf{x}}$ of \mathbf{x} , where the topology used to define neighborhood is the Euclidean topology of \mathbb{R}^n .

A basic property of the support Ξ is that it is closed in \mathbb{R}^n . Moreover, $P_{\mathbf{Z}}(\Xi^c) = 0$ since \mathbb{R}^n is the topological Hausdorff space and $P_{\mathbf{Z}}$ is a Radon measure in \mathbb{R}^n .

Consider a function $f : \mathbb{R}^m \times \Xi \rightarrow \mathbb{R} \cup \{+\infty\}$. Since $\mathbb{R} \cup \{+\infty\}$ is a totally ordered set, there is a corresponding order topology τ_{∞} . Let $\mathcal{B}_{\infty} = \mathcal{B}(\tau_{\infty})$ be a Borel sigma-algebra generated by τ_{∞} . The function f is assumed to be measurable with respect to $(\mathcal{B}(\mathbb{R}^m) \otimes \mathcal{A}, \mathcal{B}_{\infty})$, where \mathcal{A} is a Borel sigma-algebra relative to Ξ .

The effective domain of f is assumed to be

$$\text{dom} f := \{(\mathbf{x}, \xi) \in \mathbb{R}^m \times \Xi \mid f(\mathbf{x}, \xi) < +\infty\} = S \times \Xi,$$

where $S \subset \mathbb{R}^m$ is a nonempty, compact, and convex set.

Suppose that for all $\mathbf{x} \in S$, $\int_{\Xi} |f(\mathbf{x}, \xi)| dP_{\mathbf{Z}} < +\infty$.

Let $\varphi(\mathbf{x}) = \int_{\Xi} f(\mathbf{x}, \xi) dP_{\mathbf{Z}}$, $\forall \mathbf{x} \in S$. The optimization problem considered is

$$\text{minimize } \varphi(\mathbf{x}), \mathbf{x} \in S.$$

The function f is extended to the entire space as $\bar{f} : \mathbb{R}^m \times \mathbb{R}^n \rightarrow \mathbb{R} \cup \{+\infty\}$,

$$\bar{f}(\mathbf{x}, \boldsymbol{\xi}) = \begin{cases} f(\mathbf{x}, \boldsymbol{\xi}) & \text{if } (\mathbf{x}, \boldsymbol{\xi}) \in S \times \Xi, \\ +\infty & \text{otherwise.} \end{cases}$$

It is verified that this extension reserves measurability, i.e., \bar{f} is $(\mathcal{B}(\mathbb{R}^m) \otimes \mathcal{B}(\mathbb{R}^n), \mathcal{B}_\infty)$ measurable.

Suppose that \bar{f} can be written as $\bar{f} = g - h$, where $g, h : \mathbb{R}^m \times \mathbb{R}^n \rightarrow \mathbb{R} \cup \{+\infty\}$ are Borel measurable functions with $\text{dom } g = \text{dom } h = S \times \Xi$.

The first assumption of g and f is formally stated as the following:

Assumption 1

- (1) For all $\mathbf{z} \in \Xi$, $g(\cdot, \mathbf{z})$ and $h(\cdot, \mathbf{z})$ are convex, lower semicontinuous.
- (2) For all $\mathbf{w} \in S$, $g(\mathbf{w}, \mathbf{Z}), h(\mathbf{w}, \mathbf{Z}) \in L^1(\Omega)$.
- (3) For all $\mathbf{z} \in \Xi$, $\text{dom } \partial h(\cdot, \mathbf{z}) = S$.
- (4) There exists a Borel measurable selector

$$\tau : \mathbb{R}^m \times \mathbb{R}^n \rightarrow \mathbb{R}^m$$

such that

$$\forall \mathbf{w} \in S, \mathbf{z} \in \Xi, \tau(\mathbf{w}, \mathbf{z}) \in \partial_{\mathbf{w}} h(\mathbf{w}, \mathbf{z}).$$

- (5) There exists a Borel measurable function

$$\tilde{\tau} : \mathbb{R}^n \rightarrow \mathbb{R}$$

such that $\int_{\Xi} |\tilde{\tau}(\mathbf{z})| \, dP_{\mathbf{Z}} < \infty$ and

$$\text{for all } \mathbf{w} \in S, \mathbf{z} \in \Xi, \|\tau(\mathbf{w}, \mathbf{z})\| \leq \tilde{\tau}(\mathbf{z}).$$

- (6) For all $\mathbf{w} \in S$, $E(\|\tau(\mathbf{w}, \mathbf{Z})\|^2) < +\infty$. □

Assumptions 1(1) and 1(2) are merely regular assumptions, and Assumption 1(3) means that subgradient vectors of $h(\cdot, \mathbf{z})$ do not explode at the boundary of the domain. Assumption 1(4) is that we can choose a measurable selector from the beginning, and then an algorithm will choose subgradients following this selector. Assumptions 1(5) and 1(6) are for the boundedness of the selector.

Under Assumption 1, let $G(\mathbf{w}) = E(g(\mathbf{w}, \mathbf{Z}))$ and $H(\mathbf{w}) = E(h(\mathbf{w}, \mathbf{Z}))$; then $\text{dom } G = \text{dom } H = S$ and G, H are convex. Let $C = G - H$; then $\text{dom } C = S$ and the optimization problem becomes

$$\text{minimize } C(\mathbf{w}), \mathbf{w} \in \mathbb{R}^m.$$

We now add some assumptions for G and H .

Assumption 2

- (1) G, H are lower semicontinuous.
- (2) $\text{dom } \partial H = S$ and $\rho(H) > 0$.
- (3) $\sup_{\mathbf{w} \in S} |C(\mathbf{w})| < +\infty$. □

Assumption 2(1) is for the DC form of the objective function C . In fact, Assumption 2(2) can be induced by Assumption 1(1) with some additional conditions. For example, if $g(\mathbf{w}, \mathbf{Z})$ are uniform bounded below by a L^1 random variable, then Assumption 2(1) is verified by Fatou's lemma. Assumption 2(2) can be interpreted that subgradient vectors of H do not explode at the boundary of the domain. Finally, Assumption 2(3) states that C is nowhere going to infinity.

34.4.2 Online Stochastic DCA1

This subsection proposes the first online stochastic DCA scheme for solving the stochastic DC problem introduced in Sect. 34.4.1.

Firstly, let us define a function denoted by ϑ as the following:

$$\begin{aligned} \vartheta : \mathbb{R}^m \times \mathbb{R}^m &\rightarrow \mathbb{R} \cup \{+\infty\} \\ (\mathbf{w}, \mathbf{t}) &\mapsto G(\mathbf{w}) - \langle \mathbf{w}, \mathbf{t} \rangle. \end{aligned}$$

We can see that ϑ is Borel measurable and lower semicontinuous.

Since $G - \langle \cdot, \mathbf{t} \rangle$ is lower semicontinuous and S is compact, it follows that $\arg \min_{\mathbf{w} \in \mathbb{R}^m} \{G(\mathbf{w}) - \langle \mathbf{w}, \mathbf{t} \rangle\}$ is nonempty, for all $\mathbf{t} \in \mathbb{R}^m$.

By applying selection theorem [91], there exists a Borel measurable function $\kappa : \mathbb{R}^m \rightarrow \mathbb{R}^m$ such that $\kappa(\mathbf{t}) \in \arg \min_{\mathbf{w} \in \mathbb{R}^m} \{G(\mathbf{w}) - \langle \mathbf{w}, \mathbf{t} \rangle\}$, for all $\mathbf{t} \in \mathbb{R}^m$.

We now give the online stochastic DCA scheme called online stochastic DCA1 as follows.

Algorithm 1 Online stochastic DCA1

Step 1. Choose $\mathbf{w}^0 \in S$.

Step 2. For $k = 0, 1, 2, \dots$ do

1. Draw independently $\mathbf{Z}_{k,1}, \mathbf{Z}_{k,2}, \dots, \mathbf{Z}_{k,n_k}$ from \mathbf{Z} in such a way that they are also independent to the past.
2. Compute $\mathbf{t}^k = \frac{1}{n_k} \sum_{i=1}^{n_k} \tau(\mathbf{w}^k, \mathbf{Z}_{k,i})$.
3. Solve the convex program to get \mathbf{w}^{k+1} :

$$\mathbf{w}^{k+1} = \kappa(\mathbf{t}^k) \in \arg \min_{\mathbf{w} \in \mathbb{R}^m} \{G(\mathbf{w}) - \langle \mathbf{t}^k, \mathbf{w} \rangle\}.$$

4. If stopping criteria are satisfied, break. □

It is clear that online stochastic DCA1 is well-defined. Moreover, the sequence created by the algorithm is contained in S .

For short, we denote $\mathbf{Z}_k = \mathbf{Z}_{k,1:n_k}$ for every $k \in \mathbb{N}$ and let $\mathcal{P}_k = \sigma(\mathbf{Z}_0, \mathbf{Z}_1, \dots, \mathbf{Z}_{k-1})$. By the Borel measurability of τ and κ , it follows by induction that \mathbf{w}^k is \mathcal{P}_k measurable, for all $k \geq 1$, and \mathbf{t}^k is \mathcal{P}_{k+1} measurable, for all $k \geq 0$.

Lemma 34.1 *Let $0 < \bar{\rho} < \rho(H)$. Under assumptions 1,2, the following inequality holds for all $k \in \mathbb{N}$:*

$$E(C(\mathbf{w}^{k+1})|\mathcal{P}_k) \leq -\frac{\bar{\rho}}{2}E(\|\mathbf{w}^k - \mathbf{w}^{k+1}\|^2|\mathcal{P}_k) + C(\mathbf{w}^k) + \frac{V_Z(\tau(\mathbf{w}^k, \mathbf{Z}))^{\frac{1}{2}}}{\sqrt{n_k}}E(\|\mathbf{w}^{k+1} - \mathbf{w}^k\|^2|\mathcal{P}_k)^{\frac{1}{2}},$$

where

$$V_Z(\tau(\mathbf{w}^k, \mathbf{Z})) = E_Z(\|\tau(\mathbf{w}^k, \mathbf{Z})\|^2) - \|E_Z(\tau(\mathbf{w}^k, \mathbf{Z}))\|^2.$$

Proof. Since $v(\mathbf{w}^k) \in \partial_w H(\mathbf{w}^k)$, it follows that

$$H(\mathbf{w}^{k+1}) \geq H(\mathbf{w}^k) + \langle v(\mathbf{w}^k), \mathbf{w}^{k+1} - \mathbf{w}^k \rangle + \frac{\bar{\rho}}{2}\|\mathbf{w}^{k+1} - \mathbf{w}^k\|^2. \quad (34.4)$$

By the definition of \mathbf{w}^{k+1} , it follows that

$$G(\mathbf{w}^k) \geq G(\mathbf{w}^{k+1}) + \langle \mathbf{t}^k, \mathbf{w}^k - \mathbf{w}^{k+1} \rangle. \quad (34.5)$$

From (34.4) and (34.5),

$$\begin{aligned} G(\mathbf{w}^{k+1}) - H(\mathbf{w}^{k+1}) &\leq G(\mathbf{w}^k) - H(\mathbf{w}^k) \\ &\quad + \langle \mathbf{t}^k - v(\mathbf{w}^k), \mathbf{w}^{k+1} - \mathbf{w}^k \rangle \\ &\quad - \frac{\bar{\rho}}{2}\|\mathbf{w}^k - \mathbf{w}^{k+1}\|^2, \end{aligned}$$

or equivalently

$$C(\mathbf{w}^{k+1}) \leq C(\mathbf{w}^k) - \frac{\bar{\rho}}{2}\|\mathbf{w}^k - \mathbf{w}^{k+1}\|^2 + \langle \mathbf{t}^k - v(\mathbf{w}^k), \mathbf{w}^{k+1} - \mathbf{w}^k \rangle. \quad (34.6)$$

By Assumptions 1(5) and 2(3), $C(\mathbf{w}^k)$, $\langle \mathbf{t}^k - v(\mathbf{w}^k), \mathbf{w}^{k+1} - \mathbf{w}^k \rangle$ belong to $L^1(\Omega)$. By taking conditional expectation of (34.6) with respect to \mathcal{P}_k , we get

$$\begin{aligned} E(C(\mathbf{w}^{k+1})|\mathcal{P}_k) &\leq E(\langle \mathbf{t}^k - v(\mathbf{w}^k), \mathbf{w}^{k+1} - \mathbf{w}^k \rangle|\mathcal{P}_k) + C(\mathbf{w}^k) \\ &\quad - \frac{\bar{\rho}}{2}E(\|\mathbf{w}^k - \mathbf{w}^{k+1}\|^2|\mathcal{P}_k). \end{aligned}$$

By applying Schwartz inequality and Holder inequality, we get

$$\begin{aligned} E(\langle \mathbf{t}^k - v(\mathbf{w}^k), \mathbf{w}^{k+1} - \mathbf{w}^k \rangle|\mathcal{P}_k) &\leq E(\|\mathbf{t}^k - v(\mathbf{w}^k)\| \\ &\quad \times \|\mathbf{w}^{k+1} - \mathbf{w}^k\||\mathcal{P}_k) \\ &\leq E(\|\mathbf{t}^k - v(\mathbf{w}^k)\|^2|\mathcal{P}_k)^{\frac{1}{2}} \\ &\quad E(\|\mathbf{w}^{k+1} - \mathbf{w}^k\|^2|\mathcal{P}_k)^{\frac{1}{2}}. \end{aligned}$$

Therefore,

$$\begin{aligned} E(C(\mathbf{w}^{k+1})|\mathcal{P}_k) &\leq C(\mathbf{w}^k) - \frac{\bar{\rho}}{2}E(\|\mathbf{w}^k - \mathbf{w}^{k+1}\|^2|\mathcal{P}_k) \\ &\quad + E(\|\mathbf{t}^k - v(\mathbf{w}^k)\|^2|\mathcal{P}_k)^{\frac{1}{2}} \\ &\quad E(\|\mathbf{w}^{k+1} - \mathbf{w}^k\|^2|\mathcal{P}_k)^{\frac{1}{2}}. \end{aligned}$$

We now calculate $E(\|\mathbf{t}^k - v(\mathbf{w}^k)\|^2|\mathcal{P}_k)$. By the independence of $\mathbf{Z}_{k,i}$, $\mathbf{Z}_{k,j}$ when $i \neq j$, it follows that

$$\begin{aligned} E(\|\mathbf{t}^k - v(\mathbf{w}^k)\|^2|\mathcal{P}_k) &= E\left(\left\|\frac{1}{n_k}\sum_{i=1}^{n_k}(\tau(\mathbf{w}^k, \mathbf{Z}_{k,i}) - v(\mathbf{w}^k))\right\|^2|\mathcal{P}_k\right) \\ &= \frac{1}{n_k^2}\sum_{i=1}^{n_k}E(\|\tau(\mathbf{w}^k, \mathbf{Z}_{k,i}) - v(\mathbf{w}^k)\|^2|\mathcal{P}_k). \end{aligned}$$

We have an observation that

$$\begin{aligned} E(\|\tau(\mathbf{w}^k, \mathbf{Z}_{k,i}) - v(\mathbf{w}^k)\|^2|\mathcal{P}_k) &= E(\|\tau(\mathbf{w}^k, \mathbf{Z}_{k,i})\|^2|\mathcal{P}_k) + E(\|v(\mathbf{w}^k)\|^2|\mathcal{P}_k) \\ &\quad - 2E(\langle \tau(\mathbf{w}^k, \mathbf{Z}_{k,i}), v(\mathbf{w}^k) \rangle|\mathcal{P}_k) \\ &= E_Z(\|\tau(\mathbf{w}^k, \mathbf{Z})\|^2) + \|v(\mathbf{w}^k)\|^2 \\ &\quad - 2\langle E_Z(\tau(\mathbf{w}^k, \mathbf{Z}_{k,i})|\mathcal{P}_k), v(\mathbf{w}^k) \rangle \\ &= E_Z(\|\tau(\mathbf{w}^k, \mathbf{Z})\|^2) + \|v(\mathbf{w}^k)\|^2 \\ &\quad - 2\langle E_Z(\tau(\mathbf{w}^k, \mathbf{Z})), v(\mathbf{w}^k) \rangle \\ &= E_Z(\|\tau(\mathbf{w}^k, \mathbf{Z})\|^2) - \|v(\mathbf{w}^k)\|^2. \end{aligned} \quad (34.7)$$

In the computation (34.7), the theorem in appendix A is applied. This result is classic and important in martingale theory, for example, we refer to [92] for its special case. We dedicate appendix A to its detail proof.

We get the result

$$\begin{aligned} \frac{1}{n_k^2}\sum_{i=1}^{n_k}E(\|\tau(\mathbf{w}^k, \mathbf{Z}_{k,i}) - v(\mathbf{w}^k)\|^2|\mathcal{P}_k) &= \frac{1}{n_k}(E_Z(\|\tau(\mathbf{w}^k, \mathbf{Z})\|^2) - \|v(\mathbf{w}^k)\|^2). \end{aligned}$$

Therefore, we achieve

$$\begin{aligned}
E(\|\mathbf{t}^k - \nu(\mathbf{w}^k)\|^2 | \mathcal{P}_k) &= \frac{1}{n_k} (E_Z(\|\tau(\mathbf{w}^k, \mathbf{Z})\|^2) - \|\nu(\mathbf{w}^k)\|^2) \\
&\leq \frac{V_Z(\tau(\mathbf{w}^k, \mathbf{Z}))}{2\bar{\rho} \cdot n_k}. \\
&= \frac{1}{n_k} (E_Z(\|\tau(\mathbf{w}^k, \mathbf{Z})\|^2) \\
&\quad - \|E_Z(\tau(\mathbf{w}^k, \mathbf{Z}))\|^2).
\end{aligned}$$

The variance is denoted as

$$V_Z(\tau(\mathbf{w}^k, \mathbf{Z})) := E_Z(\|\tau(\mathbf{w}^k, \mathbf{Z})\|^2) - \|E_Z(\tau(\mathbf{w}^k, \mathbf{Z}))\|^2,$$

and we get an inequality

$$\begin{aligned}
E(C(\mathbf{w}^{k+1}) | \mathcal{P}_k) &\leq -\frac{\bar{\rho}}{2} E(\|\mathbf{w}^k - \mathbf{w}^{k+1}\|^2 | \mathcal{P}_k) + C(\mathbf{w}^k) \\
&\quad + \frac{V_Z(\tau(\mathbf{w}^k, \mathbf{Z}))^{\frac{1}{2}}}{\sqrt{n_k}} E(\|\mathbf{w}^{k+1} - \mathbf{w}^k\|^2 | \mathcal{P}_k)^{\frac{1}{2}}.
\end{aligned} \tag{34.8}$$

Assumption 3 (Variance is Bounded in Expectation)

There exists $M > 0$ such that

$$\forall k \in \mathbb{N}, E(V_Z(\tau(\mathbf{w}^k, \mathbf{Z}))) \leq M.$$

Theorem 34.7 Under the Assumptions 1, 2, 3, if the sequence of sample size $\{n_k\}$ satisfies

$$\sum_{k=1}^{\infty} \frac{1}{n_k} < \infty,$$

the iterates of online stochastic DCA1 satisfy:

(1) There exists $C^\infty \in L^1(\Omega)$ such that

$$C(\mathbf{w}^k) \rightarrow C^\infty \text{ a.s.}$$

(2) $\|\mathbf{w}^{k+1} - \mathbf{w}^k\| \rightarrow 0$ a.s.

(3) There exists a measurable set $\mathcal{L} \subset \Omega$ with $P(\mathcal{L}) = 1$ such that for each $\omega \in \mathcal{L}$, the sequence $\{\mathbf{w}^k(\omega)\}$ has a subsequence converging to a point $\mathbf{w}^*(\omega)$ which is a critical point of $C = G - H$.

Proof. (1) From (34.8), we apply AM-GM inequality to get

$$\begin{aligned}
E(C(\mathbf{w}^{k+1}) - C(\mathbf{w}^k) | \mathcal{P}_k) &\leq \frac{V_Z(\tau(\mathbf{w}^k, \mathbf{Z}))^{\frac{1}{2}}}{\sqrt{n_k}} E(\|\mathbf{w}^{k+1} - \mathbf{w}^k\|^2 | \mathcal{P}_k)^{\frac{1}{2}} \\
&\quad - \frac{\bar{\rho}}{2} E(\|\mathbf{w}^k - \mathbf{w}^{k+1}\|^2 | \mathcal{P}_k)
\end{aligned}$$

By the Assumption 2(3), there exists R such that $C(\mathbf{w}) \geq R, \forall \mathbf{w} \in S$.

Let $D(\mathbf{w}) = C(\mathbf{w}) - R \geq 0$; we get

$$E(D(\mathbf{w}^{k+1}) - D(\mathbf{w}^k) | \mathcal{P}_k) \leq \frac{V_Z(\tau(\mathbf{w}^k, \mathbf{Z}))}{2\bar{\rho} \cdot n_k}.$$

Let $F_k = [E(D(\mathbf{w}^{k+1}) - D(\mathbf{w}^k) | \mathcal{P}_k) > 0]$,

$$\begin{aligned}
&\sum_{k=1}^{\infty} E(1_{F_k}(D(\mathbf{w}^{k+1}) - D(\mathbf{w}^k))) \\
&= \sum_{k=1}^{\infty} E(E(1_{F_k}(D(\mathbf{w}^{k+1}) - D(\mathbf{w}^k)) | \mathcal{P}_k)) \\
&= \sum_{k=1}^{\infty} E(1_{F_k} E(D(\mathbf{w}^{k+1}) - D(\mathbf{w}^k) | \mathcal{P}_k)) \\
&\leq \frac{1}{2\bar{\rho}} \sum_{k=1}^{\infty} \frac{E(V_Z(\tau(\mathbf{w}^k, \mathbf{Z})))}{n_k} \\
&\leq \frac{M}{2\bar{\rho}} \sum_{k=1}^{\infty} \frac{1}{n_k} < +\infty.
\end{aligned}$$

Since $D(\mathbf{w}^k) \geq 0$ a.s., $\forall k \in \mathbb{N}$, it follows from semi-martingale convergence theorem [93] that there exists $D^\infty \in L^1(\Omega)$ such that

$$D(\mathbf{w}^k) \rightarrow D^\infty \text{ a.s.}$$

As a consequence,

$$C(\mathbf{w}^k) \rightarrow C^\infty := D^\infty + R \text{ a.s.}$$

(2) From (34.6),

$$\begin{aligned}
C(\mathbf{w}^{k+1}) &\leq C(\mathbf{w}^k) - \frac{\bar{\rho}}{2} \|\mathbf{w}^k - \mathbf{w}^{k+1}\|^2 \\
&\quad + \langle \mathbf{t}^k - \nu(\mathbf{w}^k), \mathbf{w}^{k+1} - \mathbf{w}^k \rangle \\
&\leq C(\mathbf{w}^k) - \frac{\bar{\rho}}{2} \|\mathbf{w}^{k+1} - \mathbf{w}^k\|^2 + \|\mathbf{t}^k - \nu(\mathbf{w}^k)\| \\
&\quad \times \|\mathbf{w}^{k+1} - \mathbf{w}^k\| \\
&\leq C(\mathbf{w}^k) + \frac{1}{\bar{\rho}} \|\mathbf{t}^k - \nu(\mathbf{w}^k)\|^2 - \frac{\bar{\rho}}{4} \|\mathbf{w}^{k+1} - \mathbf{w}^k\|^2.
\end{aligned}$$

Therefore,

$$0 \leq \frac{\bar{\rho}}{4} \|\mathbf{w}^{k+1} - \mathbf{w}^k\|^2 \leq C(\mathbf{w}^k) - C(\mathbf{w}^{k+1}) + \frac{1}{\bar{\rho}} \|\mathbf{t}^k - \nu(\mathbf{w}^k)\|^2.$$

On the other hand,

$$E(\|\mathbf{t}^k - v(\mathbf{w}^k)\|^2) = \frac{1}{n_k} E(V_Z(\tau(\mathbf{w}^k, \mathbf{Z}))) \leq \frac{M}{n_k}.$$

Therefore,

$$E\left(\sum_{k=1}^{\infty} \|\mathbf{t}^k - v(\mathbf{w}^k)\|^2\right) \leq M \sum_{k=1}^{\infty} \frac{1}{n_k} < +\infty.$$

It follows that

$$\sum_{k=1}^{\infty} \|\mathbf{t}^k - v(\mathbf{w}^k)\|^2 < +\infty \text{ a.s.}$$

As a consequence, $\|\mathbf{t}^k - v(\mathbf{w}^k)\| \rightarrow 0$ a.s. Therefore, we can conclude that

$$\|\mathbf{w}^{k+1} - \mathbf{w}^k\| \rightarrow 0 \text{ a.s.}$$

(3) Since $v(\mathbf{w}^k) \in \partial_w H(\mathbf{w}^k)$, we have

$$\langle v(\mathbf{w}^k), \mathbf{w}^k \rangle = H(\mathbf{w}^k) + H^*(v(\mathbf{w}^k)). \quad (34.9)$$

On the other hand, since $\mathbf{t}^k \in \partial G(\mathbf{w}^{k+1})$, we get

$$\langle \mathbf{t}^k, \mathbf{w}^{k+1} \rangle = G(\mathbf{w}^{k+1}) + G^*(\mathbf{t}^k). \quad (34.10)$$

From (34.9) and (34.10), we achieve

$$\begin{aligned} & G(\mathbf{w}^{k+1}) - H(\mathbf{w}^k) + G^*(\mathbf{t}^k) - H^*(v(\mathbf{w}^k)) \\ &= \langle \mathbf{w}^{k+1}, \mathbf{t}^k \rangle - \langle \mathbf{w}^k, v(\mathbf{w}^k) \rangle. \end{aligned} \quad (34.11)$$

By the definition of \mathbf{w}^{k+1} ,

$$G(\mathbf{w}^{k+1}) - \langle \mathbf{t}^k, \mathbf{w}^{k+1} \rangle \leq G(\mathbf{w}^k) - \langle \mathbf{t}^k, \mathbf{w}^k \rangle. \quad (34.12)$$

Combining (34.11) and (34.12), we get

$$G(\mathbf{w}^k) - H(\mathbf{w}^k) \geq H^*(v(\mathbf{w}^k)) - G^*(\mathbf{t}^k) + \langle \mathbf{w}^k, \mathbf{t}^k - v(\mathbf{w}^k) \rangle. \quad (34.13)$$

Moreover, since $v(\mathbf{w}^k) \in \partial_w H(\mathbf{w}^k)$, we have the inequality

$$H(\mathbf{w}^{k+1}) \geq H(\mathbf{w}^k) + \langle v(\mathbf{w}^k), \mathbf{w}^{k+1} - \mathbf{w}^k \rangle. \quad (34.14)$$

Combining (34.11) and (34.14), we get

$$G(\mathbf{w}^{k+1}) - H(\mathbf{w}^{k+1}) \leq H^*(v(\mathbf{w}^k)) - G^*(\mathbf{t}^k) + \langle \mathbf{w}^{k+1}, \mathbf{t}^k - v(\mathbf{w}^k) \rangle. \quad (34.15)$$

From (34.13) and (34.15), we get the inequalities

$$\begin{aligned} C(\mathbf{w}^k) &\geq H^*(v(\mathbf{w}^k)) - G^*(\mathbf{t}^k) + \langle \mathbf{w}^k, \mathbf{t}^k - v(\mathbf{w}^k) \rangle \\ &\geq C(\mathbf{w}^{k+1}) + \langle \mathbf{w}^k - \mathbf{w}^{k+1}, \mathbf{t}^k - v(\mathbf{w}^k) \rangle. \end{aligned}$$

It is observed that $\langle \mathbf{w}^k, \mathbf{t}^k - v(\mathbf{w}^k) \rangle \rightarrow 0$ a.s and $\langle \mathbf{w}^k - \mathbf{w}^{k+1}, \mathbf{t}^k - v(\mathbf{w}^k) \rangle \rightarrow 0$ a.s, so

$$C(\mathbf{w}^k) - H^*(v(\mathbf{w}^k)) + G^*(\mathbf{t}^k) \rightarrow 0 \text{ a.s.},$$

or equivalently,

$$G(\mathbf{w}^k) - H(\mathbf{w}^k) - H^*(v(\mathbf{w}^k)) + G^*(\mathbf{t}^k) \rightarrow 0 \text{ a.s.}$$

Since $H(\mathbf{w}^k) + H^*(v(\mathbf{w}^k)) = \langle \mathbf{w}^k, v(\mathbf{w}^k) \rangle$, we get

$$G(\mathbf{w}^k) + G^*(\mathbf{t}^k) - \langle \mathbf{w}^k, v(\mathbf{w}^k) \rangle \rightarrow 0 \text{ a.s.}$$

Let \mathcal{L} be an intersection of all sets with probability 1 gained from the almost sure true statements from the beginning of the proof, $P(\mathcal{L}) = 1$ (since we have at most countably finite statements).

Let $\omega \in \mathcal{L}$; since the sequence $\{\mathbf{w}^k(\omega)\}$ is bounded, we can extract a subsequence $\{\mathbf{w}^{k_j}(\omega)\}$ such that

$$\mathbf{w}^{k_j}(\omega) \rightarrow \mathbf{w}^*(\omega) \in S.$$

By the boundedness of v and passing to subsequence if necessary, we get

$$v(\mathbf{w}^{k_j}(\omega)) \rightarrow v(\mathbf{w}^*(\omega)).$$

On the other hand,

$$\begin{aligned} \|\mathbf{t}^{k_j}(\omega) - v(\mathbf{w}^*(\omega))\| &\leq \|\mathbf{t}^{k_j}(\omega) - v(\mathbf{w}^{k_j}(\omega))\| + \|v(\mathbf{w}^{k_j}(\omega)) \\ &\quad - v(\mathbf{w}^*(\omega))\|, \end{aligned}$$

which converges to 0. Therefore,

$$\mathbf{t}^{k_j}(\omega) \rightarrow v(\mathbf{w}^*(\omega)), \quad j \rightarrow \infty.$$

We achieve the following limit:

$$\lim_{j \rightarrow \infty} (G(\mathbf{w}^{k_j}(\omega)) + G^*(\mathbf{t}^{k_j}(\omega))) = \langle \mathbf{w}^*(\omega), v(\mathbf{w}^*(\omega)) \rangle.$$

By using the semicontinuity property of

$$\theta(\mathbf{w}, \mathbf{z}) = G(\mathbf{w}) + G^*(\mathbf{z}),$$

we achieve

$$G(\mathbf{w}^*(\omega)) + G^*(v(\mathbf{w}^*(\omega))) \leq \langle \mathbf{w}^*(\omega), v(\mathbf{w}^*(\omega)) \rangle$$

and by Young inequality, the equality must hold:

$$G(\mathbf{w}^*(\omega)) + G^*(\nu(\mathbf{w}^*(\omega))) = \langle \mathbf{w}^*(\omega), \nu(\mathbf{w}^*(\omega)) \rangle.$$

In other words, $\nu(\mathbf{w}^*(\omega)) \in \partial G(\mathbf{w}^*(\omega))$. Consequently,

$$\partial G(\mathbf{w}^*(\omega)) \cap \partial H(\mathbf{w}^*(\omega)) \neq \emptyset,$$

and we conclude that $\mathbf{w}^*(\omega)$ is a critical point of $C = G - H$. The proof is completed.

34.4.3 Online Stochastic DCA2

The whole set of assumptions for online stochastic DCA1 is applied to online stochastic DCA2, together with the following assumption.

Assumption 4

(1) *There exists a Borel measurable function*

$$\tilde{g} : \mathbb{R}^n \rightarrow \mathbb{R}$$

such that $\int_{\Xi} |\tilde{g}(z)| dP_Z < +\infty$ and

$$\text{for all } \mathbf{w} \in S, z \in \Xi, \quad |g(\mathbf{w}, z)| \leq \tilde{g}(z).$$

(2) *For all $\mathbf{w} \in S, E(g(\mathbf{w}, \mathbf{Z})^2) < +\infty$.*

(3) *The family of functions $\mathcal{G} = \{g(\cdot, z) | z \in \Xi\}$ is equicontinuous in S , i.e., for each $\mathbf{w} \in S$, for every $\epsilon > 0$, there exists $\delta > 0$ such that*

$$|g(\mathbf{w}, z) - g(\mathbf{w}', z)| < \epsilon, \forall z \in \Xi, \forall \mathbf{w}, \mathbf{w}' \in S : \|\mathbf{w} - \mathbf{w}'\| < \delta.$$

(4) *For all $\mathbf{w} \in S, g(\mathbf{w}, \cdot)$ is lower semicontinuous.*

Notice that, due to the compactness of S , the equicontinuity of \mathcal{G} is equivalent to \mathcal{G} being uniform equicontinuous, i.e., for every $\epsilon > 0$, there exists $\delta > 0$ such that

$$|g(\mathbf{w}, z) - g(\mathbf{w}', z)| < \epsilon, \forall z \in \Xi, \forall \mathbf{w}, \mathbf{w}' \in S : \|\mathbf{w} - \mathbf{w}'\| < \delta.$$

Let $\{\mathbf{Z}_p\}_{p=1}^\infty$ be a sequence of independent random variables which is of identical distribution with \mathbf{Z} . We prove that the family

$$\mathcal{J} = \left\{ \sup_{\mathbf{w} \in S} \left| p^{-1} \sum_{i=1}^p g(\mathbf{w}, \mathbf{Z}_i) - E(g(\mathbf{w}, \mathbf{Z})) \right| : p \in \mathbb{N} \right\}$$

is uniform integrable.

Proof. The proof is divided into two parts.

(a) We show that there is $\Upsilon > 0$ such that for all $X \in \mathcal{J}$, $E(|X|) \leq \Upsilon$.

Thus, due to the uniform equicontinuity of \mathcal{G} , there is $\delta > 0$ such that

$$\forall z \in \Xi, \mathbf{w}, \mathbf{w}' \in S : \|\mathbf{w} - \mathbf{w}'\| < \delta, |g(\mathbf{w}, z) - g(\mathbf{w}', z)| < 1.$$

Since $S \subset \cup_{\mathbf{w} \in S} B(\mathbf{w}, \delta)$ and S is compact, there exists $\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_r \in S$ such that

$$S \subset \cup_{i=1}^r B(\mathbf{w}_i, \delta).$$

Let $\mathbf{w} \in S$; there is $j \in \{1, 2, \dots, r\}$ such that

$$\mathbf{w} \in B(\mathbf{w}_j, \delta).$$

It follows that

$$|g(\mathbf{w}, z) - g(\mathbf{w}_j, z)| < 1, \forall z \in \Xi.$$

Let $p \in \mathbb{N}$; on $\cap_{k=1}^\infty (\mathbf{Z}_k \in \Xi)$, we have

$$\begin{aligned} & \left| p^{-1} \sum_{i=1}^p g(\mathbf{w}, \mathbf{Z}_i) - E(g(\mathbf{w}, \mathbf{Z})) \right| \\ & \leq \left| p^{-1} \sum_{i=1}^p g(\mathbf{w}_j, \mathbf{Z}_i) - E(g(\mathbf{w}_j, \mathbf{Z})) \right| \\ & \quad + p^{-1} \sum_{i=1}^p |g(\mathbf{w}, \mathbf{Z}_i) - g(\mathbf{w}_j, \mathbf{Z}_i)| + E(|g(\mathbf{w}, \mathbf{Z}) - g(\mathbf{w}_j, \mathbf{Z})|) \\ & \leq \left| p^{-1} \sum_{i=1}^p g(\mathbf{w}_j, \mathbf{Z}_i) - E(g(\mathbf{w}_j, \mathbf{Z})) \right| + 2. \end{aligned}$$

As a consequence, for all $\mathbf{w} \in S$,

$$\begin{aligned} & \left| p^{-1} \sum_{i=1}^p g(\mathbf{w}, \mathbf{Z}_i) - E(g(\mathbf{w}, \mathbf{Z})) \right| \leq \max_{j=1, \dots, r} \left| p^{-1} \sum_{i=1}^p g(\mathbf{w}_j, \mathbf{Z}_i) - E(g(\mathbf{w}_j, \mathbf{Z})) \right| + 2. \end{aligned}$$

It follows that

$$\begin{aligned} & \sup_{\mathbf{w} \in S} \left| p^{-1} \sum_{i=1}^p g(\mathbf{w}, \mathbf{Z}_i) - E(g(\mathbf{w}, \mathbf{Z})) \right| \leq \max_{j=1, \dots, r} \left| p^{-1} \sum_{i=1}^p g(\mathbf{w}_j, \mathbf{Z}_i) - E(g(\mathbf{w}_j, \mathbf{Z})) \right| + 2. \end{aligned}$$

On the other hand,

$$\begin{aligned} \max_{j=1,r} |p^{-1} \sum_{i=1}^p g(\mathbf{w}_j, \mathbf{Z}_i) - E(g(\mathbf{w}_j, \mathbf{Z}))| &\leq \sum_{j=1}^r \\ &\leq \sqrt{P(A)} \cdot \sum_{j=1}^r V(g(\mathbf{w}_j, \mathbf{Z}))^{\frac{1}{2}} + 2P(A) \\ |p^{-1} \sum_{i=1}^p g(\mathbf{w}_j, \mathbf{Z}_i) - E(g(\mathbf{w}_j, \mathbf{Z}))| &\leq \Upsilon \sqrt{P(A)}, \end{aligned}$$

By the independence of \mathbf{Z}_i 's,

$$\begin{aligned} &E \left(\left| p^{-1} \sum_{i=1}^p g(\mathbf{w}_j, \mathbf{Z}_i) - E(g(\mathbf{w}_j, \mathbf{Z})) \right| \right) \\ &\leq E \left(\left| p^{-1} \sum_{i=1}^p g(\mathbf{w}_j, \mathbf{Z}_i) - E(g(\mathbf{w}_j, \mathbf{Z})) \right|^2 \right)^{\frac{1}{2}} \\ &= \frac{V(g(\mathbf{w}_j, \mathbf{Z}))^{\frac{1}{2}}}{\sqrt{p}} \leq V(g(\mathbf{w}_j, \mathbf{Z}))^{\frac{1}{2}}. \end{aligned}$$

Therefore,

$$\begin{aligned} &E \left(\sup_{\mathbf{w} \in S} \left| p^{-1} \sum_{i=1}^p g(\mathbf{w}, \mathbf{Z}_i) - E(g(\mathbf{w}, \mathbf{Z})) \right| \right) \\ &\leq \sum_{j=1}^r V(g(\mathbf{w}_j, \mathbf{Z}))^{\frac{1}{2}} + 2 := \Upsilon, \end{aligned}$$

where Υ is finite due to the finiteness of the second moment of $g(\mathbf{w}, \mathbf{Z})$ (Assumption 4(2)).

- (b) We next prove that for every $\epsilon > 0$, there exists $\eta > 0$ such that, for every measurable set A such that $P(A) \leq \eta$ and every $X \in \mathcal{J}$, $E(|X| \mathbf{1}_A) \leq \epsilon$.

Thus, let $X \in \mathcal{J}$, from (a)

$$|X| \leq \sum_{j=1}^r \left| p^{-1} \sum_{i=1}^p g(\mathbf{w}_j, \mathbf{Z}_i) - E(g(\mathbf{w}_j, \mathbf{Z})) \right| + 2.$$

Therefore,

$$\begin{aligned} E(|X| \mathbf{1}_A) &\leq 2P(A) + \sum_{j=1}^r \\ &E \left(\left| p^{-1} \sum_{i=1}^p g(\mathbf{w}_j, \mathbf{Z}_i) - E(g(\mathbf{w}_j, \mathbf{Z})) \right| \mathbf{1}_A \right) \\ &\leq 2P(A) + \sqrt{P(A)} \sum_{j=1}^r \\ &E \left(\left| p^{-1} \sum_{i=1}^p g(\mathbf{w}_j, \mathbf{Z}_i) - E(g(\mathbf{w}_j, \mathbf{Z})) \right|^2 \right)^{\frac{1}{2}} \end{aligned}$$

which can be arbitrarily small.

We conclude that \mathcal{J} is uniform integrable. \square

Moreover, the uniform strong law of large number ensures that

$$\sup_{\mathbf{w} \in S} \left| p^{-1} \sum_{i=1}^p g(\mathbf{w}, \mathbf{Z}_i) - E(g(\mathbf{w}, \mathbf{Z})) \right| \rightarrow 0 \text{ a.s.} \quad (34.16)$$

The uniform strong law of large numbers (34.16) can be found in [94], but here we give a detail proof in appendix B.1 for the sack of completeness.

It follows from Vitali convergence theorem [95] that

$$E \left(\sup_{\mathbf{w} \in S} \left| p^{-1} \sum_{i=1}^p g(\mathbf{w}, \mathbf{Z}_i) - E(g(\mathbf{w}, \mathbf{Z})) \right| \right) \rightarrow 0$$

when $p \rightarrow \infty$.

Now let $\{\alpha_k\}$ be a sequence of positive number such that $\sum_{k=1}^{\infty} \alpha_k < \infty$; we can construct a sequence $\{N_k\}$ satisfying

$$\forall p \geq N_k, E \left(\sup_{\mathbf{w} \in S} \left| p^{-1} \sum_{i=1}^p g(\mathbf{w}, \mathbf{Z}_i) - E(g(\mathbf{w}, \mathbf{Z})) \right| \right) < \alpha_k. \quad (34.17)$$

We make an additional setting before giving a new online stochastic DCA scheme.

For every $r \in \mathbb{N}$, we consider a function called Θ_r :

$$\begin{aligned} \Theta_r &: \mathbb{R}^{nr} \times \mathbb{R}^{2m} \rightarrow \mathbb{R} \cup \{+\infty\} \\ (\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_r, \mathbf{t}, \mathbf{w}) &\mapsto \frac{1}{r} \sum_{i=1}^r g(\mathbf{w}, \mathbf{z}_i) - \langle \mathbf{t}, \mathbf{w} \rangle. \end{aligned}$$

Under Assumptions 4(3),(4), g is lower semicontinuous; therefore, Θ_r is lower semicontinuous.

Furthermore, for each $(\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_r) \in \Xi^r$ and for $\mathbf{t} \in \mathbb{R}^m$,

$$\arg \min_{\mathbf{w} \in \mathbb{R}^m} \Theta_r(\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_r, \mathbf{t}, \mathbf{w}) \neq \emptyset.$$

By selection theorem, there exists a Borel measurable function $\Gamma_r : \mathbb{R}^{nr} \times \mathbb{R}^m \rightarrow \mathbb{R}^m$ such that

$$\Gamma_r(\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_r, \mathbf{t}) \in \arg \min_{\mathbf{w} \in \mathbb{R}^m} \Theta_r(\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_r, \mathbf{t}, \mathbf{w})$$

for all $z_1, z_2, \dots, z_r \in \Xi$ and $t \in \mathbb{R}^m$. We now propose a new DCA scheme as the following.

Algorithm 2 Online stochastic DCA2.

Step 1. Choose $w^0 \in S$.

Step 2. For $k = 0, 1, 2, \dots$ do

1. Draw independently $Z_{k,1}, Z_{k,2}, \dots, Z_{k,n_k}$ from Z in such a way they are also independent to the past.
2. Compute $t^k = \frac{1}{n_k} \sum_{i=1}^{n_k} \tau(w^k, Z_{k,i})$.
3. Solve the convex program to get w^{k+1}

$$w^{k+1} = \Gamma_{n_k}(Z_{k,1}, Z_{k,2}, \dots, Z_{k,n_k}, t^k) \in \arg \min_{w \in \mathbb{R}^m} \left\{ \frac{1}{n_k} \sum_{i=1}^{n_k} g(w, Z_{k,i}) - \langle t^k, w \rangle \right\}.$$

4. If stopping criteria are satisfied, break. □

The algorithm is well-defined with probability 1. We study convergence properties of online stochastic DCA2 in the set of events which makes the algorithm works.

To be more specific, the set of events that make the algorithm works is

$$\mathcal{V} = \bigcap_{k=1}^{\infty} \bigcap_{i=1}^{n_k} (Z_{k,i} \in \Xi).$$

By the Borel measurability of Γ_r and τ , it follows by induction that w^k is \mathcal{P}_k measurable, for all $k \geq 1$, and t^k is \mathcal{P}_{k+1} measurable, for all $k \geq 0$.

Theorem 34.8 Let $0 < \bar{\rho} < \rho(H)$. Under Assumptions 1, 2, 3, 4 (Assumption 3 applying to the sequence $\{w^k\}$ generated by online stochastic DCA2), if the sequence of sample size satisfies

$$\sum_{k=1}^{\infty} \frac{1}{n_k} < \infty \text{ and } n_k \geq N_k, \forall k \in \mathbb{N},$$

where $\{N_k\}$ is determined by (34.17), the iterates of online stochastic DCA2 satisfy:

(1) There exists $C^\infty \in L^1(\Omega)$ such that

$$C(w^k) \rightarrow C^\infty \text{ a.s.}$$

(2) $\|w^{k+1} - w^k\| \rightarrow 0$ a.s.

(3) There exists a measurable set \mathcal{Y} with $P(\mathcal{Y}) = 1$ such that for every $\omega \in \mathcal{Y}$, the sequence $\{w^k(\omega)\}$ has a subsequence converging to $w^*(\omega)$ which is a critical point of $C = G - H$.

Proof. (1) Since $v(w^k) \in \partial H(w^k)$, we get

$$H(w^{k+1}) \geq H(w^k) + \langle v(w^k), w^{k+1} - w^k \rangle + \frac{\bar{\rho}}{2} \|w^{k+1} - w^k\|^2. \tag{34.18}$$

By the definition of w^{k+1} ,

$$\frac{1}{n_k} \sum_{i=1}^{n_k} g(w^{k+1}, Z_{k,i}) - \langle t^k, w^{k+1} \rangle \leq \frac{1}{n_k} \sum_{i=1}^{n_k} g(w^k, Z_{k,i}) - \langle t^k, w^k \rangle. \tag{34.19}$$

Combining these two inequalities, we get

$$\begin{aligned} & \frac{1}{n_k} \sum_{i=1}^{n_k} g(w^{k+1}, Z_{k,i}) - H(w^{k+1}) \\ & \leq \frac{1}{n_k} \sum_{i=1}^{n_k} g(w^k, Z_{k,i}) - \frac{\bar{\rho}}{2} \|w^{k+1} - w^k\|^2 \\ & \quad + \langle t^k - v(w^k), w^{k+1} - w^k \rangle - H(w^k). \end{aligned} \tag{34.20}$$

By taking the conditional expectation (34.20) with respect to \mathcal{P}_k and noticing that

$$E \left(\frac{1}{n_k} \sum_{i=1}^{n_k} g(w^k, Z_{k,i}) | \mathcal{P}_k \right) = G(w^k),$$

$$E(\langle t^k - v(w^k), w^{k+1} - w^k \rangle | \mathcal{P}_k) \leq E(\|w^{k+1} - w^k\|^2 | \mathcal{P}_k)^{\frac{1}{2}} \frac{V_Z(\tau(w^k, Z))^{1/2}}{\sqrt{n_k}},$$

we get

$$\begin{aligned} & E(C(w^{k+1}) - C(w^k) | \mathcal{P}_k) \\ & \leq -\frac{\bar{\rho}}{2} E(\|w^{k+1} - w^k\|^2 | \mathcal{P}_k) \\ & \quad + E \left(G(w^{k+1}) - \frac{1}{n_k} \sum_{i=1}^{n_k} g(w^{k+1}, Z_{k,i}) | \mathcal{P}_k \right) \\ & \quad + E(\|w^{k+1} - w^k\|^2 | \mathcal{P}_k)^{\frac{1}{2}} \frac{V_Z(\tau(w^k, Z))^{1/2}}{\sqrt{n_k}} \\ & \leq E \left(\sup_{w \in S} \left| G(w) - \frac{1}{n_k} \sum_{i=1}^{n_k} g(w, Z_{k,i}) \right| | \mathcal{P}_k \right) \\ & \quad + \frac{V_Z(\tau(w^k, Z))}{2\bar{\rho} \times n_k}. \end{aligned}$$

By Assumption 2(3), there exists R such that

$$C(w) \geq R, \forall w \in S.$$

Let $D(\mathbf{w}) = C(\mathbf{w}) - R$; we get

$$E(D(\mathbf{w}^{k+1}) - D(\mathbf{w}^k) | \mathcal{P}_k)$$

$$\leq \frac{V_{\mathbf{Z}}(\tau(\mathbf{w}^k, \mathbf{Z}))}{2\bar{\rho} \times n_k} + E \left(\sup_{\mathbf{w} \in S} | G(\mathbf{w}) - \frac{1}{n_k} \sum_{i=1}^{n_k} g(\mathbf{w}, \mathbf{Z}_{k,i}) | \mid \mathcal{P}_k \right).$$

Let $F_n = [E(D(\mathbf{w}^{k+1}) - D(\mathbf{w}^k) | \mathcal{P}_k) > 0]$,

$$\begin{aligned} & \sum_{k=1}^{\infty} E(1_{F_k}(D(\mathbf{w}^{k+1}) - D(\mathbf{w}^k))) \\ &= \sum_{k=1}^{\infty} E(E(1_{F_k}(D(\mathbf{w}^{k+1}) - D(\mathbf{w}^k)) | \mathcal{P}_k)) \\ &= \sum_{k=1}^{\infty} E(1_{F_k} E(D(\mathbf{w}^{k+1}) - D(\mathbf{w}^k) | \mathcal{P}_k)) \\ &\leq \sum_{k=1}^{\infty} E \left(\sup_{\mathbf{w} \in S} | G(\mathbf{w}) - \frac{1}{n_k} \sum_{i=1}^{n_k} g(\mathbf{w}, \mathbf{Z}_{k,i}) | \right) \\ &\quad + \frac{M}{2\bar{\rho}} \sum_{k=1}^{\infty} \frac{1}{n_k} \\ &\leq \sum_{k=1}^{\infty} \alpha_k + \frac{M}{2\bar{\rho}} \sum_{k=1}^{\infty} \frac{1}{n_k} < \infty. \end{aligned}$$

By applying semimartingale convergence theorem, there exists $D^\infty \in L^1(\Omega)$ such that

$$D(\mathbf{w}^k) \rightarrow D^\infty \text{ a.s.}$$

As a consequence, $C^\infty = D^\infty + R \in L^1(\Omega)$ and

$$C(\mathbf{w}_k) \rightarrow C^\infty \text{ a.s.}$$

(2) From (34.20), using the AM-GM inequality

$$\begin{aligned} \langle \mathbf{t}^k - v(\mathbf{w}^k), \mathbf{w}^{k+1} - \mathbf{w}^k \rangle &\leq \frac{1}{\bar{\rho}} \|\mathbf{t}^k - v(\mathbf{w}^k)\|^2 \\ &\quad + \frac{\bar{\rho}}{4} \|\mathbf{w}^{k+1} - \mathbf{w}^k\|^2, \end{aligned}$$

we achieve

$$\begin{aligned} \frac{\bar{\rho}}{4} \|\mathbf{w}^{k+1} - \mathbf{w}^k\|^2 &\leq \frac{1}{\bar{\rho}} \|\mathbf{t}^k - v(\mathbf{w}^k)\|^2 + H(\mathbf{w}^{k+1}) - H(\mathbf{w}^k) \\ &\quad + \frac{1}{n_k} \sum_{i=1}^{n_k} g(\mathbf{w}^k, \mathbf{Z}_{k,i}) - \frac{1}{n_k} \sum_{i=1}^{n_k} g(\mathbf{w}^{k+1}, \mathbf{Z}_{k,i}) \\ &= \frac{1}{\bar{\rho}} \|\mathbf{t}^k - v(\mathbf{w}^k)\|^2 - C(\mathbf{w}^{k+1}) + C(\mathbf{w}^k) \\ &\quad + G(\mathbf{w}^{k+1}) + \frac{1}{n_k} \sum_{i=1}^{n_k} g(\mathbf{w}^k, \mathbf{Z}_{k,i}) - G(\mathbf{w}^k) \end{aligned}$$

$$- \frac{1}{n_k} \sum_{i=1}^{n_k} g(\mathbf{w}^{k+1}, \mathbf{Z}_{k,i}).$$

By uniform strong law of large number,

$$\|\mathbf{t}^k - v(\mathbf{w}^k)\| \rightarrow 0 \text{ a.s.},$$

$$\frac{1}{n_k} \sum_{i=1}^{n_k} g(\mathbf{w}^k, \mathbf{Z}_{k,i}) - G(\mathbf{w}^k) \rightarrow 0 \text{ a.s.},$$

$$G(\mathbf{w}^{k+1}) - \frac{1}{n_k} \sum_{i=1}^{n_k} g(\mathbf{w}^{k+1}, \mathbf{Z}_{k,i}) \rightarrow 0 \text{ a.s.},$$

we conclude that $\|\mathbf{w}^{k+1} - \mathbf{w}^k\| \rightarrow 0$ a.s.

The uniform strong law of large number for triangular arrays,

$$\sup_{\mathbf{w} \in S} | \frac{1}{n_k} \sum_{i=1}^{n_k} g(\mathbf{w}, \mathbf{Z}_{k,i}) - G(\mathbf{w}) | \rightarrow 0 \text{ a.s.} \quad (34.21)$$

is proven in appendix B.2.

(3) Since $v(\mathbf{w}^k) \in \partial_{\mathbf{w}} H(\mathbf{w}^k)$, we have

$$\langle v(\mathbf{w}^k), \mathbf{w}^k \rangle = H(\mathbf{w}^k) + H^*(v(\mathbf{w}^k)). \quad (34.22)$$

Denoting $G_k(\mathbf{w}) = \frac{1}{n_k} \sum_{i=1}^{n_k} g(\mathbf{w}, \mathbf{Z}_{k,i})$, $\forall \mathbf{w} \in \mathbb{R}^m$, it follows from the definition of \mathbf{w}^{k+1} that

$$\langle \mathbf{w}^{k+1}, \mathbf{t}^k \rangle = G_k(\mathbf{w}^{k+1}) + G_k^*(\mathbf{t}^k). \quad (34.23)$$

From (34.22) and (34.23),

$$\begin{aligned} G_k(\mathbf{w}^{k+1}) - H(\mathbf{w}^k) + G_k^*(\mathbf{t}^k) - H^*(v(\mathbf{w}^k)) \\ = \langle \mathbf{w}^{k+1}, \mathbf{t}^k \rangle - \langle v(\mathbf{w}^k), \mathbf{w}^k \rangle. \end{aligned} \quad (34.24)$$

Combine (34.24) with the following inequality

$$H(\mathbf{w}^{k+1}) \geq H(\mathbf{w}^k) + \langle v(\mathbf{w}^k), \mathbf{w}^{k+1} - \mathbf{w}^k \rangle,$$

to get

$$\begin{aligned} G_k(\mathbf{w}^{k+1}) - H(\mathbf{w}^{k+1}) + G_k^*(\mathbf{t}^k) - H^*(v(\mathbf{w}^k)) \\ \leq \langle \mathbf{w}^{k+1}, \mathbf{t}^k - v(\mathbf{w}^k) \rangle. \end{aligned} \quad (34.25)$$

On the other hand, by combining (34.24) with the following inequality

$$G_k(\mathbf{w}^{k+1}) - \langle \mathbf{t}^k, \mathbf{w}^{k+1} \rangle \leq G_k(\mathbf{w}^k) - \langle \mathbf{t}^k, \mathbf{w}^k \rangle$$

we get

$$G_k(\mathbf{w}^k) - H(\mathbf{w}^k) + G_k^*(\mathbf{t}^k) - H^*(v(\mathbf{w}^k)) \geq \langle \mathbf{t}^k - v(\mathbf{w}^k), \mathbf{w}^k \rangle. \quad (34.26)$$

From (34.25) and (34.26), we have these inequalities

$$\begin{aligned} G_k(\mathbf{w}^k) - H(\mathbf{w}^k) &\geq H^*(v(\mathbf{w}^k)) - G_k^*(\mathbf{t}^k) + \langle \mathbf{t}^k - v(\mathbf{w}^k), \mathbf{w}^k \rangle \\ &\geq G_k(\mathbf{w}^{k+1}) - H(\mathbf{w}^{k+1}) \\ &\quad + \langle \mathbf{t}^k - v(\mathbf{w}^k), \mathbf{w}^k - \mathbf{w}^{k+1} \rangle. \end{aligned}$$

By uniform strong law of large number,

$$\begin{aligned} G_k(\mathbf{w}^k) - H(\mathbf{w}^k) &\rightarrow C^\infty \text{ a.s.}, \\ G_k(\mathbf{w}^{k+1}) - H(\mathbf{w}^{k+1}) &\rightarrow C^\infty \text{ a.s.}, \\ \|\mathbf{t}^k - v(\mathbf{w}^k)\| &\rightarrow 0 \text{ a.s.}, \end{aligned}$$

we are left with

$$G_k(\mathbf{w}^k) + G_k^*(\mathbf{t}^k) - H(\mathbf{w}^k) - H^*(v(\mathbf{w}^k)) \rightarrow 0 \text{ a.s.},$$

or equivalently,

$$G(\mathbf{w}^k) + G_k^*(\mathbf{t}^k) - \langle \mathbf{w}^k, v(\mathbf{w}^k) \rangle \rightarrow 0 \text{ a.s.}$$

We have an observation that

$$\begin{aligned} |G_k^*(\mathbf{t}^k) - G^*(\mathbf{t}^k)| &= \left| \sup_{\mathbf{x} \in S} \{ \langle \mathbf{x}, \mathbf{t}^k \rangle - G_k(\mathbf{x}) \} - \sup_{\mathbf{x} \in S} \{ \langle \mathbf{x}, \mathbf{t}^k \rangle - G(\mathbf{x}) \} \right| \\ &\leq \sup_{\mathbf{x} \in S} |G_k(\mathbf{x}) - G(\mathbf{x})| \rightarrow 0 \text{ a.s.}, \end{aligned}$$

here we use the inequality

$$\left| \sup_{\mathbf{x} \in S} u(\mathbf{x}) - \sup_{\mathbf{x} \in S} v(\mathbf{x}) \right| \leq \sup_{\mathbf{x} \in S} |u(\mathbf{x}) - v(\mathbf{x})|.$$

By this evaluation we get the result

$$G(\mathbf{w}^k) + G^*(\mathbf{t}^k) - \langle \mathbf{w}^k, v(\mathbf{w}^k) \rangle \rightarrow 0 \text{ a.s.}$$

With the same argument as the proof of online stochastic DCA1, we conclude that the sequence $\{\mathbf{w}^k\}$ admits a subsequence converging to a critical point of $C = G - H$ with probability 1.

34.5 Conclusion

In this chapter, we have studied ways to combine stochastic optimization in an online manner and DCA to make use of their premier features. The main idea is quite simple; some deterministic quantities in the traditional DCA are replaced by their corresponding stochastic approximations in order to reduce the computational cost or deal with uncertainty. Intuitively, the more deterministic quantities we replace, the

more instability the new algorithm gets. In the first online stochastic algorithm, we only use stochastic approximation for the subgradient component, while in the second one, the replacement is applied for two components including the subgradient and G . The first scheme admits an explicit condition for the rate of sample size, while an implicit condition appears in the second algorithm. For both algorithms, the number of samples used increases over time to make the approximations more accurate. Consequently, these two online stochastic algorithms are similar to the traditional DCA as time step tends to infinity. This leads to similar behaviors between online stochastic DCA and traditional DCA. Thus, these two schemes have convergence properties in terms of subsequence to critical points with probability 1. Besides the wide class of one-stage stochastic programming problems mentioned in the chapter, multistage stochastic programming is such a promising area where stochastic optimization will find many deterministic quantities to substitute. Furthermore, a deterministic function sometimes has its convenient probabilistic representation, so it would be a chance for stochastic algorithms to prove their capability. Regarding DC programming and DCA, since its day of birth in 1985, its various variations have been studied extensively such as proximal DCA [96], DCA with successive DC decomposition [1], etc. Therefore, it is a natural idea that each of these variations should have corresponding stochastic versions to offer us more options in practice as well as many nice results interfacing between probability and optimization theory to discover.

34.6 Appendix A: A Theorem on Conditional Expectation

This appendix states and proves a theorem which is used frequently in our study to manipulate conditional expectation.

Theorem A.1 *Let (Ω, \mathcal{M}, P) be a probability space and let \mathcal{P} be a sub-sigma-algebra of \mathcal{M} .*

Let \mathbf{X} be a n -dimensional random vector which is \mathcal{P} -measurable and let \mathbf{Y} be a m -dimensional random vector which is \mathcal{P} -independent.

Let $\alpha : \mathbb{R}^n \times \mathbb{R}^m \rightarrow \mathbb{R}^d$ be Borel measurable such that $E(\|\alpha(\mathbf{X}, \mathbf{Y})\|) < +\infty$. Then the following equality holds,

$$E(\alpha(\mathbf{X}, \mathbf{Y})|\mathcal{P}) = E_Y(\alpha(\mathbf{X}, \mathbf{Y})).$$

Proof. Let μ_X, μ_Y be probability measures on \mathbb{R}^n and \mathbb{R}^m generated by \mathbf{X} and \mathbf{Y} , respectively.

Since

$$\int_{\mathbb{R}^n \times \mathbb{R}^m} \|\alpha(\mathbf{x}, \mathbf{y})\| d(\mu_X \times \mu_Y) = E(\|\alpha(\mathbf{X}, \mathbf{Y})\|)$$

is finite, we have $\int_{\mathbb{R}^n} \|\alpha(\mathbf{x}, \mathbf{y})\| d(\mu_Y^*) < \infty$, for μ_X almost sure. Equivalently,

$$g(\mathbf{x}) := E(\alpha(\mathbf{x}, \mathbf{Y}))$$

is well-defined for μ_X almost sure. Moreover, we have $g \in L^1(\mathbb{R}^n, \mathcal{B}(\mathbb{R}^n), \mu_X)$.

For every set $A \in \mathcal{P}$, we show that

$$E(\alpha(\mathbf{X}, \mathbf{Y})1_A) = E(g(\mathbf{X})1_A). \quad (\text{A.27})$$

If $P(A) = 0$, (A.27) is obviously true.

Consider $P(A) > 0$, (A.27) can be written as

$$\int_A \alpha(\mathbf{X}, \mathbf{Y}) dP = \int_A g(\mathbf{X}) dP. \quad (\text{A.28})$$

Let (A, \mathcal{M}_A, P_A) be a probability space induced by (Ω, \mathcal{M}, P) on A , then (A.28) can be rewritten as

$$\int_A \alpha(\mathbf{X}, \mathbf{Y}) dP_A = \int_A g(\mathbf{X}) dP_A.$$

It is observed that,

$$\int_A \alpha(\mathbf{X}, \mathbf{Y}) dP_A = \int_{\mathbb{R}^{m+n}} \alpha(\mathbf{x}, \mathbf{y}) d\pi^*,$$

where π^* is a probability measure on \mathbb{R}^{m+n} defined by

$$\pi^*(D) = P_A(A \cap [(X, Y) \in D]), \forall D \in \mathcal{B}(\mathbb{R}^{m+n}).$$

Let μ_X^*, μ_Y^* be probability measures on \mathbb{R}^n and \mathbb{R}^m corresponding to X and Y , where X, Y are viewed as random vectors defined on probability space A ,

$$\begin{aligned} \mu_X^*(B) &= P_A(A \cap [X \in B]), \quad \forall B \in \mathcal{B}(\mathbb{R}^n), \\ \mu_Y^*(C) &= P_A(A \cap [Y \in C]), \quad \forall C \in \mathcal{B}(\mathbb{R}^m). \end{aligned}$$

We show that $\pi^* = \mu_X^* \times \mu_Y^*$.

Thus, let $B \in \mathcal{B}(\mathbb{R}^n)$, $C \in \mathcal{B}(\mathbb{R}^m)$.

$$\begin{aligned} \pi^*(B \times C) &= P_A(A \cap [(X, Y) \in B \times C]) \\ &= P_A(A \cap [X \in B] \cap [Y \in C]) \\ &= \frac{P(A \cap [X \in B] \cap [Y \in C])}{P(A)} \\ &= \frac{P(A \cap [X \in B])P(Y \in C)}{P(A)}. \end{aligned}$$

since $A \cap [X \in B]$ and $[Y \in C]$ are independent.

On the other hand,

$$\begin{aligned} (\mu_X^* \times \mu_Y^*)(B \times C) &= \mu_X^*(B)\mu_Y^*(C) \\ &= P_A(A \cap [X \in B]) \times P_A(A \cap [Y \in C]) \\ &= \frac{P(A \cap [X \in B])}{P(A)} \times \frac{P(A \cap [Y \in C])}{P(A)} \\ &= \frac{P(A \cap [X \in B])P(Y \in C)}{P(A)}, \end{aligned}$$

since A and $[Y \in C]$ are independent.

Consequently, $\pi^* \equiv \mu_X^* \times \mu_Y^*$ due to the uniqueness of product measure.

Therefore,

$$\int_{\mathbb{R}^{m+n}} \alpha(\mathbf{x}, \mathbf{y}) d\pi^* = \int_{\mathbb{R}^{m+n}} \alpha(\mathbf{x}, \mathbf{y}) d(\mu_X^* \times \mu_Y^*).$$

By applying Fubini theorem, we get

$$\int_{\mathbb{R}^{m+n}} \alpha(\mathbf{x}, \mathbf{y}) d(\mu_X^* \times \mu_Y^*) = \int_{\mathbb{R}^n} \int_{\mathbb{R}^m} \alpha(\mathbf{x}, \mathbf{y}) d\mu_Y^* d\mu_X^*$$

We show that $\mu_Y = \mu_Y^*$. Thus, let $C \in \mathcal{B}(\mathbb{R}^m)$, we have

$$\begin{aligned} \mu_Y^*(C) &= P_A(A \cap [Y \in C]) \\ &= \frac{P(A \cap [Y \in C])}{P(A)} \\ &= P(Y \in C) = \mu_Y(C). \end{aligned}$$

Therefore, we achieve

$$\begin{aligned} \int_{\mathbb{R}^{m+n}} \alpha(\mathbf{x}, \mathbf{y}) d(\mu_X^* \times \mu_Y^*) &= \int_{\mathbb{R}^n} \int_{\mathbb{R}^m} \alpha(\mathbf{x}, \mathbf{y}) d\mu_Y d\mu_X^* \\ &= \int_{\mathbb{R}^n} \int_{\Omega} \alpha(\mathbf{x}, \mathbf{Y}) dP d\mu_X^* \\ &= \int_{\mathbb{R}^n} g(\mathbf{x}) d\mu_X^* = \int_A g(\mathbf{X}) dP_A, \end{aligned}$$

the proof is completed.

Remark Roughly speaking, the theorem says that, if the information \mathcal{P} is known, it follows that X is known (since X is \mathcal{P} -measurable) and then X is fixed, denoted by $X\mathcal{P}$. On the other hand, \mathcal{P} provides no information about Y . Consequently, the conditional expectation becomes the expectation in the normal sense, $E(\alpha(X\mathcal{P}, Y))$.

34.7 Appendix B: Uniform Strong Law of Large Number

This appendix proves two uniform strong laws of large number that are used for studying online stochastic DCA.

B.1 Uniform Strong Law of Large Number for a Sequence

In this section, we prove (34.16).

Let $\epsilon \in \mathbb{Q}^+$, there exists $\delta > 0$ such that

$$\forall z \in \mathcal{E}, \mathbf{w}, \mathbf{w}' \in S : \|\mathbf{w} - \mathbf{w}'\| < \delta, |g(\mathbf{w}, z) - g(\mathbf{w}', z)| < \epsilon.$$

By the axiom of choice, we fix the way of choosing δ , denoted by δ_ϵ , i.e, δ can be seen as a function of ϵ . This idea is helpful at the end of the proof.

Since $S \subset \cup_{\mathbf{w} \in S} B(\mathbf{w}, \delta_\epsilon)$ and S is compact, there are $\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_r \in S$ such that

$$S \subset \cup_{i=1}^r B(\mathbf{w}_i, \delta_\epsilon).$$

Again, we fix the way of choosing one set $\{\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_r\}$, denoted by $\mathcal{K}(\epsilon) = \{\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_r\}$.

Let $\Lambda := \cap_{k=1}^\infty (\mathbf{Z}_k \in \mathcal{E})$, then $P(\Lambda) = 1$.

Let $\omega \in \Lambda$, $p \in \mathbb{N}$ and $\mathbf{w} \in S$, there exists j in $\{1, 2, \dots, r\}$ such that $\mathbf{w} \in B(\mathbf{w}_j, r)$, it follows that

$$\begin{aligned} |p^{-1} \sum_{i=1}^p g(\mathbf{w}, \mathbf{Z}_i(\omega)) - E(g(\mathbf{w}, \mathbf{Z}))| &\leq |p^{-1} \sum_{i=1}^p g(\mathbf{w}_j, \mathbf{Z}_i(\omega)) \\ &\quad - E(g(\mathbf{w}_j, \mathbf{Z}))| + 2\epsilon. \end{aligned}$$

Therefore

$$\begin{aligned} &|p^{-1} \sum_{i=1}^p g(\mathbf{w}, \mathbf{Z}_i(\omega)) - E(g(\mathbf{w}, \mathbf{Z}))| \\ &\leq \max_{j=1, r} |p^{-1} \sum_{i=1}^p g(\mathbf{w}_j, \mathbf{Z}_i(\omega)) - E(g(\mathbf{w}_j, \mathbf{Z}))| + 2\epsilon. \end{aligned}$$

As a consequence

$$\begin{aligned} &\sup_{\mathbf{w} \in S} |p^{-1} \sum_{i=1}^p g(\mathbf{w}, \mathbf{Z}_i(\omega)) - E(g(\mathbf{w}, \mathbf{Z}))| \\ &\leq \max_{j=1, r} |p^{-1} \sum_{i=1}^p g(\mathbf{w}_j, \mathbf{Z}_i(\omega)) - E(g(\mathbf{w}_j, \mathbf{Z}))| + 2\epsilon. \quad (\text{B.1}) \end{aligned}$$

Let $\Lambda_\epsilon \subset \Lambda$ be a set of event ω satisfying

$$\max_{j=1, r} |p^{-1} \sum_{i=1}^p g(\mathbf{w}_j, \mathbf{Z}_i(\omega)) - E(g(\mathbf{w}_j, \mathbf{Z}))| \rightarrow 0.$$

Here we write Λ_ϵ to emphasize the dependence of $\{\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_r\}$ to ϵ . By strong law of large number, it follows that $P(\Lambda_\epsilon) = 1$. Let

$$\bar{\Lambda} = \cap_{\epsilon \in \mathbb{Q}^+} \Lambda_\epsilon,$$

then $P(\bar{\Lambda}) = 1$. We now prove

$$\forall \omega \in \bar{\Lambda}, \sup_{\mathbf{w} \in S} |p^{-1} \sum_{i=1}^p g(\mathbf{w}, \mathbf{Z}_i(\omega)) - E(g(\mathbf{w}, \mathbf{Z}))| \rightarrow 0.$$

Let $\eta > 0$, we choose $\epsilon \in \mathbb{Q}^+$ and $\epsilon < \frac{\eta}{3}$. We can recover the inequality (B.1) because the choice mappings are fixed from the beginning. On the other hand, there exists M such that $\forall p \geq M$,

$$\max_{j=1, r} |p^{-1} \sum_{i=1}^p g(\mathbf{w}_j, \mathbf{Z}_i(\omega)) - E(g(\mathbf{w}_j, \mathbf{Z}))| < \frac{\eta}{3}.$$

Therefore, for all $p \geq M$,

$$\sup_{\mathbf{w} \in S} |p^{-1} \sum_{i=1}^p g(\mathbf{w}, \mathbf{Z}_i(\omega)) - E(g(\mathbf{w}, \mathbf{Z}))| < \eta.$$

The proof is completed.

B.2 Uniform Strong Law of Large Number for Triangular Arrays

In this section, we prove (34.21),

$$\sup_{\mathbf{w} \in S} | \frac{1}{n_k} \sum_{i=1}^{n_k} g(\mathbf{w}, \mathbf{Z}_{k,i}) - E(g(\mathbf{w}, \mathbf{Z})) | \rightarrow 0 \text{ a.s.}$$

Let $\epsilon \in \mathbb{Q}^+$, there exists $\delta > 0$ such that

$$\forall z \in \mathcal{E}, \mathbf{w}, \mathbf{w}' \in S : \|\mathbf{w} - \mathbf{w}'\| < \delta, |g(\mathbf{w}, z) - g(\mathbf{w}', z)| < \epsilon.$$

We fix the way of choosing δ , denoted by δ_ϵ .

Since $S \subset \cup_{\mathbf{w} \in S} B(\mathbf{w}, \delta_\epsilon)$ and S is compact, there are $\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_r \in S$ such that

$$S \subset \cup_{i=1}^r B(\mathbf{w}_i, \delta_\epsilon).$$

We also fix the way of choosing the set $\{\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_r\}$, denoted by $\mathcal{K}(\epsilon) = \{\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_r\}$.

Let $\Lambda := \cap_{k=1}^\infty \cap_{i=1}^{n_k} (\mathbf{Z}_{k,i} \in \mathcal{E})$, then $P(\Lambda) = 1$.

Let $\omega \in \Lambda$, $k \in \mathbb{N}$ and $\mathbf{w} \in S$, there exists j in $\{1, 2, \dots, r\}$ such that $\mathbf{w} \in B(\mathbf{w}_j, r)$, it follows that

$$\begin{aligned} &|n_k^{-1} \sum_{i=1}^{n_k} g(\mathbf{w}, \mathbf{Z}_{k,i}(\omega)) - E(g(\mathbf{w}, \mathbf{Z}))| \leq |n_k^{-1} \sum_{i=1}^{n_k} \\ &g(\mathbf{w}_j, \mathbf{Z}_{k,i}(\omega)) - E(g(\mathbf{w}_j, \mathbf{Z}))| + 2\epsilon. \end{aligned}$$

Therefore

$$\begin{aligned} & \left| n_k^{-1} \sum_{i=1}^{n_k} g(\mathbf{w}, \mathbf{Z}_{k,i}(\omega)) - E(g(\mathbf{w}, \mathbf{Z})) \right| \\ & \leq \max_{j=1,r} | n_k^{-1} \sum_{i=1}^{n_k} g(\mathbf{w}_j, \mathbf{Z}_{k,i}(\omega)) - E(g(\mathbf{w}_j, \mathbf{Z})) | + 2\epsilon. \end{aligned}$$

As a consequence,

$$\begin{aligned} & \sup_{\mathbf{w} \in S} | n_k^{-1} \sum_{i=1}^{n_k} g(\mathbf{w}, \mathbf{Z}_{k,i}(\omega)) - E(g(\mathbf{w}, \mathbf{Z})) | \\ & \leq \max_{j=1,r} | n_k^{-1} \sum_{i=1}^{n_k} g(\mathbf{w}_j, \mathbf{Z}_{k,i}(\omega)) - E(g(\mathbf{w}_j, \mathbf{Z})) | + 2\epsilon. \end{aligned} \quad (\text{B.2})$$

Let $\Lambda_\epsilon \subset \Lambda$ be a set of event ω satisfying

$$\max_{j=1,r} | n_k^{-1} \sum_{i=1}^{n_k} g(\mathbf{w}_j, \mathbf{Z}_{k,i}(\omega)) - E(g(\mathbf{w}_j, \mathbf{Z})) | \rightarrow 0.$$

We show that $P(\Lambda_\epsilon) = 1$. Thus, for each j in $\{1, 2, \dots, r\}$,

$$E \left(\left| n_k^{-1} \sum_{i=1}^{n_k} g(\mathbf{w}_j, \mathbf{Z}_{k,i}) - E(g(\mathbf{w}_j, \mathbf{Z})) \right|^2 \right) \leq \frac{V(g(\mathbf{w}_j, \mathbf{Z}))}{n_k}.$$

Therefore

$$\begin{aligned} & E \left(\sum_{k=1}^{\infty} \left| n_k^{-1} \sum_{i=1}^{n_k} g(\mathbf{w}_j, \mathbf{Z}_{k,i}) - E(g(\mathbf{w}_j, \mathbf{Z})) \right|^2 \right) \\ & \leq V(g(\mathbf{w}_j, \mathbf{Z})) \sum_{k=1}^{\infty} \frac{1}{n_k} < \infty. \end{aligned}$$

It follows that

$$\left| n_k^{-1} \sum_{i=1}^{n_k} g(\mathbf{w}_j, \mathbf{Z}_{k,i}) - E(g(\mathbf{w}_j, \mathbf{Z})) \right| \rightarrow 0 \text{ a.s.}$$

As a consequence,

$$\max_{j=1,r} | n_k^{-1} \sum_{i=1}^{n_k} g(\mathbf{w}_j, \mathbf{Z}_{k,i}) - E(g(\mathbf{w}_j, \mathbf{Z})) | \rightarrow 0 \text{ a.s.}$$

Let $\bar{\Lambda} = \bigcap_{\epsilon \in \mathbb{Q}^+} \Lambda_\epsilon$, then $P(\bar{\Lambda}) = 1$. We now prove

$$\begin{aligned} & \forall \omega \in \bar{\Lambda}, \\ & \sup_{\mathbf{w} \in S} | n_k^{-1} \sum_{i=1}^{n_k} g(\mathbf{w}, \mathbf{Z}_{k,i}(\omega)) - E(g(\mathbf{w}, \mathbf{Z})) | \rightarrow 0. \end{aligned}$$

Let $\eta > 0$, we choose $\epsilon \in \mathbb{Q}^+$ and $\epsilon < \frac{\eta}{3}$. We can recover the inequality (B.2) because the choice mappings are fixed from the beginning. On the other hand, there exists M such that $\forall k \geq M$,

$$\max_{j=1,r} | n_k^{-1} \sum_{i=1}^{n_k} g(\mathbf{w}_j, \mathbf{Z}_{k,i}(\omega)) - E(g(\mathbf{w}_j, \mathbf{Z})) | < \frac{\eta}{3}.$$

Therefore, for all $k \geq M$,

$$\sup_{\mathbf{w} \in S} | n_k^{-1} \sum_{i=1}^{n_k} g(\mathbf{w}, \mathbf{Z}_{k,i}(\omega)) - E(g(\mathbf{w}, \mathbf{Z})) | < \eta.$$

The proof is completed.

Abstract

Coherent systems are widely studied in reliability experiments. Under the assumption that the components of a coherent system follow a two-parameter Weibull distribution, maximum likelihood inference for n -component coherent systems with known signatures under a simple step-stress model is discussed in this paper. The detailed steps of the stochastic expectation maximization algorithm under this setup are also developed to obtain estimates of the model parameters. Asymptotic confidence intervals for

the model parameters are constructed using the observed Fisher information matrix and missing information principle. Parametric bootstrap approach is used also to construct confidence intervals for the parameters. A method based on best linear unbiased estimators is developed to provide initial values that are needed for numerical computation of maximum likelihood estimates. The performance of the methods developed is assessed through an extensive Monte Carlo simulation study. Finally, two numerical examples are presented for illustrative purpose.

35.1 Introduction

Due to their high reliability, the products that are tested in different industrial experiments often have very large mean failure times under normal operating conditions. As a result, very few failures, if any, are observed in life testing experiments involving such products. Hence, due to lack of sufficient amount of information, efficient inference regarding the lifetimes of such units cannot be made even after employing sophisticated statistical methods for Type-I or Type-II censored data. One way out for this problem is to use accelerated testing procedures, wherein the units are subjected to higher stress level than normal, in order to accelerate their failures. For example, in order to assess the effect of temperature, load, voltage, etc., on the lifetimes of engineering products, an experimenter may use accelerated tests, which may then be performed using constant stress

or linearly increasing stress levels. Once the experiment accelerates the failures of the experimental units, the obtained data may then be extrapolated using appropriate techniques to estimate the underlying failure time distribution under normal operating conditions. This process requires a model relating the stress level and the failure time distribution. For details, one may see Nelson [1, 2], Nelson and Meeker [3], Meeker and Hahn [4], Meeker and Escobar [5], and Bagdonavicius and Nikulin [6].

The step-stress experiment is a special case of accelerated testing. Here, under an initial stress level, say s_0 , n identical units are placed on a life test. Then, at pre-fixed times $\tau_1, \tau_2, \dots, \tau_k$, the stress levels are increased to s_1, s_2, \dots, s_k , respectively. Under this condition, one may then fix Type-I or Type-II censoring scheme for termination of the experiment, and suitable methods may then be applied to make necessary inference. A simple step-stress model is the one with only two stress levels; it has been studied extensively in the literature. For example, Miller and Nelson [7] and Bai et al. [8] determined the optimal time at which the stress level is changed from the first to second; DeGroot and Goel [9] developed a Bayesian framework for optimal tests. More recently, the simple-stress experiment has been discussed extensively under different censoring schemes, for different lifetime models; see Balakrishnan et al. [10], Balakrishnan [11], Balakrishnan and Xie [12, 13], Han and Balakrishnan [14], Kateri and Balakrishnan [15], and the references therein.

Coherent systems in reliability analysis can be quite complex sometimes, having many different components with many different connections. The failure of such a system, clearly, depends on the failure of one or more of its components. The system signature of a coherent system is a purely distribution-free measure that has been widely used in the literature to develop statistical inference regarding system as well as component lifetime characteristics. For details regarding system signature-based statistical inference for coherent systems, see Samaniego [16] and Navarro et al. [17], among others. Recently, Balakrishnan et al. [18, 19] have analyzed the lifetime distribution of the components of coherent systems with known system signatures based on system-level failure time data, through linear and nonparametric statistical inferential techniques.

Suppose 200 components are placed in a simple step-stress life test with the change of stress at time τ . Instead of such a step-stress test on components, one may construct a step-stress life test based on some systems that have been formed with these components. For example, Table 35.1 shows the first 30 failures from 50 4-component coherent systems with the change of stress done at time $\tau=10$ hours. In this example, the probability a system will breakdown is $0, 1/2, 1/4$, and $1/4$ after the failure of the 1st, 2nd, 3rd, and 4th components, respectively. Then, it will be of interest to develop the estimation of model parameters based on such a system lifetime data. These estimates can be then used to estimate some reliability characteristics of systems and components as well. We may also be interested in comparing the efficiency of the tests based on systems instead of on components directly. Here, we assume the components are Weibull distributed and the signature of the system under consideration is known.

In this paper, we develop statistical inference for the lifetime distribution of components of coherent systems with known signatures based on system-level failure time data, when the coherent systems are put on a simple step-stress experiment. The components of a coherent system are assumed to follow, independently and identically, a Weibull distribution, which is a widely used lifetime model. In this regard, it may be mentioned that Kateri and Balakrishnan [15] developed inference for a simple step-stress model with Weibull distributed lifetimes, under Type-II censoring. Here, we develop likelihood inference for the model parameters under the abovementioned setup. We also develop asymptotic confidence intervals (CIs) for the parameters.

It can be easily understood that for such a complex model, explicit expressions for the maximum likelihood estimates (MLEs) cannot be obtained, and one has to use a numerical technique. We take two different approaches to estimate the parameters. The first approach is the direct method of maximizing the observed likelihood by Newton-Raphson method to obtain the numerical MLEs. The other approach is based on the stochastic expectation-maximization (St-EM) algorithm, for which we develop the problem from the perspective of incomplete data. The St-EM algorithm, originally proposed by Celeux and Diebolt [20], is a variant of the expectation-maximization (EM) algorithm proposed

Table 35.1 Failure time data of four-component coherent systems with signature vector $\mathbf{P} = (0, 1/2, 1/4, 1/4)$

Stress level	Failure times					
First	6.3767	7.1181	7.5412	8.1062	8.6519	8.8920
	9.4739	9.7148				
Second	10.0610	10.1218	10.2550	10.2824	10.4467	10.5271
	10.7169	10.7643	10.7677	10.8292	10.8777	10.9346

	11.3438	11.4184	11.4482	11.4770		

by Dempster et al. [21]. While the EM algorithm is a very powerful tool for analyzing incomplete data, the algorithm may get very complex sometimes when the required conditional expectations are difficult to obtain analytically. Moreover, it is well-known that the EM algorithm suffers from the existence of local optima [22]. The St-EM algorithm is one of the many variants of the EM algorithm that have been proposed to overcome the difficulties of the original EM algorithm. We develop the steps of the St-EM algorithm under this setup, to estimate the parameters.

For a numerical estimation of the parameters, one needs to give carefully chosen initial values, especially given the complex nature of the likelihood function to be optimized. We propose a technique to provide reasonable initial values for the algorithm. Then, through an extensive Monte Carlo simulation study, we examine the performance of the proposed methods of statistical inference.

The rest of this paper is organized as follows. In Sect. 35.2, we discuss the structure of the data and present the model. The likelihood function, derivation of the MLEs, and asymptotic CIs for the parameters are discussed in Sect. 35.3. Formulating this problem as an incomplete data problem, we also present the steps of the St-EM algorithm under this setup in this section and discuss construction of asymptotic confidence intervals for the model parameters within the framework of the St-EM algorithm. In addition, this section also contains a discussion on the choice of initial values. Finally, construction of asymptotic confidence intervals for the model parameters by the observed Fisher information matrix, missing information principle, and parametric bootstrap technique are discussed in this section. We present an outline of Bayesian analysis under this setup in Sect. 35.4. In Sect. 35.5, we present the numerical results of a detailed simulation study to assess and compare the performances of the inferential methods presented in this paper. A numerical example for illustrative purpose is presented in Sect. 35.6. Finally, we conclude the paper with some comments in Sect. 35.7.

35.2 A Simple Step-Stress Model for Coherent Systems

Let there be m coherent systems, each with n components. Let T denote the lifetime of a coherent system, and let X_1, \dots, X_n denote the lifetimes of its components, which are assumed to be independently and identically (i.i.d.) distributed with probability density function (PDF) $f_X(\cdot)$ and cumulative distribution function (CDF) $F_X(\cdot)$. Let $S_X(\cdot)$ denote the survival function (SF) of the component lifetime distribution.

Then, the system signature of a coherent system is given by \mathbf{p} , where $\mathbf{p} = (p_1, \dots, p_n)'$ with

$$p_i = P(T = X_{i:n}), \quad i = 1, 2, \dots, n,$$

$X_{i:n}$ being the i -th smallest order statistic arising out of X_1, \dots, X_n . Clearly, we have

- (i) $p_i \geq 0, \forall i$,
- (ii) p_i 's do not depend on the component lifetime distribution, and
- (iii) $\sum_{i=1}^n p_i = 1$;

see Samaniego [16] for a detailed discussion on system signatures.

Equivalent to the system signature, one can define the minimal signature $\mathbf{a} = (a_1, \dots, a_n)$, with a_i 's being negative and non-negative quantities satisfying $\sum_{i=1}^n a_i = 1$; see Navarro et al. [23]. The system signature \mathbf{p} and minimal signature \mathbf{a} are related by

$$a_i = \frac{1}{i} \sum_{j=1}^n j(-1)^{i+j-n-1} \binom{j-1}{n-i} p_j \binom{n}{j}, \quad i = 1, 2, \dots, n.$$

The PDF $f_T(\cdot)$ and SF $S_T(\cdot)$ of the system lifetime T can be expressed as a mixture of distributions of order statistics arising from the component lifetimes in the system as follows (see Samaniego [24] and Kochar et al. [25]):

$$f_T(t) = \sum_{i=1}^n p_i f_{i:n}(t),$$

$$S_T(t) = \sum_{i=1}^n p_i S_{i:n}(t),$$

where $f_{i:n}(\cdot)$ and $S_{i:n}(\cdot)$ are the PDF and SF of the i -th order statistic $X_{i:n}$ arising out of X_1, \dots, X_n , given by

$$f_{i:n}(t) = \binom{n}{i} i f_X(t) [F_X(t)]^{i-1} [S_X(t)]^{n-i},$$

$$S_{i:n}(t) = \sum_{j=0}^{i-1} \binom{n}{j} [F_X(t)]^j [S_X(t)]^{n-j};$$

see Arnold et al. [26].

Using minimal signature, similarly, the distribution of T can be expressed as a generalized mixture of distributions of order statistics arising from the component lifetimes. Precisely, the PDF and SF of T can be expressed using the minimal signature as (see Navarro et al. [23])

$$f_T(t) = \sum_{i=1}^n a_i f_{1:i}(t) = \sum_{i=1}^n a_i i f_X(t) [S_X(t)]^{i-1},$$

$$S_T(t) = \sum_{i=1}^n a_i S_{1:i}(t) = \sum_{i=1}^n a_i [S_X(t)]^i.$$

Suppose $m n$ -component coherent systems are placed on a simple step-stress experiment with stress levels s_1 and s_2 and with τ being the time point at which the stress level changes from s_1 to s_2 . In practice, the experimenter will often have failure time data at the system level, i.e., he/she observes failure times of systems, rather than their components. Also, due to time constraint on the test, one always observes censored data. We assume Type-II censoring, or failure censoring, here; that is, the experiment is terminated when r system failures are observed. Let n_1 be the random number of system failures observed before time τ (i.e., at stress level s_1) and $n_2 = r - n_1$ be the random number of system failures observed after time τ (i.e., at stress level s_2). The observed Type-II censored data are then represented by the ordered system failure times

$$t_{1:m} < t_{2:m} < \dots < t_{r:m}.$$

As mentioned earlier, in a step-stress experiment, a model relates the stress level and the failure time distribution. Here, we assume the well-known cumulative exposure model; see Nelson [2]. We assume that the lifetime of a component of a system follows Weibull distribution with scale parameters θ_1 and θ_2 and a common shape parameter β , under stress levels s_1 and s_2 , respectively. Then, under the assumption of cumulative exposure model, the CDF of the lifetime of a component of a system is given by

$$F_X(t) = \begin{cases} F_1(t), & 0 < t < \tau, \\ F_2\left(\frac{\theta_2}{\theta_1}\tau + t - \tau\right), & \tau \leq t < \infty, \end{cases} \quad (35.1)$$

where $F_j(x) = 1 - e^{-(x/\theta_j)^\beta}$, with $x > 0$, $\theta_j > 0$, $\beta > 0$ $j = 1, 2$. Correspondingly, the PDF of a component is given by

$$f_X(t) = \begin{cases} \frac{\beta}{\theta_1^\beta} t^{\beta-1} e^{-(t/\theta_1)^\beta}, & 0 < t < \tau, \\ \frac{\beta}{\theta_2^\beta} \left(\frac{\theta_2}{\theta_1}\tau + t - \tau\right)^{\beta-1} e^{-\left(\frac{\theta_2}{\theta_1}\tau + t - \tau\right)^\beta}, & \tau \leq t < \infty. \end{cases} \quad (35.2)$$

The following propositions are necessary for the completeness of the model and the subsequent developments on inference.

Proposition 2.1 *Suppose the component lifetimes are Weibull distributed. Then, if a simple step-stress life test is conducted on a coherent system with lifetime T under the cumulative exposure model, it is equivalent to conducting a simple step-stress test on its components with lifetimes X_i 's, under the cumulative exposure model.*

Proof. If $F_{T,1}(\cdot)$ and $F_{T,2}(\cdot)$ are the CDFs of the system lifetime T under the first and second stress levels, respectively, then from (35.1) we have

$$\begin{aligned} F_T(t) &= \begin{cases} F_{T,1}(t), & 0 < t < \tau, \\ F_{T,2}\left(\frac{\theta_2}{\theta_1}\tau + t - \tau\right), & \tau \leq t < \infty, \end{cases} \\ &= \begin{cases} \sum_{i=1}^n p_i F_{i:n}(t), & 0 < t < \tau, \\ \sum_{i=1}^n p_i F_{i:n}\left(\frac{\theta_2}{\theta_1}\tau + t - \tau\right), & \tau \leq t < \infty, \end{cases} \\ &= \begin{cases} \sum_{i=1}^n p_i \sum_{j=i}^n \binom{n}{j} [F_X(t)]^j [S_X(t)]^{n-j}, & 0 < t < \tau, \\ \sum_{i=1}^n p_i \sum_{j=i}^n \binom{n}{j} \left[F_X\left(\frac{\theta_2}{\theta_1}\tau + t - \tau\right)\right]^j \\ \left[S_X\left(\frac{\theta_2}{\theta_1}\tau + t - \tau\right)\right]^{n-j}, & \tau \leq t < \infty. \end{cases} \end{aligned}$$

From above, the required result follows. ■

Proposition 2.2 *Under a simple step-stress life testing experiment on a coherent system with lifetime T and a Weibull component lifetime distribution as in (35.2), the SF of T is a non-decreasing function of θ_2 .*

Proof. Evidently,

$$\frac{\partial S_T(t; \theta_1, \theta_2, \beta)}{\partial \theta_2} = \begin{cases} 0, & 0 < t < \tau, \\ \frac{t-\tau}{\theta_2} f_T(t, \theta_1, \theta_2, \beta) > 0, & \tau \leq t < \infty, \end{cases}$$

which proves the required result. ■

35.3 Likelihood Inference

35.3.1 Direct Maximization of the Observed Likelihood

The statistical inference developed here assumes that the system signatures (or equivalently, minimal signatures) are available. Based on the observed ordered Type-II censored lifetimes of systems $t_{1:m} < \dots < t_{r:m}$ arising out of the m systems, the likelihood function can be written for different values of the random number of failures n_1 : (i) $n_1 = r$, i.e., all the r failures are observed in the first stress level s_1 , (ii) $n_1 = 0$, i.e., all the r failures are observed in the second stress level s_2 , and (iii) $1 \leq n_1 \leq r - 1$. We present the likelihood function below for these three cases under a simple step-stress model:

Case (i): $n_1 = r$

$$L(\theta) = C \prod_{k=1}^r \left[\sum_{i=1}^n a_i f_X(t_{k:m}) \{S_X(t_{k:m})\}^{i-1} \right] \left[\sum_{i=1}^n a_i \{S_X(t_{r:m})\}^i \right]^{m-r};$$

Case (ii): $n_1 = 0$

$$L(\theta) = C \prod_{k=1}^r \left[\sum_{i=1}^n a_i f_X(t_{k:m}) \{S_X(t_{k:m})\}^{i-1} \right] \left[\sum_{i=1}^n a_i \{S_X(t_{r:m})\}^i \right]^{m-r};$$

Case (iii): $1 \leq n_1 \leq r - 1$

$$L(\theta) = C \prod_{k=1}^{n_1} \left[\sum_{i=1}^n a_i f_X(t_{k:m}) \{S_X(t_{k:m})\}^{i-1} \right] \times \prod_{k=n_1+1}^r \left[\sum_{i=1}^n a_i f_X(t_{k:m}) \{S_X(t_{k:m})\}^{i-1} \right] \left[\sum_{i=1}^n a_i \{S_X(t_{r:m})\}^i \right]^{m-r},$$

where $C = \frac{m!}{(m-r)!}$ and θ is the parameter vector of the component lifetime distribution. Since we have assumed that the components of the systems are Weibull distributed, the likelihood function takes the following forms for the three cases; here, we have $\theta = (\theta_1, \theta_2, \beta)$:

Case (i): $n_1 = r$

$$L(\theta) = C \left(\frac{\beta}{\theta_1^\beta} \right)^r \prod_{k=1}^r \left[t_{k:m}^{\beta-1} \sum_{i=1}^n a_i i e^{-i(t_{k:m}/\theta_1)^\beta} \right] \left[\sum_{i=1}^n a_i e^{-i(t_{r:m}/\theta_1)^\beta} \right]^{m-r}; \quad (35.3)$$

Case (ii): $n_1 = 0$

$$L(\theta) = C \left(\frac{\beta}{\theta_2^\beta} \right)^r \prod_{k=1}^r \left[\left(\frac{\theta_2}{\theta_1} \tau + t_{k:m} - \tau \right)^{\beta-1} \sum_{i=1}^n a_i i e^{-i \left(\frac{\theta_2}{\theta_1} \tau + t_{k:m} - \tau \right)^\beta} \right] \times \left[\sum_{i=1}^n a_i e^{-i \left(\frac{\theta_2}{\theta_1} \tau + t_{r:m} - \tau \right)^\beta} \right]^{m-r}; \quad (35.4)$$

Case (iii): $1 \leq n_1 \leq r - 1$

$$L(\theta) = C \left(\frac{\beta}{\theta_1^\beta} \right)^{n_1} \prod_{k=1}^{n_1} \left[t_{k:m}^{\beta-1} \sum_{i=1}^n a_i i e^{-i(t_{k:m}/\theta_1)^\beta} \right]$$

$$\times \left(\frac{\beta}{\theta_2^\beta} \right)^{r-n_1} \prod_{k=n_1+1}^r \left[\left(\frac{\theta_2}{\theta_1} \tau + t_{k:m} - \tau \right)^{\beta-1} \sum_{i=1}^n a_i i e^{-i \left(\frac{\theta_2}{\theta_1} \tau + t_{k:m} - \tau \right)^\beta} \right] \times \left[\sum_{i=1}^n a_i e^{-i \left(\frac{\theta_2}{\theta_1} \tau + t_{r:m} - \tau \right)^\beta} \right]^{m-r}. \quad (35.5)$$

Note that MLE of θ_2 does not exist in Case (i). So, we shall consider the case $0 \leq n_1 \leq r - 1$ to obtain the MLEs; note that this includes both Cases (ii) and (iii). The log-likelihood function becomes

$$\begin{aligned} \log L(\theta) &= C + r \log \beta - n_1 \beta \log \theta_1 - (r - n_1) \beta \log \theta_2 \\ &+ \sum_{k=1}^{n_1} \left[(\beta - 1) \log t_{k:m} \right. \\ &+ \left. \log \left(\sum_{i=1}^n a_i i e^{-i(t_{k:m}/\theta_1)^\beta} \right) \right] \\ &+ \sum_{k=n_1+1}^r \left[(\beta - 1) \log \left(\frac{\theta_2}{\theta_1} \tau + t_{k:m} - \tau \right) \right. \\ &+ \left. \log \left(\sum_{i=1}^n a_i i e^{-i \left(\frac{\theta_2}{\theta_1} \tau + t_{k:m} - \tau \right)^\beta} \right) \right] \\ &+ (m - r) \log \left(\sum_{i=1}^n a_i e^{-i \left(\frac{\theta_2}{\theta_1} \tau + t_{r:m} - \tau \right)^\beta} \right). \quad (35.6) \end{aligned}$$

From the log-likelihood function in (35.6), we get the first-order derivatives as follows:

$$\begin{aligned} \frac{\partial \log L}{\partial \theta_1} &= -\frac{n_1 \beta}{\theta_1} + \sum_{k=1}^{n_1} \left[\frac{\beta t_{k:m}^\beta \sum_{i=1}^n a_i i^2 e^{-i(t_{k:m}/\theta_1)^\beta}}{\theta_1^{\beta+1} \sum_{i=1}^n a_i i e^{-i(t_{k:m}/\theta_1)^\beta}} \right] \\ &- \frac{\theta_2 \tau}{\theta_1^2} \sum_{k=n_1+1}^r \left[\frac{\beta - 1}{\left(\frac{\theta_2}{\theta_1} \tau + t_{k:m} - \tau \right)} \right. \\ &- \left. \frac{\beta}{\theta_2^\beta} \left(\frac{\theta_2}{\theta_1} \tau + t_{k:m} - \tau \right)^{\beta-1} \frac{\sum_{i=1}^n a_i i^2 e^{-i \left(\frac{\theta_2}{\theta_1} \tau + t_{k:m} - \tau \right)^\beta}}{\sum_{i=1}^n a_i i e^{-i \left(\frac{\theta_2}{\theta_1} \tau + t_{k:m} - \tau \right)^\beta}} \right] \end{aligned}$$

$$+ (m-r) \frac{\beta}{\theta_2^\beta} \left(\frac{\theta_2}{\theta_1} \tau + t_{r:m} - \tau \right)^{\beta-1} \frac{\sum_{i=1}^n a_i i e^{-i \left(\frac{\theta_2}{\theta_1} \tau + t_{r:m} - \tau \right) / \theta_2}^\beta}{\sum_{i=1}^n a_i i e^{-i \left(\frac{\theta_2}{\theta_1} \tau + t_{r:m} - \tau \right) / \theta_2}^\beta} \right], \quad (35.7)$$

$$\begin{aligned} \frac{\partial \log L}{\partial \theta_2} &= -\frac{(r-n_1)\beta}{\theta_2} + \sum_{k=n_1+1}^r \left[\frac{(\beta-1)\frac{\tau}{\theta_1}}{\left(\frac{\theta_2}{\theta_1} \tau + t_{k:m} - \tau \right)} + \beta \left(\frac{\theta_2}{\theta_1} \tau + t_{k:m} - \tau \right)^{\beta-1} \right. \\ &\quad \times \left. \left(\frac{t_{k:m} - \tau}{\theta_2^2} \right) \frac{\sum_{i=1}^n a_i i^2 e^{-i \left(\frac{\theta_2}{\theta_1} \tau + t_{k:m} - \tau \right) / \theta_2}^\beta}{\sum_{i=1}^n a_i i e^{-i \left(\frac{\theta_2}{\theta_1} \tau + t_{k:m} - \tau \right) / \theta_2}^\beta} \right] \\ &\quad + (m-r)\beta \left(\frac{\theta_2}{\theta_1} \tau + t_{r:m} - \tau \right)^{\beta-1} \left(\frac{t_{r:m} - \tau}{\theta_2^2} \right) \\ &\quad \times \frac{\sum_{i=1}^n a_i i e^{-i \left(\frac{\theta_2}{\theta_1} \tau + t_{r:m} - \tau \right) / \theta_2}^\beta}{\sum_{i=1}^n a_i i e^{-i \left(\frac{\theta_2}{\theta_1} \tau + t_{r:m} - \tau \right) / \theta_2}^\beta}, \end{aligned} \quad (35.8)$$

$$\begin{aligned} \frac{\partial \log L}{\partial \beta} &= \frac{r}{\beta} - n_1 \log \theta_1 - (r-n_1) \log \theta_2 \\ &\quad + \sum_{k=1}^{n_1} \left[\log t_{k:m} - \left(\frac{t_{k:m}}{\theta_1} \right)^\beta \log \left(\frac{t_{k:m}}{\theta_1} \right) \frac{\sum_{i=1}^n a_i i^2 e^{-i(t_{k:m}/\theta_1)^\beta}}{\sum_{i=1}^n a_i i e^{-i(t_{k:m}/\theta_1)^\beta}} \right] \\ &\quad + \sum_{k=n_1+1}^r \left[\log \left(\frac{\theta_2}{\theta_1} \tau + t_{k:m} - \tau \right) - \left(\frac{\theta_2}{\theta_1} \tau + t_{k:m} - \tau \right)^\beta \right. \\ &\quad \times \left. \log \left(\frac{\theta_2}{\theta_1} \tau + t_{k:m} - \tau \right) \frac{\sum_{i=1}^n a_i i^2 e^{-i \left(\frac{\theta_2}{\theta_1} \tau + t_{k:m} - \tau \right) / \theta_2}^\beta}{\sum_{i=1}^n a_i i e^{-i \left(\frac{\theta_2}{\theta_1} \tau + t_{k:m} - \tau \right) / \theta_2}^\beta} \right] \\ &\quad - (m-r) \left(\frac{\theta_2}{\theta_1} \tau + t_{r:m} - \tau \right)^\beta \log \left(\frac{\theta_2}{\theta_1} \tau + t_{r:m} - \tau \right) \\ &\quad \times \frac{\sum_{i=1}^n a_i i e^{-i \left(\frac{\theta_2}{\theta_1} \tau + t_{r:m} - \tau \right) / \theta_2}^\beta}{\sum_{i=1}^n a_i i e^{-i \left(\frac{\theta_2}{\theta_1} \tau + t_{r:m} - \tau \right) / \theta_2}^\beta}. \end{aligned} \quad (35.9)$$

Equating expressions (35.7)–(35.9) to zero and then solving these likelihood equations, we get the MLEs. It is clear from the expressions in (35.7)–(35.9) that the MLEs are not available in explicit form, and one has to employ numerical techniques, such as Newton-Raphson method, to obtain the MLE, which we denote by $\hat{\theta}$. For an iterative algorithm like Newton-Raphson, at each stage i we get an estimate $\hat{\theta}_{(i)}$ and stop at a stage l when two successive estimates at stages l and $l - 1$ are such that $|\hat{\theta}_{(l)} - \hat{\theta}_{(l-1)}| < \epsilon$, for a pre-fixed $\epsilon > 0$.

35.3.2 Estimation Using the St-EM Algorithm

Because of its stochastic nature, the St-EM algorithm can avoid some of the common pitfalls of the traditional EM algorithm. For example, to implement St-EM algorithm, it is not required to obtain the complex conditional expectations that may arise in an incomplete data problem; only the appropriate conditional distributions need to be identified. Also, the sequence of estimates obtained through St-EM algorithm does not get trapped into saddle points, if they exist, unlike the EM algorithm [27]. After it was proposed by Celeux and Diebolt [20], many researchers have investigated the St-EM algorithm in further detail and have applied it successfully to various incomplete data problems; see Celeux et al [28], Chauveau [29], Diebolt and Celeux [30], and Nielsen [31].

Broadly speaking, the St-EM algorithm has two steps – the stochastic expectation (St-E) step and the maximization (M) step. Given the observed data and current values of the parameters, random observations are generated from appropriate conditional distributions to replace the unobserved (or censored) data in the St-E step. Then, with the pseudo-complete data thus obtained, the pseudo-complete likelihood is constructed and is maximized to obtain updated estimates of the parameters in the M-step. The St-E and the M-steps are then iterated for sufficiently large number of times.

To implement St-EM algorithm, one needs to construct the pseudo-complete likelihood with the pseudo-complete data as obtained from the St-E step. To construct the pseudo-complete likelihood, in this section we follow the earlier formulation of the problem as detailed in Sect. 35.3.1. Keeping the symbols unchanged, we need to consider the following three cases: (i) $n_1 = r$, (ii) $n_1 = 0$, and (iii) $1 \leq n_1 \leq r - 1$. For these three cases, the pseudo-complete likelihood is as follows:

Case (i): $n_1 = r$

$$L_{PC}(\theta) = \prod_{j=1}^m \left\{ \sum_{i=1}^n a_i f_X(t_{j:m}) \{S_X(t_{j:m})\}^{i-1} \right\}$$

Case (ii): $n_1 = 0$

$$L_{PC}(\theta) = \prod_{j=1}^m \left\{ \sum_{i=1}^n a_i f_X(t_{j:m}) \{S_X(t_{j:m})\}^{i-1} \right\}$$

Case (iii): $1 \leq n_1 \leq r - 1$

$$L_{PC}(\theta) = \prod_{j=1}^{n_1} \left\{ \sum_{i=1}^n a_i f_X(t_{j:m}) \{S_X(t_{j:m})\}^{i-1} \right\} \times \prod_{j=n_1+1}^m \left\{ \sum_{i=1}^n a_i f_X(t_{j:m}) \{S_X(t_{j:m})\}^{i-1} \right\}$$

The St-EM algorithm under this setup takes the following shape:

Algorithm: At the l -th stage of the algorithm:

The St-E step:

- (1) Based on the value of n_1 , generate $m - r$ system lifetimes from the appropriate conditional distribution with CDF $F_T(t|r_{r:m}, \theta^l)$, where θ is the appropriate parameter vector.
- (2) Using the generated data, order the pseudo-complete data $t_{1:m} < \dots < t_{r:m} < t_{r+1:m}^g < \dots < t_{m:m}^g$, where the superscript (g) indicates the randomly generated observations.
- (3) Using the pseudo-complete data, construct the pseudo-complete likelihood depending on the value of n_1 , according to the cases (i), (ii), and (iii) as mentioned above.

The M-step: Maximize the pseudo-complete likelihood as obtained the St-E step to obtain updated estimate of the parameter vector, i.e., θ^{l+1} .

The St-E and M-steps are then repeated for N number of times, to obtain sequences of estimates for the parameters, i.e., $(\hat{\theta}_{11}, \hat{\theta}_{12}, \dots, \hat{\theta}_{1N})$, $(\hat{\theta}_{21}, \hat{\theta}_{22}, \dots, \hat{\theta}_{2N})$, and $(\hat{\beta}_1, \hat{\beta}_2, \dots, \hat{\beta}_N)$. Finally, after discarding first N_1 estimates for each of them for burn-in, we select every 5th value from these sequences starting from $(N_1 + 1)$ -th value till the N -th value and average over the selected values to get the final estimates of θ_1 , θ_2 and β . Every 5th value starting from the $(N_1 + 1)$ th value is selected to eliminate the auto-correlation, if any, among the successive values.

The conditional distributions required in the St-E step are as follows:

Case (i): $n_1 = r$

$$F_T(t|r_{r:m}, \theta) = \frac{F_{T,1}(t) - F_{T,1}(t_{r:m})}{1 - F_{T,1}(t_{r:m})}, \quad t > t_{r:m}, \quad (35.10)$$

Case (ii): $n_1 = 0$

$$F_T(t|r_{r:m}, \theta) = \frac{F_{T,2}(t) - F_{T,2}(t_{r:m})}{1 - F_{T,2}(t_{r:m})}, \quad t > t_{r:m}, \quad (35.11)$$

Case (iii): $1 \leq n_1 \leq r - 1$

$$F_T(t|t_{r:m}, \theta) = \frac{F_{T,2}(t) - F_{T,2}(t_{r:m})}{1 - F_{T,2}(t_{r:m})}, \quad t > t_{r:m}, \quad (35.12)$$

where $F_{T,1}(\cdot)$ and $F_{T,2}(\cdot)$ are as described in Proposition 2.1. If the denominator is extremely close to 0, for example, $< 10^{-8}$, we then conclude the estimates diverge.

As Ye and Ng [27] mentioned, the experimenter should choose the values of N and N_1 wisely. In particular, N should be sufficiently large so that the final estimates obtained from the St-EM algorithm closely resemble the MLEs of the model parameters. In the simulation, we choose $N_1 = 304$ and $N = 800$.

$$U_{j:m} = \begin{cases} \ln \left(\frac{T_{j:m}}{\theta_1} \right), & T_{j:m} < \tau, \\ \ln \left(\frac{T_{j:m} - \tau}{\theta_2} + \frac{\tau}{\theta_1} \right), & T_{j:m} > \tau, \end{cases} \quad (35.13)$$

and denote $\mathbf{U}_1 = (U_{1:m}, \dots, U_{n_1:m})'$ and $\mathbf{U}_2 = (U_{n_1+1:m}, \dots, U_{r:m})'$. By neglecting the fact that all entries in \mathbf{U}_1 are less than $\ln \tau/\theta_1$, we treat \mathbf{U}_1 as an ordinary Type-II censored sample from extreme-value distribution with location parameter $\mu = \ln \theta_1$ and scale parameter $\sigma = \frac{1}{\beta}$, and do similarly for \mathbf{U}_2 . Let us further denote $\boldsymbol{\mu}_1 = (\mu_{1:m}, \dots, \mu_{n_1:m})'$, $\boldsymbol{\mu}_2 = (\mu_{n_1+1:m}, \dots, \mu_{r:m})'$, $\boldsymbol{\Sigma}_1 = ((\sigma_{i,j:m}))$ for $i, j = 1, \dots, n_1$, $\boldsymbol{\Sigma}_2 = ((\sigma_{i,j:m}))$ for $i, j = n_1 + 1, \dots, r$, where $\mu_{j:m} = E(U_{j:m})$ and $\sigma_{i,j:m} = \text{cov}(U_{i:m}, U_{j:m})$. Balakrishnan et al. [18] derived the following expressions for n -component extreme-value distributed coherent system lifetimes:

35.3.3 Providing Initial Values to the Algorithm

In this subsection, we propose initial values by using best linear unbiased estimators (BLUEs) and moment estimates under the condition $1 \leq n_1 \leq r - 1$. Now, let

$$\begin{aligned} \mu_{1:m} &= m \sum_{\substack{j_1, \dots, j_n \geq 0 \\ j_1 + \dots + j_n = m-1}} \binom{m-1}{j_1, \dots, j_n} a_1^{j_1} \dots a_n^{j_n} \\ &\times \sum_{i=1}^n \frac{a_i i [-\gamma - \ln(j_1 + 2j_2 + \dots + nj_n + i)]}{(j_1 + 2j_2 + \dots + nj_n + i)}, \end{aligned} \quad (35.14)$$

$$\begin{aligned} \mu_{1:m}^{(2)} &= m \sum_{\substack{j_1, \dots, j_n \geq 0 \\ j_1 + \dots + j_n = m-1}} \binom{m-1}{j_1, \dots, j_n} a_1^{j_1} \dots a_n^{j_n} \\ &\times \sum_{i=1}^n \frac{a_i i \left\{ \frac{\pi^2}{6} + [\gamma + \ln(j_1 + 2j_2 + \dots + nj_n + i)]^2 \right\}}{(j_1 + 2j_2 + \dots + nj_n + i)}, \end{aligned} \quad (35.15)$$

$$\begin{aligned} \mu_{s,s+1:m} &= \frac{m!}{(s-1)!(m-s-1)!} \sum_{l=0}^{s-1} (-1)^l \binom{s-1}{l} \sum_{\substack{k_1, \dots, k_n \geq 0 \\ k_1 + \dots + k_n = l}} \binom{l}{k_1, \dots, k_n} \\ &\times \sum_{\substack{j_1, \dots, j_n \geq 0 \\ j_1 + \dots + j_n = m-s-1}} \binom{m-s-1}{j_1, \dots, j_n} a_1^{j_1+k_1} \dots a_n^{j_n+k_n} \sum_{i=1}^n \sum_{i'=1}^n a_i a_{i'} i i' \phi(\delta, \alpha), \end{aligned} \quad (35.16)$$

where $\mu_{j:m}^{(2)} = E[(U_{j:m})^2]$, $\mu_{i,j:m} = E(U_{i:m} U_{j:m}^*)$, $\gamma = 0.57721566490 \dots$ is the Euler-Mascheroni constant, $\delta = k_1 + 2k_2 + \dots + nk_n + i$, $\alpha = j_1 + 2j_2 + \dots + nj_n + i'$, and

We can then find all the values of $\boldsymbol{\mu}_1$, $\boldsymbol{\mu}_2$, $\boldsymbol{\Sigma}_1$, and $\boldsymbol{\Sigma}_2$, by further using the well-known triangle and rectangle rules for moments of order statistics (see Arnold et al. [26]), as

$$\begin{aligned} \phi(\delta, \alpha) &= \int_{-\infty}^{\infty} \int_{-\infty}^u t u e^{t-\delta e^t} e^{u-\alpha e^u} dt du, \\ s\mu_{s+1:m}^{(l)} + (m-s)\mu_{s:m}^{(l)} &= m\mu_{s:m-1}^{(l)}, \\ s &= 1, 2, \dots, m-1, l = 1, 2, \end{aligned} \quad (35.17)$$

$$\begin{aligned}
 (i-1)\mu_{i,j:m} + (j-i)\mu_{i-1,j:m} + (m-j+1)\mu_{i-1,j-1:m} \\
 = m\mu_{i-1,j-1:m-1}, \\
 2 \leq i < j \leq m. \quad (35.18)
 \end{aligned}$$

By using the transferred data $U_1 = (U_{1:m}, \dots, U_{n_1:m})$ obtained from the first stress level, we then have the BLUEs of μ and σ as

$$\tilde{\mu} = \mu'_1 \Gamma U_1 \quad \text{and} \quad \tilde{\sigma} = -\mathbf{1}' \Gamma U_1, \quad (35.19)$$

where

$$\Gamma = \frac{\Sigma_1^{-1} (\mu_1 \mathbf{1}' - \mathbf{1} \mu'_1) \Sigma_1^{-1}}{(\mu'_1 \Sigma_1^{-1} \mu_1) (\mathbf{1}' \Sigma_1^{-1} \mathbf{1}) - (\mu'_1 \Sigma_1^{-1} \mathbf{1})^2}.$$

Using these, we obtain the initial values of θ_1 and β as

$$\tilde{\theta}_1 = e^{\tilde{\mu}} \quad \text{and} \quad \tilde{\beta} = \tilde{\sigma}^{-1}. \quad (35.20)$$

At the second stress level, we replace θ_1, β by $\tilde{\theta}_1$ and $\tilde{\beta}$. Now, by equating

$$\begin{aligned}
 \sum_{i=n_1+1}^r (m-i+1) \left(\frac{T_{i:m} - \tau}{\theta_2} + \frac{\tau}{\tilde{\theta}_1} \right) \\
 = \sum_{i=n_1+1}^r (m-i+1) e^{\frac{\mu_{i:m}}{\tilde{\beta}}}, \quad (35.21)
 \end{aligned}$$

we then obtain the estimate of θ_2 as

$$\tilde{\theta}_2 = \frac{\sum_{i=n_1+1}^r (m-i+1)(T_{i:m} - \tau)}{\sum_{i=n_1+1}^r (m-i+1) \left(e^{\frac{\mu_{i:m}}{\tilde{\beta}}} - \frac{\tau}{\tilde{\theta}_1} \right)}. \quad (35.22)$$

To provide the initial values in the case when $n_1=1$, one can use the following two equations

$$\begin{aligned}
 \ln T_{1:m} = \frac{1}{\tilde{\beta}} \mu_{1:m} + \ln \theta_1 \quad \text{and} \\
 S_T(\tau) = \frac{m}{m+1}, \quad (35.23)
 \end{aligned}$$

where $S_T(\cdot)$ is as defined before and then use the above procedure to obtain the estimate of θ_2 . When $n_1 = 0$, one can simply take $\tilde{\theta}_1 = \tau$ and $\tilde{\beta} = 1$ and, then by using them, can proceed to obtain $\tilde{\theta}_2$ as described above.

35.3.4 Confidence Intervals

Observed Fisher Information Matrix

From the asymptotic properties of MLEs, it is known that as $m \rightarrow \infty$, we have

$$\sqrt{m}(\hat{\theta} - \theta) \xrightarrow{D} N(\mathbf{0}, \mathbf{I}^{-1}(\theta)),$$

where $\mathbf{I}(\theta)$ is estimated by the observed information matrix. Then, one can easily construct asymptotic CIs for the model parameters. The observed information matrix is given by

$$I_{obs}(\theta) = \begin{pmatrix} -\frac{\partial^2 \log L}{\partial \theta_1^2} & -\frac{\partial^2 \log L}{\partial \theta_1 \partial \theta_2} & -\frac{\partial^2 \log L}{\partial \theta_1 \partial \beta} \\ -\frac{\partial^2 \log L}{\partial \theta_2 \partial \theta_1} & -\frac{\partial^2 \log L}{\partial \theta_2^2} & -\frac{\partial^2 \log L}{\partial \theta_2 \partial \beta} \\ -\frac{\partial^2 \log L}{\partial \beta \partial \theta_1} & -\frac{\partial^2 \log L}{\partial \beta \partial \theta_2} & -\frac{\partial^2 \log L}{\partial \beta^2} \end{pmatrix}_{\theta=\hat{\theta}}.$$

The elements of the observed information matrix are presented in the Appendix.

Missing Information Principle

Louis's [32] missing information principle is a commonly used technique to obtain asymptotic variance-covariance matrix of the MLEs within the EM algorithm framework. Ye and Ng [27] adopted the missing information principle successfully within the framework of the St-EM algorithm. We follow Ye and Ng's [27] approach to construct the asymptotic variance-covariance matrix of the parameter estimates obtained by the St-EM algorithm.

Let the pseudo-complete data be denoted by

$$\mathbf{t}_{pc} = \mathbf{t} \cup \mathbf{t}^{(g)},$$

where $\mathbf{t} = t_{1:m} < \dots < t_{r:m}$ is the observed data and $\mathbf{t}^{(g)} = t_{r+1:m}^g < \dots < t_{m:m}^g$ is the randomly generated data from the appropriate conditional distributions in (35.10), (35.11), and (35.12). Let $H_1(\mathbf{t}_{pc}, \theta)$ and $H_2(\mathbf{t}_{pc}, \theta)$ denote the matrix of first derivatives and matrix of the negative of the second derivatives of the pseudo-complete likelihood with respect to θ . Then, by using the missing information principle following Ye and Ng [27], the observed information matrix is given by

$$\mathbf{I}(\theta) = E[H_2(\mathbf{t}_{pc}, \theta)|\mathbf{t}] - E[H_1^2(\mathbf{t}_{pc}, \theta)|\mathbf{t}] + \{E[H_1(\mathbf{t}_{pc}, \theta)|\mathbf{t}]\}^2. \quad (35.24)$$

For evaluating (35.24), we impute R samples $\mathbf{t}^{(g)(j)}, j = 1, \dots, R$ corresponding to the missing data, conditional on the observed data \mathbf{t} and θ , by generating samples from the appropriate conditional distributions (35.10), (35.11), and (35.12), and obtain the pseudo-complete data $\mathbf{t}_{pc}^{(j)}, j = 1, \dots, R$. Finally, estimate of (35.24) is obtained as

$$\begin{aligned}
 \widehat{\mathbf{I}}(\hat{\theta}) = \frac{1}{R} \sum_{j=1}^R H_2(\mathbf{t}_{pc}^{(j)}, \theta) - \frac{1}{R} \sum_{j=1}^R [H_1(\mathbf{t}_{pc}^{(j)}, \theta)]^2 \\
 + \left[\frac{1}{R} \sum_{j=1}^R H_1(\mathbf{t}_{pc}^{(j)}, \theta) \right]^2. \quad (35.25)
 \end{aligned}$$

Finally, (35.25) is evaluated at the estimated value of θ obtained from the St-EM algorithm, and the resulting matrix is then inverted to obtain the asymptotic variance-covariance matrix of the parameter estimates. The asymptotic confidence intervals for the model parameters can then be easily constructed.

Bootstrap Confidence Intervals

It is also possible to construct parametric bootstrap CIs for the parameters. To do so, we first compute the MLE $\hat{\theta}$ based on the Type-II censored data on $m n$ -component systems. Then, treating $\hat{\theta}$ as the true value of the parameter θ , in the same sampling framework, we generate a sample of n -component systems of size m and calculate the MLE $\hat{\theta}^*$ for this sample. This process is repeated B times, to get B bootstrap estimates $\hat{\theta}_{(1)}^*, \dots, \hat{\theta}_{(B)}^*$. Finally, a $100(1 - \alpha)\%$ CI for θ_1 , for example, can be obtained as

$$\text{LCL: } \hat{\theta}_1 - b_{\theta_1} - z_{\alpha/2}\sqrt{v_{\theta_1}}, \quad \text{UCL: } \hat{\theta}_1 - b_{\theta_1} + z_{\alpha/2}\sqrt{v_{\theta_1}},$$

where b_{θ_1} and v_{θ_1} are the bootstrap bias and variance, respectively, for the estimate of θ_1 , calculated based on the B bootstrap estimates, and z_{α} is the upper α -percentage point of a standard normal variable. The same method applies to the other parameters θ_2 and β as well.

One more variant of the $100(1 - \alpha)\%$ bootstrap CIs would be

$$\hat{\theta}_{1((\frac{\alpha B}{2})^*)}^*, \hat{\theta}_{1((1 - \frac{\alpha}{2})B)^*}^*,$$

where $\hat{\theta}_{1(k)}^*$ is the k -th smallest value in the ordered sequence of B bootstrap estimates for θ_1 , $[x]$ representing the greatest integer contained in x . One can refer to Efron and Tibshirani [33] for elaborate details on various bootstrap CIs.

Note that the inferential procedures described above are carried out conditionally on the number of failures between 1 and $r - 1$, i.e., $1 \leq n_1 \leq r - 1$, since this is the condition for the existence of the MLEs. Naturally, the different confidence intervals can be obtained under this condition only, and all subsequent computational results are carried out conditionally on this.

35.4 Outline of Bayesian Analysis

Many researchers have explored Bayesian analysis of reliability data [34]. In particular, Ganguly et al. [35] discussed Bayesian analysis of data from simple step-stress experiments under the assumption of Weibull lifetimes. Recently, Jablonka et al. [36] have presented a discussion on Bayesian inference for coherent systems with Weibull distributed components. Following these works, we present here an outline of Bayesian inference for a simple step-stress experiment

involving coherent systems with Weibull distributed components with known signatures.

While prior elicitation is an involved problem in itself, here, following Berger and Sun [37], Kundu [38], and Ganguly et al. [35], we assume gamma priors on the scale parameters θ_1 and θ_2 , i.e.,

$$\theta_1 \sim \pi_1(\theta_1), \quad \theta_2 \sim \pi_2(\theta_2),$$

where

$$\pi_i(\theta_i) \propto \theta_i^{a_i-1} e^{-b_i\theta_i}, \quad \theta_i > 0, \quad (35.26)$$

with a_i and b_i as known hyper-parameters, $i = 1, 2$. Further, we assume a gamma prior on the shape parameter β , i.e., for known hyper-parameters a_3 and b_3

$$\beta \sim \pi_3(\beta), \quad (35.27)$$

where

$$\pi_3(\beta) \propto \beta^{a_3-1} e^{-b_3\beta}, \quad \beta > 0, a_3, b_3 > 0. \quad (35.28)$$

It may be noted here that for building the theory, it is also possible to just assume that the prior on β is a log-concave density, without referring to any specific form for it [36]. Finally, we assume that the priors are independent.

The joint posterior distribution of θ_1 , θ_2 , and β is then given by

$$\begin{aligned} p(\theta_1, \theta_2, \beta | DATA) &\propto L(\theta) \times \pi_1(\theta_1) \times \pi_2(\theta_2) \times \pi_3(\beta) \\ &\propto L(\theta) \times \theta_1^{a_1-1} \theta_2^{a_2-1} \\ &\quad \beta^{a_3-1} e^{-(b_1\theta_1 + b_2\theta_2 + b_3\beta)}, \end{aligned} \quad (35.29)$$

with $L(\theta)$ as the likelihood function as given in Sect. 35.3.1 for different values of n_1 . Thus, under squared error loss function, the Bayes estimates of any parametric function $p(\theta_1, \theta_2, \beta)$ are given by

$$\begin{aligned} p(\widehat{\theta_1}, \widehat{\theta_2}, \widehat{\beta}) &= \int_0^\infty \int_0^\infty \int_0^\infty K \times p(\theta_1, \theta_2, \beta) L(\theta) \theta_1^{a_1-1} \theta_2^{a_2-1} \\ &\quad \beta^{a_3-1} e^{-(b_1\theta_1 + b_2\theta_2 + b_3\beta)} d\theta_1 d\theta_2 d\beta, \end{aligned} \quad (35.30)$$

K being a normalizing constant. Note that it is not possible to obtain closed form expression for this Bayes estimate. One can use a general purpose approximation method such as Lindley's approximation [39]. However, unfortunately, credible intervals cannot be constructed in conjunction with Lindley's approximation. Alternatively, one can use an MCMC-based approach to calculate the Bayes estimates and credible intervals. Here, following Ganguly et al. [35], we outline an algorithm based on importance sampling for obtaining

the Bayes estimate and credible intervals for the parametric function $p(\theta_1, \theta_2, \beta)$.

Note that the joint posterior density can be decomposed as

$$\pi(\theta_1, \theta_2, \beta|DATA) = g_1(\theta_1|\beta, DATA) \times g_2(\theta_2|\beta, DATA) \\ \times g_3(\beta|DATA),$$

where forms of $g_1(\cdot)$, $g_2(\cdot)$, $g_3(\cdot)$ will depend upon $L(\theta)$ based on different values of n_1 , i.e., for Cases (i)–(iii) in Sect. 35.3. It is usually possible to approximate $g_3(\beta|DATA)$ by a known log-concave density [35, 38]. To obtain an approximating density, one may plot $g_3(\beta|DATA)$ and then select an appropriate approximating density by equating the mean and variance of $g_3(\beta|DATA)$ to those of the approximating density along the lines of Kundu [38] and Ganguly et al. [35]. Let $g_4(\beta|DATA)$ denote the approximating density. Then, the joint posterior density can be written as

$$\pi(\theta_1, \theta_2, \beta|DATA) = w(\beta) \times g_1(\theta_1|\beta, DATA) \\ \times g_2(\theta_2|\beta, DATA) \times g_4(\beta|DATA),$$

where $w(\beta) = \frac{g_3(\beta|DATA)}{g_4(\beta|DATA)}$ is the weight function. Finally, an algorithm similar to the one proposed by Ganguly et al. [35] may be given as:

Algorithm:

1. Generate β_1 from $g_4(\beta|DATA)$
 2. Given β_1 , generate θ_{11} from $g_1(\theta_1|DATA)$
 3. Given β_1 , generate θ_{21} from $g_2(\theta_2|DATA)$
 4. Repeat steps 1 to 3 N times, to get $(\theta_{11}, \theta_{21}, \beta_1), \dots, (\theta_{1N}, \theta_{2N}, \beta_N)$
 5. Compute $p_i = p(\theta_{1i}, \theta_{2i}, \beta_i), i = 1, \dots, N$
 6. Compute $w_i = w(\beta_i), i = 1, \dots, N$
 7. Compute the Bayes estimate $p(\hat{\theta}_1, \hat{\theta}_2, \hat{\beta}) = \frac{1}{N} \sum_{i=1}^N w_i p_i$.
-

Embedded in this process, credible intervals for $p(\theta_1, \theta_2, \beta)$ can also be constructed using the values $p_i, i = 1, \dots, N$.

35.5 Simulation Study

In this section, we carry out a detailed Monte Carlo simulation study for several three-component systems, with $m = 50$ and 100, and by taking $\theta_1 = 1$ without loss of any generality, to numerically investigate the proposed methods of inference. The values of θ_2 are chosen as 0.50 and 0.25; values of β are chosen as 1.00, 2.00, and 3.00; and values of τ are chosen so that $F_T(\tau) = 0.20$ and 0.30, respectively, for system tests.

Based on these chosen values of the parameters, we compare the performances of the two methods of estimation, namely, the direct likelihood-based approach using numer-

ical optimization through the Newton-Raphson method and the approach based on St-EM algorithm. The results of this comparison are presented in Table 35.2, suggesting that the performances of these two approaches are quite close. For this reason, we will present only the results obtained from the direct likelihood-based approach for the remaining tables.

Based on the above settings, and for m as 150 and 300, we also carry out a simulation study for individual components, the results of which are presented in Tables 35.3 and 35.4, which are then compared with the inference obtained from the system lifetimes. For example, when $F_T(\tau) = 0.20$ for a parallel system, with the same value of τ , we found $F_X(\tau) = 0.58$ for component lifetimes. We compute the means and mean squared errors (MSEs) of $\hat{\theta}_1, \hat{\theta}_2$ and $\hat{\beta}$ through simulations. The coverage probabilities are then equi-tailed CIs obtained by the asymptotic approach. In order to compare the relative efficiency between different coherent systems, we calculate the trace and determinant of the observed Fisher information matrix, as well as the total time on test (TTT). We observe that in almost all system tests, all the MLEs are positively biased.

We would like to point out some relative advantages of testing coherent systems over individual components in this setting here. Note that one would expect to have smaller TTT when testing coherent systems as compared to testing individual components. We observe in Tables 35.3 and 35.4 that this is always the case. This is a clear advantage in the setting of step-stress experiments when TTT is a concern. Also, one may consider the information contained in coherent systems and individual components and compare them. For example, one may compare the information contained in 30 coherent systems with signature $(1/3, 2/3, 0)$ with 50 individual components, as the number of components expected to fail when 30 coherent systems with signature $(1/3, 2/3, 0)$ are tested is 50. For series and parallel systems, the comparison is clear. Note that for three-component series systems, we compare the information obtained from the first failure (or equivalently, the smallest order statistics) among a sample of size 3, with one individual component (since the expected number of failed component of a series system is 1). Clearly, the system will involve more information in this case. However, for three-component parallel systems, we actually compare the information obtained from the third failure (or equivalently, the largest order statistics) among a sample of size 3, with three individual components (since the expected number of failed component of a parallel system is 3). Clearly, the system will involve less information in this case. Thus, under this setting, from the perspective of information contained in failures, testing three-component series systems is preferred over individual components.

Based on the trace and determinant of the observed Fisher information matrix, denoted by $tr(\mathbf{I})$ and $det(\mathbf{I})$, respectively, we find that the parallel system always has the highest

Table 35.3 Simulated values of means and MSEs of the MLEs, coverage probabilities of 95% some three-component coherent systems and component life tests. The quantity $F(\tau)$ in the third equi-tailed CIs from observed Fisher information matrix and bootstrap method with $\theta_1 = 1.00$, column corresponds to $F_T(\tau)$ in case of system lifetimes and corresponds to $F_X(\tau)$ in case of TTT, trace and determinant of observed Fisher information matrix, and Type-I error/power for component lifetimes

m	r	$F(\tau)$	θ_2	$E(\hat{\theta}_1)$	$E(\hat{\theta}_2)$	$E(\hat{\beta})$	$MSE(\hat{\theta}_1)$	$MSE(\hat{\theta}_2)$	$MSE(\hat{\beta})$	CP_{θ_1}	CP_{θ_2}	CP_{β}	$tr(\mathbf{I})$	$det(\mathbf{I})$	TTT	$\frac{Error}{Power_{TL}}$	$\frac{Error}{Powers}$	
$\mathbf{P} = (0, 0, 1)$ (equivalently, $\mathbf{a} = (3, -3, 1)$)

Table 35.4 Relative efficiency of the MSEs, TTT, trace, and determinant of observed Fisher information matrix for some three-component coherent systems and component life tests. The quantity $F(\tau)$ in the third column corresponds to $F_T(\tau)$ in case of system lifetimes and corresponds to $F_X(\tau)$ in case of component lifetimes

efficiency. It is also of interest to note that the test of parallel systems in some cases results in more information (in trace) than the test of individual components even though the latter has a larger TTT.

Note that the exponential distribution is a special case of the Weibull distribution when the value of the shape parameter $\beta = 1$. Thus, it is possible to carry out a test of a hypothesis whether the data have come from an exponential distribution. In our simulation study, we calculate the Type-I error for testing the hypothesis $H_0 : \beta = 1$ based on log-likelihood ratio test and score test. For other values of β , we recorded the powers of the log-likelihood ratio test and score test, and these results are presented in Table 35.3. By comparing the likelihood ratio and score tests, we find that

the likelihood ratio test performs better in both Type-I error and power for most of the cases and hence is the one to be preferred!

Finally, we report the relative efficiency of MSEs, $tr(\mathbf{I})$, and $det(\mathbf{I})$ in Table 35.4 under the same θ_1 , θ_2 , and β , but different values of m , r , $F_T(\tau)$, and signature vectors. Here, the relative efficiency of MSE is defined as

$$RE = \frac{\text{MSE of the Model of Interest}}{\text{MSE of the Reference Model}}$$

where the models with $m = 50$, $r = 40$, $F_T(\tau) = 0.2$, and $p = (0, 0, 1)$ are the reference models. The relative efficiency of other quantities is defined similarly.

Table 35.5 MLEs of the parameters based on data in Table 35.1, their SEs, and 95% CIs based on the asymptotic approach using observed Fisher information matrix and the bootstrap method

Parm.	MLEs	Observed Fisher		Bootstrap	
		SE	Asymptotic CI	SE	Bootstrap CI
θ_1	14.6054	2.0939	(10.5012, 18.7095)	7.0973	(11.6166, 25.3188)

Table 35.6 Log-likelihood ratio test and AIC for $\beta = 1$

$\ln L_0$	$\ln L_1$	$2(\ln L_1 - \ln L_0)$	$\chi_{0.05,1}$	AIC_0	AIC_1
-76.7407	-71.2022	11.0770	3.8415	157.4814	148.4044

35.6 Illustrative Example

For the data presented in Table 35.1, we consider a Type-II censored system lifetime data in hours (with $m=50$ and $r=30$) with signature vector $\mathbf{P} = (0, 1/2, 1/4, 1/4)$. In this case, we have $n_1=8$ and $n_2 = r - n_1=30 - 8 = 22$. From Equations (35.20) and (35.22), we first determine the initial estimates of θ_1 , θ_2 , and β to be $\tilde{\theta}_1 = 14.4607$, $\tilde{\theta}_2 = 5.8330$, and $\tilde{\beta} = 3.0581$, respectively. Upon using these initial values, we determine the MLEs, as well as their standard errors (SEs) and the 95% CIs, based on the asymptotic approach and the bootstrap method. These results are presented in Table 35.5. The likelihood ratio test presented in Table 35.6 as well as the CI obtained in Table 35.5 both show that in this case, there is enough evidence against the hypothesis $H_0 : \beta = 1.0$, that is, against the exponential distribution. Once again, we notice here that the SEs from bootstrap are larger than those obtained from the observed Fisher information matrix and also the bootstrap CIs are wider than those determined by the asymptotic approach.

35.7 Concluding Remarks

In this article, we develop inference for coherent systems with known signatures when they are placed on a simple step-stress experiment and that Type-II censored data are available on system lifetimes. We assume the component lifetimes to be distributed as Weibull. It is observed that the maximum likelihood estimates of the model parameters cannot be obtained in a closed-form and a numerical algorithm needs to be employed. MLEs of the model parameters are obtained through direct maximization of the observed likelihood by using the Newton-Raphson method, and construction of asymptotic confidence intervals by using the observed Fisher information matrix and a parametric bootstrap approach is discussed. The detailed steps of the St-EM algorithm for estimating the model parameters under this setup are developed. Within the framework of the St-EM algorithm, the asymptotic confidence intervals for the model

parameters by using the missing information principle are also developed. A method based on BLUEs is proposed for providing initial values for the numerical algorithm. Through a detailed Monte Carlo study, we examine and compare the performances of the two different methods for obtaining point and interval estimates. It is noted that under this setup, the observed likelihood-based direct maximization approach and the St-EM algorithm yield results that are quite close. It is observed that the MLEs are biased, with bias decreasing as sample size increases. It is also observed that the coverage probabilities of the confidence intervals are close to the nominal confidence level in general.

Naturally, it will be of interest to extend these results in different directions, such as for step-stress experiments under time constraint (see Balakrishnan et al. [40]) and step-stress experiment with random stress change times (see Xiong and Milliken [41]). It will also be of interest to determine an optimal time τ for changing the stress level (see Gouno et al. [42]). Work on these problems is currently under progress, and we hope to report the findings in a future paper.

Dr. N. Balakrishnan is a Distinguished University Professor in the Department of Mathematics and Statistics at McMaster University, Hamilton, Ontario, Canada. He is a Fellow of the American Statistical Association, Fellow of the Institute of Mathematical Statistics and an Elected Member of the International Statistical Institute. He has received an Honorary Doctorate Degree in 2017 from The National University of Athens, Greece. He has varied research interests that include Ordered Data Analysis, Reliability Theory, Survival Inference, Censoring Methodology, and Univariate and Multivariate Distribution Theory. He is currently the Editor-in-Chief of *Communications in Statistics* (three series) published by Taylor and Francis, Philadelphia.

Debanjan Mitra received his PhD from McMaster University, Canada in 2012. He was an Assistant Professor in the Department of Mathematics, Indian Institute of Technology Guwahati. Currently, he is an Assistant Professor in Operations Management, Quantitative Methods and Information Systems Area at Indian Institute of Management Udaipur. His current research interests include lifetime data analysis, censoring methodologies, statistical quality control etc.

Dr. Xiaojun Zhu is a Lecturer in the Department of Mathematical Sciences at Xi'an Jiaotong-Liverpool University, Suzhou, Jiangsu, China. He received his PhD in Statistics from McMaster University, Ontario, Canada, in 2015. His research interests include distribution theory, order Statistics, reliability, survival analysis and non-parametric inference.

Abstract

In this chapter we mainly discuss classes of bivariate distributions with singular components. It is observed that there are mainly two different ways of defining bivariate distributions with singular components, when the marginals are absolutely continuous. Most of the bivariate

distributions available in the literature can be obtained from these two general classes. A connection between the two approaches can be established based on their copulas. It is observed that under certain restrictions both these classes have very similar copulas. Several properties can be established of these proposed classes. It is observed that the maximum likelihood estimators (MLEs) may not always exist; whenever they exist, they cannot be obtained in closed forms. Numerical techniques are needed to compute the MLEs of the unknown parameters. Alternatively, very efficient expectation maximization (EM) algorithm can be used to compute the MLEs. The corresponding observed Fisher information matrix also can be obtained quite conveniently at the last stage of the EM algorithm, and it can be used to construct confidence intervals of the unknown parameters. The analysis of one data set has been performed to see the effectiveness of the EM algorithm. We discuss different generalizations, propose several open problems, and finally conclude the chapter.

36.1 Introduction

Bivariate continuous distributions occur quite naturally in practice. An extensive amount of work has been done on different bivariate continuous distributions in the statistical literature. Some of the well-known absolutely continuous

bivariate continuous distributions are bivariate normal, bivariate- t , bivariate log-normal, bivariate gamma, bivariate extreme value, bivariate Birnbaum-Saunders distributions, bivariate skew normal distribution, bivariate geometric skew normal distribution, etc., see, for example, the books by Balakrishnan and Lai [7], Kotz et al. [27] on different bivariate and multivariate distributions, the recent review article by Balakrishnan and Kundu [6] on bivariate and multivariate Birnbaum-Saunders distributions, the article by Azzalini and Dalla Valle [4] and the monograph by Azzalini and Capitanio [3] on multivariate skew-normal distribution, the recent article by Kundu [29] on multivariate geometric skew-normal distribution, and the references cited therein. The main purpose of any bivariate distribution is to model the two marginals and also to find association between the two marginals.

It may be mentioned that although there are numerous absolutely continuous bivariate distributions available in the literature, if there are ties in the data set, then these absolutely continuous bivariate distributions cannot be used to analyze this data set. Sometimes, the ties may occur due to truncation, but in many situations the ties may occur naturally and with a positive probability. To analyze a bivariate data set with ties, one needs a bivariate model with a singular component. These class of bivariate distributions assign a positive probability on $X = Y$, where X and Y denote the two marginals, and both are assumed to be absolutely continuous.

Marshall and Olkin [44] first proposed a bivariate distribution such that its both the marginals X and Y have exponential distributions, and $P(X = Y) > 0$. From now on we call this distribution as the Marshall-Olkin bivariate exponential (MOBE) distribution, and popularly it is also known as the shock model. Since its inception, an extensive amount of work has been done related to this distribution. Several properties have been established, its characterizations, and both classical and Bayesian inferential procedures have been developed, see, for example, Arnold [2], Baxter and Rachev [8], Boland [14], Muliere and Scarsini [50], Pena and Gupta [54], Ryu [57], the review article by Nadarajah [51], and the references cited therein.

Lu [41] provided the Weibull extension of the MOBE model. Since then quite a bit of work has been done on this and some related distributions mainly developing inference procedures under complete sample and under various sampling schemes and develop the properties of the order statistics. This model has been used quite successfully to analyze dependent competing risks data. See, for example, Begum and Khan [10], Cai et al. [15], Feizjadian and Hashemi [18], Jose et al. [25], Kundu and Dey [30], Kundu and Gupta [35], and Lai et al. [39], and see the references cited therein.

Some of the other bivariate distributions with singular components which can be found in the literature are bivariate Kumaraswamy (BVK), bivariate Pareto (BVP), bivariate double generalized exponential (BDGE), bivariate exponentiated Frechet (BEF), and bivariate Gumbel (BVG) distributions; see, for example, Barreto-Souza and Lemonte [9], bivariate generalized exponential (BGE) model of Kundu and Gupta [32], Sarhan-Balakrishnan's bivariate (SBB) distribution introduced by Sarhan and Balakrishnan [58], modified Sarhan-Balakrishnan's bivariate (MSBB) distribution introduced by Kundu and Gupta [33], bivariate model with proportional reversed hazard marginals proposed by Kundu and Gupta [34], bivariate generalized linear failure rate model introduced by Sarhan et al. [60], the generalized Marshall-Olkin bivariate distributions introduced by Gupta et al. [23], and bivariate inverse Weibull distribution as proposed by Muhammed [49] and Kundu and Gupta [37], and see the references cited therein.

In many situations although the data are continuous in nature, say time, pressure, etc., they are often measured in discrete units. In a situation like this, we often get ties in a bivariate data set. But we will provide few examples where ties occur naturally.

Shock Model It was originally proposed by Marshall and Olkin [44], and it is considered to be the most classical model of a bivariate distribution with a singular component. Suppose there are two components of a system, and there are three shocks which can affect the two components. The shocks appear randomly, and they affect the systems. Shock 1 affects the Component 1, Shock 2 affects the Component 2, and Shock 3 affects both the components. The component fails as soon as it receives a shock. The failure times of the both the components are observed as a bivariate random variable. In this case clearly there is a positive probability that the failure times of the two components become equal.

Stress Model It was originally proposed by Kundu and Gupta [32], and it can be described as follows. Suppose a system has two components, and each component is subject to individual stress, say V_1 and V_2 . Other than the individual stresses, the system has an overall stress V_3 which has been propagated to both the components equally irrespective of their individual stresses. Therefore, the observed stress at the two components are $X = \max\{V_1, V_3\}$ and $Y = \max\{V_2, V_3\}$, respectively.

Soccer Model Suppose the first component of a bivariate data represents the time of the first kick goal scored by any team, and second component represents the time of the first goal of any type by the home team. In this case also if the first goal is scored by the home team and it is a kick goal,

then there is a tie of the two components, and it happens with a positive probability.

Maintenance Model Suppose a system has two components, say Component 1 and Component 2, and it is assumed that both components have been maintained independently, and also there is an overall maintenance to both the components. It is assumed that due to component maintenance, suppose the lifetime of Component i is increased by U_i amount, for $i = 1$ and 2, and because of the overall maintenance, the lifetime of each component is increased by U_3 amount. Hence, the increased lifetimes of the two components are $X_1 = \max\{U_1, U_3\}$ and $X_2 = \max\{U_2, U_3\}$, respectively, see, for example, Kundu and Gupta [32] in this respect.

Note that most of the bivariate distributions with singular components are based on two different approaches, namely, minimization approach and maximization approach. The main aim of this manuscript is to put both the methods under the same framework. It may be mentioned that any bivariate distribution is characterized by its marginals and the copula function. It is observed that based on the copula many properties can be derived for any class of bivariate distribution functions. We derive some basic properties in both the cases, and it is observed that under certain restrictions they can be generated from very similar copulas. Some specific examples have been provided.

The maximum likelihood estimators (MLEs) of the unknown parameters may not always exist, and even if they exist, they cannot be obtained in explicit forms. One needs to solve a higher dimensional optimization problem to compute the MLEs. To avoid that we have proposed to use this problem as a missing value problem, and we have used a very efficient EM algorithm to compute the MLEs of the unknown parameters. It avoids solving a higher-dimensional optimization problem. Moreover, the observed Fisher information matrix also can be obtained quite conveniently at the last step of the EM algorithm, and it can be used to construct confidence intervals of the unknown parameters. The analysis of one real-life data set has been performed to see the effectiveness of the EM algorithm.

Finally, we provide few examples, and they cannot be obtained directly using the two methods which we have mentioned above. In all the cases we have provided explicit expressions of the joint PDF and have mentioned the estimation procedures of the unknown parameters in each case. We have further mentioned few bivariate distributions with singular components which cannot be obtained by the above two methods, and finally we conclude the paper.

The rest of the paper is organized as follows. In Sect. 36.2, we provide some preliminaries, and in Sect. 36.3 we describe the two main approaches to produce bivariate distribution with a singular component. Some special cases are presented

in Sect. 36.4, and the MLEs are provided in Sect. 36.5. In Sect. 36.6 we have provided the analysis of a data set. We have provided examples of few bivariate distributions which cannot be obtained by the proposed methods in Sect. 36.7, and finally we presented several open problems and conclude the paper in Sect. 36.8.

36.2 Preliminaries

In this section we discuss two important class of distribution functions, namely, (i) proportional hazard class and (ii) proportional reversed hazard class of distribution functions. We will also discuss briefly about the copula function and three important class of distribution functions which will be used quite extensively later.

36.2.1 Proportional Hazard Class

Suppose $F_B(t; \theta)$ is a distribution with the support on the positive real axis as mentioned before and $S_B(t, \theta) = 1 - F_B(t; \theta)$ is the corresponding survival function. Let us consider the class of distribution functions which has the survival function of the following form:

$$S_{PHM}(t; \alpha, \theta) = [S_B(t; \theta)]^\alpha; \quad t > 0, \quad (36.1)$$

with parameters $\theta, \alpha > 0$, and zero otherwise. Here θ can be vector valued, and $S_B(t; \theta)$ is called as the base line survival function. In this case the class of distribution functions defined by (36.1) is known as the proportional hazard model (PHM). In this case the PDF of the PHM becomes

$$f_{PHM}(t; \alpha, \theta) = \alpha f_B(t; \theta) [S_B(t; \theta)]^{\alpha-1}; \quad t \geq 0, \quad (36.2)$$

and zero otherwise. The proportional hazard model was originally proposed by Cox [16] as a regression model in the life-table data analysis. The class of distribution functions defined through the survival function (36.1) is called the proportional hazard class because if the hazard function of $f_B(t; \theta)$ is

$$h_B(t; \theta) = \frac{f_B(t; \theta)}{S_B(t; \theta)},$$

then the hazard function of $f_{PHM}(t; \alpha, \theta)$ becomes

$$h_{PHM}(t; \alpha, \theta) = \frac{f_{PHM}(t; \alpha, \theta)}{S_{PHM}(t; \alpha, \theta)} = \alpha \frac{f_B(t; \theta)}{S_B(t; \theta)} = \alpha h_B(t; \theta).$$

Hence, in this case the hazard function of any member of the proportional hazard class is proportional to the base line hazard function. Since the inception of the model by

Cox [16], an extensive amount of work has been done related to Cox's PHMs. Most of the standard statistical books on survival analysis discuss this model in detail; see, for example, Cox and Oakes [17], Therneau and Grambsch [63], and the references cited therein.

36.2.2 Proportional Reversed Hazard Class

Suppose $F_B(t; \theta)$ is a distribution with the support on the positive real axis. Then consider the class of distribution functions of the form

$$F_{PRHM}(t; \alpha, \theta) = [F_B(t; \theta)]^\alpha; \quad t > 0, \quad (36.3)$$

with parameters $\alpha > 0$ and θ (may be a vector valued) and base line distribution function $F_B(t; \theta)$. This class of distribution functions is known as the proportional reversed hazard model (PRHM). If $F_B(t; \theta)$ admits the PDF $f_B(t; \theta)$, then the PRHM has a PDF

$$f_{PRHM}(t; \alpha, \theta) = \alpha [F_B(t; \theta)]^{\alpha-1} f_B(t; \theta); \quad t \geq 0.$$

Lehmann [43] first proposed this model in the context of hypotheses testing. It is known as the proportional reversed hazard class because if the base line distribution function $F_B(t; \theta)$ has the reversed hazard function

$$r_B(t; \theta) = \frac{f_B(t; \theta)}{F_B(t; \theta)},$$

then $F_{PRHM}(t; \alpha, \theta)$ has the reversed hazard function

$$r_{PRHM}(t; \alpha, \theta) = \frac{f_{PRHM}(t; \alpha, \theta)}{F_{PRHM}(t; \alpha, \theta)} = \alpha \frac{f_B(t; \theta)}{F_B(t; \theta)} = \alpha r_B(t; \theta).$$

Hence, the reversed hazard function of any member of the proportional reversed hazard class is proportional to the base line reversed hazard function. For a detailed discussion on this issue, one is referred to Block et al. [13]. An extensive amount of work has been done on different proportional reversed hazard classes; see, for example, exponentiated Weibull distribution of Mudholkar et al. [48], generalized exponential distribution of Gupta and Kundu [21], exponentiated Rayleigh of Surles and Padgett [62], and generalized linear failure rate model of Sarhan and Kundu [59], see also Kundu and Gupta [31] and the references cited therein.

36.2.3 Copula

The dependence between two random variables, say X and Y , is completely described by the joint distribution function

$F_{X,Y}(x, y)$. The main idea of separating $F_{X,Y}(x, y)$ in two parts, the one which describes the dependence structure, and the other one which describes the marginal behavior, leads to the concept of copula. To every bivariate distribution function $F_{X,Y}(x, y)$, with continuous marginals $F_X(x)$ and $F_Y(y)$, corresponds to a unique function $C : [0, 1] \times [0, 1] \rightarrow [0, 1]$, called a copula function such that

$$F_{X,Y}(x, y) = C(F_X(x), F_Y(y)); \quad \text{for } (x, y) \in (-\infty, \infty) \times (-\infty, \infty).$$

Note that $C(u, v)$ is a proper distribution function on $[0, 1] \times [0, 1]$. Moreover, from Sklar's theorem (see, e.g., Nelsen [53]), it follows that if $F_{X,Y}(\cdot, \cdot)$ is a joint distribution function with continuous marginals $F_X(\cdot)$, $F_Y(\cdot)$, and if $F_X^{-1}(\cdot)$, $F_Y^{-1}(\cdot)$ are the inverse functions of $F_X(\cdot)$, $F_Y(\cdot)$, respectively, then there exists a unique copula C in $[0, 1] \times [0, 1]$, such that

$$C(u, v) = F_{X,Y}(F_X^{-1}(u), F_Y^{-1}(v)); \quad \text{for } (u, v) \in [0, 1] \times [0, 1].$$

Moreover, if $S_{X,Y}(x, y)$ is the joint survival function of X and Y , and $S_X(x)$ and $S_Y(y)$ are survival functions of X and Y , respectively, then there exists unique function $\bar{C} : [0, 1] \times [0, 1] \rightarrow [0, 1]$, called a (survival) copula function such that

$$S_{X,Y}(x, y) = \bar{C}(S_X(x), S_Y(y)); \quad \text{for } (x, y) \in (-\infty, \infty) \times (-\infty, \infty).$$

In this case

$$\bar{C}(u, v) = S_{X,Y}(S_X^{-1}(u), S_Y^{-1}(v)); \quad \text{for } (u, v) \in [0, 1] \times [0, 1].$$

Moreover,

$$\bar{C}(u, v) = u + v - 1 + C(1 - u, 1 - v); \quad \text{for } (u, v) \in [0, 1] \times [0, 1].$$

It should be pointed out that the survival copula is also a copula, i.e., $\bar{C}(u, v)$ is also a proper distribution function on $[0, 1] \times [0, 1]$. It is well known that many dependence properties of a bivariate distribution are copula properties and, therefore, can be obtained by studying the corresponding copula. These properties do not depend on the marginals.

36.2.4 Three Important Distributions

In this section we discuss three important distribution functions which will be used quite extensively in our future development.

Exponential Distribution

A random variable X is said to have an exponential distribution with the parameter $\lambda > 0$, if the CDF of X is as follows:

$$F_X(x; \lambda) = P(X \leq x) = 1 - e^{-\lambda x}; \quad x > 0,$$

and zero, otherwise. The corresponding PDF of X becomes

$$f_X(x; \lambda) = \lambda e^{-\lambda x}; \quad \text{for } x > 0,$$

and zero, otherwise. From now on we will denote it by $\text{Exp}(\lambda)$. The PDF of an exponential distribution is always a decreasing function, and it has a constant hazard function for all values of λ . The exponential distribution is the most used distribution in lifetime data analysis. It has several interesting properties including the lack of memory property, and it belongs to the PHM class. Interested readers are referred to Balakrishnan and Basu [5] for a detailed discussions on exponential distribution.

Weibull Distribution

A random variable X is said to have a two-parameter Weibull distribution if it has the following CDF:

$$F_X(x; \alpha, \lambda) = 1 - e^{-\lambda x^\alpha}; \quad \text{for } x > 0,$$

and zero, otherwise. Here, $\alpha > 0$ is called the shape parameter and $\lambda > 0$ as the scale parameter. The corresponding PDF becomes

$$f_X(x; \alpha, \lambda) = \alpha \lambda x^{\alpha-1} e^{-\lambda x^\alpha}; \quad \text{for } x > 0,$$

and zero, otherwise. From now on it will be denoted by $\text{WE}(\alpha, \lambda)$.

A two-parameter Weibull distribution is more flexible than a one-parameter exponential distribution. The shape of the PDF and the hazard function depend on the shape parameter α . The PDF can be a decreasing or a unimodal function if $\alpha \leq 1$ or $\alpha > 1$, respectively. Similarly, for $\alpha \leq 1$, the hazard function is a decreasing function, and for $\alpha > 1$, the hazard function is an increasing function. Because of its flexibility it has been used quite extensively in reliability and in survival analysis. It is a PHM. An excellent handbook on Weibull distribution is by Rinne [56]. Interested readers are referred to that handbook for further reading.

Generalized Exponential Distribution

A random variable X is said to have a two-parameter generalized exponential distribution if it has the following CDF:

$$F_X(x; \alpha, \lambda) = (1 - e^{-\lambda x})^\alpha; \quad \text{for } x > 0,$$

and zero, otherwise. Here also $\alpha > 0$ is called the shape parameter and $\lambda > 0$ as the scale parameter. The corresponding PDF becomes

$$f_X(x; \alpha, \lambda) = \alpha \lambda e^{-\lambda x} (1 - e^{-\lambda x})^{\alpha-1}; \quad \text{for } x > 0,$$

and zero, otherwise. From now on we will denote it by $\text{GE}(\alpha, \lambda)$.

A two-parameter GE distribution was first introduced by Gupta and Kundu [21] as an alternative to the two-parameter Weibull and gamma distribution. Since it has been introduced, it has been used quite extensively in analyzing different lifetime data. It may be mentioned that it is a PRHM. Interested readers are referred to the review article by Nadarajah [52] or a book length treatment by Al-Hussaini and Ahsanullah [1] for different developments on the GE distribution till date.

36.3 Two Main Approaches

In this section we provide the two main approaches, namely, the minimization and maximization approaches, to construct a bivariate distribution with a singular component. We provide both the methods briefly and discuss several common properties of the general class of distribution functions. It is assumed throughout that $F_B(t; \theta)$ is an absolutely continuous distribution function with the support on the positive real axis and $S_B(t; \theta) = 1 - F_B(t; \theta)$. Moreover, the PDF of $F_B(t; \theta)$ is $f_B(t; \theta)$ for $t > 0$ and zero, otherwise. Here θ can be vector valued also as mentioned in the previous section.

36.3.1 Minimization Approach (Model 1)

In this section we provide the bivariate distributions with singular components which are based on minimum. Suppose U_1, U_2 , and U_3 are three independent nonnegative random variables with survival functions $S_1(t; \alpha_1, \theta) = [S_B(t; \theta)]^{\alpha_1}$, $S_2(t; \alpha_2, \theta) = [S_B(t; \theta)]^{\alpha_2}$, $S_3(t; \alpha_3, \theta) = [S_B(t; \theta)]^{\alpha_3}$, respectively for $\alpha_1 > 0, \alpha_2 > 0, \alpha_3 > 0$. Now we define a new bivariate random variable (X, Y) as follows:

$$X = \min\{U_1, U_3\} \quad \text{and} \quad Y = \min\{U_2, U_3\}. \quad (36.4)$$

Note that although U_1, U_2 , and U_3 are independent, due to presence of U_3 in both X and Y , X and Y are dependent. We would like to obtain the joint cumulative distribution function (JCDF) and the joint probability density function (JPDF) of X and Y . But before that let us observe the following facts. Since X is defined as in (36.4), the survival function of X becomes

$$\begin{aligned} P(X > x) &= S_X(x; \alpha_1, \alpha_3, \theta) = P(U_1 > x, U_3 > x) \\ &= P(U_1 > x)P(U_3 > x) = [S_B(x; \theta)]^{\alpha_1 + \alpha_3}. \end{aligned}$$

Hence, the survival function and the CDF of X depend on θ and $\alpha_1 + \alpha_3$. Similarly, the survival function of Y becomes

$P(Y > y) = [S_B(y; \theta)]^{\alpha_2 + \alpha_3}$. Hence, if U_1, U_2 , and U_3 are absolutely continuous random variables, then X and Y are also absolutely continuous random variables. Moreover, in this case

$$\begin{aligned} P(X = Y) &= P(U_3 < U_1, U_3 < U_2) \\ &= \alpha_3 \int_0^\infty f_B(t; \theta) [S_B(t; \theta)]^{\alpha_3 - 1} [S_B(t; \theta)]^{\alpha_1} [S_B(x; \theta)]^{\alpha_2} dt \\ &= \frac{\alpha_3}{\alpha_1 + \alpha_2 + \alpha_3} \int_0^\infty (\alpha_1 + \alpha_2 + \alpha_3) f_B(t; \theta) [S_B(t; \theta)]^{\alpha_1 + \alpha_2 + \alpha_3 - 1} \\ &= \frac{\alpha_3}{\alpha_1 + \alpha_2 + \alpha_3} > 0. \end{aligned} \quad (36.5)$$

Hence, (36.5) indicates that $X = Y$ has a positive probability and for fixed α_1 and α_2 , $\lim_{\alpha_3 \rightarrow 0} P(X = Y) = 0$ and $\lim_{\alpha_3 \rightarrow \infty} P(X = Y) = 1$. Along the same line it can be easily obtained that

$$P(X < Y) = \frac{\alpha_1}{\alpha_1 + \alpha_2 + \alpha_3} \quad \text{and} \quad P(Y < X) = \frac{\alpha_2}{\alpha_1 + \alpha_2 + \alpha_3}. \quad (36.6)$$

Now we will provide the joint survival function of X and Y and also derive the joint PDF of X and Y . The joint survival function of X and Y can be written as

$$\begin{aligned} S_{X,Y}(x, y) &= P(X > x, Y > y) \\ &= P(U_1 > x, U_2 > y, U_3 > \max\{x, y\}) \\ &= [S_B(x, \theta)]^{\alpha_1} [S_B(y, \theta)]^{\alpha_2} [S_B(z, \theta)]^{\alpha_3}, \end{aligned} \quad (36.7)$$

here $z = \max\{x, y\}$. Equivalently, (36.7) can be written as follows:

$$f(x, y) = \begin{cases} \alpha_1(\alpha_2 + \alpha_3) f_B(x, \theta) [S_B(x, \theta)]^{\alpha_1 - 1} f_B(y, \theta) [S_B(y, \theta)]^{\alpha_2 + \alpha_3 - 1} & \text{if } x < y \\ \alpha_2(\alpha_1 + \alpha_3) f_B(x, \theta) [S_B(x, \theta)]^{\alpha_1 + \alpha_3 - 1} f_B(y, \theta) [S_B(y, \theta)]^{\alpha_2 - 1} & \text{if } x > y. \end{cases}$$

Now it can be easily observed that

$$\int_0^\infty \int_0^\infty f(x, y) dx dy = \int_0^\infty \int_y^\infty f(x, y) dx dy + \int_0^\infty \int_x^\infty f(x, y) dy dx = \frac{\alpha_1 + \alpha_2}{\alpha_1 + \alpha_2 + \alpha_3} < 1.$$

Hence, clearly $S_{X,Y}(x, y)$ is not an absolutely continuous survival function. Moreover,

$$\int_0^\infty \int_0^\infty f_{X,Y}(x, y) dx dy + P(X = Y) = 1.$$

$$S_{X,Y}(x, y) = \begin{cases} [S_B(x, \theta)]^{\alpha_1} [S_B(y, \theta)]^{\alpha_2 + \alpha_3} & \text{if } x < y \\ [S_B(x, \theta)]^{\alpha_1 + \alpha_3} [S_B(y, \theta)]^{\alpha_2} & \text{if } x \geq y. \end{cases} \quad (36.8)$$

Now we will show that the joint survival function (36.7) or (36.8) is not an absolutely continuous survival function. Let us recall that a joint survival function $S(x, y)$ is said to be absolute continuous if there exists a $f(x, y) \geq 0$, such that

$$S(x, y) = \int_x^\infty \int_y^\infty f(u, v) du dv \quad \text{for all } x > 0, y > 0.$$

In that case $f(x, y)$ can be recovered from $S(x, y)$ as

$$f(x, y) = \frac{\partial^2}{\partial x \partial y} S(x, y).$$

Let us denote $f(x, y) = \frac{\partial^2}{\partial x \partial y} S_{X,Y}(x, y)$. Hence, from (36.8),

Let us denote for $x > 0$ and $y > 0$

$$f_{ac}(x, y) = \frac{\alpha_1 + \alpha_2 + \alpha_3}{\alpha_1 + \alpha_2} f(x, y). \tag{36.9}$$

Clearly, $f_{ac}(x, y)$ is a bivariate density function on the positive quadrant. Observe that for $x > 0, y > 0$ and for $z = \max\{x, y\}$,

$$\begin{aligned} S_{X,Y}(x, y) &= P(X > x, Y > y) = \int_x^\infty \int_y^\infty f(u, v) du dv + P(X = Y > z) \\ &= \frac{\alpha_1 + \alpha_2}{\alpha_1 + \alpha_2 + \alpha_3} \int_x^\infty \int_y^\infty f_{ac}(u, v) du dv + \frac{\alpha_3}{\alpha_1 + \alpha_2 + \alpha_3} \int_z^\infty f_s(u) du. \end{aligned} \tag{36.10}$$

Here $f_{ac}(u, v)$ is same as defined in (36.9) and

$$f_s(u) = (\alpha_1 + \alpha_2 + \alpha_3) f_B(u; \theta) [S_B(u; \theta)]^{\alpha_1 + \alpha_2 + \alpha_3 - 1},$$

and it is a probability density function on the positive real axis. Based on (36.10), for $x > 0, y > 0$ and for $z = \max\{x, y\}$, the random variable (X, Y) has the joint PDF $f_{X,Y}(x, y)$ of the form

$$f_{X,Y}(x, y) = \begin{cases} \alpha_1(\alpha_2 + \alpha_3) f_B(x, \theta) [S_B(x, \theta)]^{\alpha_1 - 1} f_B(y, \theta) [S_B(y, \theta)]^{\alpha_2 + \alpha_3 - 1} & \text{if } x < y \\ \alpha_2(\alpha_1 + \alpha_3) f_B(x, \theta) [S_B(x, \theta)]^{\alpha_1 + \alpha_3 - 1} f_B(y, \theta) [S_B(y, \theta)]^{\alpha_2 - 1} & \text{if } x > y \\ \alpha_3 f_B(x; \theta) [S_B(x; \theta)]^{\alpha_1 + \alpha_2 + \alpha_3 - 1} & \text{if } x = y. \end{cases} \tag{36.11}$$

In this case the random variable (X, Y) has an absolute continuous part and a singular part. The function $f_{X,Y}(x, y)$ is considered to be a density function of (X, Y) , if it is understood that the first two terms are densities with respect to a two-dimensional Lebesgue measure and the third term is a density function with respect to a one dimensional Lebesgue measure; see, for example, Bemis, Bain, and Higgins [11]. It simply means that

$$P(X > x, Y > y) = \int_x^\infty \int_y^\infty f_{X,Y}(u, v) du dv + \int_{\max\{x,y\}}^\infty f_{X,Y}(v, v) dv.$$

From (36.10) it is immediate that

$$S_{X,Y}(x, y) = \frac{\alpha_1 + \alpha_2}{\alpha_1 + \alpha_2 + \alpha_3} S_{ac}(x, y) + \frac{\alpha_3}{\alpha_1 + \alpha_2 + \alpha_3} S_{si}(x, y), \tag{36.12}$$

here $S_{ac}(x, y)$ is the absolutely continuous part of the survival function,

$$S_{ac}(x, y) = \int_x^\infty \int_y^\infty f_{ac}(u, v) du dv,$$

and $S_{si}(x, y)$ is the singular component of $S_{X,Y}(x, y)$, and it can be written for $z = \max\{x, y\}$, as

$$S_{si}(x, y) = [S_B(z; \theta)]^{\alpha_1 + \alpha_2 + \alpha_3}.$$

Now we would like to find the copula associated with $S_{X,Y}(x, y)$. Since X and Y have the survival functions as $[S_B(x; \theta)]^{\alpha_1 + \alpha_3}$ and $[S_B(y; \theta)]^{\alpha_2 + \alpha_3}$, respectively, therefore

$$\bar{C}(u, v) = \begin{cases} u^{\frac{\alpha_1}{\alpha_1 + \alpha_3}} v & \text{if } u < v^{\frac{\alpha_1 + \alpha_3}{\alpha_2 + \alpha_3}} \\ u v^{\frac{\alpha_2}{\alpha_2 + \alpha_3}} & \text{if } u \geq v^{\frac{\alpha_1 + \alpha_3}{\alpha_2 + \alpha_3}}. \end{cases}$$

If we write $\beta = \alpha_3/(\alpha_1 + \alpha_3)$ and $\delta = \alpha_3/(\alpha_2 + \alpha_3)$, then

$$\bar{C}(u, v) = \begin{cases} u^{1-\beta} v & \text{if } u^\beta < v^\delta \\ u v^{1-\delta} & \text{if } u^\beta \geq v^\delta. \end{cases}$$

If we consider a special case $\alpha_1 = \alpha_2$, and $\eta = \alpha_3/(\alpha_1 + \alpha_3) = \alpha_3/(\alpha_2 + \alpha_3)$, then

$$\bar{C}(u, v) = \begin{cases} u^{1-\eta} v & \text{if } u < v \\ u v^{1-\eta} & \text{if } u \geq v. \end{cases}$$

36.3.2 Maximization Approach (Model 2)

In the last section we had provided the bivariate distributions with singular components which are based on minimum, and in this section we provide the bivariate distributions with singular components which are based on maximum. Let us assume that V_1, V_2 , and V_3 are three independent nonnegative random variables with distribution functions $F_1(t; \beta_1, \lambda) =$

$[F_B(t; \lambda)]^{\beta_1}$, $F_2(t; \beta_2, \lambda) = [F_B(t; \lambda)]^{\beta_2}$, and $F_3(t; \beta_3, \lambda) = [F_B(t; \lambda)]^{\beta_3}$, respectively, for $\beta_1 > 0$, $\beta_2 > 0$, and $\beta_3 > 0$. Let us define a new bivariate random variable (X, Y) as follows:

$$X = \max\{V_1, V_3\} \quad \text{and} \quad Y = \max\{V_2, V_3\}. \quad (36.13)$$

In this case also similarly as before, X and Y will be dependent random variables due to the presence of V_3 . The following results can be easily obtained following the same line as the previous section. The CDFs of X and Y become

$$P(X \leq x) = F_X(x; \beta_1, \beta_3, \lambda) = [F_B(x; \lambda)]^{\beta_1 + \beta_3} \quad \text{and}$$

$$P(Y \leq y) = F_Y(y; \beta_2, \beta_3, \lambda) = [F_B(y; \lambda)]^{\beta_2 + \beta_3}.$$

$$P(X = Y) = \frac{\beta_3}{\beta_1 + \beta_2 + \beta_3}, \quad P(X < Y) = \frac{\beta_1}{\beta_1 + \beta_2 + \beta_3}, \quad P(X > Y) = \frac{\beta_2}{\beta_1 + \beta_2 + \beta_3}.$$

The joint CDF of X and Y for $z = \min\{x, y\}$ becomes

$$F_{X,Y}(x, y) = P(X \leq x, Y \leq y)$$

$$= P(V_1 \leq x, V_2 \leq y, V_3 \leq \min\{x, y\})$$

$$= [F_B(x, \lambda)]^{\beta_1} [F_B(y, \lambda)]^{\beta_2} [F_B(z, \lambda)]^{\beta_3}$$

$$= \begin{cases} [F_B(x, \lambda)]^{\beta_1 + \beta_3} [F_B(y, \lambda)]^{\beta_2} & \text{if } x < y \\ [F_B(x, \lambda)]^{\beta_2 + \beta_3} [F_B(x, \lambda)]^{\beta_1} & \text{if } x \geq y \end{cases} \quad (36.14)$$

Following the same approach as before, the joint PDF of X and Y can be obtained as

$$f_{X,Y}(x, y) = \begin{cases} \beta_2(\beta_1 + \beta_3)f_B(x, \lambda)[F_B(x, \lambda)]^{\beta_1 + \beta_3 - 1}f_B(y, \lambda)[F_B(y, \lambda)]^{\beta_2 - 1} & \text{if } x < y \\ \beta_1(\beta_2 + \beta_3)f_B(x, \lambda)[S_B(x, \theta)]^{\beta_1 - 1}f_B(y, \theta)[F_B(y, \theta)]^{\beta_2 + \beta_3 - 1} & \text{if } x > y \\ \beta_3f_B(x; \lambda)[F_B(x; \lambda)]^{\beta_1 + \beta_2 + \beta_3 - 1} & \text{if } x = y. \end{cases} \quad (36.15)$$

In this case also the joint CDF of the random variable (X, Y) has an absolute continuous part and a singular part, and the function (36.15) is considered to be the joint PDF of X and Y in the same sense as before. Moreover, the copula associate with the joint CDF $F_{X,Y}(x, y)$ becomes

$$C(u, v) = \begin{cases} uv^{\frac{\beta_2}{\beta_2 + \beta_3}} & \text{if } u < v^{\frac{\beta_1 + \beta_3}{\beta_2 + \beta_3}} \\ u^{\frac{\beta_1}{\beta_1 + \beta_3}}v & \text{if } u \geq v^{\frac{\beta_1 + \beta_3}{\beta_2 + \beta_3}} \end{cases} \quad (36.16)$$

Therefore, if we write as before that $\beta = \beta_3/(\beta_1 + \beta_3)$ and $\delta = \beta_3/(\beta_2 + \beta_3)$, then (36.16) becomes

$$C(u, v) = \begin{cases} uv^{1 - \delta} & \text{if } u^\beta < v^\delta \\ u^{1 - \beta}v & \text{if } u^\beta \geq v^\delta. \end{cases}$$

Hence, for the special case $\beta_1 = \beta_2$, and for $\eta = \beta_3/(\beta_1 + \beta_3) = \beta_3/(\beta_2 + \beta_3)$, the copula $C(u, v)$ becomes

$$C(u, v) = \begin{cases} uv^{1 - \eta} & \text{if } u < v \\ u^{1 - \eta}v & \text{if } u \geq v. \end{cases}$$

36.4 Some Special Cases

In this section we provide some special cases based on these two approaches. Different special cases have been considered in detail in the literature. In this section our main aim is to provide those special cases and mention relevant references associate with those models. We also provide some new bivariate models where more work can be done.

36.4.1 Model 1

Marshall-Olkin Bivariate Exponential Distribution

Marshall-Olkin bivariate exponential (MOBE) distribution seems to be the most popular bivariate distribution with a singular component, and it was originally introduced by Marshall and Olkin [44]. In this case the survival function of the base line distribution, namely, $S_B(t, \theta) = e^{-t}$, for $t > 0$, and zero, otherwise. Hence, U_1 , U_2 , and U_3 as defined in Sect. 36.3.1 follow $\text{Exp}(\alpha_1)$, $\text{Exp}(\alpha_2)$ and $\text{Exp}(\alpha_3)$, respectively. Hence, the joint PDF of X and Y becomes

Fig. 36.1 PDF plots of $MOBE(\alpha_1, \alpha_2, \alpha_3)$ distribution for different $(\alpha_1, \alpha_2, \alpha_3)$ values: (a) (2.0,2.0,1.0) (b) (1.0,1.0,1.0) (c) (1.0,2.0,1.0) (d) (2.0,1.0,1.0)

$$f_{X,Y}(x, y) = \begin{cases} \alpha_1(\alpha_2 + \alpha_3)e^{-\alpha_1 x}e^{-(\alpha_2 + \alpha_3)y} & \text{if } x < y \\ \alpha_2(\alpha_1 + \alpha_3)e^{-(\alpha_1 + \alpha_3)x}e^{-\alpha_2 y} & \text{if } x > y \\ \alpha_3 e^{-(\alpha_1 + \alpha_2 + \alpha_3)x} & \text{if } x = y, \end{cases}$$

and it will be denoted by $MOBE(\alpha_1, \alpha_2, \alpha_3)$. The absolute continuous part of the PDF of $MOBE(\alpha_1, \alpha_2, \alpha_3)$ for different values of α_1, α_2 , and α_3 is provided in Fig. 36.1. It is clear from the figures that for all parameter values the maximum occurs at $(0, 0)$.

Note that the marginals of the MOBE distribution are exponential distributions. In this case X and Y follow $Exp(\alpha_1 + \alpha_3)$ and $Exp(\alpha_2 + \alpha_3)$, respectively. This model is also known

as the shock model since it has been introduced as modeling shocks to a parallel system and it has an interesting connection with the homogeneous Poisson process. Interested readers are referred to the original paper of Marshall and Olkin [44] in this respect. An extensive amount of work has been done dealing with different aspects of the MOBE model. Arnold [2] discussed the existence of the maximum likelihood estimators of the unknown parameters. Bemis et al. [11] and Bhattacharyya and Johnson [12] discussed different properties of the MOBE distribution. Pena and Gupta [54] developed the Bayesian inference of the unknown parameters based on a very flexible beta-gamma priors, and

Karlis [26] provided a very efficient EM algorithm to compute the maximum likelihood estimators of the unknown parameters.

Marshall-Olkin Bivariate Weibull Distribution

It can be seen that the MOBE has exponential marginals, and due to this reason it has some serious limitations. For example, if the data indicate that the marginals have unimodal PDFs, then clearly MOBE may not be used. Due to this reason, in the same paper Marshall and Olkin [44] introduced the Marshall Olkin bivariate Weibull (MOBW) model by replacing the exponential distribution with the Weibull distribution. In this case the base line survival function is a Weibull distribution, and it is taken as $S_B(t, \theta) = e^{-t^\theta}$, for $t > 0$, and zero otherwise. Hence, the base line distribution is a Weibull distribution with the shape parameter θ and scale parameter 1. Using the same notations as in Sect. 36.3.1, it can be easily seen that U_1 , U_2 , and U_3 follow Weibull distribution with the same shape parameter θ and having scale parameter α_1 , α_2 , and α_3 , respectively. Hence, the joint PDF of X and Y becomes

$$f_{X,Y}(x, y) = \begin{cases} \theta^2 \alpha_1 (\alpha_2 + \alpha_3) x^{\theta-1} y^{\theta-1} e^{-\alpha_1 x^\theta} e^{-(\alpha_2 + \alpha_3) y^\theta} & \text{if } x < y \\ \theta^2 \alpha_2 (\alpha_1 + \alpha_3) x^{\theta-1} y^{\theta-1} e^{-(\alpha_1 + \alpha_3) x^\theta} e^{-\alpha_2 y^\theta} & \text{if } x > y \\ \theta \alpha_3 x^{\theta-1} e^{-(\alpha_1 + \alpha_2 + \alpha_3) x^\theta} & \text{if } x = y, \end{cases} \quad (36.17)$$

and it will be denoted by $\text{MOBW}(\alpha_1, \alpha_2, \alpha_3, \theta)$. The absolute continuous part of the PDF of $\text{MOBW}(\alpha_1, \alpha_2, \alpha_3, \theta)$ for different values of α_1 , α_2 , α_3 , and θ is provided in Fig. 36.2. It is clear from the figures that for all parameter values the maximum occurs at $(0, 0)$ if the common shape parameter $0 < \theta \leq 1$; otherwise it is always unimodal.

Note that the marginals of the MOBW distributions are Weibull distributions with the same shape parameter, namely, X follows $\text{WE}(\theta, \alpha_1 + \alpha_3)$ and Y follows $\text{WE}(\theta, \alpha_2 + \alpha_3)$. This model has several real-life applications, and it has an interesting connection with the renewal process. An extensive amount of work has been done mainly related to the estimation of the unknown parameters both for classical and Bayesian methods. It may be noted that the maximum likelihood estimators of the unknown parameters cannot be obtained in closed form. It needs solving a four-dimensional optimization problem. Kundu and Dey [30] developed a very efficient EM algorithm to compute the maximum likelihood estimators of the unknown parameters which needs solving only one one-dimensional optimization problem. Kundu and Gupta [36] developed a very efficient Bayesian inference of the unknown based on a very flexible priors. Different methods have been evolved for analyzing censored data also. See, for example, Lu [41, 42]. Recently, Feizjavadian and Hashemi [18] and Shen and Xu [61] used MOBW distribution for analyzing dependent competing risks data. They have developed

very efficient EM algorithm to compute the known parameters of the model. It will be interesting to develop Bayesian inference of the unknown parameters in this case also.

Weighted Marshall-Olkin Bivariate Exponential Distribution

Jamalizadeh and Kundu [24] introduced the weighted Marshall-Olkin bivariate exponential distribution as an alternative to the MOBW distribution. It is also a bivariate singular distribution, and it can be a very flexible distribution similar to the MOBW distribution. It may be recalled that a random variable X is said to have a weighted exponential (WEE) distribution with parameters $\alpha > 0$ and $\lambda > 0$, if the PDF of X is of the form:

$$f_{WEE}(x; \alpha, \lambda) = \frac{\alpha + 1}{\alpha} \lambda e^{-\lambda x} (1 - e^{-\lambda x}); \quad x > 0,$$

and 0, otherwise. The WEE distribution was originally introduced by Gupta and Kundu [22] as an alternative to the two-parameter Weibull, gamma, or generalized exponential distributions. The PDFs and the hazard functions of the WEE distribution can take a variety of shapes similar to the Weibull, gamma, or generalized exponential distributions. The weighted Marshall-Olkin bivariate exponential (BWEE) distribution introduced by Jamalizadeh and Kundu [24] has the following PDF:

$$f_{X,Y}(x, y) = \begin{cases} \frac{\alpha + \lambda}{\alpha} \lambda_1 e^{-\lambda_1 x} (\lambda_2 + \lambda_3) e^{-(\lambda_2 + \lambda_3) y} (1 - e^{-x\alpha}) & \text{if } x < y \\ \frac{\alpha + \lambda}{\alpha} (\lambda_1 + \lambda_3) e^{-(\lambda_1 + \lambda_3) x} \lambda_2 e^{-\lambda_2 y} (1 - e^{-y\alpha}) & \text{if } x > y \\ \frac{\alpha + \lambda}{\alpha} \lambda_3 e^{-\lambda x} (1 - e^{-x\alpha}) & \text{if } x = y, \end{cases} \quad (36.18)$$

for $\lambda = \lambda_1 + \lambda_2 + \lambda_3$, and it will be denoted by $\text{BWEE}(\lambda_1, \lambda_2, \lambda_3, \alpha)$. The absolute continuous part of the PDF of $\text{BWEE}(\lambda_1, \lambda_2, \lambda_3, \alpha)$ for different values of λ_1 , λ_2 , λ_3 , and α is provided in Fig. 36.3. It is clear from the figures that for all parameter values the joint PDF is unimodal.

The marginals of the BWEE distribution are WEE distributions. Jamalizadeh and Kundu [24] established different properties of a BWEE distribution. The maximum likelihood estimators of the unknown parameters cannot be obtained in explicit forms. Efficient EM algorithm has been proposed by Jamalizadeh and Kundu [24] to compute the maximum likelihood estimators of the unknown parameters.

Bivariate Kumaraswamy Distribution

Barreto-Souza and Lemonte [9] considered the bivariate Kumaraswamy (BVK) distribution whose marginals are Kumaraswamy distribution. Since the Kumaraswamy distribution has the support on $[0, 1]$, the BVK distribution has the support $[0, 1] \times [0, 1]$. It may be recalled that a random variable X is said to have a Kumaraswamy distribution with parameters $\alpha > 0$ and $\beta > 0$, if it has the following CDF and PDF, respectively

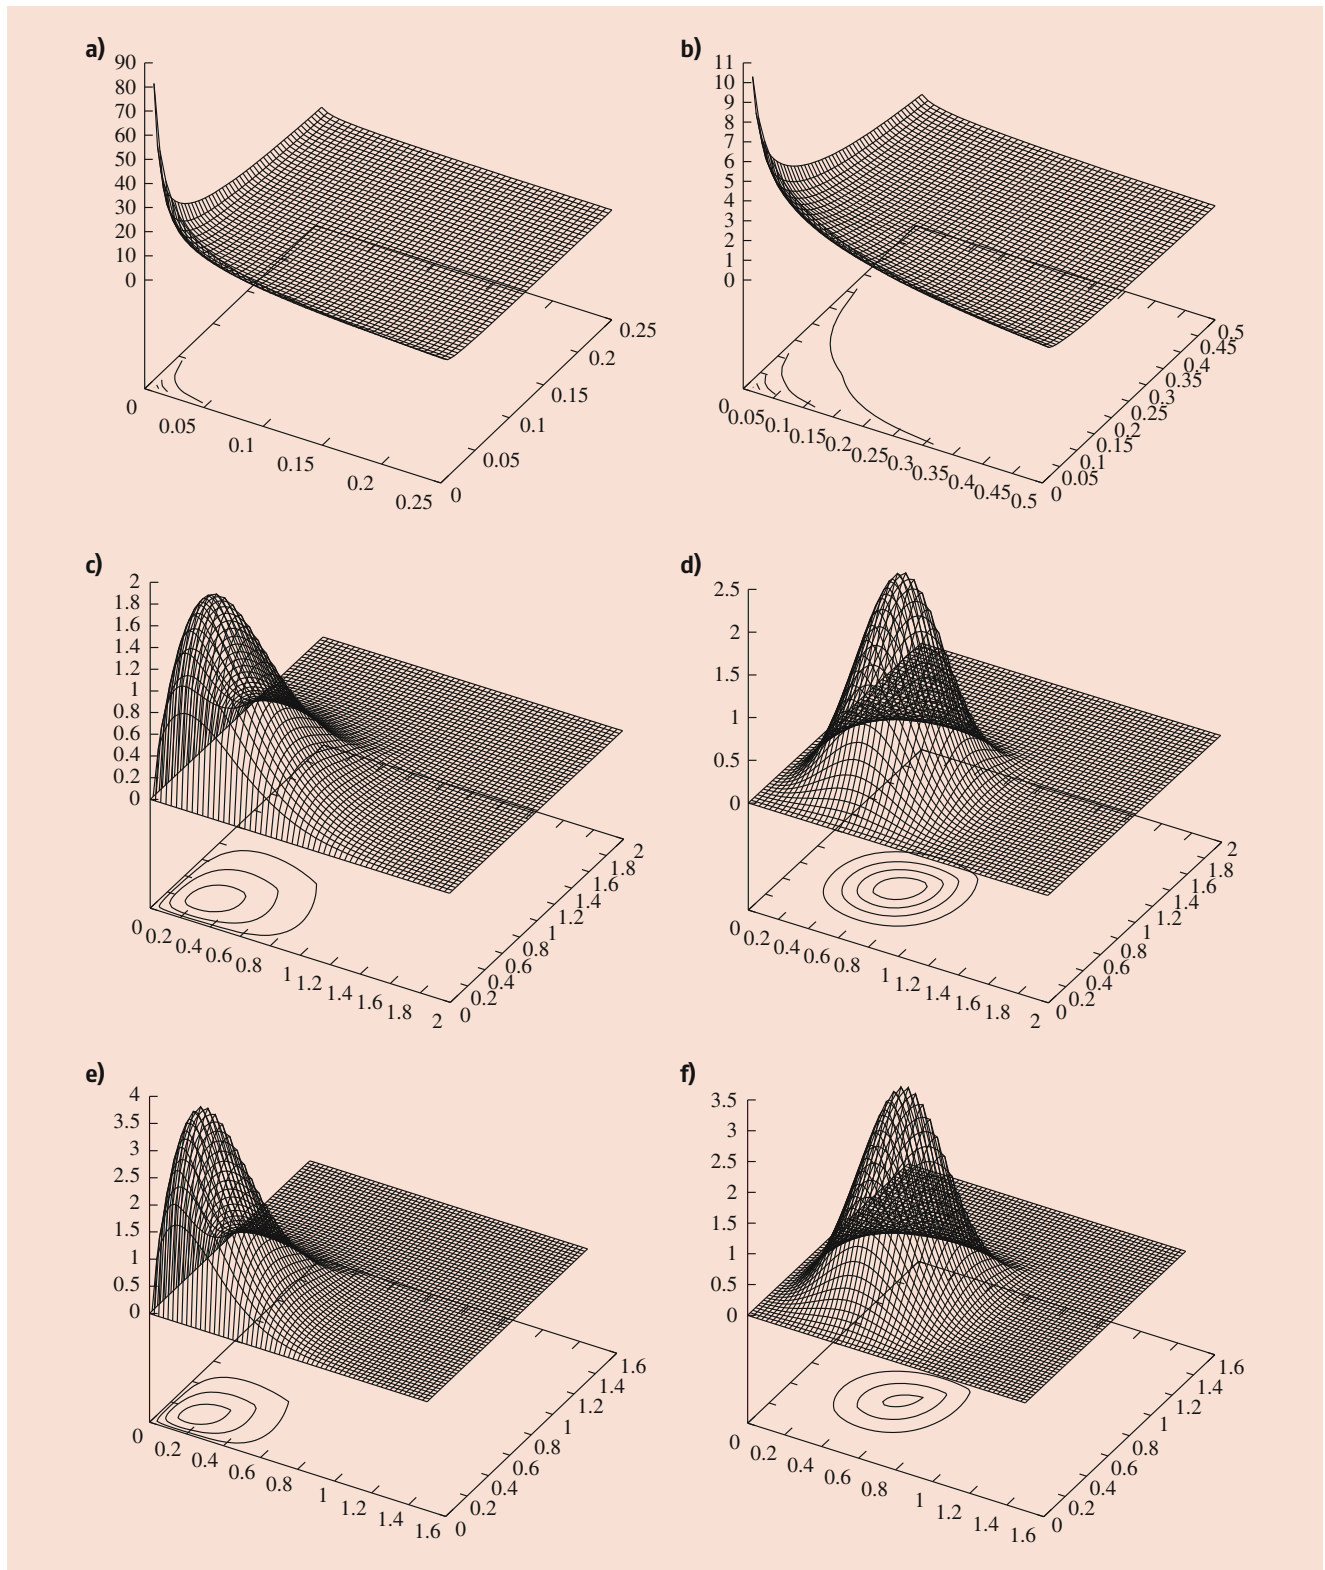

Fig. 36.2 PDF plots of $\text{MOBW}(\alpha_1, \alpha_2, \alpha_3, \theta)$ distribution for different $(\alpha_1, \alpha_2, \alpha_3, \theta)$ values: (a) (1.0,1.0,1.0,0.5) (b) (1.0,1.0,1.0,0.75) (c) (2.0,2.0,1.0,1.5) (d) (2.0,2.0,1.0,3.0) (e) (3.0,3.0,3.0,1.5) (f) (3.0,3.0,3.0,3.0)

$F_K(x; \alpha, \beta) = 1 - (1 - x^\beta)^\alpha$ and $f_K(x; \alpha, \beta) = \alpha\beta x^{\beta-1}(1 - x^\beta)^{\alpha-1}$, for $x > 0$. Hence, a BVK distribution with parameters $\alpha_1, \alpha_2, \alpha_3,$ and β has the following PDF:

$$f_{X,Y}(x, y) = \begin{cases} \alpha_1(\alpha_2 + \alpha_3)\beta^2 x^{\beta-1}(1 - x^\beta)^{\alpha_1-1} y^{\beta-1}(1 - y^\beta)^{\alpha_2+\alpha_3-1} & \text{if } x < y \\ (\alpha_1 + \alpha_3)\alpha_2\beta^2 x^{\beta-1}(1 - x^\beta)^{\alpha_1+\alpha_3-1} y^{\beta-1}(1 - y^\beta)^{\alpha_2-1} & \text{if } x > y \\ \theta\alpha_3\beta x^{\beta-1}(1 - x^\beta)^{\alpha_1+\alpha_2+\alpha_3-1} & \text{if } x = y, \end{cases} \quad (36.19)$$

and it will be denoted by $BVK(\alpha_1, \alpha_2, \alpha_3, \beta)$.

The PDF of the absolute continuous part of $BVK(\alpha_1, \alpha_2, \alpha_3, \beta)$ distribution for different $\alpha_1, \alpha_2, \alpha_3, \beta$ are provided in

Fig. 36.4. It is clear that it has bounded support on $[0,1] \times [0,1]$, and it can take a variety of shapes depending on the parameter values.

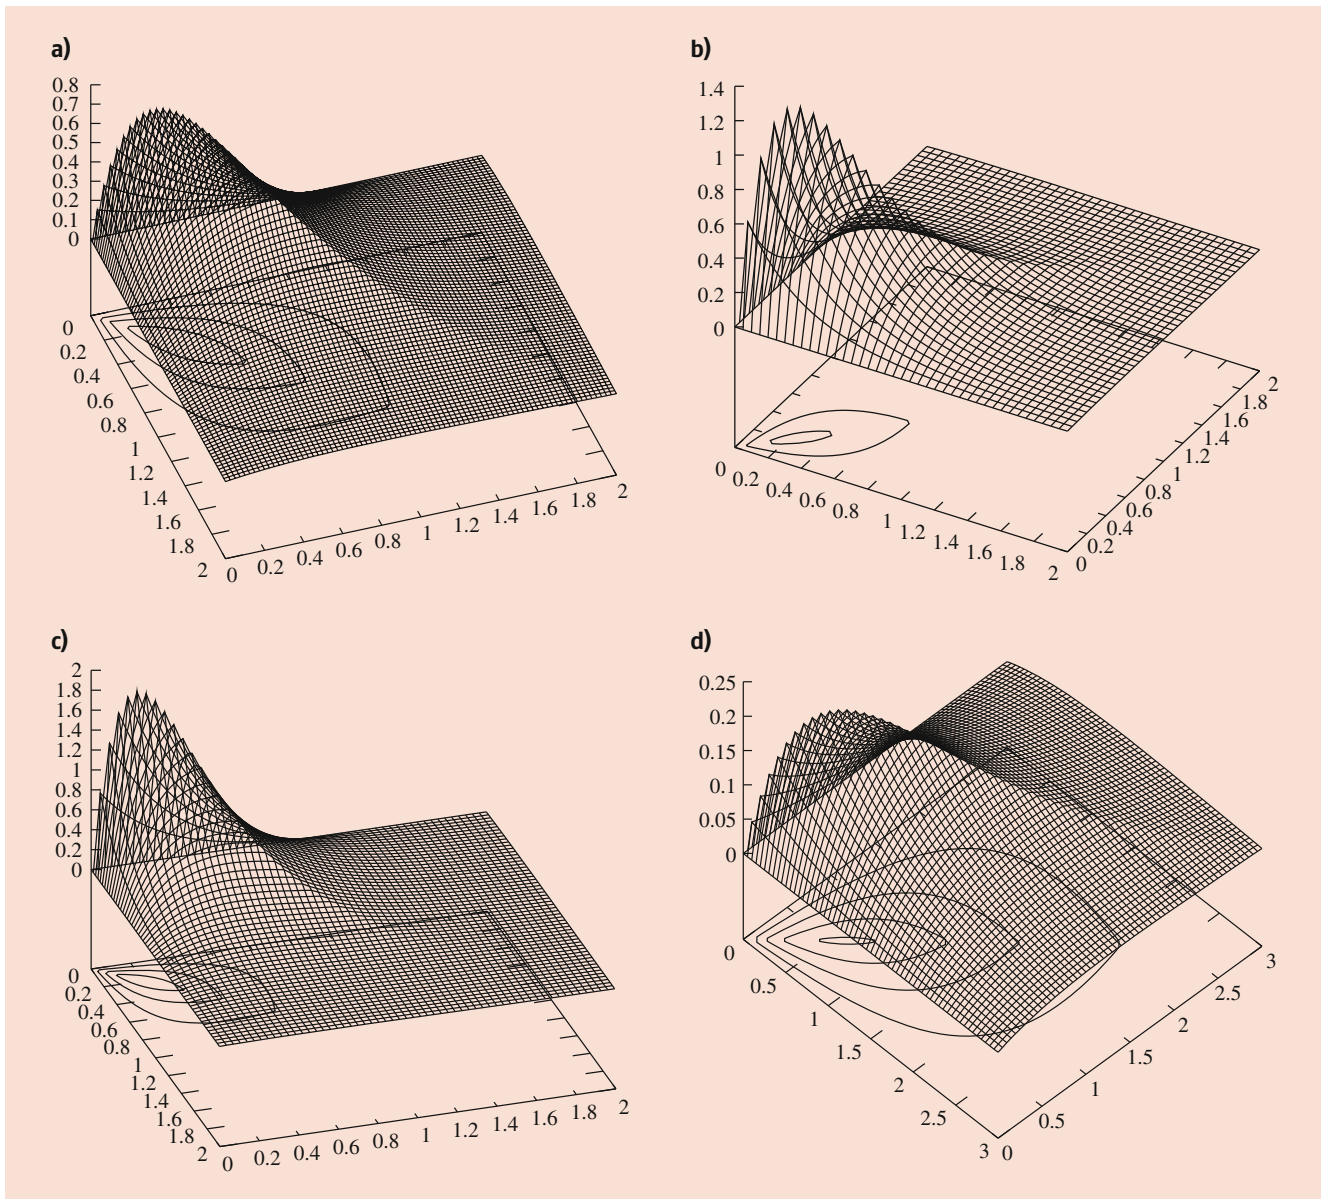

Fig. 36.3 PDF plots of $BWEE(\lambda_1, \lambda_2, \lambda_3, \alpha)$ distribution for different $(\lambda_1, \lambda_2, \lambda_3, \alpha)$ values: (a) (1.0,1.0,1.0,0.5) (b) (1.0,1.0,2.0,1.0) (c) (1.5,1.5,1.5,1.5) (d) (0.5,0.5,0.5,0.5)

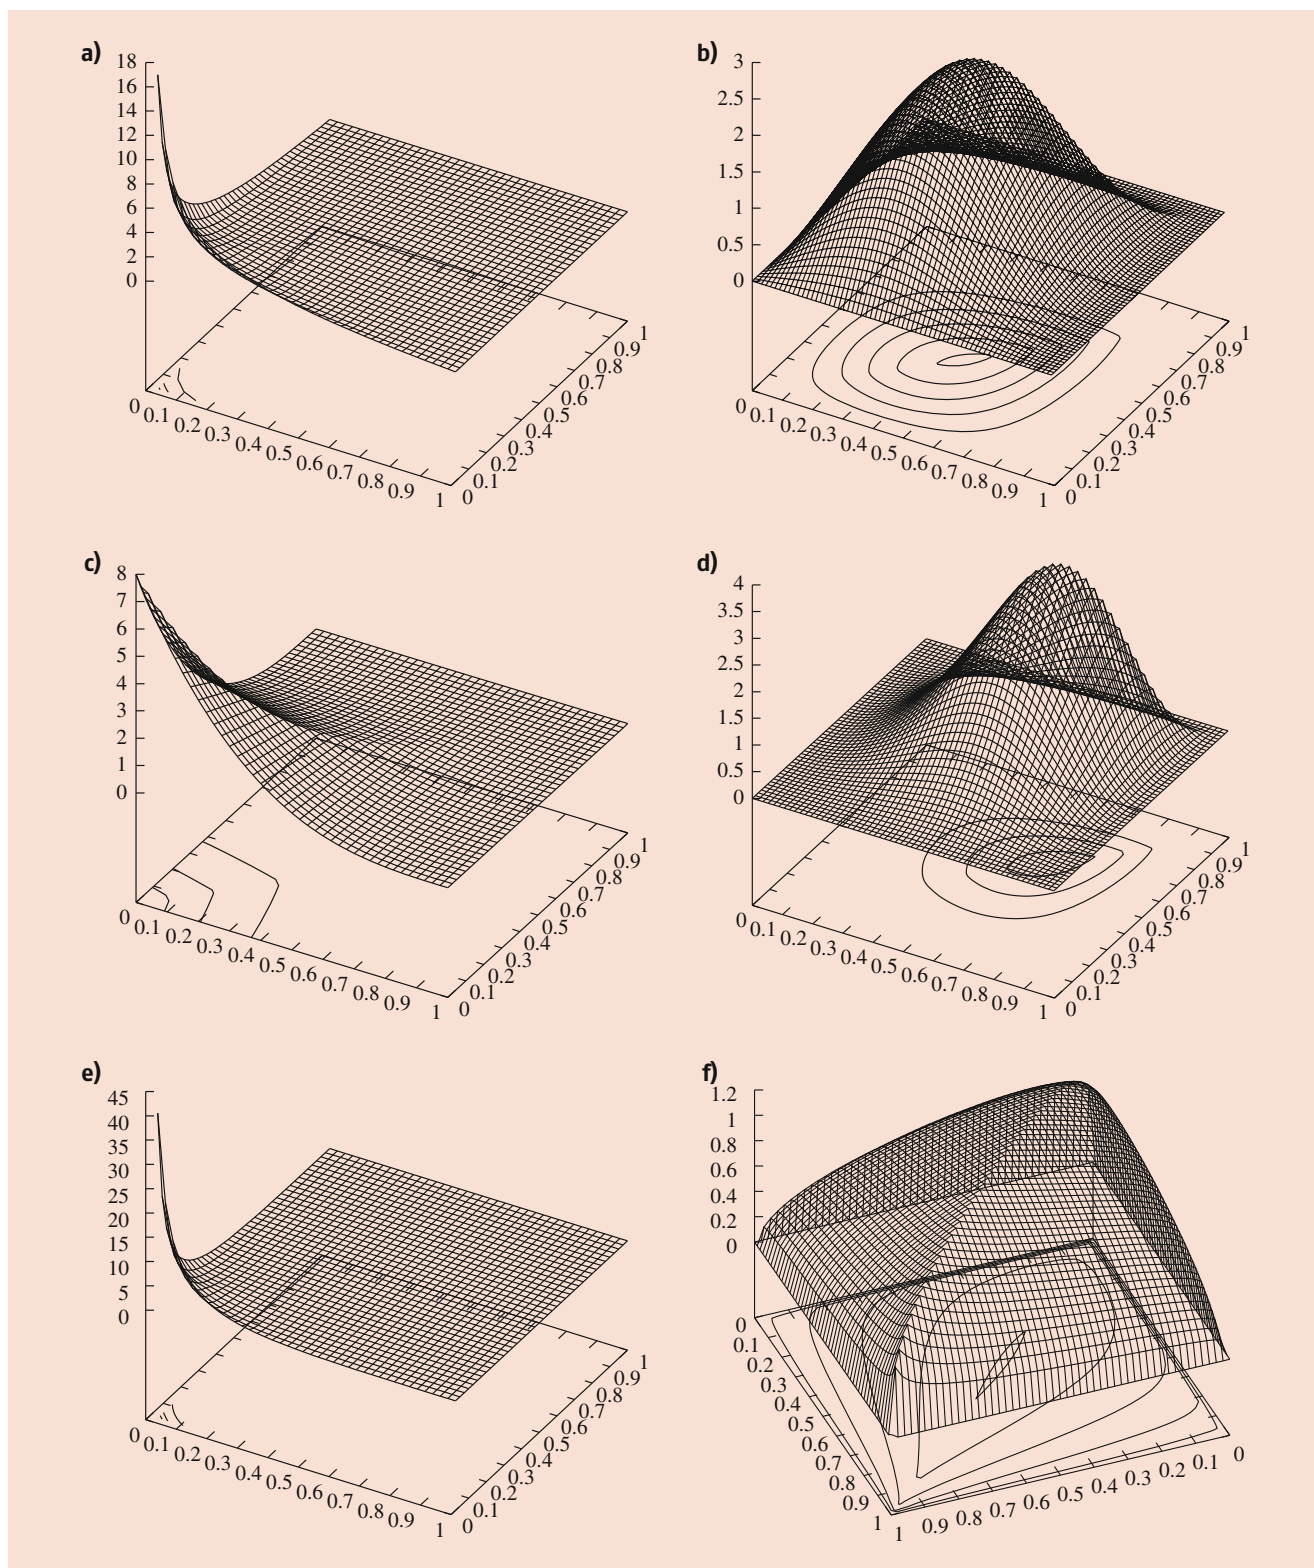

Fig. 36.4 PDF plots of $BVK(\alpha_1, \alpha_2, \alpha_3, \beta)$ distribution for different $(\alpha_1, \alpha_2, \alpha_3, \beta)$ values: (a) (1.0,1.0,1.0,0.5) (b) (2.0,2.0,2.0,2.0) (c) (2.0,2.0,2.0,1.0) (d) (2.0,2.0,2.0,3.0) (e) (2.0,2.0,2.0,0.5) (f) (0.75,0.75,0.75,1.1)

Barreto-Souza and Lemonte [9] developed several properties of the BVK distribution and also provided a very efficient EM algorithm to compute the maximum likelihood estimators of the unknown parameters. They have used this model to analyze a bivariate singular data set with bounded support.

36.4.2 Model 2

Bivariate Proportional Reversed Hazard Distribution

Kundu and Gupta [32] introduced the bivariate generalized exponential (BVGE) distribution as a stress model and as a

maintenance model. The idea is very similar to the MOBE or the MOBW distribution, but in this case the authors considered the maximization approach than the minimization method. It is assumed that the base line distribution function is an exponential distribution with the scale parameter λ , i.e., $F_B(t; \lambda) = (1 - e^{-t\lambda})$, for $t > 0$ and zero, otherwise. Let us assume that V_1 , V_2 , and V_3 have the CDFs $(1 - e^{-t\lambda})^{\beta_1}$, $(1 - e^{-t\lambda})^{\beta_2}$, and $(1 - e^{-t\lambda})^{\beta_3}$, and they are independently distributed. Here $\beta_1 > 0$, $\beta_2 > 0$, and $\beta_3 > 0$. It is clear that V_1 , V_2 , and V_3 have $GE(\beta_1, \lambda)$, $GE(\beta_2, \lambda)$, and $GE(\beta_3, \lambda)$, respectively. Hence, the joint PDF of (X, Y) in this case becomes

$$f_{X,Y}(x, y) = \begin{cases} (\beta_1 + \beta_3)\beta_2(1 - e^{-\lambda x})^{\beta_1 + \beta_3 - 1}(1 - e^{-\lambda y})^{\beta_2 - 1}e^{-\lambda(x+y)} & \text{if } 0 < x < y < \infty \\ (\beta_2 + \beta_3)\beta_1(1 - e^{-\lambda x})^{\beta_1 - 1}(1 - e^{-\lambda y})^{\beta_2 + \beta_3 - 1}e^{-\lambda(x+y)} & \text{if } 0 < y < x < \infty \\ \beta_3(1 - e^{-\lambda x})^{\beta_1 + \beta_2 + \beta_3 - 1}e^{-\lambda x} & \text{if } 0 < y = x < \infty, \end{cases} \quad (36.20)$$

and it will be denoted by $BVGE(\beta_1, \beta_2, \beta_3, \lambda)$. The absolute continuous part of the PDF of $BVGE(\beta_1, \beta_2, \beta_3, \lambda)$ for different values of β_1 , β_2 , β_3 , and λ is provided in Fig. 36.5. It is clear that the joint PDF of a BVGE is very similar to the joint PDF of a MOBW distribution for different parameter values. It is clear that if $0 < \beta_1 + \beta_3 < 1$ and $0 < \beta_1 + \beta_2 < 1$, then the maximum occurs at $(0, 0)$; otherwise it is unimodal.

It is observed that the BVGE distribution is also quite flexible like the BVWE distribution, and the marginals of the BVGE distribution follow generalized exponential distributions. Because of the presence of the four parameters, the BVGE distribution can be used quite effectively in analyzing various bivariate data sets. Kundu and Gupta [32] provided a very effective EM algorithm in computing the maximum likelihood estimators of the unknown parameters. It will be interesting to see how the EM algorithm can be modified for analyzing censored data also. No work has been done in developing Bayesian inference of the unknown parameters. It may be mentioned that as MOBW has been used for analyzing dependent competing risks data, BVGE distribution may be used for analyzing dependent complementary risks data; see, for example, Mondal and Kundu [47] in this respect.

Kundu and Gupta [34] extended the BVGE distribution to a more general class of bivariate proportional reversed hazard (BVPRH) distribution. In that paper the authors introduced three other classes of bivariate distributions, namely, (a) bivariate exponentiated Weibull (BVEW) distribution, (b) bivariate exponentiated Rayleigh (BVER) distribution, and (c) bivariate generalized linear failure rate (BVGLF) distribution. The BVEW distribution has been obtained by taking the base line distribution as $F_B(t; \alpha, \lambda) = (1 - e^{-\lambda t^\alpha})$, i.e., a

Weibull distribution with the scale parameter λ and the shape parameter α . The BVER distribution can be obtained by taking the base line distribution as a Rayleigh distribution, i.e., $F_B(t; \lambda) = (1 - e^{-\lambda t^2})$. Similarly, the BVGLF distribution can be obtained by taking $F_B(t; \lambda, \theta) = (1 - e^{-(\lambda t + \theta \lambda t^2)})$. Sarhan et al. [60] provided the detailed analysis of the BVGLF distribution. They obtained various properties and developed classical inference of the unknown parameters. It will be interesting to develop Bayesian inferences in all the above cases.

36.5 Classical Inference

In this section we present the classical inferences of the unknown parameters for both the classes of models. It may be mentioned that Arnold [2] first considered the MLEs of the unknown parameters for the Marshall-Olkin bivariate and multivariate normal distributions. Karlis [26] proposed the EM algorithm to compute the MLEs of the unknown parameters of the MOBE distribution. Kundu and Dey [30] extended the result of Karlis [26] to the case of MOBW distribution. In a subsequent paper, Kundu and Gupta [32] provided an EM algorithm to compute the MLEs of the unknown parameters for the modified Sarhan-Balakrishnan singular bivariate distribution. In this section we provide a general EM algorithm which can be used to compute the MLEs of the unknown parameters of bivariate distributions with singular components which can be obtained either by minimization or maximization approach.

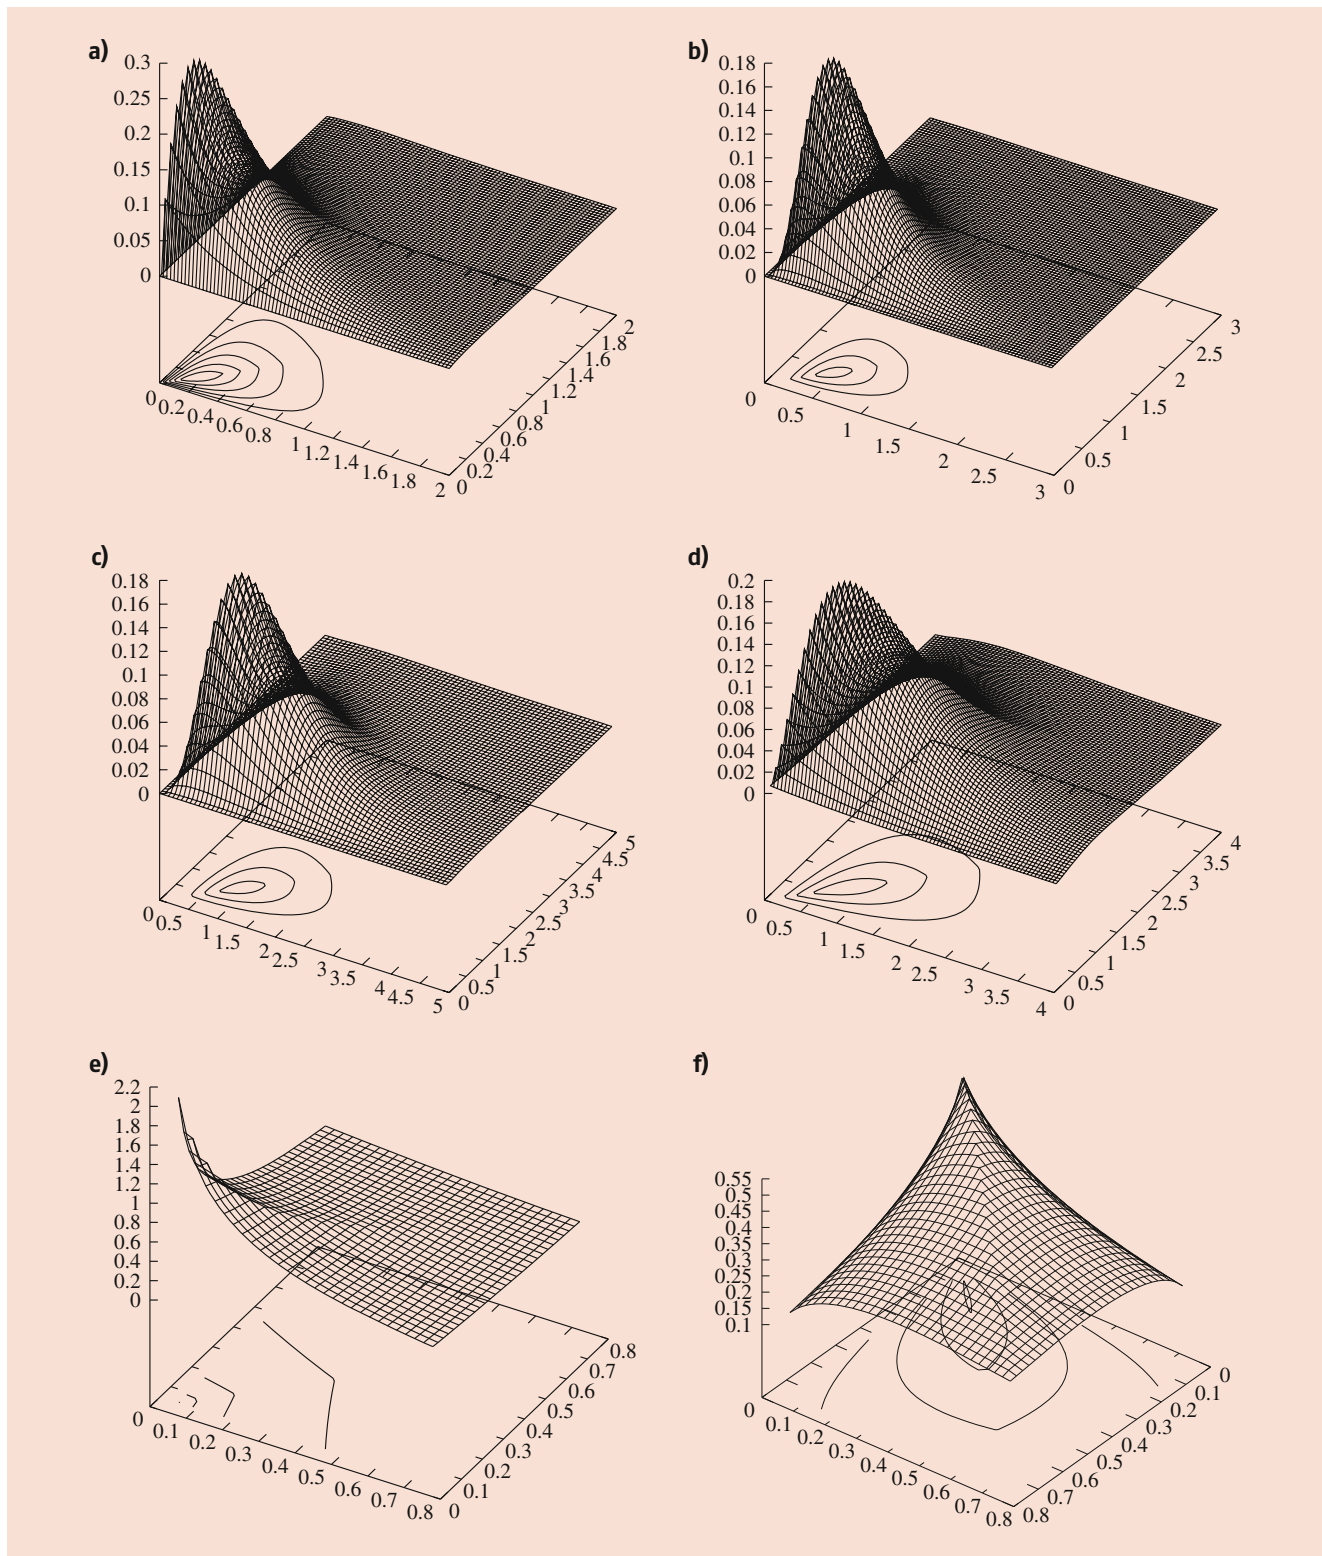

Fig. 36.5 PDF plots of $MOBE(\alpha_1, \alpha_2, \alpha_3, \theta)$ distribution for different $(\alpha_1, \alpha_2, \alpha_3, \theta)$ values: (a) (1.0,1.0,1.0,0.5) (b) (1.0,1.0,1.0,0.75) (c) (2.0,2.0,1.0,1.5) (d) (2.0,2.0,1.0,3.0) (e) (3.0,3.0,3.0,1.5) (f) (3.0,3.0,3.0,3.0)

36.5.1 EM Algorithm: Model 1

In this section we provide the EM algorithm to compute the MLEs of the unknown parameters when the data are coming from the joint PDF (36.11). It is assumed that we have the following data:

$$\mathcal{D} = \{(x_1, y_1), \dots, (x_n, y_n)\}.$$

It is assumed that $\alpha_1, \alpha_2, \alpha_3$, and θ are unknown parameters and the form of $S_B(t; \cdot)$ is known. It may be mentioned that θ

may be a vector valued also, but in this case we assume it to be a scalar for simplicity. Our method can be easily modified for the vector valued θ also. We further use the following notations:

$$I_0 = \{i : x_i = y_i\}, \quad I_1 = \{i : x_i < y_i\},$$

$$I_2 = \{i : x_i > y_i\}, \quad I = I_0 \cup I_1 \cup I_2,$$

$$|I_0| = n_0, \quad |I_1| = n_1, \quad |I_2| = n_2,$$

here $|I_j|$ for $j = 0, 1, 2$ denotes the number of elements in the set I_j . The log-likelihood function can be written as

$$\begin{aligned} l(\alpha_1, \alpha_2, \alpha_3, \theta) &= n_0 \ln \alpha_3 + n_1 \ln \alpha_1 + n_1 \ln(\alpha_2 + \alpha_3) + n_2 \ln \alpha_2 + n_2 \ln(\alpha_1 + \alpha_3) \\ &+ \sum_{i \in I} \ln f_B(x_i, \theta) + \sum_{i \in I_1 \cup I_2} \ln f_B(y_i, \theta) + (\alpha_1 + \alpha_2 + \alpha_3 - 1) \sum_{i \in I_0} \ln S_B(x_i, \theta) \\ &+ (\alpha_1 - 1) \sum_{i \in I_1} \ln S_B(x_i, \theta) + (\alpha_2 + \alpha_3 - 1) \sum_{i \in I_1} \ln S_B(y_i, \theta) \\ &+ (\alpha_1 + \alpha_3 - 1) \sum_{i \in I_1} \ln S_B(x_i, \theta) + (\alpha_2 - 1) \sum_{i \in I_1} \ln S_B(y_i, \theta). \end{aligned} \quad (36.21)$$

Hence, the MLEs of the unknown parameters can be obtained by maximizing (36.21) with respect to the unknown parameters. It is known that even in special cases, i.e., in case of exponential and Weibull distribution (see, e.g., Bemis et al. [11] and Kundu and Dey [30]), the MLEs do not exist if $n_1 n_2 n_3 = 0$. If $n_1 n_2 n_3 > 0$, then the MLEs exist, but they cannot be obtained in explicit forms. The MLEs have to be obtained by solving nonlinear equations, and it becomes a nontrivial problem. Note that in case of exponential, one needs to solve a three-dimensional optimization problem, and in case of Weibull, it is a four-dimensional optimization problem. Due to this reason several approximations and alternative estimators have been proposed in the literature; see, for example, Arnold [2] and Proschan and Sullo [55] in this respect.

We propose an EM algorithm which can be used to compute the MLEs of the unknown parameters, and it is an extension of the EM algorithm originally proposed by Karlis [26] for the exponential distribution. The basic idea of the proposed EM algorithm is quite simple. It may be observed that if instead of (X, Y) , (U_1, U_2, U_3) are known, then the MLEs of the unknown parameters can be obtained quite conveniently. Suppose we have the following complete data:

$$\mathcal{D}^c = \{(u_{11}, u_{12}, u_{13}), \dots, (u_{n1}, u_{n2}, u_{n3})\}, \quad (36.22)$$

then the log-likelihood function of the complete data can be written as

$$\begin{aligned} l_c(\alpha_1, \alpha_2, \alpha_3, \theta) &= n \ln \alpha_1 + \alpha_1 \sum_{i=1}^n \ln S_B(u_{i1}, \theta) + \sum_{i=1}^n (\ln f_B(u_{i1}, \theta) + \ln S_B(u_{i1}, \theta)) \\ &+ n \ln \alpha_2 + \alpha_2 \sum_{i=1}^n \ln S_B(u_{i2}, \theta) + \sum_{i=1}^n (\ln f_B(u_{i2}, \theta) + \ln S_B(u_{i2}, \theta)) \\ &+ n \ln \alpha_3 + \alpha_3 \sum_{i=1}^n \ln S_B(u_{i3}, \theta) + \sum_{i=1}^n (\ln f_B(u_{i3}, \theta) + \ln S_B(u_{i3}, \theta)). \end{aligned} \quad (36.23)$$

Hence, for a fixed θ , the MLEs of α_1 , α_2 , and α_3 can be obtained as

$$\widehat{\alpha}_{1c}(\theta) = -\frac{n}{\sum_{i=1}^n \ln S_B(u_{i1}, \theta)}, \quad \widehat{\alpha}_{2c}(\theta) = -\frac{n}{\sum_{i=1}^n \ln S_B(u_{i2}, \theta)}, \quad \widehat{\alpha}_{3c}(\theta) = -\frac{n}{\sum_{i=1}^n \ln S_B(u_{i3}, \theta)}. \quad (36.24)$$

Once, $\widehat{\alpha}_{1c}(\theta)$, $\widehat{\alpha}_{2c}(\theta)$, and $\widehat{\alpha}_{3c}(\theta)$ are obtained, the MLE of θ can be obtained by maximizing the profile log-likelihood function $l_c(\widehat{\alpha}_{1c}, \widehat{\alpha}_{2c}, \widehat{\alpha}_{3c}, \theta)$ with respect to θ . Therefore, instead of solving a four-dimensional optimization problem, one needs to solve only a one-dimensional optimization problem in this case. Due to this reason we treat this problem

as a missing value problem. The Table 36.1 will be useful in identifying the missing U_i s in different cases and the associated probabilities.

We need the following derivations for developing the EM algorithm for $i, j = 1, 2, 3$ and $i \neq j$.

$$E(U_j | U_j > u) = \frac{1}{[S_B(u, \theta)]^{\alpha_j}} \int_u^\infty \alpha_j t f_B(t; \theta) [S_B(t; \theta)]^{\alpha_j - 1} dt \quad (36.25)$$

$$E(U_j | \min\{U_i, U_j\} = u) = \frac{\alpha_j}{\alpha_i + \alpha_j} u + \frac{\alpha_i}{\alpha_i + \alpha_j} \times \frac{1}{[S_B(u, \theta)]^{\alpha_j}} \int_u^\infty \alpha_j t f_B(t; \theta) [S_B(t; \theta)]^{\alpha_j - 1} dt. \quad (36.26)$$

Using (36.25) and (36.26), we estimate the missing U_i s by its expected value. The expectation either can be performed by a direct numerical integration or by Monte Carlo simulations. Therefore, the following EM algorithm can be used to compute the MLEs of the unknown parameters in this case. Start with an initial guess of α_1 , α_2 , α_3 , and θ as

$\alpha_1^{(0)}$, $\alpha_2^{(0)}$, $\alpha_3^{(0)}$, and $\theta^{(0)}$, respectively. We provide the explicit method how the $(k+1)$ -th iterate can be obtained from the k -th iterate. Suppose at the k -th iterate the values of α_1 , α_2 , α_3 , and θ are $\alpha_1^{(k)}$, $\alpha_2^{(k)}$, $\alpha_3^{(k)}$, and $\theta^{(k)}$, respectively. Then if a data point $(x_i, x_i) \in I_0$, clearly, $u_{i3} = x_i$, and the missing u_{i1} and u_{i2} can be obtained as

$$u_{i1}^{(k)} = \frac{1}{[S_B(x_i, \theta^{(k)})]^{\alpha_1^{(k)}}} \int_{x_i}^\infty \alpha_1^{(k)} t f_B(t; \theta^{(k)}) [S_B(t; \theta^{(k)})]^{\alpha_1^{(k)} - 1} dt, \quad \text{and}$$

$$u_{i2}^{(k)} = \frac{1}{[S_B(x_i, \theta^{(k)})]^{\alpha_2^{(k)}}} \int_{x_i}^\infty \alpha_2^{(k)} t f_B(t; \theta^{(k)}) [S_B(t; \theta^{(k)})]^{\alpha_2^{(k)} - 1} dt.$$

Similarly, if $(x_i, y_i) \in I_1$, then $u_{i1} = x_i$, and the missing u_{i2} and u_{i3} can be obtained as

$$u_{i2}^{(k)} = \frac{y_i \alpha_2^{(k)}}{\alpha_2^{(k)} + \alpha_3^{(k)}} + \frac{\alpha_3^{(k)}}{\alpha_2^{(k)} + \alpha_3^{(k)}} \times \frac{1}{[S_B(x_i, \theta^{(k)})]^{\alpha_2^{(k)}}} \int_{y_i}^\infty \alpha_2^{(k)} t f_B(t; \theta^{(k)}) [S_B(t; \theta^{(k)})]^{\alpha_2^{(k)} - 1} dt,$$

$$u_{i3}^{(k)} = \frac{y_i \alpha_3^{(k)}}{\alpha_2^{(k)} + \alpha_3^{(k)}} + \frac{\alpha_2^{(k)}}{\alpha_2^{(k)} + \alpha_3^{(k)}} \times \frac{1}{[S_B(x_i, \theta^{(k)})]^{\alpha_3^{(k)}}} \int_{y_i}^\infty \alpha_3^{(k)} t f_B(t; \theta^{(k)}) [S_B(t; \theta^{(k)})]^{\alpha_3^{(k)} - 1} dt.$$

If $(x_i, y_i) \in I_2$, then $u_{i2} = y_i$, and the missing u_{i1} and u_{i3} can be obtained as

$$u_{i1}^{(k)} = \frac{x_i \alpha_1^{(k)}}{\alpha_1^{(k)} + \alpha_3^{(k)}} + \frac{\alpha_3^{(k)}}{\alpha_1^{(k)} + \alpha_3^{(k)}} \times \frac{1}{[S_B(y_i, \theta^{(k)})]^{\alpha_1^{(k)}}} \int_{x_i}^{\infty} \alpha_1^{(k)} t f_B(t; \theta^{(k)}) [S_B(t; \theta^{(k)})]^{\alpha_2^{(k)} - 1} dt,$$

$$u_{i3}^{(k)} = \frac{x_i \alpha_3^{(k)}}{\alpha_1^{(k)} + \alpha_3^{(k)}} + \frac{\alpha_1^{(k)}}{\alpha_1^{(k)} + \alpha_3^{(k)}} \times \frac{1}{[S_B(y_i, \theta^{(k)})]^{\alpha_3^{(k)}}} \int_{x_i}^{\infty} \alpha_3^{(k)} t f_B(t; \theta^{(k)}) [S_B(t; \theta^{(k)})]^{\alpha_2^{(k)} - 1} dt.$$

Therefore, we can obtain $\widehat{\alpha}_{1c}^{(k+1)}(\theta)$, $\widehat{\alpha}_{2c}^{(k+1)}(\theta)$, and $\widehat{\alpha}_{3c}^{(k+1)}(\theta)$ from the Eq. (36.24) by replacing (i) u_{i1} by $u_{i1}^{(k)}$ if $i \in I_0 \cup I_2$, (ii) u_{i2} by $u_{i2}^{(k)}$ if $i \in I_0 \cup I_1$, and (iii) u_{i3} by $u_{i3}^{(k)}$ if $i \in I_1 \cup I_2$. Obtain $\theta^{(k+1)}$ as

$$\theta^{(k+1)} = \arg \max_{\theta} l_c(\widehat{\alpha}_{1c}^{(k+1)}(\theta), \widehat{\alpha}_{2c}^{(k+1)}(\theta), \widehat{\alpha}_{3c}^{(k+1)}(\theta), \theta).$$

Here the function $l_c(\cdot, \cdot, \cdot, \cdot)$ is the log-likelihood function of the complete data set as defined by (36.23). Once we obtain $\theta^{(k+1)}$, $\alpha_1^{(k+1)}$, $\alpha_2^{(k+1)}$, and $\alpha_3^{(k+1)}$ can be obtained as

$$\alpha_1^{(k+1)} = \widehat{\alpha}_{1c}^{(k+1)}(\theta^{(k+1)}), \quad \alpha_2^{(k+1)} = \widehat{\alpha}_{2c}^{(k+1)}(\theta^{(k+1)}), \quad \alpha_3^{(k+1)} = \widehat{\alpha}_{3c}^{(k+1)}(\theta^{(k+1)}).$$

The process continues unless convergence takes place.

and I_2 as defined before. In this case the unknown parameters are β_1, β_2 , and β_3 and λ . In general λ can be vector valued also, but for simplicity it has been assumed to be a scalar valued. If it is assumed that the complete data are of the form

$$\mathcal{D}^c = \{(v_{11}, v_{12}, v_{13}), \dots, (v_{n1}, v_{n2}, v_{n3})\},$$

In this section we provide the EM algorithm when the data are coming from a bivariate distribution with the joint PDF (36.15). In this case we have assumed that the data are of the same form as in the previous case, and we have the sets I_0, I_1 ,

then the log-likelihood function based on the complete data can be written as

$$l_c(\beta_1, \beta_2, \beta_3, \lambda) = n \ln \beta_1 + \beta_1 \sum_{i=1}^n \ln F_B(v_{i1}, \lambda) + \sum_{i=1}^n (\ln f_B(v_{i1}, \theta) + \ln F_B(v_{i1}, \theta))$$

$$n \ln \beta_2 + \beta_2 \sum_{i=1}^n \ln F_B(v_{i2}, \theta) + \sum_{i=1}^n (\ln f_B(v_{i2}, \theta) + \ln F_B(v_{i2}, \theta))$$

$$n \ln \beta_3 + \beta_3 \sum_{i=1}^n \ln F_B(v_{i3}, \theta) + \sum_{i=1}^n (\ln f_B(v_{i3}, \theta) + \ln F_B(v_{i3}, \theta)). \tag{36.27}$$

Hence, for a fixed λ , the MLEs of β_1, β_2 , and β_3 can be obtained as

$$\widehat{\beta}_{1c}(\lambda) = -\frac{n}{\sum_{i=1}^n \ln F_B(v_{i1}, \lambda)}, \quad \widehat{\beta}_{2c}(\lambda) = -\frac{n}{\sum_{i=1}^n \ln F_B(v_{i2}, \lambda)}, \quad \widehat{\beta}_{3c}(\lambda) = -\frac{n}{\sum_{i=1}^n \ln F_B(v_{i3}, \lambda)}. \tag{36.28}$$

As before, once, $\widehat{\beta}_{1c}(\lambda)$, $\widehat{\beta}_{2c}(\lambda)$, and $\widehat{\beta}_{3c}(\lambda)$ are obtained, the MLE of λ can be obtained by maximizing the profile log-likelihood function $l_c(\widehat{\beta}_{1c}(\lambda), \widehat{\beta}_{2c}(\lambda), \widehat{\beta}_{3c}(\lambda), \lambda)$ with respect

to λ . We have a similar Table 36.2 as Table 36.1, identifying the missing V_i s in different cases. Similar to (36.25) and (36.26), we need the following expressions in this case for developing the EM algorithm for $i, j = 1, 2, 3$ and $i \neq j$.

$$E(V_j | V_j < u) = \frac{1}{[F_B(u, \lambda)]^{\beta_j}} \int_0^u \beta_j t f_B(t; \lambda) [F_B(t; \lambda)]^{\beta_j - 1} dt \quad (36.29)$$

$$E(V_j | \max\{V_i, V_j\} = u) = \frac{\beta_j}{\beta_i + \beta_j} u + \frac{\beta_i}{\beta_i + \beta_j} \frac{1}{[F_B(u, \lambda)]^{\beta_j}} \int_0^u \beta_j t f_B(t; \lambda) [F_B(t; \lambda)]^{\beta_j - 1} dt. \quad (36.30)$$

Now we provide the explicit method in this case how the $(k + 1)$ -th iterate can be obtained from the k -th iterate. Let us assume that at the k -th iterate the values of $\beta_1, \beta_2, \beta_3$, and λ are $\beta_1^{(k)}, \beta_2^{(k)}, \beta_3^{(k)}$, and $\lambda^{(k)}$, respectively. Then if a data point $(x_i, x_i) \in I_0$, clearly, $u_{i3} = x_i$, and the missing v_{i1} and v_{i2} can be obtained as

$$v_{i1}^{(k)} = \frac{1}{[F_B(x_i, \lambda^{(k)})]^{\beta_1^{(k)}}} \int_0^{x_i} \beta_1^{(k)} t f_B(t; \lambda^{(k)}) [F_B(t; \lambda^{(k)})]^{\beta_1^{(k)} - 1} dt,$$

and

$$v_{i2}^{(k)} = \frac{1}{[F_B(x_i, \lambda^{(k)})]^{\beta_2^{(k)}}} \int_0^{x_i} \beta_2^{(k)} t f_B(t; \lambda^{(k)}) [F_B(t; \lambda^{(k)})]^{\beta_2^{(k)} - 1} dt.$$

Similarly, if $(x_i, y_i) \in I_1$, then $v_{i2} = y_i$, and the missing v_{i1} and v_{i3} can be obtained as

$$v_{i1}^{(k)} = \frac{x_i \beta_1^{(k)}}{\beta_1^{(k)} + \beta_3^{(k)}} + \frac{\beta_3^{(k)}}{\beta_1^{(k)} + \beta_3^{(k)}} \times \frac{1}{[F_B(x_i, \lambda^{(k)})]^{\beta_1^{(k)}}} \int_0^{x_i} \beta_1^{(k)} t f_B(t; \lambda^{(k)}) [F_B(t; \lambda^{(k)})]^{\beta_1^{(k)} - 1} dt,$$

$$v_{i3}^{(k)} = \frac{x_i \beta_3^{(k)}}{\beta_1^{(k)} + \beta_3^{(k)}} + \frac{\beta_1^{(k)}}{\beta_1^{(k)} + \beta_3^{(k)}} \times \frac{1}{[F_B(x_i, \lambda^{(k)})]^{\beta_3^{(k)}}} \int_0^{x_i} \beta_3^{(k)} t f_B(t; \lambda^{(k)}) [F_B(t; \lambda^{(k)})]^{\beta_3^{(k)} - 1} dt.$$

If $(x_i, y_i) \in I_2$, then $v_{i1} = x_i$, and the missing v_{i2} and v_{i3} can be obtained as

$$v_{i2}^{(k)} = \frac{y_i \beta_2^{(k)}}{\beta_2^{(k)} + \beta_3^{(k)}} + \frac{\beta_3^{(k)}}{\beta_2^{(k)} + \beta_3^{(k)}} \times \frac{1}{[F_B(y_i, \lambda^{(k)})]^{\beta_2^{(k)}}} \int_0^{y_i} \beta_2^{(k)} t f_B(t; \lambda^{(k)}) [F_B(t; \lambda^{(k)})]^{\beta_2^{(k)} - 1} dt,$$

$$v_{i3}^{(k)} = \frac{y_i \beta_3^{(k)}}{\beta_2^{(k)} + \beta_3^{(k)}} + \frac{\beta_2^{(k)}}{\beta_2^{(k)} + \beta_3^{(k)}} \times \frac{1}{[F_B(y_i, \lambda^{(k)})]^{\beta_3^{(k)}}} \int_0^{y_i} \beta_3^{(k)} t f_B(t; \lambda^{(k)}) [F_B(t; \lambda^{(k)})]^{\beta_3^{(k)} - 1} dt.$$

In this case also similarly as before, we can obtain $\widehat{\beta}_{1c}^{(k+1)}(\lambda)$, $\widehat{\beta}_{2c}^{(k+1)}(\lambda)$, and $\widehat{\beta}_{3c}^{(k+1)}(\lambda)$ from the Eq. (36.28) by replacing (i) v_{i1} by $v_{i1}^{(k)}$ if $i \in I_0 \cup I_1$, (ii) v_{i2} by $v_{i2}^{(k)}$ if $i \in I_0 \cup I_2$, and (iii) v_{i3} by $v_{i3}^{(k)}$ if $i \in I_1 \cup I_2$. Obtain $\lambda^{(k+1)}$ as

$$\lambda^{(k+1)} = \arg \max l_c(\widehat{\beta}_{1c}^{(k+1)}(\lambda), \widehat{\beta}_{2c}^{(k+1)}(\lambda), \widehat{\beta}_{3c}^{(k+1)}(\lambda), \lambda).$$

Here the function $l_c(\cdot, \cdot, \cdot, \cdot)$ is the log-likelihood function of the complete data set as defined by (36.27). Once we obtain $\lambda^{(k+1)}, \beta_1^{(k+1)}, \beta_2^{(k+1)}$, and $\beta_3^{(k+1)}$ can be obtained as

$$\begin{aligned} \beta_1^{(k+1)} &= \widehat{\beta}_{1c}^{(k+1)}(\lambda^{(k+1)}), & \beta_2^{(k+1)} &= \widehat{\beta}_{2c}^{(k+1)}(\lambda^{(k+1)}), \\ \beta_3^{(k+1)} &= \widehat{\beta}_{3c}^{(k+1)}(\lambda^{(k+1)}). \end{aligned}$$

The process continues unless convergence takes place.

Table 36.1 Different cases and missing U_i s

Different cases	$X \& Y$	Set	Value of U_i 's	Missing U_i 's	Probability of Missing U_i 's
$U_3 < \min\{U_1, U_2\}$	$X = Y$	I_0	$U_3 = X = Y$	$U_1 \& U_2$	1
$U_1 < \min\{U_2, U_3\}$	$X < Y$	I_1	$X = U_1, Y = U_2$	U_3	$\frac{\alpha_2}{\alpha_2 + \alpha_3}$
$U_1 < \min\{U_2, U_3\}$	$X < Y$	I_1	$X = U_1, Y = U_3$	U_2	$\frac{\alpha_3}{\alpha_2 + \alpha_3}$
$U_2 < \min\{U_1, U_3\}$	$Y < X$	I_2	$X = U_1, Y = U_2$	U_3	$\frac{\alpha_1}{\alpha_1 + \alpha_3}$
$U_2 < \min\{U_1, U_3\}$	$Y < X$	I_2	$X = U_3, Y = U_2$	U_1	$\frac{\alpha_3}{\alpha_1 + \alpha_3}$

Table 36.2 Different cases and missing V_i s

Different cases	$X \& Y$	Set	Value of V_i s	Missing V_i s	Probability of Missing V_i s
$V_3 > \max\{V_1, V_2\}$	$X = Y$	I_0	$V_3 = X = Y$	$V_1 \& V_2$	1
$V_2 > \max\{V_1, V_3\}$	$X < Y$	I_1	$X = V_1, Y = V_2$	V_3	$\frac{\beta_1}{\beta_1 + \beta_3}$
$V_2 > \max\{V_1, V_3\}$	$X < Y$	I_1	$X = V_3, Y = V_2$	V_1	$\frac{\beta_3}{\beta_1 + \beta_3}$
$V_1 > \max\{V_2, V_3\}$	$Y < X$	I_2	$X = V_1, Y = V_2$	V_3	$\frac{\beta_2}{\beta_2 + \beta_3}$
$V_1 > \max\{V_2, V_3\}$	$Y < X$	I_2	$X = V_1, Y = V_3$	V_2	$\frac{\beta_3}{\beta_2 + \beta_3}$

In both the cases the associated Fisher information matrix can be easily obtained at the last step of the EM algorithm, and it can be used to construct confidence intervals of the unknown parameters.

36.6 Data Analysis

In this section we provide the analysis of one data set mainly to show how the proposed EM algorithms work in practice. It is observed that it might be possible to provide some physical justification also in certain cases under some simplified assumptions.

This data set is originally available in Meintanis [46], and it is presented in Table 36.3. This data set represents the soccer data where at least one goal is scored by the home team and at least one goal is scored directly from a penalty kick, foul kick, or any other direct kick by any team. All these direct goals are usually called as kick goals. Here X represents the time in minutes of the first kick goal scored by any team, and Y represents the time in minutes the first goal of any type scored by the home team. Clearly, in this case all the three possibilities are present, namely, $X < Y, X > Y,$ and $X = Y$.

Let us consider three random variables $U_1, U_2,$ and U_3 as follows:

U_1 = time in minutes that a first kick goal has been scored by the opponent

U_2 = time in minutes that a first non-kick goal has been scored by the home team

U_3 = the time in minutes that a first kick goal has been scored by the home team

Table 36.3 UEFA Champion League data

2005–2006	X	Y	2004–2005	X	Y

In this case $X = \min\{U_1, U_3\}$ and $Y = \min\{U_2, U_3\}$. If it is assumed that $U_1, U_2,$ and U_3 are independently distributed, then (X, Y) can be obtained as Model 1. In this case we have used three different $S_B(t; \theta)$ and analyze the data set. The following $S_B(t; \theta)$ has been used in this case:

(a) $S_B(t; \theta) = e^{-t},$ (b) $S_B(t; \theta) = e^{-t^\beta},$ (c) $S_B(t; \theta) = e^{-t^\beta}.$

Note that $S_B(t; \theta)$ in three different cases are as follows: (a) exponential, (b) Rayleigh, and (c) Weibull, and the corresponding hazard functions are (a) constant, (b) increasing, and (c) increasing or decreasing. We have divided all the data points by 100, and it is not going to make any difference in the inference procedure. We compute the MLEs of the

unknown parameters based on the proposed EM algorithm. We start the EM algorithm with some initial guesses and continue the process. We stop the EM algorithm when the ratio $|l(k+1) - l(k)|/|l(k)| < 10^{-8}$; here $l(k)$ denotes the value of the log-likelihood function at the k -th iterate. Based on the method proposed by Louis [40], it is possible to compute the observed Fisher information matrix at the final step of the EM algorithm. We have provided the MLEs of the unknown parameters, the associate 95% confidence intervals, and the corresponding log-likelihood values for different cases in Table 36.4.

For illustrative purposes, we have used Model 2 also to analyze this data set. We have used three different $F_B(t; \lambda)$, Namely, (i) $F_B(t; \lambda) = (1 - e^{-\lambda t})$, (ii) $F_B(t; \lambda) = (1 - e^{-\lambda t^2})$, and (iii) $F_B(t; \lambda_1, \lambda_2) = (1 - e^{-\lambda_1 t^{\lambda_2}})$. In this case (i) represents exponential, (ii) represents Rayleigh, and (iii) represents Weibull distributions. In this case also we have calculated the MLEs of the unknown parameters using EM algorithm as mentioned before, and we have used the same stopping rule as in the previous case here also. The MLEs of the unknown parameters, the associated 95% confidence intervals, and the corresponding log-likelihood values are reported in Table 36.5. In all the cases it is observed that the EM algorithm converges within 25 iterations. It seems EM algorithm works quite well for both the models.

36.7 Some Other Bivariate Distributions

In this section we provide few other bivariate distributions with singular components which are available in the literature, which cannot be obtained as special cases of Model

1 or Model 2. It can be seen that in the first two examples, although the construction remains the same, their final forms are different. Reasons will be clear soon. Efficient estimation procedures using EM algorithm can be developed in both the cases. Marshall and Olkin [45] proposed a method to introduce an extra parameter to an univariate distribution, and they have shown how it can be done in case of an exponential or Weibull distribution. They have indicated how it can be done for the bivariate cases also. Kundu and Gupta [36] developed bivariate distributions with singular components based on the idea of Marshall and Olkin [45]. Different properties and efficient estimation procedures have been developed.

36.7.1 Sarhan-Balakrishnan Bivariate Distribution

Sarhan and Balakrishnan [58] proposed this distribution based on minimization approach, but they have not taken the base line distribution as the proportional hazard class. Sarhan and Balakrishnan [58] assumed the distribution functions of U_1, U_2 , and U_3 , for $t > 0$, as $F_{U_1}(t, \alpha_1) = (1 - e^{-t})^{\alpha_1}$, $F_{U_2}(t, \alpha_2) = (1 - e^{-t})^{\alpha_2}$, and $F_{U_3}(t; \lambda) = (1 - e^{-\lambda t})$, respectively. Consider a bivariate random variable (X, Y) , such that $X = \min\{U_1, U_3\}$ and $Y = \min\{U_2, U_3\}$. It may be mentioned that although U_1, U_2 , and U_3 belong to proportional reversed hazard class, the authors considered the minimization approach. Due to that reason the joint PDF of X and Y is not a very a compact form. The joint SF and the joint PDF of X and Y also can be derived along the same way, as we have mentioned in the previous section. The joint SF of X and Y in this case becomes

$$S_{X,Y}(x, y) = P(X > x, Y > y) \\ = \begin{cases} e^{-\lambda x}(1 - (1 - e^{-x})^{\alpha_1})(1 - (1 - e^{-y})^{\alpha_2}) & \text{if } 0 < y < x < \infty \\ e^{-\lambda y}(1 - (1 - e^{-x})^{\alpha_1})(1 - (1 - e^{-y})^{\alpha_2}) & \text{if } 0 < x \leq y < \infty, \end{cases}$$

and the joint PDF can be obtained as

Here

$$f_{X,Y}(x, y) = \begin{cases} f_1(x, y) & \text{if } 0 < y < x < \infty, \\ f_2(x, y) & \text{if } 0 < x < y < \infty, \\ f_0(x) & \text{if } 0 < x = y < \infty. \end{cases}$$

$$f_1(x, y) = \alpha_2 e^{-(\lambda x + y)} (1 - e^{-y})^{\alpha_2 - 1} (\lambda - \lambda(1 - e^{-x})^{\alpha_1} + \alpha_1 e^{-x}(1 - e^{-x})^{\alpha_1 - 1}) \\ f_2(x, y) = \alpha_1 e^{-(\lambda y + x)} (1 - e^{-x})^{\alpha_1 - 1} (\lambda - \lambda(1 - e^{-y})^{\alpha_2} + \alpha_2 e^{-y}(1 - e^{-y})^{\alpha_2 - 1}) \\ f_0(x) = \lambda e^{-\lambda x} (1 - (1 - e^{-x})^{\alpha_1}) (1 - (1 - e^{-y})^{\alpha_2}).$$

Therefore, the SF and X and Y become

$$S_X(x) = P(X > x) = e^{-\lambda x} (1 - (1 - e^{-x})^{\alpha_1}) \quad \text{and} \quad S_Y(y) = P(Y > y) = e^{-\lambda y} (1 - (1 - e^{-y})^{\alpha_2}),$$

respectively. It should also be mentioned that the copula associated with the Sarhan-Balakrishnan bivariate distribution cannot be obtained in an explicit form.

where $z = \max\{x, y\}$. Hence the marginal survival function can be obtained as

$$P(X > x) = (1 - (1 - e^{-\lambda x})^{\alpha_1})(1 - (1 - e^{-\lambda z})^{\alpha_3}) \\ P(Y > y) = (1 - (1 - e^{-\lambda y})^{\alpha_2})(1 - (1 - e^{-\lambda z})^{\alpha_3}).$$

36.7.2 Modified Sarhan-Balakrishnan Bivariate Distribution

Kundu and Gupta [33] proposed a modified version of the Sarhan-Balakrishnan bivariate distribution, and the latter can be obtained as a special case of the former. The idea is as follows: Suppose U_1 , U_2 , and U_3 are three independent random variables, such that for $t > 0$, the CDF of U_1 , U_2 , and U_3 are $F_{U_1}(t; \alpha_1, \lambda) = (1 - e^{-\lambda t})^{\alpha_1}$, $F_{U_2}(t; \alpha_2, \lambda) = (1 - e^{-\lambda t})^{\alpha_2}$, and $F_{U_3}(t; \alpha_3, \lambda) = (1 - e^{-\lambda t})^{\alpha_3}$, respectively. In this case also consider a bivariate random variable (X, Y) , such that $X = \min\{U_1, U_3\}$ and $Y = \min\{U_2, U_3\}$. Clearly, the modified Sarhan-Balakrishnan bivariate distribution is more flexible than the Sarhan-Balakrishnan bivariate distribution.

The joint survival function in this case can be obtained as

$$S_{X,Y}(x, y) = P(X > x, Y > y) \\ = (1 - (1 - e^{-\lambda x})^{\alpha_1})(1 - (1 - e^{-\lambda y})^{\alpha_2}) \\ (1 - (1 - e^{-\lambda z})^{\alpha_3}),$$

Along the same line as before, the joint PDF of the modified Sarhan-Balakrishnan bivariate distribution can be obtained as

$$f_{X,Y}(x, y) = \begin{cases} f_1(x, y) & \text{if } 0 < y < x < \infty, \\ f_2(x, y) & \text{if } 0 < x < y < \infty, \\ f_0(x) & \text{if } 0 < x = y < \infty, \end{cases}$$

where

$$f_1(x, y) = f(x; \alpha_1, \lambda)[f(y; \alpha_2, \lambda) + f(y; \alpha_3, \lambda) \\ - f(y; \alpha_2 + \alpha_3, \lambda)] \\ f_2(x, y) = f(y; \alpha_2, \lambda)[f(x; \alpha_1, \lambda) + f(x; \alpha_3, \lambda) \\ - f(x; \alpha_1 + \alpha_3, \lambda)]$$

$$f_0(x) = \frac{\alpha_1}{\alpha_1 + \alpha_3} f(x; \alpha_1 + \alpha_3, \lambda) + \frac{\alpha_2}{\alpha_2 + \alpha_3} f(x; \alpha_2 + \alpha_3, \lambda) \\ - \frac{\alpha_1 + \alpha_2}{\alpha_1 + \alpha_2 + \alpha_3} f(x; \alpha_1 + \alpha_2 + \alpha_3, \lambda).$$

Here

$$f(x; \alpha, \lambda) = \begin{cases} \alpha \lambda e^{-\lambda x} (1 - e^{-\lambda x})^{\alpha-1} & \text{if } x > 0 \\ 0 & \text{if } x \leq 0. \end{cases}$$

In this also the copula associated with the modified Sarhan-Balakrishnan bivariate distribution cannot be obtained in a compact form. Note that this idea can be extended for the proportional reversed hazard classes also. The necessary EM algorithm also can be developed for this model along the same line.

36.7.3 Bivariate Weibull-Geometric Distribution

As it has been mentioned before, Marshall and Olkin [45] proposed a method to introduce a parameter in a family of

distributions. It introduces an extra parameter to a model; hence it brings more flexibility. The model has some interesting physical interpretations also. The basic idea is very simple, and it can be defined as follows. Suppose $\{X_n; n = 1, 2, \dots\}$ is a sequence of i.i.d. random variables and N is a geometric random variable with parameter $0 < p \leq 1$ having probability mass function

$$P(N = n) = p(1 - p)^{n-1}; \quad n = 1, 2, \dots \quad (36.31)$$

Here, X'_n 's and N are independently distributed. Consider the random variables,

$$Y = \min\{X_1, \dots, X_N\}.$$

We denote $S_X(\cdot)$, $S_Y(\cdot)$, $f_X(\cdot)$, and $f_Y(\cdot)$ as the survival function of X , survival function of Y , PDF of X_1 , and PDF of Y , respectively. The CDF of Y becomes

$$\begin{aligned} S_Y(y) &= P(Y > y) = P(X_1 > y, \dots, X_N > y) = \sum_{n=1}^{\infty} P(X_1 > y, \dots, X_n > y | N = n) P(N = n) \\ &= p \sum_{n=1}^{\infty} S_X^n(y) (1 - p)^{n-1} = \frac{p S_X(y)}{1 - (1 - p) S_X(y)}. \end{aligned}$$

Therefore, the PDF of Y becomes

$$f_Y(y) = \frac{p f_X(y)}{(1 - (1 - p) S_X(y))^2}.$$

If X_1 is an exponential random variable with mean $1/\lambda$, then Y is called Marshall-Olkin exponential (MOE) random variable. The PDF of a MOE distribution with parameter λ and p , MOE(p, λ), is

$$f_Y(y; p, \lambda) = \frac{p \lambda e^{-\lambda y}}{(1 - (1 - p) e^{-\lambda y})^2}; \quad y > 0. \quad (36.32)$$

When $p = 1$, it becomes an exponential random variable. From the PDF (36.32), it is clear that MOE is a weighted exponential random variable, where the weight function is

$$w(y) = \frac{p}{(1 - (1 - p) e^{-\lambda y})^2}; \quad y > 0.$$

Hence, the two-parameter MOE distribution is more flexible than the one parameter exponential distribution. Similarly, if X_1 is a Weibull random variable with the shape parameter $\alpha > 0$ and scale parameter $\lambda > 0$, with the PDF

$$f_X(x; \alpha, \lambda) = \alpha \lambda x^{\alpha-1} e^{-\lambda x^\alpha}; \quad x > 0$$

then the associated Y is said to have Marshall-Olkin Weibull (MOWE) distribution. The MOWE has the PDF

$$f_Y(y; p, \alpha, \lambda) = \frac{p \alpha \lambda y^{\alpha-1} e^{-\lambda y^\alpha}}{(1 - (1 - p) e^{-\lambda y^\alpha})^2}.$$

It is immediate that the MOWE distribution is a weighted Weibull distribution, and in this case the weight function is

$$w(y) = \frac{p}{(1 - (1 - p) e^{-\lambda y^\alpha})^2}; \quad y > 0.$$

The three-parameter MOWE distribution is more flexible than the two-parameter Weibull distribution. Marshall and Olkin [45] developed several properties of the MOE and MOWE distributions. Although Marshall and Olkin [45] did not develop any estimation procedure, very effective EM algorithm can be developed as it has been obtained in case of the corresponding bivariate model by Kundu and Gupta [36].

In the same paper Marshall and Olkin [45] mentioned how their method can be extended to the multivariate case also, although they did not provide much detail. Moreover, the extension to the bivariate or multivariate case may not be unique. Kundu and Gupta [36] first used the method of Marshall and Olkin [45] to extend MOBW distribution and called it as the bivariate Weibull-Geometric (BWG) distribution.

It has five parameters, and MOBW can be obtained as a special case of BWG distribution. The details are given below.

Suppose $\{(X_{1n}, X_{2n}); n = 1, 2, \dots\}$ is a sequence of i.i.d. random variables with parameters $\alpha_1, \alpha_2, \alpha_3, \theta$ as given in (36.17) and

$$Y_1 = \min\{X_{11}, \dots, X_{1N}\} \quad \text{and} \quad Y_2 = \min\{X_{21}, \dots, X_{2N}\},$$

then (Y_1, Y_2) is said to have BWG distribution.

The joint survival function of (Y_1, Y_2) becomes

$$P(Y_1 > y_1, Y_2 > y_2) = \sum_{n=1}^{\infty} P^n(X_{11} > y_1, X_{21} > y_2) \quad \text{where}$$

$$p(1-p)^{n-1}$$

$$g_1(y_1, y_2) = \frac{p\theta^2 y_1^{\theta-1} y_2^{\theta-1} (\alpha_3 + \alpha_1) \alpha_2 e^{-(\alpha_1 + \alpha_3) y_1^\theta - \alpha_2 y_2^\theta} (1 + (1-p)e^{-(\alpha_1 + \alpha_3) y_1^\theta - \alpha_2 y_2^\theta})}{(1 - (1-p)e^{-(\alpha_3 + \alpha_1) y_1^\theta - \alpha_2 y_2^\theta})^3}$$

$$g_2(y_1, y_2) = \frac{p\theta^2 y_1^{\theta-1} y_2^{\theta-1} (\alpha_3 + \alpha_2) \alpha_1 e^{-(\alpha_2 + \alpha_3) y_2^\theta - \alpha_1 y_1^\theta} (1 + (1-p)e^{-(\alpha_2 + \alpha_3) y_2^\theta - \alpha_1 y_1^\theta})}{(1 - (1-p)e^{-(\alpha_3 + \alpha_2) y_2^\theta - \alpha_1 y_1^\theta})^3}$$

$$g_0(y) = \frac{p\theta y^{\theta-1} \alpha_3 e^{-(\alpha_1 + \alpha_2 + \alpha_3) y^\theta}}{(\alpha_1 + \alpha_2 + \alpha_3)(1 - (1-p)e^{-(\alpha_1 + \alpha_2 + \alpha_3) y^\theta})^2}$$

$$= \frac{pP(X_{11} > y_1, X_{21} > y_2)}{1 - (1-p)P(X_{11} > y_1, X_{21} > y_2)}$$

$$= \begin{cases} \frac{pe^{-\alpha_1 y_1^\theta} e^{-(\alpha_2 + \alpha_3) y_2^\theta}}{1 - (1-p)e^{-\alpha_1 y_1^\theta} e^{-(\alpha_2 + \alpha_3) y_2^\theta}} & \text{if } y_1 \leq y_2 \\ \frac{pe^{-(\alpha_1 + \alpha_3) y_1^\theta} e^{-\alpha_2 y_2^\theta}}{1 - (1-p)e^{-(\alpha_1 + \alpha_3) y_1^\theta} e^{-\alpha_2 y_2^\theta}} & \text{if } y_1 > y_2. \end{cases}$$

The joint PDF of (Y_1, Y_2) can be obtained as

$$g(y_1, y_2) = \begin{cases} g_1(y_1, y_2) & \text{if } y_1 > y_2 \\ g_2(y_1, y_2) & \text{if } y_1 < y_2 \\ g_0(y) & \text{if } y_1 = y_2 = y, \end{cases} \quad (36.33)$$

The surface plot of the absolute continuous part of BWG for different parameter values is provided in Fig. 36.6. It is clear from Fig. 36.6 that BWG is more flexible than the MOBW distribution.

From the joint PDF of (Y_1, Y_2) it can be seen that

$$P(Y_1 = Y_2) = \frac{\alpha_3}{\alpha_1 + \alpha_2 + \alpha_3} > 0,$$

hence it has a singular component. The marginals of Y_1 and Y_2 are geometric-Weibull distribution as defined by Marshall and Olkin [45]. It may be mentioned that when $\theta = 1$, BWG distribution becomes the MOBW distribution. Therefore, MOBW distribution can be obtained as a special case of the BWG distribution. Estimation of the unknown five parameters for the BWG distribution based on a bivariate set of data set is a challenging problem. The MLEs of the unknown parameters can be obtained by solving a five-dimensional optimization problem. To avoid that, Kundu and Gupta [36] proposed a very efficient EM algorithm, which involves solving a one-dimensional optimization problem at each ‘‘E’’-step of the EM algorithm. In the same paper Kundu and Gupta [36] developed the testing problem so that based of the observed data it should be possible to test whether it is coming from BWG or MOBW model. This model can be used for modeling dependent competing risks data.

36.7.4 Bivariate PHM-Geometric Distribution

Although Kundu and Gupta [36] proposed the Marshall-Olkin method for the MOBW distribution, it can be extended for a general bivariate PHM as provided in (36.11). Similar to the bivariate Weibull-geometric model, more general the bivariate PHM-geometric distribution can be obtained as follows: Suppose $\{(X_{1n}, X_{2n}); n = 1, 2, \dots\}$ is a sequence of i.i.d. random variables with parameters $\alpha_1, \alpha_2, \alpha_3$ as follows:

$$S_{X,Y}(x, y) = \begin{cases} [S_B(x)]^{\alpha_1} [S_B(y)]^{\alpha_2 + \alpha_3} & \text{if } x < y \\ [S_B(x)]^{\alpha_1 + \alpha_3} [S_B(y)]^{\alpha_2} & \text{if } x \geq y. \end{cases} \quad (36.34)$$

Here $S_B(\cdot)$ is the base line survival function. It may depend on some parameter, but we do not make it explicit. Further, N is a geometric random variable with parameter $0 < p \leq 1$ having probability mass function as given in (36.31), and it is independent of $\{(X_{1n}, X_{2n}); n = 1, 2, \dots\}$. Consider the random variables,

$$Y_1 = \min\{X_{11}, \dots, X_{1N}\} \quad \text{and} \quad Y_2 = \min\{X_{21}, \dots, X_{2N}\},$$

then (Y_1, Y_2) is said to have bivariate PHM-Geometric (PHMG) distribution. The joint survival function of the bivariate PHMG becomes

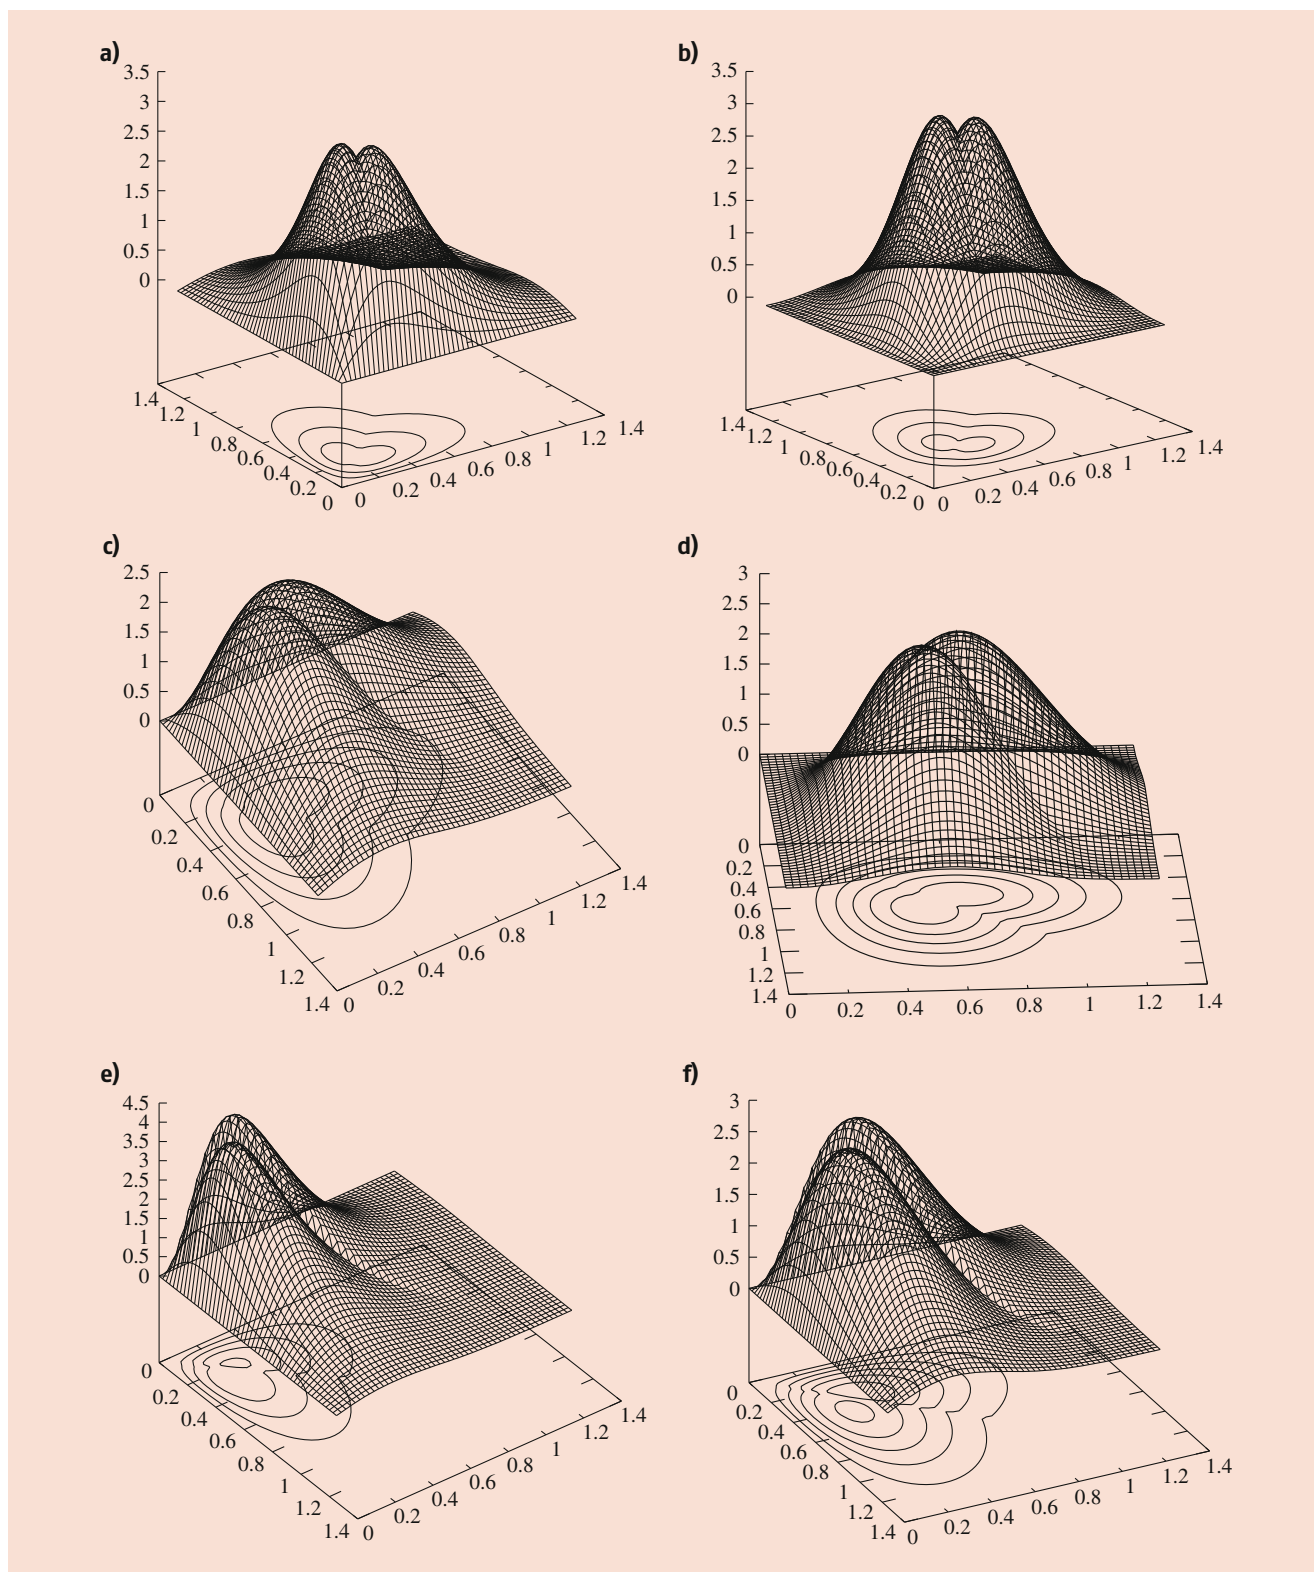

Fig. 36.6 PDF plots of $MOBE(\alpha_1, \alpha_2, \alpha_3, \theta, p)$ distribution for different $(\alpha_1, \alpha_2, \alpha_3, \theta, p)$ values: (a) (2.0,2.0,2.0,2.0,0.5) (b) (2.0,2.0,2.0,3.0,0.5) (c) (2.0,2.0,2.0,2.0,0.8) (d) (2.0,2.0,2.0,3.0,0.8) (e) (2.0,3.0,2.0,2.0,0.5) (f) (2.0,3.0,2.0,2.0,0.8)

$$\begin{aligned}
 P(Y_1 > y_1, Y_2 > y_2) &= \sum_{n=1}^{\infty} P^n(X_{11} > y_1, X_{21} > y_2) \\
 &= \frac{p(1-p)^{n-1}}{1 - (1-p)P(X_{11} > y_1, X_{21} > y_2)} \\
 &= \begin{cases} \frac{p[S_B(y_1)]^{\alpha_1}[S_B(y_2)]^{\alpha_2+\alpha_3}}{1-(1-p)[S_B(y_1)]^{\alpha_1}[S_B(y_2)]^{\alpha_2+\alpha_3}} & \text{if } y_1 \leq y_2 \\ \frac{p[S_B(y_1)]^{\alpha_1+\alpha_3}[S_B(y_2)]^{\alpha_2}}{1-(1-p)[S_B(y_1)]^{\alpha_1+\alpha_3}[S_B(y_2)]^{\alpha_2}} & \text{if } y_1 > y_2. \end{cases}
 \end{aligned}$$

If we denote $f_B(\cdot)$ as the base line PDF, then the joint PDF of the bivariate PHMG can be written as

$$g(y_1, y_2) = \begin{cases} g_1(y_1, y_2) & \text{if } y_1 > y_2 \\ g_2(y_1, y_2) & \text{if } y_1 < y_2 \\ g_0(y) & \text{if } y_1 = y_2 = y, \end{cases}$$

where

$$\begin{aligned}
 g_1(y_1, y_2) &= \frac{c_1 f_B(y_1)[S_B(y_1)]^{\alpha_1+\alpha_3-1} f_B(y_2)[S_B(y_2)]^{\alpha_2-1} (1 + (1-p)[S_B(y_1)]^{\alpha_1+\alpha_3}[S_B(y_2)]^{\alpha_2})}{(1 + (1-p)[S_B(y_1)]^{\alpha_1+\alpha_3}[S_B(y_2)]^{\alpha_2})^3} \\
 g_2(y_1, y_2) &= \frac{c_2 f_B(y_1)[S_B(y_1)]^{\alpha_1-1} f_B(y_2)[S_B(y_2)]^{\alpha_2+\alpha_3-1} (1 + (1-p)[S_B(y_1)]^{\alpha_1}[S_B(y_2)]^{\alpha_2+\alpha_3})}{(1 + (1-p)[S_B(y_1)]^{\alpha_1}[S_B(y_2)]^{\alpha_2+\alpha_3})^3} \\
 g_0(y) &= \frac{p f_B(y) \alpha_3 [S_B(y)]^{\alpha_1+\alpha_2+\alpha_3-1}}{(\alpha_1 + \alpha_2 + \alpha_3)(1 - (1-p)[S_B(y)]^{\alpha_1+\alpha_2+\alpha_3})^2}
 \end{aligned}$$

$$c_1 = p(\alpha_3 + \alpha_1)\alpha_2, \quad c_2 = p(\alpha_3 + \alpha_2)\alpha_1.$$

Clearly, bivariate PHMG is more flexible than the BWG distribution. When the base line distribution is Weibull with the scale parameter one, and the shape parameter θ , then the bivariate PHMG becomes the BWG distribution. This model can also be used for analyzing dependent competing risks data. It will be interesting to develop both classical and Bayesian inference procedures for this distribution. More work is needed in this direction.

36.7.5 Bivariate GE-Geometric Distribution

In this section first we introduce Marshall-Olkin GE (MOGE) distribution similar to the MOE and MOWE distribution. The

idea is very similar, and it can be defined as follows. Suppose $\{X_n; n = 1, 2, \dots\}$ is a sequence of i.i.d. $GE(\alpha, \lambda)$ random variables and N is a geometric random variable with the PMF as given in (36.31). Moreover, N and $\{X_n; n = 1, 2, \dots\}$ are independently distributed. Let us define a new random variable Y as

$$Y = \max\{X_1, \dots, X_N\}.$$

The random variable Y is said to have GE-Geometric (GEG) distribution with parameter p, α, λ , and it will be denoted by $GEG(p, \alpha, \lambda)$.

The CDF of Y for $y > 0$ can be obtained as

$$\begin{aligned}
 F_Y(y; \alpha, \lambda) &= P(Y \leq y) = P(X_1 \leq y, \dots, X_N \leq y) = p \sum_{n=1}^{\infty} P^n(X_1 \leq y)(1-p)^{n-1} \\
 &= \frac{p(1 - e^{-\lambda x})^\alpha}{1 - (1-p)(1 - e^{-\lambda x})^\alpha}.
 \end{aligned}$$

The corresponding PDF becomes

$$f_Y(y; p, \alpha, \lambda) = \frac{p\alpha\lambda e^{-\lambda x}(1 - e^{-\lambda x})^{\alpha-1}}{(1 - (1-p)(1 - e^{-\lambda x})^\alpha)^2} \quad \text{for } y > 0,$$

and zero, otherwise.

Now we can define bivariate GEG (BGEG) along the same line as before. Suppose $\{(X_{1n}, X_{2n}); n = 1, 2, \dots\}$ is a

sequence of i.i.d. random variables with parameters $\beta_1, \beta_2, \beta_3, \lambda$ having the joint PDF as given in (36.20) and

$$Y_1 = \max\{X_{11}, \dots, X_{1N}\} \quad \text{and} \quad Y_2 = \max\{X_{21}, \dots, X_{2N}\},$$

then (Y_1, Y_2) is said to have BGEG distribution with parameters $\beta_1, \beta_2, \beta_3, \lambda, p$.

The joint CDF of (Y_1, Y_2) becomes

$$\begin{aligned}
P(Y_1 \leq y_1, Y_2 \leq y_2) &= \sum_{n=1}^{\infty} P^n(X_{11} \leq y_1, X_{21} \leq y_2) \\
&\quad p(1-p)^{n-1} \\
&= \frac{pP(X_{11} \leq y_1, X_{21} \leq y_2)}{1 - (1-p)P(X_{11} \leq y_1, X_{21} \leq y_2)} \\
&= \begin{cases} \frac{p(1-e^{-\lambda y_1})^{\beta_1} (1-e^{-\lambda y_2})^{\beta_2+\beta_3}}{1-(1-p)(1-e^{-\lambda y_1})^{\beta_1} (1-e^{-\lambda y_2})^{\beta_2+\beta_3}} & \text{if } y_1 > y_2 \\ \frac{p(1-e^{-\lambda y_1})^{\beta_1+\beta_3} (1-e^{-\lambda y_2})^{\beta_2}}{1-(1-p)(1-e^{-\lambda y_1})^{\beta_1+\beta_3} (1-e^{-\lambda y_2})^{\beta_2}} & \text{if } y_1 \leq y_2. \end{cases}
\end{aligned}$$

It will be interesting to develop different properties of this distribution similar to the BWG distribution as it has been obtained by Kundu and Gupta [36]. Moreover, classical and Bayesian inference need to be developed for analyzing bivariate data sets with ties. This model also can be used for analyzing dependent complementary risks data. More work is needed along this direction.

36.8 Conclusions

In this chapter we have considered the class of bivariate distributions with a singular component. Marshall and Olkin [44] first introduced the bivariate distribution with singular component based on exponential distributions. Since then an extensive amount of work has taken place in this direction. In this chapter we have provided a comprehensive review of all the different models. It is observed that there are mainly two main approaches available in the literature to define bivariate distributions with singular components, and they produce two broad classes of bivariate distributions with singular components. We have shown that these two classes of distributions are related through their copulas under certain restriction. We have provided very general EM algorithms which can be used to compute the MLEs of the unknown parameters in these two cases. We have provided the analysis of one data set to show how the EM algorithms perform in real life.

There are several open problems associated with these models. Although in this chapter we have mainly discussed different methods for bivariate distributions, all the methods can be generalized for the multivariate distribution also. Franco and Vivo [20] first obtained the multivariate Sarhan-Balakrishnan distribution and developed several properties, although no inference procedures were developed. Sarhan et al. [60] provided the multivariate generalized failure rate distribution, and Franco, Kundu, and Vivo [19] developed multivariate modified Sarhan-Balakrishnan distribution. In both these papers, the authors developed different properties and very efficient EM algorithms for computing the maximum likelihood estimators of the unknown parameters. More general multivariate distributions with proportional reversed hazard marginals can be found in Kundu, Franco, and Vivo [38]. Note that all these models can be very useful to analyze

dependent competing risks model with multiple causes. No work has been done along that like; more work is needed along these directions.

Debasis Kundu Professor Debasis Kundu received his B.Stat and M.Stat from the Indian Statistical Institute in 1982 and 1984, respectively, M.A. in Mathematics from the University of Pittsburgh in 1985 and Ph.D. from the Pennsylvania State University in 1989 under the guidance of Professor C.R. Rao. After finishing his Ph.D. he joined The University of Texas at Dallas as an Assistant Professor before joining Indian Institute of Technology Kanpur in 1990. He served as the Head of the Department of Mathematics and Statistics, IIT Kanpur from 2011 to 2014 and the Dean of Faculty Affairs at IIT Kanpur from 2019 to 2022. Professor Kundu is holding an Endowed Chair Professor post of the Institute since 2008.

Professor Kundu works on different areas of Statistics. His major research interests are on Statistical Signal Processing, Lifetime Data Analysis and Statistical Computing. He has published more than 325 research papers in different well reputed Statistical and Signal Processing journals like *IEEE Transaction on Signal Processing*; *Signal Processing*; *Circuits, Systems and Signal Processing*; *Technometrics*; *Annals of the Institute of Statistical Mathematics*; *Statistica Sinica*; *Scandinavian Journal of Statistics*; *Journal of Multivariate Analysis*; *Computational Statistics and Data Analysis*;

Journal of Statistical Planning and Inference; IEEE Transactions on Reliability etc. His work has been well cited by different researchers. He has more than 16,238 google scholar citations with H index 63. He has co-authored two research monographs on Statistical Signal Processing and on Step-Stress Models, and co-edited one book on Statistical Computing. He is a Fellow of the National Academy of Sciences, India, and a Fellow of the Indian Society

of Probability and Statistics. He is currently the Editor-in-Chief of the Journal of the Indian Society of Probability and Statistics, and in the editorial boards of Sankhya, Ser. B, Indian Journal of Pure and Applied Mathematics and Journal of Statistical Theory and Practice. He was in the editorial boards of the IEEE Transactions on Reliability, Journal of Distribution Theory, Communications in Statistics - Theory and Methods, Communications in Statistics - Simulation and Computation.

Abstract

Bayesian modelling has come a long way from the first appearance of the Bayes theorem. Now it is being applied in almost every scientific field. Scientists and practitioners are choosing to use Bayesian methodologies over the classical frequentist framework because of its rigour mathematical framework and the ability to combine prior information to define a prior distribution on the possible values of the unknown parameter. Here in this chapter we briefly discuss various aspects of Bayesian modelling. Starting from a short introduction on conditional probability, the Bayes theorem, different types of prior distributions, hierarchical and empirical Bayes and point and interval estimation, we describe Bayesian regression modelling with more detail. Then we mention an array of Bayesian computational techniques, viz. Laplace approximations, E-M

algorithm, Monte Carlo sampling, importance sampling, Markov chain Monte Carlo algorithms, Gibbs sampler and Metropolis-Hastings algorithm. We also discuss model selection tools (e.g. DIC, WAIC, cross-validation, Bayes factor, etc.) and convergence diagnostics of the MCMC algorithm (e.g. Geweke diagnostics, effective sample size, Gelman-Rubin diagnostic, etc.). We end the chapter with some applications of Bayesian modelling and discuss some of the drawbacks in using Bayesian modelling in practice.

Bayesian modelling · Prior distribution · Bayesian regression · Bayesian computation · Markov chain Monte Carlo · Gibbs sampler · Metropolis-Hastings algorithm · Bayesian model selection · WAIC · Cross-validation · Bayes factor

37.1 Introduction

Bayesian has a wide range of applications in various fields, namely: (a) medicine, (b) document classification, (c) information retrieval, (d) semantic search, (e) image processing, (f) spam filter and (g) reliability.

An advantage of Bayesian statistics is its ability to combine prior information regarding a parameter with the data and compute the posterior distribution. Thus, the prominent features of available information are used in Bayesian statistics to obtain the posterior distribution which can further be used as prior with the availability of new observations.

It is usually known that the larger the data, the better is the inference regarding the population. But there is no concept of ‘too little data’ in Bayesian statistics [1]. Bayesian method is helpful in modelling data with small sample sizes with a good prediction accuracy.

Bayesian statistics follows the ‘Likelihood Principle’ which states that all information from the data that is relevant to inferences about the value of the model parameters is in the equivalence class to which the likelihood function belongs.

The Bayesian concept of a credible interval is sometimes put forward as a more practical concept than the confidence interval.

Bayesian modelling framework provides a convenient setting for a wide range of models, such as hierarchical models and missing data problems. Numerical methods (e.g., Markov chain Monte Carlo, the Laplace approximation) allow computational tractability of these models.

Different methods such as importance sampling, rejection sampling, uniform sampling, Monte Carlo Markov chain and Gibbs sampling help to give reliable estimates of parameters involving tractable computations. Also, meaningful

inferences regarding parameters can be made in presence of missing observations.

37.2 Conditional Probability

Let n_1 denote the number of persons who smoke and have cancer. Let n_2 denote the number of persons who smoke. Let n denote the total number of persons. You are now asked to find the probability that a person will have cancer given that he smokes. To answer such questions, we have to know what conditional probability is. Conditional probabilities arise naturally in the investigation of experiments where an outcome of a trial may affect the outcomes of the subsequent trials. The conditional probability of an event B given an event A is the probability that the event B will occur given the knowledge that the event A has already occurred. This can be denoted by $P(B|A)$.

Bayes’ Theorem

In probability theory and statistics, Bayes’ theorem describes the probability of an event, based on prior knowledge of conditions that might be related to the event. For example, if cancer is related to age, then, using Bayes’ theorem, a person’s age can be used to more accurately assess the probability that they have cancer, compared to the assessment of the probability of cancer made without knowledge of the person’s age. Mathematically, Bayes’ theorem can be stated as:

$$P(A|B) = \frac{P(B|A)P(A)}{P(B)},$$

where A and B are events and $P(B) \neq 0$. $P(A|B)$ is a conditional probability: the likelihood of event A occurring given that B is true. $P(B|A)$ is also a conditional probability: the likelihood of event B occurring given that A is true. $P(A)$ and $P(B)$ are the probabilities of observing A and B independently of each other; this is known as the marginal probability. In the Bayesian interpretation, probability measures a ‘degree of belief.’ Bayes’ theorem then links the degree of belief in a proposition before and after accounting for evidence, and hence the probabilities of Bayes’ theorem have the following interpretation: $P(A)$ is termed the prior, i.e. the initial degree of belief in A; $P(A|B)$ is termed the posterior, i.e. the degree of belief having accounted for B. The ratio $\frac{P(B|A)}{P(B)}$ represents the support B provides for A.

37.3 Some Examples

37.3.1 Prosecutor’s Fallacy

Prosecutor’s fallacy is a very famous application of Bayes’ rule. A fallacy for statistical reasoning, prosecutor’s fallacy, is used by the prosecution in the criminal trial to argue if

the person suspected is guilty. The problem is as follows: A number of persons in a city having a population of, say, 100, have been suspected of committing a crime, and one of the defendants is brought to trial. Further, the blood that has been found in the crime scene matches with that of the defendants'. The court has to judge if he/she is guilty or innocent. To solve the problem and to understand where the fallacy lies, let us first understand the following notations: G denotes the defendant is guilty, G^c denotes the defendant is innocent. B : Blood found in the crime scene is consistent with the defendant's blood. Let us understand the following conditional probabilities: $P(B|G^c)$ = Probability that a person who is not guilty matches the blood. $P(G^c|B)$ = Probability that a person who matches the blood description is innocent. Now the prosecutor's fallacy is, if $P(B|G^c) = 0.01$, then $P(G^c|B) = 0.01$. This means that if there is a 1% chance of a random person's blood type matching with that of the crime scene, then there is a 1% chance of the defendant being not guilty. Following the prosecutor's arguments, the conditional probabilities might seem similar. But the result of the conditional probability $P(G^c|B)$ using Bayes' theorem is inconsistent with the prosecutor's argument. Applying Bayes' theorem, $P(G|B) = \frac{P(B|G)P(G)}{P(B|G)P(G)+P(B|G^c)P(G^c)}$. Now if a person is guilty, then it is obvious that his/her blood type would match that at the crime scene. Thus, $P(B|G) = 1$. We also have $P(G|B) = \frac{1 \times P(G)}{[1 \times P(G)] + [0.01 \times P(G^c)]} = \frac{1}{0.99 + 0.01/P(G)}$.

37.3.2 Monty Hall Problem

The Monty Hall problem, a brain teaser, is a statistical puzzle named after its host Monty Hall, which was aired in the television show 'Let's Make a Deal'. In the show, each contestant was given an opportunity of winning the grand prize by selecting one of the three doors. The grand prize was a car which was placed behind one of the doors and the other two contained goats. After the contestant picked a door, Monte used to show him one of the two remaining doors which did not contain the car and the contestant was given an option to alter his decision. According to some, swapping would not be advantageous since there is a 50% chance that the car is behind one of the two unopened doors. However it can be shown using Bayes' theorem that swapping would lead to an approximate 66% chance of winning the car, whereas not swapping would lead to an approximate 33% chance of not winning the car. Let P denote the door containing the car, C denote the initial choice of the contestant and M denote the door shown by Monty. The car is placed behind a door randomly, prior to the selection made by the contestant. Thus, selection of the door is independent of the prize being placed behind a door, i.e. P is independent of C . Therefore, $P(P = p) = P(P = p|C = c) = 1/3, p = 1, 2, 3, c = 1, 2, 3$. However the door Monte shows depends on where the car is with the conditional probability, $P(M = m|P = p, C = c)$,

$c = 1, 2, 3, p = 1, 2, 3, m = 1, 2, 3$. WLG, we assume that the contestant selects door number 3. Define $Pr(P = 1) = p_1; Pr(P = 2) = p_2; Pr(P = 3) = p_3$; and $Pr(M = m|P = p, C = c) = a_{mpc}; m = 1, 2, 3; p = 1, 2, 3; c = 1, 2, 3$

$$P(P = 1|M = 2) = \frac{a_{213}p_1}{a_{213}p_1 + a_{223}p_2 + a_{233}p_3}$$

Since the contestant selects door number 3, Monty would either show door number 1 or 2 depending on where the car is. Let us say, if the car is behind door number 2, then Monty would show door number 1 and vice versa. However if the car is behind door number 3, then Monty can show door number 1 or 2. The possible cases are as follows:

m	1	2	3
$P(M=m P=1,C=3)$	0	1	0
$P(M=m P=2,C=3)$	1	0	0
$P(M=m P=3,C=3)$	0.5	0.5	0

Therefore, $P(P=1 | M=2) = \frac{1 \times 1/3}{[1 \times 1/3] + [0 \times 1/3] + [0.5 \times 1/3]} = \frac{2}{3}$.
 Again, $P(P = 3|M = 2) = \frac{a_{233}p_3}{a_{213}p_1 + a_{223}p_2 + a_{233}p_3} = \frac{0.5 \times 1/3}{[1 \times 1/3] + [0 \times 1/3] + [0.5 \times 1/3]} = \frac{1}{3}$. It is obvious that $P(P = 2|M = 2) = 0$, since Monty would not reveal the door containing the car. Thus, it can be seen that if the contestant alters their decision, then the chances of getting the car are higher.

37.3.3 Types of Prior

Improper Prior

If the prior distribution is not previously known, it is determined on a subjective or theoretical basis, which may lead to the situation $\int_{\Theta} \pi(\theta)d\theta = \infty$. In such cases the prior distribution is said to be improper (or generalised). But as long as the posterior distribution is defined, one can use the Bayesian method, even if the prior is improper.

Example

Let us consider a pdf $f(x|\theta) = N(\theta, 1)$ and $\pi(\theta) = c$, where c is an arbitrary constant. The posterior distribution is given by: $p(\theta|y) = \frac{f(x|\theta)p(\theta)}{\int_{-\infty}^{\infty} f(x|\theta)p(\theta)d\theta} = \frac{c \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}(y-\theta)^2}}{\int_{-\infty}^{\infty} c \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}(y-\theta)^2} d\theta}$. Thus, $\theta|y \sim N(y, 1)$. Hence, the prior is improper, but the posterior is tractable. ◀

Non-informative Prior

Non-informative priors favour no particular values of the parameter over others. If Θ is finite, we choose uniform prior. If Θ is infinite, there are several ways of choosing a prior distribution some of which may be improper.

Location Density For a location density $f(x|\theta) = f(x-\theta)$, the location-invariant non-informative prior is $\pi(\theta) = \pi(0)$. (a constant). We usually choose $\pi(0) = 1$ (improper prior).

Example

Suppose $X \sim N(\theta, \sigma^2)$. Let $Y = X + c$. Then $Y \sim N(\eta, \sigma^2)$, where $\eta = \theta + c$. Thus, Y has the density $f_y(y) = f(y-\eta) = \frac{1}{\sqrt{2\pi}\sigma} \exp \frac{-(y-\eta)^2}{2\sigma^2}$. Assume $\pi(\theta)$ and $\pi^*(\eta)$ are the non-informative priors of θ and $\eta = \theta+c$, respectively. Let A be any set. Then, $\int_A \pi(\theta)d\theta = \int_A \pi^*(\eta)d\eta = \int_{A-c} \pi(\theta)d\theta$ (because $\eta \in A \Leftrightarrow \theta + c \in A \Leftrightarrow \theta \in A-c$) $= \int_A \pi(\theta - c)d\theta$. Thus, $\pi(\theta) = \pi(\theta - c)$. Now, let $\theta = c$. Then $\pi(c) = \pi(0)$, a constant. It is generally convenient to choose $\pi(c) = 1$. ◀

Scale Density

For a scale density, $f(x|\sigma) = \frac{1}{\sigma} f(\frac{x}{\sigma})$, for $\sigma > 0$, the scale-invariant non-informative prior is $\pi(\sigma) \propto \frac{1}{\sigma}$.

Example

Let $X \sim N(0, \sigma^2)$ and $Y = cX$. Then, $Y \sim N(0, c^2\sigma^2)$. The density of Y is $f_y(y) = \frac{1}{\sqrt{2\pi}c\sigma} \exp -\frac{y^2}{2c^2\sigma^2} = \frac{1}{\sqrt{2\pi}\eta} \exp -\frac{y^2}{2\eta^2} = \frac{1}{\eta} f(\frac{y}{\eta})$, where $\eta = c\sigma$. ◀

Assume $\pi(\theta)$ and $\pi^*(\eta)$ are the non-informative priors of σ and $\eta = c\sigma$, respectively. Let A be any set. Then, $\int_A \pi(\sigma)d\sigma = \int_A \pi^*(\eta)d\eta = \int_{A/c} \pi(\sigma)d\sigma$ (because $\eta \in A \Leftrightarrow c\sigma \in A \Leftrightarrow \sigma \in A/c$) $= \int_A \pi(\frac{\sigma}{c}) \frac{1}{c} d\sigma$.

Thus, $\pi(\sigma) = \pi(\frac{\sigma}{c}) \frac{1}{c}$. Let, $\sigma = c$. Then, $\pi(c) = \pi(1) \frac{1}{c}$.

It is generally convenient to set $\pi(1)=1$. Then, $\pi(c) = \frac{1}{c} \Leftrightarrow$

$\pi(\sigma) = \frac{1}{\sigma}$. Note that, $\pi(\sigma) = \frac{1}{\sigma}$ is an improper prior since $\int_0^\infty \frac{1}{\sigma} d\sigma = \infty$. Jeffreys' prior is given by: $\pi(\theta) \propto I(\theta)^{1/2}$.

Example

$f(x|p) = \binom{n}{x} p^x(1 - p)^{n-x}$. $I(p) = \frac{n}{p(1-p)}$ Let y_1, y_2, \dots, y_n be n independent samples from $N(\beta x_i, 1)$ distribution where β is an unknown parameter and x_1, x_2, \dots, x_n are known. Then, $I(\beta) = S_{xx}$, where $S_{xx} = \sum_{i=1}^n x_i^2$. So Jeffreys' prior is proportional to $S_{xx}^{\frac{1}{2}}$. The posterior distribution has a $N(\frac{S_{xy}}{S_{xx}}, S_{xx}^{-1})$ where $S_{xy} = \sum_{i=1}^n x_i y_i$ ◀

Conjugate Prior

A family F of probability distributions on Θ is said to be conjugate or closed under sampling for a likelihood $f(x|\theta)$,

if for every prior $\pi \in F$, the posterior distribution $\pi(\theta | x)$ also belongs to F . Choosing a conjugate prior makes computation of posterior quantities easier. Further, updating the distribution under the new data is also convenient.

Example

Let $y \sim Poisson(\theta)$, $\theta \in (0, \infty) = \Theta$. $\theta \sim Gamma(c, \alpha)$. Then $\theta|y \sim \Gamma(c + 1, \alpha + y)$. $y|\theta \sim Bin(n, \theta)$ for $y = 0, 1, 2, \dots, n$. $f(y|\theta) = \binom{n}{y} \theta^y (1 - \theta)^{n-y}$. $\theta \sim Beta(a, b)$ with density $p(\theta) = \frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)} \theta^{a-1} (1-\theta)^{b-1}$. The posterior distribution of $\theta|y$ is given by: $\theta|y \sim Beta(y + a, n - y + b)$. The posterior distribution can be obtained by applying Bayes' theorem to the densities. $p(\theta|y) = \frac{f(y|\theta)p(\theta)}{\int f(y|\theta)p(\theta)d\theta} = \frac{\Gamma(n+a+b)}{\Gamma(y+a)\Gamma(n-y+b)} \theta^{y+a-1} (1-\theta)^{n-y+b-1}$.

Now $y_1, y_2, \dots, y_n | \theta \sim N(\theta, \sigma^2)$. Let $\tau = \frac{1}{\sigma^2}$. The likelihood function is given by: $L(y|\theta) = \prod_{i=1}^n f(y_i|\theta) = (\tau/2\pi)^{n/2} e^{-\tau/2 \sum_{i=1}^n (y_i - \theta)^2}$. $\theta \sim N(\theta_0, 1/\tau_0)$. Hence, the posterior distribution is given by: $\theta|y \sim N(\frac{\tau_0}{\tau_0+n\tau} \theta_0 + \frac{n\tau}{\tau_0+n\tau} \bar{y}, \frac{1}{\tau_0+n\tau})$. ◀

The Multinomial Distribution and the Dirichlet Prior

Suppose an experiment is conducted having n independent trials and each trial produces exactly one of the k events E_1, E_2, \dots, E_k with respective probabilities $\theta_1, \theta_2, \dots, \theta_k$. These k events are mutually exclusive and collectively exhaustive. Here, $\theta_1 + \theta_2 + \dots + \theta_k = 1$. Define:

- $X_1 =$ number of trials in which E_1 occurs.
- $X_2 =$ number of trials in which E_2 occurs.
- \vdots
- $X_k =$ number of trials in which E_k occurs.

Then $X = (X_1, X_2, \dots, X_k)$ is said to have a multinomial distribution with index n and parameter $\pi = (\theta_1, \theta_2, \dots, \theta_k)$. In most problems, n is regarded as fixed and known. Then, $f(X|\pi) \propto \prod_{i=1}^k \theta_i^{X_i}$. We here introduce the Dirichlet distribution which is nothing but the multivariate generalisation of the beta distribution as the conjugate prior distribution for the multinomial distribution. The pdf is given by: $\pi(\theta_1, \theta_2, \dots, \theta_k | \alpha_1, \alpha_2, \dots, \alpha_k) \propto \prod_{i=1}^k \theta_i^{\alpha_i - 1}$. We say that $(\theta_1, \theta_2, \dots, \theta_k) \sim Dirichlet(k; (\alpha_1, \alpha_2, \dots, \alpha_k))$. The posterior distribution of $\theta_1, \theta_2, \dots, \theta_k$ given X also follows Dirichlet with parameter set $(k; \alpha_1 + X_1, \alpha_2 + X_2, \dots, \alpha_k + X_k)$.

37.3.4 Reference Prior

A reference prior distinguishes between the parameters of interest and the nuisance parameters. Let $X \sim f(x|\theta)$

where $\theta = (\theta_1, \theta_2, \dots, \theta_p, \dots, \theta_q)$. Also, define $\theta_A = (\theta_1, \theta_2, \dots, \theta_q)$ and $\theta_B = (\theta_{q+1}, \dots, \theta_p)$. Let $\pi(\theta_B|\theta_A)$ be Jeffreys' prior associated with $f(x|\theta)$, when θ_A is fixed. To obtain the reference prior, we then derive the marginal distribution $f^*(x|\theta_A) = f^*(x|\theta_1, \theta_2, \dots, \theta_q) = \int \int \dots \int f(x|\theta) \pi(\theta_{q+1}, \dots, \theta_p|\theta_1, \theta_2, \dots, \theta_q) d\theta_{q+1} \dots d\theta_p$ and then compute Jeffreys' prior associated with $f^*(x|\theta_A)$. In this process, the nuisance parameter gets eliminated by using a Jeffreys' prior where the parameters of interest remain fixed.

Example

Let us consider the Neyman-Scott problem. Here, $x_{ij} \sim N(\mu_i, \sigma^2), i = 1, 2, \dots, n; j = 1, 2$. The goal is to estimate the variance of the whole population σ^2 . After several steps of calculation, the usual Jeffreys' prior is obtained as: $\pi(\mu_1, \mu_2, \dots, \mu_n, \sigma) = \sigma^{-n-1}$. But, by action $\mathbb{E}[\sigma^2|x_{11}, \dots, x_{n2}] = s^2/(n-2); s^2 = \sum_{i=1}^n \frac{(x_{i1}-x_{i2})^2}{2}$. The posterior expectation converges to $\sigma^2/2$. In our example $\theta_A = \sigma$ and $\theta_B = (\mu_1, \mu_2, \dots, \mu_n)$. The reference prior associated with θ_A and θ_B gives a flat prior for θ_B ; θ_B being a location parameter. Then, $f^*(x|\theta_A) = \prod_{i=1}^n e^{-(x_{i1}-x_{i2})^2/4\sigma^2} \frac{1}{\sqrt{2\pi}2\sigma}$ is a scale family and $\pi(\sigma) = \frac{1}{\sigma}$. Therefore, by action $\mathbb{E}[\sigma^2|x_{11}, \dots, x_{n2}] = s^2/(n-2)$ which is consistent for σ . ◀

37.4 Hierarchical Bayes

The choice of prior in Bayesian is subjective. So, the subjective part should be modified. On the other hand, the prior information is barely rich enough to define the prior distribution exactly. So, it is necessary to include this uncertainty in the model. Under hierarchical Bayes' analysis, the prior information decomposes the prior distribution into several parts. It improves the robustness of the resulting Bayes' estimate.

A Bayesian statistical model is hierarchical if it involves several levels of conditional prior distributions. This particular modelling of the prior information decomposes the prior distribution into several conditional levels of distributions so as to introduce a distinction between structural and subjective parts of information. In the simplest case, the hierarchical structure is used to two levels, the parameters of the first being associated with a prior distribution defined on the second. The first-level distribution is generally a conjugate prior for computational tractability.

One noteworthy drawback of the hierarchical Bayes method is that often it is difficult to derive the explicit Bayes' estimate even when the successive levels are conjugate. In such cases, one has to depend on numerical computations for obtaining posterior estimates.

Example 1 Software is to be tested before release in the market so that it carries minimum number of errors while using it. In a software testing problem, a success occurs when the software fails to provide the right output for an input. The size of a bug is defined as the number of inputs that would have eventually passed through the bug, if the bug were not fixed. From the definition of the size of the bug, the appearance of a bug may be termed as a success in a sequence of independent trials. Hence, we say that $S_i|t_i \sim Bin(n_i, t_i)$ where $S_i =$ Eventual size of the i^{th} bug; $i = 1, 2, \dots, m$. Now there should be a distribution for the probability of detection of a bug t_i , since it would vary for different bugs. One reasonable distribution is that t_i 's are i.i.d. from a beta distribution, say, $t_i|\alpha_1, \alpha_2 \sim Beta(\alpha_1, \alpha_2)$ as it is a conjugate prior. Hyperpriors can also be assigned on the parameters α_1, α_2 by deducing from domain knowledge on quantities that are comparatively easier to obtain, e.g., mean and variance.

Example 2 The regression set-up is as follows: $y_{ij} = \alpha + \beta_i + e_{ij}$ where β_i 's are identically and independently distributed as $N(0, \frac{1}{\gamma_1})$; e_{ij} 's are identically and independently distributed as $N(0, \frac{1}{\gamma_2}); i = 1, 2, \dots, p; j = 1, 2, \dots, n_i$. Here, β_i and e_{ij} 's are all independent. Thus, Y follows a multivariate normal distribution with y_{ij} following $N(\alpha, \frac{1}{\gamma_1} + \frac{1}{\gamma_2})$, where

$$Cov(y_{ij}, y_{i'j'}) = \begin{cases} 0 & \text{if } i \neq i' \\ 1/\gamma_1 & \text{if } i = i', j \neq j' \end{cases}$$

However, in Bayesian approach, the traditional method of writing the sampling model takes altogether a different notation: $y_{ij}|\eta_i, \gamma_1$ independently follows $N(\eta_i, \frac{1}{\gamma_1})$, and $\eta_i|\alpha, \gamma_1$ independently follows $N(\alpha, \frac{1}{\gamma_1})$. Here, we can see that $y_{ij} \perp \alpha, \gamma_1|\eta_i, \gamma_2$ and $\eta_i \perp \gamma_2|\alpha, \gamma_1$. It can be easily shown that: $y_{ij}|\eta_i, \gamma_1, \gamma_2$ independently follows $N(\eta_i, \frac{1}{\alpha_2}); \eta_i|\alpha, \gamma_1, \gamma_2$ independently and identically distributed as $N(\alpha, \frac{1}{\gamma_1}); i = 1, 2, \dots, p$. Since $\alpha, \gamma_1, \gamma_2$ are not known, we can specify normal, gamma and gamma priors for them respectively.

37.5 Empirical Bayes

In this method, we approximate the prior distribution by frequentist methods when the prior distribution is vague. This method can be considered as a dual method of hierarchical Bayes' analysis. It is asymptotically equivalent to

the Bayesian approach. Further, it may be an acceptable approximation in problems for which a proper Bayesian modelling is too complicated.

37.5.1 Non-parametric Empirical Bayes

Given $n+1$ independent observations x_1, x_2, \dots, x_{n+1} , with densities $f(x_i|\theta_i)$, the problem is to draw an inference on θ_{i+1} under the additional assumption that θ_i 's have all been generated according to some unknown prior distribution g , i.e. the sampling distribution $f(x_i|\theta_i)$ is known but the prior distribution is unknown.

The marginal distribution $f_g(x) = \int_{\Theta} f(x|\theta)g(\theta)d\theta$. This marginal distribution can be used to recover the distribution g from the observations, since x_1, x_2, \dots, x_n can be considered as an i.i.d. sample from $f_g(x)$. Deriving an approximation \tilde{g}_n in this way, we can use it as a substitute for the two prior distributions and prepare the approximation to the posterior distribution as

$$\tilde{\pi}(\theta_{n+1}|x_{n+1}) \propto f(x_{n+1}|\theta_{n+1})\tilde{g}_n(\theta_{n+1}).$$

This approach is not Bayesian. In Bayesian, ignorance on g would index this distribution by a hyperparameter λ and second level prior distribution $\pi_2(\lambda)$.

37.5.2 Parametric Empirical Bayes

In an exponential family setting, a sample prior choice for $f(x|\theta)$ is the conjugate prior, say $\pi(\theta|\lambda)$. The Bayesian school models uncertainty by a probability distribution over parameters. The choice of prior distribution is the most important criterion, since choosing an alternate prior could lead to a more robust inference. Let us define θ as the unknown state of nature, i.e. the parameter, and X as the data that provides information about θ . Suppose $X \sim f(x|\theta)$, where f is the possible distribution of X . In addition to having a model $f(x|\theta)$ for the data X , Bayesian assumes a distribution for θ . This distribution is called the prior distribution or simply a prior, since it quantifies the uncertainty about the parameter prior to observing the data. If the prior represents Bayesian's subjective belief and knowledge, then it is called a subjective prior. On the other hand, if it is a conventional representing small or no information, then it is an objective prior.

Given the model for the data and the prior $\pi(\theta)$ of θ , the conditional distribution of θ given $X = x$ is given by Bayes' formula, $\pi(\theta|x) = \frac{f(x|\theta)\pi(\theta)}{\int f(x|\theta)\pi(\theta)d\theta}$. To get a composite picture about final belief about θ , the posterior distribution comes into the scenario which combines the prior belief about the parameter θ and also any available sample information

about θ . Thus we can very easily say that the posterior distribution reflects the updated belief about θ after the data is being observed since the transition from the prior to the posterior is basically what we have learnt from the data. If the posterior distribution can be known, instead of reporting the whole posterior distribution, one may also report the summary descriptive measures associated with it like mean, variance, median and others. One may also use the posterior distribution to answer questions related to more structural problems like estimation and testing.

37.6 Point Estimation

37.6.1 Univariate Case

A point estimate of θ , say, $\hat{\theta}$, is obtained by simply using the commonly used summaries of the posterior distribution like mean, median and mode. Again, when we consider a flat prior for θ , the maximum likelihood estimate can also be used as an estimate of the parameter θ since here MLE simply becomes the mode. However, when the posterior distribution is symmetric, one may report the mean or the median as they become equal. If, in particular, this distribution is unimodal, the value of mode will also be equal to that of the mean and the median. A measure of extent of uncertainty is also reported together with the point estimate. We can look at the posterior SD or variance together with the posterior mean to obtain a measure of accuracy of the point estimate, $\theta(\hat{y})$. The posterior variance is given by:

$$\mathbb{E}_{\theta|y}[\theta - \theta(\hat{y})]^2.$$

Let the posterior mean be given by $\mathbb{E}_{\theta|y}(\theta) = \mu_y$; we may write

$$\begin{aligned} & \mathbb{E}_{\theta|y}[\theta - \theta(\hat{y})]^2 \\ &= \mathbb{E}_{\theta|y}[\theta - \mu + \mu - \theta(\hat{y})]^2 \\ &= \text{Var}_{\theta|y}[\theta] + (\mu - \theta(\hat{y}))^2. \end{aligned}$$

Thus, we can very easily see that if $\theta(\hat{y}) = \mu(y)$, then the posterior variance is minimised with respect to $\theta(\hat{y})$ over all point estimators $\theta(\hat{y})$. Our aim is to define the optimum estimate. So, we bring in the concept of loss function.

Define $L(\theta, a)$ as the cost of estimating the parameter θ by action a . Average loss in estimating the parameter θ by action a is given by $\mathbb{E}_{\theta|y}[L(\theta|a)] = \int_{\Theta} L(\theta, a)\pi(\theta|y)d\theta$. The estimate of θ where this loss is minimised is the best estimate called Bayes' estimate.

37.6.2 Multivariate Case

We denote estimate of a vector of parameters θ as $\hat{\theta} = (\hat{\theta}_1, \hat{\theta}_2, \dots, \hat{\theta}_p)$. The posterior mode and posterior median can be considered as estimates of θ . However computation of these quantities can be difficult to carry out in practice. Another commonly used estimator of θ is its posterior mean $\mu = \mathbb{E}_{\theta|y}[\theta]$ because it is well defined and a measure of uncertainty can be captured by the posterior covariance matrix, $V = \mathbb{E}_{\theta|y}[(\theta - \mu)(\theta - \mu)']$. It can be shown that $\mathbb{E}_{\theta|y}[(\theta - \hat{\theta}(y))(\theta - \hat{\theta}(y))'] = V + (\mu - \hat{\theta}(y))(\mu - \hat{\theta}(y))'$. Thus the posterior mean minimizes the posterior covariance.

37.7 Bayesian Interval Estimation

The confidence interval in the Bayesian approach referred to as a ‘credible set’ is analogous to that of the confidence interval concept in the frequentist approach. A set $C \subset \Theta$ is called a $100(1 - \alpha)\%$ credible set of θ if $P(C|data) \geq 1 - \alpha$, where $P(C|data)$ is expressed as $\int_C p(\theta|y)d\theta$ (if θ is continuous) or $\sum_C p(\theta|y)$ (if θ is discrete). In other words, the probability that θ lies in C given the observed data is at least $(1 - \alpha)$, i.e. it gives direct probability statements about the likelihood of θ falling in C . However, the frequentist definition of confidence interval is that if C is computed for a large number of data sets, about $(1 - \alpha)100\%$ of them would contain the true value of θ . Suppose there is only one data set. Then according to the Bayesian definition, the credible set would either contain the credible set or not. In other words, it would give an actual coverage probability (1 or 0). However according to the frequentist definition, it won’t be possible to compute C , as there is only one data set. Then if θ belongs to the 90% confidence interval, then it would belong to the 95% confidence interval as well. Credible sets are not unique. So how to determine which set would be most suitable? A technique for doing this is given by the highest posterior density, or HPD credible set, defined as the set

$C = \{\theta \in \Theta : p(\theta|data) \geq k(\alpha)\}$, where $k(\alpha)$ is the largest constant satisfying $P(C|data) \geq 1 - \alpha$.

37.8 Bayesian Regression

Regression is a widely used method in statistics, so the Bayesian approach to it is also important to practitioners. There are two main goals for doing a regression analysis: (i) to understand how some predictor(s) influence the values of the variable of interest and (ii) to predict the value of the variable of interest for some new value of predictor variable. Here we shall discuss some basics of regression analysis under the Bayesian approach.

37.8.1 Bayesian Linear Regression

Regression studies the relationship between two or more variables. Let y denote the variable of interest, also called the *response variable*, and $\mathbf{x} = (x_1, \dots, x_r)'$ denotes a vector of *predictor variables* or *covariates* which may be used to explain y . Regression method can be viewed as a problem of predicting y using the predictor variables x_1, \dots, x_r . The distribution of y given \mathbf{x} is usually studied, and the conditional mean $h(\mathbf{x}) := \mathbb{E}(y|\mathbf{x})$ can be obtained as the best predictor with respect to mean squared error criterion [2]. However in practice, the exact expression of $h(\mathbf{x})$ is not known, so the function $h(\mathbf{X})$ is needed to be estimated using data. $h(\mathbf{x})$ can be modelled in different ways; the simplest and commonly used approach is to use a *linear regression model*

$$h(\mathbf{x}) = \beta_1 x_1 + \dots + \beta_r x_r = \mathbf{x}'\boldsymbol{\beta}, \quad (37.1)$$

where $\boldsymbol{\beta} = (\beta_1, \dots, \beta_r)'$ is vector of unknown regression parameters.

Next we describe Bayesian regression with a normal linear model. Suppose we have n observations on y and also on each of the r components of \mathbf{x} : $\{(y_i, \mathbf{x}_i') = (y_i, x_{i1}, \dots, x_{ir})' : i = 1, \dots, n\}$. In matrix notation we write $\mathbf{y} = (y_1, \dots, y_n)'$, $\mathbf{X} = ((x_{ij}))_{1 \leq i \leq n, 1 \leq j \leq r}$. We assume the observation errors are independently and identically distributed normal variable with mean zero and unknown variance σ^2 . This yields the linear model

$$\mathbf{y} | \mathbf{X}, \boldsymbol{\beta}, \sigma^2 \sim \mathcal{N}_n(\mathbf{X}\boldsymbol{\beta}, \sigma^2 \mathbf{I}_n), \quad (37.2)$$

where \mathbf{I}_n denotes the $n \times n$ identity matrix. Then the parameter vector is $(\boldsymbol{\beta}, \sigma^2)$. The Bayesian approach to inference now requires a prior distribution on $(\boldsymbol{\beta}, \sigma^2)$. A standard prior distribution for this normal regression model assumes a non-informative uniform prior on $(\boldsymbol{\beta}, \log \sigma)$, or equivalently, the prior density on $(\boldsymbol{\beta}, \sigma^2)$,

$$\pi(\boldsymbol{\beta}, \sigma^2) \propto \sigma^{-2}. \quad (37.3)$$

For a large sample size and a relatively smaller dimensional $\boldsymbol{\beta}$, this non-informative prior distribution gives acceptable results and takes less effort than specifying prior knowledge in probabilistic form. We factor the joint posterior distribution of $\boldsymbol{\beta}$ and σ^2 as

$$\pi(\boldsymbol{\beta}, \sigma^2 | \mathbf{y}) = \pi_1(\boldsymbol{\beta} | \sigma^2, \mathbf{y}) \pi_2(\sigma^2 | \mathbf{y}). \quad (37.4)$$

Conditional posterior distribution of $\boldsymbol{\beta}$ given σ^2 can be obtained as

$$\boldsymbol{\beta} | \sigma^2, \mathbf{y} \sim \mathcal{N}_r(\hat{\boldsymbol{\beta}}, \sigma^2 (\mathbf{X}'\mathbf{X})^{-1}), \quad (37.5)$$

where $\hat{\beta} = (X'X)^{-1}X'y$. The marginal posterior distribution of σ^2 can be obtained as

$$\sigma^2 | y \sim \text{Inv-}\chi^2(n - r, s^2), \tag{37.6}$$

where $s^2 = (y - X\hat{\beta})'(y - X\hat{\beta}) / (n - r)$. The marginal posterior density of β , i.e. $\beta | y$, has a multivariate- t distribution with degrees of freedom $(n - r)$, mean $\hat{\beta}$ and shape matrix $s^2(X'X)^{-1}$, provided $(n - r) > 2$. The $100(1 - \alpha)\%$ highest posterior density (HPD) credible region for β is given by the ellipsoid

$$\{\beta : (\beta - \hat{\beta})'X'X(\beta - \hat{\beta}) \leq rs^2F_{r,n-r}(\alpha)\}, \tag{37.7}$$

where $F_{r,n-r}(\alpha)$ is the $(1 - \alpha)$ quantile of the $F_{r,n-r}$ distribution. For any analysis based on an improper prior distribution, it is important to check the propriety of the posterior distribution. The posterior $\pi(\beta, \sigma^2 | y)$ is proper if $n > r$ and rank of X is of full column rank r .

Suppose we wish to predict a new data set \tilde{y} with observed predictor variables \tilde{X} . The *posterior predictive density* of \tilde{y} is obtained as

$$f(\tilde{y} | y) = \int f(\tilde{y} | \beta, \sigma^2) \pi(\beta, \sigma^2 | y) d\beta d\sigma^2. \tag{37.8}$$

Note that the posterior predictive distribution has two sources of variation: the first source is due to the observational variability in the model and the second source of variability is coming from the joint posterior distribution of the parameters β and σ^2 . The above integration can be performed in two steps: first by averaging over the conditional posterior density $\pi_1(\beta | \sigma^2, y)$, we obtain the conditional posterior predictive density $f(\tilde{y} | \sigma^2, y)$, which is distributed as a normal variable with mean $\tilde{X}\hat{\beta}$ and covariance matrix $\sigma^2(I_n + \tilde{X}(X'X)^{-1}\tilde{X}')$. In the second step, we average this conditional posterior predictive density $f(\tilde{y} | \sigma^2, y)$ over the marginal posterior distribution $\pi_2(\sigma^2 | y)$. The resulting posterior predictive distribution $f(\tilde{y} | y)$ is the multivariate- t with mean $\tilde{X}\hat{\beta}$, shape matrix $s^2(I_n + \tilde{X}(X'X)^{-1}\tilde{X}')$ and $(n - r)$ degrees of freedom. To draw a random sample \tilde{y} from the posterior predictive distribution, we first draw (β, σ^2) from their joint posterior distribution and then draw a new \tilde{y} from $f(\tilde{y} | \beta, \sigma^2)$. Bayesian regression with unequal variances or unknown covariance matrix follows a similar path as discussed in [3].

Bayesian regression with unequal variances or an $n \times n$ covariance matrix follows a similar path as discussed above. If we replace the covariance matrix $\sigma^2 I_n$ with a symmetric positive definite matrix Σ in (37.2), the model becomes

$$y | X, \beta, \Sigma \sim \mathcal{N}_n(X\beta, \Sigma). \tag{37.9}$$

Assuming a non-informative uniform prior for β (i.e. $\pi(\beta | \Sigma) \propto 1$), the conditional posterior distribution of β given y and Σ follows a multivariate normal distribution with mean $\hat{\beta} = (X'\Sigma^{-1}X)^{-1}X'\Sigma^{-1}y$ and covariance matrix $(X'\Sigma^{-1}X)^{-1}$. The matrix inversion to compute the posterior covariance can be made computationally efficient by first computing a Cholesky factor of Σ , viz. $\Sigma^{1/2}$, and then by obtaining the upper triangular matrix R of a QR decomposition of $\Sigma^{-1/2}X$. Note that $(X'\Sigma^{-1}X)^{-1} = R^{-1}(R^{-1})'$ and computing inverse of an upper triangular matrix R is comparatively easier. For known Σ , we can carry out the posterior inference on β as described above. However unknown Σ , we need to obtain the posterior distribution of Σ as well. Assuming $\pi(\Sigma)$ denotes the prior density of Σ , the posterior density of Σ is then obtained from the following identity:

$$\pi(\Sigma | y) = \frac{\pi(\beta, \Sigma | y)}{\pi(\beta | \Sigma, y)} \propto \frac{f(y | X, \beta, \Sigma)\pi(\beta | \Sigma)\pi(\Sigma)}{\pi(\beta | \Sigma, y)}, \tag{37.10}$$

which must hold for any β . This calculation in (37.10) often gets very complex and depends on the prior density $\pi(\Sigma)$, and giving a prior for Σ is not an easy task. The practitioners often consider re-parameterisation of Σ to simplify the complexity, e.g. $\Sigma = \sigma^2\Sigma_0$, where Σ_0 is known, but σ^2 is unknown.

37.8.2 Hierarchical Bayesian Linear Regression

In practice, we often encounter data that are grouped into different hierarchical levels. For example, if we consider exam scores obtained by students as data, then it is organised at various hierarchical levels: students, class, school, district, etc. Analysis of hierarchical data should be analysed in an appropriate statistical framework that accounts for the different hierarchy, such as hierarchical linear modelling.

Hierarchical linear modelling can be thought of as an extension of conventional linear modelling where variability in the response variable is analysed with the predictor variables being at different hierarchical levels. Hierarchical linear models are sometimes called multi-level linear models or nested models. Hierarchical Bayesian linear model is essentially a hierarchical linear model that is estimated using Bayesian methods.

Let us explain the idea of hierarchical Bayesian linear modelling with an example. Assume that each y_j , $j = 1, 2, \dots, J$ is a vector of observation (length n_j) from a $\mathcal{N}_{n_j}(X_j\beta_j, \sigma_j^2 I_{n_j})$ population where the parameter $\beta_j = (\beta_{1j}, \dots, \beta_{rj})'$ governs the data generating process for y_j , $j = 1, 2, \dots, J$. We also assume that each of the parameters β_1, \dots, β_J follows a $\mathcal{N}_r(\alpha\mathbf{1}, \Lambda)$ and that they

are exchangeable, i.e. the joint distribution of β_1, \dots, β_j is invariant under permutations of the indices [4, 5]. The Bayesian hierarchical model contains the following stages:

$$\text{Stage 1 (Observation process): } y_j | \mathbf{X}_j, \beta_j, \sigma_j^2 \sim \mathcal{N}_{n_j}(\mathbf{X}_j \beta_j, \sigma_j^2 \mathbf{I}_{n_j})$$

$$\text{Stage 2 (Population process): } \beta_j | \alpha, \Lambda \sim \mathcal{N}_r(\alpha \mathbf{1}, \Lambda), \sigma_j^2 \sim \text{Inv-Gamma}(\tau_a, \tau_b)$$

$$\text{Stage 3 (Hyperprior distribution): } \alpha | \alpha_0, \sigma_\alpha^2 \sim \mathcal{N}(\alpha_0, \sigma_\alpha^2)$$

Here we assume Λ , τ_a , τ_b , α_0 and σ_α^2 as known quantity. However the above hierarchical Bayesian linear model can be extended to allow specification of prior distributions on these parameters if they are unknown to the practitioners. Obtaining posterior inference on such models is often not straightforward, and advance computing techniques are required to facilitate the inference. We shall discuss them in Sect. 37.9.

37.8.3 Generalised Linear Models

Generalised linear models are widely used in most areas of statistical applications. This class of modelling is applied in cases where the linear relationship between predictor variable \mathbf{x} and conditional mean of response variable $\mathbb{E}(y | \mathbf{x})$ is not appropriate (*cf.*, we have defined $\mathbb{E}(y | \mathbf{x}) = \mathbf{x}'\beta$ in the above examples of linear models). For example, in the cases where response y takes only the value 0 or 1 (binary), then a linear model will not be appropriate since the linear function $\mathbf{x}'\beta$ is likely to predict values other than 0 or 1 which are out of bounds for y . There are two components of a generalised linear model: (i) the conditional distribution of the response variable y given predictor \mathbf{x} (a matrix with dimension $n \times r$) with mean $\mathbb{E}(y | \mathbf{x}) = \mu$ and (ii) an invertible function $h(\cdot)$, called the 'link function, that relates the mean of the response variable to the linear predictor $\mathbf{x}'\beta$, i.e. $h(\mu) = \mathbf{x}'\beta$. Logistic regression, Poisson regression and probit regression are very popular examples of generalised linear models. We shall give examples of these popular regression models below.

Logistic Regression

Logistic regression is a very popular example of generalised linear modelling for binary data. Assume that $\mathbf{y} = (y_1, \dots, y_n)'$ is a vector of random variables where each component y_i independently follows a binomial distribution with parameters m_i and p_i . Note that $\mathbb{E}(y_i/m_i) = p_i$. Now we need to specify the link function to complete the generalised linear model. $\text{logit}(\cdot)$ is a very common choice for link function under this model setting: $h(p_i) = \text{logit}(p_i) = \log(\frac{p_i}{1-p_i}) = \mathbf{x}'_i \beta$.

The model likelihood function for β is

$$l(\beta | \mathbf{y}) = \prod_{i=1}^n \binom{m_i}{y_i} \left(\frac{\exp(\mathbf{x}'_i \beta)}{1 + \exp(\mathbf{x}'_i \beta)} \right)^{y_i} \left(1 - \frac{\exp(\mathbf{x}'_i \beta)}{1 + \exp(\mathbf{x}'_i \beta)} \right)^{m_i - y_i}. \quad (37.11)$$

Note that the logit link maps its argument with domain $(0, 1)$ to the whole real line, which is appropriate for a linear predictor. One then can fix a prior for the regression coefficient β to complete Bayesian formulation (e.g. a $\mathcal{N}_r(\alpha \mathbf{1}, \sigma_\beta^2 \mathbf{I}_r)$ prior or a non-informative uniform prior, etc.). Suppose $\pi(\beta)$ denotes the prior density; then the posterior density of β is

$$\pi(\beta | \mathbf{y}) = \frac{\pi(\beta) \prod_{i=1}^n \binom{m_i}{y_i} \left(\frac{\exp(\mathbf{x}'_i \beta)}{1 + \exp(\mathbf{x}'_i \beta)} \right)^{y_i} \left(1 - \frac{\exp(\mathbf{x}'_i \beta)}{1 + \exp(\mathbf{x}'_i \beta)} \right)^{m_i - y_i}}{\int_{\mathbf{b}} \pi(\mathbf{b}) \prod_{i=1}^n \binom{m_i}{y_i} \left(\frac{\exp(\mathbf{x}'_i \mathbf{b})}{1 + \exp(\mathbf{x}'_i \mathbf{b})} \right)^{y_i} \left(1 - \frac{\exp(\mathbf{x}'_i \mathbf{b})}{1 + \exp(\mathbf{x}'_i \mathbf{b})} \right)^{m_i - y_i} d\mathbf{b}}. \quad (37.12)$$

Probit Regression

The probit regression model is very similar to the logistic regression where we use a standard normal distribution function $\Phi(\cdot)$ as the link function. The probit link $h(p) = \Phi^{-1}(p) = \mathbf{x}'\beta$ is commonly used in practice. If each response y_i independently follows a Bernoulli distribution with parameter p_i , then the data distribution for probit model becomes

$$l(\beta | \mathbf{y}) = \prod_{i=1}^n (\Phi(\mathbf{x}'_i \beta))^{y_i} (1 - \Phi(\mathbf{x}'_i \beta))^{1 - y_i}. \quad (37.13)$$

Then we employ prior distribution for β to complete the Bayesian model and obtain the posterior density as

$$\pi(\beta | \mathbf{y}) = \frac{\pi(\beta) \prod_{i=1}^n (\Phi(\mathbf{x}'_i \beta))^{y_i} (1 - \Phi(\mathbf{x}'_i \beta))^{1 - y_i}}{\int_{\mathbf{b}} \pi(\mathbf{b}) \prod_{i=1}^n (\Phi(\mathbf{x}'_i \mathbf{b}))^{y_i} (1 - \Phi(\mathbf{x}'_i \mathbf{b}))^{1 - y_i} d\mathbf{b}}. \quad (37.14)$$

Poisson Regression

Count data is a frequent data type in statistics. In count data, the observations can only take non-negative integer values $\{0, 1, 2, 3, \dots\}$. So naturally, the Poisson model serves as a standard model for count data. Here we assume that response variable y_i follows a Poisson distribution with parameter $\mu_i (> 0)$, $i = 1, 2, \dots, n$. Note that $\mathbb{E}(y_i | \mu_i) = \mu_i$ for a Poisson model. Then we choose a logarithmic link function to relate the mean to the linear predictor: $h(\mu) = \log(\mu) = \mathbf{x}'\beta$. The model likelihood is then expressed as

$$l(\boldsymbol{\beta} | \mathbf{y}) = \prod_{i=1}^n \frac{1}{y_i!} \exp(-\exp(\mathbf{x}'_i \boldsymbol{\beta})) (\exp(\mathbf{x}'_i \boldsymbol{\beta}))^{y_i}. \quad (37.15)$$

We specify a prior for $\boldsymbol{\beta}$ to complete the Bayesian formulation of modelling and obtain the posterior density as

$$\pi(\boldsymbol{\beta} | \mathbf{y}) = \frac{\pi(\boldsymbol{\beta}) \prod_{i=1}^n \frac{1}{y_i!} \exp(-\exp(\mathbf{x}'_i \boldsymbol{\beta})) (\exp(\mathbf{x}'_i \boldsymbol{\beta}))^{y_i}}{\int_{\mathbf{b}} \pi(\mathbf{b}) \prod_{i=1}^n \frac{1}{y_i!} \exp(-\exp(\mathbf{x}'_i \mathbf{b})) (\exp(\mathbf{x}'_i \mathbf{b}))^{y_i} d\mathbf{b}}. \quad (37.16)$$

37.9 Bayesian Computation

Computations of various posterior quantities are needed in a Bayesian analysis. For example, posterior mean is popularly used as a standard Bayes estimate of a parameter. Posterior mode and posterior median are also used in some cases.

Posterior variance is computed to find the accuracy of the estimate, and posterior quantiles are used to find the Bayesian credible regions. As we know, posterior distribution can be obtained in a standard form by the use of conjugate priors. Posterior quantities such as above are computed very easily in these cases. However, we do not always use conjugate priors in practice and sometimes they do not even exist. If conjugate priors are not used, we often encounter a situation where posterior distributions are not in a standard form. We present a simple example of univariate case in below.

Example

Let us consider the successful passing rates $\mathbf{y} = (y_1, y_2, \dots, y_n)'$ of a football team in its past n matches. Assume that each y_i independently follows a beta distribution with parameters $(\alpha, 2)$, $y_i \in (0, 1)$, $\alpha > 0$, $i = 1, 2, \dots, n$. Unfortunately, there are not any useful conjugate priors available for this model. If we assign a gamma (b_1, b_2) prior for α (a standard choice), the posterior density function becomes: ◀

$$\begin{aligned} \pi(\alpha | \mathbf{y}) &= \frac{l(\alpha | \mathbf{y}) \pi(\alpha)}{m(\mathbf{y})} \\ &= \frac{\left\{ \prod_{i=1}^n \text{Beta}(\alpha, 2)^{-1} y_i^{\alpha-1} (1 - y_i) \right\} \times \Gamma(b_1)^{-1} b_2^{b_1} \alpha^{b_1-1} e^{-b_2 \alpha}}{\int_{\alpha_0} \left\{ \prod_{i=1}^n \text{Beta}(\alpha_0, 2)^{-1} y_i^{\alpha_0-1} (1 - y_i) \right\} \times \Gamma(b_1)^{-1} b_2^{b_1} \alpha_0^{b_1-1} e^{-b_2 \alpha_0} d\alpha_0} \\ &= \text{Const} \times \left\{ \alpha^n (\alpha + 1)^n \prod_{i=1}^n y_i^\alpha \right\} \times \alpha^{b_1-1} e^{-b_2 \alpha}, \end{aligned} \quad (37.17)$$

which does not belong to any standard family of probability distributions.

In such cases, we need different techniques to compute posterior quantities. In many cases these quantities of interest involved are obtained by integration. Even though numerical integration methods (e.g. integrate, R2Cuba packages in R software) can be used for approximation, they fail to provide accurate estimates when the number dimension of the integral gets high. In this section, we shall briefly describe different computing techniques that are needed for a Bayesian analysis.

37.9.1 Laplace Approximation

Suppose we need to compute the posterior mean of $h(\boldsymbol{\theta})$, which is expressed as

$$\mathbb{E}(h(\boldsymbol{\theta}) | \mathbf{y}) = \int_{\boldsymbol{\theta}} h(\boldsymbol{\theta}) \pi(\boldsymbol{\theta} | \mathbf{y}) d\boldsymbol{\theta} = \frac{\int_{\boldsymbol{\theta}} h(\boldsymbol{\theta}) l(\boldsymbol{\theta} | \mathbf{y}) \pi(\boldsymbol{\theta}) d\boldsymbol{\theta}}{\int_{\boldsymbol{\theta}} l(\boldsymbol{\theta} | \mathbf{y}) \pi(\boldsymbol{\theta}) d\boldsymbol{\theta}}, \quad (37.18)$$

where $l(\boldsymbol{\theta} | \mathbf{y})$ denotes the model likelihood of $\boldsymbol{\theta}$ (a p -dimensional parameter vector) given data \mathbf{y} , $\pi(\boldsymbol{\theta})$ denotes prior density and each of $h(\cdot), f(\cdot), \pi(\cdot)$ is a smooth function. Consider an integral of the form

$$I = \int_{\boldsymbol{\theta}} g(\boldsymbol{\theta}) e^{n\gamma(\boldsymbol{\theta})} d\boldsymbol{\theta}, \quad (37.19)$$

where $\gamma(\cdot)$ is a smooth function with its unique maximum at $\hat{\boldsymbol{\theta}}$. We obtain the Laplace approximation of the integral after expanding $g(\cdot)$ and $\gamma(\cdot)$ in Taylor series about $\hat{\boldsymbol{\theta}}$:

$$I = \left\{ g(\hat{\boldsymbol{\theta}}) + (\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})' g'(\hat{\boldsymbol{\theta}}) + \frac{1}{2} (\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})' \Delta_g(\hat{\boldsymbol{\theta}}) (\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}) + \dots \right\}$$

$$\begin{aligned} & \times e^{n\gamma(\hat{\theta})} \exp\left(\frac{n}{2}(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})' \Delta_{\gamma}(\hat{\boldsymbol{\theta}})(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}) + \dots\right) d\boldsymbol{\theta} \\ & = e^{n\gamma(\hat{\theta})} (2\pi)^{p/2} n^{-p/2} |\Delta_{\gamma}(\hat{\boldsymbol{\theta}})|^{-1/2} \left\{ g(\hat{\boldsymbol{\theta}}) + O(n^{-1}) \right\}. \end{aligned} \quad (37.20)$$

where $g'(\cdot)$ and $\gamma'(\cdot)$ denote the first derivative of $g(\cdot)$ and $\gamma(\cdot)$, respectively, and Δ_g and Δ_{γ} denote the Hessian matrices for $g(\cdot)$ and $\gamma(\cdot)$, respectively:

$$\Delta_g(\boldsymbol{\theta}) = \left(\left(\frac{\partial^2}{\partial \theta_i \partial \theta_j} g(\boldsymbol{\theta}) \right) \right), \quad \Delta_{\gamma}(\boldsymbol{\theta}) = \left(\left(\frac{\partial^2}{\partial \theta_i \partial \theta_j} \gamma(\boldsymbol{\theta}) \right) \right). \quad (37.21)$$

Now by letting $q(\cdot)$ as $h(\cdot)$ and 1 for the numerator and denominator of (37.18), respectively, we obtain a first order approximation of $\mathbb{E}(h(\boldsymbol{\theta}) | \mathbf{y})$ as:

$$\mathbb{E}(h(\boldsymbol{\theta}) | \mathbf{y}) \approx h(\hat{\boldsymbol{\theta}}) \left\{ 1 + O(n^{-1}) \right\}. \quad (37.22)$$

Now suppose that $h(\cdot)$ in (37.18) is positive and we let $n\gamma(\boldsymbol{\theta}) = \log h(\boldsymbol{\theta}) + \log l(\boldsymbol{\theta} | \mathbf{y}) + \log \pi(\boldsymbol{\theta})$ for the numerator and $n\gamma^*(\boldsymbol{\theta}) = \log l(\boldsymbol{\theta} | \mathbf{y}) + \log \pi(\boldsymbol{\theta})$ for the denominator in (37.18). Tierney and Kadane [6] proposed the following approximation under these conditions:

$$\begin{aligned} \mathbb{E}(h(\boldsymbol{\theta}) | \mathbf{y}) & \approx \left(\frac{|\Delta_{\gamma}(\hat{\boldsymbol{\theta}})|}{|\Delta_{\gamma^*}(\hat{\boldsymbol{\theta}})|} \right)^{1/2} \exp\left(n(\gamma^*(\hat{\boldsymbol{\theta}}) - \gamma(\hat{\boldsymbol{\theta}}))\right) \\ & \left\{ 1 + O(n^{-2}) \right\}, \end{aligned} \quad (37.23)$$

where $\gamma^*(\cdot)$ attains its maximum at $\tilde{\boldsymbol{\theta}}$ and $\gamma(\cdot)$ attains its maximum at $\hat{\boldsymbol{\theta}}$. There are many other analytic approximations in the literature which we did not include here. This is because the superior alternative computation techniques, such as Metropolis-Hastings algorithm, Gibbs algorithm, etc., have made the above analytic approximation methods less popular.

37.9.2 The E-M Algorithm

Now suppose that $\pi(\boldsymbol{\theta} | \mathbf{y})$ is of a non-standard form and computationally difficult to handle. In E-M algorithm, we augment the observed data \mathbf{y} with unobserved latent data \mathbf{z} such that the augmented posterior density $\pi(\boldsymbol{\theta} | \mathbf{y}, \mathbf{z})$ is easier to handle. E-M algorithm [see 7] is essentially an iterative method to find maximum likelihood estimates of parameters in a statistical model. Here we shall use the algorithm to estimate the maximum a posteriori (MAP). Note that $\pi(\boldsymbol{\theta} | \mathbf{y}) = \pi(\boldsymbol{\theta}, \mathbf{z} | \mathbf{y}) / f(\mathbf{z} | \mathbf{y}, \boldsymbol{\theta})$ where $f(\mathbf{z} | \mathbf{y}, \boldsymbol{\theta})$ denotes the predictive density of \mathbf{z} given \mathbf{y} and $\boldsymbol{\theta}$. From this we have

the following identity:

$$\begin{aligned} \log \pi(\boldsymbol{\theta} | \mathbf{y}) & = \int_{\mathbf{z}} \log \pi(\boldsymbol{\theta}, \mathbf{z} | \mathbf{y}) f(\mathbf{z} | \mathbf{y}, \hat{\boldsymbol{\theta}}^{(i)}) d\mathbf{z} \\ & \quad - \int_{\mathbf{z}} \log f(\mathbf{z} | \mathbf{y}, \boldsymbol{\theta}) f(\mathbf{z} | \mathbf{y}, \hat{\boldsymbol{\theta}}^{(i)}) d\mathbf{z} \\ & = Q(\boldsymbol{\theta}, \hat{\boldsymbol{\theta}}^{(i)}) - H(\boldsymbol{\theta}, \hat{\boldsymbol{\theta}}^{(i)}), \end{aligned} \quad (37.24)$$

where $\hat{\boldsymbol{\theta}}^{(i)}$ is an estimate of $\boldsymbol{\theta}$ from the i^{th} step of the iteration. The E-M algorithm essentially involves two steps at each iteration:

E-step: Calculate $Q(\boldsymbol{\theta}, \hat{\boldsymbol{\theta}}^{(i)}) = \mathbb{E}_{\mathbf{z} | \mathbf{y}, \hat{\boldsymbol{\theta}}^{(i)}}(\log \pi(\boldsymbol{\theta}, \mathbf{z} | \mathbf{y}))$

M-step: Maximise $Q(\boldsymbol{\theta}, \hat{\boldsymbol{\theta}}^{(i)})$ with respect to $\boldsymbol{\theta}$, and obtain $\hat{\boldsymbol{\theta}}^{(i+1)}$ such that

$$Q(\hat{\boldsymbol{\theta}}^{(i+1)}, \hat{\boldsymbol{\theta}}^{(i)}) = \max_{\boldsymbol{\theta}} Q(\boldsymbol{\theta}, \hat{\boldsymbol{\theta}}^{(i)}).$$

We start by finding $\mathbf{z}^{(i)} = \mathbb{E}(\mathbf{z} | \mathbf{y}, \hat{\boldsymbol{\theta}}^{(i)})$, (if exact mean is not available, we get an estimate of $\mathbb{E}(\mathbf{z} | \mathbf{y}, \hat{\boldsymbol{\theta}}^{(i)})$ as $\mathbf{z}^{(i)}$). Then we use this $\mathbf{z}^{(i)}$ to maximise $\pi(\boldsymbol{\theta} | \mathbf{y}, \mathbf{z}^{(i)})$ to obtain $\hat{\boldsymbol{\theta}}^{(i+1)}$. Then we find $\mathbf{z}^{(i+1)}$ using $\hat{\boldsymbol{\theta}}^{(i+1)}$ and continue the iterations in this manner. Also note that $\pi(\hat{\boldsymbol{\theta}}^{(i+1)} | \mathbf{y}) \geq \pi(\hat{\boldsymbol{\theta}}^{(i)} | \mathbf{y})$ for each iteration i . Therefore, the E-M algorithm can be expected to converge to a local maximum from any starting point.

37.9.3 Monte Carlo Sampling

Simulation of random processes saw its popularity only after the beginning of computer era in the 1990s. Before that, simulations were only used in a handful of studies [8, 9], mainly in the fields of physics and chemistry. Monte Carlo sampling is named after a famous casino at 'Monte Carlo' in the 1950s. Monte Carlo method is also known as 'Ordinary Monte Carlo' (OMC). Let us consider an expectation $\mu = \mathbb{E}[g(X)]$ of a random variable X , where $g(\cdot)$ is a real valued function on the state space such that this expectation is not available in closed form. If i.i.d. sample X_1, X_2, \dots can be simulated from the same distribution as X , then

$$\hat{\mu}_n = \frac{1}{n} \sum_{i=1}^n g(X_i) \quad (37.25)$$

converges almost surely to $\mathbb{E}[g(X)]$. Therefore, for large n , we can use $\hat{\mu}_n$ as an estimate of μ . If $\sigma^2 = \text{Var}[g(X)]$ is finite, then σ^2 can be estimated by $\hat{\sigma}_n^2 = \frac{1}{n} \sum_{i=1}^n (g(X_i) - \hat{\mu}_n)^2$. Now we have the asymptotic distribution of $\hat{\mu}_n$ using the central limit theorem (CLT)

$$\frac{\hat{\mu}_n - \mu}{\hat{\sigma}_n/\sqrt{n}} \xrightarrow[n \rightarrow \infty]{d} \mathcal{N}(0, 1). \tag{37.26}$$

Hence $\hat{\mu}_n \pm z_{\alpha/2} \hat{\sigma}_n/\sqrt{n}$ is an asymptotic $100(1 - \alpha)\%$ confidence interval for μ with $z_{\alpha/2}$ denoting the $100(1 - \alpha/2)\%$ quantile of standard normal distribution. Note that each additional significant figure in the estimate (i.e. a tenfold increase in accuracy) requires a hundredfold increase in the sample size. This is because accuracy is inversely proportional to the square root of the sample size (just like classical statistics). Since computer simulations do not generate random samples, they are rather pseudorandom; we call $\hat{\mu}_n$ as *Monte Carlo approximation* of μ , $\hat{\sigma}_n/\sqrt{n}$ as *Monte Carlo standard error* (MCSE) and n as *Monte Carlo sample size*.

37.9.4 Importance Sampling

Suppose we want to obtain an estimate of $\mu = \mathbb{E}[g(X)]$ and it is difficult or costly to sample from the distribution of X . In that case Monte Carlo sampling will not work and we need alternative strategy. Importance sampling uses the idea that a sample can be generated from any distribution. That means, we can use a sample generated from another distribution (other than distribution of X) to compute an estimate of μ . Assume that the probability distribution of X has a density f and there exists another density f_0 which behaves very similar to f but is easy to sample from. Then

$$\hat{\mu}_n = \frac{1}{n} \sum_{i=1}^n g(X_i) \frac{f(X_i)}{f_0(X_i)} \tag{37.27}$$

can be used as an estimate of μ for large n , where (X_1, X_2, \dots, X_n) is an i.i.d. sample generated from f_0 . Also note that

$$\begin{aligned} \mathbb{E}_0[\hat{\mu}_n] &= \frac{1}{n} \sum_{i=1}^n \mathbb{E}_0 \left[g(X_i) \frac{f(X_i)}{f_0(X_i)} \right] = \int g(X) \frac{f(X)}{f_0(X)} f_0(X) dX \\ &= \mathbb{E}[g(X)] = \mu. \end{aligned} \tag{37.28}$$

and consequently $\hat{\mu}_n$ converges to μ almost surely. The density f_0 is called an *importance function* in this context. The rationale behind this will be discussed later. Monte Carlo standard error can be calculated using s_n/\sqrt{n} in the same manner as described in (37.9.3), but by replacing $g(X_i)$ by $g(X_i)f(X_i)/f_0(X_i)$. Note that method of importance sampling also works with a Markov chain X_1, X_2, \dots drawn from f_0 rather than an i.i.d. sample.

So far we have assumed that both f and f_0 are normalised densities. In the situation where we have only unnormalised densities h and h_0 , we will require a different estimator of μ . We define

$$\bar{\mu}_n = \frac{1}{n} \sum_{i=1}^n g(X_i) w(X_i), \text{ where } w(X_i) = \frac{h(X_i)/h_0(X_i)}{\sum_{i=1}^n h(X_i)/h_0(X_i)}. \tag{37.29}$$

This new statistic $\bar{\mu}_n$ can be regarded as an estimate of μ , for large n . We also have

$$\begin{aligned} \bar{\mu}_n &\xrightarrow[n \rightarrow \infty]{a.s.} \frac{\mathbb{E}_0 \left[g(X) \frac{h(X)}{h_0(X)} \right]}{\mathbb{E}_0 \left[\frac{h(X)}{h_0(X)} \right]} = \frac{\int g(X) \frac{h(X)}{h_0(X)} f_0(X) dX}{\int \frac{h(X)}{h_0(X)} f_0(X) dX} \\ &= \frac{C}{C_0} \frac{\int g(X) f(X) dX}{\int f(X) dX} = \mathbb{E}[g(X)], \end{aligned} \tag{37.30}$$

where $f(X) = h(X)/C$ and $f_0(X) = h_0(X)/C_0$ with $C = \int h(X) dX$, $C_0 = \int h_0(X) dX$.

37.9.5 Rejection Sampling

Rejection sampling is a very standard method of stochastic simulation [10, 11]. Consider the problem where we want to simulate from an unnormalised density $g(\cdot)$. Suppose that there exists a density $h(\cdot)$ such that (a) it is easy to simulate a sample from $h(\cdot)$, (b) $h(\cdot)$ is very close to $g(\cdot)$ and (c) for some $M > 0$, we have $g(x) < Mh(x)$ for all x . Then we follow the following steps:

- Step 1.** Generate x from $h(\cdot)$ and generate u from *Uniform*(0, 1).
- Step 2.** If $u \leq \frac{g(x)}{Mh(x)}$, we accept the proposed value x .
- Step 3.** We repeat Steps 1 and 2 until we obtain a sample of size n (here n is a prefixed positive integer).

The components of the sample can be regarded as a sample from the target density $g(\cdot)$. Ideally, the positive constant M should be chosen as small as possible to complete the above sampling algorithm with fewer iterations. Note that if we choose $h(x) = g(x)/c$ where c is the normalising constant of $g(\cdot)$, the optimised value of M would be c and we would have gotten the acceptance probability of the sampling algorithm as 1.

37.9.6 Markov Chain Monte Carlo

Markov chain Monte Carlo (MCMC) came into the picture just after the invention of Monte Carlo sampling in the 1950s. The theory of MCMC shares the same motive as Monte Carlo sampling, that is, to compute expectations, but it uses Markov chains. This overcomes the serious drawback that Monte Carlo sampling has, that is, to draw samples directly from the respective distribution. In many of the Bayesian modelling in practice, posterior distribution is incompletely

or implicitly specified that is difficult to handle (e.g. joint posterior distribution of a parameter vector gets specified by their conditional distributions and marginal distributions). Therefore Monte Carlo sampling cannot be used in these cases.

MCMC draws sample by carefully constructing a Markov chain of relatively longer size. The key idea behind the theory of MCMC is that Markov chain with the same equilibrium distribution can also be used to infer about the quantity of interest. There are many available techniques to construct such a Markov chain, most famous ones are *Metropolis algorithm* [8], *Metropolis-Hastings algorithm* [a generalised version of Metropolis algorithm, 9] and *Gibbs sampler* [a special case of Metropolis-Hastings algorithm, 12]. It is to be noted that Markov chain Monte Carlo techniques can be used in both the paradigms: Bayesian and frequentist. Many of the posterior quantities in a Bayesian analysis require integrating over the posterior distribution of the parameters given the data. In likelihood-based inference, one may need to integrate the likelihood over the conditional distribution of observables given the parameters, or one simply may need to calculate a likelihood with complicated dependence [13–16].

Markov Chains and Stationarity

A sequence of random variables $\{X_n : n \geq 1\}$ is called a *stochastic process*. When these random variables also follow the *Markov property*, i.e. the probability of moving to the next state depends only on the present state and not on the past states, then the sequence $\{X_n : n \geq 1\}$ is called a *Markov chain* (here we only use a discrete-time Markov chain to explain the main ideas). We shall denote the chain $\{X_n : n \geq 1\}$ by $\{X_n\}$ for notational convenience. The set of all possible value of X_i is called the *state space* of the Markov chain, denoted by S . The marginal distribution of X_1 , denoted by $p(x)$, is called the *initial distribution*. For general state space S , the transition probabilities are specified by defining a kernel, viz. transition kernel.

Definition 1 (Transition kernel) Let S be a set and \mathcal{S} a σ -field on S . A transition kernel H is a function from $S \times S$ into $[0, 1]$ such that

- (i) $H(x, A) = \Pr(X_{n+1} \in A | X_n = x)$, $x \in S, A \in \mathcal{S}$.
- (ii) For all $x \in S$, $A \mapsto H(x, A)$ is a probability measure on (S, \mathcal{S}) .
- (iii) For all $A \in \mathcal{S}$, $x \mapsto H(x, A)$ is a measurable function on S .

A transition probability of a Markov chain is called *stationary* if the conditional probabilities $H(x, A) = \Pr(X_{n+1} \in A | X_n = x)$ do not depend on n for any $x \in S, A \in \mathcal{S}$. A Markov chain is called *stationary* (or *invariant* or *time homogeneous*) if the conditional distribution of $(X_{n+1}, X_{n+2}, \dots, X_{n+k})$ given

X_n does not depend on the value of n . It consequently follows that a Markov chain is stationary if and only if the marginal distribution of X_n does not depend on n . An initial distribution is called *stationary* (or *invariant* or *equilibrium*) for some transition probability distribution if the corresponding Markov chain specified by this initial distribution and transition probability distribution is stationary. It is to be noted that transition probability distribution of a Markov chain is stationary if the corresponding Markov chain is stationary, but the converse is not generally true.

Definition 2 Consider a Markov chain $\{X_n\}$ with general state space S and transition kernel H .

- (a) A Markov chain $\{X_n\}$ is ϕ -*irreducible* if there exists a probability distribution ϕ and a positive integer $n \geq 1$ such that the n -step transition density

$$H^{(n)}(x, A) = P(X_{n+1} \in A | X_1 = x) > 0, \quad (37.31)$$

for any $x \in S$ and for all $A \in \mathcal{S}$ with $\phi(A) > 0$. A Markov chain $\{X_n\}$ is *irreducible* if it is ϕ -irreducible for some probability distribution ϕ .

- (b) A Markov chain $\{X_n\}$ is *reversible* with respect to a probability distribution p if it satisfies the following condition:

$$p(dx) H(x, dy) = p(dy) H(y, dx) \text{ for all } x, y \in S. \quad (37.32)$$

- (c) A ϕ -irreducible Markov chain $\{X_n\}$ is *recurrent* if for all $A \in \mathcal{S}$ with $\phi(A) > 0$ we have

$$\mathbb{E}_\phi \left[\sum_{n=1}^{\infty} I(X_{n+1} \in A) \mid X_1 = x \right] = \infty, \text{ for any } x \in A. \quad (37.33)$$

- (d) An irreducible and aperiodic Markov chain $\{X_n\}$ is called *positive recurrent* if it has a stationary probability distribution, i.e. there exists a unique p such that

$$p(A) = \int_S p(x) H(x, A) dx \text{ for all } A \in \mathcal{S}. \quad (37.34)$$

- (e) A Markov chain $\{X_n\}$ with stationary distribution p is *aperiodic* if there does not exist any $d \geq 2$ and disjoint subsets $S_1, S_2, \dots, S_d \subseteq S$ with $H(x, S_{i+1}) = 1$ for all $x \in S_i, i = 1, 2, \dots, d - 1$, and $H(x, S_1) = 1$ for all $x \in S_d$, such that $p(S_1) > 0$.

Theorem 1 Consider a ϕ -irreducible and aperiodic Markov chain $\{X_n\}$ with a general state space S and transition kernel H . If the Markov chain has a stationary distribution p , then the following hold:

- (a) The chain $\{X_n\}$ is p -irreducible and the stationary distribution p is unique (that means, the chain is positive recurrent).
- (b) $\|H^{(n)}(x, \cdot) - p(\cdot)\| = \sup_{A \in \mathcal{S}} |H^{(n)}(x, A) - p(A)| \xrightarrow{n \rightarrow \infty} 0$, for p -a.e. $x \in \mathcal{S}$.
- (c) $H^{(n)}(x, A) \xrightarrow{n \rightarrow \infty} p(A)$, for p -a.e. $x \in \mathcal{S}$ and for any $A \in \mathcal{S}$ with $p(A) > 0$.
- (d) For any real valued function $g(\cdot)$ such that $\mathbb{E}_p[|g(X)|] < \infty$,

$$\hat{\mu}_n = \frac{1}{n} \sum_{i=1}^n g(X_i) \xrightarrow[n \rightarrow \infty]{a.s.} \mathbb{E}_p[g(X)] = \int_{\mathcal{S}} g(x) p(x) dx. \tag{37.35}$$

The result in Theorem 1(d) is called the *strong law of large numbers* for Markov chain. This result guarantees that each iterate of an ergodic Markov chain except a first few is approximately distributed as p . However, it does not give any information about how many iterations will be needed to reach the convergence.

Definition 3 (Geometric ergodicity) A Markov chain $\{X_n\}$ with stationary distribution p is *geometrically ergodic* if there exists a constant $\lambda \in [0, 1)$ such that

$$\|H^{(n)}(x, \cdot) - p(\cdot)\| \leq \gamma(x)\lambda^n, \quad \text{for } p\text{-a.e. } x \in \mathcal{S} \text{ and } n \geq 1. \tag{37.36}$$

with $\gamma(x) < \infty$ for p -a.e. $x \in \mathcal{S}$.

We define $\lambda^* = \inf\{\lambda : \exists \gamma(\cdot) \text{ satisfying (37.36)}\}$, i.e. the smallest λ for which there exists a function $\gamma(\cdot)$ that satisfies (37.36). This λ^* is called the *rate of convergence*. The discussion of Markov chains and stationarity for a countable state space is covered in [17].

Theorem 2 (Central Limit Theorem) Consider a ϕ -irreducible and aperiodic Markov chain $\{X_n\}$ on a general state space \mathcal{S} with transition kernel H and a stationary distribution p . Assume that p is also the initial distribution, i.e., $X_1 \sim p$. Then for a real valued function $g(\cdot) : \mathcal{S} \rightarrow \mathbb{R}$ with finite mean $\mu = \mathbb{E}_p[g(X_i)]$ and $\text{Var}_p[g(X_i)] < \infty$, the following hold:

$$\sqrt{n}(\hat{\mu}_n - \mu) \xrightarrow[n \rightarrow \infty]{d} \mathcal{N}(0, \sigma^2), \tag{37.37}$$

where $\sigma^2 = \text{Var}_p[g(X_i)] + \sum_{j=1}^{\infty} \text{Cov}_p[g(X_i), g(X_{i+j})] < \infty$.

If this σ^2 is very large compared to $\text{Var}_p[g(X_i)]$, the MCMC algorithm behaves very inefficiently [18]. We could estimate Monte Carlo variance of $\hat{\mu}_n$ by $\hat{\sigma}_n^2/n$ where

$\hat{\sigma}_n^2 = \frac{1}{n} \sum_{i=1}^n (g(X_i) - \hat{\mu}_n)^2$, but this is expected to be an underestimate of $\text{Var}(\hat{\mu}_n)$ due to the positive autocorrelation in MCMC samples. We define *effective sample size* (ESS) [19] as $ESS = n/\kappa(\mu)$ where $\kappa(\mu)$ is the autocorrelation time for μ :

$$\kappa(\mu) = 1 + 2 \sum_{j=1}^{\infty} \rho_j(\mu), \tag{37.38}$$

with $\rho_j(\mu)$ denoting the autocorrelation at lag j for μ . In practice, $\kappa(\mu)$ is computed by using the corresponding MCMC chain of μ and by truncating the summation when the sample autocorrelations get very small (e.g. below 0.1) [20]. Then we estimate $\text{Var}(\hat{\mu}_n)$ by $\hat{\sigma}_n^2/ESS(\mu)$. Another method of variance estimation is via batching. Let us define

$$\hat{\mu}_{b,n} = \frac{1}{K} \sum_{i=(b-1)K+1}^{bK} g(X_i), \quad b = 1, 2, \dots, B, \tag{37.39}$$

where iterates of the Markov chain (X_i 's) are of length $n = BK$ for a sufficiently large K . Then $\sqrt{K}(\hat{\mu}_{b,n} - \mu)$ converges in distribution to $\mathcal{N}(0, \sigma^2)$, for each $b = 1, 2, \dots, B$. Therefore σ^2 can be estimated by

$$\hat{\sigma}_{\text{bm}}^2 = \frac{K}{B-1} \sum_{b=1}^B (\hat{\mu}_{b,n} - \hat{\mu})^2. \tag{37.40}$$

Here, $\hat{\mu}_{b,n}$'s are called *batch means* and $\hat{\sigma}_{\text{bm}}^2$ is called the *batch means estimator* of σ^2 . It is known that $\hat{\sigma}_{\text{bm}}^2$ is not a consistent estimator of σ^2 [21, 22]. However, $\hat{\sigma}_{\text{bm}}^2$ is strongly consistent for σ^2 if the batch size (K) and number of batches (B) also increase with n (e.g. by setting $B = K = \lfloor n^{1/2} \rfloor$) [23].

Overlapping batch means estimator generally has better finite sample properties than $\hat{\sigma}_{\text{bm}}^2$. Here we define the batch means by $\hat{\mu}_{j,K} = K^{-1} \sum_{i=1}^K g(X_{j+i})$, for $j = 0, 1, \dots, n-K$. The overlapping batch means estimator of σ^2 is defined as

$$\hat{\sigma}_{\text{obm}}^2 = \frac{nK}{(n-K)(n-K+1)} \sum_{j=0}^{n-K} (\hat{\mu}_{j,K} - \hat{\mu})^2. \tag{37.41}$$

This $\hat{\sigma}_{\text{obm}}^2$ is also strongly consistent under some mild conditions. Under geometric ergodicity of the Markov chain and existence of a little more than fourth-order moment, both batch means estimator and overlapping batch means estimator are MSE consistent, i.e. $\mathbb{E}_p(\hat{\sigma}_n^2 - \sigma^2)^2 \rightarrow 0$ as $n \rightarrow \infty$ [24].

A reasonable Monte Carlo standard error estimate of $\hat{\mu}_n$ is given by $\hat{\sigma}_n/\sqrt{n}$, which helps to assess the accuracy of $\hat{\mu}_n$. The estimation of variance for a Markov chain is an important step in a MCMC practice and is discussed in detail in [20, 24] and the references therein. We would also like to emphasise here that we are only being able to cover basic theories and techniques on MCMC. Please refer to the following sources for a detailed treatment on the topic: [17, 18, 25, 26]. We describe some well-known MCMC algorithms in the next few sections.

Metropolis-Hastings Algorithm

In MCMC, we are interested in update techniques to construct a Markov chain $\{X_n\}$ that preserves a specified distribution p in each update. In Bayesian analysis, this specified distribution will always be the *posterior distribution*. Let us consider a general state space S , and let Q be a transition kernel with density q such that

$$q(x, y) \geq 0, \text{ for all } x, y \in S \quad (37.42)$$

$$\text{and } Q(x, S) = \int_S q(x, y) dy = 1, x \in S. \quad (37.43)$$

In practice, we chose Q in such a way that it is easy to sample from. This transition density $q(x, y)$ is sometimes referred to as *proposal density* or *candidate density*. We start the algorithm by initialising the chain at a possible state x_1 such that $p(x_1) > 0$. Then we perform the following steps for $m = 2, \dots, n$.

Step 1. Draw a *proposal value* (or *candidate value*) y from density $q(x_{m-1}, y)$.

Step 2. Compute the *Hastings ratio*

$$\rho(x_{m-1}, y) = \frac{p(y) q(y, x_{m-1})}{p(x_{m-1}) q(x_{m-1}, y)}. \quad (37.44)$$

and acceptance probability $\alpha(x_{m-1}, y) = \min\{\rho(x_{m-1}, y), 1\}$.

Step 3. Set the next iterate X_m as

$$x_m = \begin{cases} y & \text{with probability } \alpha(x_{m-1}, y), \\ x_{m-1} & \text{with probability } 1 - \alpha(x_{m-1}, y). \end{cases} \quad (37.45)$$

Observe that $\{X_n\}$ is a Markov chain with transition kernel H with density h such that $h(x, y) = \alpha(x, y) q(x, y)$ for all $x, y \in S$. Also note that $\{X_n\}$ satisfies the condition: $p(x) h(x, y) = p(y) h(y, x)$ for all $x, y \in S$ [27]. This implies that the Markov chain is $\{X_n\}$ *reversible*. Consequently, we have $\int_S p(x) H(x, A) dx = p(A)$, i.e. p is a stationary distribution for transition kernel H . This algorithm is known as the *Metropolis-Hastings algorithm* [9]. Note that it is enough to have an unnormalised version of the density p to run the algo-

rithm. This is particularly useful in Bayesian analysis where it is often difficult to compute the normalisation constant of the posterior distribution. Now if S is irreducible with respect to Q and $p(x) > 0$ for all $x \in S$, the above constructed Markov chain $\{X_n\}$ with transition kernel H and stationary distribution p is also irreducible, and hence ergodic theorem holds.

The *rejection probability* from a point $x \in S$ is defined as

$$r(x) = 1 - \int_S h(x, y) dy, \quad (37.46)$$

and the *expected acceptance rate* of the algorithm is defined as

$$a = \int_S (1 - r(x)) p(x) dx. \quad (37.47)$$

The empirical acceptance rate (i.e. the proportion of proposed updates during the MCMC iterations that are accepted) is used as an estimate of the expected acceptance rate a . For a discrete state space S , we proceed as in the general case. Here we assume the transition probability matrix $Q = ((q(i, j)))$ on the countable state space S . We define the Hasting ratio as

$$\rho(i, j) = \frac{p(j) q(j, i)}{p(i) q(i, j)}$$

and the acceptance probability as $\alpha(i, j) = \min\{\rho(i, j), 1\}$ for all $i, j \in S$.

Metropolis Algorithm

Metropolis algorithm is a special case of Metropolis-Hastings algorithm where the proposal density q is symmetric with respect to its arguments, i.e. $q(x, y) = q(y, x)$ for all states $x, y \in S$ [8]. Then the Hastings ratio in (37.44) reduces to $\rho(x, y) = p(y)/p(x)$, which is now called the *Metropolis ratio*.

Random Walk Metropolis Algorithm

Random walk Metropolis algorithm [28] is a specific case of the Metropolis-Hastings algorithm, where the candidates X_m^* are constructed as $X_m^* = X_{m-1} + \epsilon_m$, with the ϵ_m chosen to be i.i.d. with a symmetric distribution. We also assume that ϵ_m is stochastically independent of X_m . Then $q(X_{m-1}, X_m^*)$ can be expressed as $g(X_m^* - X_{m-1})$ where g denotes the density of ϵ_m . Some popular choices of the proposal density g are $\mathcal{N}(0, \tau^2)$, *Uniform* $(-\delta, \delta)$. The choice of the variance parameter τ^2 in case of a normal proposal is very important in MCMC, and choosing an optimal value of it is itself a different area of research [29, 30]. It is suggested to choose the scale parameter (e.g. τ^2 in the normal proposal) appropriately as it directly influences the overall acceptance rate of the algorithm. If τ^2 is larger than necessary, the algorithm will have high rejection rate, and as a result the chain will move slowly. If τ^2 is smaller

than necessary, the algorithm will have high acceptance rate, but will result in slow mixing within the state space. In both of these two cases, the algorithm will fail to behave efficiently.

Independence Sampler

Independence sampler is also a special case of Metropolis-Hastings algorithm where the proposal density $q(x, y) = q(y)$ and therefore transition kernel $Q(x, \cdot)$ do not depend on its first argument x . The Hastings ratio becomes

$$\rho(x, y) = \frac{p(y)q(x)}{p(x)q(y)}.$$

This algorithm is also called as the independence Metropolis-Hastings algorithm [28]. It is to be noted that the convergence of the Markov chain will be fast if the independence proposal density is a good approximation of the density of the stationary distribution. Hence the practitioner should be careful in choosing the proposal density for getting a better efficiency of the algorithm.

Gibbs Sampler

Around the time when Gibbs sampler was first developed by [12], the algorithm was mostly used in spatial statistics. It was the seminal article [31] that made the Gibbs sampler popular to the Bayesian community making them aware of this incredible method of drawing sample from the posterior distribution. The algorithm is as follows. Let p be the target distribution for a random vector $\mathbf{X} = (X_1, \dots, X_k)'$, $k \geq 2$. We assume that it is possible to generate samples from each full conditional distribution with densities $\{p(X_i | \mathbf{X}_{-i})\}$, where $\mathbf{X}_{-i} = (X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_k)'$. Gibbs sampling is then used to produce sample from the stationary distribution of the Markov chain under some regularity conditions [32], by drawing sample from these full conditional distributions. The steps of Gibbs sampling algorithm are given below. We start the sampling by fixing a set of initial values $(X_2^{(1)}, \dots, X_k^{(1)})$ for parameters (X_2, \dots, X_k) . Then we repeat the following steps for $m = 2, \dots, n$.

Step 1. Draw $X_1^{(m)}$ from $p(X_1 | X_2^{(m-1)}, X_3^{(m-1)}, \dots, X_k^{(m-1)})$.

Step 2. Draw $X_2^{(m)}$ from $p(X_2 | X_1^{(m)}, X_3^{(m-1)}, \dots, X_k^{(m-1)})$.

⋮
⋮

Step k. Draw $X_k^{(m)}$ from $p(X_k | X_1^{(m)}, X_2^{(m)}, \dots, X_{k-1}^{(m)})$.

This algorithm defines a Markov chain with transition probability from $\mathbf{X}^{(m-1)}$ to $\mathbf{X}^{(m)}$ as

$$\prod_{i=1}^k p(X_i^{(m)} | X_1^{(m)}, \dots, X_{i-1}^{(m)}, X_{i+1}^{(m-1)}, \dots, X_k^{(m-1)}).$$

The following condition, viz. the *positivity condition* [33], is needed to explain the convergence properties of Gibbs sampler without resorting to Metropolis-Hastings algorithm.

Definition 4 (Positivity condition) Suppose that $p(x_1, \dots, x_p)$ is the joint probability density of a random vector $\mathbf{X} = (X_1, \dots, X_p)'$ and $p^{(i)}(x_i)$ denotes the marginal probability density of X_i , $i = 1, \dots, p$. If $p^{(i)}(x_i) > 0$ for every $i = 1, \dots, p$ implies that $p(x_1, \dots, x_p) > 0$, then the joint density p is said to satisfy the *positivity condition*.

Under the positivity condition, it can be shown that the simulated Markov chain $\{\mathbf{X}^{(m)} : m = 1, \dots, n\}$ is irreducible. This in turn validates that the Markov chain has a stationary distribution which is same as the joint posterior distribution p . Thus after discarding all draws from the burn-in period $m = 1, \dots, n_{burn}$ (here n_{burn} is an iteration number specified by the practitioner after which the Markov chain would have approximately distributed as the stationary distribution). Summaries of the distribution can be obtained by using the sample $\{\mathbf{X}^{(m)} : m = n_{burn} + 1, \dots, n\}$, for a sufficiently large n .

It is important to note that the above full conditionals have sufficient information to uniquely determine the joint density. *Brook's lemma* [34] (also known as *the factorisation theorem*) demonstrates that given the full conditional density $p(x_i | \mathbf{x}_{-i})$, we can determine the joint density $p(x_1, x_2, \dots, x_p)$ of a random vector $\mathbf{X} = (X_1, X_2, \dots, X_p)'$.

Lemma 1 (Brook's lemma) *The joint density of a random vector $\mathbf{X} = (X_1, X_2, \dots, X_p)'$ can be determined up to a constant by its full conditionals as*

$$\begin{aligned} p(x_1, \dots, x_p) &= \frac{p(x_1 | x_2, \dots, x_p)}{p(x_{10} | x_2, \dots, x_p)} \cdot \frac{p(x_2 | x_{10}, \dots, x_p)}{p(x_{20} | x_{10}, \dots, x_p)} \\ &\dots \dots \frac{p(x_p | x_{10}, \dots, x_{p-1,0})}{p(x_{p0} | x_{10}, \dots, x_{p-1,0})} \\ &\cdot p(x_{10}, \dots, x_{p0}), \end{aligned} \tag{37.48}$$

where $\mathbf{x} = (x_1, x_2, \dots, x_p)'$ and $\mathbf{x}_0 = (x_{10}, x_{20}, \dots, x_{p0})'$ are two fixed points in the support of $p(x_1, x_2, \dots, x_p)$.

It can also be shown that Gibbs sampling algorithm is a special case of Metropolis-Hastings algorithm. Let us consider the block updating of \mathbf{X} to \mathbf{X}^* where only one component X_i is getting updated for some fixed i , i.e. $\mathbf{X}^* = (X_1, \dots, X_{i-1}, X_i^*, X_{i+1}, \dots, X_p)$. We factor the joint density of \mathbf{X} as

$$p(\mathbf{x}) = p_1(\mathbf{x}_{-i}) p_2(x_i | \mathbf{x}_{-i}),$$

where \mathbf{x}_{-i} denotes the parameter vector without the component X_i , p_1 denotes the marginal posterior density of \mathbf{x}_{-i} and p_2 denotes full conditional density of X_i . Now in Gibbs sampling, we generate x_i^* from $p_2(x_i | \mathbf{x}_{-i})$ which can be considered as the proposal distribution in Metropolis-Hastings algorithm. The corresponding Hastings ratio is

$$\begin{aligned}\rho(\mathbf{x}, \mathbf{x}^*) &= \frac{p(\mathbf{x}^*) p_2(x_i | \mathbf{x}_{-i})}{p(\mathbf{x}) p_2(x_i^* | \mathbf{x}_{-i})} \\ &= \frac{p_1(\mathbf{x}_{-i}) p_2(x_i^* | \mathbf{x}_{-i}) p_2(x_i | \mathbf{x}_{-i})}{p_1(\mathbf{x}_{-i}) p_2(x_i | \mathbf{x}_{-i}) p_2(x_i^* | \mathbf{x}_{-i})} = 1,\end{aligned}$$

implying that the proposal values are always accepted in Gibbs sampling.

Slice Sampler

Slice sampler is another popular MCMC algorithm where we use auxiliary variables [35]. Suppose we want to simulate a sample (X_1, X_2, \dots, X_n) from an unnormalised density $g(\cdot)$. In a Bayesian analysis, $g(\cdot)$ will be the unnormalised posterior, that is, the product of likelihood and the prior density. We consider an auxiliary random variable Y with $Y | X = x$ following $Uniform(0, g(x))$. Then the joint density of Y and X is

$$p(x, y) \propto g(x) \frac{1}{g(x)} I(y < g(x)) = I(y < g(x)), \quad (37.49)$$

where $I(y < g(x))$ takes the value 1 if $y < g(x)$ and 0 otherwise. This joint density is essentially a uniform density with the support $0 < Y < g(X)$. The full conditionals for a Gibbs sampler will be the following:

1. Generate Y from $Y | X = x \sim Uniform(0, g(x))$.
2. Note that $X | Y = y$ follows a uniform distribution over the values of x for which $g(x) \geq y$. Generate X from this conditional distribution.

Repeating these two steps for n iterations will obtain a sample $\{(X_1, Y_1), (X_2, Y_2), \dots, (X_n, Y_n)\}$ from the joint density $p(x, y)$, and hence (X_1, X_2, \dots, X_n) will be a sample from the marginal density $g(x)$. The name ‘*Slice sampler*’ came from the observation that the line $Y = y$ (which is horizontal to the x -axis) *slices* the unnormalised density curve $g(x)$ into two parts, and we consider only the values of X for which $g(x) \geq y$.

$$\rho\{(\boldsymbol{\theta}_k, \mathcal{M}_k), (\boldsymbol{\theta}_{k^*}^*, \mathcal{M}_{k^*}^*)\} \quad (37.51)$$

$$= \frac{l(\boldsymbol{\theta}_{k^*}^*, \mathcal{M}_{k^*}^* | \mathbf{y}) \pi(\boldsymbol{\theta}_{k^*}^* | \mathcal{M}_{k^*}^*) \pi(\mathcal{M}_{k^*}^*) q(\mathcal{M}_{k^*}^*, \mathcal{M}_k) h_{k,k^*}(\mathbf{u}^* | \boldsymbol{\theta}_{k^*}^*)}{l(\boldsymbol{\theta}_k, \mathcal{M}_k | \mathbf{y}) \pi(\boldsymbol{\theta}_k | \mathcal{M}_k) \pi(\mathcal{M}_k) q(\mathcal{M}_k, \mathcal{M}_{k^*}^*) h_{k,k^*}(\mathbf{u} | \boldsymbol{\theta}_k)} \left| \frac{\partial g(\boldsymbol{\theta}_k, \mathbf{u})}{\partial(\boldsymbol{\theta}_k, \mathbf{u})} \right|, \quad (37.52)$$

where $q(\mathcal{M}_k, \mathcal{M}_{k^*}^*)$ denotes the transition probability from model \mathcal{M}_k to model $\mathcal{M}_{k^*}^*$. We accept the proposed update $(\boldsymbol{\theta}_{k^*}^*, \mathcal{M}_{k^*}^*)$ with probability $\alpha\{(\boldsymbol{\theta}_k, \mathcal{M}_k), (\boldsymbol{\theta}_{k^*}^*, \mathcal{M}_{k^*}^*)\}$.

Repeating the above steps for n iterations will obtain a sample which can then be used to derive the posterior sum-

Reversible Jump Markov Chain Monte Carlo

The reversible jump Markov chain Monte Carlo (RJMCMC) is an extension of Metropolis-Hastings MCMC sampling algorithm where the dimension of the parameter space is also allowed to be updated in different MCMC iterations [36]. We will describe this algorithm in a Bayesian context. Suppose that we have a countable collection of competing models $\{\mathcal{M}_k, k \in \mathcal{K}\}$ for observed data \mathbf{y} . Let each model \mathcal{M}_k have an n_k dimensional parameter vector, denoted by $\boldsymbol{\theta}_k \in S_k \subset \mathbb{R}^{n_k}$. It is to be noted that n_k 's are allowed to vary for different models. Then the posterior density of $(\boldsymbol{\theta}_k, \mathcal{M}_k)$ is obtained as

$$\begin{aligned}\pi(\boldsymbol{\theta}_k, \mathcal{M}_k | \mathbf{y}) \\ = \frac{l(\boldsymbol{\theta}_k, \mathcal{M}_k | \mathbf{y}) \pi(\boldsymbol{\theta}_k | \mathcal{M}_k) \pi(\mathcal{M}_k)}{\sum_{m \in \mathcal{K}} \int l(\boldsymbol{\theta}'_m, \mathcal{M}_m | \mathbf{y}) \pi(\boldsymbol{\theta}'_m | \mathcal{M}_m) \pi(\mathcal{M}_m) d\boldsymbol{\theta}'_m}\end{aligned} \quad (37.50)$$

where $l(\boldsymbol{\theta}_k, \mathcal{M}_k | \mathbf{y})$ denotes the corresponding model likelihood, $\pi(\boldsymbol{\theta}_k | \mathcal{M}_k)$ denotes the prior density of $\boldsymbol{\theta}_k$ under model \mathcal{M}_k and $\pi(\mathcal{M}_k)$ denotes the prior density of model \mathcal{M}_k . This joint posterior density $\pi(\boldsymbol{\theta}_k, \mathcal{M}_k | \mathbf{y})$ is considered to be the target density in RJMCMC, and the new state space is given by $S = \bigcup_{k \in \mathcal{K}} (\{\mathcal{M}_k\}, S_k)$. RJMCMC is essentially a strategy of constructing a Markov chain on this general state space S with the joint posterior distribution as its stationary distribution. RJMCMC uses the following steps at each iteration.

- Step 1.** Suppose that $(\boldsymbol{\theta}_k, \mathcal{M}_k)$ denotes the current state of the chain and n_k denotes the length of $\boldsymbol{\theta}_k$. We generate a candidate model $\mathcal{M}_{k^*}^*$ with transition probability $q(\mathcal{M}_k, \mathcal{M}_{k^*}^*)$.
- Step 2.** A random vector \mathbf{u} is generated from a known density $h_{k,k^*}(\mathbf{u} | \boldsymbol{\theta}_k)$.
- Step 3.** We map $(\boldsymbol{\theta}_k, \mathbf{u})$ to $(\boldsymbol{\theta}_{k^*}^*, \mathbf{u}^*)$ by defining a bijective function $g(\cdot)$ such that $g(\boldsymbol{\theta}_k, \mathbf{u}) = (\boldsymbol{\theta}_{k^*}^*, \mathbf{u}^*)$ and $n_k + \text{length}(\mathbf{u}) = n_{k^*} + \text{length}(\mathbf{u}^*)$.
- Step 4.** The acceptance probability $\alpha\{(\boldsymbol{\theta}_k, \mathcal{M}_k), (\boldsymbol{\theta}_{k^*}^*, \mathcal{M}_{k^*}^*)\}$ of the candidate value $(\boldsymbol{\theta}_{k^*}^*, \mathcal{M}_{k^*}^*)$ is $\min(1, \rho\{(\boldsymbol{\theta}_k, \mathcal{M}_k), (\boldsymbol{\theta}_{k^*}^*, \mathcal{M}_{k^*}^*)\})$ where

maries. The dimension matching in Step 2 implies that the constructed Markov chain is reversible and hence converges to the stationary distribution as in Metropolis-Hastings algorithm.

37.10 Monitoring Convergence

Although convergence rates are available for most MCMC algorithms owing to the active research in this field, they cannot be directly used in practice to know when a chain has converged since the rates are typically available up to an arbitrary constant [37]. Practitioners usually take the help of the diagnostic tools to justify the convergence of the chain. However, it should be noted that diagnostic tools cannot prove convergence of MCMC algorithms as they use only a finite subset of the chain. It is to be noted that the chains obtained from an MCMC algorithm reach the stationary distribution only after a finite number of iterations. Because of this, we truncate these chains from the left to alleviate the effect of starting values and to keep only the part of the chain which can be taken as a sample from the stationary distribution. We call the truncated part as the *burn-in* period.

Estimating the burn-in period is an important aspect of monitoring convergence. If the burn-in is taken too small, we will have some draws left in the sample which cannot be taken as representatives from the stationary distribution; hence, the standard error of the parameter estimate will unnecessarily increase. If the burn-in period is too large, then we are essentially throwing away data which could have been used to improve accuracy of the parameter estimate.

37.10.1 Geweke Diagnostic

Assume that $\{\theta^{(1)}, \theta^{(2)}, \dots, \theta^{(n)}\}$ is an MCMC sample for a scalar parameter θ and $g(\theta)$ is the posterior quantity of interest. Let n_0 denote the iteration number where we want to check whether the chain has converged. We define $A = \{n_0 + 1, n_0 + 2, \dots, n_0 + n_A\}$, $B = \{n_0 + n^*, n_0 + n^* + 1, \dots, n\}$ where $1 < n_A < n^* < n_1$, $n_B = n_1 - n^* + 1$, $n_A + n_B < n_1$ and $n_0 + n_1 = n$. Let

$$\bar{g}_A = \frac{1}{n_A} \sum_{i \in A} g(\theta^{(i)}), \quad \bar{g}_B = \frac{1}{n_B} \sum_{i \in B} g(\theta^{(i)}), \quad (37.53)$$

and let S_g^A and S_g^B denote consistent spectral density estimates for $\{g(\theta^{(i)}) : i \in A\}$ and $\{g(\theta^{(i)}) : i \in B\}$, respectively. Then

$$Z_n = \frac{\bar{g}_A - \bar{g}_B}{\sqrt{S_g^A/n_A + S_g^B/n_B}} \xrightarrow[n \rightarrow \infty]{d} \mathcal{N}(0, 1), \quad (37.54)$$

provided that the sequence $g(\theta^{(i)})$ is stationary and the ratios n_A/n and n_B/n are fixed [38]. Using the above property, we can test the equality of mean at different windows A and B of the sample and reject the null hypothesis if $|Z_n|$ is larger than the critical point. This would indicate that the chain has

not converged by iteration n_0 . Geweke [38] suggested n_A and n_B to be $n_1/10$ and $n_1/2$. At first, the test is applied to the whole chain by considering $n_0 = 0$. If the test is rejected, we sequentially apply the test for different values of n_0 (e.g. $n/10, n/5, 3n/10, 2n/5$, etc.). If the test gets rejected at all the values of n_0 , this would indicate that the chain has not converged.

37.10.2 The Serial Correlation and the Effective Sample Size (ESS)

There is another factor to be considered while drawing inference using a Markov chain. Each component of an MCMC sample, after attaining convergence, follows the target distribution (which is the posterior distribution in case of a Bayesian analysis). Since the sample draws are correlated within themselves, the efficiency of the estimates using the correlated sample is usually lesser than what we would have obtained by using an independent sample. For instance, if we wish to reduce the standard error of an estimator by a factor of 10, we would require to increase the sample size by a factor of 100. However, sample size should be increased by a larger number if we use a correlated sample instead. In such cases, we need to first compute the effective sample size $ESS = n/\kappa$ where κ is the autocorrelation time for the corresponding parameter and can be computed from (37.38) and then increase the sample size by a factor of $100/ESS$ to reduce the standard error by a factor of 10.

37.10.3 Gelman-Rubin Diagnostic

Convergence of every quantity of interest should be monitored while running an MCMC algorithm (e.g. some parametric function, logarithm of posterior density, etc.). Gelman-Rubin diagnostic [3] assesses convergence by checking both mixing and stationarity of the simulated Markov chain. At first, one should simulate m number of chains for the parameter of interest, each of length n . Then, for each scalar parameter θ , we will have the chains $\{\theta_{ij} : i = 1, 2, \dots, n; j = 1, 2, \dots, m\}$. We compute the between-sequence variance B and within-sequence variance W as the following

$$B = \frac{n}{m-1} \sum_{j=1}^m (\bar{\theta}_{.j} - \bar{\theta}_{..})^2 \text{ and } W = \frac{1}{m} \sum_{j=1}^m s_j^2, \quad (37.55)$$

where $\bar{\theta}_{.j} = \frac{1}{n} \sum_{i=1}^n \theta_{ij}$, $\bar{\theta}_{..} = \frac{1}{n} \sum_{j=1}^m \bar{\theta}_{.j}$ and $s_j^2 = \sum_{i=1}^n (\theta_{ij} - \bar{\theta}_{.j})^2$. We estimate the marginal posterior variance $\text{Var}(\theta | y)$ by

$$\widehat{\text{Var}}(\theta | \mathbf{y}) = \frac{n-1}{n}W + \frac{1}{n}B. \quad (37.56)$$

The estimator $\widehat{\text{Var}}(\theta | \mathbf{y})$ overestimates $\text{Var}(\theta | \mathbf{y})$ if the initial distribution is overdispersed. However, the estimator is unbiased if the chain is stationary or in the limit as $n \rightarrow \infty$. On the other hand, W underestimates $\text{Var}(\theta | \mathbf{y})$ for every finite positive integer values of n , but is asymptotically unbiased as n approaches ∞ . Potential scale reduction factor \hat{R} of the distribution of θ is defined as

$$\hat{R} = \left(\frac{\widehat{\text{Var}}(\theta | \mathbf{y})}{W} \right)^{1/2}, \quad (37.57)$$

which declines to 1 in the limit as $n \rightarrow \infty$. The convergence of the chain is monitored by value of \hat{R} . In practice, a higher value of \hat{R} indicates that the practitioner should continue the simulation to improve the inference on the target distribution of θ . Gelman et al. [3] also suggests to always start by simulating at least two chains and then split each chain in half (after discarding the draws from the burn-in period), so that $m \geq 4$.

37.10.4 Model Robustness and Sensitivity Analysis

Bayesian modelling assumes every aspect of a model including the likelihood and the prior(s). So it is not surprising that the inference drawn from fitting of such models to the data is prone to be dependent on these assumptions. To check robustness, a standard approach is to study the sensitivity in the estimated posterior quantities of a Bayesian analysis when we make small changes in the likelihood or prior or other parts of the model. If the perturbations in parts of the model do not lead to effecting the conclusions, we say that the data set is informative enough for the model assumptions. If the conclusions get affected, then we rethink about the model assumptions and/or collect more data.

Example

We take an example of a beta-binomial model with observed data y following a binomial distribution with parameters n and p ; the parameter p is given a $\text{beta}(a, b)$ prior. To check the sensitivity, we increase or decrease a and b separately (and together), and then we compute the posterior quantities of interest in each of the cases. ◀

Sensitivity analysis requires further sampling, which may be time-consuming and costly in many practical scenarios. However, we can avoid the additional sampling in some situations. Suppose we have a data set $\mathbf{y} = (y_1, y_2, \dots, y_n)$

and we model it using the likelihood $l(\theta | \mathbf{y}) = \prod_{i=1}^n l(\theta | y_i)$. We want to investigate the effect of removing the observation y_j from the data set. Assume that $\{\theta^{(1)}, \theta^{(2)}, \dots, \theta^{(N)}\}$ is a sample from the posterior distribution with density $p(\theta | \mathbf{y})$. If posterior mean of $g(\theta)$ is the posterior quantity of interest, then we estimate it as

$$\hat{\mathbb{E}}(g(\theta) | \mathbf{y}) = \sum_{i=1}^N g(\theta^{(i)})/N.$$

After deleting the j -th observation from the data set \mathbf{y} , the modified posterior density can be expressed as

$$p^*(\theta | \mathbf{y}) \propto l(\theta | \mathbf{y}_{-j})p(\theta) \propto \frac{p(\theta | \mathbf{y})}{l(\theta | y_j)}.$$

We estimate the posterior mean of $g(\theta)$ after deleting y_j as

$$\hat{\mathbb{E}}^*(g(\theta) | \mathbf{y}) = \frac{\sum_{i=1}^N g(\theta^{(i)})/l(\theta | y_j)}{\sum_{i=1}^N 1/l(\theta | y_j)}, \quad (37.58)$$

using the importance sampling estimator. Thus we can obtain the posterior quantities under such cases without additional sampling.

37.10.5 Posterior Predictive Checking

Assessing the fit of the model to the data is an important part of statistical modelling. Therefore, in every Bayesian analysis, it is recommended to check the quality of the fit. If a model fits well to the data, the replicated data simulated from the model is expected to be similar as the observed data. Let \mathbf{y}^{rep} denote a replication as observed data \mathbf{y} that also could have been observed with the same model and $\tilde{\mathbf{y}}$ denote future observations. The posterior predictive density is defined as

$$p(\mathbf{y}^{\text{rep}} | \mathbf{y}) = \int l(\theta | \mathbf{y}^{\text{rep}})p(\theta | \mathbf{y})d\theta. \quad (37.59)$$

The Bayesian p -value, denoted by p_B , is defined as

$$p_B = \Pr(T(\mathbf{y}^{\text{rep}}, \theta) \geq T(\mathbf{y}, \theta) | \mathbf{y}), \quad (37.60)$$

where $T(\mathbf{y}, \theta)$ is a scalar function of both the observed data \mathbf{y} and the parameter θ . In practice, if we have an MCMC sample for θ of length n : $\{\theta^{(1)}, \theta^{(2)}, \dots, \theta^{(n)}\}$, we draw \mathbf{y}^{rep} for each iteration $\theta^{(i)}$, and consequently we have a sample $\{(\mathbf{y}^{\text{rep},(i)}, \theta^{(i)}) : i = 1, 2, \dots, n\}$ from the joint posterior distribution with density $p(\mathbf{y}^{\text{rep}}, \theta | \mathbf{y})$. The Bayesian p -value p_B is then estimated as the proportion of the n iterations such that $T(\mathbf{y}^{\text{rep},(i)}, \theta^{(i)}) \geq T(\mathbf{y}, \theta^{(i)})$, $i = 1, 2, \dots, n$. The function $T(\mathbf{y}, \theta)$ should be chosen to represent relevant aspects of the

model fitting. Choosing of the functional $T(\mathbf{y}, \theta)$ is described in detail by [3]. If the model is nearly true, p_B should be close to 0.5. If p_B is estimated as close to 0 or 1, the model is likely to be poor because of its predictions that do not fit the observed data. Under the model, (i) a scatterplot of the values $T(\mathbf{y}^{\text{rep.}(i)}, \theta^{(i)})$ against $T(\mathbf{y}, \theta^{(i)})$ should be symmetric about the 45° line, and (ii) a histogram of the differences $T(\mathbf{y}, \theta^{(i)}) - T(\mathbf{y}^{\text{rep.}(i)}, \theta^{(i)})$ should include 0. A deviation from the above expected outcomes should indicate that the assumed model possesses poor predictive ability.

37.11 Model Comparison

Model comparison is a key practice in Bayesian modelling. As we already know, all the models usually applied to the data are wrong, but among them some can be less wrong and may be informative for making comparisons between several models. Model comparison methods usually focus on predictive ability of a model while penalising for model complexity. Over the years, this topic has been an active area of research, and numerous model comparison methods have been developed. However, there is no unanimity among the Bayesian practitioners about the most appropriate model comparison method. We will not be able to go in much depth in this topic and will only be providing brief descriptions on the methods. Let us start by assuming that we have L number of competing models $\{\mathcal{M}_1, \mathcal{M}_2, \dots, \mathcal{M}_L\}$.

37.11.1 Akaike Information Criterion (AIC)

Akaike information criterion [AIC, 39] is undoubtedly the most popular model comparison method. AIC is defined as

$$\text{AIC} = -2 \log l(\hat{\theta}_{\text{mle}} | \mathbf{y}) + 2p, \quad (37.61)$$

where $l(\theta | \mathbf{y})$ denotes the model likelihood for data \mathbf{y} and parameter θ . The dimension of the parameter θ is denoted by p , and the maximum likelihood estimate is denoted by $\hat{\theta}_{\text{mle}}$. The second term in the expression of AIC stands for a bias correction for the deviance (a measure of predictive accuracy of a model)

$$D(\theta) = -2 \log l(\theta | \mathbf{y}) \quad (37.62)$$

computed at the point $\hat{\theta}_{\text{mle}}$. In fact, the approximation in AIC is based on asymptotic normality of posterior distribution. However, when the sample size is small, AIC tends to favour models with higher number of parameters. We calculate AIC for each of the L competing models $\{\mathcal{M}_1, \mathcal{M}_2, \dots, \mathcal{M}_L\}$ and choose the one with the minimum AIC value. Under some conditions, AIC has been shown to be asymptotically

equal to leave-one-out cross-validation (LOO-CV) when it is computed using the maximum likelihood estimate [40].

37.11.2 Deviance Information Criterion (DIC)

The computation of AIC or BIC requires the number of parameters to apply the bias correction. In Bayesian analyses, the number of parameters is often not clear, and the parameters are constrained by the prior in some manner. *Deviance information criterion* [DIC, 41] is defined as

$$\text{DIC} = -2 \log l(\hat{\theta} | \mathbf{y}) + 2p_d \quad (37.63)$$

where the bias correction term

$$p_D = -2 \mathbb{E}_{\theta | \mathbf{y}}[\log l(\theta | \mathbf{y})] + 2 \log l(\hat{\theta} | \mathbf{y})$$

is computed as

$$\hat{p}_D = -\frac{2}{n} \sum_{i=1}^n \log l(\theta^{(i)} | \mathbf{y}) + 2 \log l(\hat{\theta} | \mathbf{y}), \quad (37.64)$$

where $\{\theta^{(1)}, \theta^{(2)}, \dots, \theta^{(n)}\}$ denotes an MCMC sample for θ of length n and $\hat{\theta}$ denotes the estimate of posterior mean or posterior mode. An alternative version of DIC, viz. $\text{DIC}_{\text{alt}} = -2 \log l(\hat{\theta} | \mathbf{y}) + 2p_{D,\text{alt}}$, is also available [42] that makes a modification in the bias correction term

$$p_{D,\text{alt}} = 2 \text{Var}_{\theta | \mathbf{y}}[\log l(\theta | \mathbf{y})]$$

which is computed as

$$\hat{p}_{D,\text{alt}} = \frac{2}{n-1} \sum_{i=1}^n \left(\log l(\theta^{(i)} | \mathbf{y}) - \frac{1}{n} \sum_{j=1}^n \log l(\theta^{(j)} | \mathbf{y}) \right)^2. \quad (37.65)$$

We compute DIC for each model and prefer the model with smallest DIC value. It is to be noted that DIC is numerically more stable in practice than DIC_{alt} . But the bias correction term corresponding to the alternative version has the advantage of being always positive. Under some conditions, DIC has been shown to be asymptotically equal to LOO-CV using plug-in predictive densities [43].

37.11.3 Widely Applicable Information Criterion (WAIC)

Assuming that data \mathbf{y} can be partitioned into d data points such that $\mathbf{y} = (y_1, y_2, \dots, y_d)'$ and joint likelihood $l(\theta | \mathbf{y}) = \prod_{i=1}^d l(\theta | y_i)$, *widely applicable information criteria*, also

known as Watanabe-Akaike information criterion [WAIC, 44], is defined as

$$\text{WAIC} = -2 \sum_{i=1}^d \log \mathbb{E}_{\theta | y} [l(\theta | y_i)] + 2 p_{\text{WAIC}}. \quad (37.66)$$

Two versions of p_{WAIC} are generally used in practice

$$\begin{aligned} p_{\text{WAIC1}} &= 2 \sum_{i=1}^d \left\{ \log \mathbb{E}_{\theta | y} [l(\theta | y_i)] - \mathbb{E}_{\theta | y} [\log l(\theta | y_i)] \right\}, \\ p_{\text{WAIC2}} &= \sum_{i=1}^d \text{Var}_{\theta | y} [\log l(\theta | y_i)]. \end{aligned} \quad (37.67)$$

We compute p_{WAIC} using MCMC draws $\{\theta^{(1)}, \theta^{(2)}, \dots, \theta^{(n)}\}$ from $p(\theta | y)$ as follows:

$$\begin{aligned} \hat{p}_{\text{WAIC1}} &= 2 \sum_{i=1}^d \left\{ \log \left(\frac{1}{n} \sum_{m=1}^n l(\theta^{(m)} | y_i) \right) \right. \\ &\quad \left. - \frac{1}{n} \sum_{m=1}^n \log l(\theta^{(m)} | y_i) \right\}, \\ \hat{p}_{\text{WAIC2}} &= \sum_{i=1}^d \left\{ \frac{1}{n} \sum_{m=1}^n \left(\log l(\theta^{(m)} | y_i) \right. \right. \\ &\quad \left. \left. - \frac{1}{n} \sum_{m=1}^n \log l(\theta^{(m)} | y_i) \right)^2 \right\}. \end{aligned}$$

A model with smaller WAIC value is preferred. The second bias correction term p_{WAIC2} looks similar to $p_{D,\text{alt}}$ but is more stable because of summing up the variances. WAIC has the desirable property of averaging over the posterior distribution rather than conditioning on a point estimate like DIC. WAIC is considered as a fully Bayesian approach for estimating out-of-sample predictive accuracy of a model. Under some conditions, WAIC has been proven to be asymptotically equal to Bayesian LOO-CV [44].

37.11.4 Out-of-Sample Validation

If we have a large data set at hand, we split the data set into two parts – (i) one part is the within sample data $y = (y_1, y_2, \dots, y_d)'$ which is used to fit or train the model, and (ii) the other part is the out-of-sample data $y_{\text{OOS}} = (y_{1,\text{OOS}}, y_{2,\text{OOS}}, \dots, y_{d_{\text{OOS}},\text{OOS}})'$ that is used to validate the model. Suppose $\hat{y}_{\text{OOS}} = (\hat{y}_{1,\text{OOS}}, \hat{y}_{2,\text{OOS}}, \dots, \hat{y}_{d_{\text{OOS}},\text{OOS}})'$ are obtained as model predictions of the data y_{OOS} under model \mathcal{M} . The predictions \hat{y}_{OOS} can be computed as the estimate of

$$\mathbb{E}(y_{\text{OOS}} | y) = \int y_{\text{OOS}} p(y_{\text{OOS}} | y) dy_{\text{OOS}}.$$

which can be computed as $\sum_{m=1}^n y_{\text{OOS}}^{(m)} / n$. Here $y_{\text{OOS}}^{(m)}$ denotes a draw from likelihood $l(\theta^{(m)} | y_{\text{OOS}})$ at each MCMC iteration $m = 1, 2, \dots, n$. We compute the mean squared prediction error (MSPE) [42]

$$\text{MSPE} = \frac{1}{d_{\text{OOS}}} \sum_{i=1}^{d_{\text{OOS}}} (y_{i,\text{OOS}} - \hat{y}_{i,\text{OOS}})^2 \quad (37.68)$$

independently for each of the L models $\{\mathcal{M}_1, \mathcal{M}_2, \dots, \mathcal{M}_L\}$. The model which corresponds to minimum MSPE is considered to be the best model in the set.

37.11.5 Bayesian Cross-Validation

Cross-validation is a method of measuring predictive ability of a model and is very useful for smaller sample sizes. Leave-one-out cross-validation is the simplest approach for conducting a cross-validation study [3, 42]. In leave-one-out cross-validation, the *score* is defined as

$$\text{score} = \sum_{i=1}^d \log p(y_i | y_{-i}), \quad (37.69)$$

where each $p(y_i | y_{-i})$ can be computed as

$$\frac{1}{n} \sum_{m=1}^n p(y_i | y_{-i}, \theta^{(i,m)}). \quad (37.70)$$

Here $\{\theta^{(i,1)}, \theta^{(i,2)}, \dots, \theta^{(i,n)}\}$ denotes MCMC sample for parameter θ using only $y_{-i} = (y_1, y_2, \dots, y_{i-1}, y_{i+1}, \dots, y_d)'$ as data, $i = 1, 2, \dots, d$. This score statistic underestimates the predictive ability of the model as it uses only $d - 1$ data points while conditioning. The *bias* is expressed as

$$\text{bias} = \sum_{i=1}^d \log p(y_i | y) - \frac{1}{d} \sum_{i=1}^d \sum_{j=1}^d \log p(y_j | y_{-i}), \quad (37.71)$$

where each $p(y_j | y_{-i})$ can be computed as (notice the difference with (37.70))

$$\frac{1}{n} \sum_{m=1}^n p(y_j | y_{-i}, \theta^{(i,m)}). \quad (37.72)$$

The *bias corrected score* is then expressed as $\text{score}_b = \text{score} + \text{bias}$.

K -fold cross-validation can be thought of as an extension of leave-one-out cross-validation where the whole data set y

is partitioned into K subsets $\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_K$, and we define the score as

$$\text{score} = \sum_{k=1}^K \log p(\mathbf{y}_k | \mathbf{y}_{-k}). \tag{37.73}$$

where each $p(\mathbf{y}_k | \mathbf{y}_{-k})$ can be computed similarly as

$$\frac{1}{n} \sum_{m=1}^n p(\mathbf{y}_k | \mathbf{y}_{-k}, \boldsymbol{\theta}^{(k,m)}). \tag{37.74}$$

with $\{\boldsymbol{\theta}^{(k,1)}, \boldsymbol{\theta}^{(k,2)}, \dots, \boldsymbol{\theta}^{(k,n)}\}$ denoting an MCMC sample for parameter $\boldsymbol{\theta}$ using \mathbf{y}_{-k} as data, $k = 1, 2, \dots, K$. We compute the cross-validation score for each of the competing models and consider the model with largest score as the best in the model set.

37.11.6 Posterior Predictive Loss

Gelfand and Ghosh [45] recommended a decision theoretic approach for model comparison based on predictive accuracy. The goal of this approach is to obtain good predictions for replicates \mathbf{y}^{rep} of the observed data \mathbf{y} and, at the same time, to be faithful to the observed values. To attain this objective, they proposed a loss function in terms of unobserved replicate \mathbf{y}^{rep} :

$$\mathcal{L}(\mathbf{y}^{\text{rep}}, a; \mathbf{y}) = \mathcal{L}(\mathbf{y}^{\text{rep}}, a) + w \mathcal{L}(\mathbf{y}, a), \tag{37.75}$$

where \mathbf{y}^{rep} has the same first stage distribution as \mathbf{y} and a is an ‘action’ or an estimate for \mathbf{y}^{rep} . In the proposed loss function (37.75), w is constrained to be non-negative and viewed as a relative weight of how important it is for a to be close to \mathbf{y} , compared to \mathbf{y}^{rep} .

Gelfand and Ghosh [45] derived a posterior predictive risk by averaging their proposed loss function (37.75) over the predictive distribution of $y_{i,\text{rep}}$ given \mathbf{y} . The resulting risk is then minimised with respect to the prediction a_i and summed over all observations $i = 1, \dots, d$ to yield the model selection criterion

$$D_w = \sum_{i=1}^d \min_{a_i} \mathbb{E}_{y_i^{\text{rep}} | \mathbf{y}} \left[\mathcal{L}(y_i^{\text{rep}}, a_i) + w \mathcal{L}(y_i, a_i) \right]. \tag{37.76}$$

Provided a loss function $\mathcal{L}(\cdot)$ and weight w , the model with the smallest D_w is favoured. In practice, it can be difficult to carry out the computation in (37.76). If we select the squared error loss function, the criterion becomes

$$D_{w2} = \frac{w}{w+1} \sum_{i=1}^d (y_i - \mathbb{E}(y_{i,\text{rep}} | \mathbf{y}))^2 + \sum_{i=1}^d \text{Var}(y_{i,\text{rep}} | \mathbf{y}). \tag{37.77}$$

Further, by letting $w \rightarrow \infty$, we get

$$D_\infty = \sum_{i=1}^d (y_i - \mathbb{E}(y_i^{\text{rep}} | \mathbf{y}))^2 + \sum_{i=1}^d \text{Var}(y_i^{\text{rep}} | \mathbf{y}). \tag{37.78}$$

Although D_∞ was first proposed by [45, 46] showed that it comes as the limit of D_{w2} . The first term in the D_∞ criterion is the goodness-of-fit term, while the second term in the right-hand side of the above (37.78), i.e. $\sum_{i=1}^d \text{Var}(y_i^{\text{rep}} | \mathbf{y})$, can be viewed as a penalty and will tend to increase in an overfitted model where the prediction variance gets larger with an increasing number of parameters. In general, the ordering of models under D_{w2} agrees with the ordering of D_∞ . Then the model for which D_∞ is the smallest can be chosen while doing model comparison.

We compute the expectation $\mathbb{E}(y_i^{\text{rep}} | \mathbf{y})$ and variance $\text{Var}(y_i^{\text{rep}} | \mathbf{y})$ using MCMC draws. Given an MCMC sample $\{\boldsymbol{\theta}^{(1)}, \boldsymbol{\theta}^{(2)}, \dots, \boldsymbol{\theta}^{(n)}\}$ from $p(\boldsymbol{\theta} | \mathbf{y})$, we simulate $\mathbf{y}^{\text{rep},(m)}$ from $l(\boldsymbol{\theta}^{(m)} | \mathbf{y})$ for each $m = 1, 2, \dots, n$. We compute the quantities as follows:

$$\begin{aligned} \widehat{\mathbb{E}}(y_i^{\text{rep}} | \mathbf{y}) &= \frac{1}{n} \sum_{m=1}^n y_i^{\text{rep},(m)} \\ \widehat{\text{Var}}(y_i^{\text{rep}} | \mathbf{y}) &= \frac{1}{n} \sum_{m=1}^n \left(y_i^{\text{rep},(m)} - \frac{1}{n} \sum_{m=1}^n y_i^{\text{rep},(m)} \right)^2. \end{aligned}$$

37.11.7 Bayes Factor

Let $\boldsymbol{\theta}_i$ denote the vector of parameters under a model \mathcal{M}_i , with prior density $p(\boldsymbol{\theta}_i | \mathcal{M}_i)$ such that $\int p(\boldsymbol{\theta}_i | \mathcal{M}_i) d\boldsymbol{\theta}_i = 1$. Let \mathbf{y} denote the observed data with probability density $l_i(\boldsymbol{\theta}_i | \mathbf{y})$ under \mathcal{M}_i . The posterior density of $\boldsymbol{\theta}_i$ can be expressed as

$$p(\boldsymbol{\theta}_i | \mathbf{y}, \mathcal{M}_i) = \frac{l_i(\boldsymbol{\theta}_i | \mathbf{y}) p(\boldsymbol{\theta}_i | \mathcal{M}_i)}{m(\mathbf{y} | \mathcal{M}_i)} \tag{37.79}$$

where $m(\mathbf{y} | \mathcal{M}_i)$ denotes the marginal likelihood of data \mathbf{y} under \mathcal{M}_i and is computed as

$$m(\mathbf{y} | \mathcal{M}_i) = \int l_i(\boldsymbol{\theta}_i | \mathbf{y}) \pi(\boldsymbol{\theta}_i | \mathcal{M}_i) d\boldsymbol{\theta}_i. \tag{37.80}$$

This marginal likelihood is also viewed as the predictive density of the data under \mathcal{M}_i before the data is actually observed, that is, the probability density of the observed data \mathbf{y} accounting for the prior uncertainty in $\boldsymbol{\theta}_i$ specified by \mathcal{M}_i . Thus the value of the marginal or predictive density has the ability in assessing the merit of the corresponding model. The Bayes factor [see, e.g. 47] of \mathcal{M}_i relative to another model \mathcal{M}_j is defined as the ratio of respective marginal densities

$$\text{BF}(\mathcal{M}_i, \mathcal{M}_j) = \frac{m(\mathbf{y} | \mathcal{M}_i)}{m(\mathbf{y} | \mathcal{M}_j)}. \quad (37.81)$$

Now suppose we want to test

$$\mathcal{M}_0 : \boldsymbol{\theta} \in \Theta_0 \text{ versus } \mathcal{M}_1 : \boldsymbol{\theta} \in \Theta_1. \quad (37.82)$$

Let $\Pr(\mathcal{M}_i)$ be the prior probability of \mathcal{M}_i and $\pi(\boldsymbol{\theta} | \mathcal{M}_i)$ be the prior density of $\boldsymbol{\theta}$ under \mathcal{M}_i such that $\int \pi(\boldsymbol{\theta} | \mathcal{M}_i) d\boldsymbol{\theta} =$

$1, i = 0, 1$. Then the posterior model probability $\Pr(\mathcal{M}_i | \mathbf{y})$ is calculated as

$$\Pr(\mathcal{M}_i | \mathbf{y}) = \frac{m(\mathbf{y} | \mathcal{M}_i) \Pr(\mathcal{M}_i)}{m(\mathbf{y})}, \quad i = 0, 1, \quad (37.83)$$

where $m(\mathbf{y}) = \Pr(\mathcal{M}_0) m(\mathbf{y} | \mathcal{M}_0) + \Pr(\mathcal{M}_1) m(\mathbf{y} | \mathcal{M}_1)$ and $m(\mathbf{y} | \mathcal{M}_0)$ can be calculated as showed in (37.80). For the test, we compute the posterior odds of \mathcal{M}_0 relative to \mathcal{M}_1

$$\begin{aligned} \frac{\Pr(\mathcal{M}_0 | \mathbf{y})}{\Pr(\mathcal{M}_1 | \mathbf{y})} &= \frac{m(\mathbf{y} | \mathcal{M}_0) \Pr(\mathcal{M}_0) / m(\mathbf{y})}{m(\mathbf{y} | \mathcal{M}_1) \Pr(\mathcal{M}_1) / m(\mathbf{y})} = \frac{\Pr(\mathcal{M}_0)}{\Pr(\mathcal{M}_1)} \cdot \frac{m(\mathbf{y} | \mathcal{M}_0)}{m(\mathbf{y} | \mathcal{M}_1)} \\ &= \frac{\Pr(\mathcal{M}_0)}{\Pr(\mathcal{M}_1)} \times \text{BF}(\mathcal{M}_0, \mathcal{M}_1). \end{aligned} \quad (37.84)$$

Consequently, (37.84) gives us

$$\begin{aligned} \text{BF}(\mathcal{M}_0, \mathcal{M}_1) &= \text{Posterior odds}(\mathcal{M}_0, \mathcal{M}_1) \\ &\div \text{Prior odds}(\mathcal{M}_0, \mathcal{M}_1). \end{aligned} \quad (37.85)$$

This shows the importance of Bayes factor in the context of Bayesian testing and model selection. It is to be noted that it does not depend on any prior model probability $\Pr(\mathcal{M}_0)$ or $\Pr(\mathcal{M}_1)$. Higher values of $\text{BF}(\mathcal{M}_0, \mathcal{M}_1)$ suggest stronger evidence in favour of \mathcal{M}_0 . Note that Bayes factor is well defined if the assigned prior distribution on the parameters is proper. However, it can be sensitive to the choice of the prior distribution. Thus it is important to conduct a sensitivity analysis by studying the range of the Bayes factor over a class of possible prior distributions [48].

The computation of marginal likelihood of data is of considerable interest in the Bayesian literature due to its importance in Bayesian model comparison [47]. Marginal likelihood of data is obtained by integrating the likelihood function with respect to the prior distribution, which is also the normalising constant of posterior distribution of the unknown parameter. There is a vast literature on estimating the normalising constant of a given density by Markov chain Monte Carlo (MCMC) methods; more details on this can be found in [49–52]. The existing approaches for computing the marginal likelihood often use MCMC draws, even though, as attractive as it sounds, it comes with its advantages and disadvantages [see the discussion in 53]. In spite of the substantial progress, estimation of marginal likelihoods for hierarchical models is still a difficult problem, especially in high dimensions and in the presence of latent variables.

Laplace Approximation

We start by assuming that the posterior density $p(\boldsymbol{\theta}_i | \mathbf{y}, \mathcal{M}_i)$ is unimodal and has mode at $\tilde{\boldsymbol{\theta}}$. The Laplace approximation of $m(\mathbf{y} | \mathcal{M}_i)$ [6, 54] is obtained as

$$\hat{m}(\mathbf{y} | \mathcal{M}_i) = (2\pi)^{p_i/2} |\tilde{\Sigma}_i|^{1/2} l_i(\tilde{\boldsymbol{\theta}}_i | \mathbf{y}) p(\tilde{\boldsymbol{\theta}}_i | \mathcal{M}_i), \quad (37.86)$$

where $\boldsymbol{\theta}_i$ has dimension p_i and $\tilde{\Sigma}_i = \{-\mathbf{D}^2 \log(l_i(\boldsymbol{\theta}_i | \mathbf{y}) p(\boldsymbol{\theta}_i | \mathcal{M}_i))\}$ denotes the inverse of the negative Hessian matrix. Using this approximation to the $\text{BF}(\mathcal{M}_i, \mathcal{M}_j)$ yields

$$\begin{aligned} \log \text{BF}(\mathcal{M}_i, \mathcal{M}_j) &= \hat{m}(\mathbf{y} | \mathcal{M}_i) - \hat{m}(\mathbf{y} | \mathcal{M}_j) \\ &= l_i(\tilde{\boldsymbol{\theta}}_i | \mathbf{y}) - l_j(\tilde{\boldsymbol{\theta}}_j | \mathbf{y}) + \log p(\tilde{\boldsymbol{\theta}}_i | \mathcal{M}_i) - \log p(\tilde{\boldsymbol{\theta}}_j | \mathcal{M}_j) \\ &\quad + \frac{1}{2}(p_i - p_j) \log(2\pi) + \frac{1}{2}(\log |\tilde{\Sigma}_i| - \log |\tilde{\Sigma}_j|). \end{aligned} \quad (37.87)$$

The above Laplace approximation of $m(\mathbf{y} | \mathcal{M}_i)$ satisfies $m(\mathbf{y} | \mathcal{M}_i) = \hat{m}(\mathbf{y} | \mathcal{M}_i)(1 + O(d^{-1}))$ where d denotes the sample size [54].

Monte Carlo Estimator

Given a sample $\{\boldsymbol{\theta}_i^{(1)}, \boldsymbol{\theta}_i^{(2)}, \dots, \boldsymbol{\theta}_i^{(n)}\}$ from the prior density $p(\boldsymbol{\theta}_i | \mathcal{M}_i)$, we can obtain Monte Carlo estimate of the marginal likelihood $m(\mathbf{y} | \mathcal{M}_i)$ as

$$\hat{m}(\mathbf{y} | \mathcal{M}_i) = \frac{1}{n} \sum_{j=1}^n l_i(\boldsymbol{\theta}_i^{(j)} | \mathcal{M}_i). \quad (37.88)$$

This estimate may be very inaccurate if the sample from the prior density fails to include the values of $\boldsymbol{\theta}$ for which the likelihood is high. Thus a very large sample may be required to improve the accuracy of the estimate.

Importance Sampling Estimator

For a proper density $g(\boldsymbol{\theta}_i | \mathcal{M}_i)$, the following identity holds

$$m(\mathbf{y} | \mathcal{M}_i) = \int l_i(\boldsymbol{\theta}_i | \mathbf{y}) w(\boldsymbol{\theta}_i | \mathcal{M}_i) g(\boldsymbol{\theta}_i | \mathcal{M}_i) d\boldsymbol{\theta}_i, \quad (37.89)$$

where $w(\boldsymbol{\theta}_i | \mathcal{M}_i) = p(\boldsymbol{\theta}_i | \mathcal{M}_i) / g(\boldsymbol{\theta}_i | \mathcal{M}_i)$. The importance density $g(\boldsymbol{\theta}_i | \mathcal{M}_i)$ should be chosen carefully as different

choices of importance density lead to different accuracies for the importance sampling estimator [55]. For the importance sampling estimator to have a smaller variance, the importance density should have thicker tail than the prior density.

Gelfand-Dey Estimator of Marginal Likelihood of Data

Observe that the following identity holds for any proper density $g(\boldsymbol{\theta}_i | \mathcal{M}_i)$,

$$m(\mathbf{y} | \mathcal{M}_i) = \left[\int \frac{g(\boldsymbol{\theta}_i | \mathcal{M}_i) p(\boldsymbol{\theta}_i | \mathbf{y}, \mathcal{M}_i)}{l_i(\boldsymbol{\theta}_i | \mathbf{y}) p(\boldsymbol{\theta}_i | \mathcal{M}_i)} d\boldsymbol{\theta}_i \right]^{-1}. \quad (37.90)$$

Based on this identity (37.90), [49] proposed an estimator for the marginal likelihood $m(\mathbf{y} | \mathcal{M}_i)$

$$\hat{m}_{\text{GD}}(\mathbf{y} | \mathcal{M}_i) = \left[\frac{1}{n} \sum_{j=1}^n \frac{g(\boldsymbol{\theta}_i^{(j)} | \mathcal{M}_i)}{l_i(\boldsymbol{\theta}_i^{(j)} | \mathbf{y}) p(\boldsymbol{\theta}_i^{(j)} | \mathcal{M}_i)} \right]^{-1}, \quad (37.91)$$

where $\{\boldsymbol{\theta}_i^{(1)}, \boldsymbol{\theta}_i^{(2)}, \dots, \boldsymbol{\theta}_i^{(n)}\}$ is a set of MCMC draws from the posterior $\pi(\boldsymbol{\theta}_i | \mathbf{y}, \mathcal{M}_i)$ under the model \mathcal{M}_i . $\hat{m}_{\text{GD}}(\mathbf{y} | \mathcal{M}_i)^{-1}$ is an unbiased and consistent estimator of $m(\mathbf{y} | \mathcal{M}_i)^{-1}$. Even though the estimator is defined for any proper density $g(\boldsymbol{\theta}_i | \mathcal{M}_i)$, shape of $g(\boldsymbol{\theta}_i | \mathcal{M}_i)$ should be similar with thinner tails to the posterior $p(\boldsymbol{\theta}_i | \mathbf{y}, \mathcal{M}_i)$ for Gelfand-Dey estimator to have a smaller variance (like importance sampling). It also satisfies a Gaussian central limit theorem if the tails of $g(\boldsymbol{\theta}_i | \mathcal{M}_i)$ are thin enough, specifically if

$$\int \frac{g(\boldsymbol{\theta}_i | \mathcal{M}_i)^2}{l_i(\boldsymbol{\theta}_i | \mathbf{y}) p(\boldsymbol{\theta}_i | \mathcal{M}_i)} d\boldsymbol{\theta}_i < \infty.$$

In practice, it may be hard to find a density $g(\boldsymbol{\theta}_i | \mathcal{M}_i)$ that has sufficiently thin tails in all direction of the parameter space simultaneously, especially when the posterior has nonelliptical contours. If $g(\boldsymbol{\theta}_i) / \{l_i(\boldsymbol{\theta}_i | \mathbf{y}) p(\boldsymbol{\theta}_i | \mathcal{M}_i)\}$ is bounded above, then the approximation shows less variation over different simulations and the rate of convergence is likely to be practical. In addition, if the posterior density is uniformly bounded away from 0 on every compact subset of the parameter space, then the function $g(\boldsymbol{\theta}_i | \mathcal{M}_i) / \{l_i(\boldsymbol{\theta}_i | \mathbf{y}) p(\boldsymbol{\theta}_i | \mathcal{M}_i)\}$ has posterior moments of all orders [see 56]. Note that choosing $g(\boldsymbol{\theta}_i | \mathcal{M}_i) = p(\boldsymbol{\theta}_i | \mathcal{M}_i)$ gives the harmonic mean estimator:

$$\hat{m}_{\text{HM}}(\mathbf{y} | \mathcal{M}_i) = \left[\frac{1}{n} \sum_{j=1}^n \frac{1}{l_i(\boldsymbol{\theta}_i^{(j)} | \mathbf{y})} \right]^{-1}. \quad (37.92)$$

The Gelfand-Dey estimator is occasionally termed as *reciprocal importance sampling estimator* because of its similarity with importance sampling. For more details please refer to [47, 49–51].

37.11.8 Bayesian Model Averaging

Given a set of models $\{\mathcal{M}_1, \mathcal{M}_2, \dots, \mathcal{M}_L\}$ with prior model probabilities $\{\text{Pr}(\mathcal{M}_1), \text{Pr}(\mathcal{M}_2), \dots, \text{Pr}(\mathcal{M}_L)\}$, the posterior model probability $\text{Pr}(\mathcal{M}_i | \mathbf{y})$ for model \mathcal{M}_i is calculated as

$$\text{Pr}(\mathcal{M}_i | \mathbf{y}) = \frac{m(\mathbf{y} | \mathcal{M}_i) \text{Pr}(\mathcal{M}_i)}{\sum_{k=1}^L m(\mathbf{y} | \mathcal{M}_k) \text{Pr}(\mathcal{M}_k)}, \quad i = 1, 2, \dots, L. \quad (37.93)$$

where $m(\mathbf{y} | \mathcal{M}_i)$ denotes the marginal likelihood of data \mathbf{y} under \mathcal{M}_i and can be calculated as showed in (37.80). Posterior model probabilities can also be expressed in terms of Bayes factor (defined in (37.81))

$$\text{Pr}(\mathcal{M}_i | \mathbf{y}) = \frac{\text{BF}(\mathcal{M}_i, \mathcal{M}_1) \text{Pr}(\mathcal{M}_i)}{\sum_{k=1}^L \text{BF}(\mathcal{M}_k, \mathcal{M}_1) \text{Pr}(\mathcal{M}_k)}, \quad i = 1, 2, \dots, L. \quad (37.94)$$

The posterior model probabilities can be used to select or compare models, and of course, the models with higher probabilities should be preferred.

Let θ be a quantity of interest, and its marginal posterior density function is expressed as

$$\pi(\theta | \mathbf{y}) = \sum_{k=1}^L \pi(\theta | \mathbf{y}, \mathcal{M}_k) \text{Pr}(\mathcal{M}_k | \mathbf{y}) \quad (37.95)$$

which is a weighted average over all the competing models with weights $\{\text{Pr}(\mathcal{M}_1 | \mathbf{y}), \text{Pr}(\mathcal{M}_2 | \mathbf{y}), \dots, \text{Pr}(\mathcal{M}_L | \mathbf{y})\}$. The posterior means and variances can also be obtained by this model averaging

$$\begin{aligned} \mathbb{E}(\theta | \mathbf{y}) &= \sum_{k=1}^L \hat{\theta}_k \text{Pr}(\mathcal{M}_k | \mathbf{y}) \\ \text{Var}(\theta | \mathbf{y}) &= \sum_{k=1}^L (\text{Var}(\theta | \mathbf{y}, \mathcal{M}_k) + \hat{\theta}_k^2) \\ &\quad \text{Pr}(\mathcal{M}_k | \mathbf{y}) - \mathbb{E}(\theta | \mathbf{y})^2 \end{aligned} \quad (37.96)$$

where $\hat{\theta}_k = \mathbb{E}(\theta | \mathbf{y}, \mathcal{M}_k)$ [57, 58]. For more details on Bayesian model averaging, interested reader can refer to [59, 60].

37.11.9 Bayesian Information Criterion (BIC)

Bayesian information criterion [BIC, 61] is defined as

$$\text{BIC} = -2 \log l(\hat{\boldsymbol{\theta}} | \mathbf{y}) + p \log d, \quad (37.97)$$

where d denotes the sample size and $\hat{\theta}$ denotes the estimate of posterior mean or posterior mode. We calculate BIC for each of the L competing models and choose the one with the minimum BIC value. Note that BIC gives larger correction for bias as sample size increases and thus tends to favour simpler models. BIC is essentially used as an approximation of the marginal likelihood of the data \mathbf{y} and is not an estimate of the predictive accuracy of the model. In this way, it is different than AIC and the other criteria that we will discuss below.

Given a set of models $\{\mathcal{M}_1, \mathcal{M}_2, \dots, \mathcal{M}_L\}$ and their respective BIC scores $\{\text{BIC}_1, \text{BIC}_2, \dots, \text{BIC}_L\}$, the posterior probability of model \mathcal{M}_i , $i = 1, 2, \dots, L$, can be approximated as [see 62]

$$\Pr(\mathcal{M}_i | \mathbf{y}) \approx \frac{\exp(-\text{BIC}_i/2)}{\sum_{k=1}^L \exp(-\text{BIC}_k/2)}. \quad (37.98)$$

In practice, first we calculate the differences $\Delta_i = \text{BIC}_i - \text{BIC}_{\min}$, where BIC_{\min} is the minimum BIC score among the L competing models. Then we calculate

$$\Pr(\mathcal{M}_i | \mathbf{y}) \approx \frac{\exp(-\Delta_i/2)}{\sum_{k=1}^L \exp(-\Delta_k/2)}. \quad (37.99)$$

Computing the posterior model probabilities in this way helps in avoiding underflow or overflow of large quantities while exponentiating the BIC scores.

37.12 Some Applications of Bayesian Methods in Different Fields of Research

Bayesian concepts have been applied to many areas like process control, reliability and survival analysis, time series, statistical ecology and the like. We will briefly discuss some of these applications in this section. Congdon [63] has prescribed various modelling techniques for different applications. In the case of non-linear and also non-parametric Bayesian models, [3] discuss in details the part V of the book.

37.12.1 Example from Statistical Ecology

Estimation of animal abundances over large regions by integrating multiple data sources is one of the key challenges in statistical ecology. Estimating animal population size is needed to be performed at large geographical scales that will actually be useful for management and conservation. However, reliable estimation of population size is highly resource intensive (e.g. capture-recapture survey) and only possible

at a smaller scale. Cost-effective and less resource-intensive surveys on animal signs are conducted at the larger scale, but these kind of surveys do not yield animal abundance estimate; instead it provides habitat occupancy probability. In an application, [64] have developed a Bayesian smoothing model by using a conditionally autoregressive prior to address the problem. Their approach is briefly described below. Assume that the region under study is divided into p sites and the number of individuals in i^{th} site, denoted by N_i , follows a Poisson distribution with parameter λ_i , $i = 1, 2, \dots, p$. They have modelled λ_i 's as

$$v_i = \log(\lambda_i) = \mathbf{x}'_i \boldsymbol{\beta} + \phi_i, \quad i = 1, 2, \dots, p, \quad (37.100)$$

where $\boldsymbol{\beta}$ is the regression coefficient, \mathbf{x}_i is the vector of covariates and ϕ_i incorporates the spatial association between sites. Here $\boldsymbol{\phi} = (\phi_1, \phi_2, \dots, \phi_p)'$ is given a conditionally autoregressive prior

$$\boldsymbol{\phi} \sim \mathcal{N}_p(\mathbf{0}, \delta^2(D_w - \rho W)^{-1}), \quad (37.101)$$

where $\delta^2 > 0$, $\rho \in (0, 1)$, $W = (w_{ij})$ denotes a $p \times p$ proximity matrix with w_{ij} taking the value 1 if sites i and j are neighbours and 0 otherwise. They set $w_{ii} = 0$ for all i and $D_w = \text{diag}(w_{10}, \dots, w_{p0})$. They use the reliable estimates of λ_i , viz. $\hat{\lambda}_i(ct)$, as responses that are available for the sites $i = 1, 2, \dots, k_1$, ($k_1 < k$) from camera trap data. Estimates of occupancy probabilities $\hat{\psi}_1, \hat{\psi}_2, \dots, \hat{\psi}_p$ are also available for all the sites from count data on animal signs. Now observing that occupancy probability and true latent abundance are related as $\psi_i = \Pr(N_i > 0) = 1 - \exp(-\lambda_i)$, they have transformed the occupancy probability estimates to obtain indicative estimates of abundance $\hat{\lambda}_i(os) = -\log(1 - \hat{\psi}_i)$, $i = 1, 2, \dots, p$. It is also noted that the exact relationship between estimates of occupancy probability ψ_i and estimates of true latent abundance λ_i is very complex in general, and hence estimates $\hat{\lambda}_i(os)$ cannot be perceived as reliable estimates of λ_i . They have used the following notations for further model development: $\hat{v}_i(ct) = \log(\hat{\lambda}_i(ct))$, \mathbf{X} denotes the data on all the covariates including $\hat{\lambda}_i(os)$, $R = \{1, 2, \dots, k_1\}$ denotes the set of sites with reliable data and $S = \{k_1 + 1, k_1 + 2, \dots, p\}$ denotes the set of remaining sites. Consequently, $\mathbf{v} = (\mathbf{v}^R, \mathbf{v}^S)'$, where $\mathbf{v}^R = (v_1, \dots, v_{k_1})'$, $\mathbf{v}^S = (v_{k_1+1}, \dots, v_p)'$, $\hat{\mathbf{v}}^R(ct) = \hat{\mathbf{v}}(ct)$ and $\hat{\boldsymbol{\lambda}}(os) = (\hat{\boldsymbol{\lambda}}^R(os), \hat{\boldsymbol{\lambda}}^S(os))'$, $\mathbf{X} = (\mathbf{X}^R \ \mathbf{X}^S)'$. It is assumed that

$$\hat{\mathbf{v}}(ct) | \mathbf{v}, \sigma^2 \sim \mathcal{N}_{k_1}(\mathbf{v}, \sigma^2 I_{k_1}). \quad (37.102)$$

The prior on \mathbf{v} is then derived from (37.100) and (37.101) as

$$\mathbf{v} | \boldsymbol{\beta}, \rho, \delta^2 \sim \mathcal{N}_p(\mathbf{X}\boldsymbol{\beta}, \delta^2(D_w - \rho W)^{-1}), \quad (37.103)$$

where $\boldsymbol{\beta}$, δ^2 and ρ are hyper-parameters. Then they obtain

$$\hat{\mathbf{v}}(ct) \mid \sigma^2, \boldsymbol{\beta}, \delta^2, \rho \sim \mathcal{N}_{k_1}(\mathbf{X}^T \boldsymbol{\beta}, \sigma^2 \mathbf{I}_{k_1} + \delta^2 \mathbf{Q}_1(\rho)), \quad (37.104)$$

where $\mathbf{Q}_1(\rho)$ is the top $k_1 \times k_1$ square block of $(D_w - \rho W)^{-1}$. In order to obtain the posterior density $\pi(\sigma^2, \boldsymbol{\beta}, \delta^2, \rho \mid \hat{\mathbf{v}}(ct))$, one needs to assign priors on the parameters $\sigma^2, \boldsymbol{\beta}, \delta^2, \rho$. Also note that

$$\begin{pmatrix} \hat{\mathbf{v}}(ct) \\ \mathbf{v}^T \\ \mathbf{v}^S \end{pmatrix} \mid \sigma^2, \boldsymbol{\beta}, \delta^2, \rho \sim \mathcal{N}_{p+k_1} \left(\begin{pmatrix} \mathbf{X}^T \boldsymbol{\beta} \\ \mathbf{X}^T \boldsymbol{\beta} \\ \mathbf{X}^S \boldsymbol{\beta} \end{pmatrix}, \begin{pmatrix} \sigma^2 \mathbf{I}_{k_1} + \delta^2 \mathbf{Q}_1(\rho) & \delta^2 \mathbf{Q}_1(\rho) & \delta^2 \mathbf{Q}_{12}(\rho) \\ \delta^2 \mathbf{Q}_1(\rho) & \delta^2 \mathbf{Q}_1(\rho) & \delta^2 \mathbf{Q}_{12}(\rho) \\ \delta^2 \mathbf{Q}_{21}(\rho) & \delta^2 \mathbf{Q}_{21}(\rho) & \delta^2 \mathbf{Q}_2(\rho) \end{pmatrix} \right), \quad (37.105)$$

where $\mathbf{Q}_1, \mathbf{Q}_2, \mathbf{Q}_{12}$ and $\mathbf{Q}_{21} = \mathbf{Q}'_{12}$ are as in $(D_w - \rho W)^{-1} = \begin{pmatrix} \mathbf{Q}_1(\rho) & \mathbf{Q}_{12}(\rho) \\ \mathbf{Q}_{21}(\rho) & \mathbf{Q}_2(\rho) \end{pmatrix}$. From (37.105), the full posterior of \mathbf{v}^S is obtained as follows:

$$\begin{aligned} \mathbf{v}^S \mid \hat{\mathbf{v}}(ct), \sigma^2, \boldsymbol{\beta}, \delta^2, \rho \sim \mathcal{N}_{p-k_1}(\mathbf{X}^S \boldsymbol{\beta} + \delta^2 \mathbf{Q}_{21}(\rho)(\sigma^2 \mathbf{I}_{k_1} + \delta^2 \mathbf{Q}_1(\rho))^{-1}(\hat{\mathbf{v}}(ct) - \mathbf{X}^T \boldsymbol{\beta}), \\ \delta^2 \mathbf{Q}_2(\rho) - \delta^4 \mathbf{Q}_{21}(\rho)(\sigma^2 \mathbf{I}_{k_1} + \delta^2 \mathbf{Q}_1(\rho))^{-1} \mathbf{Q}_{12}(\rho)). \end{aligned} \quad (37.106)$$

The fully hierarchical Bayes estimate of \mathbf{v}^S and its posterior covariance matrix can be obtained from (37.106). From (37.105),

$$\mathbf{v} \mid \hat{\mathbf{v}}(ct), \sigma^2, \boldsymbol{\beta}, \delta^2, \rho \sim \mathcal{N}_p(\boldsymbol{\mu}(\sigma^2, \boldsymbol{\beta}, \delta^2, \rho), P(\sigma^2, \boldsymbol{\beta}, \delta^2, \rho)), \quad (37.107)$$

where (suppressing the dependence on $\hat{\mathbf{v}}(ct)$)

$$\begin{aligned} \boldsymbol{\mu}(\sigma^2, \boldsymbol{\beta}, \delta^2, \rho) &= \mathbf{X} \boldsymbol{\beta} + \delta^2 (\mathbf{Q}_1(\rho), \mathbf{Q}_{12}(\rho))' (\sigma^2 \mathbf{I}_{k_1} + \delta^2 \mathbf{Q}_1(\rho))^{-1} (\hat{\mathbf{v}}(ct) - \mathbf{X}^T \boldsymbol{\beta}), \\ P(\sigma^2, \boldsymbol{\beta}, \delta^2, \rho) &= \delta^2 \begin{pmatrix} \mathbf{Q}_1(\rho) & \mathbf{Q}_{12}(\rho) \\ \mathbf{Q}_{21}(\rho) & \mathbf{Q}_2(\rho) \end{pmatrix} \\ &\quad - \delta^4 \begin{pmatrix} \mathbf{Q}_1(\rho) \\ \mathbf{Q}_{21}(\rho) \end{pmatrix} (\sigma^2 \mathbf{I}_{k_1} + \delta^2 \mathbf{Q}_1(\rho))^{-1} \begin{pmatrix} \mathbf{Q}_1(\rho) \\ \mathbf{Q}_{21}(\rho) \end{pmatrix}'. \end{aligned} \quad (37.108)$$

Proposition 1 *The hierarchical Bayes estimate of total abundance and its posterior variance are, respectively,*

$$\begin{aligned} \mathbb{E}(A(\boldsymbol{\lambda}) \mid \hat{\mathbf{v}}(ct)) &= \sum_{i=1}^p \mathbb{E}^*(e^{\mu_i + P_{ii}/2}), \text{ and} \\ \text{Var}(A(\boldsymbol{\lambda}) \mid \hat{\mathbf{v}}(ct)) &= \mathbb{E}^* \left(\sum_{i=1}^p e^{2\mu_i + P_{ii}} (e^{P_{ii}} - 1) \right) \\ &\quad + \mathbb{E}^* \left(\sum_{i \neq j} e^{\mu_i + \mu_j + (P_{ii} + P_{jj})/2} (e^{P_{ij}} - 1) \right) + \text{Var}^* \left(\sum_{i=1}^p e^{\mu_i + P_{ii}/2} \right), \end{aligned}$$

where \mathbb{E}^* (and Var^*) denotes expectation (and variance) with respect to the posterior distribution $\pi(\sigma^2, \boldsymbol{\beta}, \delta^2, \rho \mid \hat{\mathbf{v}}(ct))$.

The above result is then used to obtain the posterior estimate of the total abundance. They have also extended their work to perform model comparison by computing the Bayes factors and developed another Bayesian spatial model that alleviates the issue of spatial confounding (i.e. multicollinearity

between spatial covariates and the spatial random effect). They have applied their developed model on tiger population survey data from the Malenad landscape of southwestern India (viz. *Malenad Tiger Landscape (MTL)*). For brevity, we are not going into the results of the application. However, interested readers are suggested to see [64] for details.

37.12.2 Process Control

Statistical process control has been a very interesting topic since the days of Shewhart, the father of Statistical Quality Control. His famous idea of control charts could help organisations for decades to keep control over a process. Later

on, problems crept in the form of less data, for example, for ‘short run’ products. Some statisticians used Bayesian concepts to use some prior ideas about the process parameters. One may refer to [65] for a detailed discussion on various modelling approaches to process control using Bayesian concepts. However, modern-day problems are generally Big Data problems where Bayesian approach can give useful results [66]. Shiau et al. [67], Niverthi and Dey [68], Cheng and Spring [69] and many others have developed Bayesian approaches in measuring process capability of a given process.

37.12.3 Reliability

Several authors have used Bayesian methodology to reliability theory. Reliability domain can broadly be classified as hardware and software. Research on hardware reliability theory has been continuing over several decades, whereas software reliability concepts and models have its origin in 1972 [70]. Some of the latest applications of Bayesian methodology in software reliability aspects can be seen in [71] and [72]. The authors have optimised the time for software release using Bayesian concepts. Various other authors have found optimum release time of software using non-Bayesian methods.

In their latest article [72], the authors propounded a new direction to develop software reliability models. Reliability of software depends very much on the remaining number of bugs in the software. However, it has been observed that even if bugs are there in the software, but if the data does not go through the path where the bug exists, then the software does not create a problem in getting the right answer. This necessitates the development of the new concept of size of a bug, where the size here basically means the number of input data that may eventually traverse through the path where the bug exists. So, even if several bugs exist in the software, but all of them are in such paths which are rarely traversed by the data sets to be used by the users, the software is expected to show high reliability. This idea was modelled through the concept of size-biased sampling, originally developed in [73]. On the hardware reliability front, Bayesian methods have been used by several authors; see, for example, [74, 75], etc.

37.13 Discussion

Although Bayesian analysis provides a natural and comprehensive approach of combining prior information with data, within a solid decision theoretical framework, it has certain issues and criticisms which stem from the paradigm.

37.13.1 Pitfalls in the Choice of Prior

As we have seen above, there are many ways to construct a prior; there is no uniformly correct way to select it. As it requires skills to mathematically formulate subjective prior information, it may generate misleading results if not proceeded carefully. Scientists who are experts in their own field but not skilled enough with the practice of Bayesian analysis can construct a prior distribution which is inconsistent and imprecise [76]. Often posterior distributions are heavily influenced by the priors which makes the results misleading and raises questions on the selection of the prior. In the absence of sufficient amount of data, the choice of prior can lead to wrong conclusions in the case of limited prior information. It is to be noted that the majority of the concerns encountered during assessment of a Bayesian analysis arise from this issue regarding the choice of prior distributions. The construction of informative priors is productive and suggested in general. If possible, involvement of subject matter experts (i.e. biologists, industry, conservationist, etc.) should be ensured in the process of construction of the priors. This helps in correctly interpreting and defending the results.

37.13.2 Computationally Intensive

It becomes extremely computationally challenging to conduct a Bayesian analysis in complex models and in models with a large number of parameters. The computational challenges come in with both mathematical skills (requiring the knowledge of probability and algebra) and computational time (requiring a high performance computer with higher RAM, cores and processing power). The posterior distributions often do not have a proper and/or standard form necessitating simulation (such as Monte Carlo or MCMC, etc.). These simulations provide a little different answers if different random seeds are used, i.e. for a particular posterior distribution, simulation-based estimates can vary for different random number generator used in the analyses. For more comprehensive and thorough treatments on the advantages and disadvantages of Bayesian analysis, see [37, 77–82].

37.13.3 Bayesian Marginalisation Paradox

Now it is well-known to the Bayesian community that apparent inconsistency may arise in the Bayesian inference due to the use of improper priors. The marginalisation paradox is a particular type of such inconsistency which arises when there are different approaches to compute the same marginal posterior [83, 84], resulting in incompatible densities by using improper priors. This inconsistency does not arise by using proper priors.

If $p(\mathbf{x} | \boldsymbol{\theta})$ denotes the density function for a certain statistical model, $\pi(\boldsymbol{\theta})$ denotes the assumed improper prior and $\pi(\boldsymbol{\theta} | \mathbf{x})$ denotes the posterior distribution of the parameter $\boldsymbol{\theta}$ given the data \mathbf{x} , the posterior $\pi(\boldsymbol{\theta} | \mathbf{x})$ is computed by using the Bayes theorem. Now suppose that $\boldsymbol{\theta} = (\theta_1, \theta_2)$ and $\mathbf{x} = (x_1, x_2)$. We also assume that the marginal density $p(x_2 | \boldsymbol{\theta})$ depends on $\boldsymbol{\theta}$ only through θ_2 and that the marginal posterior $\pi(\theta_2 | \mathbf{x})$ depends on \mathbf{x} only through x_2 . Hence we should have the posterior of θ_2 given x_2 , $\pi(\theta_2 | x_2) = p(x_2 | \theta_2) \pi(\theta_2)$ when density function of x_2 is denoted by $p(x_2 | \theta_2)$ with some prior density $\pi(\theta_2)$. This marginal density does not satisfy the Bayes theorem, although it should have. One could integrate $\pi(\theta_1, \theta_2 | x_1, x_2) \propto p(x_1, x_2 | \theta_1, \theta_2) \pi(\theta_1, \theta_2)$ with respect to θ_1 to obtain the marginal posterior density $\pi(\theta_2 | x_2)$. As an alternative approach, one could first integrate $p(x_1, x_2 | \theta_1, \theta_2) \pi(\theta_1, \theta_2)$ with respect to x_1 to obtain $p(x_2 | \theta_2)$ and then obtain $p(x_2 | \theta_2) \pi(\theta_2)$. It turns out $\pi(\theta_2 | x_2)$ obtained by the former approach is not always proportional to $p(x_2 | \theta_2) \pi(\theta_2)$ that is obtained in the latter approach. There are numerous examples of such inconsistency that arise in ordinary problems, e.g. the change point problem and the problem of discrimination parameter for two populations [84]. This paradox is important as it shows certain inconsistency which raises concerns regarding the use of improper priors in objective Bayes. Recently, under some conditions, it has been shown that the marginalisation paradox can be resolved by considering the improper inferences as probability limits [85].

37.13.4 Bayesian Discrepant Posterior Phenomenon

The posterior distribution combines the information obtained from the prior and the likelihood to provide estimates of a parameter – hence it can be expected to give an improved estimate. For example, the posterior estimate of the mean parameter in a Gaussian conjugate model (with unknown mean and known variance) is a weighted average of the maximum likelihood estimate and the prior mean. Consequently the posterior estimate lies between the estimates based on the likelihood and the prior in this model. But in a model with multivariate parameters and an informative prior, we may get counterintuitive inference on the parameter of interest based on its marginal posterior density (which is obtained by marginalising the joint posterior density), i.e. it is possible to obtain a point estimate of the parameter of interest based on its marginal posterior density which can be regarded as extreme under the prior and the posterior. This is called the discrepant posterior phenomenon (DPP) [86, 87].

For example, in a binomial clinical trial conducted by Johnson & Johnson (J&J) Inc., both the prior density and the

likelihood of the improvement $\delta = p_1 - p_0$, where p_0 denotes the control success rate and p_1 denotes the treatment success rate, had its mean, median and mode around 0.1. However, it was found that the posterior of δ has its mean, median and mode around 0.2 from several competing Bayesian models [86, see Table 3]. In Fig. 4 of [86] and Fig. 2(b) of [87], it can also be seen that the marginal posterior density of δ peaks near the region that is less likely under the marginal prior and the marginal likelihood of δ . The readers are advised to refer to [88] who provides a comprehensive discussion of the DPP. They recommend (1) to have uncorrelated dimensions for the parameters in both the prior and likelihood; (2) to do re-parameterisation for prior-likelihood curvature alignment such that the prior and likelihood is not highly skewed and homogeneous variance across dimensions is desired; and (3) in case the different dimensions of the parameter are correlated in both the prior and the likelihood, it should be made sure that the correlation patterns are the same between the prior and the likelihood which could alleviate or prevent DPP. When informative prior is needed to be used, their discussion can serve as a precaution and guidance for the Bayesian practitioners for prior constructions to mitigate the effect of DPP.

37.13.5 Lack of Inference Results

Often the Bayesian practitioners encounter a situation where an approximation of intractable integrals is needed to obtain inferences. Variational Bayesian methods (VBM) provide suites of techniques for approximating such integrals. VBMs are primarily used to provide an analytical approximation to the posterior probability of the unobserved variables (i.e. the unknown parameters and the latent variables). VBM can be seen as a quicker alternative to MCMC methods providing locally optimal exact analytic solution to posterior approximation. However, the derivation of the set of equations that are used in the iterative updates of the parameters requires more intensive mathematical work [89, 90].

Variational Bayes can be seen as an extension of the EM (expectation-maximisation) algorithm based on dependent set of equations that cannot be solved analytically – both methods require finding a maximum a posteriori (MAP) estimate of each parameter and approximating the posterior density. But unlike EM algorithm, both types of unobserved variables (i.e. parameters and latent variables) are treated as the same, i.e. as random variables. Estimates for the variables can then be derived in the standard Bayesian ways, e.g. calculating the mean of the distribution to get a single point estimate or deriving a credible interval, highest density region, etc. [91].

Dr. Ashis Kumar Chakraborty is a B.stat and M.stat from Indian Statistical Institute (ISI) Kolkata and Ph.D from Indian Institute of Science, Bangalore. His research interest is in process control, reliability, particularly software reliability and the interface area of Statistics and Machine learning. He has published three books and another book is in press with Taylor & Francis. He also contributed chapters in many other books. He has published more than 70 articles in various national and international journals. He is an elected member of the council of Operations Research Society of India (ORSI). He also serves as associate editor of two journals.

Soumen Dey received his Ph.D in Statistics from Indian Statistical Institute in 2018. He worked as a visiting scientist in the Kolkata centre of the same institute in 2019. He works now in Norwegian University of Life sciences (NMBU) as a postdoctoral researcher, focusing on research problems in spatial modelling and Bayesian model checking.

Aleena Chanda completed her Bachelors degree in Statistics from St. Xavier's Kolkata in the year 2016 and her Masters degree in Statistics from the University of Calcutta in the year 2018. She worked as a Visiting Scholar in the Indian Statistical Institute in the SQC and OR Unit under the supervision of Dr. Ashis Kumar Chakraborty in the year 2018–2019. She is currently a PhD student in the University of Nebraska-Lincoln.

Poulami Chakraborty has done her Bachelor's in Statistics (2013–2016) as well as M.Sc (2016–2018) from University of Calcutta. She worked at the Indian Statistical Institute, Kolkata in the SQC and OR unit (2018–2019). She is currently pursuing her PhD in Statistics in the Ohio State University (2019-present).

introduction defines and provides a general background to data mining knowledge discovery in databases, following by an outline of the entire process in the second part. The third part presents data handling issues, including databases and preparation of the data for analysis. The fourth part, as the core of the chapter, describes popular data mining methods, separated as supervised versus unsupervised learning. Supervised learning methods are described in the context of both regression and classification, beginning with the simplest case of linear models, then presenting more complex modeling with trees, neural networks, and support vector machines, and concluding with some methods only for classification. Unsupervised learning methods are described under two categories: association rules and clustering. The fifth part presents past and current research projects, involving both industrial and business applications. Finally, the last part provides a brief discussion on remaining problems and future trends.

Abstract

In this chapter, we provide a review of the knowledge discovery process, including data handling, data mining methods and software, and current research activities. The

Data mining (DM) is the process of exploration and analysis, by automatic or semiautomatic means, of large quantities of data to discover meaningful patterns and rules [1]. Statistical DM is exploratory data analysis with little or no human interaction using computationally feasible techniques, i.e., the attempt to find *unknown interesting* structure [2]. Knowledge discovery in databases (KDD) is a multidisciplinary research field for nontrivial extraction of implicit, previously unknown, and potentially useful knowledge from data [3]. Although some treat DM and KDD equivalently, they can be distinguished as follows. The KDD process employs DM methods (algorithms) to extract knowledge according to the specifications of measures and thresholds, using a database

along with any necessary preprocessing or transformations. DM is a step in the KDD process consisting of particular algorithms (methods) that, under some acceptable objective, produce particular patterns or knowledge over the data. The two primary fields that develop DM methods are statistics and computer science. Statisticians support DM by mathematical theory and statistical methods while computer scientists develop computational algorithms and relevant software [4]. Prerequisites for DM include: (1) advanced computer technology (large CPU, parallel architecture, etc.) to allow fast access to large quantities of data and enable computationally intensive algorithms and statistical methods and (2) knowledge of the business or subject matter to formulate the important business questions and interpret the discovered knowledge.

With competition increasing, DM and KDD have become critical for companies to retain customers and ensure profitable growth. Although most companies are able to collect vast amounts of business data, they are often unable to leverage this data effectively to gain new knowledge and insights. DM is the process of applying sophisticated analytical and computational techniques to discover exploitable patterns in complex data. In many cases, the process of DM results in actionable knowledge and insights. Examples of DM applications include fraud detection, risk assessment, customer relationship management, cross-selling, insurance, banking, retail, etc.

While many of these applications involve customer relationship management in the service industry, a potentially fruitful area is performance improvement and cost reduction through DM in industrial and manufacturing systems. For example, in the fast-growing and highly competitive electronics industry, total revenue worldwide in 2003 was estimated to be \$900 billion, and the growth rate is estimated at 8% per year (www.selectron.com). However, economies of scale, purchasing power, and global competition are making the business such that one must either be a big player or serve a niche market. Today, extremely short life cycles and constantly declining prices are pressuring the electronics industry to manufacture their products with high quality, high yield, and low production cost.

To be successful, industry will require improvements at all phases of manufacturing. Figure 38.1 illustrates the three primary phases: design, ramp-up, and production. In the production phase, maintenance of a high-performance level via improved system diagnosis is needed. In the ramp-up phase, reduction in new product development time is sought by achieving the required performance as quickly as possible. Market demands have been forcing reduced development time for new product and production system design. For example, in the computer industry, a product's life cycle has been shortened to 2–3 years recently, compared to a life cycle of 3–5 years a few years ago. As a result, there are a number of new concepts in the area of production systems,

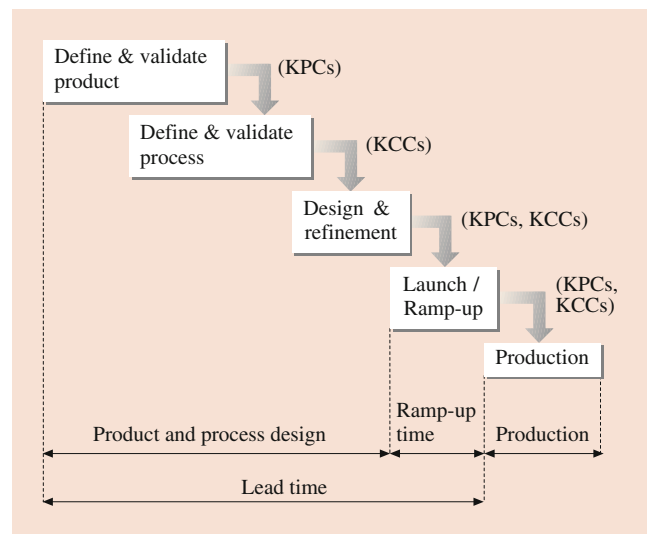

Fig. 38.1 Manufacturing system development phases. KPCs key product characteristics, KCCs key control characteristics

such as flexible and reconfigurable manufacturing systems. Thus, in the design phase, improved system performance integrated at both the ramp-up and production phases is desired. Some of the most critical factors and barriers in the competitive development of modern manufacturing systems lie in the largely uncharted area of predicting system performance during the design phase [5, 6]. Consequently, current systems necessitate that a large number of design/engineering changes be made after the system has been designed.

At all phases, system performance depends on many manufacturing process stages and hundreds or thousands of variables whose interactions are not well understood. For example, in the multistage printed circuit board (PCB) industry, the stages include process operations such as paste printing, chip placement, and wave soldering, and also include test operations such as optical inspection, vision inspection, and functional test. Due to advancements in information technology, sophisticated software and hardware technologies are available to record and process huge amounts of daily data in these process and testing stages. This makes it possible to extract important and useful information to improve process and product performance through DM and quality improvement technologies.

38.1 The KDD Process

The KDD process consists of four main steps:

1. Determination of business objectives
2. Data preparation
 - (a) Create target datasets
 - (b) Data quality, cleaning, and preprocessing
 - (c) Data reduction and projection

3. Data mining
 - (a) Identify DM tasks
 - (b) Apply DM tools
4. Consolidation and application
 - (a) Consolidate discovered knowledge
 - (b) Implement in business decisions

As an example of formulating business objectives, consider a telecommunications company. It is critically important to identify those customer traits that retain profitable customers and predict fraudulent behavior, credit risks, and customer churn. This knowledge may be used to improve programs in target marketing, marketing channel management, micromarketing, and cross-selling. Finally, continually updating this knowledge will enable the company to meet the challenges of new product development effectively in the future. Steps 2–4 are illustrated in Figs. 38.2, 38.3, and 38.4. Approximately 20–25% of effort is spent on determining business objectives, 50–60% of effort is spent on data preparation, 10–15% is spent on DM, and about 10% is spent on consolidation/application.

38.2 Handling Data

The largest percentage effort of the KDD process is spent on processing and preparing the data. In this section, common forms of data storage and tools for accessing the data are described, and the important issues in data preparation are discussed.

38.2.1 Databases and Data Warehousing

A *relational database* system contains one or more objects called tables. The data or information for the database are stored in these tables. Tables are uniquely identified by their names and are comprised of columns and rows. Columns contain the column name, data type, and any other attributes for the column. Rows contain the records or data for the columns. The structured query language (SQL) is the communication tool for relational database management systems. SQL statements are used to perform tasks such as updating data in a database, or retrieving data from a database. Some

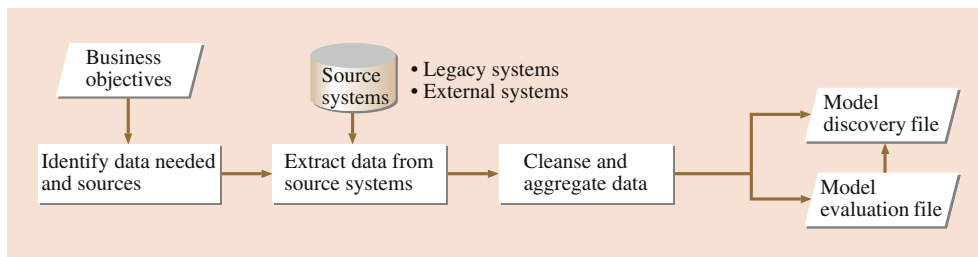

Fig. 38.2 Data preparation flow chart

Fig. 38.3 Data mining flow chart

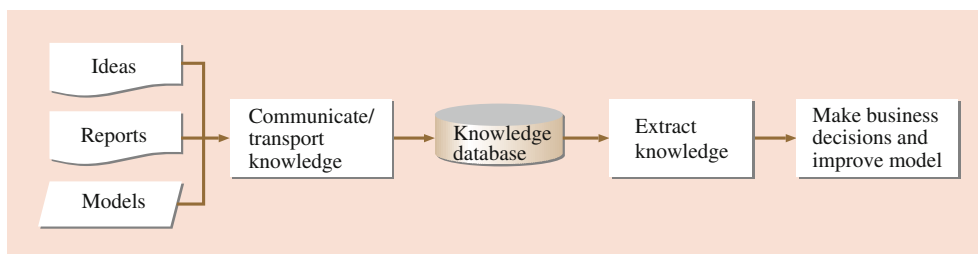

Fig. 38.4 Consolidation and application flow chart

common relational database management systems that use SQL are: Oracle, Sybase, Microsoft SQL Server, Access, and Ingres. Standard SQL commands, such as *select*, *insert*, *update*, *delete*, *create*, and *drop*, can be used to accomplish almost everything that one needs to do with a database.

A *data warehouse* holds local databases assembled in a central facility. A *data cube* is a multidimensional array of data, where each dimension is a set of sets representing domain content, such as time or geography. The dimensions are scaled categorically, for example, region of country, state, quarter of year, and week of quarter. The cells of the cube contain aggregated measures (usually counts) of variables. To explore the data cube, one can *drill down*, *drill up*, and *drill through*. Drill down involves splitting an aggregation into subsets, e.g., splitting region of country into states. Drill up involves consolidation, i.e., aggregating subsets along a dimension. Drill through involves subsets crossing multiple sets, e.g., the user might investigate statistics within a state subset by time. Other databases and tools include object-oriented databases, transactional databases, time series and spatial databases, online analytical processing (OLAP), multidimensional OLAP (MOLAP), and relational OLAP using extended SQL (ROLAP). See Chap. 2 of *Han and Kamber [7]* for more details.

38.2.2 Data Preparation

The purpose of this step in the KDD process is to identify data quality problems, sources of noise, data redundancy, missing data, and outliers. Data quality problems can involve inconsistency with external datasets, uneven quality (e.g., if a respondent fakes an answer), and biased opportunistically collected data. Possible sources of noise include faulty data collection instruments (e.g., sensors), transmission errors (e.g., intermittent errors from satellite or Internet transmissions), data entry errors, technology limitations errors, mis-used naming conventions (e.g., using the same names for different meanings), and incorrect classification.

Redundant data exists when the same variables have different names in different databases, when a raw variable in one database is a derived variable in another, and when changes in a variable over time are not reflected in the database. These irrelevant variables impede the speed of the KDD process because dimension reduction is needed to eliminate them. Missing data may be irrelevant if we can extract useful knowledge without imputing the missing data. In addition, most statistical methods for handling missing data may fail for massive datasets, so new or modified methods still need to be developed. In detecting outliers, sophisticated methods like the Fisher information matrix or convex hull peeling are available, but are too complex for massive datasets. Although outliers may be easy to visualize

in low dimensions, high-dimensional outliers may not show up in low-dimensional projections. Currently, clustering and other statistical modeling are used.

The data preparation process involves three steps: data cleaning, database sampling, and database reduction and transformation. Data cleaning includes removal of duplicate variables, imputation of missing values, identification and correction of data inconsistencies, identification and updating of stale data, and creating a unique record (case) identification (ID). Via database sampling, the KDD process selects appropriate parts of the databases to be examined. For this to work, the data must satisfy certain conditions (e.g., no systematic biases). The sampling process can be expensive if the data have been stored in a database system such that it is difficult to sample the data the way you want and many operations need to be executed to obtain the targeted data. One must balance a trade-off between the costs of the sampling process and the mining process. Finally, database reduction is used for data cube aggregation, dimension reduction, elimination of irrelevant and redundant attributes, data compression, and encoding mechanisms via quantizations, wavelet transformation, principle components, etc.

38.3 Data Mining (DM) Models and Algorithms

The DM process is illustrated in Fig. 38.5. In this process, one will start by choosing an appropriate class of models. To fit the best model, one needs to split the sample data

Fig. 38.5 Data mining process

into two parts: the training data and the testing data. The training data will be used to fit the model and the testing data is used to refine and tune the fitted model. After the final model is obtained, it is recommended to use an independent dataset to evaluate the goodness of the final model, such as comparing the prediction error to the accuracy requirement. (If independent data are not available, one can use the cross-validation method to compute prediction error.) If the accuracy requirement is not satisfied, then one must revisit earlier steps to reconsider other classes of models or collect additional data.

Before implementing any sophisticated DM methods, data description and visualization are used for initial exploration. Tools include descriptive statistical measures for central tendency/location, dispersion/spread, and distributional shape and symmetry; class characterizations and comparisons using analytical approaches, attribute relevance analysis, and class discrimination and comparisons; and data visualization using scatter-plot matrices, density plots, 3D stereoscopic scatter plots, and parallel coordinate plots. Following this initial step, DM methods take two forms: supervised versus unsupervised learning. Supervised learning is described as *learning with a teacher*, where the *teacher* provides data with correct answers. For example, if we want to classify online shoppers as buyers or nonbuyers using an available set of variables, our data would include actual instances of buyers and nonbuyers for training a DM method. Unsupervised learning is described as *learning without a teacher*. In this case, correct answers are not available, and DM methods would search for patterns or clusters of similarity that could later be linked to some explanation.

38.3.1 Supervised Learning

In supervised learning, we have a set of *input* variables (also known as predictors, independent variables, \mathbf{x}) that are measured or preset, and a set of *output* variables (also known as responses, dependent variables, \mathbf{y}) that are measured and assumed to be influenced by the inputs. If the outputs are continuous/quantitative, then we have a *regression* or *prediction* problem. If the outputs are categorical/qualitative, then we have a *classification* problem. First, a DM model/system is established based on the collected input and output data. Then, the established model is used to predict output values at new input values. The predicted values are denoted by $\hat{\mathbf{y}}$.

The DM perspective of *learning with a teacher* follows these steps:

- Student presents an answer (\hat{y}_i given \mathbf{x}_i)
- Teacher provides the correct answer y_i or an error e_i for the student's answer
- The result is characterized by some *loss function* or *lack-of-fit criterion*: LOF (y, \hat{y})
- The objective is to minimize the expected loss

Supervised learning includes the common engineering task of function approximation, in which we assume that the output is related to the input via some function $f(\mathbf{x}, \epsilon)$, where ϵ represents a random error, and seek to approximate $f(\cdot)$.

Below, we describe several supervised learning methods. All can be applied to both the regression and classification cases, except for those presented below under “Other Classification Methods.” We maintain the following notation. The j -th input variable is denoted by x_j (or random variable X_j) and the corresponding boldface \mathbf{x} (or \mathbf{X}) denotes the vector of p input variables $(x_1, x_2, \dots, x_p)^T$, where boldface x_i denotes the i -th sample point; N is the number of sample points, which corresponds to the number of observations of the response variable; the response variable is denoted by y (or random variable Y), where y_i denotes the i -th response observation. For the regression case, the response y is quantitative, while for the classification case, the response values are indices for C classes ($c = 1, \dots, C$). An excellent reference for these methods is *Hastie et al.* [8].

Linear and Additive Methods

In the regression case, the basic linear method is simply the *multiple linear* regression model form

$$\mu(\mathbf{x}; \beta) = E[Y | \mathbf{X} = \mathbf{x}] = \beta_0 + \sum_{m=1}^M \beta_m b_m(\mathbf{x}),$$

where the model terms $b_m(\mathbf{x})$ are prespecified functions of the input variables, for example, a simple linear term $b_m(\mathbf{x}) = x_j$ or a more complex interaction term $b_m(\mathbf{x}) = x_j x_k^2$. The key is that the model is *linear in the parameters* β . Textbooks that cover linear regression are abundant (e.g., [9, 10]). In particular, *Neter et al.* [11] provides a good background on residual analysis, model diagnostics, and model selection using best subsets and stepwise methods. In model selection, insignificant model terms are eliminated, thus the final model may be a subset of the original prespecified model. An alternate approach is to use a shrinkage method that employs a penalty function to *shrink* estimated model parameters toward zero, essentially reducing the influence of less important terms. Two options are ridge regression [12], which uses the penalty form $\sum \beta_m^2$, and the lasso [13], which uses the penalty form $\sum |\beta_m|$.

In the classification case, linear methods generate *linear decision boundaries* to separate the C classes. Although a direct linear regression approach could be applied, it is known not to work well. A better method is *logistic regression* [14], which uses log-odds (or logit transformations) of the posterior probabilities $\mu_c(\mathbf{x}) = P(Y = c | \mathbf{X} = \mathbf{x})$ for classes $c = 1, \dots, C - 1$ in the form

$$\begin{aligned}\log \frac{\mu_c(\mathbf{x})}{\mu_C(\mathbf{x})} &= \log \frac{P(Y = c | \mathbf{X} = \mathbf{x})}{P(Y = C | \mathbf{X} = \mathbf{x})} \\ &= \beta_{c0} + \sum_{j=1}^p \beta_{cj} x_j,\end{aligned}$$

$$\begin{aligned}\log \frac{\mu_c(\mathbf{x})}{\mu_C(\mathbf{x})} &= \log \frac{P(Y = c | \mathbf{X} = \mathbf{x})}{P(Y = C | \mathbf{X} = \mathbf{x})} \\ &= \beta_0 + \sum_{j=1}^p f_j(x_j),\end{aligned}$$

where the C posterior probabilities $\mu_c(\mathbf{x})$ must sum to one. The decision boundary between class $c < C$ and class C is defined by the hyperplane $\{\mathbf{x} | \beta_{c0} + \sum \beta_{cj} x_j = 0\}$, where the log-odds are zero. Similarly, the decision boundary between classes $c \neq C$ and $d \neq C$, derived from the log-odds for classes c and d , is defined by $\{\mathbf{x} | \beta_{c0} + \sum \beta_{cj} x_j = \beta_{d0} + \sum \beta_{dj} x_j\}$. In the binary case ($C = 2$), if we define $\mu(\mathbf{x}) = P(Y = 1 | \mathbf{X} = \mathbf{x})$, then $1 - \mu(\mathbf{x}) = P(Y = 2 | \mathbf{X} = \mathbf{x})$. The logit transformation is then defined as $g(\mu) = \mu/(1 - \mu)$.

Closely related to logistic regression is *linear discriminant analysis* [15], which utilizes exactly the same linear form for the log-odds ratio, and defines linear *discriminant functions* $\delta_c(\mathbf{x})$, such that \mathbf{x} is classified to class c if its maximum discriminant is $\delta_c(\mathbf{x})$. The difference between the two methods is how the parameters are estimated. Logistic regression maximizes the conditional likelihood involving the posterior probabilities $P(Y = c | \mathbf{X})$ while linear discriminant analysis maximizes the full log-likelihood involving the unconditional probabilities $P(Y = c, \mathbf{X})$. More general forms of discriminant analysis are discussed below under ‘‘Other Classification Methods.’’

Finally, it should be noted that the logistic regression model is one form of *generalized linear model* (GLM) [16]. GLM forms convert what appear to be nonlinear models into linear models, using tools such as transformations (e.g., logit) or conditioning on nonlinear parameters. This then enables the modeler to use traditional linear modeling analysis techniques. However, real data often do not satisfy the restrictive conditions of these models.

Rather than using prespecified model terms, as in a linear model, a *generalized additive model* (GAM) [17] provides a more flexible statistical method to enable modeling of nonlinear patterns in each input dimension. In the regression case, the basic GAM form is

$$\mu(\mathbf{x}) = \beta_0 + \sum_{j=1}^p f_j(x_j),$$

where the $f_j(\cdot)$ are unspecified (smooth) univariate functions, one for each input variable. The additive restriction prohibits inclusion of any interaction terms. Each function is fitted using a *nonparametric regression* modeling method, such as running-line smoothers (e.g., *lowess*, [18]), smoothing splines, or kernel smoothers [19–21]. In the classification case, an additive logistic regression model utilizes the logit transformation for classes $c = 1, \dots, C - 1$ as above

where an additive model is used in place of the linear model. However, even with the flexibility of nonparametric regression, GAM may still be too restrictive. The following sections describe methods that have essentially no assumptions on the underlying model form.

Trees and Related Methods

One DM decision tree model is *chi-square automatic interaction detection* (CHAID) [22, 23], which builds nonbinary trees using a chi-square test for the classification case and an F -test for the regression case. The CHAID algorithm first creates categorical input variables out of any continuous inputs by dividing them into several categories with approximately the same number of observations. Next, input variable categories that are not statistically different are combined, while a Bonferroni p -value is calculated for those that are statistically different. The best split is determined by the smallest p -value. CHAID continues to select splits until the smallest p -value is greater than a prespecified significance level (α).

The popular *classification and regression trees* (CART) [24] utilize recursive partitioning (binary splits), which evolved from the work of *Morgan and Sonquist* [25] and *Fielding* [26] on analyzing survey data. CARTs have a forward stepwise procedure that adds model terms and backward procedure for pruning. The model terms partition the \mathbf{x} -space into disjoint hyper-rectangular regions via indicator functions: $b^+(x; t) = 1\{x > t\}$, $b^-(x; t) = 1\{x \leq t\}$, where the *split-point* t defines the borders between regions. The resulting model terms are:

$$f_m(\mathbf{x}) = \prod_{l=1}^{L_m} b^{s_{l,m}}(x_{v(l,m)}; t_{l,m}), \quad (38.1)$$

where, L_m is the number of univariate indicator functions multiplied in the m -th model term, $x_{v(l,m)}$ is the input variable corresponding to the l -th indicator function in the m -th model term, $t_{l,m}$ is the split-point corresponding to $x_{v(l,m)}$, and $s_{l,m}$ is $+1$ or -1 to indicate the direction of the partition. The CART model form is then

$$f(\mathbf{x}; \beta) = \beta_0 + \sum_{m=1}^M \beta_m f_m(\mathbf{x}). \quad (38.2)$$

The partitioning of the \mathbf{x} -space does not keep the parent model terms because they are redundant. For example, suppose the current set has the model term:

$$f_a(\mathbf{x}) = 1\{x_3 > 7\} \cdot 1\{x_4 \leq 10\},$$

and the forward stepwise algorithm chooses to add

$$\begin{aligned} f_b(\mathbf{x}) &= f_a(\mathbf{x}) \cdot 1\{x_5 > 13\} \\ &= 1\{x_3 > 7\} \cdot 1\{x_4 \leq 10\} \cdot 1\{x_5 > 13\}. \end{aligned}$$

Then the model term $f_a(\mathbf{x})$ is dropped from the current set. Thus, the recursive partitioning algorithm follows a binary tree with the current set of model terms $f_m(\mathbf{x})$ consisting of the M leaves of the tree, each of which corresponds to a different region R_m .

In the regression case, CART minimizes the squared error loss function,

$$\text{LOF}(\hat{f}) = \sum_{i=1}^N [y_i - \hat{f}(\mathbf{x}_i)]^2,$$

and the approximation is a piecewise constant function. In the classification case, each region R_m is classified into one of the C classes. Specifically, define the proportion of class c observations in region R_m as

$$\hat{\delta}_{mc} = \frac{1}{N_m} \sum_{\mathbf{x}_i \in R_m} 1\{y_i = c\},$$

where N_m is the number of observations in the region R_m . Then the observations in region R_m are classified into the class c corresponding to the maximum proportion $\hat{\delta}_{mc}$. The algorithm is exactly the same as for regression, but with a different loss function. Appropriate choices include minimizing the misclassification error (i.e., the number of misclassified observations), the Gini index, $\sum_{c=1}^C \hat{\delta}_{mc} (1 - \hat{\delta}_{mc})$, or the deviance $\sum_{c=1}^C \hat{\delta}_{mc} \log(\hat{\delta}_{mc})$.

The exhaustive search algorithms for CART simultaneously conduct variable selection (x) and split-point selection (t). To reduce computational effort, the *fast algorithm for classification trees* [27] separates the two tasks. At each existing model term (leaf of the tree), F -statistics are calculated for variable selection. Then linear discriminant analysis is used to identify the split-point. A version for logistic and Poisson regression was presented by Chaudhuri et al. [28].

The primary drawback of CART and FACT is a bias toward selecting higher-order interaction terms due to the property of keeping only the leaves of the tree. As a consequence, these tree methods do not provide robust approximations and can have poor prediction accuracy. Loh and Shih [29] address this issue for FACT with a variant of their classification algorithm called QUEST that clusters classes into superclasses before applying linear discriminant analysis. For CART, Friedman et al. [30] introduced to the statistics literature the concepts of *boosting* [31] and *bagging* [32]

from the machine learning literature. The bagging approach generates many bootstrap samples, fits a tree to each, and then uses their average prediction. In the framework of boosting, a model term, called a *base learner*, is a *small tree* with only L disjoint regions (L is selected by the user), call it $B(\mathbf{x}, \mathbf{a})$, where \mathbf{a} is the vector of tree coefficients. The boosting algorithm begins by fitting a small tree $B(\mathbf{x}, \mathbf{a})$ to the data, and the first approximation, $\hat{f}_1(\mathbf{x})$, is then this first small tree. In the m -th iteration, residuals are calculated, then a small tree $B(\mathbf{x}, \mathbf{a})$ is fitted to the residuals and combined with the latest approximation to create the m -th approximation:

$$\begin{aligned} \hat{f}_m(\mathbf{x}; \beta_0, \beta_1, \dots, \beta_m) &= \hat{f}_{m-1}(\mathbf{x}; \beta_0, \beta_1, \\ &\dots, \beta_{m-1}) + \beta_m B(\mathbf{x}, \mathbf{a}), \end{aligned}$$

where a line search is used to solve for β_m . The resulting boosted tree, called a *multiple additive regression tree* (MART) [33], then consists of much lower-order interaction terms. Friedman [34] presents *stochastic gradient boosting*, with a variety of loss functions, in which a bootstrap-like bagging procedure is included in the boosting algorithm.

Finally, for the regression case only, *multivariate adaptive regression splines* (MARS) [35] evolved from CART as an alternative to its piecewise constant approximation. Like CART, MARS utilizes a forward stepwise algorithm to select model terms followed by a backward procedure to prune the model. A univariate version (appropriate for additive relationships) was presented by Friedman and Silverman [36]. The MARS approximation bends to model curvature at *knot* locations, and one of the objectives of the forward stepwise algorithm is to select appropriate knots. An important difference from CART is that MARS maintains the parent model terms, which are no longer redundant but are simply lower-order terms.

MARS model terms have the same form as (38.1), except the indicator functions are replaced with truncated linear functions,

$$[b^+(x; t) = [+(x - t)]_+, b^-(x; t) = [- (x - t)]_+,$$

where $[q]_+ = \max(0, q)$ and t is a univariate knot. The search for new model terms can be restricted to interactions of a maximum order (e.g., $L_m \leq 2$ permits up through two-factor interactions). The resulting MARS approximation, following (38.2), is a continuous, piecewise linear function. After selection of the model terms is completed, smoothness to achieve a certain degree of continuity may be applied.

Hastie et al. [8] demonstrate significant improvements in accuracy using MART over CART. For the regression case, comparisons between MART and MARS yield comparable results [34]. Thus, the primary decision between these two

methods is whether a piecewise constant approximation is satisfactory or if a continuous, smooth approximation would be preferred.

Artificial Neural Networks and Convolutional Neural Networks

Artificial neural network (ANN) models have been very popular for modeling a variety of physical relationships (for a general introduction see *Lippmann* [37] or *Haykin* [38]; for statistical perspectives see *White* [39], *Baron et al.* [40], *Ripley* [23], or *Cheng and Titterton* [41]). The original motivation for ANNs comes from how *learning* strengthens connections along neurons in the brain. Commonly, an ANN model is represented by a diagram of nodes in various layers with weighted connections between nodes in different layers (Fig. 38.6). At the input layer, the nodes are the input variables and at the output layer, the nodes are the response variable(s). In between, there is usually at least one *hidden* layer which induces flexibility into the modeling. *Activation functions* define transformations between layers (e.g., input to hidden). Connections between nodes can *feed back* to previous layers, but for supervised learning the typical ANN is *feedforward* only with at least one hidden layer.

The general form of a feedforward ANN with one hidden layer and activation functions $b_1(\cdot)$ (input to hidden) and $b_2(\cdot)$ (hidden to output) is

$$f_c(\mathbf{x}; \mathbf{w}, \mathbf{v}, \boldsymbol{\theta}, \gamma_c) = b_2 \left[\sum_{h=1}^H w_{hc} \cdot b_1 \left(\sum_{j=1}^p v_{jh} x_j + \theta_h \right) + \gamma_c \right], \quad (38.3)$$

where $c = 1, \dots, C$ and C is the number of output variables, p is the number of input variables, H is the number of hidden nodes, the weights v_{jh} link input nodes j to hidden

Fig. 38.6 Diagram of a typical artificial neural network for function approximation. The input nodes correspond to the input variables, and the output node(s) correspond to the output variable(s). The number of hidden nodes in the hidden layer must be specified by the user

nodes h and w_{hc} link hidden nodes h to output nodes c , and θ_h and γ_c are constant terms called bias nodes (like intercept terms). The number of coefficients to be estimated is $(p + 1)H + (H + 1)C$, which is often larger than N . The simplest activation function is a linear function $b(z) = z$, which reduces the ANN model in (38.3) with one response variable to a multiple linear regression equation. For more flexibility, the recommended activation functions between the input and hidden layer(s) are the S-shaped *sigmoidal* functions or the bell-shaped *radial basis functions*. Commonly used sigmoidal functions are the logistic function

$$b(z) = \frac{1}{1 + e^{-z}}$$

and the hyperbolic tangent

$$b(z) = \tanh(z) = \frac{1 - e^{-2z}}{1 + e^{-2z}}.$$

The most common radial basis function is the Gaussian probability density function.

In the regression case, each node in the output layer represents a quantitative response variable. The output activation function may be either a linear, sigmoidal, or radial basis function. Using a logistic activation function from input to hidden and from hidden to output, the ANN model in (38.3) becomes

$$f_c(\mathbf{x}; \mathbf{w}, \mathbf{v}, \boldsymbol{\theta}, \gamma_c) = \left[1 + \exp \left(- \sum_{h=1}^H w_{hc} z_h + \gamma_c \right) \right]^{-1},$$

where for each hidden node h

$$z_h = \left[1 + \exp \left(- \sum_{j=1}^p v_{jh} x_j + \theta_h \right) \right]^{-1}.$$

In the classification case with C classes, each class is represented by a different node in the output layer. The recommended output activation function is the *softmax* function. For output node c , this is defined as

$$b(z_1, \dots, z_C; c) = \frac{e^{z_c}}{\sum_{d=1}^C e^{z_d}}.$$

This produces output values between zero and one that sum to one and, consequently, permits the output values to be interpreted as posterior probabilities for a categorical response variable.

Mathematically, an ANN model is a nonlinear statistical model, and a nonlinear method must be used to estimate the

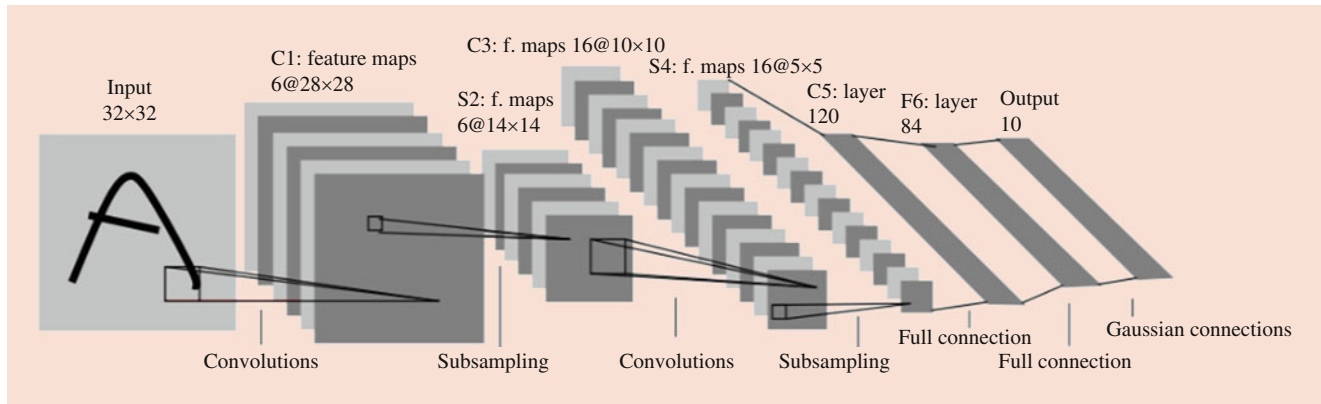

Fig. 38.7 Diagram of a typical convolutional neural network

coefficients (weights v_{jh} and w_{hc} , biases θ_h and γ_c) of the model. This estimation process is called network training. Typically, the objective is to minimize the squared error lack-of-fit criterion

$$\text{LOF}(\hat{f}) = \sum_{c=1}^C \sum_{i=1}^N [y_i - \hat{f}_c(\mathbf{x}_i)]^2.$$

The most common method for training is *backpropagation*, which is based on gradient descent. At each iteration, each coefficient (say w) is adjusted according to its contribution to the lack-of-fit

$$\Delta w = \alpha \frac{\partial (\text{LOF})}{\partial w},$$

where the user-specified α controls the step size; see *Rumelhart et al.* [42] for more details. More efficient training procedures are a subject of current ANN research.

Another major issue is the network *architecture*, defined by the number of hidden nodes. If too many hidden nodes are permitted, the ANN model will overfit the data. Many model discrimination methods have been tested, but the most reliable is validation of the model on a testing dataset separate from the training dataset. Several ANN architectures are fitted to the training dataset and then prediction error is measured on the testing dataset. Although ANNs are generally flexible enough to model anything, they are computationally intensive, and a significant quantity of representative data is required to both fit and validate the model. From a statistical perspective, the primary drawback is the overly large set of coefficients, none of which provide any intuitive understanding for the underlying model structure. In addition, since the nonlinear model form is not motivated by the true model structure, too few training data points can result in ANN approximations with extraneous nonlinearity. However, given enough good data, ANNs can outperform other modeling methods.

Convolutional neural network (CNN) [43] is a feedforward ANN network effective for pattern recognition and feature extraction of image data. The CNN combines three architectural ideas: local receptive fields, shared weights, and spatial subsampling. As in Fig. 38.7, a typical CNN for character recognition usually consists of an input layer, a convolutional layer, a pooling layer, a fully connected layer, and an output layer. Before feeding into the input plane, images of characters are size normalized and centered. In the convolutional layer, each neuron receives inputs from a set of neurons located in a small neighborhood in the previous layer. By using the same convolutional filter, the neurons share the filter weights and the number of free parameters in the convolutional layer is greatly reduced. With local receptive fields, neurons can extract elementary visual features such as corners, end points, and oriented edges. These basic features are then combined in higher layers to form useful information. Each convolutional layer is followed by an additional pooling layer which performs a local averaging and a subsampling, reducing the resolution of the feature map, as well as the sensitivity of the outputs to shifts and distortions. The CNN extracts the topological and spatial features hidden inside the image data through layer-by-layer convolution and pooling operations. These features are finally fed into the fully connected layer for classification or regression.

Support Vector Machines

Referring to the linear methods for classification described earlier, the decision boundary between two classes is a hyperplane of the form $\{\mathbf{x} | \beta_0 + \sum \beta_j x_j = 0\}$. The *support vectors* are the points that are most critical to determining the optimal decision boundary because they lie close to the points belonging to the other class. With *support vector machines* (SVM) [44], the linear decision boundary is generalized to the more flexible form

$$f(\mathbf{x}; \boldsymbol{\beta}) = \beta_0 + \sum_{m=1}^M \beta_m g_m(\mathbf{x}), \quad (38.4)$$

where the $g_m(\mathbf{x})$ are transformations of the input vector. The decision boundary is then defined by $\{\mathbf{x} | f(\mathbf{x}; \boldsymbol{\beta}) = 0\}$. To solve for the optimal decision boundary, it turns out that we do not need to specify the transformations $g_m(\mathbf{x})$, but instead require only the *kernel function* [21, 45]:

$$K(\mathbf{x}, \mathbf{x}') = \langle [g_1(\mathbf{x}), \dots, g_M(\mathbf{x})], [g_1(\mathbf{x}'), \dots, g_M(\mathbf{x}')] \rangle.$$

Two popular kernel functions for SVM are polynomials of degree d , $K(\mathbf{x}, \mathbf{x}') = (1 + \langle \mathbf{x}, \mathbf{x}' \rangle)^d$, and radial basis functions, $K(\mathbf{x}, \mathbf{x}') = \exp(-\|\mathbf{x} - \mathbf{x}'\|^2/c)$.

Given $K(\mathbf{x}, \mathbf{x}')$, we maximize the following Lagrangian dual-objective function:

$$\begin{aligned} \max_{\alpha_1, \dots, \alpha_N} \quad & \sum_{i=1}^N \alpha_i - \frac{1}{2} \sum_{i=1}^N \sum_{i'=1}^N \alpha_i \alpha_{i'} y_i y_{i'} K(\mathbf{x}_i, \mathbf{x}_{i'}) \\ \text{s.t.} \quad & 0 \leq \alpha_i \leq \gamma, \text{ for } i = 1, \dots, N \text{ and} \\ & \sum_{i=1}^N \alpha_i y_i = 0, \end{aligned}$$

where γ is an SVM tuning parameter. The optimal solution allows us to rewrite $f(\mathbf{x}; \boldsymbol{\beta})$ as

$$f(\mathbf{x}; \boldsymbol{\beta}) = \beta_0 + \sum_{i=1}^N \alpha_i y_i K(\mathbf{x}, \mathbf{x}_i),$$

where β_0 and $\alpha_1, \dots, \alpha_N$ are determined by solving $f(\mathbf{x}; \boldsymbol{\beta}) = 0$. The support vectors are those \mathbf{x}_i corresponding to nonzero α_i . A smaller SVM tuning parameter γ leads to more support vectors and a smoother decision boundary. A testing dataset may be used to determine the best value for γ .

The SVM extension to more than two classes solves multiple two-class problems. SVM for regression utilizes the model form in (38.4) and requires specification of a loss function appropriate for a quantitative response [8, 46]. Two possibilities are the ϵ -insensitive function

$$V_\epsilon(e) = \begin{cases} 0 & \text{if } |e| < \epsilon, \\ |e| - \epsilon & \text{otherwise,} \end{cases}$$

which ignores errors smaller than ϵ , and the *Huber* [47] function

$$V_H(e) = \begin{cases} e^2/2 & \text{if } |e| \leq 1.345, \\ 1.345|e| - e^2/2 & \text{otherwise,} \end{cases}$$

which is used in robust regression to reduce model sensitivity to outliers.

Other Classification Methods

In this section, we briefly discuss some other concepts that are applicable to DM classification problems. The basic

intuition behind a good classification method is derived from the *Bayes classifier*, which utilizes the posterior distribution $P(Y = c | \mathbf{X} = \mathbf{x})$. Specifically, if $P(Y = c | \mathbf{X} = \mathbf{x})$ is the maximum over $c = 1, \dots, C$, then \mathbf{x} would be classified to class c .

Nearest neighbor (NN) [48] classifiers seek to estimate the Bayes classifier directly without specification of any model form. The k -NN classifier identifies the k closest points to \mathbf{x} (using Euclidean distance) as the *neighborhood* about \mathbf{x} , then estimates $P(Y = c | \mathbf{X} = \mathbf{x})$ with the fraction of these k points that are of class c . As k increases, the decision boundaries become smoother; however, the *neighborhood* becomes less local (and less relevant) to \mathbf{x} . This problem of local representation is even worse in high dimensions, and modifications to the distance measure are needed to create a practical k -NN method for DM. For this purpose, *Hastie* and *Tibshirani* [49] proposed the discriminant adaptive NN distance measure to reshape the neighborhood adaptively at a given \mathbf{x} to capture the critical points to distinguish between the classes.

As mentioned earlier, linear discriminant analysis may be too restrictive in practice. *Flexible discriminant analysis* replaces the linear decision boundaries with more flexible regression models, such as GAM or MARS. *Mixture discriminant analysis* relaxes the assumption that classes are more or less spherical in shape by allowing a class to be represented by multiple (spherical) clusters; see *Hastie* et al. [50] and *Ripley* [23] for more details.

K-means clustering classification applies the K -means clustering algorithm separately to the data for each of the C classes. Each class c will then be represented by K clusters of points. Consequently, nonspherical classes may be modeled. For a new input vector \mathbf{x} , determine the closest cluster, then assign \mathbf{x} to the class associated with that cluster.

Genetic algorithms [51, 52] use processes such as genetic combination, mutation, and natural selection in an optimization based on the concepts of natural evolution. One generation of models competes to pass on characteristics to the next generation of models, until the best model is found. Genetic algorithms are useful in guiding DM algorithms, such as neural networks and decision trees [53].

38.3.2 Unsupervised Learning

Unsupervised learning, often called “learning without a teacher,” has been widely used for exploratory analysis to identify hidden patterns or groups in data. Unlike supervised learning, it draws inferences from data *without* predefined label information (i.e., response variables are not available). Given a set of observations of a random variable X , the goal of unsupervised learning is to directly infer properties of the probability density $P(X)$ without the label information.

It may be noted that labeled samples are sometimes significantly more expensive to collect (e.g., by asking human experts to make judgments) than unlabeled samples. Therefore, unsupervised learning has gained increasing interest in a variety of applications when labels are difficult to obtain, including biology, medicine, social science, business marketing, etc. In this subsection, we introduce two commonly used unsupervised learning techniques: association rules and cluster analysis.

Association Rules

Association rule analysis [8] seeks to discover co-occurrence between items in a collection and expresses such relationships as *association rules*. It is most often applied as *market basket analysis*, which deals with sales transactions to link specific products for the analysis of purchasing behaviors of customers. For example, the following rule:

$$\{\text{Diapers}\} \rightarrow \{\text{Beer}\}$$

suggests co-occurrence exists between the sale of diapers and beer. In other words, customers tend to purchase diapers and beer together. Such information is helpful for retailers to increase profit by optimizing their cross-promotion strategies, catalog design, stocking shelves, and customer relationship management.

In association analysis, a collection of one or more items is termed an *itemset*. If an itemset contains k items, it is called a k -itemset. For example, {Diapers, Beer, Eggs} is a 3-itemset. An important property of an itemset is its *support count* σ , which is defined as the number of transactions that contain this itemset. In the dataset below, the support count for {Diapers, Beer, Eggs} is two because only transactions #3 and #4 contain these three items.

TID	Items
#1	{Bread, Diapers}
#2	{Bread, Diapers, Milk, Eggs}
#3	{Diapers, Beer, Eggs}
#4	{Milk, Eggs, Beer, Diapers}
#5	{Bread, Milk, Diapers, Beer}

An *association rule* is expressed as $A \rightarrow B$, where A is called the *antecedent* and B is called the *consequent*. Given an itemset, association rule can be generated by assigning one or more items as the *antecedent* and one or more items as the *consequent*. Notably, A and B are disjoint sets, i.e., $A \cap B = \emptyset$. The importance of an association rule can be measured in terms of its *support* and *confidence*. *Support* (s) determines how frequently a rule appears among all transactions and it is defined as the support count of the rule over the total number of transactions N :

$$s(A \rightarrow B) = \frac{\sigma(A \cup B)}{N}$$

For example, support of rule {Diapers} \rightarrow {Beer} is 3/5 and support of rule {Diapers, Eggs} \rightarrow {Beer} is 2/5. Notably, a low support indicates the rule is uninteresting and customers seldom buy these items together. Minimum support (*minsup*) can be defined to eliminate uninteresting rules with $s < \text{minsup}$.

Confidence (c), on the other hand, represents how frequently items in B appear in transactions that contain A . It is defined as:

$$c(A \rightarrow B) = \frac{\sigma(A \cup B)}{\sigma(A)}$$

For example, the confidence of rule {Diapers} \rightarrow {Beer} is 3/5, and the confidence of rule {Diapers, Eggs} \rightarrow {Beer} is 2/3. A high confidence suggests it is likely for B to be present in transactions that contain A . In other words, customers tend to buy these items together and it is profitable to promote them together.

Furthermore, *lift* can be calculated as the ratio of the confidence over the expected confidence,

$$L(A \rightarrow B) = \frac{c(A \rightarrow B)}{\sigma(B)/N}$$

which, if greater than one, can be interpreted as the increased prevalence of B when associated with A . For example, if $\sigma(B)/N = 5\%$, then B is estimated to occur unconditionally 5% of the time. If $c(A \rightarrow B) = 40\%$, then given A occurs, B is estimated to occur 40% of the time. This results in a lift of 8, implying that B is 8 times more likely to occur if A occurs.

Cluster Analysis

Cluster analysis, or clustering, seeks to segment a set of objects into clusters, such that objects within a cluster are more similar to each other than those assigned to different clusters [54]. It is an unsupervised learning method since no predefined label information is needed. The goal of cluster analysis is to discover the underlying structure of the data to obtain insight into the data distribution, arrange objects into a natural hierarchy, or serve as a preprocessing step for other algorithms. Notably, defining the similarity measure among objects is critical for cluster analysis. Each object i can be represented as a set of measurements, x_{ip} ($p = 1, 2, \dots, P$), where P is the number of variables (also called attributes). Then, the pairwise distance between objects i and j is defined as $d(\mathbf{x}_i, \mathbf{x}_j) = \sum_{p=1}^P d_p(x_{ip}, x_{jp})$, and $d_p(x_{ip}, x_{jp})$ is the dissimilarity between the values of the p th variable. For quantitative variables, the common choice for $d_p(x_{ip}, x_{jp})$ is the squared distance, i.e., $d_p(x_{ip}, x_{jp}) = (x_{ip} - x_{jp})^2$. For nonquantitative variables (e.g., ordinal or categorical variables), numerical

coding approaches [55] or Hamming distance [56] can be used. Below, we introduce some widely used algorithms for cluster analysis.

K-means [57] is one of the most popular clustering tools. It aims to partition the N objects into K clusters $C = \{C_1, C_2, \dots, C_K\}$, so that the within-cluster distance is minimized as follows:

$$\operatorname{argmin}_C \sum_{k=1}^K \sum_{i \in C_k} \|x_i - \mu_k\|^2$$

where μ_k is the mean of objects in cluster C_k . The objective function is minimized using an iterative refinement approach: In the *assignment step*, the distance between each object to the means of K clusters are calculated and the object is assigned to the cluster with minimum distance. In the *update step*, the new means of the objects in new clusters are calculated. The initialization of cluster means can be randomly selected K objects. The *assignment step* and *update step* are repeated until assignments are no longer changed. Notably, *K-means* needs to specify the desired number of clusters K , which can be selected by using prior knowledge or by trying different values and looking for the one with the most interpretable solution. Also, it is sensitive to the initialization and may converge to a local optimum. Thus, it is crucial to run the algorithm many times from multiple random starting points. The best solution is selected with the smallest value of the objective function. In addition, it is difficult for *K-means* to handle noisy data and outliers. Many algorithms, such as *K-Medoids*, were developed to improve the robustness of *K-means* [58].

Density-based clustering (DBSCAN) [59] is rooted in the idea that clusters are dense regions with objects packed together, separated by regions of lower density. It is associated with two key parameters: the radius of a neighborhood with respect to an object (ε) and the minimum number of objects to form a dense region (*MinPts*). The ε -neighborhood of object w is defined as $N_\varepsilon(w) : \{v \mid d(w, v) \leq \varepsilon\}$. Then, objects can be segmented into three groups: if $N_\varepsilon(w)$ contains at least *MinPts* objects, then the object w is a *core object*; if object w has fewer than *MinPts* objects in its ε -neighborhood, but it is in the ε -neighborhood of a core object, it is called a *border object*; and if the object is neither a core object nor a border object, it is categorized as a *noise object*. An object v is called *directly density-reachable* from an object w w.r.t. ε and *MinPts* if w is a core object and $v \in N_\varepsilon(w)$. An object v is called *density-reachable* from w w.r.t. ε and *MinPts* if there is a chain of objects o_1, o_2, \dots, o_n with $o_1 = w$ and $o_n = v$, and o_{i+1} is directly reachable from o_i . Two objects v and w are called density-connected if there is an object o such that both v and w are density-reachable from o . Then, a cluster satisfies two properties: (i) all objects within the

cluster are mutually density-connected and (ii) if an object is density-reachable from any object of the cluster, it should be included into the cluster. To find a cluster, DBSCAN starts with an object o that has not been visited. If o is a core object, then it collects all objects that are density-reachable from o and forms a cluster. Otherwise, the object is considered as noise. As opposed to *K-means*, DBSCAN is less sensitive to outliers and better handles data with arbitrary geometric shapes. However, it cannot handle data with varying density and is sensitive to parameters settings.

Hierarchical clustering [8] seeks to build a hierarchy of clusters based on pairwise dissimilarities among objects. Strategies for hierarchical clustering generally fall into two categories: agglomerative (bottom up) and divisive (top down). Agglomerative strategies start at the bottom with each object in its own cluster. It recursively merges pairs of clusters with smallest inter-cluster dissimilarity as one moves up the hierarchy. Divisive strategies start at the top with all objects in one cluster. It moves down the hierarchy by recursively splitting an existing cluster into two new clusters with the largest inter-cluster dissimilarity. Let W and V represent two clusters of objects. The dissimilarity of W and V is computed from the pairwise dissimilarities d_{wv} , where one member of the pair w is from W and the other one v is from V . *Average linkage*: $d_{AL}(W, V) = \frac{1}{N_W N_V} \sum_{v \in V} \sum_{w \in W} d_{wv}$, *complete linkage*: $d_{CL}(W, V) = \max_{v \in V, w \in W} d_{wv}$, and *single linkage*: $d_{SL}(W, V) = \min_{v \in V, w \in W} d_{wv}$ are commonly used to measure the inter-cluster dissimilarity. It is up to the user to decide when (i.e., at which level) to stop to obtain a “natural” result: objects within each cluster are sufficiently more similar to each other than to objects assigned to different clusters. The resulting hierarchical structure can be graphically represented as a *dendrogram*.

Affinity propagation (AP) [60] is based on neighbor information propagation. It finds the optimal set of class representative objects (i.e., exemplars), which make the sum of the similarities of all objects to their nearest exemplars as large as possible. For objects i, j , and k , a similarity matrix s is defined such that $s(i, j) > s(i, k)$, if object i is more similar to object j than to k . A commonly used function is $s(i, j) = -\|x_i - x_j\|^2$. The AP algorithm proceeds by letting all objects send messages to all other objects to determine exemplars with two matrices: (1) a “responsibility matrix” with element $r(i, j)$ that quantifies how well-suited object j is to be an exemplar to object i and (2) an “availability matrix” with element $a(i, j)$ that represents how appropriate it would be for object i to choose object j as its exemplar. As such, responsibility messages are sent around as: $r(i, k) \leftarrow s(i, k) - \max_{k_1 \neq k} \{a(i, k_1) + s(i, k_1)\}$. The availability messages are updated as: $a(i, k) \leftarrow$

$\min \left\{ 0, r(k, k) + \sum_{i_1 \neq i \& i_1 \neq k} \max \{0, r(i_1, k)\} \right\}$ for $i \neq k$ and $a(k, k) \leftarrow \sum_{i_1 \neq k} \max \{0, r(i_1, k)\}$. The algorithm iterates until cluster assignments are not changed. The final exemplars are chosen as those with $r(i, i) + a(i, i) > 0$. Although exemplars are similar to “centroids” generated by the *K-means*, the AP algorithm does not require the number of clusters to be predefined.

A *self-organizing map (SOM)* [61] is a type of unsupervised ANN model that represents high-dimensional input data in a low-dimensional map, preserves the topological relationship of the original data, and organizes the data according to inherent structures. Given an input $\mathbf{x} = (x_1, x_2, \dots, x_d)$, the distance to each neuron in the SOM is calculated as $d_i = \|\mathbf{w}_i - \mathbf{x}\|$, where $\mathbf{w}_i = (w_{i1}, w_{i2}, \dots, w_{id})$ is the weight of the i th neuron in the SOM (in total M neurons). The resulting distance vector $\mathbf{d} = (d_1, d_2, \dots, d_M)$ is obtained to determine the best matching neuron (BMN) by finding the smallest d_i . Then, d_i is assigned as 1 and all other elements in \mathbf{d} are set as 0. Further, the weights of the BMN and its neighbors are updated toward the input according to the rule of the Kohonen update as: $\mathbf{w}_i^{t+1} \leftarrow \mathbf{w}_i^t + h^t \cdot (\mathbf{x}^t - \mathbf{w}_i^t)$, where t is the iteration index and h^t is a neighborhood function to characterize the closeness of the BMN to other neurons in the map. In this way, a SOM arranges high-dimensional input in a two-dimensional map such that similar inputs are mapped onto neighboring regions. Thus, similar patterns of the input data are preserved. Outputs of a SOM can be characterized using a U-matrix or a Hits Map to visualize the clustering results. Conventional SOMs are designed for unsupervised learning, whereas supervised SOMs are also investigated in the literature that integrate label information as an additional element in the input vector \mathbf{x} during the training phase [62].

38.3.3 Software

Several DM software packages and libraries are available:

- SAS Enterprise Miner (www.sas.com/technologies/analytics/datamining/miner/)
- SPSS Clementine (www.spss.com/clementine/)
- XLMiner in Excel (www.xlminer.net)
- Ghostminer (www.fqspl.com.pl/ghostminer/)
- Quadstone (www.quadstone.com/)
- Insightful Miner (www.splus.com/products/iminer/)
- Statsmodels (www.statsmodels.org)
- SciKit-Learn (www.scikit-learn.org)
- Keras (www.keras.io)
- Tensorflow (www.tensorflow.org)
- Deep Learning Toolbox (www.mathworks.com/solutions/deep-learning/)
- Darknet (www.pjreddie.com/darknet/)

Haughton et al. [63] present a review of the first five listed above. The SAS and SPSS packages have the most complete set of KDD/DM tools (data handling, DM modeling, and graphics), while Quadstone is the most limited. Insightful Miner was developed by S+ [www.splus.com], but does not require knowledge of the S+ language, which is only recommended for users that are familiar with statistical modeling. For statisticians, the advantage is that Insightful Miner can be integrated with more sophisticated DM methods available with S+, such as flexible and mixture discriminant analysis. All six packages include trees and clustering, and all except Quadstone include ANN modeling. The SAS, SPSS, and XLMiner packages include discriminant analysis and association rules. Ghostminer is the only one that offers SVM tools.

SAS, SPSS, and Quadstone are the most expensive (over \$40 000) while XLMiner is a good deal for the price (under \$2 000). The disadvantage of XLMiner is that it cannot handle very large datasets. Each package has certain specializations, and potential users must carefully investigate these choices to find the package that best fits their KDD/DM needs. Below we describe some other software options for the DM modeling methods presented.

GLM or linear models are the simplest of DM tools and most statistical software can fit them, such as SAS, SPSS, S+, and Statistica [www.statsoftinc.com/]. However, it should be noted that Quadstone only offers a regression tool via scorecards, which is not the same as statistical linear models. GAM requires access to more sophisticated statistical software, such as S+.

Software for CART, MART, and MARS is available from Salford Systems [www.salford-systems.com]. SAS Enterprise Miner includes CHAID, CART, and the machine learning program C4.5 [www.rulequest.com], which uses classifiers to generate decision trees and if-then rules. SPSS Clementine and Insightful Miner also include CART, but Ghostminer and XLMiner utilize different variants of decision trees. QUEST [www.stat.wisc.edu/loh/quest.html] is available in SPSS's AnswerTree software and Statistica.

Python provides many open-source libraries for machine learning and deep learning. Statsmodels is a library that enables its users to conduct data exploration via the use of various methods of estimation of statistical models and performing statistical assertions and analysis. Scikits are additional packages of SciPy Stack designed for specific functionalities like image processing and machine learning facilitation. Keras and Tensorflow are two most prominent and convenient open-source libraries for deep learning. Keras builds neural networks at a high level of the interface. Tensorflow is developed by Google and sharpened for machine learning. It was designed to meet the high-demand requirements of Google environment for training neural networks and is a successor of DistBelief, a machine learning system based on neural networks.

Other softwares for ANN include Matlab's [<http://www.mathworks.com>] Neural Network Toolbox, Matlab's Deep Learning Toolbox, and Darknet [<http://www.pjreddie.com/darknet/>]. The Neural Network Toolbox provides a complete package for ANN modeling. The Deep Learning Toolbox supports CNN networks for classification and regression on image data. The Darknet is an open-source deep learning framework written in C and CUDA, which is fast, easy to install, and provides state-of-art methods for real-time object detection.

38.4 DM Research and Applications

Many industrial and business applications require modeling and monitoring processes with real-time data of different types: real values, categorical, and even text and image. DM is an effective tool for extracting process knowledge and discovering data patterns to provide a control aid for these processes. Advanced DM research involves complex system modeling of heterogeneous objects, where adaptive algorithms are necessary to capture dynamic system behavior. Various data mining algorithms [63], such as logistic regression, support vector machines, convolutional neural networks, decision trees, and combinations of these, have been widely adopted in practical applications. Some application examples include activity monitoring, manufacturing process modeling, object detection, health assessment, fault diagnosis, and remaining useful life prediction. DM algorithms serve as solutions to these tasks.

38.4.1 Activity Monitoring

One important DM application is the development of an effective data modeling and monitoring system for understanding customer profiles and detecting fraudulent behavior. This is generally referred to as *activity monitoring for interesting events requiring action* [65]. Other activity monitoring examples include credit card or insurance fraud detection, computer intrusion detection, some forms of fault detection, network performance monitoring, and news story monitoring.

Although activity monitoring has only recently received attention in the information industries, solutions to similar problems were developed long ago in the manufacturing industries, under the moniker *statistical process control* (SPC). SPC techniques have been used routinely for online process control and monitoring to achieve process stability and to improve process capability through variation reduction. In general, all processes are subject to some natural variability regardless of their state. This natural variability is usually

small and unavoidable and is referred to as *common cause variation*. At the same time, processes may be subject to other variability caused by improper machine adjustment, operator errors, or low-quality raw material. This variability is usually large, but avoidable, and is referred to as *special cause variation*. The basic objective of SPC is to detect the occurrence of special cause variation (or process shifts) quickly, so that the process can be investigated and corrective action may be taken before quality deteriorates and defective units are produced. The main ideas and methods of SPC were developed in the 1920s by Walter Shewhart of Bell Telephone Laboratories and have had tremendous success in manufacturing applications [66]. *Montgomery* and *Woodall* [67] provide a comprehensive panel discussion on SPC, and multivariate methods are reviewed by *Hayter* and *Tsui* [68] and *Mason et al.* [69].

Although the principle of SPC can be applied to service industries, such as business process monitoring, fewer applications exist for two basic reasons that *Montgomery* identified. First, the system that needs to be monitored and improved is obvious in manufacturing applications, while it is often difficult to define and observe in service industries. Second, even if the system can be clearly specified, most nonmanufacturing operations do not have natural measurement systems that reflect the performance of the system. However, these obstacles no longer exist, due to the many natural and advanced measurement systems that have been developed. In the telecommunications industry, for example, advanced software and hardware technologies make it possible to record and process huge amounts of daily data in business transactions and service activities. These databases contain potentially useful information to the company that may not be discovered without knowledge extraction or DM tools.

While SPC ideas can be applied to business data, SPC methods are not directly applicable. Existing SPC theories are based on small- or medium-sized samples, and the basic hypothesis testing approach is intended to detect only simple shifts in a process mean or variance. Recently, *Jiang et al.* [70] successfully generalized the SPC framework to model and track thousands of diversified customer behaviors in the telecommunication industry. The challenge is to develop an integrated strategy to monitor the performance of an entire multistage system and to develop effective and efficient techniques for detecting the systematic changes that require action.

A dynamic business process can be described by the dynamic linear models introduced by *West* [71],

$$\text{Observation equation: } X_t = A_t \theta_t + \Delta_t,$$

$$\text{System evolution equation: } \theta_t = B_t \theta_{t-1} + \Lambda_t,$$

$$\text{Initial information: } \pi(S_0),$$

where A_t and B_t represent observation and state transition matrices, respectively, and Δ_t and Λ_t represent observation and system transition errors, respectively. Based on the dynamic system model, a model-based process monitoring and root-cause identification method can be developed. Monitoring and diagnosis include fault pattern generation and feature extraction, isolation of the critical processes, and root-cause identification. Jiang et al. [70] utilize this for individual customer prediction and monitoring. In general, individual modeling is computationally intractable and cluster models should be developed with mixture distributions [72].

One particularly competitive industry is telecommunications. Since divestiture and government deregulation, various telephone services, such as cellular, local and long distance, domestic, and commercial, have become battle grounds for telecommunication service providers. Because of the data and information-oriented nature of the industry, DM methods for knowledge extraction are critical. To remain competitive, it is important for companies to develop business planning systems that help managers make good decisions. In particular, these systems will allow sales and marketing people to establish successful customer loyalty programs for churn prevention and to develop fraud detection modules for reducing revenue loss through market segmentation and customer profiling.

A major task in this research is to develop and implement DM tools within the business planning system. The objectives are to provide guidance for targeting business growth, to forecast year-end usage volume and revenue growth, and to value risks associated with the business plan periodically. Telecommunication business services include voice and non-voice services, which can be further categorized to include domestic, local, international, products, toll-free calls, and calling cards. For usage forecasting, a minutes growth model is utilized to forecast domestic voice usage. For revenue forecasting, the average revenue per minute on a log scale is used as a performance measure and is forecasted by a double exponential smoothing growth function. A structural model is designed to decompose the business growth process into three major subprocesses: add, disconnect, and base. To improve explanatory power, the revenue unit is further divided into different customer groups. To compute confidence and prediction intervals, bootstrapping and simulation methods are used.

To understand the day effect and seasonal effect, the concept of bill-month equivalent business days (EBD) is defined and estimated. To estimate EBD, the factor characteristics of holidays (non-EBD) are identified and eliminated and the day effect is estimated. For seasonality, the US Bureau of the Census X-11 seasonal adjustment procedure is used.

38.4.2 Mahalanobis-Taguchi System

Genichi Taguchi is best known for his work on robust design and design of experiments. The Taguchi robust design methods have generated a considerable amount of discussion and controversy and are widely used in manufacturing [73–76]. The general consensus among statisticians seems to be that, while many of Taguchi's overall ideas on experimental design are very important and influential, the techniques he proposed are not necessarily the most effective statistical methods. Nevertheless, Taguchi has made significant contributions in the area of quality control and quality engineering. For DM, Taguchi has recently popularized the *Mahalanobis-Taguchi System* (MTS), a new set of tools for diagnosis, classification, and variable selection. The method is based on a Mahalanobis distance scale that is utilized to measure the level of abnormality in *abnormal* items as compared to a group of *normal* items. First, it must be demonstrated that a Mahalanobis distance measure based on all available variables is able to separate the abnormal from the normal items. Should this be successfully achieved, orthogonal arrays and signal-to-noise ratios are used to select an *optimal* combination of variables for calculating the Mahalanobis distances.

The MTS method has been claimed to be very powerful for solving a wide range of problems, including manufacturing inspection and sensing, medical diagnosis, face and voice recognition, weather forecasting, credit scoring, fire detection, earthquake forecasting, and university admissions. Two recent books have been published on the MTS method by Taguchi et al. [77] and Taguchi and Jugulum [78]. Many successful case studies in MTS have been reported in engineering and science applications in many large companies, such as Nissan Motor Co., Mitsubishi Space Software Co., Xerox, Delphi Automotive Systems, ITT Industries, Ford Motor Company, Fuji Photo Film Company, and others. While the method is getting a lot of attention in many industries, very little research [79] has been conducted to investigate how and when the method is appropriate.

38.4.3 Manufacturing Process Modeling

One area of DM research in manufacturing industries is quality and productivity improvement through DM and knowledge discovery. Manufacturing systems nowadays are often very complicated and involve many manufacturing process stages where hundreds or thousands of in-process measurements are taken to indicate or initiate process control of the system. For example, a modern semiconductor manufacturing process typically consists of over 300 steps, and in each

step multiple pieces of equipment are used to process the wafer. Inappropriate understanding of interactions among in-process variables will create inefficiencies at all phases of manufacturing, leading to long product/process realization cycle times and long development times, resulting in excessive system costs.

Current approaches to DM in electronics manufacturing include neural networks, decision trees, Bayesian models, and rough set theory [80, 81]. Each of these approaches carries certain advantages and disadvantages. Decision trees, for instance, produce intelligible rules and hence are very appropriate for generating process control or design of experiments strategies. They are, however, generally prone to outlier and imperfect data influences. Neural networks, on the other hand, are robust against data abnormalities but do not produce readily intelligible knowledge. These methods also differ in their ability to handle high-dimensional data, to discover arbitrarily shaped clusters [57] and to provide a basis for intuitive visualization [82]. They can also be sensitive to training and model building parameters [59]. Finally, the existing approaches do not take into consideration the localization of process parameters. The patterns or clusters identified by existing approaches may include parameters from a diverse set of components in the system. Therefore, a combination of methods that complement each other to provide a complete set of desirable features is necessary.

It is crucial to understand process structure and yield components in manufacturing, so that problem localization can permit reduced production costs. For example, semiconductor manufacturing practice shows that over 70% of all fatal defects and close to 90% of yield excursions are caused by problems related to process equipment [83]. Systematic defects can be attributed to many categories that are generally associated with technologies and combinations of different process operations. To implement DM methods successfully for knowledge discovery, some future research for manufacturing process control must include yield modeling, defect modeling, and variation propagation.

Yield Modeling

In electronics manufacturing, the ANSI standards [84] and practice generally assume that the number of defects on an electronics product follows a Poisson distribution with mean λ . The Poisson random variable is an approximation of the sum of independent Bernoulli trials, but defects on different components may be correlated since process yield critically depends on product groups, process steps, and types of defects [85]. Unlike traditional defect models, an appropriate logit model can be developed as follows. Let the number of defects of category X on an electronics product be

$$U_X = \sum Y_X$$

and

$$\begin{aligned} \text{logit}[E(Y_X)] &= \alpha_X^0 + \alpha_X^O \cdot O_X \\ &+ \alpha_X^C \cdot C_X + \alpha_X^{OC} \cdot O_X \cdot C_X, \end{aligned}$$

where $\text{logit}(z) = \log[z/(1 - z)]$ is the link function for Bernoulli distributions, and Y_X is a Bernoulli random variable representing a defect from defect category X . The default logit of the failure probability is α_X^0 , and α_X^O and α_X^C are the main effects of operations (O_X) and components (C_X). Since the Y_X s are correlated, this model will provide more detailed information about defects.

Multivariate Defect Modeling

Since different types of defects may be caused by the same operations, multivariate Poisson models are necessary to account for correlations among different types of defects. The *trivariate reduction method* suggests an additive Poisson model for the vector of Poisson counts $U = (U_1, U_2, \dots, U_k)'$,

$$U = AV,$$

where A is a matrix of zeros and ones, and $V = (v_1, v_2, \dots, v_p)'$ consists of independent Poisson variables v_i . The variance-covariance matrix takes the form $\text{Var}(U) = A \Sigma A' = \Phi + \nu \nu'$, where $\Phi = \text{diag}(\mu_i)$ is a diagonal matrix with the mean of the individual series, and ν is the common covariance term. Note that the v_i are essentially latent variables, and a factor analysis model can be developed for analyzing multivariate discrete Poisson variables such that

$$\log[E(U)] = \mu + L \cdot F,$$

where U is the vector of defects, L is the matrix of factor loadings, and F contains common factors representing effects of specific operations. By using factor analysis, it is possible to relate product defects to the associated packages and operations.

Multistage Variation Propagation

Inspection tests in an assembly line usually have functional overlap, and defects from successive inspection stations exhibit strong correlations. Modeling serially correlated defect counts is an important task for defect localization and yield prediction. Poisson regression models, such as the generalized event-count method [86] and its alternatives, can be utilized to account for serial correlations of defects in different inspection stations. Factor analysis methods based on hidden Markov models [87] can also be constructed to investigate how variations are propagated through assembly lines.

38.4.4 Object Detection

One area of DM image research is object detection, a computer technology related to computer vision and image processing that deals with detecting instances of semantic objects of a certain class in digital images and videos. An object-class detection is to localize and extract information of all objects in an image that belongs to a given class. Well-studied domains of object detection include face detection and pedestrian detection.

Face detection, as a specific case of object-class detection, focuses on the detection of frontal human faces. It is analogous to image detection in which the image of a person is matched bit by bit. Image matches with the image stores in database. Any facial feature changes in the database will invalidate the matching process. The main difficulties in face detection includes severe occlusion and variation of head poses.

Pedestrian detection provides fundamental information for semantic understanding of the video footages and considered an essential and significant in intelligent video surveillance system. It has an obvious extension to automotive applications due to enhance road safety and is offered as an advanced driver assistant system option by many car manufacturers in 2017. The major challenges of pedestrian detection arise from different possible posture, various appearance styles, the presence of occluding accessories, and frequent occlusions among pedestrians.

Existing methods for object detection generally fall into machine learning approaches and deep learning approaches. For machine learning approaches, it first extracts handcrafted features such as edges, corners, colors, etc. of the region of interest cropped by sliding window, then uses classifiers such as SVM to do the classification. On the other hand, deep learning approaches use CNN to extract the image features and thus able to do end-to-end object detection without specifically defining features. Ross et al. [88] prompted *regions with CNN* (R-CNN) to achieve dramatic improvements in accuracy of objects detection, which can be seen as a major breakthrough in the field of object detection. Subsequently, a series of R-CNN-based detection methods such as Fast R-CNN [89] and Faster R-CNN [90] were proposed. Those are classic two-stage object detection approaches that usually include a region proposal localization stage and a network classification stage. Then single shot detection methods, such as *single shot detector* (SSD) [91], RetinaNet [92], *you only look once* (YOLO) [93–95], etc., are developed. They skip the region proposal stage and run detection directly over a dense sampling of possible locations through a single CNN. The “one-stage” detection methods treat the detection as a single regression problem and are faster and simpler.

38.4.5 Surveillance of Public Health Systems

Public health surveillance is another important DM application. The objective of public health surveillance is to examine health trends, detect changes in disease incidence and death rates, and to plan, implement, and evaluate public health practice by systematically collecting, analyzing, and interpreting public health data (chronic or infectious diseases). Understanding challenges to nations’ public health systems and how those challenges shift over time is of crucial importance for policymakers to establish effective strategies. In public health surveillance, the volume and velocity of data streams have dramatically grown in recent decades. In spite of the growing data volume, advances in information technology have enabled collection of cause-of-death data in a more timely manner.

The availability of public health big data provides a comprehensive picture of health system status in terms of the causes of significant population-wide changes, the underlying risks, the changes in the pattern of health-related losses, etc. Numerous efforts have been made to monitor and evaluate the health of populations by taking advantage of public health big data and data mining techniques. For example, Google flu trend (GFT) is a data analytics model developed by Google for predicting weekly reported influenza-like illness (ILI) rates using instant query data [96]. However, as reported in Refs. [96, 97], GFT failed to provide accurate predictions, and predicted more than double the actual rate of doctor visits for ILI reported by the Centers for Disease Control and Prevention during the 2012–2013 season. The model’s failure has led to a large number of research papers aiming to improve its predictive accuracy [98–100]. One representative method was ARGO, proposed in Ref. [98], which not only incorporated seasonality in historical ILI rates, but also captured changes in the public’s online searching behaviors over time.

38.5 Concluding Remarks

While DM and KDD methods are gaining recognition and have become very popular in many companies and enterprises, the success of these methods is still somewhat limited. Below, we discuss a few obstacles.

First, the success of DM depends on a close collaboration of subject-matter experts and data modelers. In practice, it is often easy to identify the right subject-matter expert, but difficult to find the qualified data modeler. While the data modeler must be knowledgeable and familiar with DM methods, it is more important to be able to formulate real problems such that the existing methods can be applied. In reality, traditional academic training mainly focuses on knowledge of modeling

algorithms and lacks training in problem formulation and interpretation of results. Consequently, many modelers are very efficient in fitting models and algorithms to data, but have a hard time determining when and why they should use certain algorithms. Similarly, the existing commercial DM software systems include many sophisticated algorithms, but there is a lack of guidance on which algorithms to use.

Second, implementation of DM is difficult to apply effectively across an industry. Although it is clear that extracting hidden knowledge and trends across an industry would be useful and beneficial to all companies in the industry, it is typically impossible to integrate the detailed data from competing companies due to confidentiality and proprietary issues. Currently, the industry practice is that each company will integrate their own detailed data with the more general, aggregated industry-wide data for knowledge extraction. It is obvious that this approach will be significantly less effective than the approach of integrating the detailed data from all competing companies. It is expected that, if these obstacles can be overcome, the impact of the DM and KDD methods will be much more prominent in industrial and commercial applications.

Kwok-Leung Tsui is a chair professor in the School of Data Science at the City University of Hong Kong. He has a Ph.D. in statistics from the University of Wisconsin at Madison. Dr. Tsui is an (elected) fellow of American Statistical Association and American Society for Quality, and was a recipient of the NSF Young Investigator Award. He is currently the departmental editor of the *IISE Transactions* and a member of the Management Committee for *Technometrics*.

Victoria Chen is a professor in the Department of Industrial, Manufacturing, and Systems Engineering and director of the Center on Stochastic Modeling, Optimization, and Statistics at the University of Texas at Arlington. She is currently serving as an executive secretary on the INFORMS Board. She is a guest coeditor for the *Annals of Operations Research*.

Wei Jiang is a distinguished professor in Antai College of Economics and Management at Shanghai Jiao Tong University. He obtained his Ph.D. degree in industrial engineering and engineering management from Hong Kong University of Science and Technology in 2000. Prior to joining Shanghai Jiao Tong University, he worked as a statistical consultant at AT&T Labs, Morristown. His current research activities include statistical methods for quality control, data mining, and enterprise intelligence.

Fangfang Yang is a research fellow in School of Data Science at the City University of Hong Kong. She earned her Ph.D. in system engineering and engineering management from the City University of Hong Kong in 2017. Current research areas of Dr. Yang include prognostics and health management, degradation modeling, and deep learning.

Chen Kan is an assistant professor in the Department of Industrial, Manufacturing, and Systems Engineering, the University of Texas at Arlington. He earned his Ph.D. in industrial and manufacturing engineering from the Pennsylvania State University in 2018. Current research areas of Dr. Kan include complex systems modeling and monitoring, smart manufacturing and IoT, and health informatics. He is a member of IEEE, IISE, and INFORMS.

a challenging topic in multivariate statistics. In this book chapter, we aim to review the current literature on statistical models and methods for tensor data analysis.

Keywords

Discriminant analysis · Dimension reduction · Generalized linear model · Multivariate linear regression · Tensor data

39.1 Background

39.1.1 Popularity and Challenges

In many contemporary datasets, the measurements on each observation are stored in the form of a tensor. For example, in neuroimaging studies, electroencephalography (EEG) data are collected as two-way tensors (i.e., matrices), where the rows correspond to electrodes placed at different locations on the scalp, and the columns correspond to times points. The anatomical magnetic resonance image (MRI) is a three-way tensor, as it measures the activities of brains in the 3D space. By adding the time domain, functional MRI is a four-way tensor. Other research areas that frequently involve tensor data include computational biology, personalized recommendation, signal processing, computer vision, graph analysis, and data mining [42].

However, the popularity of tensor data is accompanied by many challenges in the analysis. We highlight two of them here. On the one hand, tensor data are often of intimidating dimensions. For example, in the benchmark EEG data (<http://kdd.ics.uci.edu/databases/eeg/eeg.data.html>), each subject is measured by 64 channels of electrodes at 256 time points. The resulting 64×256 matrix has a total number of 16,384

Abstract

This book chapter provides a brief introduction of tensors and a selective overview of tensor data analysis. Tensor data analysis has been an increasingly popular and also

elements in total. The modeling of such a high-dimensional dataset is generally impossible with classical statistical methods. Moreover, in many applications we have tensors of higher orders, and the issue of high dimensionality is even more severe.

On the other hand, there is a lack of analysis methods that directly target tensor data. Most familiar statistical methods are designed for vector data. While one can always force a tensor to be a vector, we lose the information contained in the tensor structure in doing so. To see this, again consider the EEG data as an example. In principle, we can stack the columns in the data matrix to form a long vector and proceed with vector-based methods. However, each column in the matrix corresponds to measurements at the same time point. Once we transform the matrix to a vector, we no longer have such an intuitive interpretation for the data. The statistical analysis is thus susceptible to loss of efficiency for the same reason. Consequently, although there have been impressive developments in high-dimensional statistics [25, 26, 28, 29, 47, 51, 55, 57, 72, 83, 88, 98, 99, e.g.], we are still in demand of tensor data analysis methods.

These challenges have motivated many research efforts on tensor data analysis. A central interest in such research is the control of model complexity by leveraging the tensor structure. Usually this is achieved by imposing low-rank, sparse, and/or separable covariance assumptions. In Sects. 39.2–39.5, we review several methods that resort to such assumptions. But we first introduce some basics for tensor that are necessary to understand the methods in this chapter. A comprehensive review on tensor operation can be found in [42].

39.1.2 Basics

For a positive integer M , an M -way tensor is an object in $\mathbb{R}^{p_1 \times \dots \times p_M}$, where \mathbb{R} denotes the field of real numbers and p_m 's are positive integers. It is easy to see that a vector is a one-way tensor, and a matrix is a two-way tensor.

For an M -way tensor $\mathbf{A} \in \mathbb{R}^{p_1 \times \dots \times p_M}$, p_m is its dimension along the m -th mode. We can vectorize \mathbf{A} to $\text{vec}(\mathbf{A}) \in \mathbb{R}^p$, where $p = \prod_{m=1}^M p_m$. The element $a_{i_1 \dots i_M}$ becomes the j -th element in $\text{vec}(\mathbf{A})$, where $j = 1 + \sum_{m=1}^M (i_m - 1) \prod_{m'=1}^{m-1} p_{m'}$. Similarly, a tensor can be unfolded along a mode to form a matrix. The mode- m matricization of \mathbf{A} is denoted as $\mathbf{A}_{(m)}$, a $p_m \times \prod_{j \neq m} p_j$ matrix. The element $a_{i_1 \dots i_M}$ in \mathbf{A} is mapped to be the (i_m, j) element in $\mathbf{A}_{(m)}$, where $j = 1 + \sum_{k=1, k \neq m}^M (i_k - 1) J_k$ with $J_k = \sum_{m' \neq m} p_{m'}$. The norm of \mathbf{A} is denoted as $\|\mathbf{A}\| = \sqrt{\sum_{j_1, \dots, j_M} a_{j_1 \dots j_M}^2} = \sqrt{\text{vec}^T(\mathbf{A}) \text{vec}(\mathbf{A})}$. For two tensors \mathbf{A}, \mathbf{B} of the same dimensions, their inner product is defined as $\langle \mathbf{A}, \mathbf{B} \rangle = \text{vec}^T(\mathbf{A}) \text{vec}(\mathbf{B})$.

A tensor can be multiplied with matrices or vectors along each mode. For $\mathbf{G} \in \mathbb{R}^{d \times p_m}$, we define the mode- m matrix product of \mathbf{A} with \mathbf{G} to be $\mathbf{D} = \mathbf{A} \times_m \mathbf{G} \in \mathbb{R}^{p_1 \times \dots \times p_{m-1} \times p_{m+1} \times \dots \times p_M}$ if and only if $\mathbf{D}_{(m)} = \mathbf{G} \mathbf{A}_{(m)}$. Similarly, we define the mode- m vector product of \mathbf{A} with a vector $\mathbf{v} \in \mathbb{R}^{p_m}$ to be $\mathbf{A} \bar{\times}_m \mathbf{v} \in \mathbb{R}^{p_1 \times \dots \times p_{m-1} \times p_{m+1} \times \dots \times p_M}$, with the $(i_1, \dots, i_{m-1}, i_{m+1}, \dots, i_M)$ element being $\sum_{i_m=1}^{p_m} a_{i_1 \dots i_M} v_{i_m}$.

In particular, for matrices $\mathbf{G}_m \in \mathbb{R}^{d_m \times p_m}$ and M -way tensor $\mathbf{C} \in \mathbb{R}^{d_1 \times \dots \times d_M}$, if $\mathbf{A} = \mathbf{C} \times_1 \mathbf{G}_1 \times_2 \mathbf{G}_2 \dots \times_M \mathbf{G}_M \in \mathbb{R}^{p_1 \times \dots \times p_M}$, we use the shorthand notation

$$\mathbf{A} = \llbracket \mathbf{C}; \mathbf{G}_1, \dots, \mathbf{G}_M \rrbracket. \quad (39.1)$$

Alternatively, (39.1) is also called the Tucker decomposition of \mathbf{A} . See Fig. 39.1 for an illustration when \mathbf{A} and \mathbf{C} are three-way tensors.

The matrix Kronecker product often appears in tensor literature. For two matrices $\mathbf{F} \in \mathbb{R}^{I \times J}$, $\mathbf{G} \in \mathbb{R}^{K \times L}$, we define their Kronecker product to be

$$\mathbf{F} \otimes \mathbf{G} = \begin{pmatrix} f_{11} \mathbf{G} & f_{12} \mathbf{G} & \dots & f_{1J} \mathbf{G} \\ \vdots & \vdots & \ddots & \vdots \\ f_{I1} \mathbf{G} & f_{I2} \mathbf{G} & \dots & f_{IJ} \mathbf{G} \end{pmatrix} \in \mathbb{R}^{(IK) \times (JL)}. \quad (39.2)$$

For a series of matrix $\mathbf{G}_m, m = 1, \dots, M$, $\mathbf{G} = \otimes_{m=1}^M \mathbf{G}_m$ is invertible if and only if \mathbf{G}_m^{-1} exists for $m = 1, \dots, M$. Moreover, $\mathbf{G}^{-1} = \otimes_{m=1}^M \mathbf{G}_m^{-1}$. With Kronecker product, we note a useful fact about the Tucker decomposition. If $\mathbf{A}, \mathbf{C}, \mathbf{G}_m, m = 1, \dots, M$ satisfy (39.1), then we must have that $\text{vec}(\mathbf{A}) = (\mathbf{G}_M \otimes \dots \otimes \mathbf{G}_1) \text{vec}(\mathbf{C}) = (\otimes_{m=1}^M \mathbf{G}_m) \text{vec}(\mathbf{C})$, where \otimes is the Kronecker product.

Another related matrix product is the Khatri-Rao product. For $\mathbf{F} \in \mathbb{R}^{I \times K}$, $\mathbf{G} \in \mathbb{R}^{J \times K}$, their Khatri-Rao product is

$$\mathbf{F} \circ \mathbf{G} = [\mathbf{f}_1 \otimes \mathbf{g}_1 \quad \dots \quad \mathbf{f}_M \otimes \mathbf{g}_M] \in \mathbb{R}^{(IJ) \times K}. \quad (39.3)$$

Fig. 39.1 An illustration of the Tucker decomposition $\mathbf{A} = \llbracket \mathbf{C}; \mathbf{G}_1, \mathbf{G}_2, \mathbf{G}_3 \rrbracket$

39.1.3 The CANDECOMP/PARAFAC Decomposition

In this section, we highlight the CANDECOMP/PARAFAC (CP) decomposition that serves as the foundation of many statistical methods [41]. It can be viewed as a generalization of singular value decomposition for matrices.

Consider $\mathbf{X} \in \mathbb{R}^{p_1 \times \dots \times p_M}$. For a pre-chosen positive integer R , the CP decomposition looks for R sets of vectors $\mathbf{a}_r^{(m)}$, $m = 1, \dots, M$ that jointly best approximate \mathbf{X} . In other words, for each (j_1, \dots, j_M) , we expect

$$x_{j_1 \dots j_M} \approx \sum_{r=1}^R a_{rj_1}^{(1)} a_{rj_2}^{(2)} \dots a_{rj_M}^{(M)}. \tag{39.4}$$

Two equivalent shorthand notations for the CP decomposition are

$$\mathbf{X} \approx \sum_{r=1}^R \mathbf{a}_r^{(1)} \circ \dots \circ \mathbf{a}_r^{(M)} = \llbracket \mathbf{A}^{(1)}, \dots, \mathbf{A}^{(M)} \rrbracket, \tag{39.5}$$

where $\mathbf{A}^{(m)} = [\mathbf{a}_1^{(m)} \dots \mathbf{a}_R^{(m)}]$. See Fig. 39.2 for a demonstration of CP decomposition on a three-way tensor.

The CP decomposition is formally recast as the following minimization problem:

$$\begin{aligned} \{\mathbf{a}_r^{(m)}\}_{m=1, \dots, M; r=1, \dots, R} &= \arg \min \|\mathbf{X} - \widehat{\mathbf{X}}\|^2, \\ \text{s.t. } \widehat{\mathbf{X}} &= \llbracket \mathbf{A}^{(1)}, \dots, \mathbf{A}^{(M)} \rrbracket. \end{aligned} \tag{39.6}$$

This problem can be solved iteratively over the $\mathbf{A}^{(m)}$'s. When $\mathbf{A}^{(m')}$ are fixed for all $m' \neq m$, (39.6) reduces to a least squares problem over $\mathbf{A}^{(m)}$. This iterative algorithm is known as the alternating least squares (ALS) [8, 37]. Since the introduction of the ALS algorithm, many other efforts have been spent on alternative ways to perform the CP decomposition [62, 73, 74], but the ALS algorithm seems to remain the most popular.

The CP decomposition is widely used on tensor data in a way much like principal component analysis on vector data. Many researchers obtain a multilinear reduction of \mathbf{X} and

Fig. 39.2 CP decomposition of a three-way tensor \mathbf{X}

then perform analysis on the reduced predictor [9, 52, 87, e.g.]. Alternatively, one could use the CP decomposition to reduce the number of parameters, as the tensor generalized linear mode we discuss in Sect. 39.2.

39.1.4 The Tensor Normal Distribution

We will repeatedly use the tensor normal distribution that generalizes the matrix normal distribution [35]. A tensor $\mathbf{Z} \in \mathbb{R}^{p_1 \times \dots \times p_M}$ is said to be a standard tensor normal random variable if each element in \mathbf{Z} has the univariate standard normal distribution. Then, for any \mathbf{X} of the same dimension of \mathbf{Z} , we say \mathbf{X} is tensor normal, i.e., $\mathbf{X} \sim TN(\boldsymbol{\mu}; \boldsymbol{\Sigma}_1, \dots, \boldsymbol{\Sigma}_M)$, if

$$\mathbf{X} = \boldsymbol{\mu} + \llbracket \mathbf{Z}; \boldsymbol{\Sigma}_1^{1/2}, \dots, \boldsymbol{\Sigma}_M^{1/2} \rrbracket, \tag{39.7}$$

where $\boldsymbol{\mu} \in \mathbb{R}^{p_1 \times \dots \times p_M}$ and $\boldsymbol{\Sigma}_m \in \mathbb{R}^{p_m \times p_m}$ are symmetric positive definite matrices (Fig. 39.3). The parameters $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}_m$ are similar to the mean and covariance parameters for the multivariate normal distribution. In particular, $\boldsymbol{\mu} = E(\mathbf{X})$ is the expectation of \mathbf{X} , and

$$\boldsymbol{\Sigma}_m \propto E \{ (\mathbf{X} - \boldsymbol{\mu})_{(m)} (\mathbf{X} - \boldsymbol{\mu})_{(m)}^T \} \tag{39.8}$$

characterizes the dependence structure along the m -th mode of \mathbf{X} .

The tensor normal distribution is related to the multivariate normal distribution by the fact that $\text{vec}(\mathbf{X}) = \text{vec}(\boldsymbol{\mu}) + \boldsymbol{\Sigma}^{1/2} \text{vec}(\mathbf{Z})$, where $\boldsymbol{\Sigma} = \otimes_{m=1}^M \boldsymbol{\Sigma}_m \in \mathbb{R}^{p \times p}$, where $p = \prod_{m=1}^M p_m$. In other words, $\text{vec}(\mathbf{X}) \sim N(\text{vec}(\boldsymbol{\mu}), \boldsymbol{\Sigma})$. Note that, although $\boldsymbol{\Sigma}$ is of dimension $p \times p$, it is fully determined by $\sum_{m=1}^M p_m(p_m + 1)/2$ free parameters.

A minor issue with the tensor normal distribution is, though, that the covariances $\boldsymbol{\Sigma}_m$ are not identifiable themselves. We can change their scales without affecting the tensor normal distribution. For example, when $M = 2$, $TN(0; \boldsymbol{\Sigma}_1, \boldsymbol{\Sigma}_2)$ is exactly the same as $TN(0; c\boldsymbol{\Sigma}_1, c^{-1}\boldsymbol{\Sigma}_2)$ for any $c > 0$. In practice, researchers often resolve this issue by fixing the scale of all the covariance matrices except for 1. For

Fig. 39.3 A demonstration for tensor normal distribution when \mathbf{X} is a three-way tensor

example, we could require the Frobenius norms of Σ_m , $m < M$ to be 1, and only allow Σ_M to have an arbitrary Frobenius norm. Alternatively, we could require $\sigma_{m,11} = 1$, $m < M$. In the following sections, we do not reiterate on this issue unless necessary, as this is not a central problem in tensor modeling.

39.1.5 Notation and Organization

Throughout the rest of this chapter, a scalar is written as a lower-case letter (e.g., x), a vector is written as a lower-case letter in boldface (\mathbf{x}), and a tensor (2-way and above) is written as a capital letter in boldface (\mathbf{X}). For any positive integer r , \mathbf{I}_r denotes the identity matrix with dimension $r \times r$. The notation $\mathbf{X} \perp \mathbf{Y}$ means that the random variables \mathbf{X} and \mathbf{Y} are independent, while $\mathbf{X} \stackrel{d}{=} \mathbf{Y}$ means that \mathbf{X} and \mathbf{Y} have the same distribution. For ease of presentation, if a matrix is of the form $\Phi = \Phi_M \otimes \cdots \otimes \Phi_1$, we denote $\Phi_{-m} = \Phi_M \otimes \cdots \otimes \Phi_{m+1} \otimes \Phi_{m-1} \otimes \cdots \otimes \Phi_1$.

In Sect. 39.2 we introduce generalized linear models with tensor predictors. Section 39.3 contains an introduction to the tensor response regression; a tensor partial least squares (PLS) algorithm is presented in Sect. 39.4. In Sect. 39.5 we discuss classification based on a mixture of tensor and vector predictors. In each section we first introduce the related vector methods and then proceed to tensor data. We emphasize that the research in tensor data analysis has witnessed rapid developments in the recent years [3, 63, 69, 75, 84, 86, 87, e.g.]. It is impossible to conduct an exhaustive review, but we list some papers that propose methods closely related to those we introduce in Sects. 39.2–39.5. Finally, a real data example is given in Sect. 39.6.

Regression with tensor predictors (related to Sect. 39.2) is one of the most studied topics in tensor analysis. See [34, 40, 49, 53, 63, 64, 70, 76, 77, 89, 92, 95, 97]. Tensor response regression (related to Sect. 39.3) is studied in [44, 68, 80]. Tensor PLS algorithms (related to Sect. 39.4) are proposed in [5, 24, 93]. Classification methods (related to Sect. 39.5) are developed in [1, 43, 50, 71, 82, 85, 94].

39.2 The Tensor Generalized Linear Model

39.2.1 Background: The Generalized Linear Model

The generalized linear model (GLM) includes a family of most popular statistical models for vector data, with linear regression and logistic regression as two important examples. Consider $\{Y, \mathbf{X}\}$, where $Y \in \mathbb{R}$ is the response and $\mathbf{X} \in \mathbb{R}^p$ is the vector predictor. GLM assumes that Y is drawn from an exponential family with a probability mass or density function of the form

$$f(y | \theta, \phi) = \exp \left\{ \frac{y\theta - b(\theta)}{a(\phi)} + c(y, \phi) \right\}, \quad (39.9)$$

where θ is the natural parameter and $\phi > 0$ is the dispersion parameter. Denote $\mu = E(Y | \mathbf{X})$ and g as a strictly increasing link function. GLM assumes that

$$g(\mu) = a + \boldsymbol{\beta}^\top \mathbf{X},$$

where $\boldsymbol{\beta} \in \mathbb{R}^p$. The parameter of interest, $\boldsymbol{\beta}$, is often estimated by the maximum likelihood estimator (MLE). For most generalized linear models such as logistic regression and Poisson regression, the MLE does not have an explicit form, but efficient algorithms have been developed to find the solution. More recently, there have been considerable interests in regularized estimators for GLM, where penalty functions are added to enhance stability and/or enforce variable selection [28, 72, 99, e.g.].

When the predictor \mathbf{X} is a tensor instead of a vector, in principle we could fit GLM on $Y, \text{vec}(\mathbf{X})$. However, this brutal-force approach leads to an overwhelmingly large number of parameters. In most applications we do not have sufficient samples to estimate all these parameters, and the computation could be painfully slow. In note of this issues, tensor GLM is proposed to control the number of parameters by utilizing the tensor structure. Also, tensor GLM allows us to model vector and tensor predictors simultaneously, as we discuss in Sect. 39.2.2.

39.2.2 Model

Consider $\{Y, \mathbf{U}, \mathbf{X}\}$, where $Y \in \mathbb{R}$ is the response, $\mathbf{U} \in \mathbb{R}^q$ is the vector predictor, and $\mathbf{X} \in \mathbb{R}^{p_1 \times \cdots \times p_M}$ is the tensor predictor. Just as in GLM, we assume that Y is drawn from an exponential family with the probability mass or density function in (39.9). Similarly, define $\mu = E(Y | \mathbf{U}, \mathbf{X})$ and a strictly increasing link function $g(\mu)$. Tensor GLM assumes that

$$g(\mu) = \beta_0 + \boldsymbol{\gamma}^\top \mathbf{U} + \left\langle \sum_{r=1}^R \boldsymbol{\beta}_1^{(r)} \circ \boldsymbol{\beta}_2^{(2)} \circ \cdots \circ \boldsymbol{\beta}_M^{(r)}, \mathbf{X} \right\rangle, \quad (39.10)$$

where $r \geq 1$ is a positive integer, $\boldsymbol{\gamma} \in \mathbb{R}^q$, and $\boldsymbol{\beta}_m^{(r)} \in \mathbb{R}^{p_m}$ for $r = 1, \dots, R$. Obviously, tensor GLM inherits the nice interpretation of GLM that the predictors have linear effects on $g(\mu)$. As a concrete example, one may consider the simplest case where $R = 1, M = 2$. Now \mathbf{X} is a matrix, and the model in (39.10) reduces to

$$g(\mu) = \beta_0 + \boldsymbol{\gamma}^\top \mathbf{U} + \boldsymbol{\beta}_1^\top \mathbf{X} \boldsymbol{\beta}_2, \quad (39.11)$$

where $\beta_1 \in \mathbb{R}^{p_1}$ is the effect across rows of \mathbf{X} , while $\beta_2 \in \mathbb{R}^{p_2}$ is the effect across the columns of \mathbf{X} . In this sense, β_1, β_2 jointly reduces \mathbf{X} by row and column. A similar idea has also been proposed in the framework of the so-called dimension folding on tensor data [45], although dimension folding is proposed for sufficient dimension reduction [6, 14–16, 46, 48, 56, 96].

To further see that tensor GLM reduces the number of parameters by honoring the tensor structure, we compare it to GLM on $\{Y, \mathbf{U}, \text{vec}(\mathbf{X})\}$. The vectorized GLM is equivalent to

$$g(\mu) = \beta_0 + \boldsymbol{\gamma}^\top \mathbf{U} + \langle \mathbf{B}, \mathbf{X} \rangle, \quad (39.12)$$

where $\mathbf{B} \in \mathbb{R}^{p_1 \times \dots \times p_M}$; recall that $\langle \mathbf{B}, \mathbf{X} \rangle = \text{vec}^\top(\mathbf{B})\text{vec}(\mathbf{X})$. It is now apparent that the tensor GLM is a special case of the vectorized GLM by requiring that the coefficient tensor \mathbf{B} has a rank- R CP decomposition, i.e., $\mathbf{B} = \sum_{r=1}^R \beta_1^{(r)} \circ \beta_2^{(r)} \circ \dots \circ \beta_M^{(r)}$. The low-rank assumption on \mathbf{B} reduces the number of free parameters from $q + \prod_{m=1}^M p_m$ to $q + R \sum_m p_m$.

39.2.3 Estimation

Similar to classical GLM, tensor GLM is estimated by maximizing the likelihood function. Let

$$\mathbf{B} = \sum_{r=1}^R \beta_1^{(r)} \circ \beta_2^{(r)} \circ \dots \circ \beta_M^{(r)} = \llbracket \mathbf{B}_1, \dots, \mathbf{B}_M \rrbracket,$$

where $\mathbf{B}_m = [\beta_m^{(1)}, \dots, \beta_m^{(R)}] \in \mathbb{R}^{p_m \times R}$. The log-likelihood function for tensor GLM is

$$l(\alpha, \boldsymbol{\gamma}, \mathbf{B}_1, \dots, \mathbf{B}_M) = \sum_{i=1}^n \frac{y_i \theta_i - b(\theta_i)}{a(\phi)} + \sum_{i=1}^n c(y_i, \phi), \quad (39.13)$$

where θ_i is linked to the parameters through the model in (39.10).

Although $g(\mu)$ is not linear in $(\mathbf{B}_1, \dots, \mathbf{B}_M)$, it is linear in \mathbf{B}_m when we fix $\mathbf{B}_{m'}$ for $m' \neq m$. More specifically, it can be shown that

$$\begin{aligned} & \left\langle \sum_{r=1}^R \beta_1^{(r)} \circ \beta_2^{(r)} \circ \dots \circ \beta_M^{(r)}, \mathbf{X} \right\rangle \\ &= \langle \mathbf{B}_m, \mathbf{X}_{(m)} (\mathbf{B}_M \odot \dots \odot \mathbf{B}_{m+1} \odot \mathbf{B}_{m-1} \odot \dots \odot \mathbf{B}_1) \rangle, \end{aligned}$$

where we recall that \odot is the Khatri-Rao product between matrices.

It follows that, given $\mathbf{B}_{m'}, m' \neq m$, we can fit a classical GLM over $\{Y, \mathbf{U}, \text{vec}(\widehat{\mathbf{X}}^{(m)})\}$ to obtain \mathbf{B}_m , where $\widehat{\mathbf{X}}^{(m)} = \mathbf{X}_{(m)} (\mathbf{B}_M \odot \dots \odot \mathbf{B}_{m+1} \odot \mathbf{B}_{m-1} \odot \dots \odot \mathbf{B}_1)$. Iteratively updating

\mathbf{B}_m yields our final estimator. Note that, in each step of this iterative algorithm, we only need to solve for the parameter \mathbf{B}_m of dimension $p_m \times R$, which is usually efficient, especially when R is small. Hence, the iterative algorithm can fit models on large tensors within a reasonably short amount of time.

If we want to further boost the stability in our estimation of tensor GLM, regularization can be applied just as in classical GLM. Denote $P_\alpha(t, \lambda)$ as a penalty function, where λ is the tuning parameter, and α is an index for the penalty function. For example, the elastic net penalty is $P_\alpha(t, \lambda) = \lambda[(\alpha - 1)t^2/2 + (2 - \lambda)t]$, $\lambda \in [1, 2]$. The regularized estimator is defined as the maximizer of

$$l(\beta_0, \boldsymbol{\gamma}, \mathbf{B}_1, \dots, \mathbf{B}_M) - \sum_{m=1}^M \sum_{r=1}^R \sum_{j=1}^{p_m} P_\alpha(|\beta_{mj}^{(r)}|, \lambda). \quad (39.14)$$

The regularized estimator can be found by an iterative algorithm as well. When we fix $\mathbf{B}_{m'}, m' \neq m$, \mathbf{B}_m is the regularized estimator for GLM over $\{Y, \mathbf{U}, \text{vec}(\widehat{\mathbf{X}}^{(m)})\}$. For various penalty functions, efficient algorithms have been developed for their combination with the classical GLM. These algorithms can be readily borrowed to implement regularized tensor GLM.

We close this section by listing some theoretical properties for tensor GLM. We focus on tensor GLM without regularization. The consistency of tensor GLM involves an identifiability condition that does not appear in classical GLM. Note that the CP decomposition of \mathbf{B} is not identifiable in general. We can permute and/or rescale the basis $\mathbf{B}_1, \dots, \mathbf{B}_M$ without changing the coefficient tensor \mathbf{B} . To resolve this issue, we consider the parameter space

$$\mathcal{B} = \left\{ (\mathbf{B}_1, \dots, \mathbf{B}_M) : \beta_{m1}^{(r)} = 1, \text{ for } m = 1, \dots, M, \right. \\ \left. r = 1, \dots, R \text{ and } \beta_{M1}^{(1)} > \dots > \beta_{M1}^{(R)} \right\},$$

which is open and convex. If we restrict our attention to this parameter space and further assume that the parameters are identifiable, it can be shown that $\text{vec}(\widehat{\mathbf{B}}_1, \dots, \widehat{\mathbf{B}}_M)$ are \sqrt{n} -consistent estimators for $\text{vec}(\mathbf{B}_1, \dots, \mathbf{B}_M)$.

39.3 Envelope Tensor Response Regression

39.3.1 Multivariate Response Envelope Model

In this section, we review the multivariate response regression that motivates the tensor response regression. We also briefly discuss the envelope assumption that will be developed in parallel for tensor data. Consider $\{Y, \mathbf{X}\}$, where $Y \in \mathbb{R}^q$ is the response and $\mathbf{X} \in \mathbb{R}^p$ is the predictor. The classical multivariate response regression model is

$$\mathbf{Y} = \boldsymbol{\beta}\mathbf{X} + \boldsymbol{\epsilon}, \tag{39.15}$$

where $\boldsymbol{\beta} \in \mathbb{R}^{q \times p}$ is the coefficient matrix and $\boldsymbol{\epsilon} \in \mathbb{R}^q$ is the statistical error independent of \mathbf{X} with $E\boldsymbol{\epsilon} = 0$ and $\text{var}(\boldsymbol{\epsilon}) = \boldsymbol{\Sigma} \in \mathbb{R}^{q \times q}$. Without loss of generality, we assume that the intercept is zero. The parameter of interest $\boldsymbol{\beta}$ can be estimated with the ordinary least squares (OLS) estimator. If we further assume that $\boldsymbol{\epsilon}$ is normal, the OLS estimator is also the MLE, although statisticians often use the OLS estimator even without the normality assumption.

The envelope assumption is more recently proposed to improve estimation efficiency. When the dimension of \mathbf{Y} , q , is large, likely not all of them are related to the predictor \mathbf{X} . Hence, the envelope assumption indicates that the response is only related to the predictor when refined on a low-dimensional subspace. In other words, there exists a subspace $\mathcal{S} \subseteq \mathbb{R}^q$ such that

$$\mathbf{Q}_{\mathcal{S}}\mathbf{Y} \mid \mathbf{X} \stackrel{d}{=} \mathbf{Q}_{\mathcal{S}}\mathbf{Y}, \quad \mathbf{Q}_{\mathcal{S}}\mathbf{Y} \perp \mathbf{P}_{\mathcal{S}}\mathbf{Y} \mid \mathbf{X}, \tag{39.16}$$

where $\mathbf{P}_{\mathcal{S}}$ is the projection on to \mathcal{S} and $\mathbf{Q}_{\mathcal{S}} = \mathbf{I}_q - \mathbf{P}_{\mathcal{S}}$. These assumptions imply that the subspace \mathcal{S} contains all the material information for the regression, while its complement only brings in variability that degrades our inference about it is desirable to identify \mathcal{S} before estimating $\boldsymbol{\beta}$.

The multivariate response envelope model can be estimated by MLE. A key step is rewriting the envelope assumption in (39.16) into a new parameterization of $\boldsymbol{\beta}$ and $\boldsymbol{\Sigma}$. With some linear algebra it can be shown that (39.16) is equivalent to that $\text{span}(\boldsymbol{\beta}) \subset \mathcal{S}$ and $\boldsymbol{\Sigma} = \mathbf{P}_{\mathcal{S}}\boldsymbol{\Sigma}\mathbf{P}_{\mathcal{S}} + \mathbf{Q}_{\mathcal{S}}\boldsymbol{\Sigma}\mathbf{Q}_{\mathcal{S}}$. Hence, we can estimate the coordinate of \mathcal{S} and estimate the other parameters accordingly. For more background on [12, 13, 17, 18, 66, 67, 90].

39.3.2 Model

On tensor data, it often makes sense to treat the tensor as the response and perform regression on vector predictors. For example, in the EEG data, we may want to compare the brain activities for subjects with and without recent alcohol consumption. Such comparison can be viewed as a regression problem with the EEG tensor as the response and an indicator function of alcohol consumption as the predictor. The coefficients in these model characterize the difference between EEGs. In some other applications, additional covariates may be available as well, such as age and gender. These covariates can be included as part of the vector predictor to eliminate possible confounding factors.

For the tensor response $\mathbf{Y} \in \mathbb{R}^{q_1 \times \dots \times q_M}$ and the vector predictor $\mathbf{X} \in \mathbb{R}^p$, we consider the tensor response linear model:

$$\mathbf{Y} = \mathbf{B} \bar{\times}_{(M+1)} \mathbf{X} + \boldsymbol{\epsilon}, \tag{39.17}$$

where $\mathbf{B} \in \mathbb{R}^{q_1 \times \dots \times q_M \times p}$ is the parameter of interest and $\boldsymbol{\epsilon} \in \mathbb{R}^{q_1 \times \dots \times q_M}$. We assume that $\boldsymbol{\epsilon} \sim TN(0; \boldsymbol{\Sigma}_1, \dots, \boldsymbol{\Sigma}_M)$, although the normality is not essential. Rather, the main advantage in this assumption is that we determine the covariance of $\boldsymbol{\epsilon}$ with a smaller number of parameters in $\boldsymbol{\Sigma}_m, m = 1, \dots, M$. Such an approach is common in the tensor literature; see Sects. 39.4 and 39.5 for example. Other works that involve similar assumptions include [30, 39].

Similar to tensor GLM, estimation of \mathbf{B} is difficult without additional assumptions, because \mathbf{B} is extremely high dimensional. To this end, we further assume that the parameter \mathbf{B} has the envelope structure. Let $\mathbb{P}(\mathbf{Y}) = \llbracket \mathbf{Y}; \mathbf{P}_1, \dots, \mathbf{P}_M \rrbracket$ and $\mathbb{Q}(\mathbf{Y}) = \mathbf{Y} - \mathbb{P}(\mathbf{Y})$, where $\mathbf{P}_m \in \mathbb{R}^{q_m \times q_m}$ is the projection matrix onto a linear subspace $S_m \subset \mathbb{R}^{q_m}$. We consider the following envelope assumption:

$$\mathbb{Q}(\mathbf{Y}) \mid \mathbf{X} \stackrel{d}{=} \mathbb{Q}(\mathbf{Y}), \quad \mathbb{Q}(\mathbf{Y}) \perp \mathbb{P}(\mathbf{Y}) \mid \mathbf{X}. \tag{39.18}$$

Parallel to the multivariate response envelope model, the envelope assumption in (39.18) indicates that there is a series of possibly low-rank subspaces s_1, \dots, s_M that contain all the information for the estimation of \mathbf{B} . If we identify these subspaces, we can discard their complements without any loss of information.

Moreover, if we set $u_m \leq q_m$ to be the rank of S_m , $\boldsymbol{\Gamma}_m \in \mathbb{R}^{q_m \times u_m}$ to be a basis for S_m and $\boldsymbol{\Gamma}_{0m}$ to be the orthogonal complement of $\boldsymbol{\Gamma}_m$, the envelope assumption leads to the following parsimonious representation of \mathbf{B} and $\boldsymbol{\Sigma}_m$:

$$\mathbf{B} = \llbracket \boldsymbol{\Theta}; \boldsymbol{\Gamma}_1, \dots, \boldsymbol{\Gamma}_M, \mathbf{I}_p \rrbracket, \quad \boldsymbol{\Sigma}_m = \boldsymbol{\Gamma}_m \boldsymbol{\Omega}_m \boldsymbol{\Gamma}_m^T + \boldsymbol{\Gamma}_{0m} \boldsymbol{\Omega}_{0m} \boldsymbol{\Gamma}_{0m}^T, \tag{39.19}$$

where $\boldsymbol{\Theta} \in \mathbb{R}^{u_1 \times \dots \times u_M \times p}$, $\boldsymbol{\Omega}_m \in \mathbb{R}^{u_m \times u_m}$, and $\boldsymbol{\Omega}_{0m} \in \mathbb{R}^{(q_m - u_m) \times (q_m - u_m)}$. As a result, we can extract all the information about \mathbf{B} by focusing on the ‘‘surrogate response’’ $\mathbf{Z} = \llbracket \mathbf{Y}; \boldsymbol{\Gamma}_1^T, \dots, \boldsymbol{\Gamma}_M^T \rrbracket \in \mathbb{R}^{u_1 \times \dots \times u_M}$. With the envelope representation, the number of free parameters reduces from $p \prod_{m=1}^M q_m + \sum_{m=1}^M q_m(q_m + 1)/2$ to $p \prod_{m=1}^M u_m + \sum_{m=1}^M \{u_m(q_m - u_m) + u_m(u_m + 1)/2 + (q_m - u_m)(q_m - u_m + 1)/2\}$, which leads to a reduction of $p(\prod_{m=1}^M q_m - \prod_{m=1}^M u_m)$ free parameters. The smaller number of parameter encourages efficient estimation and computation in the estimation, which we discuss in the next section.

39.3.3 Estimation

The parameters in the tensor response envelope model are estimated by MLE. For the covariance matrices $\boldsymbol{\Sigma}_m$, we let $\boldsymbol{\Sigma} = \boldsymbol{\Sigma}_M \otimes \dots \otimes \boldsymbol{\Sigma}_1$. We want to minimize the negative log-likelihood function:

$$\begin{aligned} \ell(\mathbf{B}, \boldsymbol{\Sigma}) &= \log |\boldsymbol{\Sigma}| + \frac{1}{n} \sum_{i=1}^n \left\{ \text{vec}(\mathbf{Y}_i) - \mathbf{B}_{(M+1)}^\top \mathbf{X}_i \right\}^\top \\ &\quad \boldsymbol{\Sigma}^{-1} \left\{ \text{vec}(\mathbf{Y}_i) - \mathbf{B}_{(M+1)}^\top \mathbf{X}_i \right\}. \end{aligned} \quad (39.20)$$

Note that, because of our envelope assumption in (39.19), the objective function $\ell(\mathbf{B}, \boldsymbol{\Sigma})$ implicitly depends on $\boldsymbol{\Gamma}_m$, $\boldsymbol{\Theta}$, $\boldsymbol{\Omega}_m$, $\boldsymbol{\Omega}_{0m}$ as well.

The minimization of (39.20) is performed by minimizing $\ell(\mathbf{B}, \boldsymbol{\Sigma})$ over one parameter while fixing all the others fixed. We start by finding initial estimates for \mathbf{B} and $\boldsymbol{\Sigma}$. We fit each element of the tensor response \mathbf{Y} versus \mathbf{X} to find the OLS estimator \mathbf{B}_{OLS} and use it as the initial value $\mathbf{B}^{(0)}$. For $\boldsymbol{\Sigma}_m^{(0)}$, we employ the following estimator similar to that in [23]:

$$\boldsymbol{\Sigma}_m^{(0)} = \frac{1}{n \prod_{j \neq m} p_j} \sum_{i=1}^n \mathbf{e}_{i(m)} \{ \boldsymbol{\Sigma}_{-m}^{(0)} \}^{-1} \mathbf{e}_{i(m)}, \quad (39.21)$$

where $\mathbf{e}_{i(m)}$ is the mode- m matricization of $\mathbf{e}_i = \mathbf{Y}_i - \mathbf{B}^{(0)} \times_{M+1} \mathbf{X}_i$.

We iterate over m to determine $\boldsymbol{\Sigma}_m^{(0)}$. In the following iterations, it is easy to update \mathbf{B} and $\boldsymbol{\Sigma}$ when $\boldsymbol{\Gamma}_m$, $\boldsymbol{\Theta}$, $\boldsymbol{\Omega}_m$, $\boldsymbol{\Omega}_{0m}$ are fixed, thanks to (39.19). Thus we focus on the update of $\boldsymbol{\Theta}$, $\boldsymbol{\Omega}_m$, $\boldsymbol{\Omega}_{0m}$ at the $(t+1)$ -th iteration. It can be shown that

$$\begin{aligned} \boldsymbol{\Gamma}_m^{(t+1)} &= \arg \min_{\mathbf{G}_m \in \mathbb{R}^{q_m \times u_m}} \log |\mathbf{G}_m^\top \mathbf{M}_m^{(t)} \mathbf{G}_m| \\ &\quad + \log |\mathbf{G}_m^\top (\mathbf{N}_m^{(t)})^{-1} \mathbf{G}_m|, \\ \text{s.t. } \mathbf{G}_m^\top \mathbf{G}_m &= \mathbf{I}_{u_m}, \end{aligned} \quad (39.22)$$

where $\mathbf{M}_m^{(t)} = (n \prod_{j \neq m} q_j)^{-1} \sum_{i=1}^n \boldsymbol{\delta}_{i(m)}^{(t)} \{ \boldsymbol{\Sigma}_{-m}^{(t)} \}^{-1} \boldsymbol{\delta}_{i(m)}^\top$, $\mathbf{N}_m^{(t)} = (n \prod_{j \neq m} q_j)^{-1} \sum_{i=1}^n \mathbf{Y}_{i(m)}^{(t)} \{ \boldsymbol{\Sigma}_{-m}^{(t)} \}^{-1} \mathbf{Y}_{i(m)}^\top$, and $\boldsymbol{\delta}_i^{(t)} = \mathbf{Y}_i - \llbracket \mathbf{B}_{\text{OLS}}; \mathbf{P}_{\Gamma_1}^{(t)}, \dots, \mathbf{P}_{\Gamma_{m-1}}^{(t)}, \mathbf{I}_{q_m}, \mathbf{P}_{\Gamma_{m+1}}^{(t)}, \dots, \mathbf{P}_{\Gamma_M}^{(t)}, \mathbf{I}_p \rrbracket \times_{(M+1)} \mathbf{X}_i^\top$ is the current fitted envelope model residual. The optimization in (39.22) is over all $(q_m \times u_m)$ -dimensional Grassmann manifolds and is the most time-consuming step in our estimation.

With $\{\boldsymbol{\Gamma}_m\}_{m=1}^M$, the parameter $\boldsymbol{\Theta}$ can be estimated by restricting our attention to the regression problem with the surrogate response $\mathbf{Z} = \llbracket \mathbf{Y}; \boldsymbol{\Gamma}_1^\top, \dots, \boldsymbol{\Gamma}_M^\top \rrbracket$ and the predictor \mathbf{X} . More specifically, define $\mathbf{Z}_i^{(t)} = \llbracket \mathbf{Y}_i; (\boldsymbol{\Gamma}_1^{(t+1)})^\top, \dots, (\boldsymbol{\Gamma}_M^{(t+1)})^\top \rrbracket$ and stack them to form $\mathbb{Z}^{(t)} \in \mathbb{R}^{u_1 \times \dots \times u_M \times n}$. Similarly, stack \mathbf{X}_i to form $\mathbb{X} \in \mathbb{R}^{p \times n}$. Our estimate for $\boldsymbol{\Theta}$ is

$$\boldsymbol{\Theta}^{(t+1)} = \mathbb{Z}^{(t)} \times_{(M+1)} \{ (\mathbb{X} \mathbb{X}^\top)^{-1} \mathbb{X} \}. \quad (39.23)$$

Finally, we have

$$\boldsymbol{\Omega}_m^{(t+1)} = \frac{1}{n \prod_{j \neq m} q_j} \sum_{i=1}^n \mathbf{s}_{i(m)}^{(t)} \left\{ \boldsymbol{\Omega}_{-m}^{(t+1)} \right\}^{-1} \mathbf{s}_{i(m)}^\top, \quad (39.24)$$

$$\begin{aligned} \boldsymbol{\Omega}_{0m}^{(t+1)} &= \frac{1}{n \prod_{j \neq m} q_j} \sum_{i=1}^n \left(\boldsymbol{\Gamma}_{0m}^{(t+1)} \right)^\top \mathbf{Y}_{i(m)} \\ &\quad \left\{ \boldsymbol{\Sigma}_{-m}^{(t+1)} \right\}^{-1} \mathbf{Y}_{i(m)}^\top \boldsymbol{\Gamma}_{0m}^{(t+1)}, \end{aligned} \quad (39.25)$$

where $\mathbf{s}_i^{(t)} = \mathbf{Z}_i^{(t)} - \boldsymbol{\Theta}^{(t+1)} \times_{(M+1)} \mathbf{X}_i$.

With these results, the MLE can be found with an iterative algorithm. However, if time becomes an issue, one could consider two modifications to speed up the computation. First, the most challenging step in the optimization is apparently (39.22). One could carry out this step with an efficient 1D algorithm [19] shown to be faster and more stable. Second, instead of iterating over the steps, we can only update the estimates once. As it turns out, whether we iterate until convergence or not, the final estimates are \sqrt{n} -consistent, with smaller asymptotic variance than the OLS estimator.

Finally, we note that the envelope dimensions u_m are typically unknown in practice [91]. We select them individually by minimizing

$$\begin{aligned} \text{BIC}_m &= -\frac{n}{2} \log |\boldsymbol{\Gamma}_m^\top \boldsymbol{\Sigma}_m^{(0)} \boldsymbol{\Gamma}_m| - \frac{n}{2} \log |\boldsymbol{\Gamma}_m^\top (\mathbf{N}_m^{(0)})^{-1} \boldsymbol{\Gamma}_m| \\ &\quad + \log n \cdot p u_m. \end{aligned} \quad (39.26)$$

Since the dimensions are selected marginally, the computation is usually very fast for this aspect.

39.3.4 A Technical Remark

Although seemingly straightforward, the estimation of the tensor response regression is made possible by a striking difference between vector and tensor data. Note that to find the initial value $\boldsymbol{\Sigma}_m^{(0)}$, we have to invert the large covariance $\boldsymbol{\Sigma}_{-m}^{(0)} \in \mathbb{R}^{(\prod_{j \neq m} p_j) \times (\prod_{j \neq m} p_j)}$. It is well-known that, on vector data, we want to avoid inverting the covariance if the dimension is large, because the inverse does not exist when the dimension exceeds the sample size. However, this is not an issue for tensor data even when $\prod_{j \neq m} p_j$ is much larger than the sample size. Note that $\boldsymbol{\Sigma}_{-m}^{(0)}$ is invertible if and only if $\boldsymbol{\Sigma}_j^{(0)}$, $j \neq m$ are all invertible. With some linear algebra we can show that this is true as long as $n \prod_{j \neq m} p_j > p_m$. In most tensor data applications, p_j , $j = 1, \dots, M$ are roughly of the same order. It follows that $\boldsymbol{\Sigma}_j^{(0)}$ is typically invertible, even for very small sample sizes.

Moreover, because of the tensor structure, finding the inverse is generally fast. Recall that $\{ \boldsymbol{\Sigma}_{-m}^{(0)} \}^{-1} = \otimes_{j \neq m} \{ \boldsymbol{\Sigma}_j^{(0)} \}^{-1}$. Hence, there is no need to direct invert the large matrix $\boldsymbol{\Sigma}_{-m}^{(0)}$. Instead, we only need to invert the much smaller matrices $\boldsymbol{\Sigma}_j^{(0)}$. Indeed, this trick is used in many tensor methods that require inverting the separable covariance.

Algorithm 1 The SIMPLS algorithm

1. Initialize $\mathbf{C}_0 = \text{cov}(\mathbf{X}, \mathbf{Y}) \in \mathbb{R}^{p \times q}$.
2. For $j = 1, \dots, u$, do the following:
 - a. Find $\mathbf{w}_j = \arg \max_{\mathbf{w} \in \mathbb{R}^p} \mathbf{w}^T \mathbf{C}_{j-1} \mathbf{C}_{j-1} \mathbf{w}$, s.t. $\mathbf{w}^T \mathbf{w} = 1$;
 - b. Let $u_j = \mathbf{w}_j^T \mathbf{X} \in \mathbb{R}$;
 - c. Compute $\mathbf{v}_j = \text{cov}(\mathbf{X}, t_j) / \text{var}(t_j) \in \mathbb{R}^p$;
 - d. Deflate the cross covariance $\mathbf{C}_j = \mathbf{Q}_j \mathbf{C}_0$, where $\mathbf{Q}_j \in \mathbb{R}^{p \times p}$ is the projection matrix onto the orthogonal subspace of $\text{span}(\mathbf{v}_1, \dots, \mathbf{v}_j)$.
3. Reduce $\mathbf{X} \in \mathbb{R}^p$ to $\mathbf{U} = \mathbf{W}^T \mathbf{X} = (t_1, \dots, t_u) \in \mathbb{R}^u$, where $\mathbf{W} = (\mathbf{w}_1, \dots, \mathbf{w}_u)$.
4. Regress $\mathbf{Y} \in \mathbb{R}^q$ on $\mathbf{U} \in \mathbb{R}^u$.

39.4 Tensor Envelope Partial Least Squares Regression

39.4.1 Partial Least Squares Regression

We first review partial least squares (PLS) for vector data. Consider the response $\mathbf{Y} \in \mathbb{R}^q$ and the predictor $\mathbf{X} \in \mathbb{R}^p$. PLS looks for a reduction of \mathbf{X} in the form of $\mathbf{U} = \mathbf{W}^T \mathbf{X} \in \mathbb{R}^u$ that is used in the follow-up regression as the predictor. Conceptually, PLS attempts to fit a factor model

$$\mathbf{X} = \mathbf{T}\mathbf{U} + \mathbf{E}, \quad \mathbf{Y} = \mathbf{V}\mathbf{U} + \mathbf{F}, \quad (39.27)$$

where $\mathbf{U} \in \mathbb{R}^u$ contains the factors shared by \mathbf{X} and \mathbf{Y} , $\mathbf{T} \in \mathbb{R}^{p \times u}$, $\mathbf{V} \in \mathbb{R}^{q \times u}$ are the loadings, and \mathbf{E}, \mathbf{F} are statistical errors. PLS first recovers the latent factor \mathbf{U} and then estimates the loading \mathbf{V} by fitting a regression model on $\{\mathbf{Y}, \mathbf{U}\}$.

However, unlike many other statistical methods, PLS was first proposed as a heuristic algorithm, without a clear statistical model behind it. Nevertheless, its competitive performance wins its wide popularity. Up until today, many PLS algorithms have been developed [21, 79, e.g.]. We only review one of them named SIMPLS, as it is one of the rare PLS algorithms with a population interpretation [11, 38]. SIMPLS is listed in Algorithm 1. To avoid notation proliferation, we use the parameters such as the cross variance in this algorithm, but of course in practice these parameters are replaced with their sample estimates. SIMPLS sequentially maximizes the correlation between the predictor and the response. It can be shown that on the population level SIMPLS finds an envelope of \mathbf{X} that contains all the information for \mathbf{Y} .

39.4.2 A Tensor PLS Algorithm

Consider a regression problem with $Y \in \mathbb{R}^q$ as the response and $\mathbf{X} \in \mathbb{R}^{p_1 \times \dots \times p_M}$ as the predictor. This is different from the tensor response regression discussed in Sect. 39.3, as now

Algorithm 2 The tensor PLS algorithm

1. Initialize $\mathbf{C}_0 = \text{cov}(\mathbf{X}, \mathbf{Y}) \in \mathbb{R}^{p_1 \times \dots \times p_M \times q}$ and the covariance matrices $\Sigma_{\mathbf{Y}} = \text{cov}(\mathbf{Y})$ and $\Sigma_{\mathbf{X}} = \text{cov}\{\text{vec}(\mathbf{X})\} = \Sigma_M \otimes \dots \otimes \Sigma_1$.
2. For $m = 1, \dots, M$, do the following:
 - a. Standardize the mode- m cross covariance matrix:
$$\tilde{\mathbf{C}}_{0m} = \mathbf{C}_{0(m)} (\Sigma_{\mathbf{Y}}^{-1/2} \otimes \Sigma_{-m}^{-1/2}) \in \mathbb{R}^{p_m \times (q \prod_{k \neq m} p_k)} \quad (39.28)$$
 - b. For $j = 1, \dots, u_m$, do the following
 - i. Find $\mathbf{w}_{mj} = \arg \max_{\mathbf{w} \in \mathbb{R}^{p_m}} \mathbf{w}^T \tilde{\mathbf{C}}_{j-1, m} \tilde{\mathbf{C}}_{j-1, m} \mathbf{w}$, s.t. $\mathbf{w}^T \mathbf{w} = 1$;
 - ii. Let $u_j = \mathbf{w}_j^T \mathbf{X} \in \mathbb{R}$;
 - iii. Compute $\mathbf{v}_j = \text{cov}(\mathbf{X}, t_j) / \text{var}(t_j) \in \mathbb{R}^p$;
 - iv. Deflate the cross covariance $\tilde{\mathbf{C}}_{jm} = \mathbf{Q}_{jm} \tilde{\mathbf{C}}_{0m}$, where $\mathbf{Q}_{jm} \in \mathbb{R}^{p_m \times p_m}$ is the projection matrix onto the orthogonal subspace of $\text{span}(\Sigma_m \mathbf{W}_{jm})$, and $\mathbf{W}_{jm} = (\mathbf{w}_{1m}, \dots, \mathbf{w}_{jm}) \in \mathbb{R}^{p_m \times j}$.
3. Reduce $\mathbf{X} \in \mathbb{R}^{p_1 \times \dots \times p_M}$ to $\mathbf{U} = [\mathbf{X}; \mathbf{W}_1^T, \dots, \mathbf{W}_M^T] \in \mathbb{R}^{u_1 \times \dots \times u_M}$, where $\mathbf{W}_m = (\mathbf{w}_{1m}, \dots, \mathbf{w}_{u_m m}) \in \mathbb{R}^{p_m \times j}$.
4. Regress $\mathbf{Y} \in \mathbb{R}^q$ on $\mathbf{U} \in \mathbb{R}^{u_1 \times \dots \times u_M}$.

the tensor is in the place of the predictor. A natural way to extend the PLS algorithm is to seek a low-rank reduction $\mathbf{U} = [\mathbf{X}; \mathbf{W}_1^T, \dots, \mathbf{W}_M^T]$, where $\mathbf{W}_m \in \mathbb{R}^{p_m \times u_m}$. However, close attention is required to multiple details to ensure a statistical interpretation behind the algorithm. We introduce one such algorithm in Algorithm 2 [89].

We make two remarks concerning Algorithm 2. First, we again use the parameters to avoid notation proliferation, but in practice they should be replaced with estimates. The parameters $\mathbf{C}_0, \Sigma_{\mathbf{Y}}$ are replaced with their usual sample estimates. We explain the more involved estimators for $\Sigma_m, m = 1, \dots, M$ in $\Sigma_{\mathbf{X}}$. By (39.8), The moment-based estimators are

$$\hat{\Sigma}_m = \left(n \prod_{j \neq m} p_j \right)^{-1} \sum_{i=1}^n \mathbf{X}_{i(m)} \mathbf{X}_{i(m)}^T. \quad (39.29)$$

Alternatively, if one strongly believes in the normality assumptions, MLE can be applied [59]. It can be shown that the MLE, $\hat{\Sigma}_m^{\text{MLE}}, m = 1, \dots, M$ must satisfy

$$\hat{\Sigma}_m^{\text{MLE}} = \frac{1}{n \prod_{j \neq m} p_j} \sum_{i=1}^n \mathbf{X}_{i(m)} \left\{ \hat{\Sigma}_{-m}^{\text{MLE}} \right\}^{-1} \mathbf{X}_{i(m)}. \quad (39.30)$$

Hence, the MLEs can be computed iteratively over m .

Second, the tensor PLS algorithm has a similar structure to SIMPLS, but it reduces the tensor predictor along all the modes. Such reduction is important for the sake of both computational and statistical efficiency. Because the reduction is performed along each mode, the number of parameters is under control even when the tensors have a huge number of elements. Moreover, the tensor PLS algorithm turns out to have a population interpretation as well, as we explain in the next section.

39.4.3 A Population Model

Recall that we have a q -dimensional response \mathbf{Y} and a tensor predictor \mathbf{X} . Consider the model

$$Y_k = \langle \mathbf{B}_{::k}, \mathbf{X} \rangle + \epsilon_k, \quad k = 1, \dots, q, \quad (39.31)$$

where $\mathbf{B}_{::k} \in \mathbb{R}^{p_1 \times \dots \times p_M}$ is the coefficient tensor for (Y_k, \mathbf{X}) and ϵ_k is the statistical error independent of \mathbf{X} . We collect the coefficients $\mathbf{B}_{::k}$ to form the coefficient tensor $\mathbf{B} \in \mathbb{R}^{p_1 \times \dots \times p_M \times q}$. The regression model in (39.31) can be equivalently written as

$$\mathbf{Y} = \mathbf{B}_{(M+1)} \text{vec}(\mathbf{X}) + \boldsymbol{\epsilon}, \quad (39.32)$$

where $\boldsymbol{\epsilon} \in \mathbb{R}^q$. We further assume that the covariance of \mathbf{X} is separable in that $\boldsymbol{\Sigma}_{\mathbf{X}} = \text{cov}\{\text{vec}(\mathbf{X})\} = \boldsymbol{\Sigma}_M \otimes \dots \otimes \boldsymbol{\Sigma}_1$. Finally, similar to the tensor response regression model, we assume an envelope structure exists. More specifically, we assume the existence of a series of subspaces $S_m \in \mathbb{R}^{p_m}$, $m = 1, \dots, M$ such that

$$\mathbf{X} \times_m \mathbf{Q}_m \perp \mathbf{X} \times_m \mathbf{P}_m, \quad \mathbf{Y} \perp \mathbf{X} \times_m \mathbf{Q}_m \mid \mathbf{X} \times_m \mathbf{P}_m, \quad (39.33)$$

where $\mathbf{P}_m \in \mathbb{R}^{p_m \times p_m}$ is the projection matrix onto S_m and $\mathbf{Q}_m = \mathbf{I}_{p_m} - \mathbf{P}_m$ is the orthogonal complement. Let $\boldsymbol{\Gamma}_m \in \mathbb{R}^{p_m \times u_m}$ be a basis of S_m and $\boldsymbol{\Gamma}_{0m} \in \mathbb{R}^{p_m \times (p_m - u_m)}$ be a basis of the complement of S_m . The envelope assumption implies that that $\llbracket \mathbf{X}; \mathbf{P}_1, \dots, \mathbf{P}_M \rrbracket$ contains all the information for \mathbf{Y} . Extracting this material part improves the estimation efficiency and lowers the computation cost.

The envelope assumption is integrated into the estimation by noting that

$$\mathbf{B} = \llbracket \boldsymbol{\Theta}; \boldsymbol{\Gamma}_1, \dots, \boldsymbol{\Gamma}_M, \mathbf{I}_q \rrbracket, \quad \text{for some } \boldsymbol{\Theta} \in \mathbb{R}^{u_1 \times \dots \times u_M},$$

$$\boldsymbol{\Sigma}_m = \boldsymbol{\Gamma}_m \boldsymbol{\Omega}_m \boldsymbol{\Gamma}_m^\top + \boldsymbol{\Gamma}_{0m} \boldsymbol{\Omega}_{0m} \boldsymbol{\Gamma}_{0m}^\top, \quad m = 1, \dots, M,$$

where $\boldsymbol{\Omega}_m \in \mathbb{R}^{u_m \times u_m}$, $\boldsymbol{\Omega}_{0m} \in \mathbb{R}^{(p_m - u_m) \times (p_m - u_m)}$ are symmetric positive definite matrices. When u_m 's are small, we achieve noticeable reduction in the number of free parameters.

It can be shown that the tensor PLS algorithm estimates the above model. Let $\mathcal{W}_m \subset \mathbb{R}^{p_m}$ be the subspace spanned by $(\mathbf{w}_{1m}, \dots, \mathbf{w}_{u_m m}) \in \mathbb{R}^{p_m \times u_m}$. As $n \rightarrow \infty$, \mathcal{W}_m converges to S_m . Also, the resulting estimator $\hat{\mathbf{B}}$ is a \sqrt{n} -consistent estimator for \mathbf{B} . This fact provides supports and explanations for the favorable performance of tensor PLS.

39.5 Covariate-Adjusted Tensor Classification in High Dimensions

39.5.1 Linear Discriminant Analysis

The method covariate-adjusted tensor classification in high dimensions (CATCH) is partially motivated by the well-known linear discriminant analysis (LDA). We review some basics for LDA for completeness. For a more comprehensive introduction to LDA, see [60]. Consider the class label $Y = 1, \dots, K$ and the vector predictor $\mathbf{X} \in \mathbb{R}^p$. The LDA model assumes that

$$\Pr(Y = y) = \pi_y, \quad \mathbf{X} \mid Y = y \sim N(\boldsymbol{\mu}_y, \boldsymbol{\Sigma}), \quad (39.34)$$

where $\boldsymbol{\mu}_y \in \mathbb{R}^p$, $\boldsymbol{\Sigma} \in \mathbb{R}^{p \times p}$. The optimal classifier can be explicitly derived under this model, which takes the form

$$\hat{Y} = \arg \max_{k=1, \dots, K} \Pr(Y = k \mid \mathbf{X}) = \arg \max_{k=1, \dots, K} \{a_k + \boldsymbol{\beta}_k^\top \mathbf{X}\}, \quad (39.35)$$

where $\boldsymbol{\beta}_k = \boldsymbol{\Sigma}^{-1}(\boldsymbol{\mu}_k - \boldsymbol{\mu}_1)$ and $a_k = \log(\pi_k/\pi_1) - \boldsymbol{\beta}_k^\top(\boldsymbol{\mu}_k + \boldsymbol{\mu}_1)/2$. LDA has been well-received since its introduction, due to its elegant linear form and competitive performance [36, e.g.,]. We note that the linear form is a result of the normality assumption and the homogeneity across classes. In the past a few years, there have been considerable interests in generalizing LDA to high dimensions [7, 10, 27, 54, 58, 65, 78, 81], but these methods are not adapted to tensor classification.

39.5.2 Model

Consider random variables $\{\mathbf{U}, \mathbf{X}, Y\}$, where $\mathbf{U} \in \mathbb{R}^q$ is the vector predictor, $\mathbf{X} \in \mathbb{R}^{p_1 \times \dots \times p_M}$ is the tensor predictor, and $Y = 1, \dots, K$ is the class label. Our goal is to build a classifier for the prediction of Y based on $\{\mathbf{U}, \mathbf{X}\}$. The CATCH model assumes that

$$\Pr(Y = k) = \pi_k, \quad \mathbf{U} \mid (Y = k) \sim N(\boldsymbol{\phi}_k, \boldsymbol{\Psi}), \quad (39.36)$$

$$\mathbf{X} \mid (\mathbf{U} = \mathbf{u}, Y = k) \sim TN(\boldsymbol{\mu}_k + \boldsymbol{\alpha} \bar{\times}_{(M+1)} \mathbf{u}, \boldsymbol{\Sigma}_1, \dots, \boldsymbol{\Sigma}_M), \quad (39.37)$$

where $\boldsymbol{\phi}_k \in \mathbb{R}^q$ and $\boldsymbol{\Psi} \in \mathbb{R}^{q \times q}$ are the mean and the covariance of \mathbf{U} within Class k . The parameter $\boldsymbol{\alpha} \in \mathbb{R}^{p_1 \times \dots \times p_M \times q}$ is the effect of \mathbf{U} on \mathbf{X} within class. After we adjust \mathbf{X} for \mathbf{U} , its within-class mean and variance are given by $\boldsymbol{\mu}_k \in \mathbb{R}^{p_1 \times \dots \times p_M}$, and $\boldsymbol{\Sigma}_m \in \mathbb{R}^{p_m \times p_m}$, $m = 1, \dots, M$, respectively.

The CATCH model is similar to the LDA model in the assumption of normality and constant covariance. Indeed, if we ignore \mathbf{X} , then (Y, \mathbf{U}) follows the LDA model. However, in the CATCH model there are two layers of dependence, which allows us to model the relationship between \mathbf{X} and \mathbf{U} as well. Within Class $Y = k$, \mathbf{X} and \mathbf{U} are connected with a tensor response regression model with \mathbf{X} as the response and \mathbf{U} as the predictor; see Sect. 39.3. Moreover, in the absence of \mathbf{U} , \mathbf{X} is assumed to follow the tensor normal distribution:

$$\mathbf{X} | Y = k \sim TN(\boldsymbol{\mu}_k; \boldsymbol{\Sigma}_1, \dots, \boldsymbol{\Sigma}_M). \quad (39.38)$$

This can be viewed as a model for tensor discriminant analysis (TDA) that generalizes LDA to tensor data. The tensor normal distribution reduces the number of free parameters in the covariance of \mathbf{X} .

Under the CATCH model, we derive the optimal classifier to be

$$\begin{aligned} \hat{Y} &= \arg \max_{k=1, \dots, K} \Pr(Y = k | \mathbf{X}, \mathbf{U}) \\ &= \arg \max_{k=1, \dots, K} \{a_k + \boldsymbol{\gamma}_k^\top \mathbf{U} + \langle \mathbf{B}_k, \mathbf{X} - \boldsymbol{\alpha} \bar{\mathbf{x}}_{(M+1)} \mathbf{U} \rangle\}, \end{aligned} \quad (39.39)$$

where $\boldsymbol{\gamma}_k = \boldsymbol{\Psi}^{-1}(\boldsymbol{\phi}_k - \boldsymbol{\phi}_1)$, $\mathbf{B}_k = \llbracket \boldsymbol{\mu}_k - \boldsymbol{\mu}_1; \boldsymbol{\Sigma}_1^{-1}, \dots, \boldsymbol{\Sigma}_M^{-1} \rrbracket$, and $a_k = \log(\pi_k/\pi_1) - \frac{1}{2} \boldsymbol{\gamma}_k^\top (\boldsymbol{\phi}_k + \boldsymbol{\phi}_1) - \langle \mathbf{B}_k, \frac{1}{2}(\boldsymbol{\mu}_k + \boldsymbol{\mu}_1) \rangle$ is a scalar that does not involve \mathbf{X} or \mathbf{U} . The coefficient $\boldsymbol{\gamma}_k$ is the direct effect of \mathbf{U} on Y , while $\boldsymbol{\alpha}$ is the indirect effect of \mathbf{U} on Y through \mathbf{X} . The coefficients \mathbf{B}_k summarizes the net effect of \mathbf{X} on Y after it is adjusted for \mathbf{U} . We demonstrate the structure of our CATCH model in Fig. 39.4.

So far we only utilize the tensor structure of \mathbf{X} by making the tensor normal assumption. When the tensor is large, more efforts may be needed for parsimonious modeling. We achieve this goal by assuming that the coefficients \mathbf{B}_k are sparse. Note that, for any $j_1 \cdots j_M$, the coefficients $b_{2, j_1 \cdots j_M}, \dots, b_{K, j_1 \cdots j_M}$ are related to the same element $x_{j_1 \cdots j_M}$. They are the effects of the same element in distinguishing

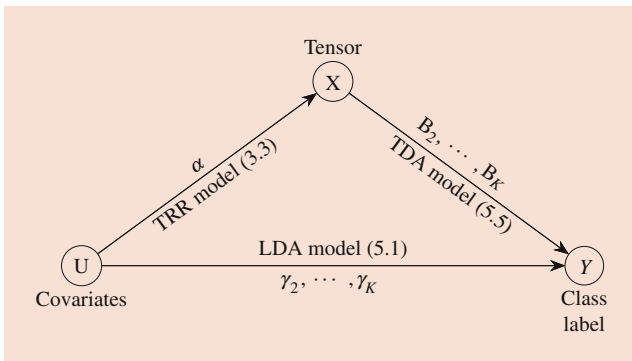

Fig. 39.4 Graphical illustration of the CATCH model. TRR stands for tensor response regression. A similar demonstration was presented in the original proposal of CATCH [61] as well

between different pairs of classes. It follows that the sparsity in \mathbf{B}_k has a group structure:

$$\begin{aligned} x_{j_1 \cdots j_M} \text{ is not important for classification} &\Leftrightarrow b_{2, j_1 \cdots j_M} \\ &= \dots = b_{K, j_1 \cdots j_M} = 0. \end{aligned} \quad (39.40)$$

We will incorporate such sparsity assumption in estimation.

39.5.3 Estimation

Suppose that we collect n observations $\{\mathbf{X}_i, \mathbf{U}_i, Y_i\}_{i=1}^n$. We construct estimators of the parameters in the optimal classifier (39.39). The estimators for $\{\pi_k, \boldsymbol{\phi}_k, \boldsymbol{\gamma}_k, \boldsymbol{\mu}_k, \mathbf{B}_k\}$ can be easily found by maximizing the likelihood function, although we need more notation to ease the presentation. For the observations with $Y_i = k$, let $\tilde{\mathbf{X}}_i = \mathbf{X}_i - \bar{\mathbf{X}}_k$ and $\tilde{\mathbf{U}}_i = \mathbf{U}_i - \bar{\mathbf{U}}_k$ be the centered tensor and vector predictors. We further stack these centered predictors to form $\tilde{\mathbf{X}} \in \mathbb{R}^{p_1 \times \dots \times p_M \times n}$ and $\tilde{\mathbf{U}} \in \mathbb{R}^{q \times n}$, respectively. Straightforward calculation shows that the MLEs are

$$\hat{\pi}_k = \frac{1}{n} \sum_{i=1}^n 1(Y_i = k), \quad \hat{\boldsymbol{\phi}}_k = \bar{\mathbf{U}}_k, \quad \hat{\boldsymbol{\gamma}}_k = \hat{\boldsymbol{\Psi}}^{-1}(\hat{\boldsymbol{\phi}}_k - \hat{\boldsymbol{\phi}}_1), \quad k = 1, \dots, K,$$

$$\hat{\boldsymbol{\alpha}} = \tilde{\mathbf{X}} \times_{(M+1)} \{(\tilde{\mathbf{U}} \tilde{\mathbf{U}}^\top)^{-1} \tilde{\mathbf{U}}\},$$

$$\text{where } \hat{\boldsymbol{\Psi}} = \frac{1}{n} \sum_{k=1}^K \sum_{Y_i=k} (\mathbf{U}_i - \hat{\boldsymbol{\phi}}_k)(\mathbf{U}_i - \hat{\boldsymbol{\phi}}_k)^\top.$$

The estimation for \mathbf{B}_k requires more attention, though, as we want to impose sparsity. A most popular way to obtain sparse estimates is to apply penalization. But to use penalty functions, we first need to find an estimating equation for \mathbf{B}_k . We note that, on the population level, $\mathbf{B}_2, \dots, \mathbf{B}_K$ are the solution to the following optimization problem:

$$\begin{aligned} (\mathbf{B}_2, \dots, \mathbf{B}_K) &= \arg \min_{\mathbf{B}_2, \dots, \mathbf{B}_K} \sum_{k=2}^K \{ \langle \mathbf{B}_k, \llbracket \mathbf{B}_k; \boldsymbol{\Sigma}_1, \dots, \boldsymbol{\Sigma}_M \rrbracket \rangle \\ &\quad - 2 \langle \mathbf{B}_k, \boldsymbol{\mu}_k - \boldsymbol{\mu}_1 \rangle \}. \end{aligned} \quad (39.41)$$

Equation (39.41) can be used as an estimating equation as long as we find estimates of $\boldsymbol{\Sigma}_m$ and $\boldsymbol{\mu}_k$. By the properties of the tensor normal distribution in Sect. 39.1.4, we construct the following moment-based estimators:

$$\begin{aligned} \hat{\boldsymbol{\mu}}_k &= \bar{\mathbf{X}}_k - \hat{\boldsymbol{\alpha}} \bar{\mathbf{x}}_{(M+1)} \bar{\mathbf{U}}_k, \quad k = 1, \dots, K, \\ \hat{\boldsymbol{\Sigma}}_j &= \tilde{s}_{j,11}^{-1} \tilde{\mathbf{S}}_j \text{ for } j = 1, \dots, M-1; \quad \hat{\boldsymbol{\Sigma}}_M = \frac{\widehat{\text{var}}(X_{1\dots 1})}{\prod_{j=1}^M \tilde{s}_{j,11}} \tilde{\mathbf{S}}_M, \end{aligned}$$

where $\tilde{\mathbf{S}}_j = (n \prod_{l \neq j} p_l)^{-1} \sum_{i=1}^n \hat{\mathbf{E}}_{(j)}^i (\hat{\mathbf{E}}_{(j)}^i)^\top$ with $\hat{\mathbf{E}}_{(j)}^i = \mathbf{X}^i - \hat{\boldsymbol{\mu}}_k - \hat{\boldsymbol{\alpha}} \bar{\mathbf{x}}_{(M+1)} \mathbf{U}^i = (\mathbf{X}^i - \bar{\mathbf{X}}_k) - \hat{\boldsymbol{\alpha}} \bar{\mathbf{x}}_{(M+1)} (\mathbf{U}^i - \bar{\mathbf{U}}_k)$. We

Table 39.1 Classification errors on the ADHD datasets. Reported error rates are averages based on 100 replicates, and standard errors are in parentheses. CP-GLM is not applicable for multiclass problem because multinomial logistic has not been implemented

	CATCH		CP-GLM		ℓ_1 -logistic regression		ℓ_1 -SVM	
Binary	22.79	(0.2)	25.05	(0.19)	23.99	(0.16)	27.54	(0.31)
Multiclass	35.22	(0.25)	NA		35.66	(0.21)	41.28	(0.32)

plug in these estimators and add the group-Lasso penalty to (39.41). The parameters \mathbf{B}_k are estimated by

$$\min_{\mathbf{B}_2, \dots, \mathbf{B}_K} \left[\sum_{k=2}^K \langle \mathbf{B}_k, [\mathbf{B}_k; \hat{\Sigma}_1, \dots, \hat{\Sigma}_M] \rangle - 2 \langle \mathbf{B}_k, \hat{\mu}_k - \hat{\mu}_1 \rangle \right. \\ \left. + \lambda \sum_{j_1 \dots j_M} \sqrt{\sum_{k=2}^K b_{k, j_1 \dots j_M}^2} \right], \quad (39.42)$$

The problem in (39.42) can be solved by a blockwise coordinate descent algorithm where in each step we soft-threshold $b_{k, j_1 \dots j_M}$, $k = 2, \dots, K$. This algorithm is implemented in the R package `catch` available on CRAN. It can be shown that, with a probability of 1, the blockwise coordinate descent algorithm converges to the global minimizer.

The CATCH classifier is also supported by theoretical results. When $\log p_m = o(n)$, under mild conditions the CATCH classifier converges to the optimal classifier. The classification error of CATCH converges to the lowest classification error possible as well.

39.6 A Real Data Example

We demonstrate the performance of CATCH and CP-GLM on a real dataset regarding the attention-deficit hyperactive disorder (ADHD). The ADHD dataset is shared by Neuru Bureau at https://fcon_1000.projects.nitrc.org/indi/adhd200/. The results in this section were originally reported by Pan et al. [61].

The ADHD dataset contains complete rs-fMRI and s-MRI data of 930 subjects. These subjects are divided into four categories: typically developing children (TDC), ADHD combined, ADHD hyperactive, and ADHD inattentive. In addition to the images, age, gender, and handedness are also recorded. Because of the apparent difference between genders, we stratify the data according to the gender of each subject. The MRI data are treated as the tensor predictor (\mathbf{X}), while age and handedness are treated as the vector predictor (\mathbf{U}). The MRI data are preprocessed to be of size $24 \times 27 \times 24$. Two classification problems are considered: a binary problem where we predict whether a subject shows hyperactivity and a three-class problem where subjects are classified into typically developing children (TDC), ADHD combined/hyperactive, and ADHD inattentive.

We repeatedly form training sets of 762 subjects and testing sets of 168 subjects. Two well-known classifiers, ℓ_1 -logistic regression [31, 33] and ℓ_1 -support vector machine (SVM) [2, 4, 20, 22, 32], are also included as baselines. The results are listed in Table 39.1. The tensor methods are very competitive, yielding similar or better accuracies than the baselines.

Abstract

One of the most commonly encountered problems in biomedical studies is analyzing censored survival data. Survival analysis differs from standard regression problems by one central feature: the event of interest may not be fully observed. Therefore, statistical methods used to analyze this data must be adapted to handle the missing information. In this chapter, we provide a brief introduction of right-censored survival data and introduce survival random forest models for analyzing them. Random forests are among the most popular machine learning algorithms. During the past decade, they have seen tremendous success in biomedical studies for prediction and decision-making. In addition to the statistical formulation, we also provide details of tuning parameters commonly considered in practice. An analysis example of breast cancer relapse free survival data is used as a demonstration. We further introduce the variable importance measure that serves as a variable selection tool in high-dimensional analysis. These examples are carried out using a newly developed R package RLT, which is available on GitHub.

40.1 Right-Censored Data and Survival Analysis

Survival analysis focuses mainly on analyzing time-to-event data. However, the event times may not be fully observed due to losing a subject to follow-up, the study ending before all

subjects experience the event, or due to other reasons. This information loss is referred to as censoring. In this chapter, we consider only the most commonly encountered censoring type: right censoring. To be specific, assume that each subject is waiting to experience a failure event, with the (random) waiting time denoted as T . T is also commonly referred to as the failure time. The subject may also be at risk of being lost to follow-up, which would happen at a (random) censoring time C . When C happens before T , we have a right-censoring scenario in the sense that the failure time is at the right-hand side of the censoring time. Hence, the failure time T cannot be fully observed, and we observe C instead.

Following standard notations in survival analysis literature, e.g., [1], let $\mathcal{D}_n = \{\mathbf{x}_i, y_i, \delta_i\}_{i=1}^n$ be a set of n independently and identically distributed (i.i.d.) observed copies of the triplet $\{\mathbf{X}, Y, \Delta\}$, where \mathbf{X} is a p -dimensional random covariate vector, Y is the observed outcome defined as $Y = \min(T, C)$, where T is the random time until the event of interest and C is the random time until the subject is lost to follow-up. We only observe the shorter of the two times. Lastly, $\Delta = \mathbb{1}(T \leq C)$ is a censoring indicator, which indicates if subject i experienced the event of interest or was lost to follow-up. Note that both T and C may depend on the covariate vector \mathbf{X} and, therefore, so do Y and Δ . Using the observed data \mathcal{D}_n , our main goal is to estimate the conditional survival function of T , defined as

$$S(t, \mathbf{x}) = P(T > t | \mathbf{X} = \mathbf{x}). \quad (40.1)$$

The survival function is also one minus the cumulative distribution function $F(t, \mathbf{x})$, defined as $P(T \leq t | \mathbf{X} = \mathbf{x})$. Similar notations are used for other quantities in the remaining parts of this section. Two important related concepts are the cumulative hazard function (CHF), defined as

$$\Lambda(t, \mathbf{x}) = -\log\{S(t, \mathbf{x})\}, \quad (40.2)$$

and the hazard function, defined as

$$\lambda(t, \mathbf{x}) = d\Lambda(t, \mathbf{x})/dt. \quad (40.3)$$

It is then easy to see that knowing any of the above quantities will allow us to calculate the rest. It should also be noted that, for identifiability issues [1], we often assume conditional independence ($T \perp C | \mathbf{X}$), which essentially states that given the covariate values \mathbf{X} , the failure time and censoring time do not provide any additional information to each other. An example that violates this assumption is when C could, with a certain probability, happen at $T - q$ for some unknown value q . In that case, we will not be able to estimate the distribution of T . For information regarding statistical properties and assumptions of survival analysis models, we refer to [1].

40.1.1 Survival Estimation

To facilitate later arguments, we introduce two methods for estimating a survival function given the data $\{y_i, \delta_i\}_{i=1}^n$. First, a Nelson-Aalen estimator [2, 3] for the cumulative hazard function is defined as

$$\hat{\Lambda}(t) = \sum_{k:t_k \leq t} \frac{\sum_{i=1}^n \mathbb{1}(\delta_i = 1) \mathbb{1}(y_i = t_k)}{\sum_{i=1}^n \mathbb{1}(y_i \geq t_k)}, \quad (40.4)$$

where $\{t_1, \dots, t_K\}$ is an ordered set of K unique failure times (y_i 's with $\delta_i = 1$) within the observed data, with t_1 as the minimum. Then, the estimated survival function $\hat{S}(t)$ can be calculated [4] by

$$\hat{S}(t) = e^{-\hat{\Lambda}(t)}. \quad (40.5)$$

Another commonly used estimator for the survival function is the Kaplan-Meier estimator [5], given by

$$\hat{S}(t) = \prod_{k:t_k \leq t} \left\{ 1 - \frac{\sum_{i=1}^n \mathbb{1}(y_i = t_k) \mathbb{1}(\delta_i = 1)}{\sum_{i=1}^n \mathbb{1}(y_i \geq t_k)} \right\}. \quad (40.6)$$

The two estimators are asymptotically equivalent [6] and are both widely used in survival analysis.

For simplicity, no covariate information is used in this section. In later sections, the covariate information will be used to build a random forest, and the following quantities can be used as an estimator at each terminal node and averaged over all trees of a random forest. For details on the estimation process, see Sect. 40.3.2.

40.1.2 Parametric and Semi-Parametric Models for Survival Data

For modeling with covariates, the Cox proportional hazards model [7] is the most popular choice. A Cox model assumes that the effect of covariates acts multiplicatively on the hazard function [8] such that

$$\lambda(t, \mathbf{x}) = \lambda_0(t) \exp(\mathbf{x}^T \boldsymbol{\beta}), \quad (40.7)$$

where $\lambda_0(t)$ is called a baseline hazard function. This assumption also implies that the log hazard ratio is a linear function of the covariates. Furthermore, using the relationships we introduced previously, the survival function can be defined as

$$S(t, \mathbf{x}) = \exp\{-\Lambda_0(t)\} \exp(\mathbf{x}^T \boldsymbol{\beta}), \quad (40.8)$$

where the baseline cumulative hazard $\Lambda_0(t) = \int_0^t \lambda_0(s) ds$. The Cox model is a semi-parametric model in the sense that the hazard (or cumulative hazard) function is modeled non-parametrically, while the effects of covariates are modeled parametrically. The nice property of a Cox model is that these parameters can be estimated by maximizing the partial log-likelihood function, which does not involve estimating the hazard function. To this end, the proportional hazard assumption is crucial for formulating the Cox. Cox model usually works well in practice. However, the proportional hazard assumption can also be restrictive since it implies that the fitted survival curves of the two subjects cannot cross each other. If the underlying true curves cross, a Cox model may fail to capture the effect of the covariates. For an example of proportional versus nonproportional hazards, see Fig. 40.1. The pair in Fig. 40.1a is Exponential(e^X), with $X = 1$ in orange and $X = 2$ in blue. The effect of X satisfies the proportional hazard assumption since the hazard function of an exponential distribution is its rate parameter. The pair in Fig. 40.1b is Beta($\alpha = 5, \beta = 10$) for $X = 0$ in blue and Exponential(3) for $X = 1$ in orange. Their survival functions cross at around 0.4. This intersection may cause trouble for the parameter estimate of X , which does not display a strongly monotone effect on the hazard.

There are many alternatives to the Cox model, including the accelerated failure time model [9], the proportional odds model [10], the frailty model [11], and many others. However, all of these models are composed of specific parametric components and underlying assumptions that could be violated, especially in a high-dimensional setting. In contrast, a random forest model provides a more flexible nonparametric framework for model estimation. We will focus on

introducing a breed of random forest models that can handle right-censored survival outcomes. We start with introducing tree-based models which serve as essential components of a random forests.

40.2 Tree-Based Models

A random forest is an ensemble of trees. Hence, we will first introduce a single tree model as well as its estimation and prediction procedures. A tree model recursively partitions a p -dimensional feature space \mathcal{X} (e.g., $[0, 1]^p$) into disjoint rectangular terminal nodes [12]. The model starts with a root node \mathcal{X} containing all observations and proceeds by constructing binary splits in the form of $\mathbb{1}(\mathbf{x}^{(j)} \leq c)$, where $\mathbf{x}^{(j)}$ denotes the j th variable. It splits the current node into two child nodes based on the output of this indicator function. Note that this methodology does not only split the feature space but also separates the observations into two subsets, one for each child node. The process is then recursively applied to each child node until reaching some stopping criteria, which produces a terminal node that contains a few observations. Following the notation in [6], we denote the collection of terminal nodes in a tree as $\mathcal{A} = \{A_u\}_{u \in \mathcal{U}}$, where \mathcal{U} is a collection of indices. These terminal nodes satisfy two properties: they jointly cover the whole feature space, i.e., $\mathcal{X} = \bigcup_{u \in \mathcal{U}} A_u$, and they do not overlap, i.e., $A_u \cap A_l = \emptyset$ for any $u \neq l$. Throughout the following, we use \mathcal{A} to represent a single tree, i.e., one possible partition of the feature space \mathcal{X} resulting from a binary tree.

As a demonstration, we refer to Fig. 40.2. This tree was built using the R packages `rpart` [13] and `partykit` [14].

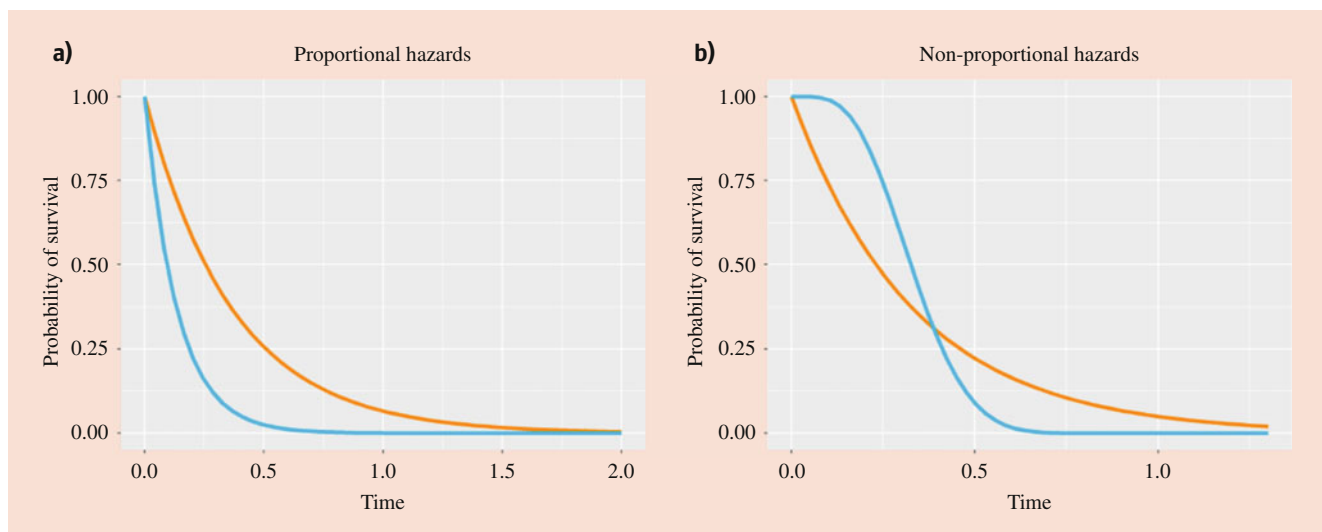

Fig. 40.1 Proportional versus nonproportional hazards. (a) is distributed as Exponential(e^X), where $X = 1$ is orange and $X = 2$ is blue. (b) is distributed as Exponential(3) when $X = 1$ is blue and Beta(5,10) when $X = 0$ is orange

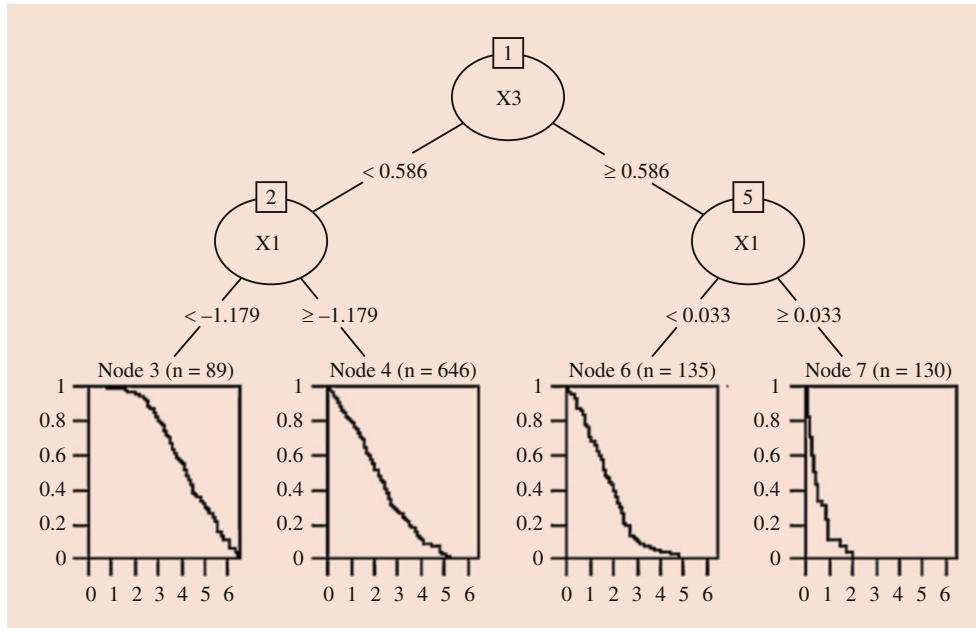

Fig. 40.2 A tree model, built from survival data with $p = 3$ covariates using `rpart` [13] and `partykit` [14]

In this example, $p = 3$ and $n = 1000$ (for more details on the generation of this data, see Sect. 40.6.2). The root node A , at the top of the figure and labeled 1, contains all $n = 1000$ observations. Then the tree has a binary split on $x^{(3)}$ at 0.586. If an observation i has a value of $x_i^{(3)} < 0.586$, it is sent to node A_L , labeled in Fig. 40.2 with a 2. Otherwise, it is sent to node A_R , labeled in this plot with a 5. Then the left and right nodes are each split one more time, creating four terminal nodes that contain 89, 646, 135, and 130 observations, respectively. The survival curves of each terminal node are estimated using the Kaplan-Meier estimator (40.6) and plotted as the terminal nodes. For example, the furthest left terminal node (labeled as *Node 3*) contains 89 observations where $x^{(3)} < 0.586$ and $x^{(1)} < -1.179$, and these limits do not overlap with any other node. It also has the highest estimated survival curve through the entire time domain, which implies that the observations that fall into that node are estimated to have the highest probability of survival. For this tree, $\mathcal{A} = \{A_3, A_4, A_6, A_7\}$, or $\mathcal{A} = \{A_u\}_{u \in \mathcal{U}}$ where $\mathcal{U} = \{3, 4, 6, 7\}$. Also note that, despite the fact $p = 3$, the tree never splits on $x^{(2)}$. Not all variables will necessarily be used for splitting. Hence, a tree model can potentially be a sparse model.

There are many types of trees. They mainly differ in terms of the criteria to find the splitting rule $\mathbb{1}(x^{(j)} \leq c)$. For example, [12] introduced classification and regression trees and [15] outlined survival trees. There is a rich literature of building survival trees, for example [16–18], and [19]. We refer to [20] for a comprehensive review. However, the tree building mechanisms are essentially the same for all these methods. We will introduce a couple of versions that can handle right-censored survival data.

40.2.1 Splitting Mechanism

At any internal node A of a tree \mathcal{A} , we search for a splitting rule $\mathbb{1}(x^{(j)} \leq c)$. This process leads to two child nodes: $A_L = A \cap \{x_i^{(j)} \leq c\}$, i.e., all the observations i from A that have a value of $x_i^{(j)} \leq c$ for a constant c , and $A_R = A \cap \{x_i^{(j)} > c\}$. The best split is the split that maximizes the difference between the observations in A_L and A_R . In the regression and classification settings, the variance reduction and Gini index [12] are commonly used to quantify this difference. In the survival context, any calculation of the differences between two potential child nodes has to account for censoring. In this section, we introduce the log-rank test statistic [1, 15] which is the default choice in many implementations, and an alternative choice, the supremum log-rank test [21], which is more sensitive to the distributional difference between two survival curves.

Log-Rank Test

The log-rank test is a two-sample test that compares the survival distributions of two groups when the observations are subject to censoring. It can be viewed as an analog of the two-sample t test in the regression setting. Here, the two potential child nodes are treated as the two groups in this test. To calculate the log-rank test statistic, we first define a few key quantities. Consider any node A , let $N(t)$ be the total number of at-risk observations at time t , i.e.,

$$N(t) = \sum_{i=1}^n \mathbb{1}(x_i \in A) \mathbb{1}(y_i \geq t), \quad (40.9)$$

and let $O(t)$ be the number of failure observations at time t , i.e.,

$$O(t) = \sum_{i=1}^n \mathbb{1}(x_i \in A) \mathbb{1}(y_i = t) \mathbb{1}(\delta_i = 1). \quad (40.10)$$

For both $N(t)$ and $O(t)$, we can correspondingly define the child node versions for the left and right nodes. Denote these quantities as $N_L(t)$, $N_R(t)$, $O_L(t)$, and $O_R(t)$, where L and R indicate the side. Furthermore, define

$$E_L(t) = O_L(t) \frac{N_L(t)}{N(t)} \quad (40.11)$$

to be the expected failure counts at time t for the left child node. This expectation is based on the intuition that the two groups have the same failure rate at time point t under the null hypothesis. Among the observed y_i values within an internal node A , we again use the notation $\{t_1, \dots, t_K\}$ as the ordered set of uniquely observed failure time points. We can then construct the log-rank test statistic [7] for a possible split as

$$\frac{\sum_{k=1}^K (O_L(t_k) - E_L(t_k))}{\sqrt{\sum_{k=1}^K E_L(t_k) \frac{N_R(t_k)}{N(t_k)} \frac{N(t_k) - O_L(t_k)}{N(t_k) - 1}}}. \quad (40.12)$$

It can be shown that this test statistic follows asymptotically a standard normal distribution, which leads to a valid p value. Essentially, the log-rank test statistic calculates the difference between the observed failure counts and the failure counts that would be expected if the groups came from the same distribution. In the case that the alternative hypothesis is proportional hazards (Fig. 40.1a), this statistic is asymptotically efficient for testing the difference between the two groups. However, this test may also have low power against some alternatives. For example, when the hazards are similar over most of the interval but diverge over a particular segment [21] or the expected values are the same (see Fig. 40.1b and Sect. 40.2.1), the log-rank test may fail. As an alternative, [21] developed a supremum version of the log-rank test statistic, hereafter referred to as the supremum log-rank test statistic.

Supremum Log-Rank Test

In the case of nonproportional hazards or when the distributions diverge but expected values are the same, the power of the supremum log-rank test is higher than that of the log-rank test. Using the same notation as the previous calculations, we can construct the supremum log-rank test [21, 22] statistic for a possible split as

$$\max_{j \in \{1, \dots, K\}} \frac{\left| \sum_{k=1}^j \frac{N_L(t_k) N_R(t_k)}{N(t_k)} \left(\frac{O_L(t_k)}{N_L(t_k)} - \frac{O_R(t_k)}{N_R(t_k)} \right) \right|}{\sqrt{\sum_{k=1}^K \frac{N_L(t_k) N_R(t_k)}{N(t_k)} \frac{O(t_k)}{N(t_k)} \left(1 - \frac{O(t_k) - 1}{N(t_k) - 1} \right)}}. \quad (40.13)$$

Instead of summing over every time point, it searches for a time point that displays the maximum divergence. Hence, the supremum log-rank test can be used to detect any distributional differences between two potential child nodes, rather than comparing the expected failures from the two groups.

Choosing the Best Split

For either the log-rank test or supremum log-rank test, a more significant p value indicates a better split. We exhaust all possible indices $j \in \{1, \dots, p\}$ of the splitting variables and cutting point c from all unique $\mathbf{x}^{(j)}$ values within node A to define the two groups. The splits that leads to the most significant test is then used. However, this exhaustive search may not be required when fitting a random forest model. Section 40.3.3 introduces the details of these modifications. As proposed by Ishwaran et al. [23], the splitting will stop when there are too few failure observations in a node.

A Toy Example

To demonstrate the two splitting rules, we will use a set of samples from the nonproportional hazard distribution setting shown in Fig. 40.1b. We randomly sample 60 failure times T_{is} , with 30 of them from Exponential(3) and another 30 from Beta(5,10). We use a corresponding covariate value $x_i^{(1)} = 0$ or 1 to indicate their group. For all observations, the censoring times C are generated independently from a Uniform(0,1) distribution to calculate the observed time y and censoring indicator δ . Therefore, the maximum observed time is less than or equal to 1, as the censoring time has an upper bound. Additionally, we generated another group indicator $x_i^{(2)}$ with $P(x_i^{(2)} = 0) = P(x_i^{(2)} = 1) = 0.5$ independently from all other quantities. This covariate mimics the situation that we might be facing with other noise variables that are not associated with survival time. For more details on this simulation, see the sample code provided in the supplementary material (Sect. 40.8).

The log-rank test statistic using $x^{(1)}$ as the group indicator is 1.57, with a p -value of 0.2. When we use $x^{(2)}$ as the group indicator, we get a log-rank test statistic of 3.64, with a p -value of 0.06. For a split on this node using these results, we would choose to split on $x^{(2)}$ with a cutting point between 0 and 1. However, take a look at Fig. 40.3 again. The true distributions of both groups have an expected survival time equal to 1/3, but these two groups do not have the same true survival distribution. There is about an equal area where the orange line is greater than the blue line as the opposite. Therefore, the log-rank test has trouble detecting the difference between these particular two groups. On the other hand, the supremum log-rank test for $x^{(1)}$ yields a p -value of 0.05 compared to $x^{(2)}$ with a p -value of 0.11. As the supremum log-rank test searches over the domain for the section of greatest divergence, it selects the signal variable first.

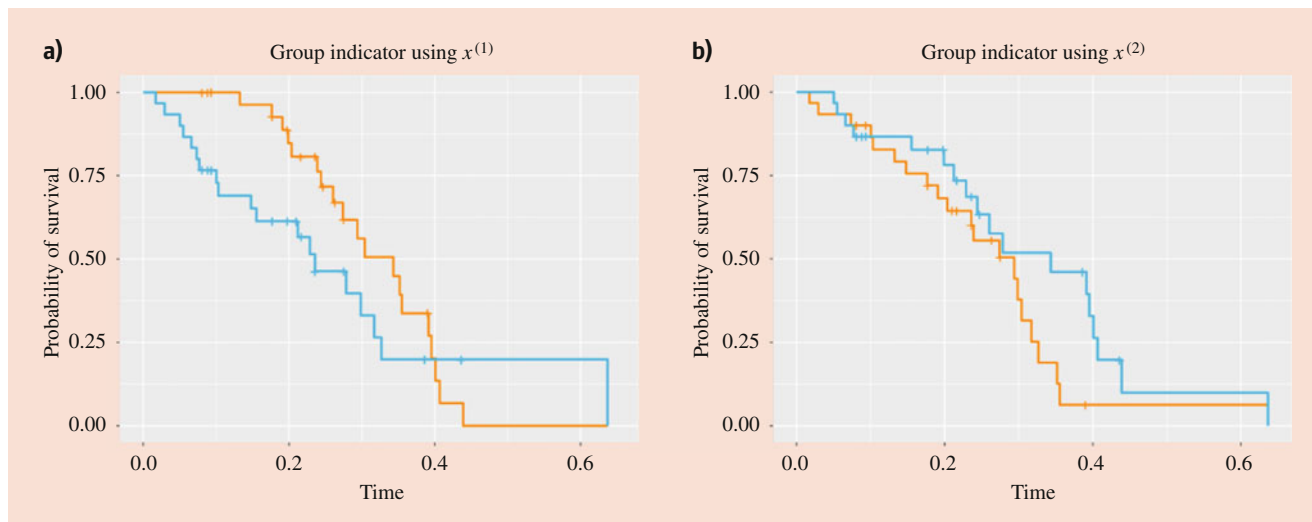

Fig. 40.3 (a): A sample of 30 observations from each of the distributions referenced in 40.1b. $x^{(1)} = 0$ is from Exponential(3) (orange), $x^{(1)} = 1$ is from Beta(5,10) (blue). (b): the same sample as in (a),

but $x^{(2)}$ is randomly assigned as 0 (orange) or 1 (blue). “+” indicates censored observations. The survival curves are estimated using the Kaplan-Meier estimator (40.6)

Other Splitting Rules

There are many variations on survival trees and survival splitting rules. Besides the literature above, [24] uses the imputation of censored data to improve prediction, and [6,25] develop splitting rules that correct the bias caused by the censoring distribution. For more splitting rules that can account for bias, see Sect. 40.6. After splitting is complete, one possible next step is to prune the tree: starting from the fully fitted tree, remove unnecessary branches to prevent overfitting. For example, the cost-complexity pruning is used in [12] for the regression setting. For general concepts of overfitting in statistical learning algorithms, we refer to [26].

40.2.2 Tree Prediction

Using a partition of the feature space, we can produce predictions for any target point $\mathbf{x}_0 \in \mathcal{X}$. For survival analysis, the prediction for \mathbf{x}_0 is simply the survival function estimator as defined in (40.4) or (40.6) applied to the data from the terminal node that contains \mathbf{x}_0 . For example, the Nelson-Aalen estimator for the target point is given by

$$\widehat{\Lambda}(t, \mathbf{x}_0) = \sum_{k:t_k \leq t} \frac{\sum_{i=1}^n \mathbb{1}(\delta_i = 1) \mathbb{1}(y_i = t_k) \sum_u \mathbb{1}(\mathbf{x}_0 \in A_u) \mathbb{1}(\mathbf{x}_i \in A_u)}{\sum_{i=1}^n \mathbb{1}(y_i \geq t_k) \sum_u \mathbb{1}(\mathbf{x}_0 \in A_u) \mathbb{1}(\mathbf{x}_i \in A_u)}. \quad (40.14)$$

This formula resembles a form of the kernel estimator [27, 28] (see Sect. 40.7 for more details), making tree-based methods nonparametric by nature. From this point forward,

we will use the shortened notation, which indicates whether two points \mathbf{x}_i and \mathbf{x}_j ever fall into the same terminal node in a given tree:

$$K(\mathbf{x}_i, \mathbf{x}_j) = \sum_{u \in \mathcal{U}} \mathbb{1}(\mathbf{x}_i \in A_u) \mathbb{1}(\mathbf{x}_j \in A_u). \quad (40.15)$$

Then the Nelson-Aalen formula for a terminal node becomes

$$\widehat{\Lambda}(t, \mathbf{x}_0) = \sum_{k:t_k \leq t} \frac{\sum_{i=1}^n \mathbb{1}(\delta_i = 1) \mathbb{1}(y_i = t_k) K(\mathbf{x}_0, \mathbf{x}_i)}{\sum_{i=1}^n \mathbb{1}(y_i \geq t_k) K(\mathbf{x}_0, \mathbf{x}_i)}. \quad (40.16)$$

However, a tree model and its induced kernel function are not smooth because there are abrupt jumps in the prediction once the target point moves from one terminal node to another. To introduce a smoother and more stable model, we can build many trees with variations and average them.

40.3 Random Forests for Right-Censored Survival Data

40.3.1 An Ensemble of Trees with Randomness

Random forest proposed by Breiman [29] is a prediction model that consists of a collection of trees, with bootstrap samples [30] and random feature selections [31, 32] incorporated into each tree. The tree construction process stops when the node sample size is sufficiently small, and the algorithm does not perform pruning. Each tree produces a prediction model for the outcome variable, and the forest generates

a prediction from the average of the tree predictions [29] in the regression setting, while majority voting is used for classification. Random forests have been adapted to many settings besides regression and classification, such as survival analysis [23, 24, 33], quantile regression [34], unsupervised learning [35], etc.

Random forests [29] utilize two main mechanics to control for over-fitting and to reduce correlations among trees: bagging and random feature selection. To build each tree, the bagging (bootstrap aggregating) procedure takes bootstrap samples from the original data set [30]. Then trees are grown using each bootstrap sample. These trees are then averaged to produce a forest prediction. Note that other implementations also consider sampling without replacement [36]. These choices may affect the calculation of other quantities, such as the variable importance measure that will be introduced later in Sect. 40.4.

The second main mechanic for controlling over-fitting is the random feature selection. This procedure takes place within the tree-building process. When trying to find a split at any internal node, the algorithm considers only a set of randomly selected `mtree` variables without replacement. The splitting variables will be searched only within this set at this internal node. When proceeding to the next node, this set will be regenerated. This method is motivated by works such as [31] and [32] which lead to less correlated trees. By the corresponding statistical theory, averaging weakly correlated estimators (trees) results in a smaller variation of the averaged estimator (random forest). Hence, the prediction accuracy of a random forest may be significantly better than a simple tree version.

We note that there are other possible random mechanisms such as the extremely randomized trees proposed by Geurts et al. [37] that considers choosing random cut points when splitting an internal node. In this case, one or several random cut points are generated for each variable. The splitting test statistic is calculated for each of them, and the best split among them is selected. This mechanism further reduces the correlation among trees and has a significant computational advantage due to less number of evaluations of the test statistics.

40.3.2 Ensemble Prediction

Random forest prediction is, in most cases, an averaged tree predictor. For example, the prediction for a target point based on a single tree is from one of the terminal nodes in a tree $\mathcal{A} = \{A_u\}_{u \in \mathcal{U}}$. For a random forest, we have a collection of B such trees, which can be denoted as $\{\mathcal{A}_b\}_{b=1}^B = \{\{A_u^b\}_{u \in \mathcal{U}^b}\}_{b=1}^B$. Based on Eq. (40.14), we obtain a set of predictions $\hat{\Lambda}_b(t, \mathbf{x}_0)$, $b = 1, \dots, B$, calculated using

$$\hat{\Lambda}_b(t, \mathbf{x}_0) = \sum_{k:t_k \leq t} \frac{\sum_{i=1}^{n_b} \mathbb{1}(\delta_i^b = 1) \mathbb{1}(y_i^b = t_k) K_b(\mathbf{x}_i, \mathbf{x}_0)}{\sum_{i=1}^{n_b} \mathbb{1}(y_i^b \geq t_k) K_b(\mathbf{x}_i, \mathbf{x}_0)}, \quad (40.17)$$

where $\{\mathbf{x}_i^b, y_i^b, \delta_i^b\}_{i=1}^{n_b}$ is the set of bootstrap/resampling observations used in the b th tree and $K_b(\mathbf{x}_i, \mathbf{x}_0) = \sum_{u \in \mathcal{U}^b} \mathbb{1}(\mathbf{x}_i \in A_u^b) \mathbb{1}(\mathbf{x}_0 \in A_u^b)$ is the corresponding kernel (see Eq. (40.15)) that indicates whether \mathbf{x}_i and \mathbf{x}_j fall in the same terminal node in tree b . Then the forest survival function estimator is simply aggregating these tree estimators with

$$\hat{\Lambda}(t, \mathbf{x}_0) = \frac{1}{B} \sum_{b=1}^B \hat{\Lambda}_b(t, \mathbf{x}_0), \quad (40.18)$$

while the survival function can be calculated using

$$\hat{S}(t, \mathbf{x}_0) = e^{-\hat{\Lambda}(t, \mathbf{x}_0)}. \quad (40.19)$$

We may also consider alternative definitions of the survival function estimation. For example, [24] considered directly averaging the Kaplan-Meier estimators [5] (40.6) from each tree. Another possibility is to view the entire forest as a single kernel, stacked from each individual tree. Then the kernel version of the cumulative hazard function can be defined as

$$\hat{\Lambda}(t, \mathbf{x}_0) = \sum_{k:t_k \leq t} \frac{\sum_b \sum_{i=1}^{n_b} \mathbb{1}(\delta_i^b = 1) \mathbb{1}(y_i^b = t_k) K_b(\mathbf{x}_i, \mathbf{x}_0)}{\sum_b \sum_{i=1}^{n_b} \mathbb{1}(y_i^b \geq t_k) K_b(\mathbf{x}_i, \mathbf{x}_0)}. \quad (40.20)$$

Similar approaches of the kernel version of random forests have been considered in the regression [38] and generalized versions [39]. However, it has yet been reported if any of the aforementioned averaging method lead to superior performance.

40.3.3 Tuning Parameters

Tuning parameter selection is probably the most important part in the application of random forests. There are many R packages such as `randomForest` [40], `randomForestSRC` [41], and `ranger` [42] that offers a variety of tuning parameter. We will use a newly developed R package `RLT` [43] as demonstration. The `RLT` package offers both standard tuning parameters and addition features that improve the model fitting process and computational performance. It is available on GitHub. The major tuning parameters involved in a random forest aim at controlling the randomness across different trees and the splitting mechanism.

- Sampling size (`resample.prob`): The proportion of the total sample used for building each tree. In RLT, `resample.prob = 1` means each tree is fitted using n observations.
- Sampling type (`resample.replace`): Whether the resampling of observations for a tree is done with or without replacement. In RLT, `resample.replace=TRUE` indicates sampling with replacement.
- Number of trees (`ntrees`): The default value for `ntrees` is 500. This value should be set as a relatively large number so that the averaged model is stable.
- Number of random features sampled (`mtry`): This implements the random feature selection at each internal node and only compares these selected features to search for the best splitting rule. Common settings are `mtry = \sqrt{p}` , `$p/3$` , and possibly `p` , which exhausts all variables.
- Splitting score (`split.rule` under `param.control` settings): The type of measure used to pick the best split. The options for survival analysis are "logrank" (40.12) and "suplogrank" (40.13).
- Type of search for the cutting point (`split.gen`): The method used to generate potential cutting points for a splitting rule. The common choices are `split.gen = "best"` or "random". "best" is the mechanism described Sect. 40.2.1: it considers all possible splits. "random" generates a set of random cutting point and selects the best among them. This setting mimics the mechanism proposed in [37].
- Number of random splits (`nsplit`): if `split.gen = "random"`, this parameter controls the number of randomly generated cutting points. This number is usually small to achieve computational efficiency.
- Terminal node size (`nmin`): Splitting will not occur on a node with less than $2 \times nmin$ observations. Under random splitting, there may not be at minimum `nmin` observations at a terminal node. For survival analysis, it can be beneficial to require $2 \times nmin$ number of observed failure events to perform a split.
- Child node size control (`alpha` under `param.control` settings): At an internal node, if the sample size is n , `alpha` ensures each child node contains at least `alpha \times n` observations. This parameter is not effective when the `split.gen = "random"`. Setting a nonzero `alpha` value can ensure additional theoretical properties especially when `nmin` is small.
- Variable importance control (`importance`): Whether variable importance (see Sect. 40.4) should be calculated. In RLT, `importance=FALSE` will not calculate variable importance, which will make the algorithm faster if this measure is not desired for the analysis.

Finally, we provide a high-level algorithm for general random forest models in Algorithm 1. Note that for different

types of random forest models, the main differences are the splitting rule and terminal node estimation.

Algorithm 1: General algorithm for random forest models

Input: Training data set \mathcal{D}_n and parameters from Sect. 40.3.3.
Let $B = n_{trees}$.

```

1 for  $b = 1$  to  $B$  do
2   Initiate  $A = \mathcal{X}$ , a bootstrap sample  $\mathcal{D}_n^b$  of size
   resample.prob  $\times$  n from  $\mathcal{D}_n$ , and the set of terminal
   nodes  $\mathcal{A}_b = \emptyset$ ;
3   At a node  $A$ , if  $\sum_{x_i \in \mathcal{D}_n^b} \mathbb{1}(x_i \in A) < 2 \times nmin$ , proceed
   to Line 5. Otherwise, construct a splitting rule
   (Sect. 40.2.1) such that  $A = A_L \cup A_R$ , where  $A_L \cap A_R = \emptyset$ 
   and  $\min(\sum_{x_i \in A} \mathbb{1}(x_i \in A_L), \sum_{x_i \in A} \mathbb{1}(x_i \in A_R)) >$ 
   alpha  $\times$   $\sum_{x_i \in \mathcal{D}_n^b} \mathbb{1}(x_i \in A)$ ;
4   Send the two child nodes  $A_L$  and  $A_R$  to Line 3 separately;
5   Conclude the current node  $A$  as a terminal node and update
    $\mathcal{A}_b = \mathcal{A}_b \cup A$ .
6 end
7 return  $\{\mathcal{A}_b\}_{b=1}^B$ .
```

40.3.4 Evaluation Criteria for Survival Models

For regression, the commonly used error is the mean squared error. Classification models often use the misclassification rate. When calculating the error for a survival model, we have to compare a fitted function (hazard or survival function) with the observed survival outcomes. There are two popular survival error metrics used in practice: the C-index error [44] and the Brier Score error [45]. Other possible choices, such as the Cox-Snell residual and the martingale residual, are more commonly used for diagnosis in semi-parametric models.

The C-index is essentially a classification measure adjusted for censoring. It measures the probability that, for two randomly drawn subjects, the subject with the lower survival time is classified correctly as having a worse prediction (higher hazard function or lower survival function) than the other subject. However, since these functions are varying according to t , we need a scalar summary of the prediction to indicator whether a prediction is better or worse. As proposed in [23], this prediction is defined as

$$v_i = \sum_{k=1}^K \widehat{\Lambda}(t_k, \mathbf{x}_i), \quad (40.21)$$

for each subject i . Hence, $v_i < v_j$ indicates that subject j has a worse predicted outcome than subject i . Then, we calculate the ratio of corrected classified pairs over permissible pairs, where the number of permissible pairs is defined as

$$P = \sum_{\substack{i < j: y_i \neq y_j, \\ \delta_i = 1 \text{ if } y_i < y_j, \\ \text{or } \delta_j = 1 \text{ if } y_j < y_i}} 1 + \sum_{\substack{i < j: y_i = y_j \\ \text{and } \delta_i + \delta_j > 0}} 1,$$

and the number of correctly classified pairs is

$$\begin{aligned}
 C = & \sum_{\substack{i < j: y_i < y_j \\ \delta_i = 1}} \left\{ \mathbb{1}(v_i > v_j) + 0.5 \cdot \mathbb{1}(v_i = v_j) \right\} \\
 & + \sum_{\substack{i < j: y_j < y_i \\ \delta_j = 1}} \left\{ \mathbb{1}(v_i < v_j) + 0.5 \cdot \mathbb{1}(v_i = v_j) \right\} \\
 & + \sum_{\substack{i < j: y_j = y_i \\ \delta_i = 1, \delta_j = 1}} \left\{ \mathbb{1}(v_j = v_i) + 0.5 \cdot \mathbb{1}(v_j \neq v_i) \right\} \\
 & + \sum_{\substack{i < j: y_j = y_i \\ \delta_i + \delta_j = 1}} 0.5 \cdot \left\{ 1 + \mathbb{1}(v_j > v_i) \mathbb{1}(\delta_j = 1) + \mathbb{1}(v_i > v_j) \mathbb{1}(\delta_i = 1) \right\}.
 \end{aligned}
 \tag{40.22}$$

Then the C-index for a prediction function \hat{f} is simply

$$\text{C-index} = \frac{C}{P}, \tag{40.23}$$

with larger values indicating better model fits. The C-index error is then $1 - C/P$.

Another choice is the Brier score, which was first introduced by Brier [46] as a classification measure and eventually adjusted for survival [45]. Unlike the C-index, the Brier score requires the conditional censoring distribution $G(t, \mathbf{x}) = P(C > t | \mathbf{X} = \mathbf{x})$ to be specified. Since the true censoring distribution is unknown, the performances of a Brier score can be affected by the choice of the censoring model to estimate this distribution. In practice, this is often simplified to a marginal censoring distribution $G(t) = P(C > t)$, which can be estimated through a Kaplan-Meier estimator (40.6) using the data with $1 - \delta_i$ as the censoring indicator. Alternatively, one can estimate the conditional function $G(t, \mathbf{x})$ using a Cox proportional hazard model with the same strategy of reversing the censoring indicator. Using an estimator $\hat{G}(t, \mathbf{x})$, the Brier Score at time t can be calculated as

$$\begin{aligned}
 \text{BS}(t) &= \frac{1}{n} \sum_{i=1}^n \left(\frac{\mathbb{1}(y_i \leq t) \mathbb{1}(\delta_i = 1) \hat{S}(t, \mathbf{x}_i)^2}{\hat{G}(y_i^-, \mathbf{x}_i)} + \frac{\mathbb{1}(y_i > t) (1 - \hat{S}(t, \mathbf{x}_i))^2}{\hat{G}(t, \mathbf{x}_i)} \right),
 \end{aligned}
 \tag{40.24}$$

where y^- is the left limit to incorporate the fact that $\hat{G}(t, \mathbf{x})$ is often times not smooth. Note that the Brier Score is only defined on a single time point, we often use the integrated Brier Score to summarize the errors. This is defined as

$$\text{IBS}(\hat{f}) = \int_{t=0}^{\tau} \text{BS}(t) dt, \tag{40.25}$$

where τ is a pre-chosen maximal time point, e.g., the maximum observed failure time. The integral has to be calculated as a summation over all observed time points in practice.

It should be noted that if the observed data are extremely noisy, empirical evaluations of both C-index and Brier score could be insensitive to the performance.

40.3.5 Out-of-Bag Error

When using sampling with replacement (bootstrap) in random forests, a sample size of n consists of approximately $0.632 \times n$ unique samples. This is based on the fact that each observation has a $1 - 1/n$ chance not to be selected if we randomly pick one observation and the probability of being in the testing data is then $(1 - 1/n)^n$, which converges to e^{-1} . This means that each tree excludes about one-third of the data. These excluded observations are called the out-of-bag samples (corresponding to the particular tree). It also allows calculation of prediction error by treating them as an independent testing set against the corresponding tree. This testing set is particularly useful when evaluating the model performance and selecting variables. The resulting test error is referred to as the out-of-bag error for the corresponding tree. The mechanism of out-of-bag error is essentially a type of cross-validation. However, as an ensemble method, random forests have their unique way of aggregating these out-of-bag errors over the entire forest. Hence it does not require explicitly splitting the data into training and testing samples.

For each of the training observations, we may look at all the trees that do not use that observation for building the tree, i.e., the observation is in the out-of-bag sample of these trees. As long as `resample.replace=TRUE` or `resample.prob<1`, there will be an out-of-bag sample, and the out-of-bag error can be calculated. Denote the collection of such out-of-bag samples as $\{\mathcal{L}_b^{\text{oob}}\}_{b=1}^B$. The out-of-bag prediction for \mathbf{x}_i is the average prediction over the trees that exclude \mathbf{x}_i . In the survival case, (40.18) would be modified to

$$\hat{\Lambda}_{\text{oob}}(t, \mathbf{x}_i) = \frac{1}{\sum_{b=1}^B I(\mathbf{x}_i \in \mathcal{L}_b^{\text{oob}})} \sum_{b=1}^B I(\mathbf{x}_i \in \mathcal{L}_b^{\text{oob}}) \hat{\Lambda}_b(t, \mathbf{x}_i). \tag{40.26}$$

This prediction can then be compared with the observed outcome value $\{y_i, \delta_i\}$ to calculate a prediction error, such as the C-index or Brier score.

40.4 Variable Selection via Variable Importance in High-Dimensional Settings

High-dimensional data are commonly observed in biomedical studies. Gene expression data sets often consist of 30K~35K variables. Variable selection tools are highly

desirable for handling large amounts of variables. Random forests provide a built-in mechanism, the variable importance measure, for estimating and ranking the contribution of each variable. This measure is again a by-product of the bootstrapping and out-of-bag prediction errors. The basic procedure works as follows:

- For the b th tree, calculate the prediction error of the out-of-bag samples $\mathcal{L}_b^{\text{oob}}$ using the fitted tree. Denote the out-of-bag error as Err_b for $b = 1, \dots, B$.
- For each tree, take the out-of-bag samples and randomly shuffle the values of a variable j within these samples. Using this newly created out-of-bag data, evaluate the prediction error. Denote the errors as $\text{Err}_b^{(j)}$, for $b = 1, \dots, B$ and $j = 1, \dots, p$.
- Calculate the j th variable importance as

$$\text{VI}(j) = \frac{1}{B} \sum_{b=1}^B \frac{\text{Err}_b^{(j)}}{\text{Err}_b} - 1.$$

Alternatively, one can also use $B^{-1} \sum_{b=1}^B (\text{Err}_b^{(j)} - \text{Err}_b)$. In practice, we may use any of the previously introduced error metrics for Err_b . The logic behind the variable importance measure is that after randomly shuffling a variable j within the out-of-bag data, its association with the outcome is destroyed. Hence, if this variable is initially informative for predicting the survival time, the prediction error $\text{Err}_b^{(j)}$ should be much larger than Err_b calculated from original data due to this loss of information. Hence, by taking the averaged ratio (or difference) of the two, and subtracting one, the variable importance measure should be positive. On the other hand, if a variable is non-informative for predicting the outcome, we would expect its variable importance to be approximately zero. Theoretical analysis of the variable importance under regression settings has been done by Zhu et al. [43], which essentially explains these properties. However, note that the variable importance relies on the behavior of the fitted tree models. Therefore, random forest with different turnings may lead to different rankings of the variable importance. As a consequence, the variable importance from a random forest should be interpreted as the importance reflected from the model itself, rather than the importance of the underlying truth. Of course when random forest can consistently estimate the underlying model [47], the two concepts are asymptotically the same. These subtle differences are often ignored in practice.

40.4.1 Other Methods for Calculating Variable Importance

The process mentioned above (hereafter referred to as “permutation variable importance”) is not the only way to

determine which variables have more predictive power. The most naive approach is simple: count the number of times each variable is used as a splitting variable within the forest and rank accordingly [48]. However, the naive method is strongly biased toward selecting continuous variables, as these variables have more places to split.

One potential issue with permutation variable importance arises when the variables are correlated [49]. For example, let $\mathbf{x}^{(j)}$ and $\mathbf{x}^{(l)}$ be two correlated variables. When $\mathbf{x}^{(j)}$ is permuted, $\mathbf{x}^{(l)}$ will still have its original values. Therefore, $\mathbf{x}^{(l)}$ may help correctly classify the observations even without $\mathbf{x}^{(j)}$. In that case, the importance of correlated predictor variables may be suppressed. It should be noted that, from a statistical point of view, these issues are mainly caused by an identifiability issue, in which the focus is variable selection. However, from a prediction point of view, one may be interested in both variables regardless of which is the truth. Hence, again, a variable importance measure may be better interpreted as the importance presented in the current fitted model as we explained previously.

Nonetheless, some existing methods can be used to deal with correlated variables, such as [49] who developed conditional variable importance. Their process is a variation on permutation variable importance that includes conditioning on a second variable. For a variable j , determine all other variables $Z = \{j^{(1)}, j^{(2)}, \dots, j^{(q)}\}$ that are correlated with j . It is suggested in [49] to use only the variables whose correlation with variable j exceeds a certain threshold. Then we calculate conditional variable importance as follows:

- For the b th tree, calculate the prediction error of the out-of-bag samples $\mathcal{L}_b^{\text{oob}}$ using the fitted tree. Denote the out-of-bag error as Err_b for $b = 1, \dots, B$.
- For the b th tree, for each variable in the index set Z , extract the cutting points used to split it and construct a grid by bisecting the sample space using all variables and their corresponding cutting points.
- Randomly shuffle the values of a variable j within each section of the grid. Using this newly shuffled data, evaluate the out-of-bag prediction error. Denote the errors as $\text{Err}_b^{(j|Z)}$, for $b = 1, \dots, B$.
- Calculate the conditional variable importance of the j th variable as

$$\text{VI}(j|Z) = \frac{1}{B} \sum_{b=1}^B \frac{\text{Err}_b^{(j|Z)}}{\text{Err}_b} - 1$$

One obvious problem is that variables j and Z may not occur in the same tree. However, [49] mentioned that with enough trees, the different combinations should appear often enough for an accurate estimate. While [49] developed the method for regression forests, the same process can be adapted to survival forests.

Fig. 40.4 A survival tree with $p = 3$ covariates. Nodes are labeled with depth measure

Another method for variable selection relies on using maximal sub-trees [50] for a variable $x^{(j)}$, defined as “the largest sub-tree (a connected tree within a tree) whose root node is split using” the variable of interest. The associated measure of the variable $x^{(j)}$ ’s strength is the distance from the root of the tree to the maximal sub-tree of $x^{(j)}$. As a smaller distance indicates that $x^{(j)}$ is closer to the root, a smaller value indicates a variable with higher predictive power. For example, consider the tree in Fig. 40.4 from the model defined in Sect. 40.6.2. We generated a plot using `rpart` [13] and `rpart.plot` [51]. There are three sub-trees for $x^{(1)}$: one starting at the split $x^{(1)} < -1.2$, a second at $x^{(1)} < 0.033$, and lastly, one at $x^{(1)} < -0.91$. These three trees have depth 1, 1, and 2, respectively, from the root node. Therefore, the minimal depth of $x^{(1)}$ is 1. $x^{(3)}$ has two sub-trees: one starting at the root node and the other at the split $x^{(3)} < -0.82$. These trees have depth 0 and 2, respectively, for a minimum depth of 0. As $x^{(2)}$ is not used in the tree, its minimum depth is infinity. The advantage of this minimal depth importance is that it does not depend on the particular type of outcome. Hence, it does not rely on the accuracy of the error measurement. Again, all the variable importance measures introduced here rely on the accuracy of the fitted tree model and should be viewed as a way of interpreting the black-box algorithm.

40.5 Example: Breast Cancer Data Analysis

We use the data collected by Wang et al. [52] for analyzing breast cancer relapse time as an illustration of random survival forest. The data is available on the

Gene Expression Omnibus [53] under the ascension number GSE2034 (<https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE2034>). The goal of this analysis is to provide a better way to assess the risk of relapse for patients with lymph-node-negative breast cancer [52]. The code to pull the data, the data itself, and the full code for our analysis are available on Sarah E. Formentini’s GitHub repository (<https://github.com/sarahef2/springer-surv>). We used the RLT package, which is available on GitHub (<https://github.com/teazrq/RLT>) to fit the survival random forest model. In the analysis from [52], the authors used the estrogen receptor (ER) status (+/–) as a stratification factor for analysis. A univariate Cox proportional hazards model was used to identify genetic covariates associated with relapse-free survival for ER+ and ER– individually. The authors further identified 60 genes related to ER+ patients and 16 genes related to ER– patients. Together, the authors refer to this group of 76 genes as a “gene signature.” They show this gene signature to be powerful for predicting high risks of breast cancer relapse [52].

40.5.1 Data Processing and Description

The data has 22,283 genes, the ER status, and the time until relapse for the 286 patients. For this example, we did not use the full 22,283 genetic variables. As [52] defined a 76 variable gene signature, we include these variables in our analysis. We additionally selected the top 500 variables using marginal screening via a Cox proportional hazards model, similar to the initial analysis step in [52], but not stratified by ER status. This selection leads to a total of 552 unique genetic variables in our analysis. To mirror the study in [52], we also included ER status as a covariate. None of the other clinical variables such as age are available online with the rest of the data, so they are not included.

A plot of the marginal survival function stratified by the ER status of patients is given in Fig. 40.5. The patients’ censoring times are marked with “+” on the survival functions. There are only 107 failures in the data set, which gives a total failure rate of 37%. The median observed time until relapse is 28 months, and the median censoring time is 104 months.

40.5.2 Fitting Survival Random Forest

To fit the model, we first consider a set of tuning parameters to select the best tuning. We consider `mtry = \sqrt{p} , $p/3$, and p , $nmin = 1, \log(n)$, and $n^{1/3}$, split.rule=logrank and suplogrank, and split.gen=best and random. For each tuning, we use 20,000 trees, sampling with replacement, and a bootstrap sample size of n . The rest of the tuning parameters were left as their package defaults.`

Fig. 40.5 Marginal survival function until relapse, stratified by ER status. The *orange line* is ER+; the *blue line* is ER-. “+” indicates censored observations

Using the out-of-bag C-index error as the selection criteria, the best combination of parameters is `mtry = $p/3 \approx 184$` , `nmin = 1`, `split.rule=logrank`, and `random split`, with an out-of-bag C-index error of about 0.262. The worst combination, `mtry = p` , `nmin = 1`, `split.rule=logrank`, and `best split`, has an out-of-bag C-index error of 0.296, which is 13% larger. In this case, the worst combination of parameters was the set that tried every single variable and every cutting point on that variable in every node, as well as only requiring a single observation in each terminal node. That model likely overfit to the noise in the fitting data, making it a poor predictor to new data. Additionally, `split.rule=suplogrank` performed rather similarly to `split.rule=logrank`. Alternatively, we could have chosen the best set of parameters using k -fold cross-validation. However, that would have required running the algorithm k times for each combination of parameters, which would be much more computationally expensive.

Using the best tuning parameter settings, we ran the final model and calculated variable importance. Of the top 40 variables by importance (Fig. 40.6), 4 are among the 76 gene signature provided by Wang et al. [52]. The other 36 are from marginal screening. Finally, we plot the fitted survival functions of four subjects. These four subjects were selected based on ER status (“+” and “-”) and the variable with the highest importance, the genetic variable 219478_at (high or low). The chosen subjects have the maximum or minimum value of 219478_at within the ER+ and ER- groups. Their out-of-bag predicted survival curves are plotted in Fig. 40.7. The ER+ subject with a high level of 219478_at has a shorter predicted survival time than the ER+ subject with a low 219478_at value, and a similar effect is observed with the ER- subjects. A large divergence in the most important variable, 219478_at, led to very different predictions.

40.6 Bias and Corrections of Survival Forests

Ideally, we would observe the time until the event in every case. However, due to censoring, we only have incomplete data about the time until the event. This is the central concern of survival analysis. However, parametric and semi-parametric models for handling censored data could be potentially biased if the model is mis-specified. For example, the Cox proportional hazard model is built to handle right censored data. However, when there is no censoring, it does not reduce to a standard linear regression model [54]. The resulting bias is especially pronounced when the hazards are not proportional. Some methods, such as the accelerated failure time model [55], do reduce to an ordinary linear regression model when there is no censoring. However, the problem of bias is not confined solely to linear models.

40.6.1 Biasedness of Survival Forests

In many cases, especially in the case of genetics data, many of the variables may be weakly (or even strongly) correlated. In particular, some variables that affect failure times (“failure variables”) may be correlated with variables that affect censoring times (“censoring variables”). Ideally, we would split primarily on failure variables rather than censoring variables. However, as long as there is a weak dependence, splitting on censoring variables may be unavoidable using the previously mentioned methods [6]. This phenomenon may cause biased tree structure, as well as biased estimations.

Random forest models also suffer biasedness although they are nonparametric in nature. This is mainly caused by the single variable splitting rule. A splitting rule at any internal node essentially compares the survival curves computed from two potential child nodes. Most existing analyses of the Kaplan-Meier estimator assume that the observations are i.i.d. [56, 57] or at least one set of the failure times or censoring times are i.i.d. [58]. However, these assumptions are almost always not true for tree-based methods because both T_i and C_i typically depend on some shared covariates. Thus, by leveraging the standard Kaplan-Meier estimator or Nelson-Aalen estimator, the child node estimations of the survival functions are not the true averaged failure distribution within the node. Hence, splitting on a nonideal covariate may not be avoidable due to an entanglement between the failure and censoring distributions. We shall see this clearly from a toy example in the next section.

40.6.2 A Motivating Example

To demonstrate the problem within forests, consider the example presented in [6], which we duplicated under slightly

Fig. 40.6 Top 40 variables by variable importance, plotted in order. The *blue bars* are the only ones included in the 76 variable gene signature found by Wang et al. [52]

different settings. Consider $n = 1000$ and $p = 3$. The covariate matrix \mathbf{X} follows a multivariate normal distribution with mean 0 and the covariance between $\mathbf{X}^{(1)}$ and $\mathbf{X}^{(2)}$ is 0.8, while $\mathbf{X}^{(3)}$ is independent of both $\mathbf{X}^{(1)}$ and $\mathbf{X}^{(2)}$. The time until event, T , follows $\text{Exponential}(\exp(1.25\mathbf{X}^{(1)} + \mathbf{X}^{(3)} - 2))$. Hence $\mathbf{X}^{(1)}$ contributes a stronger signal than $\mathbf{X}^{(3)}$. For better understanding, we consider the split at the root node. As such, ideally, the random forest would always split on $\mathbf{X}^{(1)}$ first.

We use two types of censoring distributions. In the first scenario, censoring time is distributed as $\text{Exponential}(\exp(-2))$, so the censoring distribution is independent of all the variables in \mathbf{X} . In the second scenario, the censoring distribution is $\text{Exponential}(\exp(3\mathbf{X}^{(2)} - 2))$, so the censoring distribution is no longer independent of the signal variables. In both cases, approximately 50% of the observations are censored.

The results of our simulation using the log-rank test are displayed in Table 40.1. When the censoring is independent of the signal variables ($\mathbf{X}^{(1)}$ and $\mathbf{X}^{(3)}$), the random forest correctly splits on $\mathbf{X}^{(1)}$ first approximately 86% of the time.

However, when the censoring distribution depends on $\mathbf{X}^{(2)}$ and therefore is no longer independent of $\mathbf{X}^{(1)}$, the random forest splits on $\mathbf{X}^{(1)}$ first in only 34% of cases. It splits first on $\mathbf{X}^{(2)}$ in 56% of the cases, when, ideally, we would not split on $\mathbf{X}^{(2)}$ at all. It is clear that the censoring distribution biases the choice of splitting variables. The consequence of this bias on the consistency of survival trees is much more involved as the entire tree structure can be altered by the censoring distribution. Cui et al. [6] developed a concentration bound on the difference between the accurately predicted hazard function (what we could find with complete data and an unbiased model) and the censoring contaminated predicted hazard function.

40.6.3 Some Solutions for Bias Correction

There have been multiple proposed adjustments to the survival random forest algorithm to deal with the bias. For example, the inverse probability of censoring weights is

Fig. 40.7 Out-of-bag predicted survival functions for four selected subjects with high or low values of gene “219478_at” and ER+ or ER–

Table 40.1 Probability of selecting each variable in the first split

Censoring mechanism	$X^{(1)}$	$X^{(2)}$	$X^{(3)}$
Independent of signal variables	0.863	0.048	0.089
Not independent of signal variables	0.340	0.562	0.098

extensively considered in the literature [54,59]. For example, [25] proposed utilizing censoring unbiased transformations (CUTs). In particular, they developed a generalized doubly robust transformation that is a CUT when either the survival distribution or the censoring distribution is correctly specified but not necessarily both. They used the CUT to develop a loss function that, when no censoring is present, reduces to a full data function. Then the loss function is used as a splitting rule to create a censoring unbiased regression tree that can then be used for survival random forests.

However, CUTs work in the case where expected values are the focus of analysis. We have seen an example earlier in Sect. 40.2.1 where the expected values were not sufficient to determine the difference between two distributions. To help with bias and deal with the whole distribution (rather than only expected values), we consider a different type of correction. Cui et al. [6] proposed tackling the bias by using a weighted Nelson-Aalen estimator, which is a variation on (40.14):

$$\widehat{\Lambda}(t, \mathbf{x}_0) = \sum_{k:t_k \leq t} \frac{\sum_{i=1}^n \mathbb{1}(\delta_i = 1) \mathbb{1}(y_i = t_k) K(\mathbf{x}_0, \mathbf{x}_i) / [1 - \widehat{G}(t_k, \mathbf{x}_i)]}{\sum_{i=1}^n \mathbb{1}(y_i \geq t_k) K(\mathbf{x}_0, \mathbf{x}_i) / [1 - \widehat{G}(t_k, \mathbf{x}_i)]} \quad (40.27)$$

As in the calculation of the Brier score (40.24), $\widehat{G}(t_k, \mathbf{x}_i)$'s for consistency are estimates of the conditional censoring distribution, which can be estimated by a separate model, or simply plug-in the marginal censoring distributing estimation. Cui et al. [6] estimated and compared the inverse probability weighted hazard functions with the weights $\delta_i / \{1 - \widehat{G}(t_k | \mathbf{x}_i)\}$ at each internal node, which accounts for the bias caused by censoring and allows for the choice of the two most divergent child nodes. This type of splitting rule, like the supremum log-rank test (40.13), compares the survival functions rather than the expected survival time.

Another appeal of this bias-corrected survival forest is in high-dimensional settings. Cui et al. [6] showed that a survival forest model with a marginal splitting rule has the rate of convergence depending on the total number of variables included in both failure time and censoring time. While [6] developed their results under a general framework where the covariates are allowed to be weakly correlated, their approach directly extends to the case where all the variables in \mathbf{x} are independent. In such cases, the biasedness is not due to correlated variables but the entanglement between failure time and censoring time marginally. For example, if the censoring time and failure time depend on a shared variable, all the other variables involved in the censoring distribution may play a role in the limiting distribution of (40.14). Hence, there is no guarantee of splitting only on the failure variables, especially when the dimensionality is high. The new type of survival forests in [6] that leverages (40.27) untangles the failure and censoring distributions and improves the rate of convergence of tree model so that the rate depends only on the number of important variables that define the failure distribution.

40.7 Theoretical Properties of Random Forest

Theoretical analysis of random forests has been an active research topic in recent years. Under assumptions of the additive model, [47] showed the consistency of random forests. One of the earlier attempts was made by Lin and Jeon [60], which formulates random forests as a nearest-neighbor model. An interesting insight provided by this paper is that a random forest defines its neighborhood adaptively. For a variable with a stronger signal, it will be repeatedly used as the splitting rule, making the width of the variable in a terminal node much smaller than other variables [43]. This partition resembles the properties of multidimensional kernel estimators with adaptive bandwidth selection [61]. For random forests, we can easily derive the induced kernel distance as an extension of (40.15)

$$K(\mathbf{x}_i, \mathbf{x}_j) = \frac{1}{B} \sum_{b=1}^B \sum_{u \in \mathcal{U}^b} \mathbb{1}(\mathbf{x}_i \in A_u^b) \mathbb{1}(\mathbf{x}_j \in A_u^b), \quad (40.28)$$

which can be used for a kernel version of the prediction [38]. Further exploiting the properties of this induced kernel is of great interest. The technique may be universally applicable to many types of random forest models and shed light on proving the consistency of the method.

Another topic of random forests is to quantify its variation. In statistics, this quantification is an important issue because we may be able to provide a valid inference of the estimated survival function and draw conclusions. For example, in precision medicine [62, 63], one has to compare the survival function estimations that resulted from applying two potential treatments and select the better one [64–66]. Being able to quantify the confidence intervals of the estimations is practically useful. To this end, recent literature proposes to use jackknife [67, 68] or U-statistics [69]. U-statistic [70] is a classical tool that provides asymptotic normality of an averaged estimator based on all possible subsampling combinations. The particular version applicable to the random forest is incomplete [69, 71] in the sense that a relatively small number (`nrtrees`) of such subsamples are used. With suitable conditions, a normality result can be established, and the variance can be estimated by deriving the leading term in the Hoeffding decomposition. However, a relatively restrictive condition is that the subsample size must be smaller than \sqrt{n} . This restriction is a limitation in practice since a small sample size in each tree will lead to significant bias. Being able to relax these conditions while not drastically increasing the computational cost is a challenging statistical issue.

40.8 Supplementary Material

All examples provided in this chapter are created using the R [72]. Source code for the examples is available at <https://github.com/sarahef2/springer-surv>. The RLT package is available at <https://github.com/teazrq/RLT>.

Ruqing Zhu is an Associate Professor at the Department of Statistics at UIUC. He obtained his Ph.D from UNC Chapel Hill in 2013 and completed his postdoc training at Yale University in 2015. His expertise is in statistical methodology and theory of machine learning methods and their applications to biomedical data. Currently, his research focuses on personalized medicine, random forests, reinforcement learning and survival analysis.

Sarah E. Formentini received her Ph.D. in Statistics at the University of Illinois at Urbana-Champaign in 2022. Her research focused on survival analysis and random forests, including survival data integration and survival random forest variation estimation.

Yifan Cui received his Ph.D. from University of North Carolina at Chapel Hill in 2018. He is currently a tenure track faculty member at the Center for Data Science in Zhejiang University (ZJU). He has worked at Wharton Statistics Department, University of Pennsylvania as a postdoctoral researcher and Department of Statistics and Data Science, National University of Singapore as an assistant professor. His main research interests include nonparametric and semiparametric statistics, random forests, causal inference, precision medicine, survival analysis, generalized fiducial inference, and foundations of statistics.

41.1 The Measure of Dependence

We first introduce the mixing conditions defined on σ -fields. Fix the probability space as $(\Omega, \mathcal{F}, \mathbb{P})$. For any two σ -fields \mathcal{A}, \mathcal{B} belonging to \mathcal{F} , define the following four measures of dependence between \mathcal{A} and \mathcal{B} (cf. Chapter 3, [10]):

$$\alpha(\mathcal{A}, \mathcal{B}) := \sup_{A \in \mathcal{A}, B \in \mathcal{B}} \left| \mathbb{P}(A \cap B) - \mathbb{P}(A)\mathbb{P}(B) \right|,$$

$$\beta(\mathcal{A}, \mathcal{B}) := \sup \frac{1}{2} \sum_{i=1}^I \sum_{j=1}^J \left| \mathbb{P}(A_i \cap B_j) - \mathbb{P}(A_i)\mathbb{P}(B_j) \right|,$$

$$\phi(\mathcal{A}, \mathcal{B}) := \sup_{A \in \mathcal{A}, B \in \mathcal{B}, \mathbb{P}(A) > 0} \left| \mathbb{P}(B | A) - \mathbb{P}(B) \right|,$$

$$\rho(\mathcal{A}, \mathcal{B}) := \sup \left\{ \left| \text{Corr}(f, g) \right|, f \in \mathcal{L}_{\mathbb{R}}^2(\mathcal{A}), g \in \mathcal{L}_{\mathbb{R}}^2(\mathcal{B}) \right\},$$

Abstract

Study of time series data often involves measuring the strength of temporal dependence, on which statistical properties like consistency and central limit theorem are built. Historically, various dependence measures have been proposed. In this note, we first survey some of the most well-used dependence measures as well as various probability and moment inequalities built upon them under a high-dimensional triangular array time series setting. We then argue that this triangular array setting will pose substantially new challenges to the verification of some dependence conditions. In particular, “textbook results” could now be misleading and hence are recommended to be used with caution.

where the supremum in the definition of $\beta(\mathcal{A}, \mathcal{B})$ is taken over all pairs of partitions $\{A_1, \dots, A_I\}$ and $\{B_1, \dots, B_J\}$ such that $A_i \in \mathcal{A}$ and $B_j \in \mathcal{B}$ for all i, j , and for any $p \in [1, \infty]$, let $\mathcal{L}_{\mathbb{R}}^p(\mathcal{A})$ represent the family of all real valued, \mathcal{A} -measurable random variables X on Ω such that $\|X\|_{L_p} := (\mathbb{E}|X|^p)^{1/p} < \infty$. We refer to [9] for basic properties and historical developments on these dependence measures.

Now let’s consider a (not necessarily stationary) time series $\{X_t \in \mathbb{R}^d\}_{t \in \mathbb{Z}}$ with \mathbb{Z} and \mathbb{R}^d representing the sets of all integers and all d -dimensional real vectors. For each “time gap” $m = 1, 2, \dots$, with the above dependence measures, we are now ready to define the following four mixing coefficients that appear frequently in literature:

$$\begin{aligned} \alpha(\{X_t\}_{t \in \mathbb{Z}}; m) &:= \sup_{j \in \mathbb{Z}} \alpha(\sigma(\{X_t\}_{t \leq j}), \sigma(\{X_t\}_{t \geq j+m})), \\ \beta(\{X_t\}_{t \in \mathbb{Z}}; m) &:= \sup_{j \in \mathbb{Z}} \beta(\sigma(\{X_t\}_{t \leq j}), \sigma(\{X_t\}_{t \geq j+m})), \\ \phi(\{X_t\}_{t \in \mathbb{Z}}; m) &:= \sup_{j \in \mathbb{Z}} \phi(\sigma(\{X_t\}_{t \leq j}), \sigma(\{X_t\}_{t \geq j+m})), \\ \rho(\{X_t\}_{t \in \mathbb{Z}}; m) &:= \sup_{j \in \mathbb{Z}} \rho(\sigma(\{X_t\}_{t \leq j}), \sigma(\{X_t\}_{t \geq j+m})). \end{aligned}$$

Here for any random variable X , $\sigma(X)$ is understood to be the σ -field generated by X . A review of the history of these mixing coefficients can be found in Section 2.1 in [9]. We also refer readers to the books of [10, 16], and [39].

The above mixing coefficients are defined on σ -fields and are usually difficult to be explicitly calculated in practice, though when the model is fixed, asymptotic bounds on coefficients can be derived for many time series models and have been established in many works. This is one of the reasons to define weak dependence measures that are often much easier to calculate. In the following we introduce several of the most well-used ones.

Bickel and Bühlmann [8] and Doukhan and Louhichi [17] introduced a notion of weak dependence that facilitates explicit calculation of the independence strength between “past” and “future” without resorting to the latent σ -fields. They could be roughly understood as upper bounding

$$\text{Cov}(f(\text{“past”}), g(\text{“future”}))$$

by the gap between “past” and “future” as well as some parameters of the functions f and g . In detail, for a function $g : (\mathbb{R}^d)^u \rightarrow \mathbb{R}$, let’s define

$$\text{Lip}_\delta g := \sup \left\{ \frac{|g(x_1, \dots, x_u) - g(y_1, \dots, y_u)|}{\delta((x_1, \dots, x_u), (y_1, \dots, y_u))} : (x_1, \dots, x_u) \neq (y_1, \dots, y_u) \right\},$$

where $\delta(\cdot)$ represents a certain metric on the real vector space. Denote $\Lambda_\delta := \{g : (\mathbb{R}^d)^u \rightarrow \mathbb{R} \text{ for some } u : \text{Lip}_\delta g < \infty\}$ and $\Lambda_\delta^{(1)} := \{g \in \Lambda_\delta : \|g\|_\infty \leq 1\}$ with $\|g\|_\infty := \sup_x |g(x)|$. In the following, \mathbb{N} represents the set of all natural numbers.

Definition 1.1 ([17, 18]) The process $\{X_t\}_{t \in \mathbb{Z}}$ is $(\Lambda_\delta^{(1)}, \psi, \zeta)$ -weakly dependent if and only if there exists a function $\psi : \mathbb{R}_+^2 \times \mathbb{N}^2 \rightarrow \mathbb{R}_+$ and a sequence $\zeta = \{\zeta(n)\}_{n \geq 0}$ decreasing to 0 as n goes to infinity, such that for any $g_1, g_2 \in \Lambda_\delta^{(1)}$ with $g_1 : (\mathbb{R}^d)^u \rightarrow \mathbb{R}, g_2 : (\mathbb{R}^d)^v \rightarrow \mathbb{R}, u, v \in \mathbb{N}$, and any u -tuple (s_1, \dots, s_u) and any v -tuple (t_1, \dots, t_v) with $s_1 \leq \dots \leq s_u < t_1 \leq \dots \leq t_v$, the following inequality is satisfied:

$$\begin{aligned} & \left| \text{Cov} \left\{ g_1(x_{s_1}, \dots, x_{s_u}), g_2(x_{t_1}, \dots, x_{t_v}) \right\} \right| \\ & \leq \psi(\text{Lip}_\delta g_1, \text{Lip}_\delta g_2, u, v) \zeta(t_1 - s_u). \end{aligned}$$

Important examples of $(\Lambda_\delta^{(1)}, \psi, \zeta)$ -weakly dependent processes include θ -, η -, κ -, and λ -dependences, which are listed in Table 41.1. They correspond to different choices of the function ψ . Similar to the mixing coefficients, the sequence ζ describes the degree of dependence over the process.

Later, in [13] and [14], the authors introduced a new set of dependence measures that, instead of putting focus on the covariance structure, highlights the intrinsic “coupling” property of the sequence. This note shall focus on one important member in this family, the τ -dependence. Consider a general probability space $(\Omega, \mathcal{F}, \mathbb{P})$ and a random variable X taking value in a Polish space $(\mathcal{X}, \|\cdot\|_{\mathcal{X}})$ endowed with a norm $\|\cdot\|_{\mathcal{X}}$ and satisfying $\|X - x_0\|_{\mathcal{X}} \|L_1 < \infty$ for some $x_0 \in \mathcal{X}$. Consider a σ -field $\mathcal{A} \subset \mathcal{F}$. The τ -measure of dependence between X and \mathcal{A} is defined to be

$$\begin{aligned} \tau(\mathcal{A}, X; \|\cdot\|_{\mathcal{X}}) &= \left\| \sup_{g \in \Lambda(\|\cdot\|_{\mathcal{X}})} \left\{ \int g(x) \mathbb{P}_{X|\mathcal{A}}(dx) \right. \right. \\ & \quad \left. \left. - \int g(x) \mathbb{P}_X(dx) \right\} \right\|_{L_1}, \end{aligned}$$

where \mathbb{P}_X and $\mathbb{P}_{X|\mathcal{A}}$ represent the distribution and the conditional distributions of X and X given \mathcal{A} and $\Lambda(\|\cdot\|_{\mathcal{X}})$ stands for the set of 1-Lipschitz functions from \mathcal{X} to \mathbb{R} with respect to the norm $\|\cdot\|_{\mathcal{X}}$.

The following theorem, extracted from [13] and [15], characterizes the intrinsic “coupling property” of the τ -measure of dependence and, as a matter of fact, gives an alternative definition of τ -measure that is usually easier to use.

Theorem 1.1 (Lemma 3 in [13], Lemma 5.3 in [15]) Let $(\Omega, \mathcal{F}, \mathbb{P})$ be a probability space, \mathcal{A} be a σ -field of \mathcal{F} , and X be a random variable with values in a Polish space $(\mathcal{X}, \|\cdot\|_{\mathcal{X}})$. If Y is a random variable distributed as X and independent of \mathcal{A} , then

$$\tau(\mathcal{A}, X; \|\cdot\|_{\mathcal{X}}) \leq \mathbb{E} \|X - Y\|_{\mathcal{X}}.$$

Table 41.1 Important examples of weak dependence

θ -dependence:	$\psi(\text{Lip}_\delta g_1, \text{Lip}_\delta g_2, u, v) = v \text{Lip}_\delta g_2$
η -dependence:	$\psi(\text{Lip}_\delta g_1, \text{Lip}_\delta g_2, u, v) = u \text{Lip}_\delta g_1 + v \text{Lip}_\delta g_2$
κ -dependence:	$\psi(\text{Lip}_\delta g_1, \text{Lip}_\delta g_2, u, v) = uv \text{Lip}_\delta g_1 \text{Lip}_\delta g_2$
λ -dependence:	$\psi(\text{Lip}_\delta g_1, \text{Lip}_\delta g_2, u, v) = u \text{Lip}_\delta g_1 + v \text{Lip}_\delta g_2 + uv \text{Lip}_\delta g_1 \text{Lip}_\delta g_2$

Assume that $\int \|x - x_0\|_{\mathcal{X}} \mathbb{P}_X(\mathrm{d}x)$ is finite for any $x_0 \in \mathcal{X}$. Assume that there exists a random variable U uniformly distributed over $[0, 1]$, independent of the sigma-field generated by X and \mathcal{A} . Then there exists a random variable \tilde{X} , measurable with respect to $\mathcal{A} \vee \sigma(X) \vee \sigma(U)$, independent of \mathcal{A} and distributed as X , such that

$$\tau(\mathcal{A}, X; \|\cdot\|_{\mathcal{X}}) = \mathbb{E}\|X - \tilde{X}\|_{\mathcal{X}}.$$

We now apply the notion of τ -dependence to a time series model. Let $\{X_j\}_{j \in J}$ be a set of \mathcal{X} -valued random variables with index set J of finite cardinality. Then define

$$\tau(\mathcal{A}, \{X_j \in \mathcal{X}\}_{j \in J}; \|\cdot\|_{\mathcal{X}}) = \left\| \sup_{g \in \Lambda(\|\cdot\|'_{\mathcal{X}})} \left\{ \int g(x) \mathbb{P}_{\{X_j\}_{j \in J} | \mathcal{A}}(\mathrm{d}x) - \int g(x) \mathbb{P}_{\{X_j\}_{j \in J}}(\mathrm{d}x) \right\} \right\|_{L_1},$$

where $\mathbb{P}_{\{X_j\}_{j \in J}}$ and $\mathbb{P}_{\{X_j\}_{j \in J} | \mathcal{A}}$ represent the distribution of $\{X_j\}_{j \in J}$ and the conditional distribution of $\{X_j\}_{j \in J}$ given \mathcal{A} respectively, and $\Lambda(\|\cdot\|'_{\mathcal{X}})$ stands for the set of 1-Lipschitz functions:

$$\Lambda(\|\cdot\|'_{\mathcal{X}}) := \left\{ f : \underbrace{\mathcal{X} \times \dots \times \mathcal{X}}_{\text{Card}(J)} \rightarrow \mathbb{R}; \right. \\ \left. f \text{ is 1-Lipschitz with respect to } \|\cdot\|'_{\mathcal{X}} \right\}$$

with $\|x\|'_{\mathcal{X}} := \sum_{j \in J} \|x_j\|_{\mathcal{X}}$ for any $x = (x_1, \dots, x_J) \in \mathcal{X}^{\text{Card}(J)}$.

Using these concepts, for a time series $\{X_t\}_{t \in \mathbb{Z}}$, it is ready to define measure of temporal correlation strength as

$$\tau(\{X_t\}_{t \in \mathbb{Z}}; m, \|\cdot\|_{\mathcal{X}}) := \sup_{i > 0} \max_{1 \leq \ell \leq i} \ell^{-1} \sup \left\{ \tau(\sigma(X_{-\infty}^a), \{X_{j_1}, \dots, X_{j_\ell}\}; \|\cdot\|_{\mathcal{X}}), a \right. \\ \left. + m \leq j_1 < \dots < j_\ell \right\},$$

where the inner supremum is taken over all $a \in \mathbb{Z}$ and all ℓ -tuples (j_1, \dots, j_ℓ) .

In the end, let's consider $\{X_t\}_{t \in \mathbb{Z}}$ to be a real stationary causal process of the form

$$X_i = g(\dots, \epsilon_{i-1}, \epsilon_i), \tag{41.1}$$

with $\{\epsilon_i\}_{i \in \mathbb{Z}}$ an independent and identically distributed (i.i.d.) sequence and $g(\cdot)$ a measurable function such that the above time series model is properly defined. In [42], the author introduced the functional dependence measure, as manifested below.

Definition 1.2 (Functional Dependence Measure, [42]) Let $\{\epsilon_i, \epsilon'_j\}_{i,j \in \mathbb{Z}}$ be i.i.d. random variables. Let $X'_m := g(\dots, \epsilon_{-2}, \epsilon_{-1}, \epsilon'_0, \epsilon_1, \dots, \epsilon_m)$. The functional dependence measure with regard to the L_p norm is defined to be

$$\theta_{m,p} := \|X_m - X'_m\|_{L_p}$$

with the tail sum $\Theta_{m,p} := \sum_{k=m}^{\infty} \theta_{k,p}$.

The functional dependence measure $\theta_{m,p}$ is flexible and easy to compute in many applications; we refer the readers of interest to [43] for a systematic review. In addition, given the data generating mechanism g , one could numerically compute functional dependence measures by Monte Carlo simulations. In contrast, numeric computation of other dependence measures can be highly nontrivial due to their definitions.

We also mention a connection between physical dependence and τ -dependence. As is apparent by comparing Theorem 1.1 with Definition 1.2, τ -dependence and functional dependence measure are interestingly intrinsically connected. In particular, they are both adaptable to a notion of coupling. However, as noted in Remark 3.1 in [15], coupling in functional dependence is given in [13] with all elements in the past, while in [42] with only element in the past.

41.2 Probability and Moment Inequalities Under Dependence

Probability and moment inequalities play an important role in studying the statistical properties of estimators of parameters in statistical models. They are key in high-dimensional statistical theory, which is by its nature nonasymptotic. Of particular importance are those that give rise to efficient control of tail deviations, namely, higher-order moment and exponential-type inequalities. In this section we will give a brief review of some developed inequalities for time series, which are promising to be applied to the analysis of high-dimensional time series data. For this, this note is restricted to those built on the weak dependence measures introduced in Sect. 41.1, while those built on other structures like Markov chains or martingales, though related, shall not be covered.

Before diving into the details, let's first fix what we mean a high-dimensional time series model. To characterize the impact of dimensionality on the performance of an estimator, it has become well-accepted in literature to model high-dimensional data under a triangular-array setting; see, for example, Section 1 in [21] for a comprehensive illustration. Applied to time series models, the following model will be used throughout the rest of this paper: For each $n \in \mathbb{N}$, let $\{X_{t,n}\}_{t \in \mathbb{Z}}$ denote a d_n -dimensional real time series with $d_n \in \mathbb{N}$ as well as the time series itself depending on n .

For each $n \in \mathbb{N}$, a length of n fragment $\{X_{i,n}\}_{i \in [n]}$, with $[n] := \{1, 2, \dots, n\}$, is observed from the time series $\{X_{t,n}\}_{t \in \mathbb{Z}}$. For different n , a different time series with possibly different dimension is observed. In particular, as n goes to infinity, the dimension of the n fragment time series, d_n , is allowed to increase to infinity as well.

To name one particular example, let's consider the observations $\{X_{i,n}\}_{i \in [n]}$ to be generated from a VAR(1) model, \mathcal{M}_n , that is changing with n :

$$\mathcal{M}_n : \left\{ \{X_{t,n}\}_{t \in \mathbb{Z}} : X_{t,n} = A_n X_{t-1,n} + E_{t,n}, \text{ for all } t \in \mathbb{Z} \right\}.$$

Here A_n is a $d_n \times d_n$ -dimensional transition matrix, and $E_{t,n}$ is a d_n -dimensional vector of error term. The value A_n and the dimension d_n are both allowed to change with n ; e.g., it could be true that

As $n = 1$, a 1-dimensional, length of 1 fragment, $\{X_{1,1}\}$, is observed from the model \mathcal{M}_1 with $A_1 = 0.5$;

As $n = 2$, a 2-dimensional, length of 2 fragment time series, $\{X_{1,2}, X_{2,2}\}$, is observed from the model \mathcal{M}_2 with

$$A_2 = \begin{pmatrix} 0.5 & 0.1 \\ 0.2 & 0.25 \end{pmatrix};$$

As $n = 3$, a 4-dimensional, length of 3 fragment time series, $\{X_{1,3}, X_{2,3}, X_{3,3}\}$, is observed from the model \mathcal{M}_3 with

$$A_3 = \begin{pmatrix} 0.2 & 0 & 0.1 & 0.4 \\ 0.2 & 0.1 & 0.1 & 0.2 \\ 0.1 & 0.2 & 0.3 & 0.1 \\ 0 & 0 & 0 & 0.1 \end{pmatrix};$$

.....

41.2.1 Sample Sum for Scalars with $d_n = 1$

Several of the most essential moment inequalities are centered around the sample sum. In detail, for any $n \in \mathbb{N}$, consider a time series $\{X_{t,n}\}_{t \in \mathbb{Z}}$ and its size- n fragment $\{X_{i,n}\}_{i \in [n]}$. Our aim is to characterize the moment and tail properties for $\sum_{i=1}^n (X_{i,n} - \mathbb{E}X_{i,n})$. Without loss of generality, in the following it is assumed that the time series has margin mean-zero. In this section we are focused on the sample sum $S_n := \sum_{i=1}^n X_{i,n}$ of fixed dimension $d_n = 1$; in the later sections we shall allow d_n to increase to infinity.

To start with, let's first consider the case of linear processes by assuming that $\{X_{t,n}\}_{t \in \mathbb{Z}}$ follows a linear process

$$X_{t,n} = \sum_{j=0}^{\infty} f_{j,n} \epsilon_{t-j,n}, \tag{41.2}$$

with $\{\epsilon_{j,n}\}_{j \in \mathbb{Z}}$ understood to be an i.i.d. scalar sequence with mean zero and $\|\epsilon_{0,n}\|_{L_p} < \infty$ for some $p > 2$, and $f_n := \{f_{j,n}\}$

as a real coefficient sequence satisfying $\|f_n\|_2^2 := \sum_{j=0}^{\infty} f_{j,n}^2 < \infty$. The form (41.2) is very general and includes many famous time series models such as the ARMA processes.

The first result concerns such time series of the particular form (41.2) and is from [44]. It gives a Nagaev-type inequality for linear processes, including both short- and long-range dependence cases.

Theorem 2.1 (Theorem 1, [44]) *Assume the linear process in (41.2). Then the following two statements are true.*

(i) (Short-range dependence) *Let $c_p := 2e^{-p}(p+2)^{-2}$. If $\|f_n\|_1 := \sum_{j=0}^{\infty} |f_{j,n}| < \infty$, then for any $x > 0$ we have*

$$\mathbb{P}(|S_n| \geq x) \leq \left(1 + \frac{2}{p}\right)^p \cdot \frac{n \|f_n\|_1^p \|\epsilon_{0,n}\|_{L_p}^p}{x^p} + 2 \exp\left(-\frac{c_p x^2}{n \|f_n\|_1^2 \|\epsilon_{0,n}\|_{L_2}^2}\right).$$

(ii) (Long-range dependence) *Assume $K_n := \sup_{j \geq 0} |f_{j,n}|(1+j)^\beta < \infty$ for some $1/2 < \beta < 1$. Then there exist constants C_1, C_2 only depending on p and β such that, for all $x > 0$,*

$$\mathbb{P}(|S_n| \geq x) \leq C_1 \frac{n^{1+p(1-\beta)} K_n^p \|\epsilon_{0,n}\|_{L_p}^p}{x^p} + 2 \exp\left(-\frac{C_2 x^2}{n^{3-2\beta} \|\epsilon_{0,n}\|_{L_2}^2 K_n^2}\right).$$

We then move on to the general possibly nonlinear case. The first of such results considers the ϕ -mixing case and is from [14].

Theorem 2.2 (Proposition 5, [14]) *Let $\{X_{t,n}\}_{t \in \mathbb{Z}}$ be a mean-zero stationary sequence of dimension d_n fixed to be 1. Let $\phi_n(m) := \phi(\{X_{t,n}\}_{t \in \mathbb{Z}}; m)$ and $|X_{0,n}| \leq C_n$ for some constant C_n that possibly depends on n . Then, for every $p = 2, 3, \dots$ and any $n \geq 1$, the following inequality holds:*

$$\mathbb{E}|S_n|^p \leq \left(8C_n^2 p \sum_{i=0}^{n-1} (n-i)\phi_n(i)\right)^{p/2}.$$

The next result considers the α - and τ -mixing cases and is from [35].

Theorem 2.3 (Theorem 2, [35]) *Let $\{X_{t,n}\}_{t \in \mathbb{Z}}$ be a stationary mean-zero sequence of dimension d_n fixed to be 1. Suppose that the sequence satisfies either a geometric α -mixing condition:*

$$\alpha(\{X_{t,n}\}_{t \in \mathbb{Z}}; m) \leq \exp(-\gamma_n m), \text{ for } m = 1, 2, \dots$$

or a geometric τ -mixing condition:

$$\tau(\{X_{t,n}\}_{t \in \mathbb{Z}}; m, |\cdot|) \leq \exp(-\gamma_n m), \text{ for } m = 1, 2, \dots$$

with some positive constant γ_n that could depend on n , and there exists a positive constant B_n such that $\sup_{i \geq 1} \|X_{i,n}\|_{L_\infty} \leq B_n$. Then there are positive constants $C_{1,n}$ and $C_{2,n}$ depending only on γ_n such that for all $n \geq 2$ and positive $t < 1/[C_1 B_n (\log n)^2]$, the following inequality holds:

$$\log[\mathbb{E} \exp(tS_n)] \leq \frac{C_{2,n} t^2 (n\sigma_n^2 + B_n^2)}{1 - C_{1,n} t B_n (\log n)^2},$$

where σ_n^2 is defined by

$$\sigma_n^2 := \text{Var}(X_{1,n}) + 2 \sum_{i>1} \left| \text{Cov}(X_{1,n}, X_{i,n}) \right|.$$

We note here that the dependence of $C_{1,n}$ and $C_{2,n}$ on γ_n could be explicitly calculated, as have been made in [6] and [23]; also refer to the later Theorems 2.10 and 2.11.

The next result considers the weak dependence case and is the foundation of dependence measures proposed in [17]. We refer to [17] and [18] for the relation between those weak dependences defined in Definition 1.1 and the following Eqs. (41.3) and (41.4).

Theorem 2.4 (A Slight Modification to Theorem 1 in [18]) Suppose $\{X_{i,n}\}_{i \in [n]}$ are real-valued random variables with mean 0, defined on a common probability space $(\Omega, \mathcal{A}, \mathbb{P})$. Let $\Psi : \mathbb{N}^2 \rightarrow \mathbb{N}$ be one of the four functions defined in Table 41.1. Assume that there exist constants $K_n, M_n, L_{1,n}, L_{2,n} > 0$, $a_n, b_n \geq 0$, and a nonincreasing sequence of real coefficients $\{\rho_n(i)\}_{i \geq 0}$ such that for any u -tuple (s_1, \dots, s_u) and v -tuple (t_1, \dots, t_v) with $1 \leq s_1 \leq \dots \leq s_u < t_1 \leq \dots \leq t_v \leq n$, we have

$$\left| \text{Cov} \left(\prod_{i=1}^u X_{s_i,n}, \prod_{j=1}^v X_{t_j,n} \right) \right| \leq K_n^2 M_n^{u+v} \{(u+v)!\}^{b_n} \Psi(u, v) \rho_n(t_1 - s_u), \quad (41.3)$$

where the sequence $\{\rho_n(i)\}_{i \geq 0}$ satisfies

$$\sum_{s=0}^{\infty} (s+1)^k \rho_n(s) \leq L_{1,n} L_{2,n}^k (k!)^{a_n}, \text{ for any } k \in \mathbb{N}. \quad (41.4)$$

Moreover, we require that the following moment condition holds:

$$\mathbb{E}|X_{i,n}|^k \leq (k!)^{b_n} M_n^k, \text{ } i = 1, \dots, n, \text{ for any } k \in \mathbb{N}.$$

Then, for any $n \geq 1$ and any $x > 0$, we have

$$\mathbb{P}(S_n \geq x) \leq \exp \left\{ - \frac{x^2}{C_{1,n} n + C_{2,n} x^{(2a_n+2b_n+3)/(a_n+b_n+2)}} \right\},$$

where $C_{1,n}$ and $C_{2,n}$ are constants that can be chosen to be

$$C_{1,n} = 2^{a_n+b_n+3} K_n^2 M_n^2 L_{1,n} (K_n^2 \vee 2),$$

$$C_{2,n} = 2 \{M_n L_{2,n} (K_n^2 \vee 2)\}^{1/(a_n+b_n+2)}.$$

Proof. The proof follows that of Theorem 1 in [18] with minor modifications, as listed below. Restricted to this proof, we inherit the notation in [18] and abandon the subscript n .

Equation (30) in [18] can be strengthened to

$$\mathbb{E}|Y_j| \leq 2^{k-j-1} \{(k-j+1)!\}^b K^2 M^k \rho(t_{i+1} - t_i).$$

This leads to

$$|\bar{\mathbb{E}}(X_{t_1} \cdots X_{t_k})| \leq 2^{k-1} (k!)^b K^2 M^k \rho(t_{i+1} - t_i), \quad (41.5)$$

which corresponds to Lemma 13 in [18]. Using (41.5), we obtain that

$$\begin{aligned} \left| \Gamma(X_{t_1}, \dots, X_{t_k}) \right| &\leq \sum_{v=1}^k \sum_{\cup_{p=1}^v I_p = I} N_v(I_1, \dots, I_v) 2^{k-v} (k!)^b K^{2v} M^k \\ &\leq K^2 (K^2 \vee 2)^{k-1} M^k (k!)^b \{(k-1)!\} \min_{1 \leq i < k} \rho(t_{i+1} - t_i) \\ &\leq K^2 (K^2 \vee 2)^{k-1} M^k (k!)^b \min_{1 \leq i < k} \rho(t_{i+1} - t_i). \end{aligned}$$

Thus, we have

$$\left| \Gamma_k(S_n) \right| \leq n K^2 (K^2 \vee 2)^{k-1} M^k (k!)^{b+1} \sum_{s=0}^{n-1} (s+1)^{k-2} \rho(s). \quad (41.6)$$

Equation (41.6) corresponds to Lemma 14 in [18]. The rest follows the same technique as in [18]. \square

Lastly we consider the functional dependence setting. The first result is a Rosenthal-type inequality and is from [33].

Theorem 2.5 (Theorem 1, [33]) Assume $\{X_{t,n}\}_{t \in \mathbb{Z}}$ is of dimensional $d_n = 1$ and is generated from the model (41.1) with functional dependence measures $\theta_{m,p,n}$, which is of an additional subscript n to highlight its dependence on n . Assume further that $\mathbb{E}X_{0,n} = 0$, $\mathbb{E}|X_{0,n}|^p < \infty$, and $p > 2$. Then we have, for any $n \geq 1$,

$$\begin{aligned} \|S_n\|_{L_p} &\leq n^{1/2} \left[\frac{87p}{\log p} \sum_{j=1}^n \theta_{j,2,n} + 3(p-1)^{1/2} \right. \\ &\quad \left. \sum_{j=n+1}^{\infty} \theta_{j,p,n} + \frac{29p}{\log p} \|X_{0,n}\|_{L_2} \right] + n^{1/p} \left[\frac{87p(p-1)^{1/2}}{\log p} \right. \\ &\quad \left. \sum_{j=1}^n j^{1/2-1/p} \theta_{j,p,n} + \frac{29p}{\log p} \|X_{0,n}\|_{L_p} \right]. \end{aligned}$$

The second is a Nagaev-type inequality and is also from [33].

Theorem 2.6 (Theorem 2, [33]) Assume $\{X_{t,n}\}_{t \in \mathbb{Z}}$ is of dimensional $d_n = 1$ and is generated from the model (41.1) with functional dependence measures $\theta_{m,p,n}$. Assume further that $\mathbb{E}X_{0,n} = 0$, $\mathbb{E}|X_{0,n}|^p < \infty$, and $p > 2$. Then we have the following bounds for any $n \geq 1$.

(i) Denote

$$\mu_{j,n} := (j^{p/2-1} \theta_{j,p,n}^p)^{1/(p+1)} \quad \text{and} \quad v_n := \sum_{j=1}^{\infty} \mu_{j,n} < \infty.$$

Then, for any $x > 0$,

$$\begin{aligned} \mathbb{P}(|S_n| \geq x) &\leq c_p \frac{n}{x^p} \left(v_n^{p+1} + \|X_{0,n}\|_{L_p}^p \right) \\ &\quad + 4 \sum_{j=1}^{\infty} \exp \left(-\frac{c_p \mu_{j,n}^2 x^2}{n v_n^2 \theta_{j,2,n}^2} \right) \\ &\quad + 2 \exp \left(-\frac{c_p x^2}{n \|X_{0,n}\|_{L_2}^2} \right), \end{aligned}$$

where $c_p > 0$ is a constant only depending on p .

(ii) Assume that $\Theta_{m,p,n} := \sum_{k=m}^{\infty} \theta_{k,p,n} = O(m^{-\alpha})$ as m goes to infinity, with some constant $\alpha > 1/2 - 1/p$. Then there exist absolute positive constants C_1 and C_2 such that, for any $x > 0$,

$$\mathbb{P}(|S_n| \geq x) \leq \frac{C_1 \Theta_{0,p,n}^p n}{x^p} + 4G_{1-2/p} \left(\frac{C_2 x}{\sqrt{n} \Theta_{0,p,n}} \right),$$

where for any $y > 0$, $q > 0$, $G_q(y)$ is defined to be

$$G_q(y) = \sum_{j=1}^{\infty} \exp(-j^q y^2).$$

(iii) If $\Theta_{m,p,n} = O(m^{-\alpha})$ as m goes to infinity, with some constant $\alpha < 1/2 - 1/p$, then

$$\begin{aligned} \mathbb{P}(|S_n| \geq x) &\leq \frac{C_1 \Theta_{0,p,n}^p n^{p(1/2-\alpha)}}{x^p} + 4G_{(p-2)/(p+1)} \\ &\quad \left(\frac{C_2 x}{n^{(2p-1-2\alpha p)/(2+2p)} \Theta_{0,p,n}} \right). \end{aligned}$$

It should be noted that Theorems 2.5 and 2.6 actually apply to cases beyond the sample sum, and the same inequalities hold for the partial sum process

$$S_n^* := \max_{1 \leq k \leq n} \left| \sum_{i=1}^k X_{i,n} \right|.$$

However, if S_n , instead of S_n^* , is of interest, Theorem 2.6 could be further strengthened, as was made in [44]. To this end, let's first introduce the dependence adjusted norm (DAN) for the process $\{X_{t,n}\}_{t \in \mathbb{Z}}$ as

$$\|X_{\cdot,n}\|_{p,\alpha} := \sup_{m \geq 0} (m+1)^\alpha \Theta_{m,p,n}. \quad (41.7)$$

Theorem 2.7 (Theorem 2, [44]) Assume $\{X_{t,n}\}_{t \in \mathbb{Z}}$ is of dimensional $d_n = 1$ and is generated from the model (41.1) with functional dependence measures $\theta_{m,p,n}$. Assume further that $\mathbb{E}X_{0,n} = 0$ and $\|X_{\cdot,n}\|_{p,\alpha} < \infty$ for some $p > 2$ and $\alpha > 0$. Let

$$a_n = \begin{cases} 1, & \text{if } \alpha > 1/2 - 1/p, \\ n^{p/2-1-\alpha p}, & \text{if } \alpha < 1/2 - 1/p. \end{cases}$$

Then there exist positive constants C_1, C_2 , and C_3 only depending on q and α such that, for all $x > 0$, we have

$$\mathbb{P}(|S_n| \geq x) \leq C_1 \frac{a_n n \|X_{\cdot,n}\|_{p,\alpha}^p}{x^p} + C_2 \exp \left(-\frac{C_3 x^2}{n \|X_{\cdot,n}\|_{2,\alpha}^2} \right).$$

41.2.2 Sample Sum for Random Vectors with $d_n \geq 1$

In this section we will concern the sample sum case when $d = d_n$ potentially diverges with n . Let $\{X_{t,n}\}_{t \in \mathbb{Z}}$ be a d_n -dimensional real time series of the form (41.1):

$$X_{t,n} = g_n(\dots, \epsilon_{t-1,n}, \epsilon_{t,n}) = \begin{pmatrix} g_{1,n}(\dots, \epsilon_{t-1,n}, \epsilon_{t,n}) \\ g_{2,n}(\dots, \epsilon_{t-1,n}, \epsilon_{t,n}) \\ \vdots \\ g_{d,n}(\dots, \epsilon_{t-1,n}, \epsilon_{t,n}) \end{pmatrix}. \tag{41.8}$$

Assume $\mathbb{E}X_{t,n} = 0$ and let $S_n = \sum_{i=1}^n X_{i,n}$. Theorem 2.8 below provides a tail probability for $|S_n|_\infty$, where for any vector $v = (v_1, \dots, v_d)^\top$ let $|v|_\infty = \max_{j \in [d]} |v_j|$. Assume $\mathbb{E}|X_{i,n}|^q < \infty, q > 2$, and define the uniform functional dependence measure

$$\delta_{i,q,n} = \||X_{i,n} - X_{i,\{0\},n}|_\infty\|_{L_q}, \tag{41.9}$$

where

$$|X_{i,n} - X_{i,\{0\},n}|_\infty := \max_{j \leq d} \left| g_{j,n}(\dots, \epsilon_{i-1,n}, \epsilon_{i,n}) - g_{j,n}(\dots, \epsilon_{-2,n}, \epsilon_{-1,n}, \epsilon'_0, \epsilon_{1,n}, \dots, \epsilon_{i,n}) \right|. \tag{41.10}$$

Define the vector version DAN (cf. (41.7)) as

$$\||X_{\cdot,n}|_\infty\|_{q,\alpha} = \sup_{m \geq 0} (m+1)^\alpha \Omega_{m,q,n}, \text{ where } \Omega_{m,q,n} = \sum_{i=m}^\infty \delta_{i,q,n}. \tag{41.11}$$

The constants $C_{q,\alpha} > 0$ in Theorem 2.8 only depend on q and α , and their values may change from place to place.

Theorem 2.8 (Theorem 6.2 in [45]) Assume $\||X_{\cdot,n}|_\infty\|_{q,\alpha} < \infty$, where $q > 2, \alpha > 0$. Let

$$\Psi_{2,\alpha,n} = \max_{j \leq d} \|X_{j,n}\|_{q,\alpha}$$

be the counterpart of $\||X_{\cdot,n}|_\infty\|_{q,\alpha}$ with the maximum over $j \in [d_n]$ taken outside instead of inside the expectation. Let $\ell_n = \max(1, \log d_n)$. Then the following two statements hold:

(i) If $\alpha > 1/2 - 1/q$, then for all $x \geq C_{q,\alpha}(\sqrt{n\ell_n}\Psi_{2,\alpha,n} + n^{1/q}\ell_n^{3/2}\||X_{\cdot,n}|_\infty\|_{q,\alpha})$, we have

$$\mathbb{P}\{|S_n|_\infty \geq x\} \leq C_{q,\alpha} \frac{n\ell_n^{q/2}\||X_{\cdot,n}|_\infty\|_{q,\alpha}^q}{x^q} + C_{q,\alpha} \exp\left(-C_{q,\alpha} \frac{x^2}{n\Psi_{2,\alpha,n}^2}\right).$$

(ii) If $\alpha < 1/2 - 1/q$, then for all $x \geq C_{q,\alpha}(\sqrt{n\ell_n}\Psi_{2,\alpha,n} + n^{1/2-\alpha}\ell_n^{3/2}\||X_{\cdot,n}|_\infty\|_{q,\alpha})$, we have

$$\mathbb{P}\{|S_n|_\infty \geq x\} \leq C_{q,\alpha} \frac{n^{q/2-\alpha q} \ell_n^{q/2} \||X_{\cdot,n}|_\infty\|_{q,\alpha}^q}{x^q} + C_{q,\alpha} \exp\left(-C_{q,\alpha} \frac{x^2}{n\Psi_{2,\alpha,n}^2}\right).$$

Example 2.1 As an application of Theorem 2.8, consider the following example, with the subscript n omitted for presentation simplicity. Let

$$W_i = \sum_{j=0}^\infty a_j \epsilon_{i-j}$$

be a linear process, where ϵ_j are i.i.d. innovations with finite q th moment $\mu_q := \|\epsilon_i\|_{L_q} < \infty, q > 2$, and a_j are coefficients satisfying $a_* := \sup_{m \geq 0} (m+1)^\alpha \sum_{i=m}^\infty |a_i| < \infty$. Let

$$X_{ij} = g_j(W_i) - E g_j(W_i),$$

where g_j are Lipschitz continuous functions with constants bounded by L . Then

$$|X_i - X_{i,\{0\}}|_\infty \leq L|a_i|\|\epsilon_0 - \epsilon'_0\| \text{ and } \delta_{i,q} \leq 2L|a_i|\mu_q.$$

The dependence adjusted norms

$$\|X_{\cdot,j}\|_{q,\alpha} \leq 2L\mu_q a_* \text{ and } \||X_{\cdot}|_\infty\|_{q,\alpha} \leq 2L\mu_q a_*.$$

In comparison with Theorem 2.7, the bound in Theorem 2.8 is sharp up to a multiplicative logarithmic factor $(\log d)^{q/2}$, adjusting for multi-dimensionality.

Example 2.2 (Largest Eigenvalues of Sample Auto-Covariance Matrices) Let W_i in Example 2.1 be of the form of stationary causal process (41.1) with $\mathbb{E}W_i = 0, \mathbb{E}|W_i|^q < \infty, q > 2$. Again let's omit the subscript n for no confusion will be made. Let

$$a_i = \|W_i - W'_i\|_{L_q}$$

be the associated functional dependence measure, and assume the dependence adjusted norm $\|X_{\cdot}\|_{q,\alpha} < \infty, \alpha > 1/2 - 1/q$. Let

$$S_n(\theta) = \sum_{t=1}^n W_t \exp(\sqrt{-1}t\theta), \quad 0 \leq \theta \leq 2\pi,$$

be the Fourier transform of $(W_t)_{t=1}^n$, where $\sqrt{-1}$ is the imaginary unit. Let

$$d = n^9 \text{ and } \lfloor \theta \rfloor_d = 2\pi \lfloor d\theta / (2\pi) \rfloor / d.$$

By Theorem 2.8(i), the inequality therein holds with

$$\max_{0 \leq \theta \leq 2\pi} |S_n(\lfloor \theta \rfloor_d)| = \max_{j \leq d} |S_n(2\pi j/d)|.$$

Noting that

$$\| \max_{\theta} |S_n(\lfloor \theta \rfloor_d) - S_n(\theta)| \|_q \leq \|W_1\|_q / n^6.$$

Thus with elementary manipulations the same inequality in Theorem 2.8(i) holds with the term $\max_{0 \leq \theta \leq 2\pi} |S_n(\theta)|$.

Given $(W_t)_{t=1}^n$, let the sample covariance matrix

$$\widehat{\Sigma}_n = (\widehat{\gamma}_{j-k}), \text{ where } \widehat{\gamma}_k = n^{-1} \sum_{l=k+1}^n W_l W_{l-k}, \quad 0 \leq k \leq n-1,$$

Notice that the largest eigenvalues

$$\lambda_{\max}(\widehat{\Sigma}_n) \leq \max_{0 \leq \theta \leq 2\pi} |S_n(\theta)|^2 / n.$$

We obtain the tail probability inequality

$$\begin{aligned} \mathbb{P}(\lambda_{\max}(\widehat{\Sigma}_n) \geq u) &\leq \mathbb{P}\left(\max_{0 \leq \theta \leq 2\pi} |S_n(\theta)| \geq (nu)^{1/2}\right) \\ &\leq C_{q,\alpha} \frac{n(\log n)^{q/2} \|X\|_{q,\alpha}^q}{(nu)^{q/2}} \\ &\quad + C_{q,\alpha} \exp\left(-C_{q,\alpha} \frac{u}{\|X\|_{2,\alpha}^2}\right), \end{aligned}$$

when $u \geq C_{q,\alpha} \|X\|_{2,\alpha}^2 \log n$ for a sufficient large constant $C_{q,\alpha}$.

41.2.3 Sample Sum for Random Matrices with $d_n \geq 1$

In this section we will consider the case of time-dependent random matrices. Here $X_{t,n} \in \mathbb{R}^{d_n \times d_n}$ is a d_n -dimensional random matrix, and $\{X_{t,n}\}_{t \in \mathbb{Z}}$ is a matrix-valued time series. Tail probability inequalities for spectral norms for the sum $\sum_{t=1}^n X_{t,n}$ will be presented. The latter results are useful for statistical inference of auto-covariance matrices generated from high-dimensional time series.

Ahlswede and Winter [2], Oliveira [37], and Tropp [41], among many others, have studied such bounds when $\{X_{t,n}\}_{t \in \mathbb{Z}}$ are mutually independent. For instance, [37] and [41] have introduced the following Bernstein-type inequality for tails.

The result in [37] also applies to martingales (cf. Freedman’s Inequality for matrix martingales [19]). Also see [34] for further extensions to conditionally independent sequences and combinatorial sums.

Theorem 2.9 (Corollary 7.1 in [37], Theorem 1.4 in [41])

Let $X_{1,n}, \dots, X_{n,n}$ be real, mean-zero, symmetric independent $d_n \times d_n$ random matrices and assume there exists a positive constant M_n such that $\lambda_{\max}(X_{i,n}) \leq M_n$ for all $1 \leq i \leq n$. Then for any $x \geq 0$,

$$\mathbb{P}\left\{\lambda_{\max}\left(\sum_{i=1}^n X_{i,n}\right) \geq x\right\} \leq d_n \exp\left(-\frac{x^2}{2\sigma_n^2 + 2M_n x/3}\right),$$

where $\sigma_n^2 := \lambda_{\max}(\sum_{i=1}^n \mathbb{E}X_{i,n}^2)$ and recall that $\lambda_{\max}(\cdot)$ represents the largest eigenvalue of the input.

Assuming $\{X_{t,n}\}_{t \in \mathbb{Z}}$ satisfies a geometrically β -mixing decaying rate:

$$\beta(\{X_{t,n}\}_{t \in \mathbb{Z}}; m) \leq \exp\{-\gamma_n(m-1)\}, \quad \text{for } m = 1, 2, \dots \tag{41.12}$$

with some constant $\gamma_n > 0$ possibly depending on n , [6] proved the following theorem that extends the matrix Bernstein inequality to the β -mixing case. In the sequel, for any set A , we denote $\text{Card}(A)$ to be its cardinality.

Theorem 2.10 (Theorem 1 in [6]) Let $\{X_{t,n}\}_{t \in \mathbb{Z}}$ be a sequence of mean-zero symmetric $d_n \times d_n$ random matrices with $\sup_{i \in [n]} \lambda_{\max}(X_{i,n}) \leq M_n$ for some positive constant M_n . Further assume the β -mixing condition (41.12) holds. Then there exists a universal positive constant C such that, for any $n \geq 2$ and $x > 0$,

$$\begin{aligned} \mathbb{P}\left\{\lambda_{\max}\left(\sum_{i=1}^n X_{i,n}\right) \geq x\right\} \\ \leq d_n \exp\left\{-\frac{Cx^2}{v_n^2 n + M_n^2/\gamma_n + xM_n \tilde{\gamma}(\gamma_n, n)}\right\}, \end{aligned}$$

where

$$\begin{aligned} v^2 &:= \sup_{K \subset [n]} \frac{1}{\text{Card}(K)} \lambda_{\max}\left\{\mathbb{E}\left(\sum_{i \in K} X_{i,n}\right)^2\right\} \quad \text{and} \\ \tilde{\gamma}(\gamma_n, n) &:= \frac{\log n}{\log 2} \max\left(2, \frac{32 \log n}{\gamma_n \log 2}\right). \end{aligned}$$

Later, this result is further extended to the τ -mixing case, which was made in [23].

Theorem 2.11 (Theorem 4.3 in [23]) Consider a sequence of real, mean-zero, symmetric $d_n \times d_n$ random matrices

$\{X_{t,n}\}_{t \in \mathbb{Z}}$ with $\sup_{i \in [n]} \|X_{i,n}\| \leq M_n$ for some positive constant M_n that is allowed to depend on n and $\|\cdot\|$ represents the matrix spectral norm. In addition, assume that this sequence is of a geometrically decaying τ -mixing rate, i.e.,

$$\tau(\{X_{t,n}\}_{t \in \mathbb{Z}}; m, \|\cdot\|) \leq M_n \psi_{1,n} \exp\{-\psi_{2,n}(m-1)\},$$

for $m = 1, 2, \dots$

with some constants $\psi_{1,n}, \psi_{2,n} > 0$. Denote $\tilde{\psi}_{1,n} := \max\{d_n^{-1}, \psi_{1,n}\}$. Then for any $x \geq 0$ and any $n \geq 2$, we have

$$\mathbb{P}\left\{\lambda_{\max}\left(\sum_{i=1}^n X_{i,n}\right) \geq x\right\} \leq d_n \exp\left\{-\frac{x^2}{8(15^2 n v_n^2 + 60^2 M_n^2 / \psi_{2,n}) + 2x M_n \tilde{\psi}(\tilde{\psi}_{1,n}, \psi_{2,n}, n, d_n)}\right\},$$

where

$$v_n^2 := \sup_{K \subset [n]} \frac{1}{\text{Card}(K)} \lambda_{\max}\left\{\mathbb{E}\left(\sum_{i \in K} X_{i,n}\right)^2\right\}$$

and $\tilde{\psi}(\tilde{\psi}_{1,n}, \psi_{2,n}, n, d_n) := \frac{\log n}{\log 2} \max\left\{1, \frac{8 \log(\tilde{\psi}_{1,n} n^6 d_n)}{\psi_{2,n}}\right\}$.

We note that the above matrix Bernstein inequalities for weakly dependent data can be immediately applied to study the behavior of many statistics of importance in analyzing a high-dimensional time series model. In particular, tail behaviors for the largest eigenvalues of sample auto-covariances in weakly dependent high-dimensional time series models have been characterized in Theorems 2.1 and 2.2 in [23], with bounds delivered for both general and Gaussian weakly dependent time series (the later using a different set of techniques tailored for Gaussian processes) separately; see also Sect. 41.4 ahead for a concrete example.

41.2.4 U- and V-Statistics

Consider $\{X_{i,n}\}_{i \in [n]}$ to be n random variables of identical distribution in a measurable space $(\mathcal{X}, \mathcal{B}_{\mathcal{X}})$. Given a symmetric kernel function $h_n(\cdot) : \mathcal{X}^r \rightarrow \mathbb{R}$, the U- and V-statistic $U_n(h_n)$ and $V_n(h_n)$ of order r_n are defined as

$$U_n(h_n) := \binom{n}{r_n}^{-1} \sum_{1 \leq i_1 < \dots < i_{r_n} \leq n} h_n(X_{i_1,n}, \dots, X_{i_{r_n},n})$$

and $V_n(h_n) := n^{-r_n} \sum_{i_1, \dots, i_{r_n}=1}^n h_n(X_{i_1,n}, \dots, X_{i_{r_n},n})$.

The V- and U-statistics are popular alternatives to sample sums and have been routinely used in statistics nowadays (cf. the textbooks [31] and [28]).

Nonasymptotic probability and moment inequalities for V- and U-statistics in the i.i.d. case have been extensively studied [1, 3, 20, 24]. Assuming $\{X_{t,n}\}_{t \in \mathbb{Z}}$ to be geometrically ϕ -mixing, [22] established the following theorem that gives an exponential inequality for dependent U-statistics.

Theorem 2.12 (Theorem 2.1, [22]) *Let $\{X_{t,n}\}_{t \in \mathbb{Z}}$ satisfy*

$$\phi(\{X_{t,n}\}_{t \in \mathbb{Z}}; m) \leq c_n \exp(-C_n m) \text{ for } m = 1, 2, \dots$$

with two constants $c_n, C_n > 0$. Assume further that

$$\|h_n\|_{\infty} \leq M_n,$$

symmetric and is mean-zero (i.e., $\mathbb{E}h_n = 0$ with regard to the product measure). Then there exist two constants $c'_n, C'_n > 0$ that only depend on c_n, C_n , and r_n , such that, for any $x \geq 0$ and $n \geq 4$,

$$\begin{aligned} \mathbb{P}(|U_n(h_n)| \geq c'_n M_n / \sqrt{n} + x) \\ \leq 2 \exp\left(-\frac{C'_n x^2 n}{M_n^2 + M_n x (\log n) (\log \log 4n)}\right). \end{aligned}$$

With tedious calculations, the dependence of c'_n, C'_n on r_n, c_n, C_n in Theorem 2.12 can be explicitly obtained, as was made in Theorems 2.10 and 2.11.

In order to present the next result, let's first introduce more concepts in U- and V-statistics. For presentation clearness, let us assume the kernel $h_n(\cdot)$, its order r_n , and the dimension d_n are fixed and hence written as $h(\cdot)$, r , and d without the subscript. Assume $\{X_{t,n}\}_{t \in \mathbb{Z}}$ to be stationary for any $n \in \mathbb{N}$. Let $\{\tilde{X}_{i,n}\}_{i \in [n]}$ be an i.i.d. sequence with $\tilde{X}_{1,n}$ identically distributed as $X_{1,n}$. The mean value of a symmetric kernel h (with regard to the marginal probability measure \mathbb{P}_n) is defined as

$$\theta_n := \theta_n(h) := \mathbb{E}h(\tilde{X}_{1,n}, \dots, \tilde{X}_{r,n}).$$

The kernel $h(\cdot)$ is called degenerate of level $k-1$ ($2 \leq k \leq r$) with regard to the measure \mathbb{P}_n if and only if

$$\mathbb{E}h(x_1, \dots, x_{k-1}, \tilde{X}_{k,n}, \dots, \tilde{X}_{r,n}) = \theta_n$$

for any $(x_1^\top, \dots, x_{k-1}^\top)^\top \in \text{supp}(\mathbb{P}_n^{k-1})$, the support of the product measure \mathbb{P}_n^{k-1} .

When h is degenerate of level $k - 1$, its Hoeffding decomposition takes the form

$$h(x_1, \dots, x_r) - \theta_n = \sum_{1 \leq i_1 < \dots < i_k \leq r} h_{k,n}(x_{i_1}, \dots, x_{i_k}) + \dots + h_{r,n}(x_1, \dots, x_r),$$

where $\{h_{p,n}\}_{p=k}^r$ are recursively defined as

$$h_{1,n}(x) := g_{1,n}(x),$$

$$h_{p,n}(x_1, \dots, x_p) := g_{p,n}(x_1, \dots, x_p) - \sum_{k=1}^p h_{1,n}(x_k) - \dots - \sum_{1 \leq k_1 < \dots < k_{p-1} \leq p} h_{p-1,n}(x_{k_1}, \dots, x_{k_{p-1}}),$$

for $p = 2, \dots, r$, with $\{g_{p,n}\}_{p=1}^r$ defined as $g_{r,n} := h - \theta_n$, and

$$g_{p,n}(x_1, \dots, x_p) := \mathbb{E}h(x_1, \dots, x_p, \tilde{X}_{p+1,n}, \dots, \tilde{X}_{r,n}) - \theta_n$$

for $1 \leq p \leq r - 1$. For each $1 \leq p \leq r$, we denote the V-statistic generated by $h_{p,n}$ by

$$V_n(h_{p,n}) := n^{-p} \sum_{i_1, \dots, i_p=1}^n h_{p,n}(X_{i_1,n}, \dots, X_{i_p,n}).$$

Theorem 2.13 (A Slight Modification to Theorem 1 in [40]) *Suppose $\{X_{i,n}\}_{i=1}^n$ is part of a stationary sequence $\{X_{t,n}\}_{t \in \mathbb{Z}}$ that is geometrically α -mixing with coefficient*

$$\alpha(\{X_{t,n}\}_{t \in \mathbb{Z}}; m) \leq c_n \exp(-C_n m) \quad \text{for all } m \geq 1,$$

where c_n and C_n are two positive constants. Suppose $h \in L_1(\mathbb{R}^{rd})$ is fixed, symmetric, continuous, and its Fourier transform $\widehat{h}(u) := \int h(x)e^{-2\pi i u^\top x} dx$ satisfies

$$\int_{\mathbb{R}^{rd}} |\widehat{h}(u)| \|u\|^q du < \infty$$

for some $q \geq 1$, where $\|\cdot\|$ represents the Euclidean norm. Then, there exists a positive constant $C'_n = C(r, c_n, C_n)$ such that for each $1 \leq p \leq r$, and any $n \geq 2, x > 0$,

$$\mathbb{P}\left(|V_n(h_{p,n})| \geq x\right) \leq 6 \exp\left\{-\frac{C'_n n x^{2/p}}{A_{p,n}^{1/p} + x^{1/p} M_{p,n}^{1/p}}\right\}$$

with

$$A_{p,n} = 2^{2r} \|\widehat{h}\|_{L_1}^2 \left\{ \frac{64c_n^{1/3}}{1 - \exp(-C_n/3)} + \frac{(\log n)^4}{n} \right\}^p \quad \text{and}$$

$$M_{p,n} = 2^r \|\widehat{h}\|_{L_1} (\log n)^{2p}.$$

As Theorem 2.12, the dependence of C'_n on r, c_n, C_n in the above theorem could be explicitly calculated. We also note that, though $h(\cdot)$ itself is assumed to be fixed, the ‘‘degenerate’’ kernels $h_{p,n}$ could depend on n through the measure \mathbb{P}_n in the triangular array setting, and hence the subscript n is kept.

41.3 A Cautionary Example

Section 41.2 exemplifies the use of dependence measures to construct desired moment/probability inequalities for quantifying the statistical properties of procedures in a high-dimensional time series model. The problem then reduces to characterizing these dependence measures in a triangular array setting as highlighted at the beginning of Sect. 41.2. As is apparent from reading their definitions, those dependence measures introduced in [13, 17], and [42] can be explicitly calculated. Therefore, the verification of those dependence measures, as were made in Section 3 in [15] as well as in [23, 42], and many other places, are obviously still valid under the high-dimensional triangular array framework.

The verifications for the mixing conditions introduced at the beginning of Sect. 41.1, on the other hand, should be checked with caution under this new framework. In the following we will use the example of β -mixing to showcase this new challenge of high dimensionality in establishing mixing-type dependence for time series data.

In literature, for a time series model that is fixed (i.e., not changing when more data points are observed), there have been a variety of results to establish bounds for β -mixing coefficients. See, for example, [32] for a review and [11] for β -mixing of Markov processes. Let’s focus on a particular example. Consider the following simple d -dimensional stationary Gaussian VAR(1) model:

$$X_t = \kappa X_{t-1} + E_t = \sum_{j=0}^{\infty} \kappa^j E_{t-j}, \quad \text{for all } t \in \mathbb{Z}. \quad (41.13)$$

Here the autocorrelation coefficient $\kappa \in \mathbb{R}$ is assumed to be fixed and satisfy $0 < \kappa < 1$ for simplicity, and the innovation noises $\{E_t \in \mathbb{R}^d\}$ are i.i.d. Gaussian. Then it is immediate (cf. Proposition 2 in [32]) that $\{X_t\}$ is geometrically β -mixing satisfying

$$\beta(\{X_t\}; m) \leq C\gamma^m \quad (41.14)$$

for some fixed constants $C > 0, \gamma < 1$.

However, in high dimensions such a derivation is problematic. Let’s fix the framework first. Adopting the triangular array setting as described in the last section, we assume that the studied model could change as more observations are

available to us. In other words, let's adopt a parallel model to Eq. (41.13): for any $n = 1, 2, 3, \dots$, write

$$X_{t,n} = \begin{pmatrix} X_{t,1,n} \\ X_{t,2,n} \\ \vdots \\ X_{t,d_n,n} \end{pmatrix} = \begin{pmatrix} \kappa_n & 0 & \dots & 0 \\ 0 & \kappa_n & \dots & 0 \\ \vdots & \vdots & \ddots & 0 \\ 0 & 0 & 0 & \kappa_n \end{pmatrix} \underbrace{\begin{pmatrix} X_{t-1,1,n} \\ X_{t-1,2,n} \\ \vdots \\ X_{t-1,d_n,n} \end{pmatrix}}_{X_{t-1,n} \in \mathbb{R}^{d_n}} + \underbrace{\begin{pmatrix} E_{t,1,n} \\ E_{t,2,n} \\ \vdots \\ E_{t,d_n,n} \end{pmatrix}}_{E_{t,n} \in \mathbb{R}^{d_n}},$$

for all $t \in \mathbb{Z}$.
(41.15)

Here for any n , the observed data $\{X_{1,n}, X_{2,n}, \dots, X_{n,n}\}$ are assumed to be generated from a process $\sum_{j=0}^{\infty} \kappa_n^j E_{t-j,n}$, where first of all the dimension of the time series d_n has been allowed to change with the sample size n . Moreover, as an implicit consequence of the above high-dimensional triangular array framework, all the parameters in Model (41.15), including $\kappa_n \in \mathbb{R}$, $\text{Cov}(X_{t,n}) \in \mathbb{R}^{d_n \times d_n}$, and $\text{Cov}(E_{t,n}) \in \mathbb{R}^{d_n \times d_n}$, are now allowed to change as the sample size n is increasing.

Once such a framework is fixed, it becomes clear that the analysis of various dependence conditions has to be nonasymptotic, i.e., we now have to provide an analysis of the β -mixing coefficient that takes the change of d_n, κ_n , and all the other model parameters into account. With these concepts in mind, we first state a somewhat comforting result that certain desirable properties could still be established for α -mixing (in contrast to the β -mixing) coefficient under the triangular array setting.

Theorem 3.1 Consider the following simple stationary Gaussian vector autoregressive model that generalizes (41.15) by relaxing restrictions on the transition matrix:

$$X_{t,n} = A_n X_{t-1,n} + E_{t,n}, \quad t \in \mathbb{Z}. \quad (41.16)$$

We then have

$$\alpha(\{X_{t,n}\}_{t \in \mathbb{Z}}; m) \leq \left\{ \frac{\lambda_{\max}(\Sigma_n)}{\lambda_{\min}(\Sigma_n)} \right\}^{1/2} \|A_n\|^m,$$

where $\Sigma_n := \text{Cov}(X_{0,n})$, $\lambda_{\min}(\cdot)$ stands for the smallest eigenvalue of the input, and $\|\cdot\|$ is the matrix spectral norm.

Proof. For notation simplicity, let's remove n from the subscript. Since VAR(1) is a stationary Markov chain, by [9], we have the ρ -mixing coefficient

$$\rho\{\sigma(X_{-\infty}^0), \sigma(X_m^\infty)\} = \rho\{\sigma(X_0), \sigma(X_m)\}.$$

By Theorem 1 from [27], if $U_1, U_2, \dots, U_m, V_1, V_2, \dots, V_\ell$ are jointly normal random variables, then there exist real numbers $a_1, a_2, \dots, a_m, b_1, b_2, \dots, b_\ell$ such that

$$\begin{aligned} & \rho\{\sigma(U_k, 1 \leq k \leq m), \sigma(V_k, 1 \leq k \leq \ell)\} \\ &= \text{Corr}\left(\sum_{k=1}^m a_k U_k, \sum_{k=1}^{\ell} b_k V_k\right). \end{aligned}$$

Since (X_0, X_m) is multivariate normal, there exist real numbers $a = (a_1, a_2, \dots, a_p)^\top, b = (b_1, b_2, \dots, b_p)^\top$ such that

$$\begin{aligned} \rho\{\sigma(X_0), \sigma(X_m)\} &= \text{Corr}(a^\top X_0, b^\top X_m) = \frac{a^\top \Sigma(A^m)^\top b}{\sqrt{a^\top \Sigma a b^\top \Sigma b}} \\ &\leq \sqrt{\|\Sigma^{\frac{1}{2}}(A^m)^\top \Sigma^{-1}(A^m) \Sigma^{\frac{1}{2}}\|}, \end{aligned}$$

where the last inequality is followed by Cauchy-Schwarz. Hence we have

$$\rho\{\sigma(X_{-\infty}^0), \sigma(X_m^\infty)\} \leq \left\{ \frac{\lambda_{\max}(\Sigma)}{\lambda_{\min}(\Sigma)} \right\}^{\frac{1}{2}} \|A\|^m.$$

Now noticing

$$\alpha\{\sigma(X_{-\infty}^0), \sigma(X_m^\infty)\} \leq \rho\{\sigma(X_{-\infty}^0), \sigma(X_m^\infty)\}$$

finishes the proof. □

Applying Theorem 3.1 to Model (41.15), it is clear that the α -mixing coefficient for Model (41.15) is bounded by κ_n^m , which will be exponentially tending to 0 if $\kappa_n < 1$ is fixed, regardless of how large the dimension d_n is. We then state a possibly striking result, that, even if restricting to the Model (41.15) and fixing κ_n , the β -mixing coefficient of the time series $\{X_{t,n}\}_{t \in \mathbb{Z}}$ could still be tending to 1 if d_n is sufficiently larger than the time gap. Thusly, β -mixing coefficient is dimension dependent.

Theorem 3.2 Consider the model (41.15) under the triangular array setting. If we further assume that $E_{0,n} = (E_{0,1,n}, \dots, E_{0,d_n,n})^\top$ have i.i.d. components, then for any positive integers n and m , we have

$$\beta(\{X_{t,n}\}_{t \in \mathbb{Z}}; m) \geq 1 - 2 \exp\left(-\frac{d_n \kappa_n^{2m}}{18\pi^2}\right).$$

In particular, if (1) $d_n = d$ is not changing with n but $\lim_{n \rightarrow \infty} \kappa_n^{2n} > \frac{18\pi^2 \log 2}{d}$, or (2) $\kappa_n = \kappa$ is not changing with n but $\lim_{n \rightarrow \infty} d_n \kappa^{2n} > 18\pi^2 \log 2$, then $\liminf_{n \rightarrow \infty} \beta(\{X_{t,n}\}_{t \in \mathbb{Z}}; n) > 0$.

Theorem 3.2 is concerning a particularly simple model that is merely aggregating d_n i.i.d. AR(1) Gaussian sequences once we have n data points. It is very unlikely that any assumption in a general theorem for quantifying the behavior of a high-dimensional time series could exclude such a simple case. However, it has been apparent from this result that, once

the triangular array framework is adopted, many simple and elegant properties like Eq. (41.14) could no longer be trusted because otherwise, the case that $\lim_{n \rightarrow \infty} \beta(\{X_{t,n}\}_{t \in \mathbb{Z}}; n) \neq 0$ shall never happen. The reason is, once the model $\{X_{t,n}\}$ is allowed to change with n , the values of C and γ in (41.14) will depend on the sample size n . Any solid analysis of the β -mixing coefficient hence has to be fully nonasymptotic. This, however, violates the spirit beneath the definition of various mixing coefficients and, to the authors' knowledge, cannot be trivially handled (except for the α - and ρ -mixing coefficients under a Gaussian process, as showcased above in Theorem 3.1).

Proof of Theorem 3.2 The proof is nonasymptotic and relies on several known results in the mixing literature. For presentation clearness, we omit the subscript n in the following when no confusion is made.

In the first step, we need to establish a lower bound for the marginal α -mixing coefficient $\alpha(\sigma(X_{0,1}), \sigma(X_{m,1}))$ with the understanding that

$$X_t = (X_{t,1}, \dots, X_{t,d})^\top.$$

For any bivariate Gaussian random vector $(Z_1, Z_2)^\top \in \mathbb{R}^2$, the following two facts are known.

(1) One has

$$\begin{aligned} \alpha(\sigma(Z_1), \sigma(Z_2)) &\leq \rho(\sigma(Z_1), \sigma(Z_2)) \\ &\leq 2\pi\alpha(\sigma(Z_1), \sigma(Z_2)). \end{aligned}$$

See, for example, Equation (1.9) in Chapter 4 of [25] or Theorem 2 in [27].

(2) Theorem 1 in [27] gives

$$\rho(\sigma(Z_1), \sigma(Z_2)) = |\text{Corr}(Z_1, Z_2)|.$$

The above two results then yield

$$\alpha(\sigma(X_{0,1}), \sigma(X_{m,1})) \geq \frac{1}{2\pi} |\text{Corr}(X_{0,1}, X_{0,m})| = \frac{\kappa^m}{2\pi}.$$

In the second step, we are going to establish a lower bound on $\beta(\sigma(X_0), \sigma(X_m))$ based on the derived lower bound for the marginal α -mixing coefficient. For any $j \in [d]$, since

$$\alpha(\sigma(X_{0,j}), \sigma(X_{m,j})) \geq \frac{\kappa^m}{2\pi},$$

by definition, there must exist sets $G \in \sigma(X_{0,j})$ and $H \in \sigma(X_{m,j})$ such that

$$\begin{aligned} \left| \mathbb{P}(X_{0,j} \in G, X_{m,j} \in H) - \mathbb{P}(X_{0,j} \in G)\mathbb{P}(X_{m,j} \in H) \right| \\ \geq \frac{\kappa^m}{3\pi} =: \eta. \end{aligned}$$

Without loss of generality, we may assume that

$$\begin{aligned} \theta := \mathbb{P}(X_{0,j} \in G, X_{m,j} \in H) &> \mathbb{P}(X_{0,j} \in G)\mathbb{P}(X_{m,j} \in H) \\ &=: \xi. \end{aligned}$$

For $j \in [d]$, let's define V_j, W_j as

$$V_j = \mathbf{1}(X_{0,j} \in G) \quad \text{and} \quad W_j = \mathbf{1}(X_{m,j} \in H),$$

where $\mathbf{1}(\cdot)$ represents the indicator function. Then we have

- (1) For each $j \in [d]$, $\mathbb{E}V_j = \mathbb{P}(X_{0,j} \in G)$, $\mathbb{E}W_j = \mathbb{P}(X_{m,j} \in H)$, $\mathbb{E}(V_j W_j) = \theta$.
- (2) By i.i.d.-ness of $E_{0,1}, \dots, E_{0,d}$, $\{(V_j, W_j), j \in [d]\}$ is an i.i.d. sequence.

Let's now consider the following event

$$\left\{ \frac{1}{d} \sum_{j=1}^d V_j W_j \geq \theta - \frac{\eta}{2} \right\}. \tag{41.17}$$

By Hoeffding's inequality for i.i.d. data [24], we have

$$\mathbb{P}\left(\frac{1}{d} \sum_{j=1}^d V_j W_j \geq \theta - \frac{\eta}{2}\right) \geq 1 - \exp(-d\eta^2/2).$$

On the other hand, consider a comparable event to (41.17) under the product measure:

$$\left\{ \frac{1}{d} \sum_{j=1}^d V_j \tilde{W}_j \geq \theta - \frac{\eta}{2} \right\},$$

where $\{\tilde{W}_j\}_{j \in [d]}$ is a copy of $\{W_j\}_{j \in [d]}$ and is independent of $\{V_j\}_{j \in [d]}$. Again, by Hoeffding's inequality, we have

$$\begin{aligned} \mathbb{P}\left(\frac{1}{d} \sum_{j=1}^d V_j \tilde{W}_j \geq \theta - \frac{\eta}{2}\right) &\leq \mathbb{P}\left(\frac{1}{d} \sum_{j=1}^d V_j \tilde{W}_j \geq \xi + \frac{\eta}{2}\right) \\ &\leq \exp(-d\eta^2/2) \end{aligned}$$

as $\theta - \xi \geq \eta$.

By definition of β -mixing coefficient, we then have

$$\begin{aligned} \beta(\sigma(X_0), \sigma(X_m)) &\geq \left| \mathbb{P}\left(\frac{1}{d} \sum_{j=1}^d V_j W_j \geq \theta - \frac{\eta}{2}\right) \right. \\ &\quad \left. - \mathbb{P}\left(\frac{1}{d} \sum_{j=1}^d V_j \tilde{W}_j \geq \theta - \frac{\eta}{2}\right) \right| \\ &\geq 1 - 2 \exp\left(-\frac{d\kappa^{2m}}{18\pi^2}\right). \end{aligned}$$

Lastly, by noticing that the model studied is naturally a Markov chain and by using Theorem 7.3 in [10], one obtains

$$\beta(\{X_t\}; m) = \beta(\sigma(X_0), \sigma(X_m)),$$

which finishes the proof. \square

41.4 Statistical Applications

In this section, let's consider one particular example of statistical application to exemplify a (correct) use of the probability inequalities for analyzing a high-dimensional time series analysis problem. In the following we omit the subscript n when no confusion is possible.

We focus on the following simple lag-one vector autoregressive model that has been discussed in Theorem 3.1,

$$X_t = AX_{t-1} + E_t, \quad t \in \mathbb{Z}, \quad X_t \in \mathbb{R}^d. \quad (41.18)$$

In this section our task is to, given n observations X_1, \dots, X_n of a triangular array Model (41.18), estimate the transition matrix A in Model (41.18) under a low-rank assumption. Here the assumption, $r := \text{rank}(A) < d$, is regular in the related literature [4,5,7,12,29,30,36,38]. In particular, it is motivated by latent factor models, where a few latent factors drive the main movement of the multivariate time series.

The problem of transition matrix estimation is naturally related to multiple regression. For this, under the low-rank assumption on A , the least squares estimator (LSE),

$$\hat{A}^{\text{LSE}} := \operatorname{argmin}_{Q \in \mathbb{R}^{d \times d}} \frac{1}{n-1} \sum_{t=2}^n \|X_t - QX_{t-1}\|_F^2,$$

where $\|\cdot\|_F$ represents the matrix Hilbert-Schmidt norm, is not statistically efficient for estimating A [26]. For improving estimation efficiency, there have been a number of methods introduced in the literature. In particular, [36] proposed the following penalized-LSE:

$$\hat{A}_\lambda := \operatorname{argmin}_{Q \in \mathbb{R}^{d \times d}} \frac{1}{n-1} \sum_{t=2}^n \|X_t - QX_{t-1}\|_F^2 + \lambda \|Q\|_*. \quad (41.19)$$

Here the matrix nuclear norm $\|\cdot\|_*$ is added to induce the sparsity of the estimator's singular values and hence encourages low-rankness. The obtained estimator is easy to implement and proves to enjoy good empirical performance as well as preliminary theoretical properties under an additional Gaussian process assumption.

In this section we plan to give a new analysis of the estimator \hat{A}_λ based on the newly developed probability bounds in [23] (elaborated in Theorem 2.11), which is shown to be able to eliminate the Gaussian assumption that is essential in the original analysis of [36].

We start from the following general setting. Suppose $M \in \mathbb{R}^{d \times d}$ and $M_1 \in \mathbb{R}^{d \times d}$ both to be of dimension d , are two real matrices, M is symmetric and positive definite, and the matrix of interest A could be written as $A = M_1^\top M^{-1} \in \mathbb{R}^{d \times d}$ of rank $r \leq d$. Let \hat{M} and \hat{M}_1 be estimates of M and M_1 , and define

$$\hat{A}_\lambda^{\text{G}} := \operatorname{argmin}_{Q \in \mathbb{R}^{d \times d}} L_\lambda(Q; \hat{M}, \hat{M}_1),$$

$$\text{where } L_\lambda(Q; \hat{M}, \hat{M}_1) := \langle -2\hat{M}_1 + \hat{M}Q^\top, Q^\top \rangle + \lambda \|Q\|_*.$$

It is direct to check that \hat{A}_λ is a special case of $\hat{A}_\lambda^{\text{G}}$ with \hat{M} and \hat{M}_1 chosen to the sample covariance and lag-one auto-covariance matrices; this is the famous Yule-Walker formula.

The following lemma relates the analysis of \hat{A}_λ to that of analyzing the marginal and first-order auto-covariance matrices. Its proof is straightforward given the literature.

Lemma 4.1 *Assume \hat{M} and \hat{M}_1 are the estimates of $M \in \mathbb{R}^{d \times d}$ and $M_1 \in \mathbb{R}^{d \times d}$ based on n observations, satisfying*

$$\mathbb{P}(\|\hat{M} - M\| \leq \delta_1) \geq 1 - \epsilon_1 \quad \text{and} \quad \mathbb{P}(\|\hat{M}_1 - M_1\| \leq \delta_2) \geq 1 - \epsilon_2.$$

Here $\delta_1, \delta_2, \epsilon_1, \epsilon_2$ are functions of (n, d) , and ϵ_1, ϵ_2 go to zero as (n, d) increases to infinity. Further assume

$$\begin{aligned} M &= M^\top, \quad \lambda_{\min}(M) \geq \gamma_{\min}, \quad A := M_1^\top M^{-1}, \\ \text{rank}(A) &\leq r, \quad \|A\|_2 \leq \gamma_{\max}, \end{aligned}$$

and

$$\lambda \geq 2(\gamma_{\max} \delta_1 + \delta_2) \quad \text{and} \quad \mu \leq \gamma_{\min} - \delta_1,$$

where γ_{\min} and γ_{\max} are two absolute positive constants. We then have

$$\mathbb{P}\left(\|\widehat{A}_\lambda^G - A\|_F \geq \frac{\lambda + 2\sqrt{2}(\gamma_{\max}\delta_1 + \delta_2)}{2\mu} \sqrt{r}\right) \leq \epsilon_1 + \epsilon_2.$$

The next result establishes convergence of sample auto-covariance matrices in the following general VAR(p) model:

$$Y_t = A_1 Y_{t-1} + \dots + A_2 Y_{t-p} + E_t,$$

where $\{E_t\}_{t \in \mathbb{Z}}$ is a sequence of zero-mean and subgaussian independent (not necessarily identically distributed) vectors such that for all $t \in \mathbb{Z}$ and $u \in \mathbb{R}^d$, $\|u^\top E_t\|_{\psi_2} < \infty$ for some universal constant $c' > 0$. Here $\|\cdot\|_{\psi_2}$ is the Orlicz ψ_2 norm defined as

$$\|X\|_{\psi_2} := \inf \left\{ k \in (0, \infty) : \mathbb{E}[\exp\{|X|/k\}^2] - 1 \leq 1 \right\}.$$

In addition, assume $\|A_k\| \leq a_k < 1$ for all $1 \leq k \leq p$, and $\sum_{k=1}^p a_k < 1$, where $\{a_k\}_{k=1}^p$ and p are some universal constants.

Under these conditions, we have the following theorem, which is a direct implementation of Theorem 2.11.

Theorem 4.1 For the above $\{Y_t\}_{t \in \mathbb{Z}}$, let $\widehat{\Sigma}_m := (n - m)^{-1} \sum_{t=1}^{n-m} Y_t Y_t^\top$ be the m -th order auto-covariance matrix. Define

$$\begin{aligned} \kappa_1 &:= \sup_{t \in \mathbb{Z}} \sup_{u \in \mathbb{S}^{d-1}} \|u^\top Y_t\|_{\psi_2} < \infty, \\ \kappa_* &:= \sup_{t \in \mathbb{Z}} \sup_{v \in \mathbb{S}^{d-1}} \|v^\top Y_t\|_{\psi_2}, \text{ and } r^* = \kappa_*^2 / \kappa_1^2, \end{aligned}$$

with the notations that

$$\begin{aligned} \mathbb{S}^{d-1} &:= \{x \in \mathbb{R}^d : \|x\|_2 = 1\}, \\ \overline{\mathbb{S}}^{d-1} &:= \{x \in \mathbb{R}^d : |x_1| = \dots = |x_p| = 1\}, \end{aligned}$$

and whose finiteness is guaranteed by that of $\|u^\top E_t\|_{\psi_2}$. Let us write

$$\begin{aligned} \gamma_1 &= (\kappa_* / \kappa_1) (\|\overline{A}\| / \rho_1)^K, \gamma_2 = \log(\rho_1^{-1}), \\ \gamma_3 &= p (\|\overline{A}\| / \rho_1)^K, \gamma_4 = \log(\rho_1^{-1}). \end{aligned}$$

Here we denote

$$\overline{A} := \begin{bmatrix} a_1 & a_2 & \dots & a_{d-1} & a_d \\ 1 & 0 & \dots & 0 & 0 \\ & & \dots & & \\ 0 & 0 & \dots & 1 & 0 \end{bmatrix},$$

ρ_1 is a universal constant such that $\rho(\overline{A}) < \rho_1 < 1$ whose existence is guaranteed by the assumption that $\sum_{k=1}^d a_k < 1$, and K is some constant only depending on ρ_1 .

Assume further

$$\gamma_1 = O(\sqrt{r^*}) \text{ and } \gamma_3 = O(1).$$

Then, for any integer $n \geq 2$ and $0 \leq m \leq n - 1$, we have

$$\mathbb{E} \|\widehat{\Sigma}_m - \mathbb{E} \widehat{\Sigma}_m\| \leq C \kappa_1^2 \left\{ \sqrt{\frac{r_* \log ep}{n - m}} + \frac{r_* \log ep (\log np)^3}{n - m} \right\}$$

for some universal constant C .

Combining Lemma 4.1 and Theorem 4.1 directly yields the following large-sample property on approximating A using \widehat{A}_λ .

Theorem 4.2 Assume Model (4.1.18), the spectrum of $\Sigma_0 := \mathbb{E} \widehat{\Sigma}_0$ upper and lower bounded by universal positive constants, and assume the transition matrix $A \in \mathcal{A}(r, \gamma_{\max})$ with

$$\mathcal{A}_M(r, \gamma_{\max}) := \left\{ M \in \mathbb{R}^{d \times d} : \text{rank}(M) \leq r, \|M\| \leq \gamma_{\max} \right\}$$

for some universal positive constant $\gamma_{\max} < 1$. Suppose further that $\lambda \asymp \sqrt{d/n}$ and $\|u^\top E_t\|_{\psi_2} < \infty$. We then have

$$\|\widehat{A}_\lambda - A\|_F = O_p(\sqrt{dr \log d/n}),$$

provided that $dr \log d/n = o(1)$.

focus on practical algorithms of various machine learning techniques and their evolutions. An in-depth analysis and comparison based on the main concepts are presented. Different learning types are studied to investigate each technique's goals, limitations, and advantages. Moreover, a case study is presented to illustrate the concepts explained and make a practical comparison. This chapter helps researchers understand the challenges in this area, which can be turned into future research opportunities, and at the same time gain a core understanding of the most recent methodologies in machine learning.

Abstract

We are living in the golden era of machine learning as it has been deployed in various applications and fields. It has become the statistical and computational principle for data processing. Despite the fact that most of the existing algorithms in machine learning have been around for decades, the area is still booming. Machine learning aims to study the theories and algorithms in statistics, computer science, optimization, and their interplay with each other. This chapter provides a comprehensive review of past and recent state-of-the-art machine learning techniques and their applications in different domains. We

42.1 Introduction

Machine learning has become one of the most exciting and popular areas in science and technology for a number of reasons. This field is rapidly expanding and tremendously fast-paced with novel algorithms and ideas introduced every day. While the concepts of machine learning have been around for decades, the progress toward developing its basis in today's technology and society is rather a new phenomenon.

In the recent decade, the growing mass of available data and invention of powerful computational processing tools has empowered machine learning and its applications significantly. Machine learning (ML) now plays an important role in today's modern life and is an indispensable part of our lives. Impacting many different businesses, we can say that machine learning and Artificial Intelligence have caused an industrial revolution by bringing many critical innovations in technology. Consider finding the fastest route to your destination using GPS navigation services such as

Google Maps, the recommendations you receive every day in Amazon and Netflix, and Fraud alerts on your credit card, to more important applications such as Medical Diagnosis; all are applications of ML in our lives.

The main goal in machine learning is to develop computer programs and algorithms that can conduct experiments on the data and learn from it to find specific patterns. In all algorithms, the goal is to transform the raw input data to an informative output. The computer (machine) is programmed to automatically perform a model or algorithm on the input dataset in order to get the desired output. However, some of the complex learning algorithms in machine learning have completely changed our perception of data processing such as Neural Networks, boosting algorithms, and ensemble methods. This chapter presents a comprehensive literature review and future prospect of algorithms in machine learning with a multiscope perspective. In addition to in-depth analysis of algorithms, formulations, applications of machine learning, challenges, and research avenues are discussed.

42.1.1 History

Traditional statistical theories used for predictive analysis purposes before 1950s are the basis of many machine learning algorithms. However, we can say that the concept of machine learning that we know today began after the 1950s with a series of inventions, and after the 1990s, mainly the last 30 years, machine learning entered its golden era. Machine learning was first introduced by Arthur L. Samuel in the 1950s, and the term “machine learning” was defined as a “computer’s ability to learn without being explicitly programmed” [1]. He designed a computer program that could learn which moves and strategies win better in checkers and improved as it ran. In 1957, Frank Rosenblatt designed the first artificial neural network, called Perceptron, with the idea to simulate the processes of the human brain [2]. The limitations of Perceptron to recognize many classes of patterns lead to the discovery of multilayer perceptron in the 1960s. In the 1970s, the concept of Backpropagation was developed [3] and was implemented in neural networks in 1986 [4]. In 1967, the “nearest neighbor” algorithm was developed for pattern classification [5]. Bayesian methods and probabilistic inference started to appear in machine learning research in the 1980s. In the 1990s, Machine learning began focusing on more data-driven approaches instead of parametric ones. In 1995, Vapnik developed a modified classification algorithm for handling nonlinearly separable classes using Support vector machines (SVMs) [6]. Tree-based learning algorithms and Random forests were also introduced [7].

In the twenty-first century, with the invention of GPUs, which have much more processing power compared to CPUs,

along developing parallel computing frameworks and tools, scientists began developing algorithms that can analyze large amounts of data with the tools that speed up the training process. Introducing models such as Boosting algorithms, Ensemble methods, and Neural Networks which have increasing accuracy and adaptive learning pace also played an important role in ML industry in the past 20 years. ML algorithms combined with new computing technologies have boosted scalability and improve accuracy and efficiency. Nowadays, machine learning is the one of the important reasons for significant advancements in technology and has created many application-based concepts. The applications vary from predicting events and product recommendations to analyzing stocks market.

42.1.2 Machine Learning Importance

Machine learning is a dynamic domain which intersects statistics, operation research, and computer science. The mathematical theories behind the algorithms, optimization methods in hyper parameter estimation, and efficient computing frameworks are all used in ML which makes it one of the most popular fields. Despite the progress and advancements, there are still numerous challenges that machine learning faces today. High dimensional unstructured data, finding the balance point in the trade of overfitting and underfitting, and achieving the satisfying accuracy level versus expensive implementation and computational needs are among some of the challenges data scientists deal with today. Data analysts use these practical challenges and turn them into opportunities which makes machine learning a fast-evolving field. As a result, there are new methodologies and models developed by scientists every day. Machine learning is mainly related to computational statistics; however, many algorithms are driven by applications in real-world problems. How machine learning impacts many industries, and the jobs within them, has made it a competence area for researchers in all fields. Applications are varying from health care to finance and banking.

Another reason for the rapid developments of new algorithms and models in ML is the need for different algorithms based on different characteristics and the goal. Different algorithms have different efficacy on datasets and systems. For example, working with big scale unstructured data such as images or text for predicting problems, neural networks tend to outperform other algorithms. However, neural networks required high working and storing memory space. On the other hand, when it comes to structured or tabular data, decision tree-based models are better choices historically. These differences in the algorithms and also datasets and systems necessitate developing new algorithms with faster,

less memory consuming, and easier implementation models and frameworks. Here, we intend to go through the most popular algorithms in ML in both mathematical and practical aspect. In addition, various machine learning applications are reviewed to help other researchers expand their view in machine learning. In Sect. 42.2, popular machine learning categorizations by scientists are presented. Section 42.3 discusses several algorithms, techniques, and frameworks in machine learning in depth along with a number of machine learning applications. Machine learning has been used for a prediction case study to present a number of differences, advantages, and limitations of some of machine learning algorithms in Sect. 42.4. Finally, Sect. 42.5 concludes the chapter with a summary.

42.2 Machine Learning Categories

42.2.1 Types of Learning

Most common categorization of machine learning algorithms is based on their learning type. Algorithms learning types can be supervised, semisupervised, unsupervised, and reinforcement learning. In the proceeding, we go through what each learning type means and investigate the most common algorithms in their domain.

Supervised Learning

Supervised learning aims to predict the label or outcome (dependent variable) based on a set of predictors (independent variables). The algorithm generates a mapping function that takes the input data or training set and learns to map it to the label or targeted variable (e.g., true/false). This function can be used to predict the label of new or unseen data. Most important property of supervised learning is that the dataset is a collection of labeled examples $\{(x_i, y_i)\}$ where x_i 's are the predictors, independent variables, or features vector and y_i is the label, response, or targeted variable. The goal of supervised learning algorithms is to take labeled training data and a set of features vector x as the input and output a model that predicts the label of the testing set y_i .

Unsupervised Learning

Contrary to supervised learning, in unsupervised learning the input datasets are not labeled. This learning type can be used when we only have input data x with no output variables or labels corresponding to the x_i 's. Giving no labels to the learning algorithm, a function is designed to find the patterns in the datasets. Considering x as the feature vector, the main goal in unsupervised learning is to produce a model that takes this vector x as input and transforms it into an informative value that can be used to find the structure of new unseen datasets.

Semisupervised Learning

Semisupervised learning is a mixture of supervised and unsupervised learning meaning the dataset contains both labeled and unlabeled data y 's. The goal in semisupervised learning is the same as the goal of the supervised learning algorithms but with the difference that an incomplete training dataset with missing target outputs is available. Semisupervised learning is often used in situations where the cost associated with the labeling process is expensive, whereas unlabeled data is relatively inexpensive, and semisupervised learning can help the learning process to result in a more accurate model.

Reinforcement Learning

Reinforcement learning is different than the three previous learning types in the way that the machine learns from the predefined actions and rewards associated with them. Here the machine must take actions in a dynamic environment in order to gain as many rewards as possible using training data that is given as feedbacks to the machine's actions [8]. Reinforcement learning is primarily based on Markov decision process, and the algorithm learns to choose actions in different situations to maximize the reward or feedback signal. Furthermore, the environment is formulated as a Markov decision process, situations are defined as different states in the state space, and the machine can execute actions in every state. The algorithm is trained to learn and find the most rewarding actions by trial and error. Each action brings different rewards and moves the machine to another state of the environment. The goal of a reinforcement learning algorithm is to learn to map actions to the proceeding states and their corresponding reward. It takes the feature vector of a state as input and outputs an optimal action to execute in that state by maximizing the expected average reward. Reinforcement learning is useful in sequential decision-making problems with long-term objectives and therefore has applications in domains such as robotics, resource management, and logistics. Another interesting topic that has been recently introduced is deep reinforcement learning in which deep neural network is implemented to avoid the need of explicitly designing the state space [9, 10]. Most famous algorithms used in Reinforcement learning are Q-learning, Deep Q networks, Deep Deterministic Policy Gradient (DDPG), and State-Action-Reward-State-Action (SARSA) [11–15].

42.2.2 Parametric Versus Nonparametric Learning

Learning algorithms can be parametric or nonparametric. For instance, most supervised learning algorithms are parametric or model based. Parametric algorithms use the training data to create a model that has parameters learned from the training data. On the other hand, nonparametric or instance-based

learning algorithms use the whole dataset to fit a model with no specified parameters. One example of these algorithms are instance-based classifiers, also called lazy learners, that store all of the training samples and do not build a classifier until a new, unlabeled sample needs to be classified. Consider Regression problems, the most popular nonparametric algorithms include K -Nearest Neighbors (KNN), Gaussian Process, and Random Forests. Parametric algorithms used for such problems include Ordinary Least Squares, MARS, and ridge regression.

42.2.3 Deep Learning

In the conventional machine learning, the parameters of the model are directly learnt from the dataset which is also known as shallow learning. Deep learning, on the other hand, is based on multilayer artificial neural networks and have high level of complexity [16]. In deep learning, most model parameters are learned not directly from the features of the training instances, but rather from the outputs of the inner or hidden layers of an artificial neural networks. In this case, we can consider shallow learning as the output of a single layer feed forward network. These concepts will be discussed more in the artificial neural networks chapter.

Deep learning algorithms such as deep belief networks (DBN), recurrent neural networks (RNN) [17], convolutional neural networks (CNN) [18, 19] and Auto-Encoders [20, 21] have shown high performances in many applications such as computer vision and image processing, speech recognition, natural language processing, and audio recognition [15, 22]. Generative adversarial network (GAN) is one of the newest concepts in deep learning introduced in recent years which outperforms many techniques in areas such as computer vision [23].

42.3 Machine Learning Algorithms Based on Applications

Another categorization of machine learning task arises when one considers the desired output of a machine-learned system. Classification and prediction are two forms of data analysis that can be used to extract models describing important data classes or to predict future data trends. In what follows, we will go through most popular ML techniques and categorize them based on their applications, linearity or nonlinearity, accuracy, and preference over each other in different situations. One of the challenges data analysts face at the beginning is to use a linear model or nonlinear one in their analysis. Despite the fact that nowadays there are many nonlinear models to use which usually give you high accuracy, many people still prefer linear models because of

their computational simplicity and interpretability. Moreover, it has been shown that linear models tend to perform better with small sample sizes.

Bias – Variance One of the important concepts in ML is bias-variance trade-off in estimated models. The Mean Square Error (MSE) can be decomposed into three terms, two of which are in the hands of analyst.

$$\begin{aligned} \text{MSE}(x_0) &= E[f(x_0) - \hat{y}_0]^2 = E[\hat{y}_0 - E(\hat{y}_0)]^2 \\ &+ E[E(\hat{y}_0) - f(x_0)]^2 = \text{Var}(\hat{y}_0) + \text{Bias}^2(\hat{y}_0) + \varepsilon \end{aligned} \quad (42.1)$$

Flexible algorithms such as K -Nearest Neighbors will give a high-variance but low-bias model whereas nonflexible algorithms like least square regression will give a low-variance, but high bias model compared to the flexible ones.

42.3.1 Supervised Learning

Classification Algorithms

Classification is a problem of automatically predicting the label or class of a data point. Spam detection in emails is a famous example of classification. In machine learning, the classification problem can be solved by different classification learning algorithms that they all take a collection of labeled examples (training dataset) as inputs and create a model that can take an unlabeled example as input and either directly output a label or class or they give a value that can be used by the analysts to deduce the output label such as the probability of being in each class. There are two main approaches for classification among statisticians; the generative approach and the discriminative approach. Given an independent variable X and a target variable Y , Ng and Jordan (2002) distinguish the two categories as follows: A generative classification model is a statistical model based on the joint probability distribution of $X \times Y$, $P(x, y)$. A discriminative classification model is based on the conditional probability of the Y given an observation x , $P(Y|X = x)$ [24]. Examples of generative classifiers are Naive Bayes classifier and Linear Discriminant Analysis (LDA). And nonmodel classifier or loss discriminative is support vector machine. The most famous and used algorithms in classification problems are discussed in the following.

K -Nearest Neighbors (KNN)

A nonparametric, instance-based learning method finds the k closest observations in the training set (x_i) in input space to the new observation (x) and averages their responses (y_i) in

order to find predicted response \hat{Y} :

$$\hat{Y}(x) = \frac{1}{K} \sum_{x_i \in N_k(x)} y_i \tag{42.2}$$

where $N_k(x)$ is the k closest neighbors of x in the training sample and Euclidean distance is used mostly as the measure of closeness. In regression problems, \hat{Y} is the average of responses (y_i 's), and if it is a classification problem, \hat{Y} is the majority vote. KNN will provide a nonlinear decision boundary (nonlinear regression fit) for observations in different classes. Choosing k to be small (e.g., $k = 1$) will cause the model to have a high variance but low bias. On the other hand, if k is large (e.g., $k = 10$), a smoother decision boundary will be obtained with low variance but rather higher bias than the first case. Moreover, as dimension increases, MSE tends to increase as dimension increases. The increase in the bias term, and not the variance, is the reason for that since when dimension increases the average distance to nearest neighbors increases and causes the estimate to be bias.

Support Vector Machines (SVM)

This method classifies observations by constructing an optimal separating hyperplane between two classes. Two cases can happen: Either two classes are linearly separable or nonlinear separable, where the classes overlap. In both cases, SVM and its extension to nonlinear decision boundary can be used.

Linear Case Considering our training dataset consists of $\{x_i, y_i\}$ where y_i is either $+1$ or -1 , we define a hyperplane by

$$\{x : f(x) = x^T \beta + \beta_0\} \tag{42.3}$$

And then a classification rule is set by

$$G(x) = \text{sign} [x^T \beta + \beta_0] \tag{42.4}$$

Here we want to find the hyperplane which creates the biggest margin between training points of class $+1$ and -1 . Here we want to maximize the marginal which can be rephrased as

$$M = \frac{1}{\|\beta\|} \tag{42.5}$$

In this way, the optimization problem becomes

$$\min_{\beta, \beta_0, \|\beta\|=1} \|\beta\| \tag{42.6}$$

$$\text{subject to } y_i (x_i^T \beta + \beta_0) \geq 1, \quad i = 1, \dots, N \tag{42.7}$$

Nonlinear Case If the classes overlap in feature space so that we cannot separate them using linear hyperplane, we can use a modified version of the linear case in such way that we not only still maximize M but also allow some instances to be on the wrong side of the margin. In this way, we need to define slack variables ξ and modify the optimization problem.

$$\min_{\beta, \beta_0} \|\beta\| \tag{42.8}$$

$$\text{subject to } y_i (x_i^T \beta + \beta_0) \geq 1 - \xi_i, \quad i = 1, \dots, N \tag{42.9}$$

$$\xi_i \geq 0, \quad \sum \xi_i \leq \text{constant} \tag{42.10}$$

Probabilistic Models

LDA (Linear Discriminant Analysis)

LDA is based on Bayes' Theorem for classifications in such a way that the Bayes' classifier chooses the class with the highest posterior probability for minimum error. If we consider $f_k(x)$ as the class conditional density of X in class k and π_k as the prior probability of class k , the theorem gives

$$\begin{aligned} \widehat{\text{Pr}}(G = k | X = x) &= \frac{\widehat{\text{Pr}}(X = x | G = k) \widehat{\text{Pr}}(G = k)}{\sum_{l=1}^K \widehat{\text{Pr}}(X = x | G = l) \text{Pr}(G = l)} \\ &= \frac{f_k(x) \pi_k}{\sum_{l=1}^K f_l(x) \pi_l} \end{aligned} \tag{42.11}$$

Considering the class densities as multivariate Gaussian distribution with common covariance matrix Σ , μ_k the mean of the input variables for class k , and p as the number of variables

$$\widehat{\text{Pr}}(X = x | G = k) = \hat{f}_k(x) \tag{42.12}$$

$$\widehat{\text{Pr}}(G = k) = \hat{\pi}_k \tag{42.13}$$

$$f_k(x) = \frac{1}{(2\pi)^{\frac{p}{2}} |\Sigma|^{\frac{1}{2}}} e^{-\frac{1}{2}(x-\mu_k)^T \Sigma_k^{-1} (x-\mu_k)} \tag{42.14}$$

We can get the linear discriminant functions δ_k

$$\delta_k(x) = x^T \Sigma^{-1} \mu_k - \frac{1}{2} \mu_k^T \Sigma^{-1} \mu_k + \log \pi_k \quad (42.15)$$

which are equivalent to descriptions of the decision rule so that

$$G(x) = \operatorname{argmax}_k \delta_k(x) \quad (42.16)$$

π_k is estimated as the fraction of training samples of class k .

Considering we have only two classes, the LDA rule classifies a new observation x to class 2 if

$$x^T \Sigma^{-1} (\hat{\mu}_2 - \hat{\mu}_1) > \frac{1}{2} (\hat{\mu}_2 + \hat{\mu}_1)^T \Sigma^{-1} (\hat{\mu}_2 - \hat{\mu}_1) + \log \left(\frac{N_2}{N_1} \right) \quad (42.17)$$

QDA (Quadratic Discriminant Analysis)

LDA was a special case when the density functions have common covariance matrix Σ . If Σ_k are not assumed to be equal, we get quadratic discriminate function

$$\delta_k(x) = -\frac{1}{2} \log |\Sigma_k| - \frac{1}{2} (x - \mu_k)^T \Sigma_k^{-1} (x - \mu_k) + \log \pi_k \quad (42.18)$$

Logistic Regression

Logistic regression is a linear method, for that classifies observations based on conditional probabilities and gives the posterior probabilities of classes using linear function in x . It has the form of $(K - 1)$ log-odds or logit transformations.

$$\log \frac{\Pr(G = i | X = x)}{\Pr(G = K | X = x)} = \beta_{i0} + \beta_i^T x, \quad i = 1, \dots, K - 1 \quad (42.19)$$

which is equivalent to

$$\begin{aligned} \Pr(G = i | X = x) \\ = \frac{\exp(\beta_{i0} + \beta_i^T x)}{1 + \sum_{l=1}^{K-1} \exp(\beta_{l0} + \beta_l^T x)}, \quad i = 1, \dots, K - 1 \end{aligned} \quad (42.20)$$

$$\Pr(G = K | X = x) = \frac{1}{1 + \sum_{l=1}^{K-1} \exp(\beta_{l0} + \beta_l^T x)} \quad (42.21)$$

Here the last class, class K , has been used as the denominator in the odds-ratio, but in general it could be arbitrary.

Additionally, we should keep in mind that the sum of the probabilities should be equal to 1.

Naïve Bayes Classifier

Naïve Bayes algorithm estimates the class conditional probability density function (pdf) by assuming that the features X_i 's are conditionally independent given the class label. If we consider $f_k(x)$ as the class conditional density of X in class k , we can find it by:

$$f_k(X) = \prod_{i=1}^p f_{ki}(X_i) \quad (42.22)$$

The assumption of independency among features is generally not true, but it simplifies the estimation specially when p or the number of dimensions is high.

Tree-Structured Learning

Classification and Regression Tree (CART)

Decision tree method consists of first dividing the feature (predictors) space into a number of regions or rectangles by a set of recursive binary splitting rules and then fitting a simple regression or classification model in each one. In order to make predictions for new observations in classification and regression tree, known as CART, we usually take the mean (regression setting) or majority votes (classification setting) of trainings observations in the region it belongs to. Your prediction values are at terminal nodes of leaves. ID3 (Iterative Dichotomize 3) was the first Decision Tree implementations developed by Ross Quinlan 1986. C4.5 is the successor to ID3 which did not have the restriction that features must be categorical, and C5.0 is the most recent algorithm developed by Quinlan [25, 26]. Decision trees are simple and easy to interpret but not comparable to other methods in terms of accuracy. Many advanced and powerful algorithms are based on combining many decision trees to get the better prediction accuracy. Considering a regression problem with R_1, \dots, R_M regions, the predictions y_i 's in each region will be a constant c_m which is the average of response values in that region.

$$f(x) = \sum_{m=1}^M c_m I(x \in R_m) \quad (42.23)$$

$$\hat{c}_m = \frac{1}{N_m} \sum_{x_i \in R_m} y_i \quad (42.24)$$

where N_m is instances in training set that belong to region R_m

$$N_m = \sum_{i=1}^N I(x_i \in R_m) \tag{42.25}$$

The challenge in decision tree is how to grow the tree. In other words, what is the best partition regions of input space means deciding the splitting variable and split point at each step of the tree. Considering variable j and split point s if we define regions as

$$R_1(j, s) = \{X|X_j \leq s\} \quad \text{and} \quad R_2(j, s) = \{X|X_j > s\}, \tag{42.26}$$

we find the best split by the following optimization problem

$$\min_{j,s} \left[\min_{c_1} \sum_{x_i \in R_1(j,s)} (y_i - \hat{c}_1)^2 + \min_{c_2} \sum_{x_i \in R_2(j,s)} (y_i - \hat{c}_2)^2 \right] \tag{42.27}$$

In decision trees, the tree size is a tuning parameter that needs to be optimized. In order to avoid overfitting, the idea is to grow a really deep tree, T_0 , until some minimum node size is reached, and then prune it by collapsing some internal nodes so that it meets a certain cost complexity.

If we define a subtree $T \subset T_0$, we will have the within-node squared error as

$$Q_m(T) = \frac{1}{N_m} \sum_{x_i \in R_m} (y_i - \hat{c}_m)^2 \tag{42.28}$$

And define cost complexity as

$$C_\alpha(T) = \sum_{m=1}^T N_m Q_m(T) + \alpha |T| \tag{42.29}$$

Where $|T|$ is the tree size or number of terminal nodes in the tree T , and we try to select the subtree with minimum C_α .

In classification setting, the squared error impurity measure cannot be used. If we consider the proportion of class k observations in region m as

$$\hat{p}_{mk} = \frac{1}{N_m} \sum_{x_i \in R_m} I(y_i = k), \tag{42.30}$$

we classify the observations in node m to the majority class in node m

$$k(m) = \operatorname{argmax}_k \hat{p}_{mk} \tag{42.31}$$

The three impurity measures for classification are
Misclassification error:

$$\frac{1}{N_m} \sum_{x_i \in R_m} I(y_i \neq k_m) = 1 - \hat{p}_{mk(m)} \tag{42.32}$$

Gini index:

$$\sum_{k=1}^K \hat{p}_{mk} (1 - \hat{p}_{mk}) \tag{42.33}$$

Cross-entropy or deviance:

$$-\sum_{k=1}^K \hat{p}_{mk} \log \hat{p}_{mk} \tag{42.34}$$

There is a special case when $k = 2$; Gini index will be the sum of all variances which is the same as the impurity measure in regression setting. Moreover, Gini index and cross-entropy are sensitive to different splits unlike misclassification error. In this regard, misclassification error is not really used for growing the tree among all measures. Gini index is also computationally preferred to cross-entropy. Usually, Gini index is used to grow the trees since we want each group in each split node to be as pure as possible, and then misclassification error and cross-entropy are referred for performance evaluation. There are some types of functions and datasets that CART does have trouble approximating. Additive functions, functions with categorical variables, and datasets with many missing observations are among them.

Bagging

Bagging averages predictions of bootstrap samples in order to reduce the variance in expected error. For each bootstrap sample Z^b , $b = 1, \dots, B$, we can get the prediction $\hat{f}^b(x)$, and the bagged estimate will be:

$$\hat{f}_{\text{bag}}(x) = \frac{1}{B} \sum_{b=1}^B \hat{f}^b(x) \tag{42.35}$$

In Bagging, bootstrap samples of original training set are used to make sure sample predictions are independent of each other. Bagging is especially useful in prediction methods with high variance and unstable results like decision trees as it lowers variance and improves prediction. However, if the predictions are correlated, the variance will rise. That is one of the reasons random forest was invented.

Random Forest

As previously mentioned, because of the correlation between trees in bagging method, the alternative, random forests, came up to use uncorrelated trees and averages them. The major modification is that rather than choosing the best j variable among all variables x_1, \dots, x_p to grow the tree, we

choose a subset M of size m randomly from $\{x_1, \dots, x_p\}$ at each step of the tree. This way, the trees become much more uncorrelated. In fact, the higher the number of variables in the subset m , the higher chance of correlation between variables. Therefore, a smaller subset of m will more likely give uncorrelated trees. In random forest, we draw a bootstrap sample Z^b , $b = 1, \dots, B$, from the training and grow a random forest T_b to the dataset by selecting m variables randomly at each node.

$$\hat{f}_{\text{rf}}(x) = \frac{1}{B} \sum_{b=1}^B T_b(x) \quad (42.36)$$

The default values for m , for regression problems, are usually $\lfloor \frac{p}{3} \rfloor$ and $\lfloor \sqrt{p} \rfloor$ for classification problems. One important aspect in random forest and bagging is the use of Out-of-Bag samples. Since in bagging and random forest the trees are fit to bootstrapped samples of observations, one can show that approximately 30% of your data will not be selected in the samples structuring the trees. This way, we get the out-of-bag (OOB) error rate by predicting the response for the observations by using only the trees that were not fit using those observations and were OOB. The OOB error rate is equivalent to the test error rate in cross-validation approach. Mean Decrease in Impurity (MDI) and Mean Decrease in Accuracy (MDA) are used for variable importance measure and model selection.

Boosting Methods

The main idea in boosting is to combine many so-called “weak learners” or base learners (decision stumps) to produce a powerful model. “weak learner” is defined as one whose error rate is slightly better than random guessing. In this respect, it is similar to Bagging and other committee-based approaches. In this study, most known boosting algorithms will be reviewed.

AdaBoost

Considering a classification problem $Y \in \{1, -1\}$, boosting applies weak classification algorithm and iteratively changes weights of data points in training set so that at each round more attention is paid to the misclassified ones. This way, a sequence of weak classifiers $G_m(x)$, $m = 1, 2, \dots, M$ is produced, and the prediction from all of them combined with a weighted majority vote (contribution of each $G_m(x)$) gives the final prediction $G(x)$.

$$G(x) = \text{sign} \left[\sum_{m=1}^M \alpha_m G_m(x) \right] \quad (42.37)$$

Here, α_m 's are the weights in order to increase the influence of more accurate classifiers in sequence. We initialize

the algorithms with all data points (x_i, y_i) , $i = 1, \dots, N$ having the same weight $w_i = \frac{1}{N}$, and then from $m = 2$ to M , we proceed by assigning more weights α_m , to the data points that were misclassified in the previous step according to err_m , and train the classifier $G_m(x)$.

$$\text{err}_m = \frac{\sum_{i=1}^N w_i I(y_i \neq G_m(x_i))}{\sum_{i=1}^N w_i} \quad (42.38)$$

And

$$\alpha_m = \log \left(\frac{1 - \text{err}_m}{\text{err}_m} \right) \quad (42.39)$$

And weights for next iteration classifier $G_{m+1}(x)$ are computed by

$$w_i = w_i \cdot \exp[\alpha_m I(y_i \neq G_m(x_i))], \quad i = 1, 2, \dots, N \quad (42.40)$$

Generally speaking, AdaBoost fits an additive model using an exponential loss function, and the population minimizer of this exponential loss function is the log-odds of the class probabilities. Decision trees are found to be the ideal weak learners or base learners for boosting. However, in some situation where the data is noisy(outliers) or there is a misspecification of class labels in the training set, the performance of AdaBoost (generally exponential loss function) degrades and is far less robust.

Gradient Boosting

Gradient boosting algorithm is a forward stepwise procedure that solves an optimization problem to find the next tree given the current model $f_{m-1}(x)$, and it incorporates gradient descent into it.

At each iteration, a weak learner $h(x)$ (typically a regression tree) whose predictions are as close as possible to the current residuals (negative gradient values) of the loss function is added, as if in each iteration f_{m+1} tries to correct the errors of f_m .

$$f_{m+1} = f_m(x) + h(x) = y \quad (42.41)$$

$$h(x) = f_m(x) - y \quad (42.42)$$

This is of course an approximation algorithm in order to find a good numerical result. This loss function could be squared error, absolute error, or Huber for regression and multinomial deviance for classification. In this algorithm, we first initialize the model by the optimal constant model which is a single terminal node tree.

$$f_0(x) = \operatorname{argmin}_\gamma \sum_{i=1}^N L(y_i, \gamma) \quad (42.43)$$

$$L(q) = \min \sum_{i=1}^N L(y_i, f_{m-1}(x_i) + h_m(x_i)) + \sum_{m=1}^M \Omega(h_m) \quad (42.50)$$

Where N is the number of observations in the training dataset $\{(x_i, y_i)\}$, and L is the chosen loss function. And for iteration $m = 1$ to M , we calculate the pseudoresiduals by:

$$r_{im} = - \left[\frac{\partial L(y_i, f(x_i))}{\partial f(x_i)} \right]_{f=f_{m-1}} \quad (42.44)$$

A base learner $h_m(x)$ is fitted to pseudoresiduals using the training set afterward, followed by computing the multiplier γ_m (weight or proportion of $h_m(x)$ to be added to $f_{m-1}(x)$) by solving the following optimization problem:

$$\gamma_m = \operatorname{argmin}_\gamma \sum_{i=1}^N L(y_i, f_{m-1}(x_i) + \gamma h_m(x_i)) \quad (42.45)$$

And update the model:

$$f_m(x) = f_{m-1}(x) + \gamma_m h_m(x) \quad (42.46)$$

The final output is the prediction estimate

$$\hat{f}(x) = f_M(x) \quad (42.47)$$

Gradient Boosting Machine (Gradient Tree Boosting)

We can use this method using regression tree as our base learners (for both classification and regression problem) also known as MART (Multiple Additive Regression Trees) or GBM (gradient boosting machine); r_{jm} gives us the regions R_{jm} , and $h(x)$ becomes:

$$h_m(x) = I(x \in R_{jm}) \quad (42.48)$$

Consequently,

$$f_m(x) = f_{m-1}(x) + \sum_{j=1}^{J_m} \gamma_{jm} I(x \in R_{jm}) \quad (42.49)$$

There are two tuning parameters, number of iteration M and size of each constituent tree $J_m = 1, \dots, M$.

XGBoost

XGBoost method is an implementation of gradient boosting algorithm with additional regularized loss (objective) function in order to counter overfitting.

where the added term Ω penalizes the complexity of the model and is defined as $\Omega(h) = \gamma T + \frac{1}{2} \lambda \|w\|^2$, T is the number of leaves in the tree, and q is the tree structure where each leaf in the tree has a score w_j , and the final prediction is found by summing up the score in the corresponding leaves.

After expanding the loss function similar to Taylor series, we can find the optimal weight w_j^* of leaf j and the loss function:

$$w_j^* = - \frac{\sum_{i \in I_j} g_i}{\sum_{i \in R_m} h_i + \lambda} \quad (42.51)$$

$$L(q) = - \frac{1}{2} \sum_{j=1}^T \frac{(\sum_{i \in I_j} g_i)^2}{\sum_{i \in I_j} h_i + \lambda} + \gamma T \quad (42.52)$$

where g_i and h_i are the first- and second-order gradient statistics on the loss function L and I_j is the instance set in leaf j . This last equation is used as a scoring function in order to find the tree structure q by measuring the gain in different splitting nodes. An approximate algorithm that starts with a leaf and adds branches based on the gain is implemented in XGBoost. The Gain when a leaf is split into two leaves, where instance sets of the Left node I_L and Right node I_R and $I = I_R \cup I_L$, is calculated as (loss before splitting – loss after splitting), and $L(q)$ becomes:

$$L_{\text{split}} = \frac{1}{2} \left[\frac{(\sum_{i \in I_L} g_i)^2}{\sum_{i \in I_L} h_i + \lambda} + \frac{(\sum_{i \in I_R} g_i)^2}{\sum_{i \in I_R} h_i + \lambda} - \frac{(\sum_{i \in I} g_i)^2}{\sum_{i \in I} h_i + \lambda} \right] - \gamma \quad (42.53)$$

If the gain $< \gamma$, that branch will not be added to the model and can be removed from the tree. Furthermore, XGBoost uses two additional techniques in order to avoid overfitting, column (feature) subsampling that speeds up parallel computation, and shrinkage introduced by Friedman. For the split-finding algorithms, XGBoost uses an approximate algorithm instead of the common exact greedy algorithm; that is because the exact algorithm is computationally expensive and impossible when the data does not fit into memory. In the approximate algorithm, candidate splitting points are chosen based on the percentiles of feature distribution, and then based on the aggregated statistics the best solution among the candidates is found. In order to do the approximate algorithm more efficiently, they use column block for parallel learning which means collecting statistics for each column (feature)

will be parallelized, giving us parallel algorithm for split finding. Additionally, the column block technique also enables column subsampling which was mentioned previously.

As previously mentioned, it has been seen that decision trees do poorly with sparse data. In this regard, XGBoosting suggests an improved sparsity-aware split-finding technique in order to make the algorithm aware of the sparsity pattern in the data. They propose a default direction in each splitting node such that if a value is missing, the instance goes to the default direction. The optimal directions are learnt from the data and set as the default direction in each branch, and the big improvement then would be that the algorithm only visits the nonmissing entries. This way, the sparsity aware algorithm runs 50 times faster than the naïve version.

XGBoost might be preferred to some competitive algorithms such as Neural network because of fewer number of parameters to tune, and also it is easy to implement. Light GBM and Catboost are also new boosting algorithms that came out in 2017 as a modification of XGboost [27, 28].

Artificial Neural Networks (ANN)

Neural network is different than the previous methodologies as it constructs a framework that investigates underlying behavioral trends of the system. Neural network recognizes the hidden relationships between input variables and the relationship between input and output variables that helps making more accurate predictions [29]. Neural networks are capable of learning complicated nonlinear relationships and capture complex data patterns and hidden features. These properties make them preferable for classification and prediction problems that involve the detection of complicated nonlinear patterns specially in high-dimensional datasets.

Perceptron learning is the foundation for the neural network models introduced by Rosenblatt in 1958 [30]. A Perceptron in neural network is an artificial neuron that performs certain functions to the input data in order to generate features. In neural network, we can have single-layer Perceptron which can only learn linearly separable patterns or multilayer Perceptron that have more than two layers and perform better on more complex problems.

Neural networks use the Kolmogorov-Arnold representation theorem that any function $f(x)$ can be exactly represented by a (possibly infinite) sequence of addition, multiplication, and composition with functions that are universal and do not depend on $f(x)$.

$$f(x) = \sum_{m=1}^M g_m(w_m^T x) \quad (42.54)$$

Here the g_m or g function is called the activation function which does not depend on M and is typically taken to be sigmoid function. However, hyperbolic tangent and rectified

linear unit (ReLU) are among the most popular ones now in industry. W_m is called the inner-layer or hidden layer weight vector, and M is the width or number of hidden units ($w_m^T x$). In order to find the Risk function or the deviance, we use gradient descent; the most popular learning technique in neural network is back-propagation.

$$\hat{R} = \frac{1}{N} \sum_{i=1}^N \sum_{k=1}^K (y_{ik} - f_k(x_i))^2 \quad (42.55)$$

where $f(x)$ has the form of

$$f(x) = \sum_{m=1}^M \beta_m \sigma(\alpha_{0m} + \alpha_m^T x) \quad (42.56)$$

Neural network uses a set of chain rules in order to find the minimum of R function. The parameters in this equation that need to be optimized can be found with backpropagation equations

$$\frac{\partial R_i}{\partial \beta_{km}} = -2 (y_i - f_k(x_i)) g_k^T(T) Z_{mi} \quad (42.57)$$

$$\frac{\partial R_i}{\partial \alpha_{ml}} = -2 (y_i - f_k(x_i)) g_k'(T) \beta_{km} \sigma'(\alpha_{0m} + \alpha_m^T x_i) x_{il} \quad (42.58)$$

where

$$Z_{mi} = \sigma(\alpha_{0m} + \alpha_m^T x_i) \quad (42.59)$$

One of the disadvantages of neural networks is that it is very subjective, where the model and results vary significantly on the data analyst network configuring and architecture, initialization, and parameter tuning. The problem may rise as there are many parameters to be optimized in NN, and overfitting might happen. In this regard, usually scientists initialize the parameters with standard normal distribution and add a penalization term to the risk function.

There are multiple neural network types, some of which are most popular among researchers. Feedforward Neural Network is the simplest and easiest type of neural network in which the information can only move from the input layer through the hidden layers and the output layer. On the other hand, in Recurrent Neural Network (RNN) the output of a layer is fed back to the input in order to improve the final predictions. Convolutional Neural Networks (CNN) are similar to feed forward neural networks but contain one or more convolutional layers in which a convolutional operation is performed to the input before passing to the next layer. CNNs show highly competitive results in image and video

recognition and natural language processing. Auto-Encoders are another popular type of neural networks that are used in unsupervised learning, specifically dimension reduction and denoising. Further discussion about neural network and deep learning is out of scope of this chapter but can be found in references [31, 32].

Regression Algorithms

Regression is a problem of predicting a real-valued label (often called a target) given an unlabeled example. The regression problem is solved by a regression learning algorithm that takes a collection of labeled examples as inputs and produces a model that can take an unlabeled example as input and output a target.

Linear Regression Methods

Least Squares Linear Regression

Least Squares Linear regression is a popular regression algorithm that learns a model in which target value is a linear combination of features of the input observation. Least Squares Linear regression is widely used because of computational simplicity and good estimation for small sample sizes. Suppose we have N observations $\{(x_i, y_i)\}$, and we want to fit a linear regression function $f(x_i)$ to our feature vector in order to predict value of y_i :

$$Y = f(x) + \varepsilon \tag{42.60}$$

where ε is observed as independent and identically distributed random variable with mean zero and constant variance σ^2 . In other words, we want to estimate the function:

$$f(x) = E\{Y|X = x\} = \beta_0 + \sum_{j=1}^p \beta_j X_j \tag{42.61}$$

where $X = (X_1, \dots, X_p)^T$ and p is the number of predictors x . Least square method is used to estimate β 's by minimizing the Residual Sum of Square Errors:

$$\begin{aligned} \text{RSS}(\beta) &= \frac{1}{N} \sum_{i=1}^N (y_i - \beta^T x_i)^2 \\ &= \frac{1}{N} \|Y - X\beta\|^2 \text{ (in the matrix format)} \end{aligned} \tag{42.62}$$

where $\beta = (\beta_0, \beta_1, \dots, \beta_p) \in \mathbb{R}^{p+1}$. If N is greater than p , this equation is solvable, but if N is smaller than p , we cannot find a unique solution and we should do regularization. Least square method solution for β 's is:

$$\hat{\beta}_{LS} = (X^T X)^{-1} X^T Y \tag{42.63}$$

Based on the Gauss–Markov theorem, least square is the best linear unbiased estimator among all estimations. Now suppose we want a prediction at a new input X_0 :

$$Y_0 = f(X_0) + \varepsilon_0 \tag{42.64}$$

$$\tilde{f}(X_0) = X_0^T \tilde{\beta}_0 \tag{42.65}$$

We can find our prediction accuracy using expected prediction error:

$$E\left[\left(Y_0 - \hat{f}(X_0)\right)^2\right] = \text{Var}(\varepsilon_0) + \text{MSE}(\tilde{f}(X_0)) \tag{42.66}$$

Shrinkage Methods via Regularization

Overfitting is a common issue in machine learning problems and among different approaches to overcome this issue. Regularization is the most popular approach among researchers in order to resolve and avoid overfitting. Regularized Regression methods retain a subset of the predictors and regularize or shrink the remaining predictor's coefficient estimates toward zero or excluding them from the model. This can be done by adding a penalty term to the lost (cost) function.

Ridge Regression

Ridge regression coefficients minimize a penalized residual sum of squares, and λ is the parameter for controlling the shrinkage. If λ is zero, then Ridge regression is the same as ordinary sum of squares regression, and if we choose a large λ , there will be more shrinkage. Ridge regression enforces the β coefficients toward zero but does not set them to zero, which means it does not omit insignificant features but rather minimizes their impact on the model.

$$\text{RSS}(\beta) = \frac{1}{N} \sum_{i=1}^N (y_i - \beta^T x_i)^2 + \lambda \cdot \text{penalty}(\beta) \tag{42.67}$$

$$\text{penalty}(\beta) = \sum_{j=1}^p \beta_j^2 \tag{42.68}$$

$$\text{writing } B \text{ Ridge in terms of } B \text{ Least square} = \frac{1}{\lambda + 1} \hat{\beta}_{LS} \tag{42.69}$$

LASSO

Lasso is the same as ridge regression but uses L1 regularization instead of L2. However, Lasso sets coefficients of irrelevant features to zero instead of minimizing them. This is one of Lasso's advantages because this way fewer features are included in the model, meaning a subset selection and coefficient estimation at the same time.

$$\text{RSS}(\beta) = \frac{1}{N} \sum_{i=1}^N (y_i - \beta^T x_i)^2 + \lambda \cdot \text{penalty}(\beta) \quad (42.70)$$

$$\text{penalty}(\beta) = \sum_{j=1}^p |\beta_j| \quad (42.71)$$

writing BLASSO in terms of B Least square

$$= \left(\text{sign} \hat{\beta}_{ls} \right) \left(\left| \hat{\beta}_{ls} \right| - \frac{\lambda}{2} \right) \quad (42.72)$$

Elastic Net

Elastic net is the combination of Ridge and LASSO

$$\text{RSS}(\beta) = \frac{1}{N} \sum_{i=1}^N (y_i - \beta^T x_i)^2 + \lambda \cdot \text{penalty}(\beta) \quad (42.73)$$

$$\text{penalty}(\beta) = \lambda \left(\alpha \sum_{j=1}^p |\beta_j|^2 + (1 - \alpha) \sum_{j=1}^p |\beta_j| \right) \quad (42.74)$$

where α is the mixing parameter of ridge and lasso. When $\alpha = 1$, it becomes fully ridge regression, and when $\alpha = 0$, it becomes Lasso.

Support Vector Regression (SVR)

Support Vector Machine for Regression (SVR) is the same as SVM for classification setting but with little modification. The objective in SVM is to find a hyperplane that separates the two classes with the minimum error in a way that the distance between the training data points from either of the two classes is maximized. However, the goal in SVR is to find a hyperplane (function $f(x)$) with points on both sides but deviates from y_n by errors that do not exceed the threshold ε for each training point x . Considering our training, dataset consists of $\{x_i, y_i\}$ where y_i is continued:

$$\{x : f(x) = x^T \beta + \beta_0\} \quad (42.75)$$

The optimization problem becomes

$$\min_{\beta, \beta_0, \|\beta\|=1} \|\beta\| \quad (42.76)$$

$$\text{subject to} \quad |y_i - (x_i^T \beta + \beta_0)| \leq \varepsilon, \quad i = 1, \dots, N \quad (42.77)$$

In order to overcome infeasible constraints of the optimization problem, formulation is modified with slack variables ξ_i, ξ_i^* :

$$\min_{\beta, \beta_0} \|\beta\| + C \sum_{i=1}^N \xi_i + \xi_i^* \quad (42.78)$$

$$\text{subject to} \quad y_i - (x_i^T \beta + \beta_0) \leq \varepsilon + \xi_i \quad (42.79)$$

$$(x_i^T \beta + \beta_0) - y_i \leq \varepsilon + \xi_i^*, \quad i = 1, \dots, N \quad (42.80)$$

$$\xi_i, \xi_i^* \geq 0 \quad (42.81)$$

42.3.2 Unsupervised Learning

In unsupervised learning, we are interested in estimating the probability density $p(x)$ based on a set of observations (x_1, \dots, x_N) without considering its relationship to other variables and having a “label” or associated response variable Y . In this regard, we cannot use previous loss functions like squared error to evaluate the methods. Unsupervised learning can be categorized into clustering algorithms, dimension reduction, and density estimation. There are many density estimation methodologies such as Gaussian mixture, kernel density, and deep Boltzmann machine, but it is a broad topic by itself and cannot be covered in this chapter. Some researchers categorize kernel methods as the fourth group in unsupervised learning.

Clustering Analysis

Clustering is related to grouping or segmenting the dataset into subsets or clusters in order to present $p(x)$ by simpler densities in a way that observations within each cluster are more closely related to one another. One of the main applications in clustering is to perform market segmentation. Similarity/dissimilarity is the metric that shows how close or far the data points are from clusters and each other in clustering. Each clustering method attempts to group the dataset points based on the dissimilarity measure defined in that methodology.

In clustering algorithms, each observation x_i is assigned to one and only one cluster k , where k is specified and less than N (total number of observations). This cluster assignment can be defined as $c(i) = k$ where $k \in \{1, \dots, K\}$. In this way, we will have the global dissimilarity of all clusters as

$$W(c) = \frac{1}{2} \sum_{k=1}^K \sum_{c(i)=k} \sum_{c(i')=k} D(x_i, x_{i'}) \quad (42.82)$$

where the inner summations give the within cluster dissimilarity or scatter. We can show that minimizing the within cluster scatter is equivalent to maximizing between cluster scatter, if we consider T as all possible cluster assignments and $B(c)$ as between clusters point scatter:

$$\begin{aligned} T &= \frac{1}{2} \sum_{i=1}^p \sum_{i'=1}^p D(x_i, x_{i'}) \\ &= \frac{1}{2} \sum_{k=1}^K \sum_{c(i)=k} \left[\sum_{c(i')=k} D(x_i, x_{i'}) + \sum_{c(i') \neq k} D(x_i, x_{i'}) \right] \\ &= W(c) + B(c) \end{aligned} \quad (42.83)$$

$$W(c) = T - B(c) \quad (42.84)$$

The best cluster assignment is $\hat{C} = \operatorname{argmin}_c W(c) = \operatorname{argmax}_c B(c)$. We can see that the number of cluster assignments needed to be checked is huge.

K-means Clustering

K-mean is the most popular iterative clustering method if all variables are quantitative type. In K-mean, squared Euclidean distance is used as the dissimilarity measure. In K-means, we initialize the algorithm so that for a given cluster assignment c , the total cluster variance is minimized with respect to the means of currently assigned clusters, m_1, \dots, m_k .

$$\begin{aligned} W(c) &= \frac{1}{2} \sum_{k=1}^K \sum_{c(i)=k} \sum_{c(i')=k} D(x_i, x_{i'}) \\ &= \sum_{k=1}^K \sum_{j=1}^p \hat{\operatorname{Var}}(x_j | c(i) = k) \times N_k^2 \end{aligned} \quad (42.85)$$

where

$$\hat{\operatorname{Var}}(x_j | c(i) = k) = \frac{1}{N_k} \sum_{c(i)=k} (x_{ij} - \bar{m}_{jk})^2 \quad (42.86)$$

$$\bar{m}_{jk} = \bar{x}_{jk} = \frac{1}{N_k} \sum_{c(i)=k} x_{ij} \quad (42.87)$$

N_k is the number of observations in cluster k . Considering the definitions above, $W(c)$ becomes:

$$W(c) = \min_{m_1, \dots, m_k} \sum_{k=1}^K \sum_{j=1}^p N_k \sum_{c(i)=k} (x_{ij} - \bar{m}_{jk})^2 \quad (42.88)$$

$\hat{C} = \min_{c, M} W(c, M)$ where M is the vector of means $M = \{m_1, \dots, m_k\}$. Now given a current set of means vector, we minimize $W(c, M)$ by assigning each observation to the closest current cluster mean, i.e., $c(i) = \min_{1 \leq k \leq K} \sum_{j=1}^p (x_{ij} - m_{jk})^2$ and repeat the process until cluster assignments do not change. There are many clustering algorithms based on variations of k -means modifications and centroid-based such as k -medoids, k -medians, or fuzzy c -means [33–35].

Hierarchical Clustering

One of the disadvantages of K -means or K -medoids is that the number of clusters and the initial assignments must be selected. Therefore, the clustering results depend on the analyst's choice for the number of clusters and a starting initialization. However, in hierarchical method based on the measure of dissimilarity given, we can find the agglomerative (bottom-up) or divisive (top-down) clusters. Agglomerative method starts from the bottom and at each level joins a pair of clusters into a single cluster based on the similarity measure. Divisive method performs the opposite by starting at the top and splitting each cluster into two clusters. In these methods, we get a tree-structured map of the clusters and dissimilarities between groups. Mostly, agglomerative is popular among analysts because of an interesting feature in its clustering map's graphical display called a dendrogram. The dendrogram is plotted in a way that the length (tree height) between each main cluster and subcluster is proportional to the dissimilarity between them. The terminal nodes of the dendrogram are the individual observations. In agglomerative method, we can perform single linkage, complete linkage, and group average clustering.

Density-Based Spatial Clustering of Applications with Noise (DBSCAN)

DBSCAN is a popular density-based clustering algorithm proposed by Ester et al. in 1996 [36]. It is a nonparametric clustering algorithm that finds neighborhoods with high densities. How it differs from k -mean algorithm is that a constant ε is predetermined so that any two points with distance between them lower or equal to "eps" are considered as neighbors. Furthermore, the minimum number of data points within each neighborhood ε is also defined. DBSCAN defines the neighborhoods recursively and setting all other points outside of neighborhoods as Noise or outlier. Consequently, this algorithm works well with noisy datasets.

Dimension Reduction Techniques

Principal Components Analysis

Principal Components Analysis (PCA) is a useful method in many problems. The most important task of PCA is to repre-

sent the variability of a large number of correlated variables in a much lower dimension. PCA provides a tool that finds a low-dimensional representation of a data set, called principal components Z_1, \dots, Z_k , with as much information and variation as possible. In order to find the principal component of the features x_1, \dots, x_p , we look for normalized linear combinations of the features that have the largest variance.

$$Z_1 = \varnothing_{11}x_1 + \varnothing_{21}x_2 + \dots + \varnothing_{p1}x_p \quad (42.89)$$

where $\sum_{j=1}^p \varnothing_{j1}^2 = 1$, Z_1 is the first PC, and vector \varnothing_i is the PC loading vector. We need to solve the following optimization to find the maximum sample variance of z_{i1} which can be solved with eigen decomposition method.

$$\max_{\varnothing_{11}, \dots, \varnothing_{p1}} \left[\frac{1}{n} \sum_{i=1}^n \left(\sum_{j=1}^p \varnothing_{j1}x_{ij} \right)^2 \right] = \max \frac{1}{n} \sum_{i=1}^n z_{i1}^2 \quad (42.90)$$

$$\text{subject to } \sum_{j=1}^p \varnothing_{j1}^2 = 1 \quad (42.91)$$

The second principal component is again the linear combination of x_1, \dots, x_p with maximum variance that is uncorrelated with Z_1 . In order to find Z_2 , the same optimization problem should be solved with an additional constraint that the direction of \varnothing_2 should be orthogonal to the direction \varnothing_1 in order for them to be uncorrelated. It is recommended to scale all variables to have mean zero before performing PCA. One important metric in PCA is the proportion of variance explained (PVE) by each principal component. The cumulative PVE of the first M principal components can be calculated by summing over each of the first M PVEs.

$$\text{PVE}_m = \frac{\sum_{i=1}^n \left(\sum_{j=1}^p \varnothing_{jm}x_{ij} \right)^2}{\sum_{j=1}^p \sum_{i=1}^n x_{ij}^2} \quad (42.92)$$

Furthermore, PCA transformation can also be helpful as a preprocessing step before clustering the data. PCA helps identify those data points which bring higher variance in the original data and also removing multicollinearity among different features. The results of PCA depend on the scale of the variables, so it is better to scale each feature by its standard deviation.

PCA can also be used in regression problems. To perform principal components regression (PCR), we simply use principal components as predictors in a regression model instead of the original variables. Partial least squares (PLS) method works the same way as PCR [37, 38].

t-Distributed Stochastic Neighbor Embedding (t-SNE) unlike PCA is a nonlinear dimensionality reduction technique that is primarily used for visualization purposes of high-dimensional datasets. t-SNE is a newer machine learning algorithm compared to PCA and PLS developed in 2008 [39]. PCA works with quantitative variables; however, multiple correspondence analysis (MCA) is the PCA version for qualitative variables [40].

42.3.3 Semisupervised Learning

Semisupervised learning comes when the cost of labeling process may be large, some parts of labels are missing, or a fully labeled data is infeasible. In these situations, semisupervised learning can be used where we have a mixed dataset of labeled and unlabeled observations. All semisupervised algorithms assume the following about the data:

Continuity Assumption: Points which are closer to each other with high probability will have the same output label. Cluster Assumption: Assuming the data is divided into different clusters, points in the same cluster are more likely to have the same output label. Manifold Assumption: The data lie approximately on a manifold of much lower dimension than the input space. Semisupervised learning is rather new and evolving in machine learning. There are some popular algorithms such as self-training, generative methods, mixture models, graph-based methods, and semisupervised SVM (S3VMs) [41–47].

42.4 Case Study

Datasets containing energy consumption in Netherlands between 2010 and 2020 have been used to investigate supervised prediction techniques mentioned in previous sections [48]. Enexis, Liander, and Stedin are the three major energy providers of the Netherlands, and the yearly energy consumption of the areas under their administration is available online. Each year dataset consists of annual energy consumption of different neighborhood (including zip codes and street names) in different cities under the company's territory. Each dataset is for a specific network administrator for a specific year and contains the following columns: network manager, purchase area, street name, zip code from and zip code to (two columns for the range of zip codes covered), city name, number of connections (number of connections in that range of zip codes), delivery percentage (percentage of the net consumption of electricity or gas – the lower this number the more energy was given back to the grid for instance if that neighborhood had solar panels to produce energy), percentage of active connections, type of connection (principal type of connection in the zip code range), type of

Table 42.1 Summary of statistics

	Number of connections	Delivery %	% of active connections	Type connection %	Annual consumption low tariff %	Smart meter %	Year	Annual consumption
Count	156,791	156,791	156,791	156,791	156,791	156,791	156,791	156,791
Mean	30.17	99.28	91.45	77.28	25.93	20.40	2014.59	3478.69
Std	22.81	3.69	17.47	20.33	30.36	30.73	2.88	3220.31
Min	10	3.26	0	18	0	0	2010	52

Max	669	100	100	100	100	100	2019	59,207

connection percentage, annual consume low tariff percentage (percentage of consume during the low tariff hours -from 10 p.m. to 7 a.m. and during weekends), smart meter percentage and finally annual consume kWh.

One of the important factors about this dataset is the information it has about Smart meters. Smart meters record energy consumption and send the observed data to the electricity supplier. This information can be used for by the suppliers for many applications such as monitoring and billing purposes. Since smart meters enable the intelligent controlling systems, they play an important role in the future energy grids. The most important benefits of smart meters are increasing the energy efficiency, reducing energy costs by enhancing the provision of ancillary services, and empowering utilities electricity production by integrating energy storages and renewable energies during high demands [49, 50]. Moreover, smart meters provide data for analysis of power quality and power outages. Smart meters provide a two-way communication between grid and smart meter which has data storage capability of outage records that can be used for predicting blackouts [51].

Moreover, the consumers can also get direct information about their energy consumption which motivates higher energy savings or consuming during low tariff times. The last remark gives us the second most important information in our dataset which is “percentage of consume during low tariff hour.” Furthermore, The Netherlands has aimed to ban petrol and diesel cars in the coming years making electric vehicles a sustainable transport alternative. Concerning the remarks mentioned about electricity in Netherlands, we chose this dataset to help enlighten some useful information.

42.4.1 Exploratory Data Analysis (EDA)

For the purpose of this chapter, we focus only on the dataset for the city of Amsterdam and predicting the coming year’s energy consumption based on the information available. Liander is the main company providing energy in Amsterdam. The final dataset consists of both categorical

and numerical features. Combining the datasets for all years, the final dataset consists of nine features or independent variables including “year” as one of the features and one response variable or dependent variable “energy consumption.” The goal in this case study would be to predict the energy consumption for the coming year of 2020.

The training data did not have any missing values to be omitted or imputed, but categorical variables with categories less than 10 times frequency have been omitted. Table 42.1 shows the summary of statistics for the numerical variables.

The histograms and pairwise scatterplot of numerical variables are presented below (Figs. 42.1 and 42.2 respectively). We can visually see the relationship between annual consumption versus all numerical variables (Fig. 42.2).

Moreover, the bar chart of the categorical variables (type of connections and network manager) versus the annual consumption is presented below (Fig. 42.3).

In order to evaluate the dependency among independent variables and assess multicollinearity, the correlation matrix is also presented (Fig. 42.4). We can see that annual consumption has a positive correlation with annual consumption of low-tariff electricity which is reasonable. Furthermore, we can see as years have passed the number of installed smart meters has increased, and consequently the percentage of low tariff annual consumption has risen significantly. This shows the importance of smart meters in increasing low-tariff consumption for bill management and decrease of annual consumption.

42.4.2 Modeling Selection Criteria

In order to evaluate the algorithms mentioned earlier, there are numbers of evaluation metrics. MSE (mean squared error) is the most basic and famous metric used for regression purposes. In order to compare different models, test MSE may not be enough since in all regression models we fit a model using least squares. More specifically, we estimate the regression coefficients such that residual sum of squares (RSS) is minimized. Therefore, other probabilistic statistical metrics that quantify both the model performance and the

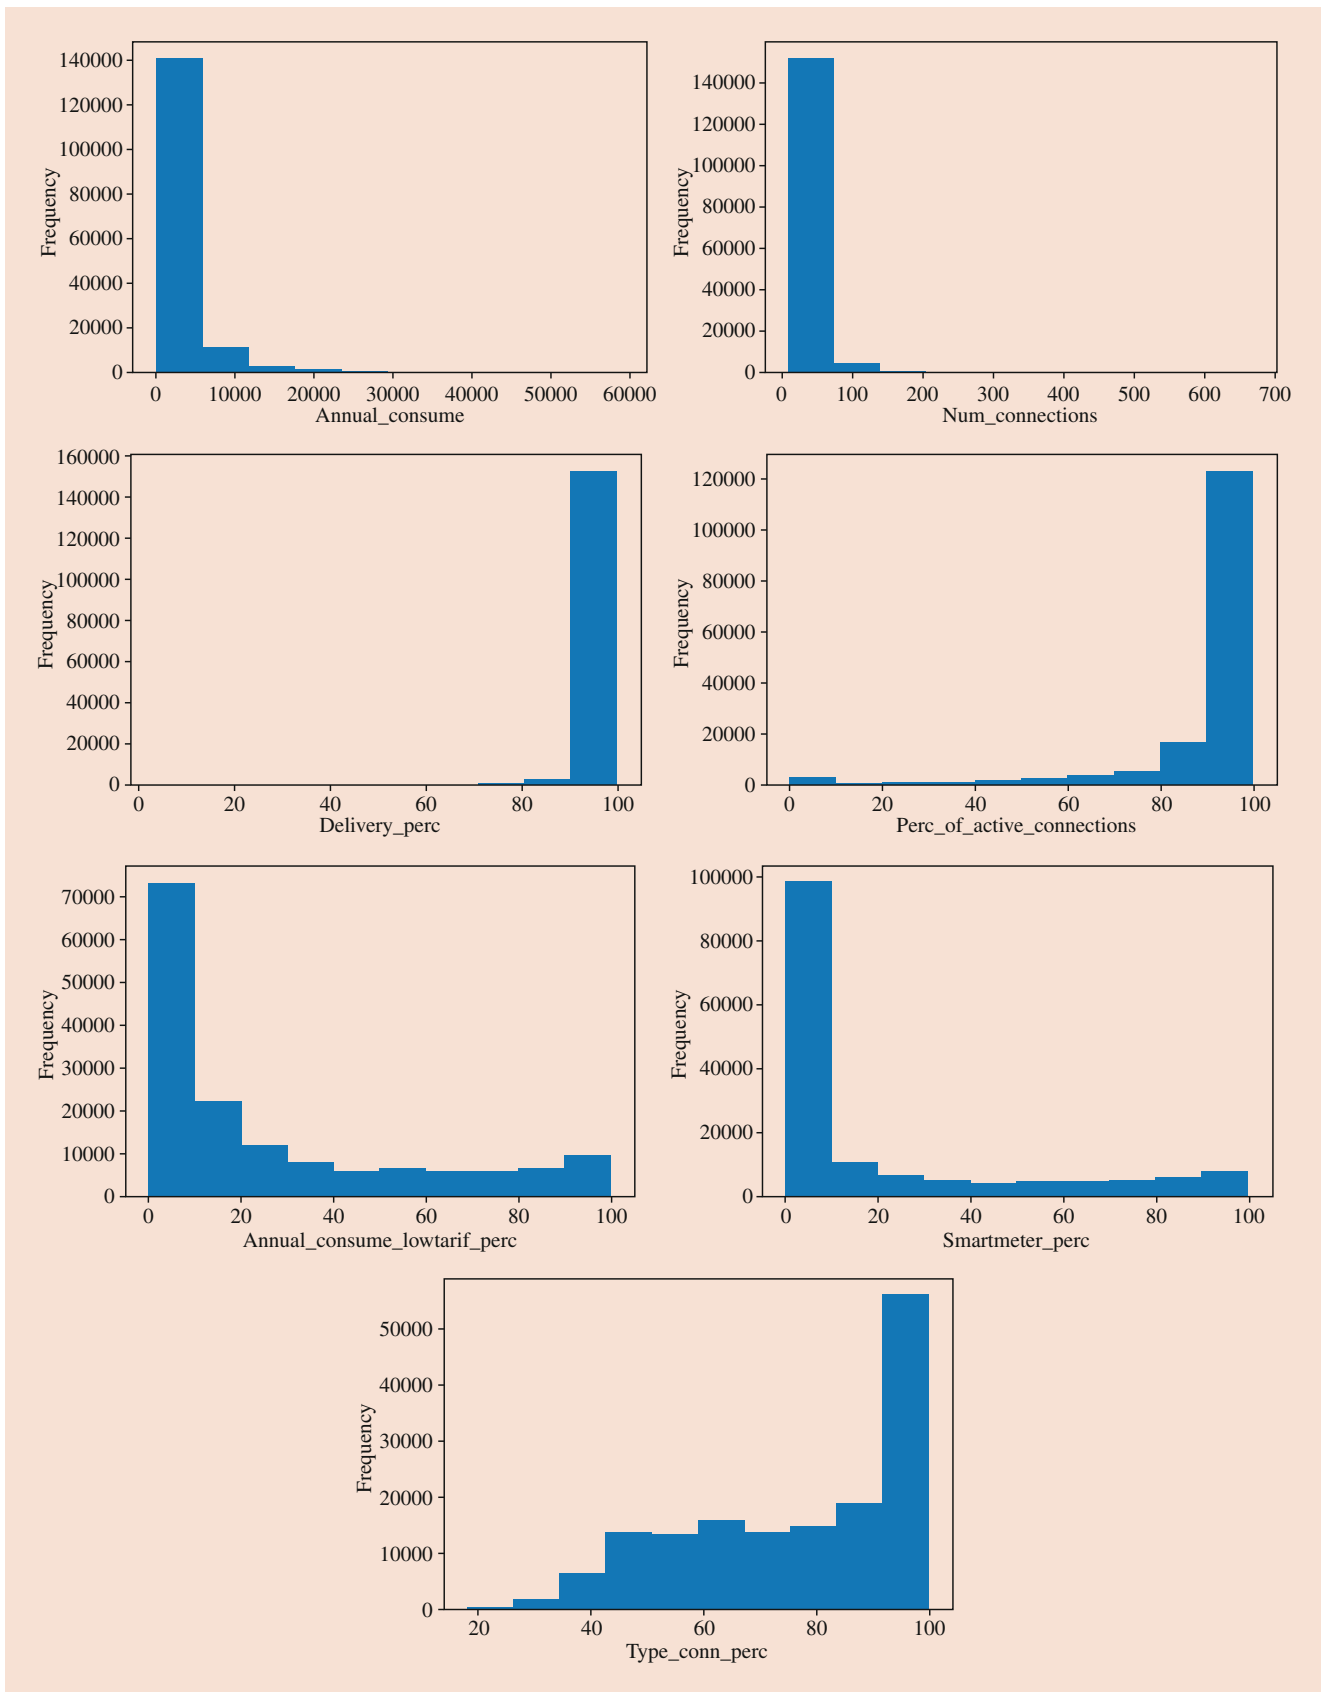

Fig. 42.1 Histograms of the numerical variables

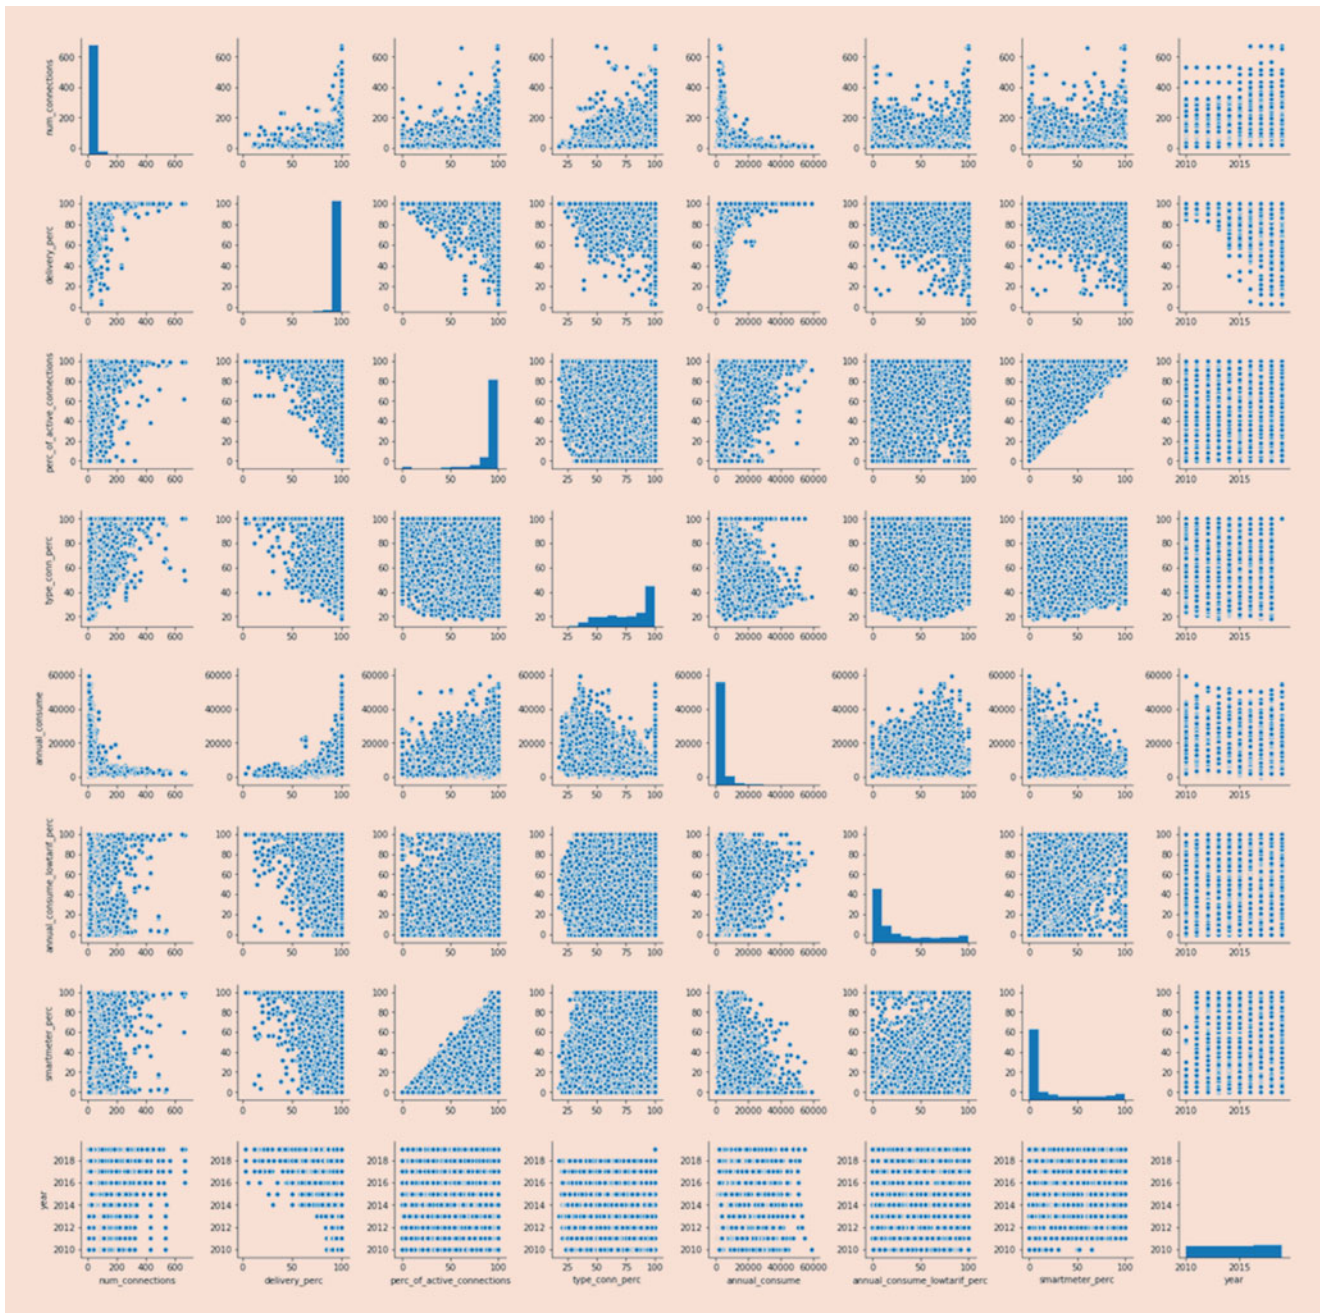

Fig. 42.2 Pair plot of numerical variables

complexity of the model are also investigated. Among some of most important ones are RMSE, MAE, R^2 , AIC, and BIC. Each of these metrics is insightful in different aspects. RMSE measures the difference between the model predictions and the truth values. A large RMSE is equivalent to a large average error, so smaller values of RMSE are preferable. RMSE presents the error in the units being measured which makes it easily interpretable to say how incorrect the model might be on unseen data. On the other hand, Mean Absolute Error (MAE) is more robust to outliers compared to RMSE which

punishes large errors. R^2 or the coefficient of determination is the proportion of the variance in the response variable that is explainable or predictable using the selected model and the independent variables in it.

Akaike Information Criterion (AIC) is derived from frequentist probability, and Bayesian Information Criterion (BIC) is derived from Bayesian probability – these are two ways of scoring models based on its complexity and goodness of the fit using loglikelihood. The lower AIC score is, the better the model is. For example, the AIC score is a trade-off

Fig. 42.3 Bar chart of the categorical variables versus annual consumption

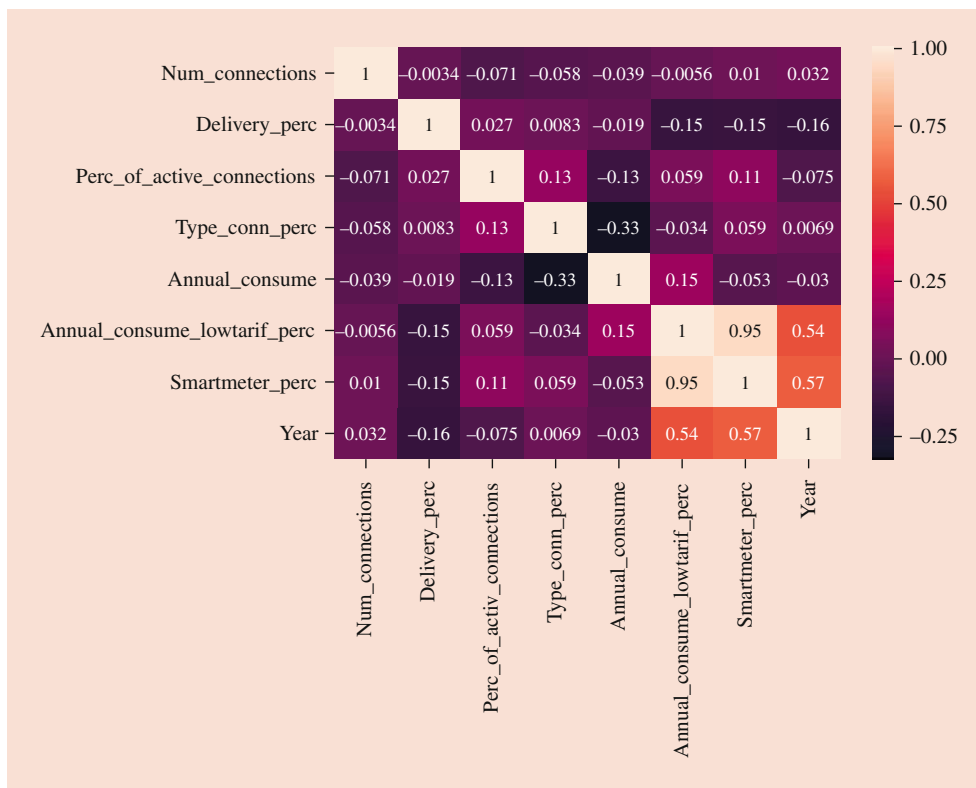

Fig. 42.4 Correlation matrix heatmap

between a high goodness-of-fit score and model simplicity, or the relative amount of information lost by a model and the risk of overfitting and underfitting in it.

Table 42.2 presents the definition of each metric. Here n is the number of observations, \hat{y}_i is the predicted value of observation i and y_i is the true value, k is the number of parameters in the model, and \hat{L} is the estimated maximum likelihood of the function for the model. We must note that another equivalent formulation for AIC and BIC when assuming a Gaussian model for the dataset with unknown

constant variance are $2k + n \ln \sum_{i=1}^n (y_i - \hat{y}_i)^2$ and $k \ln n + n \ln \sum_{i=1}^n (y_i - \hat{y}_i)^2$, respectively.

42.4.3 Results Analysis

The study dataset for Amsterdam energy consumption consists of 156,963 observations. Total 30% of the dataset is set as a testing set, and the remaining 70% is used for training

and building models. After exploratory data analysis, we used Cross-Validation (CV) to test the generalization ability of the models and also tuning parameters in different models. In this machine learning study, after the data is split into training and testing set, 10-Fold CV is implemented in which we further split our training set into ten numbers of subsets (folds).

Each time, we fit the model on nine ($K - 1$) of the folds and test it on the tenth (K th) fold. After finding the best parameters of the models using K -Fold CV and hyper parameter tuning, the final models are used to predict the test dataset and the results are presented in Table 42.3.

Here Ensemble models such as boosting and bagging algorithms have been used with decision tree as the base learner of the model. Moreover, we can see that more advanced machine learning models such as XGBoosting, LightGBM, or Neural Network perform better compared to simpler one such as OLS, Ridge, or KNN for our dataset. For instance, R -square increases from 0.5 for linear model to 0.7 for more flexible. More precisely, LightGBM outperforms all algorithms with the lowest MSE and RMSE and highest R^2 . XGboosting comes in the second-best model in terms of MSE and RMSE. However, if we compare MAE metric which is a more robust metric, we can see that AdaBoost has the lowest

MAE, and afterward XGBoosting and Gradient Boosting methods come as second-best models.

Lowest AIC and BIC again present lightGBM as the best model. In this study, we have implemented a simple sequential neural network model with three hidden layers using Keras. Keras is an open source deep learning library that we have the ability to define models as a sequence of layers (Sequential model) and add layers to add more complexity to the model [52]. As discussed previously, Neural Networks might not perform very well for tabular structured datasets which is the case for our dataset too. Overall, in our case lightGBM outperforms all other algorithms because of its flexibility, and AdaBoost is the more robust model to choose. XGboosting comes in second place for almost all metrics which makes it a good choice too, but this is still subjective to the analysts and their objectives.

The main purpose in developing models in ML is to use them as a prediction tool in unseen data and provide useful information for our problem. Considering that, we used the model with the better accuracy overall, LightGBM, to predict the year 2020 energy consumption in Amsterdam. Performing prediction for year 2020 with the fitted LightGBM model on years 2010–2019, we get the mean absolute percentage deviation (MAPD) or the relative error of 28.17% which is rather a good result in real-world problems. In other words, Amsterdam energy consumption can be predicted using the ML algorithms with 28.17% error rate.

Table 42.2 Model evaluation metrics

Metric	Definition
MSE	$\frac{1}{n} \sum_{i=1}^n (y_i - \hat{y}_i)^2$
RMSE	$\sqrt{\frac{1}{n} \sum_{i=1}^n (y_i - \hat{y}_i)^2}$
MAE	$\frac{\sum_{i=1}^n y_i - \hat{y}_i }{n}$
R^2	$1 - \frac{\sum_{i=1}^n (y_i - \hat{y}_i)^2}{\sum_{i=1}^n (y_i - \bar{y})^2}$
AIC	$2k - 2 \ln(\hat{L})$
BIC	$k \ln(n) - 2 \ln(\hat{L})$

42.5 Summary

For decades, scientists in machine learning have tried to explore and discover meaningful patterns from the raw data. Machine learning has become a new and interesting topic that is defined as linear and nonlinear processing algorithms in or-

der to learn underlying representation of datasets. Therefore, it has provided new opportunities and solutions to many real-world problems and created many applications. This chapter surveys the state-of-the-art algorithms and techniques in machine learning starting with a history of machine learning since the 1950s and moves to the recent and popular machine learning algorithms. The most popular categorizations of the algorithms such as learning types are discussed to present differences between these algorithms and the necessity on developing new novel algorithms. A little introduction to deep learning as a black box solution for many applications that can work with massive amount of unstructured data and its difference with Machine learning is discussed.

Then, the popular and key algorithms as well as techniques in this are presented with detailed mathematical formulations for better understanding. Several findings of this chapter are summarized in this section. First, traditional classification and regression methods and several supervised machine learning algorithms are introduced each of which have assumptions, advantages, and limits. For instance, KNN is a very flexible nonparametric algorithm which is simple to implement and fits nonlinear boundary/predictions to datasets. KNN is rather robust to noise and outliers in the input data, however not very efficient compared to other models since the entire dataset is used for predicting each new observation. SVM works well with complex and high-dimensional dataset specially because of kernel trick and tends to avoid overfitting because of regularization. But the model might underperform for large datasets which also has long training time. Optimizing the kernel function, lack of interpretability of the model, and variables importance and weights are other limits of SVM. Linear and Quadratic Discriminant Analysis models assume normality for the conditional densities which might not be true in many applications. Logistic regression, on the other hand, assumes linearity of independent variables and log odds of the dependent variable which can be a limit. Moreover, logistic regression returns the probabilities for only two possible outcomes in a classification problem. On the other hand, Naive Bayes classifier performs well in multiclass prediction but has the assumption of independency between predictors which is impossible in many real-life problems. Classification and Regression Tree (CART) is simple to implement and interpretable in business purposes but has limits such as sensitivity to even small changes in the data, high training time, and low accuracy. Traditional regression methods with regularizations have been discussed in detail and show how they overcome overfitting in regression problems. Ridge regression, for example, performs L2 regularization and does not produce unbiased estimators, so the variance of the model can be very large. Moreover, Ridge model does not perform feature selection whereas Lasso with L1 regularization does so.

Afterward, more advanced algorithms such as ensemble models and boosting algorithms are discussed. Bagging basi-

cally consists of weak learners operating independently from each other in parallel and average them at the end. Boosting, however, considers weak learners sequentially operating in such a way that each model depends on the previous ones, trying to improve it, and combines them by averaging all at the end. Popular Boosting algorithms such as AdaBoost, XGBoost, and lightGBM are explained thoroughly. The differences between each of the algorithms and how they built up upon each other show the historical time line. Different types of Neural Networks and their applications have been discussed.

In the following section, this chapter reviews the most successful unsupervised learning methods such as clustering analysis and dimension reduction techniques. K-Means is most relatively simple to implement and computationally faster than hierarchical clustering. However, in K-Means the number of clusters should be chosen beforehand. Hierarchical clustering with structured tree diagram for the number of clusters is more informative but has time complexity and is sensitive to outliers. PCA as a statistical technique to reduce the number of features (dimension) of data is discussed. Moreover, definition and challenges in semisupervised learning have also been briefly provided.

Thereafter, a small case study is presented to illustrate some of the algorithms and their differences more explicitly. To summarize, this chapter discusses many algorithms and challenges in machine learning and provides several existing solutions to these challenges. However, there are still challenges and possible future research venues that need to be addressed in the future of machine learning. Some of which that have been found in this chapter are as follows: The interpretability of many of machine-learning algorithms can be investigated in the future. Many machine learning models need extensive datasets for training before predicting the unseen data, and this can be a problem when small datasets are only available, or the data needs to be processed in real time. In this regard, small sample learning, one-shot learning and zero-shot learning, and online learning have got attention among researchers the past years. Additionally, the machine learning industry is gradually shifting its focus to unsupervised and semisupervised learning instead of supervised learning so that the machine can process data without manual human labels. All in all, machine learning as a new fast evolving area has numerous challenges as well as opportunities in a variety of applications.

implies certain sparse structure on the covariance and precision matrices. In this chapter, we first overview the Cholesky-based covariance and precision matrices estimation. It is known that the Cholesky-based matrix estimation depends on a prespecified ordering of variables, which is often not available in practice. To address this issue, we then introduce several techniques to enhance the Cholesky-based estimation of covariance and precision matrices. These approaches are able to ensure the positive definiteness of the matrix estimate and applicable in general situations without specifying the ordering of variables. The advantage of Cholesky-based estimation is illustrated by numerical studies and several real-case applications.

Abstract

In many engineering applications, estimation of covariance and precision matrices is of great importance, helping researchers understand the dependency and conditional dependency between variables of interest. Among various matrix estimation methods, the modified Cholesky decomposition is a commonly used technique. It has the advantage of transforming the matrix estimation task into solving a sequence of regression models. Moreover, the sparsity on the regression coefficients

43.1 Introduction

Estimation of covariance and precision matrices is of fundamental importance in the multivariate analysis [5]. It has received wide attentions of scholars in various engineering applications such as additive manufacturing [30, 31], biomedical engineering [17], and tissue engineering [39]. The resultant matrix estimation has also been widely used in various statistical methods and applications. For example, dimension reduction via the principal component analysis (PCA) usually relies on the estimation of covariance matrix. In the classification problem, the linear discriminant analysis (LDA) constructs the classification rule through the precision matrix. In the financial area, the portfolio optimization uses the precision matrix to minimize the portfolio risk. In signal

processing, the covariance matrix helps to distinguish between signals and noise. The covariance and precision matrices also arise in the graphical models, multivariate volatility, weather forecasting, social network, fMRI analysis, and so forth.

For the matrix estimation, a desirable property is the sparsity in the sense that some elements in an estimated matrix are zeros [13, 16, 20, 26, 37]. A sparse covariance matrix estimate is useful for the subsequent statistical analysis, such as inferring the correlation pattern among the predictor variables. A sparse precision matrix estimate often implies the conditional independence among the corresponding predictor variables. Therefore, a variety of classical approaches has been developed in literature for estimating the covariance and precision matrices with particular interest of sparse structure. Yuan and Lin [38] introduced the graphical Lasso (Glasso) model, which gives a sparse precision matrix estimate by imposing an L_1 penalty on the negative log-likelihood function. Bickel and Levina [1] proposed to threshold the small elements of the sample covariance matrix directly to zeroes with a large number of predictor variables. More work on the sparse estimation of the covariance and precision matrices can be found in [3–5, 10, 15, 21, 27, 32, 34, 36], among others.

Another important property of covariance and precision matrices is that they need to be positive definite for proper inference. The modified Cholesky decomposition (MCD) is a popular and commonly used technique for the matrix estimation, which ensures the estimated matrix to be positive definite. The MCD provides an unconstrained and statistically interpretable parameterization of a matrix by sequentially regressing the variables in a random variable vector. This method reduces the challenge of estimating a covariance or precision matrix into an easier task of solving a sequence of linear regression models. However, it is known that the Cholesky-based matrix estimation relies on the preknowledge of the ordering of variables. When the variable ordering is not naturally available, we need to consider several techniques to enhance the Cholesky-based estimation of covariance and precision matrices. Such techniques are able to ensure the positive definiteness of the matrix estimate and applicable in general situations without specifying the ordering of variables.

The remaining of this chapter is organized as follows. Sect. 43.2 provides a comprehensive overview of the MCD for the estimation of covariance and precision matrices, respectively. We then point out the variable ordering issue in the MCD and consider a couple of techniques to address the variable ordering issue in Sect. 43.3. Several real-data applications and numerical examples are presented in Sects. 43.4 and 43.5 to examine the performances of the Cholesky-based matrix estimates. We conclude this chapter with some discussion in Sect. 43.6.

43.2 Review of Modified Cholesky Decomposition

In this section, we review the modified Cholesky decomposition (MCD) in detail for estimating the covariance and precision matrices, respectively. As proposed by Pourahmadi [24], the MCD approach is statistically meaningful and guarantees the positive definiteness of a matrix estimate. The sparsity can be encouraged in the estimated matrix via the MCD technique.

43.2.1 MCD for Precision Matrix Estimation

Without loss of generality, suppose that $\mathbf{X} = (X_1, \dots, X_p)'$ is a p -dimensional random vector with mean $\mathbf{0}$ and covariance matrix Σ . Denote by $\mathbf{x}_1, \dots, \mathbf{x}_n$ the n independent and identically distributed observations following a multivariate distribution with mean $\mathbf{0}$ and covariance matrix Ω^{-1} , where $\Omega = \Sigma^{-1}$ is the precision matrix. The key idea of the MCD is that Ω can be diagonalized by a lower triangular matrix constructed from the regression coefficients when X_j is regressed on its predecessors X_1, \dots, X_{j-1} . Specifically, for $j = 2, \dots, p$, define

$$\begin{aligned} X_j &= \sum_{i=1}^{j-1} a_{ji} X_i + \epsilon_j \\ &= \mathbf{Z}_j^T \mathbf{a}_j + \epsilon_j, \end{aligned} \quad (43.1)$$

where $\mathbf{Z}_j = (X_1, \dots, X_{j-1})'$, and $\mathbf{a}_j = (a_{j1}, \dots, a_{jj-1})'$ is the corresponding vector of regression coefficients. The error term ϵ_j has population expectation $E(\epsilon_j) = 0$ and population variance $\text{Var}(\epsilon_j) = d_j^2$. Hence, a lower triangular matrix \mathbf{A} can be formed as

$$\mathbf{A} = \begin{pmatrix} 0 & 0 & 0 & \dots & 0 \\ a_{21} & 0 & 0 & \dots & 0 \\ a_{31} & a_{32} & 0 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ a_{p1} & a_{p2} & \dots & a_{p,p-1} & 0 \end{pmatrix},$$

which contains all the regression coefficients in (43.1). Also define

$$d_j^2 = \text{Var}(\epsilon_j) = \begin{cases} \text{Var}(X_1), & j = 1, \\ \text{Var}(X_j - \mathbf{Z}_j^T \mathbf{a}_j), & j = 2, \dots, p. \end{cases} \quad (43.2)$$

Let $\mathbf{D} = \text{diag}(d_1^2, \dots, d_p^2)$ be the diagonal covariance matrix of the vector $\boldsymbol{\epsilon} = (\epsilon_1, \dots, \epsilon_p)'$. Then, move the term $\sum_{k=1}^{j-1} a_{jk} X_k$ in Eq. (43.1) to the left side and rewrite it in the following matrix form:

$$\boldsymbol{\epsilon} = (\mathbf{I} - \mathbf{A})\mathbf{X} = \mathbf{TX}, \quad (43.3)$$

where \mathbf{I} represents the $p \times p$ identity matrix and $\mathbf{T} = \mathbf{I} - \mathbf{A}$ is a unit lower triangular matrix having ones on its diagonal. The matrices \mathbf{T} and \mathbf{D} are called the Cholesky factor matrices. By taking the variance operator on both sides of Eq. (43.3), one can easily obtain

$$\mathbf{D} = \text{Var}(\boldsymbol{\epsilon}) = \text{Var}(\mathbf{TX}) = \mathbf{T}\boldsymbol{\Sigma}\mathbf{T}',$$

and thus

$$\boldsymbol{\Omega} = \boldsymbol{\Sigma}^{-1} = \mathbf{T}'\mathbf{D}^{-1}\mathbf{T}. \quad (43.4)$$

As a result, the decomposition (43.1) converts the constraint entries of $\boldsymbol{\Sigma}$ into two groups of unconstrained “regression” and “variance” parameters. Conceptually, this approach reduces the challenge of modeling a precision matrix into the task of solving $(p - 1)$ linear regression models, which is much easier to implement.

A straightforward estimate $\hat{\mathbf{T}}$ of \mathbf{T} can be obtained from the least squares estimates of the regression coefficients

$$\hat{\mathbf{a}}_j = \arg \min_{\mathbf{a}_j} \|\mathbf{x}^{(j)} - \mathbb{Z}^{(j)}\mathbf{a}_j\|_2^2, \quad j = 2, \dots, p, \quad (43.5)$$

where $\mathbf{x}^{(j)}$ is the j th column of the data matrix $\mathbb{X} = (\mathbf{x}_1, \dots, \mathbf{x}_n)'$ and $\mathbb{Z}^{(j)} = (\mathbf{x}^{(1)}, \dots, \mathbf{x}^{(j-1)})$ stands for the first $(j-1)$ columns of \mathbb{X} . The estimate $\hat{\mathbf{D}}$ of \mathbf{D} is constructed from the corresponding residual variances according to (43.2). Because the optimization (43.5) uses the ordinary least squares, this approach of precision matrix estimation is only suitable in low-dimensional settings with the number of predictor variables p smaller than the sample size n . When applying the MCD to the high-dimensional situations where p is close to or even larger than n , the least squares estimation is inaccurate or not available. In such cases, a natural idea is to employ the Lasso regularization [33] to shrink the regression estimates and encourage the sparsity on the Cholesky factor matrix \mathbf{T}

$$\hat{\mathbf{a}}_j = \arg \min_{\mathbf{a}_j} \|\mathbf{x}^{(j)} - \mathbb{Z}^{(j)}\mathbf{a}_j\|_2^2 + \lambda_j \|\mathbf{a}_j\|_1, \quad j = 2, \dots, p, \quad (43.6)$$

where $\lambda_j \geq 0$ is a tuning parameter and $\|\cdot\|_1$ stands for the vector L_1 norm. Note that the penalty in Eq. (43.6) is often suitable for data with large number of variables such as engineering data, social network data, and imaging data, since their underlying matrix is usually sparse with no specific sparse pattern. The optimization problem (43.6) can be solved by the coordinate descent algorithm [12]. The tuning parameters are determined by the cross-validation scheme

for each Lasso regression. In addition, one can alternatively consider the estimation of $\mathbf{a}_2, \dots, \mathbf{a}_p$ in the Cholesky factor matrix \mathbf{T} under a joint fashion as

$$\hat{\mathbf{a}}_2, \dots, \hat{\mathbf{a}}_p = \arg \min_{\mathbf{a}_2, \dots, \mathbf{a}_p} \sum_{j=2}^p \|\mathbf{x}^{(j)} - \mathbb{Z}^{(j)}\mathbf{a}_j\|_2^2 + \lambda \sum_{j=2}^p \|\mathbf{a}_j\|_1. \quad (43.7)$$

Such a joint estimation approach is used in [6, 13, 14, 40], among others.

After obtaining $\hat{\mathbf{a}}_j$, the lower triangular matrix $\hat{\mathbf{T}}$ is established with ones on its diagonal and $\hat{\mathbf{a}}_j'$ as its j th row. Meanwhile, the diagonal matrix $\hat{\mathbf{D}}$ has its j th diagonal element equal to \hat{d}_j^2 , where

$$\hat{d}_j^2 = \begin{cases} \widehat{\text{Var}}(\mathbf{x}^{(1)}), & j = 1, \\ \widehat{\text{Var}}(\mathbf{x}^{(j)} - \mathbb{Z}^{(j)}\hat{\mathbf{a}}_j), & j = 2, \dots, p, \end{cases}$$

where $\widehat{\text{Var}}(\cdot)$ denotes the sample variance. Consequently,

$$\hat{\boldsymbol{\Omega}} = \hat{\mathbf{T}}'\hat{\mathbf{D}}^{-1}\hat{\mathbf{T}} \quad (43.8)$$

is a sparse estimate for the precision matrix $\boldsymbol{\Omega}$.

Remark 1 For the optimization problem in (43.6) with $\lambda_j = 0$ and $n > p$, the estimated precision matrix in (43.8) is equivalent to the inverse of the sample covariance matrix.

43.2.2 MCD for Covariance Matrix Estimation

From (43.4), it is easy to see that a Cholesky-based estimate for a covariance matrix can be expressed as

$$\boldsymbol{\Sigma} = \mathbf{T}^{-1}\mathbf{D}\mathbf{T}'^{-1}. \quad (43.9)$$

The construction of the Cholesky factor matrices (\mathbf{T}, \mathbf{D}) through a series of linear regressions (43.1) is thoroughly discussed in Sect. 43.2.1. Such a covariance matrix estimate via the MCD can perform well if one does not require the estimated covariance matrix to be sparse. In other words, the estimate obtained based on Eq. (43.9) generally does not have sparse structure even though the Cholesky factor matrix \mathbf{T} is sparse. This is because the matrix \mathbf{T}^{-1} often does not inherit any sparse property from \mathbf{T} , leading to a dense estimate of covariance matrix $\boldsymbol{\Sigma}$. It is thus not convenient to impose a sparse structure on the estimate of $\boldsymbol{\Sigma}$ via Eq. (43.9).

Alternatively, one can consider a Cholesky-based latent variable regression model, which enables the regularization more easily. Write $\mathbf{X} = \mathbf{L}\boldsymbol{\epsilon}$, implying the predictor variable X_j is regressed on its previous latent variables $\epsilon_1, \dots, \epsilon_{j-1}$,

and hence $\mathbf{L} = (l_{ji})_{p \times p}$ is a unit lower triangular matrix constructed from the regression coefficients of the following sequential regressions:

$$X_j = \mathbf{l}_j^T \boldsymbol{\epsilon} = \sum_{i=1}^{j-1} l_{ji} \epsilon_i + \epsilon_j, \quad j = 2, \dots, p, \quad (43.10)$$

where $\mathbf{l}_j = (l_{ji})$ is the j th row of \mathbf{L} . Here $l_{jj} = 1$ and $l_{ji} = 0$ for $i > j$. This decomposition is interpreted as resulting from a different sequence of regressions, where each variable X_j is regressed on all the previous latent variable $\epsilon_1, \dots, \epsilon_{j-1}$ rather than themselves. As a result, this form of the MCD by the latent variable regression model provides a re-parameterization of the covariance matrix

$$\begin{aligned} \text{Var}(\mathbf{X}) &= \text{Var}(\mathbf{L}\boldsymbol{\epsilon}) \\ \boldsymbol{\Sigma} &= \mathbf{L}\mathbf{D}\mathbf{L}' \end{aligned}$$

This decomposition connects the covariance matrix $\boldsymbol{\Sigma}$ with linear regressions (43.10), such that the Lasso penalty can be imposed on the coefficients of the linear regressions, thus conveniently encouraging the sparsity in the Cholesky factor matrix \mathbf{L} and the estimated covariance matrix.

Denote by $\mathbf{x}^{(j)}$ the j th column of the data matrix $\mathbb{X} = (\mathbf{x}_1, \dots, \mathbf{x}_n)'$. Let $\mathbf{e}^{(j)}$ represent the residuals for the linear regression when $\mathbf{x}^{(j)}$ is treated as the response data, $j \geq 2$, and $\mathbf{e}^{(1)} = \mathbf{x}^{(1)}$. Let $\mathbb{W}^{(j)} = (\mathbf{e}^{(1)}, \dots, \mathbf{e}^{(j-1)})$ be the matrix containing the first $(j - 1)$ residuals. Now we construct the matrix \mathbf{L} by employing the Lasso penalty to select important predictor variables

$$\hat{\mathbf{l}}_j = \arg \min_{\mathbf{l}_j} \|\mathbf{x}^{(j)} - \mathbb{W}^{(j)} \mathbf{l}_j\|_2^2 + \lambda_j \|\mathbf{l}_j\|_1, \quad j = 2, \dots, p, \quad (43.11)$$

where $\lambda_j \geq 0$ is a tuning parameter and selected by cross-validation. $\mathbf{e}^{(j)} = \mathbf{x}^{(j)} - \mathbb{W}^{(j)} \hat{\mathbf{l}}_j$ is used to construct the residuals for the last column of $\mathbb{W}^{(j+1)}$. Then the element d_j^2 of the diagonal matrix $\mathbf{D} = \text{diag}(d_1^2, \dots, d_p^2)$ is estimated as the sample variance of $\mathbf{e}^{(j)}$

$$\hat{d}_j^2 = \widehat{\text{Var}}(\mathbf{e}^{(j)}) = \widehat{\text{Var}}(\mathbf{x}^{(j)} - \mathbb{W}^{(j)} \hat{\mathbf{l}}_j)$$

Consequently,

$$\hat{\boldsymbol{\Sigma}} = \hat{\mathbf{L}} \hat{\mathbf{D}} \hat{\mathbf{L}}' \quad (43.12)$$

is a sparse estimate for the covariance matrix $\boldsymbol{\Sigma}$. It is worth pointing out that one can also consider estimating $\mathbf{l}_2, \dots, \mathbf{l}_p$ in a joint fashion similar as in (43.7). But the estimation procedure will become more complicated since it involves latent variables.

Remark 2 For the optimization problem in (43.11) with $\lambda_j = 0$ and $n > p$, the estimated covariance matrix in (43.12) is equivalent to the sample covariance matrix.

43.2.3 MCD for Banded Matrix Estimation

In some applications such as assimilation [22] and social unrest study [35], the variables are strongly correlated with the ones that are close to them in the ordering, and the variables far apart in the ordering are weakly correlated. For example, in the random variable vector $\mathbf{X} = (X_1, \dots, X_p)'$, the variable X_3 may have a strong correlation with its neighbor variables X_1, X_2, X_4 , and X_5 , but it could be weakly correlated with variables X_j for $j > 5$. In this situation, the covariance or precision matrices are usually assumed to have a banded structure. The k th banded structure means that the first $k < p$ sub-diagonals elements of a matrix are non-zeroes with the rest elements being zeroes. Bickel and Levina [2] proposed a banded estimate for the covariance matrix by banding the sample covariance matrix. Note that their estimate cannot guarantee the positive definiteness. The MCD technique can also be used for estimating a banded matrix by banding the Cholesky matrix factor [28]. In this section, we focus on the estimation for banded precision matrix via the MCD. The Cholesky-based estimation for the banded covariance matrix follows the similar principle by considering the banded \mathbf{L} in (43.12).

The key idea is to band the Cholesky factor matrix \mathbf{T} . Recall that in the decomposition (43.1), the predictor variable X_j is regressed on all of its predecessors X_1, \dots, X_{j-1} . To accommodate a banded estimate of precision matrix, each predictor variable X_j is regressed only on its k previous variables X_{j-k}, \dots, X_{j-1} , for all $j = 2, \dots, p$. The index $j - k$ is interpreted to mean $\max(1, j - k)$. Hence, we solve the following $(p - 1)$ linear regression models instead of (43.1)

$$X_j = \sum_{i=j-k}^{j-1} a_{ji} X_i + \epsilon_j \quad (43.13)$$

to construct the Cholesky factors (\mathbf{T}, \mathbf{D}) . As a result, the unit lower triangular matrix \mathbf{T} , with ones as its diagonal and $(0, \dots, 0, a_{j,j-k}, \dots, a_{j,j-1})$ as its j th row, has a banded structure on its bottom left part. Then the estimate for the precision matrix $\boldsymbol{\Omega} = \mathbf{T}' \mathbf{D}^{-1} \mathbf{T}$ obtained from (43.13) has a k th banded structure. This approach is designated to estimate a banded matrix and guarantees the positive definiteness of the estimated matrix.

43.2.4 Adaptive Banding in the MCD

Note that the k th banded matrix estimation in Sect. 43.2.3 considers the banding width k to be the same for each vari-

able. In this section, we discuss a more flexible case where the band for each variable to be different. That is, we allow $k = k_j$ in the j th linear regression of (43.13), where the j th variable is regressed on its k_j closest predecessors with k_j depending on j . We call such a procedure as adaptive banding, which is useful when each variable may depend on an unknown number of its predecessors. It preserves sparsity in the resulting estimate of precision matrix and produces a better estimate by being able to adapt to the data. Next we introduce two types of adaptive banding. They use two different techniques to obtain an adaptively banded estimate for the Cholesky factor \mathbf{T} .

Adaptive Banding: Levina and Zhu [19] applied a nested Lasso penalty imposed on the negative normal log-likelihood function to produce matrix \mathbf{T} with adaptive banding k_j . Specially, the negative log-likelihood of the data, up to a constant, is

$$\begin{aligned} \ell(\boldsymbol{\Sigma}, \mathbf{x}_1, \dots, \mathbf{x}_n) &= n \log |\boldsymbol{\Sigma}| + \sum_{i=1}^n \mathbf{x}_i' \boldsymbol{\Sigma}^{-1} \mathbf{x}_i \\ &= n \log |\mathbf{D}| + \sum_{i=1}^n \mathbf{x}_i' \mathbf{T}' \mathbf{D}^{-1} \mathbf{T} \mathbf{x}_i \\ &= \sum_{j=1}^p \ell_j(d_j, \mathbf{a}_j, \mathbf{x}_1, \dots, \mathbf{x}_n), \end{aligned}$$

where \mathbf{a}_j stands for the vector of regression coefficients for the j th regression in the MCD and

$$\ell_j(d_j, \mathbf{a}_j, \mathbf{x}_1, \dots, \mathbf{x}_n) = n \log d_j^2 + \sum_{i=1}^n \frac{1}{d_j^2} \left(x_{ij} - \sum_{l=1}^{j-1} a_{jl} x_{il} \right)^2.$$

Minimizing the negative log-likelihood $\ell(\boldsymbol{\Sigma}, \mathbf{x}_1, \dots, \mathbf{x}_n)$ is equivalent to minimizing each $\ell_j(d_j, \mathbf{a}_j, \mathbf{x}_1, \dots, \mathbf{x}_n)$. Then one can consider to minimize

$$\ell_j(\boldsymbol{\Sigma}, \mathbf{x}_1, \dots, \mathbf{x}_n) + J(\mathbf{a}_j), \quad (43.14)$$

where $J(\mathbf{a}_j)$ is the nested Lasso penalty as

$$J(\mathbf{a}_j) = \lambda \left(|a_{j,j-1}| + \frac{|a_{j,j-2}|}{|a_{j,j-1}|} + \frac{|a_{j,j-3}|}{|a_{j,j-2}|} + \dots + \frac{|a_{j,1}|}{|a_{j,2}|} \right),$$

where $\lambda \geq 0$ is a tuning parameter, and we define $0/0 = 0$. The effect of variable selection by the nested Lasso penalty is that if the l th variable is not included in the j th regression ($a_{jl} = 0$), then all the subsequent variables ($l - 1$ through 1) are also excluded. Hence, the j th linear regression only has $k_j \leq j - 1$ closest predecessors, with values of k_j varying for each regression.

Since the expression in (43.14) is highly nonconvex and nonlinear, an iterative algorithm is developed to minimize it for constructing the Cholesky factor matrices \mathbf{T} and \mathbf{D} . Let $\hat{\mathbf{a}}_j^{(m)}$ and $\hat{d}_j^{(m)}$ represent the estimates of \mathbf{a}_j and d_j at the m th iteration. Then we repeat the following steps 1 and 2 until convergence.

Step 1: Given $\hat{\mathbf{a}}_j^{(m)}$, solve for $\hat{d}_j^{(m)}$

$$(\hat{d}_j^{(m)})^2 = \frac{1}{n} \sum_{i=1}^n \left(x_{ij} - \sum_{l=1}^{j-1} \hat{a}_{jl}^{(m)} x_{il} \right)^2.$$

Step 2: Given $\hat{\mathbf{a}}_j^{(m)}$ and $\hat{d}_j^{(m)}$, solve for $\hat{\mathbf{a}}_j^{(m+1)}$. Here we use the local quadratic approximation [9, 13]

$$|a_{jl}^{(m+1)}| \approx \frac{(a_{jl}^{(m+1)})^2}{2 |a_{jl}^{(m)}|} + \frac{|a_{jl}^{(m)}|}{2}.$$

Then the estimate of \mathbf{a}_j at iteration $m + 1$ is

$$\begin{aligned} \hat{\mathbf{a}}_j^{(m+1)} &= \arg \min_{\mathbf{a}_j} \frac{1}{(\hat{d}_j^{(m)})^2} \sum_{i=1}^n \left(x_{ij} - \sum_{l=1}^{j-1} a_{jl} x_{il} \right)^2 \\ &\quad + \frac{\lambda}{2} \left(\frac{a_{j,j-1}^2}{|\hat{a}_{j,j-1}^{(m)}|} + \sum_{l=1}^{j-2} \frac{a_{jl}^2}{|\hat{a}_{jl}^{(m)}| \cdot |\hat{a}_{j,l+1}^{(m)}|} \right). \end{aligned}$$

This is a quadratic optimization problem, which can be solved in closed form. Note that the algorithm needs an initial value for \mathbf{a}_j . One could use the least squares estimates when $p < n$. If $p > n$, we initialize with $\hat{a}_{jl}^{(0)} = \hat{a}_{jl}^*$, which are found by regressing X_j on X_l alone, for $l = 1, \dots, j - 1$.

Forward Adaptive Banding: Instead of imposing a nested Lasso penalty on the likelihood function, Leng and Li [18] proposed a forward adaptive banding approach to determine k_j for each linear regression by minimizing their modified Bayesian information criterion (BIC). Operationally, for the j th variable, we fit $j - 1$ nested linear models by regressing X_j on $X_{j-1}, \dots, X_{j-k_j}$ for $k_j = 1, \dots, j - 1$. Then the optimal k_j is chosen to minimize

$$\begin{aligned} \text{BIC} &= n \log |\hat{\boldsymbol{\Sigma}}| + \sum_{i=1}^n \mathbf{x}_i' \hat{\mathbf{T}}' \hat{\mathbf{D}}^{-1} \hat{\mathbf{T}} \mathbf{x}_i + C_n \log(n) \sum_{j=1}^p k_j \\ &= \sum_{j=1}^p \left\{ n \log \hat{d}_j^2 + \sum_{i=1}^n \frac{1}{\hat{d}_j^2} \left(x_{ij} - \sum_{l=1}^{k_j} a_{j,j-l} x_{i,j-l} \right)^2 + C_n \log(n) k_j \right\}, \end{aligned} \quad (43.15)$$

for all $k_j \leq \min\{n/(\log n)^2, j - 1\}$ ($j = 2, \dots, p$) with some diverging C_n . The expression in (43.15) implies that the banding width k_j can be chosen separately for each j . The penalty coefficient $C_n \log n$ is set to different values to accommodate the diverging number of predictor variables p . Leng and Li [18] proved that this modified BIC is model selection consistent under some regular conditions. The advantage of this approach is that we determine the value of k_j by only fitting a sequence of linear models. Therefore, it can be easily and efficiently implemented.

43.3 Ordering Issue in the MCD

Although the MCD approach has been widely investigated for the matrix estimation, only a few work contributed to solve a potential problem, the ordering issue. From the decompositions (43.1) and (43.10), it is clear to see that different orderings of the predictor variables X_1, \dots, X_p used in the MCD would lead to different linear regressions. If a regularization is adopted to shrink the coefficients of the linear regressions, such as the Lasso penalty in (43.6), the Cholesky factor matrices estimates would be different under different variable orderings, thus leading to the different estimates for the covariance and precision matrices. As a statistical decision problem, ordering variables is quite challenging. In practice, the MCD method can be suitably used to estimate a matrix without this ordering issue when the predictor variables have a natural ordering among themselves, as in time series, longitudinal data, or spatial data. However, there are a large number of applications where such a natural ordering is not available or the variable ordering cannot be determined before the analysis, for example, gene expressions, financial, and economic data. In these cases, one may need to first determine a proper ordering among the variables before employing the MCD method. Next, we introduce three commonly used techniques to tackle this issue. In this part, we focus on the ordering issue in the MCD for the estimation of precision matrix. Ordering issue for Cholesky-based estimation of covariance matrix can be addressed in a similar fashion.

BIC: A search algorithm for ordering the predictor variables based on the BIC criterion can be easily implemented. In each step, a new variable is selected into the ordering with the smallest value of BIC when regressing it on the rest of the candidate variables. Specifically, suppose we want to construct an ordering for p variables X_1, \dots, X_p . In the first step, each variable $X_j, j = 1, \dots, p$ is regressed on the rest of variables, producing p values of BIC from p linear regressions. Then the first variable determined into the ordering is the response variable of the linear regression that gives the minimum value of BIC. This selected variable is denoted by X_{i_p} , and it is assigned to the p th position of the

ordering. All the variables excluding the selected variable X_{i_p} consist of the candidate set \mathcal{C} . In the second step, from the set \mathcal{C} , each variable is regressed on the rest of variables, producing $p - 1$ values of BIC from $p - 1$ linear regressions. Then the second variable, denoted by $X_{i_{p-1}}$, determined into the ordering is the response variable of the linear regression that gives the minimum value of BIC. The variable $X_{i_{p-1}}$ is assigned to the $(p - 1)$ th position of the ordering. Then all the variables excluding X_{i_p} and $X_{i_{p-1}}$ compose of the candidate set for the next round.

To sum up this procedure, let $\mathcal{C} = \{X_{i_1}, \dots, X_{i_k}\}$ be the candidate set of variables, and there are $p - k$ variables already chosen into the ordering. By regressing each $X_j, j = i_1, \dots, i_k$ on the rest of the variables in \mathcal{C} , the variable corresponding to the minimum BIC value among the k regressions is assigned to the k th position of the ordering. Then the ordering created by this procedure is used for the MCD.

BPA: A popular method to recover the variable ordering for the autoregressive model is the best permutation algorithm (BPA) developed by Rajaratnam and Salzman [25]. It is formulated as a well-defined optimization problem where the optimal ordering is determined as the one minimizing the sum of squared diagonal entries of the Cholesky factor matrix D in the MCD. For the convenience of presentation, define a permutation mapping $\pi : \{1, \dots, p\} \rightarrow \{1, \dots, p\}$ by

$$(\pi(1), \pi(2), \dots, \pi(p)). \tag{43.16}$$

Denote the corresponding permutation matrix by P_π of which the entries in the j th column are all 0 except taking 1 at position $\pi(j)$. Let S_p be the symmetric group of all permutations of the integers $1, \dots, p$. For a given $\pi \in S_p$, let Ω_π be the precision matrix corresponding to the variable ordering π and

$$\Omega_\pi = T'_\pi D_\pi^{-1} T_\pi$$

be its MCD. Since the conditional variances can be used as natural measures to quantify the extent to which the variability of a random variable is explained by the ones that precede it. Hence, the conditional variances give a sense of closeness between variables. From this viewpoint, the BPA is to find an ordering π^* in S_p to minimize $\|D_{\pi^*}\|_F^2$, where $\|\cdot\|_F$ represents the Frobenius norm. Then $\hat{\Omega} = P_{\pi^*} \hat{\Omega}_{\pi^*} P_{\pi^*}' = P_{\pi^*} \hat{T}'_{\pi^*} \hat{D}_{\pi^*}^{-1} \hat{T}_{\pi^*} P_{\pi^*}'$ is an estimate of precision matrix based on BPA. Rajaratnam and Salzman [25] showed the consistency of this approach in recovering the natural order of variables in underlying autoregressive models.

Ordering-averaged method (OAM): To address the problem that the ordering of variables is often not available in practice, we consider a Cholesky-based model averaging idea [40] by averaging a representative set of individual matrix estimates obtained from random permutations of the variable orderings. This method does not require any prior knowledge

of the orderings of variables; hence, it is suitable for the case where there is no natural ordering among the variables, or such an ordering cannot be easily determined. Use the definition of permutation mapping π in (43.16), a precision matrix estimate under π is $\mathbf{\Omega}_\pi = \mathbf{T}'_\pi \mathbf{D}_\pi^{-1} \mathbf{T}_\pi$. Transforming back to the original ordering, we can estimate $\mathbf{\Omega}$ as

$$\hat{\mathbf{\Omega}} = \mathbf{P}_\pi \hat{\mathbf{\Omega}}_\pi \mathbf{P}'_\pi = \mathbf{P}_\pi \mathbf{T}'_\pi \mathbf{D}_\pi^{-1} \mathbf{T}_\pi \mathbf{P}'_\pi. \quad (43.17)$$

By incorporating several permutations of π s, one can obtain a pool of precision matrix estimates. Taking the average of these estimates leads to an ordering-averaged estimation. In practice, a modest number of permutations are sufficient to serve this purpose. Therefore, we randomly generate multiple permutations $\pi_k, k = 1, \dots, M$ and obtain the corresponding estimates $\hat{\mathbf{\Omega}}$ in (43.17), denoted by $\hat{\mathbf{\Omega}}_k$ for the permutation π_k . The model averaging estimate of $\mathbf{\Omega}$ is

$$\hat{\mathbf{\Omega}}_{OAM} = \frac{1}{M} \sum_{k=1}^M \hat{\mathbf{\Omega}}_k. \quad (43.18)$$

Similarly, it is very convenient to apply the OAM for the estimation of the covariance matrix. Combining Eq. (43.9) and the averaging idea of (43.18), we have the model averaging estimate of $\mathbf{\Sigma}$ as

$$\begin{aligned} \hat{\mathbf{\Sigma}}_{OAM} &= \frac{1}{M} \sum_{k=1}^M \hat{\mathbf{\Sigma}}_k = \frac{1}{M} \sum_{k=1}^M \mathbf{P}_k \hat{\mathbf{\Sigma}}_k \mathbf{P}'_k \\ &= \frac{1}{M} \sum_{k=1}^M \mathbf{P}_k \hat{\mathbf{T}}_k^{-1} \hat{\mathbf{D}}_k (\hat{\mathbf{T}}_k')^{-1} \mathbf{P}'_k, \end{aligned}$$

where $\hat{\mathbf{T}}_k, \hat{\mathbf{D}}_k$, and $\hat{\mathbf{\Sigma}}_k$ represent the estimates of \mathbf{T}, \mathbf{D} , and $\mathbf{\Sigma}$ under the permutation π_k . According to the finite population sampling survey theory [7], the selection of permutations π_k is not essential when we use a reasonable size M . Although choosing a larger M would further reduce the variability of the OAM estimate, Zheng et al. [40] showed that a modest number $M = 30$ is seen to lead to stable results.

43.4 Real Applications

The covariance and precision matrices have been widely used in various areas such as portfolio selection, risk assessment, principle component analysis, social network, graphical models, classification, and so forth. In this section, real-data examples are used to illustrate the application of the MCD approach for the estimation of covariance and precision matrices.

43.4.1 MCD for Varying Covariance Matrix Estimation in Multivariate Time Series

In the financial management with multivariate time series, a major task is to estimate the time-varying covariance matrices $\{\mathbf{\Sigma}_t\}$ based on the (conditionally) independently distributed data $\mathbf{x}_t \sim N(\mathbf{0}, \mathbf{\Sigma}_t), t = 1, 2, \dots, n$. The data \mathbf{x}_t can be viewed as the returns of p assets in a portfolio at time t .

By the decomposition (43.9), the estimation of time-varying covariance matrix is given by

$$\mathbf{\Sigma}_t = \mathbf{T}^{-1} \mathbf{D}_t \mathbf{T}'^{-1},$$

where the Cholesky factor matrix $\mathbf{T} = \mathbf{T}_t$ for all $t = 1, 2, \dots, n$ is assumed to be time-invariant to reduce a large number of parameters. For each element of the diagonal matrix $\mathbf{D}_t = \text{diag}(d_{1,t}^2, \dots, d_{p,t}^2)$, the $\log d_{j,t}^2, j = 1, 2, \dots, p$, is modeled using the log-GARCH(u, v) defined recursively in time as

$$\begin{aligned} \log d_{j,t}^2 &= \beta_0^{(j)} + \sum_{i=1}^v \left(\alpha_{i+}^{(j)} 1_{\{\epsilon_{j,t-i} > 0\}} + \alpha_{i-}^{(j)} 1_{\{\epsilon_{j,t-i} < 0\}} \right) \log \epsilon_{j,t-i}^2 \\ &\quad + \sum_{k=1}^u \beta_k^{(j)} \log d_{j,t-k}^2. \end{aligned} \quad (43.19)$$

where $1_{\{\cdot\}}$ is the indicator function and $\beta_0^{(j)}, \beta_k^{(j)}, \alpha_{i+}^{(j)}, \alpha_{i-}^{(j)}$ are corresponding coefficients. The quasi-maximum likelihood approach in Francq and Zakoian [11] is used to fit the model (43.19). Therefore, we combine the MCD method and the log-GARCH model to analyze a stock return data from the Standard and Poor's 100 index (S&P100). The data set comprises of $n = 436$ returns and $p = 97$ stocks weekly recorded from August 23, 2004, to December 12, 2012. For simplicity, the log-GARCH (1, 1) model is used to estimate \mathbf{D}_t .

To measure the accuracy of the covariance matrix estimates, we consider the following loss functions: the entropy loss Δ_{1t} , the Kullback-Leibler loss Δ_{2t} , and the quadratic loss functions Δ_{3t} (up to some scale) defined as

$$\begin{aligned} \Delta_{1t} &= \frac{1}{p} \left[\text{tr}[\mathbf{\Sigma}_t^{-1} \hat{\mathbf{\Sigma}}_t] - \log |\mathbf{\Sigma}_t^{-1} \hat{\mathbf{\Sigma}}_t| - p \right], \\ \Delta_{2t} &= \frac{1}{p} \left[\text{tr}[\hat{\mathbf{\Sigma}}_t^{-1} \mathbf{\Sigma}_t] - \log |\hat{\mathbf{\Sigma}}_t^{-1} \mathbf{\Sigma}_t| - p \right], \\ \Delta_{3t} &= \frac{1}{p} \left[\text{tr}(\hat{\mathbf{\Sigma}}_t^{-1} \mathbf{\Sigma}_t - \mathbf{I})^2 \right]. \end{aligned}$$

We also use the mean absolute error and mean squared error loss functions given by

$$\text{MAE}_t = \frac{1}{p^2} \sum_{i=1}^p \sum_{j=1}^p |\hat{\omega}_{ij;t} - \omega_{ij;t}| \quad \text{and}$$

$$\text{MSE}_t = \frac{1}{p^2} \sum_{i=1}^p \sum_{j=1}^p (\hat{\omega}_{ij;t} - \omega_{ij;t})^2,$$

where $\hat{\Sigma}_t = (\hat{\omega}_{ij;t})_{p \times p}$ stands for the estimate of the covariance matrix $\Sigma_t = (\omega_{ij;t})_{p \times p}$, $t = 1, \dots, n$. For each loss measure, we report their averages over the time t as $\text{MAE} = \sum_{t=1}^n \text{MAE}_t/n$, $\text{MSE} = \sum_{t=1}^n \text{MSE}_t/n$, and $\Delta_i = \sum_{t=1}^n \Delta_{it}/n$, $i = 1, 2, 3$.

Since the true realized covariance matrix Σ_t is unknown, we employ a moving blocks approach to get a reliable proxy [23]. Table 43.1 reports the averaged loss measures over time t and their standard errors in parenthesis for methods including ORIG, BIC, BPA, DCC, and OAM. ORIG represents the Cholesky-based method for the estimation of covariance matrix based on the original ordering of variables. Similarly, BIC and BPA are the Cholesky-based methods for the estimation of covariance matrix based on the BIC and BPA to determine the ordering of variables, respectively. OAM stands for the Cholesky-based estimate of covariance matrix using the ordering-averaged model. DCC represents for the dynamic conditional correlation GARCH model, which is a popular tool to fit time series data in finance. It imposes a dynamic structure on the conditional correlation matrices.

It is clear to see from Table 43.1 that the OAM estimate based on the MCD gives the best performance regarding all the loss functions. The possible reason is that the stocks have no natural ordering among themselves. For example, it is not reasonable to order the stocks of Apple Inc., Dow Chemical Co., Microsoft Corp, and Bank of America Corp. Hence, the ordering-averaged model shows a relatively accurate estimation. The second best is the BPA, which is slightly inferior to the OAM. The DCC model does not provide accurate estimates for the time-varying covariance matrices compared with the OAM and BPA for this data set. The ORIG and BIC methods produce large losses, especially in terms of the quadratic loss Δ_3 and MSE. Overall, the MCD approach is suitable for the time-varying covariance matrix estimation for this time-series data.

43.4.2 MCD for Portfolio Optimization

Now we consider a portfolio optimization process that determines the portfolio allocation of multiple assets to minimize the portfolio variance. The risk of a portfolio $w = (w_1, \dots, w_p)$ is measured by the variance $w' \Sigma w$ of its return, where $w_i \geq 0$ and $\sum_{i=1}^p w_i = 1$. The estimated minimum variance portfolio optimization problem is formulated as

$$\min_w w' \hat{\Sigma} w \tag{43.20}$$

$$\text{s.t.} \quad \sum_{i=1}^p w_i = 1,$$

where $\hat{\Sigma}$ is an estimate of the true covariance matrix Σ of asset returns.

We illustrate the performances of each method, including ORIG, BIC, BPA, OAM, and DCC, applied into the portfolio optimization problem using the same data set of 97 stock returns from S&P100 as in Sect. 43.4.1. The first t observations are used to estimate the Cholesky factor matrices (T, D_t) and then predict the covariance matrices $\hat{\Sigma}_{t+1} = \hat{T}^{-1} \hat{D}_{t+1} \hat{T}'^{-1}$ at time $t + 1$, $t = 350, 351, \dots, 435$. Note that the value of $d_{j,t+1}^2$, which is the diagonal element of D_{t+1} , can be estimated from Eq. (43.19) by generating $\hat{\epsilon}_{j;t} = \hat{d}_{j;t} \eta_t$, where η_t is a random variable with mean 0. For this application, we choose $\eta_t \sim t_{df=5}$ distribution. The estimated portfolio \hat{w}_{t+1} is the solution of (43.20) by replacing $\hat{\Sigma}$ with $\hat{\Sigma}_{t+1}$. In practice, the researchers care not only the portfolio risk in (43.20) but also the reward and the information ratio (reward to risk). Hence, the performance measures of interest are the average annual realized return

$$\text{AVG} = \frac{1}{86} \sum_{t=350}^{435} 52 * \hat{w}'_{t+1} x_{t+1},$$

their standard deviation (SD), and the information ratio AVG/SD . Notice that the optimization (43.20) is designed to minimize the portfolio variance rather than to maximize the expected return or the information ratio. Therefore, any portfolio should be primarily evaluated by how successfully it achieves the minimum SD. A large realized return and a high value of information ratio are naturally also desirable

Table 43.1 The averages and standard errors (in parenthesis) of loss measures for the weekly returns of 97 stocks

	Δ_1	Δ_2	Δ_3	MAE	MSE
ORIG	3.397 (0.054)	3.196 (0.036)	1017 (28.35)	6.380 (0.089)	90.61 (2.167)
BIC	3.017 (0.077)	3.376 (0.049)	1176 (32.69)	9.004 (0.486)	364.0 (87.92)
BPA	0.747 (0.029)	0.446 (0.010)	14.94 (0.970)	3.877 (0.096)	36.12 (1.594)
DCC	0.902 (0.049)	0.825 (0.029)	142.3 (11.35)	5.338 (0.223)	172.8 (27.32)
OAM	0.681 (0.024)	0.335 (0.005)	6.183 (0.344)	3.687 (0.102)	35.27 (1.897)

Table 43.2 The comparison of portfolio performances for the weekly returns of 97 stocks

	ORIG	BIC	BPA	DCC	OAM
AVG	8.078	10.93	10.70	8.738	9.840
SD	14.59	17.09	8.007	8.800	7.230
AVG/SD	0.554	0.640	1.336	0.993	1.361

but should be considered of secondary importance from the point of view of evaluating the quality of a covariance matrix estimate.

Table 43.2 summarizes the portfolio performances for each method in terms of AVG, SD, and the information ratio. The OAM estimate provides the smallest SD and the largest information ratio, followed by the BPA method. Although the BIC produces the highest value of the realized return, it has the worst portfolio risk among all the approaches, hence resulting in a low information ratio. The ORIG gives inferior performance with relatively small AVG and large SD. The DCC model does not perform well as the OAM and BPA, but it is better than the BIC and ORIG for this set of data.

43.4.3 MCD for Linear Discriminant Analysis

Linear discriminant analysis (LDA) is a commonly used classification method in statistics and machine learning to construct a decision boundary via a linear combination of predictor variables that separates two or more classes of objects. For a multiple-class discriminant problem, each observation \mathbf{x} belongs to some class $k \in 1, 2, \dots, K$. Let $Y \in \{1, 2, \dots, K\}$ represent K classes. Under the assumption that the conditional density function $f(\mathbf{x}|Y = k)$ follows a normal distribution $N(\boldsymbol{\mu}_k, \boldsymbol{\Sigma})$, the LDA classification rule is

$$\eta_k(\mathbf{x}) = \mathbf{x}'\boldsymbol{\Sigma}^{-1}\boldsymbol{\mu}_k - \frac{1}{2}\boldsymbol{\mu}_k'\boldsymbol{\Sigma}^{-1}\boldsymbol{\mu}_k + \log \pi_k, \quad (43.21)$$

where π_k is the prior probability for class k . The observation \mathbf{x} is assigned to the class k^* if $k^* = \underset{k}{\arg \max} \eta_k(\mathbf{x})$.

There are several unknown parameters in the classification rule (43.21), the population mean $\boldsymbol{\mu}_k$, precision matrix $\boldsymbol{\Sigma}^{-1}$, and prior probability π_k . We estimate them from the training data set. Let C_k be the set composed of the training observations belonging to the class k . Denote by $\hat{\boldsymbol{\mu}}_k$ the $p \times 1$ vector of the sample mean for the training data in class k . Let $\hat{\boldsymbol{\Sigma}}_{LDA} = \frac{1}{n-K} \sum_{k=1}^K \sum_{i \in C_k} (\mathbf{x}_i - \hat{\boldsymbol{\mu}}_k)(\mathbf{x}_i - \hat{\boldsymbol{\mu}}_k)'$ be the estimated within-class covariance matrix based on the training data. Then the estimated LDA classification rule is

$$\mathbf{x}'\hat{\boldsymbol{\Sigma}}_{LDA}^{-1}\hat{\boldsymbol{\mu}}_k - \frac{1}{2}\hat{\boldsymbol{\mu}}_k'\hat{\boldsymbol{\Sigma}}_{LDA}^{-1}\hat{\boldsymbol{\mu}}_k + \log \hat{\pi}_k,$$

Table 43.3 Misclassification rates (in percentage) under 50 times randomly splitting for hand movement data

Method	BIC	BPA	Glasso	GLDA	DLDA	OAM
Misclassification	40.1	39.0	39.1	51.0	46.3	38.9
SE	0.5	0.5	0.6	0.5	0.6	0.5

where $\hat{\pi}_k$ is the frequency of class k in the training data set. It is clear that the estimation accuracy of the covariance or precision matrix will have a profound effect on the accuracy of the classification accuracy of the LDA methods. See the derivation in the appendix for the details. For the high-dimensional data, the $\hat{\boldsymbol{\Sigma}}_{LDA}$ is often unstable or singular. Hence some other estimates of $\boldsymbol{\Sigma}^{-1}$ are used such as the generalized inverse of the within-class covariance matrix (GLDA) or Glasso estimate [38]. In this section, we consider $\boldsymbol{\Sigma}^{-1}$ estimated by some Cholesky-based precision matrix estimation methods such as BIC, OAM, and BPA and examine their performances under the LDA framework. We also present the classification results obtained by estimating $\boldsymbol{\Sigma}^{-1}$ from Glasso, GLDA, and DLDA methods. The DLDA assumes the off-diagonal elements of the precision matrix to be zeroes.

We apply each method into the hand movement data set [29], which contains 15 classes with 24 observations in each class. Every class refers to a hand movement type. The hand movement is represented as a two-dimensional curve performed by the hand in a period of time, where each curve is mapped in a representation with 90 predictor variables. The whole data set is randomly split into a training set with 160 observations and testing set with the rest 200 observations. The 160 observations in the training set are used to estimate the population means $\boldsymbol{\mu}_k$, the population covariance matrix $\boldsymbol{\Sigma}$, and the prior probability π_k in the classification rule (43.21). Then the testing data are used to compute the misclassification rate for each method. The above procedure is repeated 50 times, and Table 43.3 reports the averages and standard errors (SE) of the misclassification rate in percentage for each method.

We see that the Cholesky-based estimates of BIC, OAM, BPA, and Glasso estimate perform comparably with respect to the misclassification rate. The DLDA produces an inferior performance result, possibly due to the reason that the underlying precision matrix of the 90 predictor variables might not be a diagonal structure. In other words, some variables are not conditional independent with each other. The GLDA does not perform well for this data set. It only has a half chance of assigning a new object to the correct class. Note that the misclassification rate of each method is relatively large, since the data contain 15 classes, which makes the discriminant analysis more difficult.

43.5 Numerical Study

In this section, we provide several numerical examples to further illustrate the Cholesky-based estimation of covariance and precision matrices. Here we consider the following two covariance and two precision matrix structures.

Model 1. $\Sigma_1 = \text{MA}(0.5, 0.3)$. The diagonal elements are 1 with the first sub-diagonal elements 0.5 and the second sub-diagonal elements 0.3.

Model 2. Σ_2 is generated by randomly permuting rows and corresponding columns of Σ_1 .

Model 3. Ω_2 is a diagonal matrix with its diagonal elements the inverse of vector $(p, p - 1, p - 2, \dots, 1)'$.

Model 4. $\Omega_1 = \text{AR}(0.5)$. The conditional covariance between any two random variables X_i and X_j is fixed to be $0.5^{|i-j|}$, $1 \leq i, j \leq p$.

Model 1 is a banded sparse matrix, while **Model 2** is an unstructured sparse matrix. **Model 3** is a diagonal matrix. **Model 4** is an autoregressive structure that has homogeneous variances and correlations declining with distance. This model is more dense than the other models. For each model, data x_1, \dots, x_n are generated independently from the normal distribution $N(\mathbf{0}, \Sigma)$ with $n = 50$ and $p \in \{30, 50\}$. We use the same loss functions as in the application section to evaluate the accuracy of the estimates. Besides, to examine the performances of the estimates in catching the sparse structure, the false selection loss (FSL) is used, which is the summation of false positive (FP) and false negative (FN). The FSL is computed in percentage as $(\text{FP} + \text{FN}) / p^2$. Tables 43.4 and 43.5 report the averages of loss measures and their

corresponding standard errors (in parenthesis), respectively, for each method based on 50 replications. The dashed lines in the tables represent the corresponding values not available due to matrix singularity.

In Table 43.4, we compare the performances of the sample covariance matrix S , BIC, BPA, OAM, and RLZ. The RLZ represents the covariance estimator proposed by Rothman et al. [28] (see details in Sect. 43.2.3), which is designated for the banded matrix estimation. From the table, it is seen that the ordering-averaged method OAM gives better results than the sample covariance matrix, BIC and BPA with respect to $\Delta_1, \Delta_2, \Delta_3$, MAE, and MSE, since it takes advantage of multiple variable orderings over one single ordering. However, the OAM does not capture the sparse structure, which is destroyed by the average operation in (43.18). The BIC and BPA can have some sparsity regarding FSL due to the Lasso regularization when constructing the Cholesky factors. But their FSL are worse than that of RLZ, which directly forces most of elements in the Cholesky factors to be zeroes. In addition, it is not surprising to observe that the RLZ performs better for the covariance matrix Σ_1 than Σ_2 , since Σ_2 is no longer a banded matrix after random permutations of rows and columns.

Table 43.5 presents the results obtained by the BIC, BPA, OAM, and Glasso methods. The ordering-averaged method OAM performs generally well but produces no sparsity for the matrix. In contrast, the Glasso estimate is good at catching the sparse structure as seen from FSL. The Glasso method [38] imposes an L_1 type penalty on the negative likelihood function of Ω , hence encouraging the sparsity in the esti-

Table 43.4 The averages and standard errors of estimates for covariance matrix Σ

			Δ_1	Δ_2	Δ_3	MAE	MSE	FSL(%)
Σ_1	$p = 30$	S	12.3 (0.12)	38.7 (1.11)	89.9 (4.54)	3.51 (0.04)	19.9 (0.46)	84.0 (0.02)
		BIC	7.11 (0.12)	11.0 (0.53)	8.11 (0.84)	1.74 (0.02)	10.6 (0.19)	52.0 (0.80)

mated precision matrix. Because the underlying precision matrix Ω_2 is denser than Ω_1 , the Glasso method appears to perform better with respect to FSL for Ω_1 . Additionally, the Glasso also performs well regarding the loss measures Δ_3 and MAE. We also note that the BPA gives a superior performance than BIC estimate. This superiority is more evident for the precision matrix Ω_2 compared with Ω_1 , since Ω_2 is an autoregressive model.

43.6 Discussion

This chapter reviews the modified Cholesky decomposition (MCD) method for the estimation of covariance and precision matrices. It is seen that the MCD method has the flexibility of handling matrix estimation by transforming the problem into a sequence of regression-based problems. The sparsity can be easily imposed on the Cholesky factor matrices via the linear regressions and hence encouraging the sparse structure in the matrix estimate. The Cholesky-based methods guarantee the positive definiteness of the estimated matrix. Note that such Cholesky-based methods often require the knowledge on the ordering of variables when estimating a sequence of regressions. To address this issue, we thoroughly discuss the ordering issue in the MCD approach and examine several solutions to this ordering issue from the literature.

It is worth pointing out that the use of Cholesky-based approach is not restricted for estimating covariance and precision matrices under the conventional setting. The idea of MCD can also be used in constructing the covariance function in spatial analysis such as Kriging and Gaussian process [8], especially when involving the qualitative input variables. Because of the Cholesky decomposition on the matrix, the induced covariance matrix would have attractive

property in the Gaussian process modeling. Another direction of using the MCD is the multi-response regression, where the multivariate responses have certain dependency structures. Under this situation, the MCD method of estimating the covariance or precision matrix for the multivariate responses will be coupled with the estimation of regression coefficients.

Acknowledgments The authors would like to thank the editor and reviewers for the constructive and insightful comments, which have significantly enhanced the quality of this article.

Appendix

Proof of Remark 1 and 2 Since the conclusions of Remarks 1 and 2 are much similar, we only provide the proof of Remark 2 here. Assume that there are n independent and identically distributed observations $\mathbf{x}_1, \dots, \mathbf{x}_n$, which are centered. Let $\mathbf{S} = \frac{1}{n} \sum_{i=1}^n \mathbf{x}_i \mathbf{x}_i'$ be the sample covariance matrix and assume that \mathbf{S} is non-singular since $n > p$. We denote $\hat{\Sigma}_0$ as the estimated covariance matrix from (43.12) with tuning parameters equal to zeroes in (43.11). Then Remark 2 states that $\hat{\Sigma}_0 = \mathbf{S}$ in spite of any permutation of $\mathbf{x}_1, \dots, \mathbf{x}_n$. Below is the proof.

Based on the sequential regression of (43.11), it is known that the first step is $X_1 = \epsilon_1$. It means that

$$e_{i1} = x_{i1}, 1 \leq i \leq n, \text{ and } \hat{\sigma}_1^2 = \frac{1}{n} \sum_{i=1}^n e_{i1}^2$$

Then the second step is to consider $X_2 = l_{21}\epsilon_1 + \epsilon_2$, which provides

$$\hat{l}_{21} = \frac{\sum_{i=1}^n x_{i2}e_{i1}}{\sum_{i=1}^n e_{i1}^2}, \quad e_{i2} = x_{i2} - \hat{l}_{21}e_{i1}, \quad 1 \leq i \leq n$$

$$\hat{\sigma}_2^2 = \frac{1}{n} \sum_{i=1}^n e_{i2}^2, \quad \sum_{i=1}^n e_{i2}e_{i1} = 0$$

In general, the j th step is to consider the regression problem as

$$X_j = \sum_{k < j} l_{jk} \epsilon_k + \epsilon_j$$

and we can obtain

$$\hat{l}_{j1} = \frac{\sum_{i=1}^n x_{ij}e_{i1}}{\sum_{i=1}^n e_{i1}^2}, \dots, \hat{l}_{jk} = \frac{\sum_{i=1}^n x_{ij}e_{ik}}{\sum_{i=1}^n e_{ik}^2}, \dots, \hat{l}_{j,j-1} = \frac{\sum_{i=1}^n x_{ij}e_{i,j-1}}{\sum_{i=1}^n e_{i,j-1}^2}$$

$$e_{ij} = x_{ij} - \sum_{k < j} \hat{l}_{jk} e_{ik}, \quad 1 \leq i \leq n$$

$$\hat{\sigma}_j^2 = \frac{1}{n} \sum_{i=1}^n e_{ij}^2, \quad \sum_{i=1}^n e_{ij}e_{i1} = 0, \dots, \sum_{i=1}^n e_{ij}e_{i,j-1} = 0$$

Therefore, we can express the (s, t) entry of the covariance matrix estimate using the regression coefficients as

$$(\hat{\Sigma})_{st} = (\hat{\mathbf{L}}\hat{\mathbf{D}}\hat{\mathbf{L}}^T)_{st} = \sum_{u=1}^{\min(s,t)} \hat{l}_{su}\hat{l}_{tu}\hat{\sigma}_u^2 \quad (\hat{l}_{uu} = 1).$$

Note that

$$x_{is} = \sum_{u=1}^s \hat{l}_{su}e_{iu} \quad (\hat{l}_{uu} = 1), \quad 1 \leq i \leq n,$$

$$x_{it} = \sum_{v=1}^t \hat{l}_{tv}e_{iv} \quad (\hat{l}_{vv} = 1), \quad 1 \leq i \leq n,$$

and the (s, t) entry of the sample covariance matrix is

$$(\mathbf{S})_{st} = \frac{1}{n} \sum_{i=1}^n x_{is}x_{it} = \frac{1}{n} \sum_{i=1}^n \left(\sum_{u=1}^s \hat{l}_{su}e_{iu} \right) \left(\sum_{v=1}^t \hat{l}_{tv}e_{iv} \right)$$

$$= \frac{1}{n} \sum_{u=1}^s \sum_{v=1}^t \hat{l}_{su}\hat{l}_{tv} \left(\sum_{i=1}^n e_{iu}e_{iv} \right)$$

$$= \sum_{u=1}^{\min(s,t)} \hat{l}_{su}\hat{l}_{tu}\hat{\sigma}_u^2 \quad (\hat{l}_{uu} = 1).$$

The last equality holds because of

$$\sum_{i=1}^n e_{iu}e_{iv} = \begin{cases} n\sigma_u^2 & u = v; \\ 0 & u \neq v. \end{cases}$$

Thus, we can establish the result

$$\mathbf{S} = \hat{\mathbf{L}} \text{diag}(\hat{\sigma}_1^2, \dots, \hat{\sigma}_p^2) \hat{\mathbf{L}}^T.$$

□

Conditional Misclassification Error of LDA

Without loss of generality, we consider a two-class classification problem here. Suppose the binary classifier function for LDA is $g(\mathbf{x}) = \log[P(Y = 1|\mathbf{X} = \mathbf{x})/P(Y = 2|\mathbf{X} = \mathbf{x})]$. Then

$$g(\mathbf{x}) \triangleq \mathbf{a}^T \mathbf{x} - b = (\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2)^T \boldsymbol{\Sigma}^{-1} \mathbf{x} - \left[\frac{1}{2} (\boldsymbol{\mu}_1 + \boldsymbol{\mu}_2)^T \boldsymbol{\Sigma}^{-1} (\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2) - \log \frac{\pi_1}{\pi_2} \right],$$

where π_1 and π_2 are the prior probabilities for class 1 and 2, respectively, i.e., $\pi_1 = P(Y = 1)$ and $\pi_2 = P(Y = 2)$. For a new observation \mathbf{x} , we predict its class $Y = 1$ if $g(\mathbf{x}) > 0$, and $Y = 2$ otherwise. Then the conditional misclassification error is

$$P(g(\mathbf{x}) = 1|Y = 2)P(Y = 2) + P(g(\mathbf{x}) = 2|Y = 1)P(Y = 1)$$

$$= P(\mathbf{a}^T \mathbf{x} - b > 0|Y = 2)\pi_2 + P(\mathbf{a}^T \mathbf{x} - b \leq 0|Y = 1)\pi_1.$$

Since $\mathbf{x}|Y = 1 \sim N(\boldsymbol{\mu}_1, \boldsymbol{\Sigma})$, and $\mathbf{x}|Y = 2 \sim N(\boldsymbol{\mu}_2, \boldsymbol{\Sigma})$, obviously $\mathbf{a}^T \mathbf{x}|Y = 1 \sim N(\mathbf{a}^T \boldsymbol{\mu}_1, \mathbf{a}^T \boldsymbol{\Sigma} \mathbf{a})$, and $\mathbf{a}^T \mathbf{x}|Y = 2 \sim N(\mathbf{a}^T \boldsymbol{\mu}_2, \mathbf{a}^T \boldsymbol{\Sigma} \mathbf{a})$. Therefore,

$$P(\mathbf{a}^T \mathbf{x} - b > 0|Y = 2) = \Phi \left(\frac{\mathbf{a}^T \boldsymbol{\mu}_2 - b}{\sqrt{\mathbf{a}^T \boldsymbol{\Sigma} \mathbf{a}}} \right),$$

$$P(\mathbf{a}^T \mathbf{x} - b \leq 0|Y = 1) = \Phi \left(-\frac{\mathbf{a}^T \boldsymbol{\mu}_1 - b}{\sqrt{\mathbf{a}^T \boldsymbol{\Sigma} \mathbf{a}}} \right),$$

where $\Phi(\cdot)$ is the cumulative distribution function of the standard normal random variable. As a result, the conditional misclassification error is

$$\pi_2 \Phi \left(\frac{\mathbf{a}^T \boldsymbol{\mu}_2 - b}{\sqrt{\mathbf{a}^T \boldsymbol{\Sigma} \mathbf{a}}} \right) + \pi_1 \Phi \left(-\frac{\mathbf{a}^T \boldsymbol{\mu}_1 - b}{\sqrt{\mathbf{a}^T \boldsymbol{\Sigma} \mathbf{a}}} \right).$$

Assume $\pi_1 = \pi_2 = 1/2$. Then with the estimates of \mathbf{a} and b through $\hat{\boldsymbol{\mu}}_1, \hat{\boldsymbol{\mu}}_2, \hat{\boldsymbol{\Sigma}}$, the conditional misclassification error $\gamma(\hat{\boldsymbol{\Sigma}}, \hat{\boldsymbol{\mu}}_1, \hat{\boldsymbol{\mu}}_2)$ is

$$\gamma(\hat{\boldsymbol{\Sigma}}, \hat{\boldsymbol{\mu}}_1, \hat{\boldsymbol{\mu}}_2)$$

$$= \frac{1}{2} \Phi \left(\frac{(\hat{\boldsymbol{\mu}}_1 - \hat{\boldsymbol{\mu}}_2)^T \hat{\boldsymbol{\Sigma}}^{-1} \boldsymbol{\mu}_2 - \frac{1}{2} (\hat{\boldsymbol{\mu}}_1 + \hat{\boldsymbol{\mu}}_2)^T \hat{\boldsymbol{\Sigma}}^{-1} (\hat{\boldsymbol{\mu}}_1 - \hat{\boldsymbol{\mu}}_2)}{\sqrt{(\hat{\boldsymbol{\mu}}_1 - \hat{\boldsymbol{\mu}}_2)^T \hat{\boldsymbol{\Sigma}}^{-1} \boldsymbol{\Sigma} \hat{\boldsymbol{\Sigma}}^{-1} (\hat{\boldsymbol{\mu}}_1 - \hat{\boldsymbol{\mu}}_2)}} \right)$$

$$+ \frac{1}{2} \Phi \left(-\frac{(\hat{\boldsymbol{\mu}}_1 - \hat{\boldsymbol{\mu}}_2)^T \hat{\boldsymbol{\Sigma}}^{-1} \boldsymbol{\mu}_1 - \frac{1}{2} (\hat{\boldsymbol{\mu}}_1 + \hat{\boldsymbol{\mu}}_2)^T \hat{\boldsymbol{\Sigma}}^{-1} (\hat{\boldsymbol{\mu}}_1 - \hat{\boldsymbol{\mu}}_2)}{\sqrt{(\hat{\boldsymbol{\mu}}_1 - \hat{\boldsymbol{\mu}}_2)^T \hat{\boldsymbol{\Sigma}}^{-1} \boldsymbol{\Sigma} \hat{\boldsymbol{\Sigma}}^{-1} (\hat{\boldsymbol{\mu}}_1 - \hat{\boldsymbol{\mu}}_2)}} \right).$$

Abstract

One of the main goals of statistical learning is to characterize how the excess risk depends on the sample size n , on the complexity of the hypothesis class, and on the underlying complexity of the prediction problem itself. A related problem is to control the generalization error, which is a measure of how accurately an algorithm is able to predict outcome values for previously unseen data. Establishing probability error bounds for these problems can be converted into a problem of uniform convergence. We first introduce some commonly used technical tools for uniform convergence. Along the way, we highlight the recent development of learning theory for deep neural networks (DNNs) and explain the theoretical benefit to improve the generalization error in practice. Furthermore, we

present the generalization of DNNs for robust adversarial learning with ℓ_∞ attacks. For general machine learning tasks, we show that adversarial Rademacher complexity is always larger than natural counterpart, but the effect of adversarial perturbations can be limited under the weight normalization framework.

Keywords

Adversarial learning · Excess risk · Generalization error · Learning theory · Rademacher complexity · Uniform convergence

44.1 What Is Statistical Learning

In supervised learning problems such as classification and regression, our target is to predict an output $y \in \mathcal{Y}$ based on a set of features $\mathbf{x} \in \mathcal{X} \subseteq \mathbb{R}^d$. Informally, we choose a predictor $f : \mathcal{X} \rightarrow \mathcal{Y}$ from the hypothesis class \mathcal{F} such that $f(\mathbf{x})$ is a good prediction of y . Let (\mathbf{x}, y) be from an unknown distribution \mathcal{D} and the loss function be $\ell(\cdot, \cdot) : \mathcal{Y} \times \mathcal{Y} \mapsto \mathbb{R}$. Define the *expected risk* as $R(f) = \mathbb{E}_{(\mathbf{x}, y) \sim \mathcal{D}} [\ell(f(\mathbf{x}), y)]$, and our goal is to find the expected risk minimizer which is denoted by $f^* \in \arg \min_{f \in \mathcal{F}} R(f)$. Given n i.i.d. samples $S = \{(\mathbf{x}_1, y_1), \dots, (\mathbf{x}_n, y_n)\}$, where each pair is from \mathcal{D} over $\mathcal{X} \times \mathcal{Y}$, the approximation of f^* is obtained by minimizing the *empirical risk*:

$$\widehat{R}(f) = \frac{1}{n} \sum_{i=1}^n \ell(f(\mathbf{x}_i), y_i). \quad (44.1)$$

The trained predictor f is also called the *empirical risk minimizer* (ERM) defined as any hypothesis $f \in \mathcal{F}$ that minimizes Eq. (44.1):

$$\widehat{f} \in \arg \min_{f \in \mathcal{F}} \widehat{R}(f). \quad (44.2)$$

In practice, we often choose the quadratic loss for regression problems, while the hinge loss and the cross entropy loss are commonly used in classification tasks. Statistical learning is an active area of research in the past two decades: well-known monographs in this area include [8, 26, 37].

The key question of statistical learning is to analyze and control the *excess risk*, which is the difference between $R(f^*)$ and $R(\hat{f})$. The excess risk characterizes the gap between the expected risk of \hat{f} and the optimal f^* . Another related concept is called the *generalization error*, which is the difference between $R(\hat{f})$ and $\widehat{R}(\hat{f})$. Mathematically, the generalization error is a measure of how accurately an algorithm is able to predict outcome values for previously unseen data. The generalization error can be minimized by avoiding overfitting in the learning algorithm. We will show later that the generalization error is easy to control if the excess risk is bounded. So, how do we analyze the excess risk? Note that the excess risk is a random variable depending on the training set via \hat{f} , and the sample size n is finite. Therefore, the central limit theorem in asymptotics cannot be directly applied here. We formulate the analysis as a probability statement. Given $\eta \in (0, 1)$, the excess risk is upper bounded by some ϵ with probability at least $1 - \eta$, that is, $\mathbb{P}(R(\hat{f}) - R(f^*) \leq \epsilon) \geq 1 - \eta$, or equivalently,

$$\mathbb{P}(R(\hat{f}) - R(f^*) \geq \epsilon) \leq \eta, \quad (44.3)$$

where ϵ is a function relying on η and the complexity of the hypothesis class \mathcal{F} .

To explicitly describe ϵ , we rewrite the excess risk as

$$R(\hat{f}) - R(f^*) = \underbrace{R(\hat{f}) - \widehat{R}(\hat{f})}_{(a)} + \underbrace{\widehat{R}(\hat{f}) - \widehat{R}(f^*)}_{(b)} + \underbrace{\widehat{R}(f^*) - R(f^*)}_{(c)}.$$

Term (b), $\widehat{R}(\hat{f}) - \widehat{R}(f^*)$, is nonpositive, because \hat{f} is chosen to minimize $\widehat{R}(f)$ in the hypothesis class \mathcal{F} . Term (c) is the difference between a sample average and an expectation in terms of the fixed function f^* , such that

$$\widehat{R}(f^*) - R(f^*) = \frac{1}{n} \sum_{i=1}^n \ell(f^*(\mathbf{x}_i), y_i) - \mathbb{E}_{(\mathbf{x}, y) \sim \mathcal{D}} [\ell(f^*(\mathbf{x}), y)].$$

The law of large numbers shows that this term converges to zero. With information about the tails of $\ell(f^*(\mathbf{x}), y)$ such as boundedness, we can use concentration inequalities that we will introduce in the next section to bound its value. Term (a), $R(\hat{f}) - \widehat{R}(\hat{f})$, is more interesting and complicated, since \hat{f} is random based on the chosen data. An easy approach is to provide a uniform upper bound,

$$R(\hat{f}) - \widehat{R}(\hat{f}) \leq \sup_{f \in \mathcal{F}} |R(f) - \widehat{R}(f)|,$$

which motivates us to study the uniform convergence. Suppose we can ensure that $R(f)$ and $\widehat{R}(f)$ were close (say within $\epsilon/2$) for all $f \in \mathcal{F}$. Then, we could guarantee that $R(\hat{f})$ and $\widehat{R}(\hat{f})$ were within $\epsilon/2$, as well as $R(f^*)$ and $\widehat{R}(f^*)$. Therefore, Eq. (44.3) can be written formally as

$$\mathbb{P}(R(\hat{f}) - R(f^*) \geq \epsilon) \leq \mathbb{P}\left(\sup_{f \in \mathcal{F}} |R(f) - \widehat{R}(f)| \geq \frac{\epsilon}{2}\right). \quad (44.4)$$

On the right-hand side is a statement about uniform convergence, which describes the probability of the event that the largest difference between the empirical and expected risk is at least $\epsilon/2$, or equivalently, the event that this difference exceeds $\epsilon/2$ for at least one $f \in \mathcal{F}$.

44.1.1 Literature Review

Statistical learning has been widely used to analyze the generalization performance such as kernel methods, support vector machine (SVM), and deep neural networks (DNNs).

The good generalization ability of SVM is usually explained by the existence of a large margin. Such bounds on the error rate for a hyperplane that separates the data with some margin were obtained in [3, 31], which are mainly based on the VC dimension. Reference [38] showed that the generalization ability of SVM depends on more complex geometrical constructions than large margin by proposing a new concept called the span of support vectors. Kernel methods have been successfully used in SVM, and the choice of kernel is very critical. There is a large body of literature dealing with the problem of learning kernels. For example, [33] gave generalization bounds for linear combinations of kernels with L_1 regularization that have an order of $\mathcal{O}(\sqrt{(p + 1/\rho^2)/n})$, where p is the number of kernels combined, n is the sample size, and ρ is the margin of the learned classifier. Cortes et al. [10] presented new generalization bounds for the family of convex combinations of base kernels by using the Rademacher complexity of the hypothesis set, which is of order $\mathcal{O}(\sqrt{(\log p)/(\rho^2 n)})$.

The generalization bound of DNNs has been extensively studied in literature, especially norm-constrained fully connected DNNs [4, 6, 13, 22, 27, 28, 34]. In particular, spectral norm-constrained fully connected DNNs were studied in [6, 22, 27]. Assume that the spectral norm of the weight matrix in each layer equals to 1, and the width of each hidden layer is d . Then the corresponding bound of generalization error is of order $\sqrt{d^3 L^2/n}$ [6, 27] and $\sqrt{dLr/n}$ [22], respectively,

where n is the sample size, L is the depth, and r is the rank of weight matrices. On the other hand, a lower bounds for the generalization error with an order of $\sqrt{d/n}$ is established in [13]. In addition, some special cases of the matrix mixed $L_{p,q}$ norm-constrained fully connected DNNs were studied in [4, 13, 28, 34, 39]. For example, [28] provided an exponential bound on the width d based on the Frobenius norm of the weight matrices; [6] provided a polynomial bound on L and d based on the spectral norm and the $L_{2,1}$ norm.

However, many recent studies have shown that DNNs are vulnerable to adversarial attacks [7, 11, 36], which means DNNs may not predict correct labels for inputs with small adversarial perturbations. Reference [30] showed that for natural learning, $\mathcal{O}(1)$ training data is enough to correctly classify two separated d -dimensional Gaussian distribution, but $\Theta(\sqrt{d})$ data is needed for adversarial learning. Reference [2] provided adversarial generalization bounds only considering a finite number of potential adversarial attacks. Reference [40] used the SDP relaxation proposed by [29] to establish adversarial generalization bound, but their results are limited to linear classifiers and single hidden layer neural networks. Reference [17] used a surrogate adversarial loss called tree transform to upper bound the actual adversarial loss and reduced the problem of deriving bounds on the adversarial risk to the problem of deriving risk bounds using standard learning-theoretic techniques. However, their bounds rely on ℓ_∞ -operator norms, Frobenius norms, and $L_{p,\infty}$ norms of weight matrices, and polynomially depend on the depth of DNNs. Reference [12] extended PAC-Bayes framework to bound the generalization error for DNNs under several particular adversarial strategies, but they focused on ℓ_2 perturbations rather than ℓ_∞ perturbations, and their results are based on spectral norms and Frobenius norms.

44.2 Uniform Convergence

In this section, we introduce some commonly used techniques for establishing uniform convergence.

44.2.1 Concentration Inequalities

Let us first recall the central limit theorem. Assume X_1, \dots, X_n are n independent random variables with $\mathbb{E}X_i = \mu$ and $\text{Var}X_i = \sigma^2 < \infty$, then

$$\lim_{n \rightarrow \infty} \mathbb{P}(\bar{X}_n \geq \mu + \sigma t / \sqrt{n}) = 1 - \Phi(t) \quad (44.5)$$

The central limit theorem tells us what happens asymptotically, but we usually have a fixed sample size. In this case, what is $\mathbb{P}(|\bar{X}_n - \mu| \geq \epsilon)$? It is answered by concentration inequalities, a very powerful set of techniques providing

bounds on this kind of probability that \bar{X}_n is concentrated about its mean. We start from Markov's inequality, a simple tool that allows us to control the deviation of a nonnegative random variable from its mean using the expectation of that random variable.

Theorem 44.2.1 (Markov's Inequality) For a random variable $X \geq 0$ a.s., $\mathbb{E}X < \infty$, $t > 0$: $\mathbb{P}(X \geq t) \leq \frac{\mathbb{E}X}{t}$.

We use $|X - \mathbb{E}X|$ to replace X in Markov's inequality and consider a strictly monotonic function $f : [0, \infty) \mapsto [0, \infty)$. Assume $\mathbb{E}[f(|X - \mathbb{E}X|)] < \infty$, we have

$$\begin{aligned} \mathbb{P}(|X - \mathbb{E}X| \geq t) &= \mathbb{P}(f(|X - \mathbb{E}X|) \geq f(t)) \\ &\leq \frac{\mathbb{E}[f(|X - \mathbb{E}X|)]}{f(t)} \end{aligned}$$

Different choices of f lead to different inequalities. $f(a) = a^2$ gives Chebyshev's inequality

$$\mathbb{P}(|X - \mathbb{E}X| \geq t) \leq \frac{\text{Var}(X)}{t^2}.$$

When $f(a) = a^k$, we have

$$\mathbb{P}(|X - \mathbb{E}X| \geq t) \leq \frac{\mathbb{E}|X - \mathbb{E}X|^k}{t^k}.$$

When $f(a) = \exp(\lambda a)$ for $\lambda > 0$, we have the Chernoff inequality

$$\begin{aligned} \mathbb{P}(X - \mathbb{E}X \geq t) &= \mathbb{P}(\exp(\lambda(X - \mathbb{E}X)) \geq \exp(\lambda t)) \\ &\leq e^{-\lambda t} M_{X-\mu}(\lambda), \end{aligned} \quad (44.6)$$

where $\mathbb{E}X = \mu$, and $M_{X-\mu}(\lambda) = \mathbb{E} \exp(\lambda(X - \mu))$ is the moment generating function. Consider a special case of Gaussian distribution where $X \sim N(\mu, \sigma^2)$, then $M_{X-\mu}(\lambda) = \exp(\lambda^2 \sigma^2 / 2)$. Thus,

$$\mathbb{P}(X - \mu \geq t) \leq \inf_{\lambda} \exp\left(\frac{\lambda^2 \sigma^2}{2} - \lambda t\right) \leq \exp\left(-\frac{t^2}{2\sigma^2}\right),$$

using the optimal choice $\lambda = t/\sigma^2 > 0$. How about non-Gaussian variables? Note that the bounds would still hold as long as $M_{X-\mu}(\lambda)$ is upper bounded. This leads to the definition of sub-Gaussian.

Definition 44.2.1 X is sub-Gaussian with parameter σ^2 if, for all $\lambda \in \mathbb{R}$,

$$M_{X-\mu}(\lambda) \leq \exp\left(\frac{\lambda^2 \sigma^2}{2}\right).$$

If X is a Gaussian random variable from $N(0, \sigma^2)$, then X is sub-Gaussian with parameter σ^2 . However, exponential and Gamma variables are not sub-Gaussian, since the tails of these distributions are too fat. There are some properties of sub-Gaussian.

- X sub-Gaussian iff $-X$ sub-Gaussian.
- If X_1, X_2 are independent sub-Gaussian with parameters σ_1^2, σ_2^2 , then $X_1 + X_2$ is sub-Gaussian with parameter $\sigma_1^2 + \sigma_2^2$.
- If X is sub-Gaussian with parameter σ^2 , then for any $c > 0$, cX is sub-Gaussian with parameter $c^2\sigma^2$.

Equipped with this machinery, we can easily obtain the following classic tail bound for bounded random variables.

Theorem 44.2.2 For independent X_1, \dots, X_n , $\mathbb{E}X_i = \mu_i$, and X_i is sub-Gaussian with parameter σ_i^2 , then for all $t > 0$,

$$\mathbb{P}\left(\sum_{i=1}^n (X_i - \mu_i) \geq t\right) \leq \exp\left(-\frac{t^2}{2\sum_{i=1}^n \sigma_i^2}\right).$$

The proof is easy by applying the Chernoff inequality. If each X_i is bounded in $[a_i, b_i]$, then $\sigma_i^2 = (b_i - a_i)^2/4$. Thus, we have Hoeffding’s inequality

$$\mathbb{P}\left(\frac{1}{n}\sum_{i=1}^n X_i - \frac{1}{n}\sum_{i=1}^n \mu_i \geq t\right) \leq \exp\left(-\frac{2n^2t^2}{\sum_{i=1}^n (b_i - a_i)^2}\right).$$

Another important tool is the McDiarmid’s inequality, which is a generalization of the Hoeffding’s inequality, where we want to bound not the average of random variables $X_1 \dots, X_n$ but any function on X_1, \dots, X_n satisfying an appropriate bounded differences condition.

Theorem 44.2.3 (McDiarmid’s Inequality) Let X_1, \dots, X_n be independent random variables with support on \mathcal{X} . Let $f : \mathcal{X}^n \mapsto \mathbb{R}$ be a function satisfying the following bounded difference condition,

$$(\forall i, \forall x_1, \dots, x_n, x'_i) \quad \left|f(x_1, \dots, x_i, \dots, x_n) - f(x_1, \dots, x'_i, \dots, x_n)\right| \leq B_i,$$

then,

$$\begin{aligned} \mathbb{P}(|f(X_1, \dots, X_n) - \mathbb{E}[f(X_1, \dots, X_n)]| \geq t) \\ \leq 2 \exp\left(-\frac{2t^2}{\sum_i B_i^2}\right). \end{aligned}$$

We apply martingale to prove this inequality, and please refer to [26] for more details. This is a quite powerful result, as

it holds for any independent random variables, even if f is complex such as neural networks. As long as the function is not too sensitive to perturbations in one of its arguments, we get good concentration.

So far, we have introduced several main concentration inequalities. To have a better understanding, we now use them to analyze the generalization results for a finite hypothesis class. This is accomplished by a two-step concentration and the union bound.

Theorem 44.2.4 Let $S = \{(x_1, y_1), \dots, (x_n, y_n)\}$ be n i.i.d. samples from the unknown distribution \mathcal{D} . Assume that \mathcal{F} is a finite hypothesis class, i.e., $\mathcal{F} = \{f_1, \dots, f_k\}$, where $k < \infty$ and $f_j : \mathcal{X} \mapsto \mathcal{Y}$ for $\forall j$. Let ℓ be the zero-one loss, i.e., $\ell(f(\mathbf{x}), y) = \mathbb{I}[f(\mathbf{x}) \neq y]$. Let \hat{f} be the ERM defined in Eq. (44.2). For fix $\eta \in (0, 1)$, with probability at least $1 - \eta$, we have

$$R(\hat{f}) - R(f^*) \leq \sqrt{\frac{2(\log k + \log(2/\eta))}{n}}.$$

44.2.2 Rademacher Complexity

In the previous section, we analyzed the excess risk with a finite hypothesis class \mathcal{F} , i.e., $|\mathcal{F}| < \infty$. However, the union bound cannot be applied to infinite hypothesis classes. This motivates us to explore more sophisticated approaches to measure the capacity of a hypothesis class. In this section, we will introduce a framework called *Rademacher complexity* to uniformly bound the difference between the expected and empirical risk for any $f \in \mathcal{F}$.

Definition 44.2.2 (Empirical Rademacher Complexity)

Let \mathcal{H} be a class of real-valued functions $h : \mathcal{Z} \mapsto \mathbb{R}$. The empirical Rademacher complexity of \mathcal{H} is defined as

$$\widehat{\mathfrak{R}}_n(\mathcal{H}) = \mathbb{E}_\delta \left[\sup_{h \in \mathcal{H}} \frac{1}{n} \sum_{i=1}^n \delta_i h(z_i) \right],$$

where $S = \{z_1, \dots, z_n\}$ includes n i.i.d. samples from distribution \mathcal{D} and $\delta = \{\delta_1, \dots, \delta_n\}$ are n i.i.d. Rademacher variables satisfying $\mathbb{P}(\delta_i = 1) = \mathbb{P}(\delta_i = -1) = 1/2$.

It is clear that the empirical Rademacher complexity is a random variable depending on the data. By further taking exception on these random samples, we have the definition of Rademacher complexity.

Definition 44.2.3 (Rademacher Complexity)

Let \mathcal{H} be a class of real-valued functions $h : \mathcal{Z} \mapsto \mathbb{R}$. The Rademacher complexity of \mathcal{H} is defined as $\mathfrak{R}_n(\mathcal{H}) = \mathbb{E}_{S \sim \mathcal{D}^n} [\widehat{\mathfrak{R}}_n(\mathcal{H})]$.

Here we give an intuitive explanation about the Rademacher complexity. Consider the simple binary classification problem with inputs z_1, \dots, z_n . If the corresponding labels are random $\delta_1, \dots, \delta_n$, this becomes a meaningless learning problem. Therefore, the Rademacher complexity is used to capture how well the best function from the function class \mathcal{H} can fit these random labels. A large \mathcal{H} will be able to fit noise better and thus have a larger Rademacher complexity. As we will see later, we would like $\mathfrak{R}_n(\mathcal{H})$ to go to zero as n increases.

The basic properties of Rademacher complexity are listed as follows:

- $\mathfrak{R}_n(\mathcal{H}) = 0$ for $\mathcal{H} = \{h\}$.
- $\mathfrak{R}_n(\mathcal{H}_1) \leq \mathfrak{R}_n(\mathcal{H}_2)$ if $\mathcal{H}_1 \subseteq \mathcal{H}_2$.
- $\mathfrak{R}_n(\mathcal{H}_1 + \mathcal{H}_2) \leq \mathfrak{R}_n(\mathcal{H}_1) + \mathfrak{R}_n(\mathcal{H}_2)$ for $\mathcal{H}_1 + \mathcal{H}_2 = \{h_1 + h_2 : h_1 \in \mathcal{H}_1, h_2 \in \mathcal{H}_2\}$
- $\mathfrak{R}_n(c\mathcal{H}) = |c|\mathfrak{R}_n(\mathcal{H})$
- $\mathfrak{R}_n(\text{co}(\mathcal{H})) = \mathfrak{R}_n(\mathcal{H})$, where $\text{co}(\mathcal{H})$ is the convex hull of \mathcal{H} .
- $\mathfrak{R}_n(\phi \circ \mathcal{H}) \leq c_\phi \mathfrak{R}_n(\mathcal{H})$, where $\phi \circ \mathcal{H} = \{z \mapsto \phi(h(z)) : h \in \mathcal{H}\}$ and c_ϕ is the Lipschitz constant of ϕ . This is also called Ledoux-Talagrand contraction inequality (see [21] for detailed proof).

The Ledoux-Talagrand contraction inequality is quite useful when analyzing the Rademacher complexity of loss class $\ell \circ \mathcal{F}$, since we can transfer it to analyze the complexity of our hypothesis class \mathcal{F} . Next, we will show the crucial theorem that links the uniform convergency and Rademacher complexity.

Theorem 44.2.5 *Let $S = \{(x_1, y_1), \dots, (x_n, y_n)\}$ be n i.i.d. samples drawn from the unknown distribution \mathcal{D} . Let \mathcal{F} be a hypothesis class and ℓ be the loss function where $\ell \circ \mathcal{F}$ belongs to $\{\ell(f(\mathbf{x}), y) \mid \ell \circ f : \mathcal{X} \times \mathcal{Y} \rightarrow [0, 1], f \in \mathcal{F}\}$. Fix $\eta \in (0, 1)$. With probability at least $1 - \eta$, we have*

$$(\forall f \in \mathcal{F}) R(f) \leq \widehat{R}(f) + 2\mathfrak{R}_n(\ell \circ \mathcal{F}) + \sqrt{\frac{\log(1/\eta)}{2n}}.$$

Equipped with this theorem, we further need several steps to bound Eq. (44.3). We analogously define $G'(S)$ for the negative loss $\ell'(f(\mathbf{x}), y) = -\ell(f(\mathbf{x}), y)$, so

$$\mathbb{P}\left(R(\widehat{f}) - R(h^*) \geq \epsilon\right) \leq \mathbb{P}\left(\sup_{f \in \mathcal{F}} |R(f) - \widehat{R}(f)| \geq \frac{\epsilon}{2}\right) \leq \mathbb{P}\left(G(S) \geq \frac{\epsilon}{2}\right) + \mathbb{P}\left(G'(S) \geq \frac{\epsilon}{2}\right).$$

Note that by the proof of Theorem 44.2.5 (see [5]), $\mathbb{E}[G(S)] \leq 2\mathfrak{R}_n(\ell \circ \mathcal{F})$ and

$$\mathbb{P}\left(G(S) - \mathbb{E}[G(S)] \geq \epsilon\right) \leq \exp(-2n\epsilon^2).$$

Since $\mathfrak{R}_n(\ell \circ \mathcal{F}) = \mathfrak{R}_n(-\ell \circ \mathcal{F})$, we have $\mathbb{E}[G'(S)] \leq 2\mathfrak{R}_n(\ell \circ \mathcal{F})$. Therefore,

$$\begin{aligned} \mathbb{P}\left(G(S) \geq \frac{\epsilon}{2}\right) &\leq \exp\left(-2n\left(\frac{\epsilon}{2} - \mathbb{E}[G(S)]\right)^2\right) \\ &\leq \exp\left(-2n\left(\frac{\epsilon}{2} - 2\mathfrak{R}_n(\ell \circ \mathcal{F})\right)^2\right) \\ &\quad \text{for } \epsilon \geq 4\mathfrak{R}_n(\ell \circ \mathcal{F}) \\ &\stackrel{\text{def}}{=} \frac{\eta}{2} \end{aligned}$$

Similarly, we have $\mathbb{P}\left(G(S) \geq \frac{\epsilon}{2}\right) \leq \frac{\eta}{2}$. Adding them together and solving for ϵ , with probability at least $1 - \eta$, we have

$$R(\widehat{f}) - R(f^*) \leq 4\mathfrak{R}_n(\ell \circ \mathcal{F}) + \sqrt{\frac{2 \log(2/\eta)}{n}}.$$

Using this conclusion and the Ledoux-Talagrand contraction lemma, we can easily bound the difference between empirical risk and expected risk as well as the excess risk once we have the Rademacher complexity of hypothesis class \mathcal{F} . There are several tools helping control $\mathfrak{R}_n(\mathcal{F})$ such as VC dimension and covering number that we will see later.

Next, we provide a simple example of how to upper bound the empirical Rademacher complexity for a class of linear predictors.

Example 44.2.1 Let $\{\mathbf{x}_1, \dots, \mathbf{x}_n\}$ be n i.i.d. samples from $\mathcal{X} = \{\mathbf{x} \in \mathbb{R}^d : \|\mathbf{x}\|_2 \leq B\}$. Let \mathcal{F} be the class of linear predictors, i.e.,

$$\mathcal{F} = \{(\mathbf{w}, \mathbf{x}) \mid \mathbf{w} \in \mathbb{R}^d \text{ and } \|\mathbf{w}\|_2 \leq c\}.$$

We have $\widehat{\mathfrak{R}}_n(\mathcal{F}) \leq \frac{Bc}{\sqrt{n}}$.

44.2.3 Growth Function and VC Dimension

So far, we have set up Rademacher complexity as a measure of the capacity of infinite hypothesis class. Let us instantiate Rademacher complexity when the function class has finite possible outputs such as binary classification problem. Assume the dataset $S = \{z_1, \dots, z_n\}$ contains n i.i.d. samples from distribution \mathcal{D} . In general, we assume a function class $\mathcal{H} \subseteq \{h|h : \mathcal{Z} \rightarrow \{0, 1\}\}$. We introduce the following shorthand notation: $\mathcal{H}(S) = \{(h(z_1), \dots, h(z_n)) \in \{0, 1\}^n \mid h \in \mathcal{H}\}$. That is, $\mathcal{H}(S)$ contains all the $\{0, 1\}^n$ vectors that can be produced by applying all functions in \mathcal{H} to the dataset S .

Definition 44.2.4 (Growth Function) The growth function (or shatter coefficient) of a class of functions $\mathcal{H} \subseteq \{h|h : \mathcal{Z} \rightarrow \{0, 1\}\}$ for n samples is

$$G(\mathcal{H}, n) = \max_{S \in \mathcal{Z}^n} |\mathcal{H}(S)|.$$

For example, for the class of functions $\mathcal{H} = \{z \mapsto \mathbb{I}[z \leq \alpha] : z \in \mathbb{R}, \alpha \in \mathbb{R}\}$, we have $|\mathcal{H}(S)| \leq G(\mathcal{H}, n) = n + 1$. Meanwhile, for boolean functions, if $G(\mathcal{H}, n) = 2^n$, meaning we obtain all possible labels, we say \mathcal{H} shatters any n points z_1, \dots, z_n that achieve the maximum of $\mathcal{H}(S)$. One advantage of growth function is that it turns the infinite function class to a finite coefficient. Therefore, we can directly use the following Massart’s finite lemma to link with Rademacher complexity.

Lemma 44.2.1 (Massart’s Finite Lemma) For $\mathcal{A} \subseteq \mathbb{R}^n$ with $R^2 = \frac{\max_{a \in \mathcal{A}} \|a\|_2^2}{n}$,

$$\mathbb{E} \left[\sup_{a \in \mathcal{A}} \frac{1}{n} \sum_{i=1}^n \delta_i a_i \right] \leq \sqrt{\frac{2R^2 \log |\mathcal{A}|}{n}},$$

where $\delta = \{\delta_1, \dots, \delta_n\}$ are n i.i.d. Rademacher random variables.

Taking $\mathcal{A} = \mathcal{H}(S)$, we have $R^2 \leq 1$. By Massart’s finite lemma, it is straightforward that

$$\widehat{\mathfrak{R}}_n(\mathcal{H}) \leq \sqrt{\frac{2 \log G(\mathcal{H}, n)}{n}}.$$

Thus, to get meaningful bounds, we want $G(\mathcal{H}, n)$ to grow sub-exponentially with n . Otherwise, the Rademacher complexity will not go to zero, and we will not obtain uniform convergence. This is expected since if \mathcal{H} can really hit all labels for all n , we would be able to fit any label of the data, leading to massive overfitting.

Although the growth function nicely captures the behavior of an infinite \mathcal{H} , it is not necessarily the most convenient quantity to get a handle on. In the following, we use a concept called *VC dimension* to gain more intuition about the growth function.

Definition 44.2.5 The VC dimension of a class of functions \mathcal{H} with Boolean outputs is the maximum number of points that can be shattered by \mathcal{H} :

$$VC(\mathcal{H}) = \max_{n \in \mathbb{N}} \{n | G(\mathcal{H}, n) = 2^n\}$$

Here we list several examples of VC dimension.

- For $\mathcal{H} = \{z \mapsto \mathbb{I}[z \leq \alpha] : \alpha \in \mathbb{R}\}$, $VC(\mathcal{H}) = 1$.
- For $\mathcal{H} = \{z \mapsto \mathbb{I}[z \text{ below and to left of } y] : y \in \mathbb{R}^2\}$, $VC(\mathcal{H}) = 2$.

- For $\mathcal{H} = \{z \mapsto \mathbb{I}[z \text{ in box defined by } a, b] : a, b \in \mathbb{R}^d\}$, $VC(\mathcal{H}) = 2d$
- For $\mathcal{H} = \{x \mapsto \mathbb{I}[\sin(\theta x) \geq 0] : \theta \in \mathbb{R}\}$, $VC(\mathcal{H}) = \infty$.

Theorem 44.2.6 For the class of thresholded linear functions,

$$\mathcal{H} = \{z \mapsto \mathbb{I}[f(x) \geq 0] : f \in \mathcal{F}\},$$

where \mathcal{F} is a linear space, $VC(\mathcal{H}) = \dim(\mathcal{F})$.

Lemma 44.2.2 (Sauer-Shelah Lemma) For a function class \mathcal{H} with Boolean outputs and VC dimension d , then we have

$$G(\mathcal{H}, n) \leq \sum_{i=0}^d \binom{n}{i} \leq (n+1)^d.$$

This proof of Sauer-Shelah Lemma is very technical. For more details please refer to [26]. Combining this theorem with the previous conclusion, we have

$$\widehat{\mathfrak{R}}_n(\mathcal{H}) \leq \sqrt{\frac{2 \log G(\mathcal{H}, n)}{n}} \leq \sqrt{\frac{2VC(\mathcal{H}) \log(n+1)}{n}}.$$

44.2.4 Covering Number

For infinite hypothesis classes, we observe that growth function and VC dimension are appropriate measures since all that mattered was the behavior of a function class on a finite set of points. However, these two approaches only work for functions that return a finite number of values. Can we retain the combinatorial nature of growth function but allow for real-valued functions such as regression problems? We explore covering numbers in the section to solve this problem. Covering numbers count the number of balls of size ϵ one needs to cover the hypothesis class, then the Massart’s finite lemma can be applied to control the representatives. In essence, covering numbers allow us to discretize the problem.

Definition 44.2.6 A metric space (\mathcal{X}, ρ) is a set \mathcal{X} and a function $\rho : \mathcal{X} \times \mathcal{X} \mapsto [0, \infty)$ satisfying

- Identity of indiscernibles: $\rho(x, x) = 0$
- Symmetry: $\rho(x, y) = \rho(y, x)$
- Triangle inequality: $\rho(x, z) \leq \rho(x, y) + \rho(y, z)$

If $\rho(x, y) = 0$ is possible for $x \neq y$, then we say ρ is a pseudometric. In this section, we will work with the pseudometric. For example, the pseudometric for a set of functions \mathcal{H} mapping from \mathcal{Z} to \mathbb{R} is

$$\rho(h, h') = \|h - h'\|_{L_1(P_n)} := \frac{1}{n} \sum_{i=1}^n |h(z_i) - h'(z_i)|.$$

Definition 44.2.7

- An ϵ -cover of a subset \mathcal{H} of a pseudometric space (\mathcal{X}, ρ) is a finite set $\mathcal{H}' \subset \mathcal{H}$ such that for each $h \in \mathcal{H}$ there is a $h' \in \mathcal{H}'$ such that $\rho(h, h') \leq \epsilon$.
- The ϵ -covering number of \mathcal{H} is

$$\mathcal{N}(\epsilon, \mathcal{H}, \rho) = \min\{|\mathcal{H}'| : \mathcal{H}' \text{ is an } \epsilon\text{-cover of } \mathcal{H}\}.$$

- $\log \mathcal{N}(\epsilon, \mathcal{H}, \rho)$ is the metric entropy of \mathcal{H} .
- If $\lim_{\epsilon \rightarrow 0} \log \mathcal{N}(\epsilon) / \log(1/\epsilon)$ exists, it is called the metric dimension.

From above definitions, it is straightforward that as ϵ decreases, h' in the cover \mathcal{H}' is a better approximation of h , but $\mathcal{N}(\epsilon, \mathcal{H}, \rho)$ also increases. In general, we would like $\mathcal{N}(\epsilon, \mathcal{H}, \rho)$ to be small, so what is the trade-off? The following theorems establish that the covering number enables to upper bound the Rademacher complexity, which also provide hints for this trade-off.

Theorem 44.2.7 (Discretization Theorem) *Let $S = \{z_1, \dots, z_n\} \in \mathcal{Z}$ be n i.i.d. samples from distribution \mathcal{D} . Let \mathcal{H} be a class of functions $h : \mathcal{Z} \mapsto [-1, 1]$, and consider the $L_2(P_n)$ pseudometric on \mathcal{H} ,*

$$\rho(h, h') = \left[\frac{1}{n} \sum_{i=1}^n (h(z_i) - h'(z_i))^2 \right]^{1/2}.$$

Then,

$$\widehat{\mathfrak{R}}_n(\mathcal{H}) \leq \inf_{\epsilon > 0} \left(\sqrt{\frac{2 \log(2\mathcal{N}(\epsilon, \mathcal{H}, \rho))}{n}} + \epsilon \right).$$

The first term on the right-hand side is the covering number, which increases as ϵ decreases as we discussed. The second term is ϵ , which can be regarded as the penalty we pay for having a discretization. We now introduce a clever technique called chaining gets at the intuition by constructing covers at multiple levels of resolution and using functions in the coarser covers as waypoints. The idea is that the fewer functions in the coarse cover can have larger deviation, and the many functions in the finer covers has smaller deviation. Note that compared with the discretization theorem, this bound involves an integral that sweeps across different resolutions ϵ and importantly removes the additive ϵ penalty.

Theorem 44.2.8 (Dudley's Theorem) *Let \mathcal{H} be a family of functions $h : \mathcal{Z} \mapsto \mathbb{R}$. Consider the $L_2(P_n)$ pseudometric on \mathcal{H} , then*

$$\widehat{\mathfrak{R}}_n(\mathcal{H}) \leq 12 \int_0^\infty \sqrt{\frac{2 \log \mathcal{N}(\epsilon, \mathcal{H}, \rho)}{n}} d\epsilon.$$

In simple discretization, we apply Massart's finite class lemma on functions whose magnitude is $\sup_{h \in \mathcal{H}} \|h\|_{L_2(P_n)}$, whereas in chaining, we apply this lemma on differences between functions in \mathcal{H}'_j and \mathcal{H}'_{j-1} whose range is $3\epsilon_j$. This leads chaining to produce better results.

44.3 Learning Theory for Deep Learning

In this section, we will mainly summarize recent results on the generalization error of deep neural networks (DNNs). DNNs are the essence of deep learning models. The goal of a DNN is to approximate the unknown true function. Reference [16] stated that a neural network with at least one hidden layer with any "squashing" activation function (such as the logistic sigmoid activation function) can approximate any Borel measurable function with any desired nonzero amount of error, provided that the network is given enough hidden units. This universal property makes it the basis of many important commercial applications. For instance, the convolutional neural networks used for object recognition from photos are a specialized kind of neural network. It is also a conceptual stepping stone on the path to recurrent networks, which power many natural language applications.

The architecture of neural networks is composed of an input layer, multiple hidden layers, and an output layer. We use $\mathcal{F}_{\mathcal{W}_L}$ to denote a class of neural networks. Given the input domain $\mathcal{X} = \{\mathbf{x} : \mathbf{x} \in \mathbb{R}^{d_0}\}$, the form of each $f_{\mathcal{W}_L} \in \mathcal{F}_{\mathcal{W}_L}$ is

$$f_{\mathcal{W}_L}(\mathbf{x}) = \sigma_L(W_L \sigma_{L-1}(W_{L-1} \cdots \sigma_1(W_1 \mathbf{x}))), \quad (44.7)$$

where for $i = 1, \dots, L$, W_i is the $\mathbb{R}^{d_i} \times \mathbb{R}^{d_{i-1}}$ weight matrix, and $\sigma_i(\cdot)$ is element-wise nonlinear activation functions satisfying $\sigma_i(\mathbf{0}) = \mathbf{0}$. In the above, we use \mathcal{W}_L to denote all weight matrices (W_1, \dots, W_L) . We denote L as the depth and $d = \max\{d_0, \dots, d_L\}$ as the width of the neural network, which are the total number of layers and the maximum number of neurons in each layer, respectively. Typical examples of activation functions include sigmoid, tanh, and Relu. Note that Relu owns good properties, satisfying $\sigma(0) = 0$ and 1-Lipschitz contentiousness.

Existing results imply that Rademacher complexity of DNNs can be sufficiently controlled by the product of norms of weight matrices, especially the spectral norm and the Frobenius norm. In this section, we use $\|W\|_2$ to denote the spectral norm, which is the maximum singular value of W . And we use $\|W\|_{p,q}$ to denote $L_{p,q}$ -norm, defining as

$$\|W\|_{p,q} = \left(\sum_j \left(\sum_i |w_{ij}|^p \right)^{q/p} \right)^{1/q}.$$

When $p = q = 2$, this refers to Frobenius norm, denoted by $\|W\|_F$. The ℓ_p -norm of a vector \mathbf{x} is denoted by $\|\mathbf{x}\|_p$.

Reference [28] mainly focused on Relu and $L_{p,q}$ -norm of weight matrices. They extended prior work on per-unit regularization for two-layer networks to the overall norm regularization, which corresponds to the commonly used technique of weight decay.

Theorem 44.3.1 ([28]) *For any $L, q \geq 1$, any $1 \leq p < \infty$, and any n i.i.d. samples $\{\mathbf{x}_1, \dots, \mathbf{x}_n\}$ from \mathcal{X} , we have*

$$\widehat{\mathfrak{R}}_n(\mathcal{F}_{\mathcal{W}_L}) \leq \sqrt{\frac{1}{n} \prod_{j=1}^L \|W_j\|_{p,q}^2 \left(2d^{\lfloor \frac{1}{p^*} - \frac{1}{q} \rfloor_+}\right)^{2(L-1)} \min\{p^*, 4 \log(2d_0)\} \max_i \|\mathbf{x}_i\|_{p^*}^2},$$

where p^* is such that $\frac{1}{p} + \frac{1}{p^*} = 1$.

When $p = q = 2$, and if the ℓ_2 -norm of each sample is bounded by B , the upper bound of $\widehat{\mathfrak{R}}_n(\mathcal{F}_{\mathcal{W}_L})$ can be reduced to

$$\mathcal{O}\left(\frac{B^{2L} \prod_{j=1}^L \|W_j\|_F}{\sqrt{n}}\right).$$

Although this bound has no explicit dependence on the network width, it has a very strong exponential dependence on the network depth L , even if $\|W_j\|_F \leq 1$ for all j .

Reference [6] shows the generalization error of DNN is proportional to its Lipschitz constant, particularly the Lipschitz constant normalized by the margin of the predictor. It is easy to prove that the Lipschitz constant of DNNs is actually the product of spectral norms of all weight matrices. A detailed description of the margin of the predictor is as follows. Given a neural network $f_{\mathcal{W}_L}$ defined in Eq. (44.7), mapping from \mathbb{R}^{d_0} to \mathbb{R}^{d_L} , where d_L is also the number of classes, the most natural way to predict classes is to select the output coordinate with the largest magnitude, meaning $\mathbf{x} \mapsto \arg \max_j f_{\mathcal{W}_L}(\mathbf{x})_j$. Then, the margin is defined as $f_{\mathcal{W}_L}(\mathbf{x})_y - \max_{j \neq y} f_{\mathcal{W}_L}(\mathbf{x})_j$, which measures the gap between the output for the correct label and other labels. The following theorem shows the generalization bound for DNNs under this setting.

Theorem 44.3.2 ([6]) *Let $(\sigma_1, \dots, \sigma_L)$ be 1-Lipschitz activation function satisfying $\sigma_i(0) = 0$. Then for $(\mathbf{x}, y), (\mathbf{x}_1, y_1), \dots, (\mathbf{x}_n, y_n)$ drawn i.i.d. from \mathcal{D} , with probability at least $1 - \eta$ over $\{(\mathbf{x}_i, y_i)\}_{i=1}^n$, every margin $\gamma > 0$ and network $f_{\mathcal{W}_L} : \mathbb{R}^{d_0} \mapsto \mathbb{R}^{d_L}$ satisfy*

$$\begin{aligned} & \Pr \left[\arg \max_j f_{\mathcal{W}_L}(\mathbf{x})_j \neq y \right] \\ & \leq \frac{1}{n} \sum_{i=1}^n \mathbb{I} \left[f_{\mathcal{W}_L}(\mathbf{x}_i)_{y_i} \leq \gamma + \max_{j \neq y_i} f_{\mathcal{W}_L}(\mathbf{x}_i)_j \right] \\ & + \tilde{\mathcal{O}} \left(\frac{\|X\|_F R_{\mathcal{W}}}{\gamma n} \ln(d) + \sqrt{\frac{\ln(1/\eta)}{n}} \right), \end{aligned}$$

where $\|X\|_F = \sqrt{\sum_i \|\mathbf{x}_i\|_2^2}$ and

$$R_{\mathcal{W}} := \left(\prod_{j=1}^L \|W_j\|_2 \right) \left(\sum_{j=1}^L \frac{\|W_j^\top\|_{2,1}^{2/3}}{\|W_j\|_2^{2/3}} \right)^{3/2}.$$

As we can see, the above result mainly relies on the term $R_{\mathcal{W}}$, which actually polynomially depends on the depth of DNNs. Since for any weight matrix W_j ,

$$\frac{\sum_l \sqrt{\sum_k W_j(l, k)^2}}{\|W_j\|_2} \geq \frac{\|W_j\|_F}{\|W_j\|_2} \geq 1,$$

this means $R_{\mathcal{W}}$ can never be smaller than $\prod_{j=1}^L \|W_j\|_2 \sqrt{L^3}$.

Recently, [13] proposed a nearly size-independent sample complexity of DNNs based on Frobenius norms of weight matrices. For linear predictor $f(\mathbf{x}) = \mathbf{w}^\top \mathbf{x}$, we have proved that the Rademacher complexity is upper bounded by $\mathcal{O}(\|\mathbf{w}\|_2 \|\mathbf{x}\|_2 / \sqrt{n})$, which is apparently independent of the number of parameters. Motivated by this observation, they came up with a nearly size-independent bound under some mild conditions.

Theorem 44.3.3 ([13]) *Let $(\mathbf{x}_1, \dots, \mathbf{x}_n)$ be n i.i.d. samples from $\mathcal{X} = \{\mathbf{x} : \|\mathbf{x}\|_2 \leq B\}$. Let $(\sigma_1, \dots, \sigma_L)$ be 1-Lipschitz activation function satisfying $\sigma_i(0) = 0$. Assume that parameter matrices W_j satisfy $\prod_{j=1}^L \|W_j\|_2 \geq \Gamma$. With additional assumptions about the loss function ℓ and DNNs class $\mathcal{F}_{\mathcal{W}_L}$, it holds that*

$$\begin{aligned} \widehat{\mathfrak{R}}_n(\ell \circ \mathcal{F}) & \leq \mathcal{O} \left(\frac{B \prod_{j=1}^L \|W_j\|_F}{\gamma} \right. \\ & \left. \min \left\{ \frac{\log^{3/4}(n) \sqrt{\log \left(\frac{1}{\Gamma} \prod_{j=1}^L \|W_j\|_F \right)}}{n^{1/4}}, \sqrt{\frac{L}{n}} \right\} \right), \end{aligned}$$

where $\log(z) := \max\{1, \log(z)\}$ and γ is the margin.

Ignoring logarithmic factors and replacing the min by its first argument, the bound in is at most

$$\tilde{\mathcal{O}} \left(\frac{B \prod_{j=1}^L \|W_j\|_F}{\gamma} \sqrt{\frac{\log \left(\frac{1}{\Gamma} \prod_{j=1}^L \|W_j\|_F \right)}{\sqrt{n}}} \right).$$

Assuming that $\prod_{j=1}^L \|W\|_F$ and $\prod_{j=1}^L \|W\|_F / \Gamma$ are bounded by a constant, a bound that does not depend on the width or depth of the network can be obtained.

The above works discussed DNNs without including bias terms. However, [39] provided some examples to state that these conclusions may fail when bias terms are added for each hidden layer. For the bias-included DNNs, the dimension of each weight matrix W_j is now $\mathbb{R}^{d_j} \times \mathbb{R}^{d_{j-1}+1}$, and we denote such DNNs class as $\mathcal{F}_{\mathcal{W}_{L,b}}$. An $L_{p,q}$ -norm based upper bound on the Rademacher complexity of $\mathcal{F}_{\mathcal{W}_{L,b}}$ is established. For simplicity, they assume that the $L_{p,q}$ norms of weight matrices of hidden layers are the same, i.e., $\|W_j\|_{p,q} \equiv c$ for $j = 1, \dots, L-1$, and the norm of output layer is controlled by a constant, i.e., $\|W_L\|_{p,q} \leq c_o$.

Theorem 44.3.4 ([39]) For any $q \geq 1$, $c, c_o > 0$, and n i.i.d. samples $\{\mathbf{x}_1, \dots, \mathbf{x}_n\}$ from \mathcal{X} , we have

1.
$$\widehat{\mathfrak{R}}_n(\mathcal{F}_{\mathcal{W}_{L,b}}) \leq \mathcal{O} \left(c_o c^{L-1} \sqrt{\frac{L-1}{n}} \right).$$

2. for $p \in (1, \infty)$,

$$\widehat{\mathfrak{R}}_n(\mathcal{F}_{\mathcal{W}_{L,b}}) \leq \mathcal{O} \left(c_o \sqrt{\frac{L-1}{n}} \left(\sum_{i=2}^{L-1} c^{L-i} \prod_{l=i}^{L-1} d_l^{\left[\frac{1}{p^*} - \frac{1}{q}\right]_+} \right) \right),$$

where p^* is such that $\frac{1}{p} + \frac{1}{p^*} = 1$.

In Theorem 44.3.4, it is easy to show that the result has no dependence on widths if $q \in [1, p^*]$.

As a summary, we can see that the Rademacher complexity of DNNs with and without bias terms can be controlled by the product of norms of weight matrices. This infers that the outstanding generalization performance of DNNs is not due to the large number of parameters but the norms of weight matrices. Under reasonable assumptions and appropriate norm constraints, DNNs can achieve both high training accuracy and testing accuracy even if we use DNNs with small width and depth. Typically in practice, we can add weight decay [20] or use spectral weight normalization [41] to improve the generalization behavior of DNNs.

44.4 Learning Theory for Robust Adversarial Learning

Many recent studies have shown that DNNs are actually vulnerable to adversarial attacks [7, 11, 36]. The adversarial inputs are called *adversarial examples*, which are typically generated by adding small perturbations that are imperceptible to human eyes [35]. Although many deep learning models achieve the state-of-the-art performance in benchmark datasets, they perform poorly on these adversarial examples. For example, the adversarial test accuracy on CIFAR10 is reported as only 47% in [24], instead the natural test accuracy on CIFAR10 is around 95% [32]. Hence, it is necessary to study the adversarial robust generalization property of DNNs to theoretically gain deeper understanding of this problem.

As in the previous sections, assume that (\mathbf{x}, y) is from an unknown distribution \mathcal{D} . For adversarial learning, we focus on the ℓ_∞ white box adversarial attacks where an adversary is allowed to observe the trained model. We choose some \mathbf{x}' such that $\|\mathbf{x}' - \mathbf{x}\|_\infty \leq \epsilon$ and $\ell(f(\mathbf{x}'), y)$ is maximized. Therefore, the adversarial robust model is learned by minimizing the *empirical adversarial risk*, that is,

$$\min_{f \in \mathcal{F}} \frac{1}{n} \sum_{i=1}^n \max_{\|\mathbf{x}'_i - \mathbf{x}_i\|_\infty \leq \epsilon} \ell(f(\mathbf{x}'_i), y_i), \quad (44.8)$$

where $\{(\mathbf{x}_1, y_1), \dots, (\mathbf{x}_n, y_n)\}$ are n i.i.d. training samples from \mathcal{D} . The generalization behavior of the adversarial risk when \mathcal{F} is a set of predictors is the difference between the *expected adversarial risk*

$$\mathbb{E}_{(\mathbf{x}, y) \sim \mathcal{D}} \left[\max_{\|\mathbf{x}' - \mathbf{x}\|_\infty \leq \epsilon} \ell(f(\mathbf{x}'), y) \right]$$

and the empirical adversarial risk in (44.8).

Let us start from simple predictors. Reference [40] proved tight upper and lower bounds for the adversarial Rademacher complexity of binary classifiers. Assume $f_{\mathbf{w}}(\mathbf{x}) = \langle \mathbf{w}, \mathbf{x} \rangle$ is the predictor, where $\mathbf{w} \in \mathbb{R}^d$. The label is then predicted as the sign of $f_{\mathbf{w}}(\mathbf{x})$. Since the label space $\mathcal{Y} = \{-1, 1\}$, the loss $\ell(f(\mathbf{x}), y)$ can be written as $\ell(f(\mathbf{x}), y) = \phi(y \langle \mathbf{w}, \mathbf{x} \rangle)$, where $\phi(\cdot) : \mathbb{R} \mapsto [0, A]$ is monotonically nonincreasing and L_ϕ -Lipschitz. Under the adversarial setting, we therefore have

$$\max_{\|\mathbf{x}' - \mathbf{x}\|_\infty \leq \epsilon} \ell(f_{\mathbf{w}}(\mathbf{x}'), y) = \phi \left(\min_{\|\mathbf{x}' - \mathbf{x}\|_\infty \leq \epsilon} y \langle \mathbf{w}, \mathbf{x}' \rangle \right)$$

Then it is easy to derive the Rademacher complexities with adversarial attacks. The following theorem shows that the adversarial Rademacher complexity is always at least as large as the Rademacher complexity in the natural setting.

Theorem 44.4.1 ([40]) Let $\mathcal{F} = \{f_{\mathbf{w}}(\mathbf{x}) : \|\mathbf{w}\|_p \leq c\}$ and $\tilde{\mathcal{F}} = \{\min_{\|\mathbf{x}' - \mathbf{x}\|_\infty \leq \epsilon} y \langle \mathbf{w}, \mathbf{x}' \rangle : \|\mathbf{w}\|_p \leq c\}$. Suppose that $\frac{1}{p} + \frac{1}{q} = 1$. Then, there exists a universal constant $C \in (0, 1)$ such that

$$\max \left\{ \mathfrak{R}_n(\mathcal{F}), C\epsilon c \frac{d^{\frac{1}{q}}}{\sqrt{n}} \right\} \leq \mathfrak{R}_n(\tilde{\mathcal{F}}) \leq \mathfrak{R}_n(\mathcal{F}) + \epsilon c \frac{d^{\frac{1}{q}}}{\sqrt{n}}.$$

For neural network classifiers, deriving the adversarial Rademacher complexity is more sophisticated, because Eq. (44.8) is an intractable optimization problem. The well-known fast gradient sign method (FGSM) [15] proposes to compute the adversarial examples as

$$\tilde{\mathbf{x}}_i = \mathbf{x}_i + \epsilon \cdot \text{sign}(\nabla_{\mathbf{x}} \ell(f(\mathbf{x}_i), y_i)), \quad i = 1, \dots, n. \quad (44.9)$$

The class of DNNs with spectral norm constraints and under such adversarial attacks is defined as

$$\tilde{\mathcal{F}}_{\mathcal{W}_L} = \left\{ \mathbf{x} \mapsto f_{\mathcal{W}_L}(\tilde{\mathbf{x}}) : \tilde{\mathbf{x}} = \mathbf{x} + \epsilon \cdot \text{sign}(\nabla_{\mathbf{x}} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y)); \right. \\ \left. \|W_j\|_2 \leq c_j; \text{rank}(W_j) \leq r_j, \forall j \right\}, \quad (44.10)$$

where $f_{\mathcal{W}_L}(\mathbf{x})$ is defined in Eq. (44.7) and c_j and r_j are positive constants. The Rademacher complexity of $\tilde{\mathcal{F}}_{\mathcal{W}_L}$ is given as follows.

Theorem 44.4.2 Given $\{\mathbf{x}_1, \dots, \mathbf{x}_n\}$ from $\mathcal{X} = \{\mathbf{x} \in \mathbb{R}^{d_0} : \|\mathbf{x}\| \leq B\}$, each \mathbf{x}_i is perturbed by $\epsilon \cdot \text{sign}(\nabla_{\mathbf{x}_i} \ell(f_{\mathcal{W}_L}(\mathbf{x}_i), y_i))$. Assume that the activation function $\sigma(\cdot)$ is 1-Lipschitz and 1-smooth. Assume that the loss function $\ell(\cdot, y)$ is 1-Lipschitz and 1-smooth for any fixed label y , and $\min_{p \in [d]} |\nabla_{\mathbf{x}_i}^{(p)} \ell(f_{\mathcal{W}_L}(\mathbf{x}_i), y_i)| \geq \kappa$ holds for a constant $\kappa > 0$, where $\nabla_{\mathbf{x}_i}^{(p)} \ell(f_{\mathcal{W}_L}(\mathbf{x}_i), y_i)$ is the p -th element of $\nabla_{\mathbf{x}_i} g(f_{\mathcal{W}_L}(\mathbf{x}_i), y_i)$, for $p = 1, \dots, d$. Then $\mathfrak{R}_n(\ell \circ \tilde{\mathcal{F}}_{\mathcal{W}_L})$ is upper bounded by

$$\mathcal{O} \left(\frac{\prod_{j=1}^L c_j (B + \sqrt{d}\epsilon)}{\sqrt{n}} \sqrt{d \sum_{j=1}^L r_j \ln \left(L\sqrt{n} \left(1 + \frac{\Theta}{B + \sqrt{d}\epsilon} \right) \right)} \right),$$

where $\Theta = \epsilon \frac{1}{\kappa} (1 + \frac{1}{\kappa} \prod_{j=1}^L c_j) \prod_{j=1}^L c_j (1 + \frac{B}{L} \sum_{j=1}^L (j \prod_{k=1}^j c_k))$

This theorem shows that the effect of adversarial attacks on generalization performance is an additional linear term with ϵ . Besides an extra logarithm term, the coefficient of this linear term for ϵ includes the Lipschitz constant of the neural network, the width of the neural network, and the sum of ranks of weight matrices. Assuming the ranks are all equal

to r , $\sum_{j=1}^L r_j$ turns to be a linear function of the depth, which implies that the depth influences the generalization error of adversarial learning to a certain extent.

Several interesting observations will lead this upper bound to a tighter one. An L -layer neural network $f_{\mathcal{W}_L} : \mathbb{R}^{d_0} \rightarrow \mathbb{R}^{d_L}$ is a $\prod_{j=1}^L \|W_j\|_2$ -Lipschitz continuous function if all activation functions are 1-Lipschitz. It is easy to show that the covering number of DNNs class is independent of the network depth if we regard the whole network as a Lipschitz continuous function. In addition, weight matrices tend to be low rank in many empirical results, and dropout can be treated as the low-rank regularization. These take-home points motivate us to decompose $f_{\mathcal{W}_L}$ as a shallow network and a low-dimensional Lipschitz continuous function. Relying on this decomposition, we established a tighter upper bound on the Rademacher complexity in adversarial setting and further limit the effect of adversarial perturbations on the adversarial generalization performance.

In particular, suppose $W_l = U_l \Sigma_l V_l^\top$ for $\forall l \in \{1, \dots, L\}$, where U_l and V_l are column-orthogonal matrices, and $\Sigma_l \in \mathbb{R}^{r_l \times r_l}$ is a diagonal matrix whose entries are nonzero singular values of W_l . Then we rewrite $f_{\mathcal{W}_L}(\tilde{\mathbf{x}})$ as

$$f_{\mathcal{W}_L}(\tilde{\mathbf{x}}) = h_{r_l} \circ f_{\mathcal{W}_l}(\tilde{\mathbf{x}}),$$

where

$$f_{\mathcal{W}_l}(\tilde{\mathbf{x}}) = V_l^\top \sigma_{l-1}(\dots \sigma_1(W_l(\tilde{\mathbf{x}})))$$

is a depth- l neural network and

$$h_{r_l}(\mathbf{z}) = \sigma_L(W_L \sigma_{L-1}(W_{L-1} \dots \sigma_l(U_l \Sigma_l \mathbf{z})))$$

is a Lipschitz continuous function with low-dimensional input, mapping from \mathbb{R}^{r_l} to \mathbb{R}^{d_L} . The composition implies that $\ell \circ \tilde{\mathcal{F}}_{\mathcal{W}_L}$ is a subset of $\ell \circ \mathcal{H}_{r_l} \circ \tilde{\mathcal{F}}_{\mathcal{W}_l}$, where

$$\mathcal{H}_{r_l} = \left\{ h_{r_l}(\mathbf{z}) \mid \|\mathbf{z}\| \leq \prod_{j=1}^{l-1} \|W_j\|_2 (B + \sqrt{d}\epsilon), \right. \\ \left. \text{Lipschitz constant is } \prod_{j=l}^L \|W_j\|_2 \right\}. \quad (44.11)$$

According to the properties of Rademacher complexity, we have

$$\widehat{\mathfrak{R}}_n(\ell \circ \tilde{\mathcal{F}}_{\mathcal{W}_L}) \leq \widehat{\mathfrak{R}}_n(\ell \circ \mathcal{H}_{r_l} \circ \tilde{\mathcal{F}}_{\mathcal{W}_l}).$$

Since this decomposition holds true for any l , we further obtain the upper bound on $\widehat{\mathfrak{R}}_n(\ell \circ \tilde{\mathcal{F}}_{\mathcal{W}_L})$ by choosing the minimum among all $\widehat{\mathfrak{R}}_n(\ell \circ \mathcal{H}_{r_l} \circ \tilde{\mathcal{F}}_{\mathcal{W}_l})$ for $l = 1, \dots, L$.

Lemma 44.4.1 Under the same assumptions in Theorem 44.4.2, and define $\Lambda = \prod_{j=1}^L c_j (B + \sqrt{d}\epsilon)$, we have

1. When $r_l = 1$, $\widehat{\mathfrak{R}}_n(\ell \circ \mathcal{H}_{r_l} \circ \widetilde{\mathcal{F}}_{\mathcal{W}_l})$ satisfies

$$R_l^1 := \mathcal{O}\left(\frac{\Lambda}{\sqrt{n}} \sqrt{d \sum_{j=1}^l r_j \ln\left(l\sqrt{n}\left(1 + \frac{\Theta}{B + \sqrt{d}\epsilon}\right)\right)}\right).$$

2. When $r_l = 2$, $\widehat{\mathfrak{R}}_n(\ell \circ \mathcal{H}_{r_l} \circ \widetilde{\mathcal{F}}_{\mathcal{W}_l})$ satisfies

$$R_l^2 := \mathcal{O}\left(\frac{\Lambda}{\sqrt{n}} \left(\sqrt{(\ln \sqrt{n})^3} + \sqrt{d \sum_{j=1}^l r_j \ln\left(l\sqrt{n}\left(1 + \frac{\Theta}{B + \sqrt{d}\epsilon}\right)\right)}\right)\right).$$

3. When $r_l \geq 3$, $\widehat{\mathfrak{R}}_n(\ell \circ \mathcal{H}_{r_l} \circ \widetilde{\mathcal{F}}_{\mathcal{W}_l})$ satisfies

$$R_l^{r_l} := \mathcal{O}\left(\frac{\Lambda}{\sqrt[n]{n}} \left(\frac{\sqrt{24^{r_l} \ln(\sqrt[n]{n})}}{r_l} + \sqrt{d \sum_{j=1}^l r_j \ln\left(l\sqrt[n]{n}\left(1 + \frac{\Theta}{B + \sqrt{d}\epsilon}\right)\right)}\right)\right).$$

Theorem 44.4.3 For $i = 1, \dots, d$, define

$$l^{(i)} = \min_{j \in [L]} \{j : \text{rank}(W_j) = i\}.$$

Then,

$$\widehat{\mathfrak{R}}_n(g \circ \widetilde{\mathcal{F}}_{\mathcal{W}_L}) \leq \min_{i \in [d]} R_{l^{(i)}}^i,$$

where the $R_{l^{(i)}}^i$ is defined in Lemma 44.4.1.

We ignore logarithmic factors for simplicity. Consider two different scenarios. The first case is that there are low rank matrices with rank 1 or 2 at layer l among weight matrices. Theorem 44.4.3 shows that the upper bound on the Rademacher complexity of $\ell \circ \widetilde{\mathcal{F}}_{\mathcal{W}_L}$ is at most of order

$$\frac{\left(\prod_{j=1}^L \|W_j\|_2\right) (B + \sqrt{d}\epsilon) \sqrt{d \sum_{j=1}^l r_j}}{\sqrt{n}}.$$

The second case is that the ranks of weight matrices are all greater than or equal to 3. Theorem 44.4.3 shows that the upper bound is at most of order

$$\left(\prod_{j=1}^L \|W_j\|_2\right) (B + \sqrt{d}\epsilon) \cdot \min\left(\sqrt{\frac{d \sum_{j=1}^L r_j}{n}}, \frac{\sqrt{d \sum_{j=1}^l r_j} + \sqrt{24^{r_l}/r_l}}{\sqrt[n]{n}}\right).$$

These bounds are depth-free, depend on the Lipschitz constant $\prod_{j=1}^L \|W_j\|_2$, and have a linear relationship with ϵ whose coefficient is linear in the width d .

Following the above conclusion, it is clear that the Rademacher complexity of DNNs under adversarial setting only relies on the shallow part if a low rank weight matrix exists. Correspondingly, the linear coefficient of adversarial perturbations reduces to $\mathcal{O}(\sqrt{\sum_{j=1}^l r_j})$. Thus, adversarial attacks have a smaller influence on the Rademacher complexity and also the generalization behavior of the DNNs. To improve the training accuracy and testing accuracy for experiments, we may adopt spectral normalization and dropout.

44.5 Example: Generalization Bounds for Logistic Regression

In this section, we consider a widely used model in statistical machine learning, which is the logistic regression, to illustrate the previous theoretical results. Let (\mathbf{x}, y) be the sample from $\mathcal{X} \times \mathcal{Y}$, where $\mathcal{X} = \{\mathbf{x} \in \mathbb{R}^{d_0} : \|\mathbf{x}\|_2 \leq B\}$ and $\mathcal{Y} = \{0, 1\}$ are input domain and output domain, respectively. The non-linear logistic regression model is

$$f(\mathbf{x}) := \mathbb{P}(Y = 1 | \mathbf{x}) = \frac{\exp(h(\mathbf{x}))}{1 + \exp(h(\mathbf{x}))},$$

where, for simplicity, $h(\mathbf{x}) = \mathbf{w}^T \sigma(W\mathbf{x})$ is modeled by a single hidden layer neural network, σ is the Sigmoid activation function, and $W \in \mathbb{R}^{d_1 \times d_0}$ and $\mathbf{w} \in \mathbb{R}^{d_1}$ are weight parameters. Let \mathcal{F} be a class of logistic regressions functions with spectral normalization,

$$\mathcal{F} = \{\mathbf{x} \mapsto f(\mathbf{x}) : \|W\|_2 \leq c_1, \|\mathbf{w}\|_2 \leq c_2, \text{rank}(W) \leq r_1\}.$$

To find the optimal estimations for parameters, we minimize the negative log-likelihood

$$\ell(f(\mathbf{x}), y) = -y \ln(f(\mathbf{x})) - (1 - y) \ln(1 - f(\mathbf{x})).$$

It is easy to show that the Sigmoid activation function is 1-Lipschitz and 1-smooth. The log loss also satisfies these conditions if the input is lower bounded by 1. Furthermore, we may set $\kappa \leq c \min_p \{|\mathbf{w}^T W^{(p)}|\}$ for some constant c , where $W^{(p)}$ is the p -th column of W for $p = 1, \dots, d_0$. This satisfies the condition for κ in Theorem 44.4.2. Given n i.i.d. samples $(\mathbf{x}_1, y_1), \dots, (\mathbf{x}_n, y_n)$ from $\mathcal{X} \times \mathcal{Y}$, we consider the FGSM attack, that is, the perturbed predictors are $\tilde{\mathbf{x}}_i = \mathbf{x}_i + \epsilon \cdot \text{sign}(\nabla_{\mathbf{x}} \ell(f(\mathbf{x}_i), y_i))$ for $i = 1, \dots, n$. Then, with probability at least $1 - \eta$ for $\eta \in (0, 1)$, the generalization error under the FGSM attack satisfies

$$\begin{aligned} & \mathbb{E}_{(x,y)} \ell(f(\tilde{x}), y) - \frac{1}{n} \sum_{i=1}^n \ell(f(\tilde{x}_i), y_i) \\ & \leq \mathcal{O} \left(\frac{c_1 c_2 (B + \sqrt{d}\epsilon)}{\sqrt{n}} \right. \\ & \quad \left. \sqrt{d(1+r_1) \ln \left(\sqrt{n} \left(1 + \frac{\Theta}{B + \sqrt{d}\epsilon} \right) \right)} + \sqrt{\frac{\ln(1/\eta)}{n}} \right), \end{aligned}$$

where $d = \max\{d_0, d_1\}$ and $\Theta = \epsilon \frac{c_1 c_2}{\kappa} (1 + \frac{c_1 c_2}{\kappa}) (1 + \frac{B(c_1 + 2c_1 c_2)}{2})$.

The upper bound on generalization error in natural learning case is straightforward by setting $\epsilon = 0$. That is,

$$\begin{aligned} & \mathbb{E}_{(x,y)} \ell(f(x), y) - \frac{1}{n} \sum_{i=1}^n \ell(f(x_i), y_i) \leq \mathcal{O} \\ & \left(\frac{c_1 c_2 B \sqrt{d(1+r_1) \ln(\sqrt{n})}}{\sqrt{n}} + \sqrt{\frac{\ln(1/\eta)}{n}} \right). \end{aligned}$$

The crucial observation is that, for logistic regression, the adversarial generalization bound is always larger than its natural learning counterpart, but the effect of adversarial perturbations can be limited under our weight normalization framework.

44.6 Discussion

We have presented a systematic framework of statistical learning for supervised learning problems. This includes common technical tools, generalization error bounds for DNNs, and the sample complexity of DNNs for robust adversarial learning with ℓ_∞ attacks. We have omitted several important theoretical results for other deep learning models, which include generative adversarial networks (GANs) [1, 14], deep graphical models [19], deep reinforcement learning [23, 25], etc. In the end, we point out a few future directions and hope that these open problems serve as a stimulus for further statistical learning research.

- *Generative Models.* There are two main approaches for generative modeling. The first one is called *variational auto-encoders* (VAEs) [18], which use variational inference to learn a model by maximizing the lower bound of the likelihood function. VAEs have elegant theoretical foundations, but the drawback is that they tend to produce blurry images. The second approach is called *generative adversarial networks* (GANs) [14], which learn a model by using a powerful discriminator to distinguish between real data points and generative data points. GANs produce

more visually realistic images but suffer from the unstable training and the mode collapse problem. How to provide a unifying framework combining the best of VAEs and GANs in a principled way is yet to be discovered.

- *Trade-off between robustness and standard accuracy.* The trade-off between robustness and standard accuracy has been consistently reported in the machine learning literature. Although the problem has been widely studied to understand and explain this trade-off, no studies have shown the possibility of a no trade-off solution. Is there any way to overcome this trade-off?
- *Latent variable models and the MLE.* Latent variable models are powerful and cover a broad range of statistical and machine learning models, such as Bayesian models, linear mixed models, and Gaussian mixture models. Existing methods often suffer from two major challenges in practice: (a) A proper latent variable distribution is difficult to be specified, and (b) making an exact likelihood inference is formidable due to the intractable computation. Is there any framework which can overcome these limitations and allows efficient and exact maximum likelihood inference?

Appendix

Proof of Theorem 44.4.2

To prove Theorem 44.4.2, we need the covering number of $\tilde{\mathcal{F}}_{\mathcal{W}_L}$ first.

Lemma 44.6.1 *Under the same conditions as Theorem 44.4.2, we have the covering number of $\tilde{\mathcal{F}}_{\mathcal{W}_L}$ with respect to the metric ρ_n satisfies*

$$\mathcal{N}(\tau, \tilde{\mathcal{F}}_{\mathcal{W}_L}, \rho_n) \leq \left(\frac{9L(B + \sqrt{d}\epsilon + \Theta) \prod_{j=1}^L c_j}{\tau} \right)^{(2d+1) \sum_{j=1}^L r_j},$$

where ρ_n is the $L_2(P_n)$ metric and $\Theta = \epsilon \frac{1}{\kappa} (1 + \frac{1}{\kappa} \prod_{j=1}^L c_j) \prod_{j=1}^L c_j (1 + \frac{B}{L} \sum_{j=1}^L (j \prod_{k=1}^j c_k))$.

We use the following Lemma 44.6.2, Lemma 44.6.3 and Lemma 44.6.4 to prove Lemma 44.6.1.

Lemma 44.6.2 *Let $S_{c,r} = \{W : W \in \mathbb{R}^{d_2 \times d_1}, \|W\|_2 \leq c, \text{rank}(W) \leq r\}$. Then there exists an τ -covering of $S_{c,r}$ with respect to the spectral norm obeying*

$$\mathcal{N}(\tau, S_{c,r}, \|\cdot\|_2) \leq \left(\frac{9c}{\tau} \right)^{r(d_2+d_1+1)}.$$

Proof. We prove the lemma by extending the arguments from [9]. We do SVD of W in $S_{c,r}$,

$$W = U\Sigma V^\top = cU\frac{\Sigma}{c}V^\top := cU\tilde{\Sigma}V^\top, \quad (44.12)$$

where $\Sigma \in \mathbb{R}^{r \times r}$ is the diagonal matrix with singular values and $U \in \mathbb{R}^{d_2 \times r}$ and $V \in \mathbb{R}^{d_1 \times r}$ are column orthogonal matrices. Thus, $\|U\|_2 = \|V\|_2 = 1$, and $\|\tilde{\Sigma}\|_2 \leq 1$. We will construct a τ -covering for $S_{c,r}$ by covering the set of U , $\tilde{\Sigma}$ and V . we assume $d_1 = d_2 = d$ for simplicity.

Let Γ be the set of diagonal matrices with nonnegative entries and spectral norm less than 1. We take Γ' to be an $\tau/(3c)$ -net for Γ with

$$|\Gamma'| \leq \left(\frac{9c}{\tau}\right)^r.$$

Let $O_{d,r} = \{U \in \mathbb{R}^{d \times r} : \|U\|_2 = 1\}$. There also exists an $\tau/(3c)$ -net $O'_{d,r}$ for $O_{d,r}$ obeying

$$|O'_{d,r}| \leq \left(\frac{9c}{\tau}\right)^{dr}.$$

We now let $S'_{c,r} = \{cU'\Sigma'V'^\top : U', V' \in O'_{d,r}, \Sigma' \in \Gamma'\}$. Thus,

$$|S'_r| \leq |O'_{d,r}|^2 |\Gamma'| \leq \left(\frac{9c}{\tau}\right)^{r(2d+1)}.$$

It remains to show that there exists $S'_{c,r}$ for $S_{c,r}$, such that $\|W - W'\|_2 \leq \tau$.

$$\begin{aligned} & \|W - W'\|_2 \\ &= c \left\| U\tilde{\Sigma}V^\top - U'\Sigma'V'^\top \right\|_2 \\ &= c \left\| U\tilde{\Sigma}V^\top - U'\tilde{\Sigma}V^\top + U'\tilde{\Sigma}V^\top - U'\Sigma'V'^\top \right. \\ & \quad \left. + U'\Sigma'V'^\top - U'\Sigma'V'^\top \right\|_2 \\ &\leq c \left(\left\| (U - U')\tilde{\Sigma}V^\top \right\|_2 + \left\| U'(\tilde{\Sigma} - \Sigma')V^\top \right\|_2 \right. \\ & \quad \left. + \left\| U'\Sigma'(V - V')^\top \right\|_2 \right) \end{aligned}$$

For the first term,

$$\left\| (U - U')\tilde{\Sigma}V^\top \right\|_2 \leq \|U - U'\|_2 \|\tilde{\Sigma}\|_2 \|V\|_2 \leq \frac{\tau}{3c}.$$

The same argument gives $\|U'\Sigma'(V - V')^\top\|_2 \leq \tau/(3c)$. For the second term,

$$\left\| U'(\tilde{\Sigma} - \Sigma')V^\top \right\|_2 \leq \|\tilde{\Sigma} - \Sigma'\|_2 \leq \frac{\tau}{3c}.$$

Therefore, $\|W - W'\|_2 \leq \tau$. This completes the proof. \square

Lemma 44.6.3 *Under the same conditions as Theorem 44.4.2, given $\mathcal{W}_L = (W_1, \dots, W_L)$, there exists $\mathcal{W}'_L = (W'_1, \dots, W'_L)$, where W'_j is from the τ_j -covering of S_{c_j, r_j} , for $j = 1, \dots, L$. Then*

$$\begin{aligned} & \left\| \nabla_{\mathbf{x}} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y) - \nabla_{\mathbf{x}} \ell(f_{\mathcal{W}'_L}(\mathbf{x}), y) \right\|_2 \leq \prod_{j=1}^L c_j \sum_{j=1}^L \\ & \left(\frac{\tau_j}{c_j} + B \prod_{k=1}^j c_k \sum_{k=1}^j \frac{\tau_k}{c_k} \right). \end{aligned}$$

Proof. According to the Lipschitz and smooth assumptions of the activation function and loss function, we have

$$\begin{aligned} & \left\| \nabla_{\mathbf{x}} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y) - \nabla_{\mathbf{x}} \ell(f_{\mathcal{W}'_L}(\mathbf{x}), y) \right\|_2 \\ & \leq \left\| \nabla_{\mathbf{x}} f_{\mathcal{W}_L}(\mathbf{x}) (\nabla \ell)(f_{\mathcal{W}_L}(\mathbf{x}), y) - \nabla_{\mathbf{x}} f_{\mathcal{W}'_L}(\mathbf{x}) (\nabla \ell)(f_{\mathcal{W}_L}(\mathbf{x}), y) \right\|_2 \\ & \quad + \left\| \nabla_{\mathbf{x}} f_{\mathcal{W}'_L}(\mathbf{x}) (\nabla \ell)(f_{\mathcal{W}_L}(\mathbf{x}), y) - \nabla_{\mathbf{x}} f_{\mathcal{W}'_L}(\mathbf{x}) (\nabla \ell)(f_{\mathcal{W}'_L}(\mathbf{x}), y) \right\|_2 \\ & \leq \left\| \nabla_{\mathbf{x}} f_{\mathcal{W}_L}(\mathbf{x}) - \nabla_{\mathbf{x}} f_{\mathcal{W}'_L}(\mathbf{x}) \right\|_2 + \left\| \nabla_{\mathbf{x}} f_{\mathcal{W}'_L}(\mathbf{x}) \right\|_2 \\ & \quad \left\| (\nabla \ell)(f_{\mathcal{W}_L}(\mathbf{x}), y) - (\nabla \ell)(f_{\mathcal{W}'_L}(\mathbf{x}), y) \right\|_2 \\ & \leq \left\| \nabla_{\mathbf{x}} f_{\mathcal{W}_L}(\mathbf{x}) - \nabla_{\mathbf{x}} f_{\mathcal{W}'_L}(\mathbf{x}) \right\|_2 + \left\| \nabla_{\mathbf{x}} f_{\mathcal{W}'_L}(\mathbf{x}) \right\|_2 \\ & \quad \left\| f_{\mathcal{W}_L}(\mathbf{x}) - f_{\mathcal{W}'_L}(\mathbf{x}) \right\|_2 \end{aligned} \quad (44.13)$$

$$\leq \left\| \nabla_{\mathbf{x}} f_{\mathcal{W}_L}(\mathbf{x}) - \nabla_{\mathbf{x}} f_{\mathcal{W}'_L}(\mathbf{x}) \right\|_2 + \prod_{j=1}^L c_j^2 B \sum_{j=1}^L \frac{\tau_j}{c_j}. \quad (44.14)$$

Note that (44.13) holds because $\ell(\cdot)$ is 1-smooth, and $\|f_{\mathcal{W}_L}(\mathbf{x}) - f_{\mathcal{W}'_L}(\mathbf{x})\|_2 \leq \prod_{j=1}^L c_j B \sum_{j=1}^L \tau_j / c_j$ in (44.14) can be obtained from [6]. Next, we prove the following inequality by induction.

$$\begin{aligned} & \left\| \nabla_{\mathbf{x}} f_{\mathcal{W}_L}(\mathbf{x}) - \nabla_{\mathbf{x}} f_{\mathcal{W}'_L}(\mathbf{x}) \right\|_2 \leq \prod_{j=1}^L c_j \sum_{j=1}^L \\ & \left(\frac{\tau_j}{c_j} + B \prod_{k=1}^{j-1} c_k \sum_{k=1}^{j-1} \frac{\tau_k}{c_k} \right). \end{aligned} \quad (44.15)$$

When $L = 0$, $f_{\mathcal{W}_0}(\mathbf{x}) = \mathbf{x}$, $\left\| \nabla_{\mathbf{x}} f_{\mathcal{W}_0}(\mathbf{x}) - \nabla_{\mathbf{x}} f_{\mathcal{W}'_0}(\mathbf{x}) \right\|_2 = 0$. Assume (44.15) holds when there are $L - 1$ layers for DNN. Then, we have

$$\begin{aligned} & \left\| \nabla_{\mathbf{x}} f_{\mathcal{W}_L}(\mathbf{x}) - \nabla_{\mathbf{x}} f_{\mathcal{W}'_L}(\mathbf{x}) \right\|_2 \\ &= \left\| \nabla_{\mathbf{x}} f_{\mathcal{W}_{L-1}}(\mathbf{x}) (\nabla \sigma_{L-1})(f_{\mathcal{W}_{L-1}}(\mathbf{x})) W_L^\top \right. \\ & \quad \left. - \nabla_{\mathbf{x}} f_{\mathcal{W}'_{L-1}}(\mathbf{x}) (\nabla \sigma_{L-1})(f_{\mathcal{W}'_{L-1}}(\mathbf{x})) W_L^\top \right\|_2 \\ &\leq \left\| \nabla_{\mathbf{x}} f_{\mathcal{W}_{L-1}}(\mathbf{x}) (\nabla \sigma_{L-1})(f_{\mathcal{W}_{L-1}}(\mathbf{x})) W_L^\top \right. \\ & \quad \left. - \nabla_{\mathbf{x}} f_{\mathcal{W}_{L-1}}(\mathbf{x}) (\nabla \sigma_{L-1})(f_{\mathcal{W}'_{L-1}}(\mathbf{x})) W_L^\top \right\|_2 \end{aligned}$$

$$\begin{aligned}
& + \|\nabla_{\mathbf{x}} f_{\mathcal{W}_{L-1}}(\mathbf{x})(\nabla \sigma_{L-1})(f_{\mathcal{W}'_{L-1}}(\mathbf{x}))W_L^\top \\
& \quad - \nabla_{\mathbf{x}} f_{\mathcal{W}_{L-1}}(\mathbf{x})(\nabla \sigma_{L-1})(f_{\mathcal{W}'_{L-1}}(\mathbf{x}))W_L^{\top T}\|_2 \\
& + \|\nabla_{\mathbf{x}} f_{\mathcal{W}_{L-1}}(\mathbf{x})(\nabla \sigma_{L-1})(f_{\mathcal{W}'_{L-1}}(\mathbf{x}))W_L^\top - \nabla_{\mathbf{x}} f_{\mathcal{W}'_{L-1}}(\mathbf{x}) \\
& \quad (\nabla \sigma_{L-1})(f_{\mathcal{W}'_{L-1}}(\mathbf{x}))W_L^{\top T}\|_2 \\
& \leq \prod_{j=1}^{L-1} c_j \|f_{\mathcal{W}_{L-1}}(\mathbf{x}) - f_{\mathcal{W}'_{L-1}}(\mathbf{x})\|_2 c_L \\
& \quad + \prod_{j=1}^{L-1} c_j \tau_j + \|\nabla_{\mathbf{x}} f_{\mathcal{W}_{L-1}}(\mathbf{x}) - \nabla_{\mathbf{x}} f_{\mathcal{W}'_{L-1}}(\mathbf{x})\|_2 c_L \\
& \leq \prod_{j=1}^L c_j \prod_{j=1}^{L-1} c_j B \sum_{j=1}^{L-1} \frac{\tau_j}{c_j} + \prod_{j=1}^{L-1} c_j \tau_j + \prod_{j=1}^L c_j \sum_{j=1}^{L-1} \\
& \quad \left(\frac{\tau_j}{c_j} + B \prod_{k=1}^{j-1} c_k \sum_{k=1}^{j-1} \frac{\tau_k}{c_k} \right) \\
& \leq \prod_{j=1}^L c_j \sum_{j=1}^L \left(\frac{\tau_j}{c_j} + B \prod_{k=1}^{j-1} c_k \sum_{k=1}^{j-1} \frac{\tau_k}{c_k} \right)
\end{aligned}$$

Combining (44.14) and (44.15), we can get the conclusion. \square

Lemma 44.6.4 *Under the same assumptions as Theorem 44.4.2, we have*

$$\begin{aligned}
& \|\text{sign}(\nabla_{\mathbf{x}} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y)) - \text{sign}(\nabla_{\mathbf{x}} \ell(f_{\mathcal{W}'_L}(\mathbf{x}), y))\|_2 \\
& \leq \frac{1}{\kappa} \left(1 + \frac{1}{\kappa} \prod_{j=1}^L c_j \right) \prod_{j=1}^L c_j \sum_{j=1}^L \left(\frac{\tau_j}{c_j} + B \prod_{k=1}^j c_k \sum_{k=1}^j \frac{\tau_k}{c_k} \right)
\end{aligned}$$

Proof. According to the definition,

$$\text{sign}(\nabla_{\mathbf{x}} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y)) = \Phi^{-1} \nabla_{\mathbf{x}} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y),$$

where

$$\Phi = \begin{pmatrix} |\nabla_{\mathbf{x}}^{(1)} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y)| & & & \\ & |\nabla_{\mathbf{x}}^{(2)} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y)| & & \\ & & \ddots & \\ & & & |\nabla_{\mathbf{x}}^{(d)} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y)| \end{pmatrix},$$

in which $\nabla_{\mathbf{x}}^{(p)} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y)$ is the p -th element of $\nabla_{\mathbf{x}} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y)$. Similarly, define

$$\Phi' = \text{diag}(|\nabla_{\mathbf{x}} \ell(f_{\mathcal{W}'_L}(\mathbf{x}), y)|).$$

Then, for fixed y ,

$$\begin{aligned}
& \|\text{sign}(\nabla_{\mathbf{x}} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y)) - \text{sign}(\nabla_{\mathbf{x}} \ell(f_{\mathcal{W}'_L}(\mathbf{x}), y))\|_2 \\
& = \|\Phi^{-1} \nabla_{\mathbf{x}} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y) - (\Phi')^{-1} \nabla_{\mathbf{x}} \ell(f_{\mathcal{W}'_L}(\mathbf{x}), y)\|_2 \\
& \leq \|\Phi^{-1} \nabla_{\mathbf{x}} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y) - \Phi^{-1} \nabla_{\mathbf{x}} \ell(f_{\mathcal{W}'_L}(\mathbf{x}), y)\|_2 \\
& \quad + \|\Phi^{-1} \nabla_{\mathbf{x}} \ell(f_{\mathcal{W}'_L}(\mathbf{x}), y) + (\Phi')^{-1} \nabla_{\mathbf{x}} \ell(f_{\mathcal{W}'_L}(\mathbf{x}), y)\|_2 \\
& \leq \|\Phi^{-1}\|_2 \|\nabla_{\mathbf{x}} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y) - \nabla_{\mathbf{x}} \ell(f_{\mathcal{W}'_L}(\mathbf{x}), y)\|_2 \\
& \quad + \|\Phi^{-1} - (\Phi')^{-1}\|_2 \|\nabla_{\mathbf{x}} \ell(f_{\mathcal{W}'_L}(\mathbf{x}), y)\|_2 \\
& \leq \left(\|\Phi^{-1}\|_2 + \frac{1}{\kappa^2} \|\nabla_{\mathbf{x}} \ell(f_{\mathcal{W}'_L}(\mathbf{x}), y)\|_2 \right) \\
& \quad \|\nabla_{\mathbf{x}} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y) - \nabla_{\mathbf{x}} \ell(f_{\mathcal{W}'_L}(\mathbf{x}), y)\|_2 \tag{44.16}
\end{aligned}$$

$$\begin{aligned}
& \leq \frac{1}{\kappa} \left(1 + \frac{1}{\kappa} \prod_{j=1}^L c_j \right) \|\nabla_{\mathbf{x}} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y) - \nabla_{\mathbf{x}} \ell(f_{\mathcal{W}'_L}(\mathbf{x}), y)\|_2 \\
& \tag{44.17}
\end{aligned}$$

$$\begin{aligned}
& \leq \frac{1}{\kappa} \left(1 + \frac{1}{\kappa} \prod_{j=1}^L c_j \right) \prod_{j=1}^L c_j \sum_{j=1}^L \left(\frac{\tau_j}{c_j} + B \prod_{k=1}^j c_k \sum_{k=1}^j \frac{\tau_k}{c_k} \right). \\
& \tag{44.18}
\end{aligned}$$

Under the assumptions, (44.16) is obtained by

$$\begin{aligned}
\|\Phi^{-1} - (\Phi')^{-1}\|_2 & = \max_{p \in [d]} \\
& \frac{|\nabla_{\mathbf{x}}^{(p)} \ell(f_{\mathcal{W}'_L}(\mathbf{x}), y)| - |\nabla_{\mathbf{x}}^{(p)} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y)|}{|\nabla_{\mathbf{x}}^{(p)} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y)| |\nabla_{\mathbf{x}}^{(p)} \ell(f_{\mathcal{W}'_L}(\mathbf{x}), y)|} \\
& \leq \frac{1}{\kappa^2} \max_{p \in [d]} \left| |\nabla_{\mathbf{x}}^{(p)} \ell(f_{\mathcal{W}'_L}(\mathbf{x}), y)| - |\nabla_{\mathbf{x}}^{(p)} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y)| \right| \\
& \leq \frac{1}{\kappa^2} \max_{p \in [d]} |\nabla_{\mathbf{x}}^{(p)} \ell(f_{\mathcal{W}'_L}(\mathbf{x}), y) - \nabla_{\mathbf{x}}^{(p)} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y)| \\
& \leq \frac{1}{\kappa^2} \|\nabla_{\mathbf{x}} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y) - \nabla_{\mathbf{x}} \ell(f_{\mathcal{W}'_L}(\mathbf{x}), y)\|_2.
\end{aligned}$$

Equation (44.17) is obtained by $\|\Phi^{-1}\|_2 = \max_{p \in [d]} (1/|\nabla_{\mathbf{x}}^{(p)} \ell(f_{\mathcal{W}_L}(\mathbf{x}), y)|) \leq 1/\kappa$ and

$$\nabla_{\mathbf{x}} \ell(f_{\mathcal{W}'_L}(\mathbf{x}), y) = \nabla_{\mathbf{x}} f_{\mathcal{W}'_L}(\mathbf{x})(\nabla \ell)(f_{\mathcal{W}'_L}(\mathbf{x}), y) \leq \prod_{j=1}^L c_j.$$

(44.18) is obtained from Lemma 44.6.3. \square

Now, we prove that under the assumptions of Lemma 44.6.3, given $\tau > 0$,

$$\rho_n = \sqrt{\left(\frac{1}{n} \sum_{i=1}^n \|f_{W_L}(\mathbf{x}_i + \epsilon \cdot \text{sign}(\nabla_{\mathbf{x}_i} \ell(f_{W_L}(\mathbf{x}_i), y))) - f_{W'_L}(\mathbf{x}_i + \epsilon \cdot \text{sign}(\nabla_{\mathbf{x}_i} \ell(f_{W'_L}(\mathbf{x}_i), y)))\|_2^2 \right)} \leq \tau$$

by choosing

$$\tau_j = \frac{\tau c_j}{L(B + \sqrt{d}\epsilon + \Theta) \prod_{i=1}^L c_i}. \quad (44.19)$$

First, we inductively prove that

$$\begin{aligned} & \|f_{W_L}(\mathbf{x} + \epsilon \cdot \text{sign}(\nabla_{\mathbf{x}} \ell(f_{W_L}(\mathbf{x}), y))) \\ & - f_{W'_L}(\mathbf{x} + \epsilon \cdot \text{sign}(\nabla_{\mathbf{x}} \ell(f_{W'_L}(\mathbf{x}), y)))\|_2 \\ & \leq \prod_{j=1}^L c_j \sum_{j=1}^L \frac{\tau_j}{c_j} (B + \sqrt{d}\epsilon) + \prod_{j=1}^L c_j \epsilon \\ & \quad \|\text{sign}(\nabla_{\mathbf{x}} \ell(f_{W_L}(\mathbf{x}), y)) - \text{sign}(\nabla_{\mathbf{x}} \ell(f_{W'_L}(\mathbf{x}), y))\|_2 \end{aligned}$$

When $L = 0$, it is obvious that the above inequality holds.

Then,

$$\begin{aligned} & \|f_{W_L}(\mathbf{x} + \epsilon \cdot \text{sign}(\nabla_{\mathbf{x}} \ell(f_{W_L}(\mathbf{x}), y))) \\ & - f_{W'_L}(\mathbf{x} + \epsilon \cdot \text{sign}(\nabla_{\mathbf{x}} \ell(f_{W'_L}(\mathbf{x}), y)))\|_2 \\ & \leq \|W_L \sigma_{L-1}(f_{W_{L-1}}(\mathbf{x} + \epsilon \cdot \text{sign}(\nabla_{\mathbf{x}} \ell(f_{W_L}(\mathbf{x}), y)))) \\ & \quad - W'_L \sigma_{L-1}(f_{W_{L-1}}(\mathbf{x} + \epsilon \cdot \text{sign}(\nabla_{\mathbf{x}} \ell(f_{W_L}(\mathbf{x}), y))))\|_2 \\ & + \|W'_L \sigma_{L-1}(f_{W_{L-1}}(\mathbf{x} + \epsilon \cdot \text{sign}(\nabla_{\mathbf{x}} \ell(f_{W_L}(\mathbf{x}), y)))) \\ & \quad - W'_L \sigma_{L-1}(f_{W'_{L-1}}(\mathbf{x} + \epsilon \cdot \text{sign}(\nabla_{\mathbf{x}} \ell(f_{W'_L}(\mathbf{x}), y))))\|_2 \\ & \leq \tau_L \prod_{j=1}^{L-1} c_j (B + \sqrt{d}\epsilon) + c_L \|f_{W_{L-1}}(\mathbf{x} + \epsilon \cdot \text{sign} \\ & \quad (\nabla_{\mathbf{x}} \ell(f_{W_L}(\mathbf{x}), y))) - f_{W'_{L-1}}(\mathbf{x} + \epsilon \cdot \text{sign}(\nabla_{\mathbf{x}} \ell(f_{W'_L}(\mathbf{x}), y)))\|_2 \\ & \leq \tau_L \prod_{j=1}^{L-1} c_j (B + \sqrt{d}\epsilon) + \prod_{j=1}^L c_j \sum_{j=1}^{L-1} \frac{\tau_j}{c_j} (B + \sqrt{d}\epsilon) \\ & \quad + \prod_{j=1}^L c_j \epsilon \|\text{sign}(\nabla_{\mathbf{x}} \ell(f_{W_L}(\mathbf{x}), y)) - \text{sign}(\nabla_{\mathbf{x}} \ell(f_{W'_L}(\mathbf{x}), y))\|_2 \\ & \leq \prod_{j=1}^L c_j \sum_{j=1}^L \frac{\tau_j}{c_j} (B + \sqrt{d}\epsilon) + \prod_{j=1}^L c_j \epsilon \|\text{sign}(\nabla_{\mathbf{x}} \ell(f_{W_L}(\mathbf{x}), y)) \\ & \quad - \text{sign}(\nabla_{\mathbf{x}} \ell(f_{W'_L}(\mathbf{x}), y))\|_2. \end{aligned}$$

Applying Lemma 44.6.4 and (44.19), we have

$$\begin{aligned} & \|f_{W_L}(\mathbf{x} + \epsilon \cdot \text{sign}(\nabla_{\mathbf{x}} \ell(f_{W_L}(\mathbf{x}), y))) - f_{W'_L}(\mathbf{x} + \epsilon \cdot \\ & \quad \text{sign}(\nabla_{\mathbf{x}} \ell(f_{W'_L}(\mathbf{x}), y)))\|_2 \end{aligned}$$

$$\begin{aligned} & \leq \prod_{j=1}^L c_j \left(\sum_{j=1}^L \frac{\tau_j}{c_j} (B + \sqrt{d}\epsilon) + \epsilon \frac{1}{\kappa} \left(1 + \frac{1}{\kappa} \prod_{j=1}^L c_j \right) \right. \\ & \quad \left. \prod_{j=1}^L c_j \sum_{j=1}^L \left(\frac{\tau_j}{c_j} + B \prod_{k=1}^j c_k \sum_{k=1}^j \frac{\tau_k}{c_k} \right) \right) \\ & \leq \tau \end{aligned}$$

Therefore, the covering number of $\tilde{\mathcal{F}}_{W_L}$ is

$$\begin{aligned} \mathcal{N}(\tau, \tilde{\mathcal{F}}_{W_L}, \rho_n) & \leq \prod_{j=1}^L \sup_{\substack{W_1, \dots, W_{j-1} \\ \forall i < j, W_i \in \mathcal{S}_{c_i, r_i}}} \\ & \quad \mathcal{N}\left(\tau_j, \left\{W_j : W_j \in \mathcal{S}_{c_j, r_j}\right\}, \|\cdot\|_2\right) \\ & \leq \prod_{j=1}^L \left(\frac{9c_j}{\tau_j}\right)^{r_j(d_j + d_{j-1} + 1)} \\ & \leq \left(\frac{9L(B + \sqrt{d}\epsilon + \Theta) \prod_{j=1}^L c_j}{\tau}\right)^{(2d+1) \sum r_j}. \end{aligned}$$

This completes the proof of the covering number.

By standard Dudley's entropy integral, we have

$$\begin{aligned} \hat{\mathfrak{R}}_n(\tilde{\mathcal{F}}_{W_L}) & \lesssim \inf_{\beta > 0} \left\{ \beta + \frac{1}{\sqrt{n}} \int_{\beta}^{\alpha} \sqrt{\ln \mathcal{N}(\tau, \tilde{\mathcal{F}}_{W_L}, \rho_n) d\tau} \right\} \\ & \leq \inf_{\beta > 0} \left\{ \beta + \frac{1}{\sqrt{n}} \int_{\beta}^{\alpha} \right. \\ & \quad \left. \sqrt{(2d+1) \sum_{j=1}^L r_j \ln \left(\frac{9L(B + \sqrt{d}\epsilon + \Theta) \prod_{j=1}^L c_j}{\tau} \right)} d\tau \right\} \\ & \leq \inf_{\beta > 0} \left\{ \beta + \frac{\alpha}{\sqrt{n}} \right. \\ & \quad \left. \sqrt{(2d+1) \sum_{j=1}^L r_j \ln \left(\frac{9L(B + \sqrt{d}\epsilon + \Theta) \prod_{j=1}^L c_j}{\beta} \right)} \right\} \end{aligned}$$

Here $\alpha = \prod_{j=1}^L c_j (B + \sqrt{d}\epsilon)$. Take $\beta = \alpha / \sqrt{n}$, we have

$$\hat{\mathfrak{R}}_n(\ell \circ \tilde{\mathcal{F}}_{W_L}) \leq \hat{\mathfrak{R}}_n(\tilde{\mathcal{F}}_{W_L}) \leq \mathcal{O}$$

$$\left(\frac{\prod_{j=1}^L c_j (B + \sqrt{d}\epsilon)}{\sqrt{n}} \sqrt{d \sum_{j=1}^L r_j \ln \left(L \sqrt{n} \left(1 + \frac{\Theta}{B + \sqrt{d}\epsilon} \right) \right)} \right).$$

Proof of Lemma 44.4.1

Besides the covering number of DNNs, Lemma 44.4.1 is obtained with the help of the covering number of Lipschitz function.

Lemma 44.6.5 *Given (z_1, \dots, z_n) from $\mathcal{Z} = \{z \in \mathbb{R}^r : \|z\| \leq A\}$, assume that $\tilde{\mathcal{H}}$ is a class of M -Lipschitz continuous functions mapping from \mathbb{R}^r to \mathbb{R} . Then, the covering number of $\tilde{\mathcal{H}}$ with respect to the metric ρ_∞ satisfies*

$$\mathcal{N}(\tau, \tilde{\mathcal{H}}, \rho_\infty) \leq \left(2 \left\lceil \frac{4MA}{\tau} \right\rceil + 1\right)^{\left(\frac{6MA}{\tau}\right)^r}.$$

Proof. We first scale $z \in \mathcal{Z}$ to be a unit ball, denoting as \mathcal{Z}/A for simplicity. For any $\tau_1 > 0$, there exists a τ_1 -covering of \mathcal{Z}/A consisting of $\mathcal{N}(\tau_1, \mathcal{Z}/A, \rho_\infty)$ balls: $\mathcal{B}_1, \dots, \mathcal{B}_{\mathcal{N}(\tau_1, \mathcal{Z}/A, \rho_\infty)}$. By [9], we have

$$\mathcal{N}(\tau_1, \mathcal{Z}/A, \rho_\infty) = \left(\frac{3}{\tau_1}\right)^r$$

Choose the center \mathbf{o}_t in each of the ball \mathcal{B}_t , for $t \in [\mathcal{N}(\tau_1, \mathcal{Z}/A, \rho_\infty)]$. The function $\tilde{h}(z)$ on the set \mathcal{Z} will be approximated by the construction:

$$\tilde{h}'(z) = \left\lceil \frac{2\tilde{h}(\mathbf{A}\mathbf{o}_t)}{\tau_2} \right\rceil \frac{\tau_2}{2} \text{ for } z \in \mathcal{B}_t$$

Take $\tau_1 = \tau_2/(2MA)$, we have

$$\begin{aligned} \sup_z |\tilde{h}(z) - \tilde{h}'(z)| &\leq \sup_z \left| \tilde{h}(z) - \frac{2\tilde{h}(\mathbf{A}\mathbf{o}_t)}{\tau_2} \frac{\tau_2}{2} \right| \\ &\quad + \sup_z \left| \frac{2\tilde{h}(\mathbf{A}\mathbf{o}_t)}{\tau_2} \frac{\tau_2}{2} - \left\lceil \frac{2\tilde{h}(\mathbf{A}\mathbf{o}_t)}{\tau_2} \right\rceil \frac{\tau_2}{2} \right| \\ &\leq \sup_z |\tilde{h}(z) - \tilde{h}(\mathbf{A}\mathbf{o}_t)| + \frac{\tau_2}{2} \\ &\leq M \sup_z \|z - \mathbf{A}\mathbf{o}_t\|_2 + \frac{\tau_2}{2} \\ &\leq MA \sup_z \|z/A - \mathbf{o}_t\|_2 + \frac{\tau_2}{2} \leq MA\tau_1 \\ &\quad + \frac{\tau_2}{2} \leq \tau_2 \end{aligned}$$

Let $s = 2\lceil 4AM/\tau_2 \rceil + 1$. The function $\tilde{h}'(z)$ assumes no more than $\mathcal{N}(\tau_1, \mathcal{Z}/A, \rho_\infty)$ values on each set s , and, therefore, the total number of all functions is no greater than the number $s^{\mathcal{N}(\tau_1, \mathcal{Z}/A, \rho_\infty)}$, that is,

$$\mathcal{N}(\tau_2, \tilde{\mathcal{H}}, \rho_\infty) \leq \left(2 \left\lceil \frac{4MA}{\tau_2} \right\rceil + 1\right)^{\left(\frac{6MA}{\tau_2}\right)^r}. \quad \square$$

Note that Lemma 44.6.1 is also applied for any fixed $l \in \{1, \dots, L\}$. Using Lemmas 44.6.1 and 44.6.5, we compute the Rademacher complexity for the decomposed DNN. First, we argue that for $\tau > 0$

$$\mathcal{N}(\tau, \ell \circ \mathcal{H}_{r_l} \circ \tilde{\mathcal{F}}_{\mathcal{W}_l}, \rho_n) \leq \mathcal{N}\left(\frac{\tau}{2}, \ell \circ \mathcal{H}_{r_l}, \rho_\infty\right) \mathcal{N}\left(\frac{\tau}{2 \prod_{j=l}^L c_j}, \tilde{\mathcal{F}}_{\mathcal{W}_l}, \rho_n\right).$$

Pick any function $\tilde{h}_{r_l} := \ell \circ h_{r_l} \in \ell \circ \mathcal{H}_{r_l}$ and $f_{\mathcal{W}_l} \in \tilde{\mathcal{F}}_{\mathcal{W}_l}$, and let \tilde{h}'_{r_l} and $f'_{\mathcal{W}_l}$ be the closest function in $\ell \circ \mathcal{H}_{r_l}$ and $\tilde{\mathcal{F}}_{\mathcal{W}_l}$, respectively. Since \tilde{h}'_{r_l} is $\prod_{j=l}^L c_j$ -Lipschitz, we have

$$\begin{aligned} \rho_n(\tilde{h}_{r_l} f_{\mathcal{W}_l}, \tilde{h}'_{r_l} f'_{\mathcal{W}_l}) &= \sqrt{\frac{1}{n} \sum_{i=1}^n |\tilde{h}_{r_l} f_{\mathcal{W}_l} - \tilde{h}'_{r_l} f'_{\mathcal{W}_l}|^2} \\ &\leq \sqrt{\frac{1}{n} \sum_{i=1}^n |\tilde{h}_{r_l} f_{\mathcal{W}_l} - \tilde{h}'_{r_l} f_{\mathcal{W}_l}|^2 + \frac{1}{n} \sum_{i=1}^n |\tilde{h}'_{r_l} f_{\mathcal{W}_l} - \tilde{h}'_{r_l} f'_{\mathcal{W}_l}|^2} \\ &\leq \sup_{\tilde{x}} |\tilde{h}_{r_l}(\tilde{x}) - \tilde{h}'_{r_l}(\tilde{x})| + \prod_{j=l}^L c_j \sqrt{\frac{1}{n} \sum_{i=1}^n \|f_{\mathcal{W}_l} - f'_{\mathcal{W}_l}\|_2^2} \\ &\leq \frac{\tau}{2} + \frac{\tau}{2} = \tau \end{aligned}$$

Therefore, we can choose \tilde{h}'_{r_l} and $f'_{\mathcal{W}_l}$ from the covers of $\ell \circ \mathcal{H}_{r_l}$ and $\tilde{\mathcal{F}}_{\mathcal{W}_l}$ to cover $\ell \circ \mathcal{H}_{r_l} \circ \tilde{\mathcal{F}}_{\mathcal{W}_l}$. By standard Dudley's entropy integral, we have

$$\begin{aligned}
\widehat{\mathfrak{R}}_n(\ell \circ \mathcal{H}_{r_l} \circ \tilde{\mathcal{F}}_{\mathcal{W}_l}) &\lesssim \inf_{\beta > 0} \left\{ \beta + \frac{1}{\sqrt{n}} \int_{\beta}^{\alpha} \sqrt{\ln \mathcal{N}(\tau, \ell \circ \mathcal{H}_{r_l} \circ \tilde{\mathcal{F}}_{\mathcal{W}_l}, \rho_n)} d\tau \right\} \\
&\leq \inf_{\beta > 0} \left\{ \beta + \frac{1}{\sqrt{n}} \int_{\beta}^{\alpha} \sqrt{\ln \mathcal{N}\left(\frac{\tau}{2}, \ell \circ \mathcal{H}_{r_l}, \rho_{\infty}\right)} d\tau + \frac{1}{\sqrt{n}} \int_{\beta}^{\alpha} \sqrt{\ln \mathcal{N}\left(\frac{\tau}{2 \prod_{j=1}^L c_j}, \tilde{\mathcal{F}}_{\mathcal{W}_l}, \rho_n\right)} d\tau \right\} \\
&\leq \inf_{\beta > 0} \left\{ \beta + \frac{1}{\sqrt{n}} \int_{\beta}^{\alpha} \sqrt{\left(\frac{12(B + \sqrt{d}\epsilon) \prod_{j=1}^L c_j}{\tau}\right)^{r_l} \ln\left(2 \left\lceil \frac{8(B + \sqrt{d}\epsilon) \prod_{j=1}^L c_j}{\tau} \right\rceil + 1\right)} d\tau \right. \\
&\quad \left. + \frac{1}{\sqrt{n}} \int_{\beta}^{\alpha} \sqrt{(2d+1) \sum_{j=1}^l r_j \ln\left(\frac{18 \prod_{j=1}^L c_j l (B + \sqrt{d}\epsilon + \Theta)}{\tau}\right)} d\tau \right\} \\
&:= \inf_{\beta > 0} \{P + Q\},
\end{aligned}$$

where

$$\alpha = \sup_{\substack{\mathbf{x} \in \mathcal{X} \\ \ell h_{r_l} f_{\mathcal{W}_l}(\mathbf{x}, 0) = (B + \sqrt{d}\epsilon) \prod_{j=1}^L c_j}} \rho_n(\ell h_{r_l} f_{\mathcal{W}_l}(\mathbf{x}, 0)) = (B + \sqrt{d}\epsilon) \prod_{j=1}^L c_j + \frac{16\alpha}{\sqrt{n}} \sqrt{\frac{2\pi}{2-r_l}} \mathbb{E}t^2 = \beta + \sqrt{\frac{2\pi}{m}} \frac{16\alpha}{(2-r_l)^{3/2}}$$

We consider Q ,

$$\begin{aligned}
Q &= \frac{1}{\sqrt{n}} \int_{\beta}^{\alpha} \sqrt{(2d+1) \sum_{j=1}^l r_j \ln\left(\frac{18 \prod_{j=1}^L c_j l (B + \sqrt{d}\epsilon + \Theta)}{\tau}\right)} d\tau \\
&\leq \frac{\alpha}{\sqrt{n}} \sqrt{(2d+1) \sum_{j=1}^l r_j \ln\left(\frac{18l(\alpha + \prod_{j=1}^L c_j \Theta)}{\beta}\right)}
\end{aligned}$$

Then we consider P ,

$$\begin{aligned}
P &= \beta + \frac{1}{\sqrt{n}} \int_{\beta}^{\alpha} \sqrt{\left(\frac{12\alpha}{\tau}\right)^{r_l} \ln\left(2 \left\lceil \frac{8\alpha}{\tau} \right\rceil + 1\right)} d\tau \\
&\lesssim \beta + \frac{1}{\sqrt{n}} \int_{\beta}^{\alpha} \sqrt{\left(\frac{16\alpha}{\tau}\right)^{r_l} \ln\left(\frac{16\alpha}{\tau}\right)} d\tau \\
&\leq \beta + \frac{32\alpha}{\sqrt{n}} \int_{-\sqrt{\ln \frac{16\alpha}{\beta}}}^{-\sqrt{\ln 16}} e^{(r_l/2-1)t^2} t^2 dt
\end{aligned}$$

(a) When $r_l/2 - 1 < 0$, i.e., $r_l = 1$,

$$P \leq \beta + \frac{32\alpha}{\sqrt{n}} \int_{-\sqrt{\ln \frac{16\alpha}{\beta}}}^{-\sqrt{\ln 16}} e^{(r_l/2-1)t^2} t^2 dt \leq \beta$$

Therefore,

$$\begin{aligned}
P + Q &\leq \beta + \sqrt{\frac{2\pi}{m}} \frac{16\alpha}{(2-r_l)^{3/2}} + \frac{\alpha}{\sqrt{n}} \\
&\quad \sqrt{(2d+1) \sum_{j=1}^l r_j \ln\left(\frac{18l(\alpha + \prod_{j=1}^L c_j \Theta)}{\beta}\right)}
\end{aligned}$$

Take $\beta = \alpha/\sqrt{n}$, we have

$$\begin{aligned}
\widehat{\mathfrak{R}}_n(\ell \circ \mathcal{H}_{r_l} \circ \tilde{\mathcal{F}}_{\mathcal{W}_l}) &\lesssim \frac{\alpha}{\sqrt{n}} \left(1 + 16\sqrt{2\pi}\right. \\
&\quad \left. + \sqrt{(2d+1) \sum_{j=1}^l r_j \ln\left(18l\sqrt{n}\left(1 + \frac{\Theta}{B + \sqrt{d}\epsilon}\right)\right)}\right)
\end{aligned}$$

(b) When $r_l/2 - 1 = 0$, i.e., $r_l = 2$,

$$\begin{aligned}
P &\leq \beta + \frac{32\alpha}{\sqrt{n}} \int_{-\sqrt{\ln \frac{16\alpha}{\beta}}}^{-\sqrt{\ln 16}} t^2 dt = \beta + \frac{32\alpha}{3\sqrt{n}} \\
&\quad \left(\left(\ln \frac{16\alpha}{\beta}\right)^{3/2} - (\ln 16)^{3/2}\right)
\end{aligned}$$

Hence,

$$P + Q \leq \beta + \frac{32\alpha}{3\sqrt{n}} \left(\left(\ln \frac{16\alpha}{\beta} \right)^{3/2} - (\ln 16)^{3/2} \right) + \frac{\alpha}{\sqrt{n}} \sqrt{(2d+1) \sum_{j=1}^l r_j \ln \left(\frac{18l(\alpha + \prod_{j=1}^l c_j \Theta)}{\beta} \right)}$$

Choose $\beta = \alpha/\sqrt{n}$, we have

$$\widehat{\mathfrak{R}}_n(\ell \circ \mathcal{H}_{r_l} \circ \widetilde{\mathcal{F}}_{\mathcal{W}_l}) \lesssim \frac{\alpha}{\sqrt{n}} \left(1 + 16 \left(\left(\ln(16\sqrt{n}) \right)^{3/2} - (\ln 16)^{3/2} \right) \right) + \frac{\alpha}{\sqrt{n}} \left(\sqrt{(2d+1) \sum_{j=1}^l r_j \ln \left(18l\sqrt{n} \left(1 + \frac{\Theta}{B + \sqrt{d}\epsilon} \right) \right)} \right).$$

(c) When $r_l/2 - 1 > 0$, i.e., $r_l > 2$,

$$P \leq \beta + \frac{32\alpha}{\sqrt{n}} \int_{-\sqrt{\ln \frac{16\alpha}{\beta}}}^{-\sqrt{\ln 16}} e^{(r_l/2-1)t^2} t^2 dt \leq \beta + \frac{16\alpha}{r_l/2 - 1} \sqrt{\frac{\ln(16\alpha/\beta)}{m}} \left(\left(\frac{16\alpha}{\beta} \right)^{r_l/2-1} - 16^{r_l/2-1} \right)$$

Therefore,

$$P + Q \leq \beta + \frac{16\alpha}{r_l/2 - 1} \sqrt{\frac{\ln(16\alpha/\beta)}{m}} \left(\left(\frac{16\alpha}{\beta} \right)^{r_l/2-1} - 16^{r_l/2-1} \right) + \frac{\alpha}{\sqrt{n}} \sqrt{(2d+1) \sum_{j=1}^l r_j \ln \left(\frac{18l(\alpha + \prod_{j=1}^l c_j \Theta)}{\beta} \right)}$$

Let $\beta = \alpha/\sqrt[2]{m}$, we have

$$\widehat{\mathfrak{R}}_n(\ell \circ \mathcal{H}_{r_l} \circ \widetilde{\mathcal{F}}_{\mathcal{W}_l}) \lesssim \frac{\alpha}{\sqrt[2]{n}} \left(1 + \frac{32}{r_l - 2} \sqrt{16^{r_l-2} \ln(16\sqrt[2]{n})} \right) + \frac{\alpha}{\sqrt[2]{n}} \left(\sqrt{(2d+1) \sum_{j=1}^l r_j \ln \left(18l\sqrt[2]{n} \left(1 + \frac{\Theta}{B + \sqrt{d}\epsilon} \right) \right)} \right).$$

This completes the proof.

can be divided into two groups. If the event of interest does not occur (zero event) for all subjects in one of the groups, the resulting likelihood function is monotonic and consequently the covariate effects are difficult to estimate. In this chapter, we carry out an in-depth examination of the conditions of the monotone likelihood problem under a parametric regression model and the partial likelihood under the Cox proportional hazards regression model. We review and discuss Bayesian approaches to handle the monotone likelihood and partial likelihood problems. We analyze the test data from a tire reliability study in details.

Abstract

The monotone likelihood problem is often encountered in the analysis of time-to-event data under a parametric regression model or a Cox proportional hazards regression model when the sample size is small or the events are rare. For example, with a binary covariate, the subjects

45.1 Introduction

In [27], an overview of many aspects of the semiparametric proportional hazards regression model of [6] is provided. The overview covers parameter estimation, hypothesis testing, estimation of the survival and cumulative hazard functions, goodness-of-fit and model checking, and extensions to accommodate stratified data and time-dependent covariates. The authors also deal with models including random effects, nonproportional hazards, and multivariate survival data. An analysis of a data set on fatigue limit of two steel specimens is given as illustration. All the methods discussed in [27] are based on a frequentist (classic) point of view.

In many studies involving time-to-event data, it is often the case that experimental units within at least one group of the study will experience very few events or no event at all. This could be due to the length of the study or due to

the nature of the study itself. For example, among the subset of the Surveillance, Epidemiology, and End Results (SEER) program prostate cancer data in Example 3, no patients who receive surgery treatment die. If the interest is to analyze the surgery treatment effect on the time-to-event data in Example 3, then the nonoccurrence of events in the surgery treatment group will lead to a model identifiability issue.

We investigate the monotone likelihood problem when fitting the piecewise constant hazards regression and Cox proportional hazards regression models. Although we mainly focus on these two models, the monotone likelihood problem may also exist under different models such as accelerated failure time models [17, Ch. 7], parametric hazards models, and so on.

This chapter is organized as follows. In Sect. 45.2, we describe the monotone likelihood problem and give some examples. Section 45.3 is dedicated to Bayesian inference, including prior and posterior distributions as well as conditions for posterior propriety. In Sect. 45.4, we report results from the analysis of data on a tire reliability study. Alternative prior distributions, model comparison criteria, and software for fitting the Cox proportional hazards regression model are discussed in Sect. 45.5.

45.2 Models, Examples, and Monotone Likelihood

45.2.1 Preliminary

Let y_i denote the minimum of the censoring time C_i and the survival time T_i , and let $\mathbf{x}_i = (x_{i1}, \dots, x_{ip})'$ be the $p \times 1$ vector of covariates associated with y_i for the i th subject. Denote by $\boldsymbol{\beta} = (\beta_1, \dots, \beta_p)'$ the $p \times 1$ vector of regression coefficients. Also, $v_i = 1\{T_i = y_i\}$ is the failure indicator for $i = 1, \dots, n$, where n is the total number of subjects and $\mathcal{R}(t) = \{i : y_i \geq t\}$ is the set of subjects at risk at time t . We assume throughout this chapter that $\boldsymbol{\beta}$ does not include an intercept and that given \mathbf{x}_i , T_i , and C_i are independent. Let $\mathcal{D}_{\text{obs}} = \{(y_i, v_i, \mathbf{x}_i) : i = 1, \dots, n\}$ denote the observed right censored data. Also write $\mathbf{y} = (y_1, \dots, y_n)'$ and $\mathbf{v} = (v_1, \dots, v_n)'$.

45.2.2 Piecewise Constant Hazards Regression Model

As discussed in [14, Ch. 3], one of the most popular models for semiparametric survival or reliability analysis is the piecewise constant hazards regression model. This model is constructed as follows. We first let $0 = s_0 < s_1 < s_2 < \dots < s_J = \infty$ denote a finite partition of the time axis. Then, we have J intervals $(0, s_1], (s_1, s_2], \dots, (s_{J-1}, \infty)$. In the j th interval, we assume a constant baseline hazard $h_0(y) = \lambda_j$,

for $y \in (s_{j-1}, s_j]$. Letting $\boldsymbol{\lambda} = (\lambda_1, \dots, \lambda_J)'$, the likelihood function of $(\boldsymbol{\beta}, \boldsymbol{\lambda})$ is given by

$$L(\boldsymbol{\beta}, \boldsymbol{\lambda} | \mathcal{D}_{\text{obs}}) = \prod_{i=1}^n \prod_{j=1}^J \{ \lambda_j \exp(\mathbf{x}'_i \boldsymbol{\beta}) \}^{\delta_{ij} v_i} \times \exp \left[- \delta_{ij} \left\{ \lambda_j (y_i - s_{j-1}) + \sum_{g=1}^{j-1} \lambda_g (s_g - s_{g-1}) \right\} \exp(\mathbf{x}'_i \boldsymbol{\beta}) \right], \quad (45.1)$$

where $\delta_{ij} = 1$ if the i th subject failed or was censored in the j th interval and 0 otherwise. Define $\Delta_j(t)$ as follows:

$$\Delta_j(t) = \begin{cases} 0, & \text{if } t < s_{j-1}, \\ t - s_{j-1}, & \text{if } s_{j-1} \leq t < s_j, \\ s_j - s_{j-1}, & \text{if } t \geq s_j. \end{cases} \quad (45.2)$$

$L(\boldsymbol{\beta}, \boldsymbol{\lambda} | \mathcal{D}_{\text{obs}})$ in (45.1) can also be written as

$$L(\boldsymbol{\beta}, \boldsymbol{\lambda} | \mathcal{D}_{\text{obs}}) = \prod_{i=1}^n \{ \exp(\mathbf{x}'_i \boldsymbol{\beta}) \}^{v_i} \prod_{j=1}^J \lambda_j^{\sum_{i=1}^n \delta_{ij} v_i} \exp \left\{ - \sum_{j=1}^J \sum_{i=1}^n \Delta_j(y_i) \exp(\mathbf{x}'_i \boldsymbol{\beta}) \lambda_j \right\}. \quad (45.3)$$

Assume $\sum_{i=1}^n \delta_{ij} v_i > 0$, for $j = 1, \dots, J$. After plugging in the profile maximum likelihood estimator of $\boldsymbol{\lambda}$ in (45.3), the profile likelihood function is given by

$$L_{pf}(\boldsymbol{\beta} | \mathcal{D}_{\text{obs}}) = \prod_{i=1}^n \left\{ \frac{\exp(\mathbf{x}'_i \boldsymbol{\beta})}{\sum_{j=1}^J \Delta_j(y_i) \exp(\mathbf{x}'_i \boldsymbol{\beta})} \right\}^{v_i} \times \exp \left(- \sum_{i=1}^n v_i \right) \prod_{j=1}^J \left(\sum_{i=1}^n \delta_{ij} v_i \right)^{\sum_{i=1}^n \delta_{ij} v_i}, \quad (45.4)$$

where j_i is the interval in which the i th subject failed or was censored.

45.2.3 Cox Proportional Hazards Regression Model

The likelihood function under the Cox proportional hazards regression model [7] is given by

$$L(\boldsymbol{\beta}, h_0 | \mathcal{D}_{\text{obs}}) = \prod_{i=1}^n \{ h_0(y_i) \exp(\mathbf{x}'_i \boldsymbol{\beta}) \}^{v_i} \exp \{ - H_0(y_i) \exp(\mathbf{x}'_i \boldsymbol{\beta}) \}, \quad (45.5)$$

where $H_0(t) = \int_0^t h_0(u)du$ is the cumulative baseline hazard function. Then, the partial likelihood function is given by

$$L_p(\boldsymbol{\beta}|\mathcal{D}_{\text{obs}}) = \prod_{i=1}^n \left\{ \frac{\exp(\mathbf{x}'_i \boldsymbol{\beta})}{\sum_{j \in \mathcal{R}(y_i)} \exp(\mathbf{x}'_j \boldsymbol{\beta})} \right\}^{v_i}. \quad (45.6)$$

45.2.4 Illustrative Examples

In this section, we provide a few examples in which the monotone likelihood or the monotone partial likelihood problem arise.

Example 1 Consider a survival data set with $n = 3$ subjects, $p = 2$ covariates, $\mathbf{x}_1 = (0, 1)'$, $\mathbf{x}_2 = (1, 0)'$, $\mathbf{x}_3 = (0, 1)'$, $\mathbf{v} = (1, 0, 0)'$, and $(y_1, y_2, y_3)' = (1, 1, 1)'$. In this case, $\mathcal{R}(y_1) = \{1, 2, 3\}$. Assuming $J = 1$ and letting $\lambda = \lambda_1$, the likelihood function in (45.1) takes the form

$$L(\boldsymbol{\beta}, \lambda|\mathcal{D}_{\text{obs}}) = \lambda \exp(\beta_2) \exp \left[-\lambda \{ \exp(\beta_1) + 2 \exp(\beta_2) \} \right]. \quad (45.7)$$

Thus, $L(\boldsymbol{\beta}, \lambda|\mathcal{D}_{\text{obs}})$ is monotonic in β_1 . The partial likelihood function in (45.6) is given by

$$L_p(\boldsymbol{\beta}|\mathcal{D}_{\text{obs}}) = \exp(\beta_2) / \{ \exp(\beta_1) + 2 \exp(\beta_2) \}. \quad (45.8)$$

It is easy to see that $L_p(\boldsymbol{\beta}|\mathcal{D}_{\text{obs}})$ is a monotonic function of β_1 or β_2 , as displayed in Fig. 45.1. The maximum of $L_p(\boldsymbol{\beta}|\mathcal{D}_{\text{obs}})$ is attained when $\beta_1 - \beta_2 \rightarrow -\infty$. It is interesting to mention that after profiling λ out in (45.7), the profile likelihood function is given by

$$L_{pf}(\boldsymbol{\beta}|\mathcal{D}_{\text{obs}}) = \exp(\beta_2 - 1) / \{ \exp(\beta_1) + 2 \exp(\beta_2) \},$$

which is proportional to $L_p(\boldsymbol{\beta}|\mathcal{D}_{\text{obs}})$ given in (45.8).

Example 2 Chen et al. [5] considered data, which consist of $n = 550$ men who were treated with radiation therapy between 1989 and 2002 following with 6 months of with short-course androgen suppression therapy for localized prostate cancer with at least one adverse risk factor represented by prostate-specific antigen (PSA) > 10 ng/ml, biopsy Gleason score 7 to 10, or 2002 American Joint Commission on Cancer (AJCC) clinical tumor category T2b or T2c. The outcome variable (y_i) in years was time to prostate cancer death, which is continuous and subject to right censoring, and $v_i = 1$ if the i th subject died due to prostate cancer and 0 otherwise. Define $A = 1\{\text{PSA} > 10\}$, $B = 1\{\text{Gleason} \geq 7\}$, and $C = 1\{\text{T2b or T2c}\}$. The Cox proportional hazards model with covariates $A \times B$, $A \times C$, $B \times C$, $A \times B \times C$, and age (in years)

Fig. 45.1 Log partial likelihood function for $(\beta_1, \beta_2)'$ in Example 1

Table 45.1 Output from SAS PHREG procedure—Example 2

Variable	DF	Parameter Estimate	Standard Error	Chi-square	Pr > ChiSq
A×B	1	0.39759	1.23355	0.1039	0.7472
A×C	1	-14.30314	2107	0.0000	0.9946
B×C	1	0.59060	1.22714	0.2316	0.6303
A×B×C	1	2.22155	0.80450	7.6253	0.0058
Age	1	0.02262	0.04821	0.2201	0.6390

was fitted to this data set and the results are displayed in Table 45.1.

From Table 45.1, we see that the absolute value of the estimate of the regression coefficient corresponding to $A \times C$ was large and the corresponding standard error was huge, which certainly implies a monotone partial likelihood problem.

Example 3 Wu et al. [29] considered 1840 men subjects from the SEER prostate cancer data between 1973 to 2013, who had all of the three intermediate risk factors: clinical tumor stage is T2b or T2c, Gleason score equals 7, and PSA level between 10 and 20 ng/ml. Among those 1840 subjects, the total number of events due to prostate cancer was 8. The covariates considered in the analysis were PSA level, surgery treatment indicator (RP), radiation treatment only indicator (RT), African-American indicator (Black), year of diagnosis (Year_diag), and age (in years). The Cox proportional hazards model was fitted to study the death due to prostate cancer. The resulting maximum partial likelihood estimates (MPLEs) are shown in Table 45.2. Note that in Table 45.2, N_c represents the number of censored, and N_{pc} represents the number of prostate cancer deaths. We see from Table 45.2 that for RP, the MPLE (Est) and the standard error (SE) were -17.745 and 1680, respectively. These results indicate that

Table 45.2 Maximum partial likelihood estimates for the prostate cancer data—Example 3

Variable	N_c	N_{pc}	Est	SE	p -value
PSA	1840		0.253	0.468	0.5881
RP	842	0	-17.745	1680	0.9916
RT	576	3	-1.150	0.742	0.1210
Black	279	1	-0.539	1.125	0.6318
Year_diag	1840		-0.377	0.743	0.6118
Age	1840		-0.372	0.416	0.3712

RP is not identifiable for the death caused by prostate cancer, which is due to the absence of events (prostate cancer death) in the “surgery treatment” group of patients.

45.2.5 Monotone Likelihood

Piecewise Constant Hazards Regression Model

Note that the profile likelihood function in (45.4) is log-concave with respect to β . Here, we give a general definition of the monotone likelihood problem for the piecewise constant hazards regression model: the profile likelihood function in (45.4) converges to a finite value when at least one parameter estimate goes to $-\infty$ or $+\infty$, and thus the maximum likelihood estimate (MLE) of the corresponding parameter does not exist.

Cox Proportional Hazards Regression Model

Similarly, the monotone likelihood problem for the Cox proportional hazards regression model is defined as follows: the

partial likelihood function in (45.6) converges to a finite value when at least one parameter estimate goes to $-\infty$ or $+\infty$, and thus the MPLE does not exist. For the Cox proportional hazards model, Bryson and Johnson [2] pointed out that for any sample size, there is a non-null probability that the MPLE of β will be infinite. Quoting Heinze and Ploner [12], “The probability of occurrence of monotone likelihood is too high to be negligible.”

45.3 Bayesian Inference

45.3.1 Prior and Posterior Distributions

Piecewise Constant Hazards Regression Model

Let $\pi(\beta)$ and $\pi(\lambda)$ denote the prior distributions for β and λ , respectively. To construct the joint prior for (β, λ) , we assume that β and λ_j are independent, for $j = 1, \dots, J$. We further assume a Jeffreys-type prior for $\lambda_j, j = 1, \dots, J$. Then, the joint prior is specified as

$$\pi(\beta, \lambda) = \pi(\beta) \prod_{j=1}^J \pi(\lambda_j) = \pi(\beta) \prod_{j=1}^J 1/\lambda_j. \quad (45.9)$$

By combining the likelihood function in (45.1) with the prior distribution in (45.9), the posterior distribution for (β, λ) is then given by

$$\begin{aligned} \pi(\beta, \lambda | \mathcal{D}_{\text{obs}}) &\propto \pi(\beta, \lambda) L(\beta, \lambda | \mathcal{D}_{\text{obs}}) = \pi(\beta) \prod_{j=1}^J 1/\lambda_j \prod_{i=1}^n \prod_{j=1}^J \{\lambda_j \exp(\mathbf{x}'_i \beta)\}^{\delta_{ij} v_i} \\ &\quad \times \exp \left[-\delta_{ij} \left\{ \lambda_j (y_i - s_{j-1}) + \sum_{g=1}^{j-1} \lambda_g (s_g - s_{g-1}) \right\} \exp(\mathbf{x}'_i \beta) \right] \\ &= \pi(\beta) \prod_{i=1}^n \left\{ \exp(\mathbf{x}'_i \beta)^{v_i} \right\} \prod_{j=1}^J \lambda_j^{\sum_{i=1}^n \delta_{ij} v_i - 1} \exp \left\{ -\sum_{j=1}^J \sum_{i=1}^n \Delta_j(y_i) \exp(\mathbf{x}'_i \beta) \lambda_j \right\}. \end{aligned} \quad (45.10)$$

If we further assume $\pi(\beta) \propto 1$ in (45.9), the posterior distribution in (45.10), after integrating out λ , is proportional to the profile likelihood function in (45.4).

Cox Proportional Hazards Regression Model

Kalbfleisch [16] and Sinha et al. [25] showed that the partial likelihood function in (45.6) can be obtained as a limiting case of the marginal posterior distribution of β with continuous time survival data under a gamma process prior for the cumulative baseline hazard function $H_0(\cdot)$ using the

likelihood function in (45.5). If we treat the partial likelihood $L_p(\beta | \mathcal{D}_{\text{obs}})$ in (45.6) as the likelihood function, the posterior distribution for β is then given by

$$\begin{aligned} \pi(\beta | \mathcal{D}_{\text{obs}}) &\propto \pi(\beta) L_p(\beta | \mathcal{D}_{\text{obs}}) = \pi(\beta) \\ &\quad \times \prod_{i=1}^n \left\{ \frac{\exp(\mathbf{x}'_i \beta)}{\sum_{j \in \mathcal{R}(y_i)} \exp(\mathbf{x}'_j \beta)} \right\}^{v_i}. \end{aligned} \quad (45.11)$$

45.3.2 Conditions for Posterior Propriety

Piecewise Constant Hazards Regression Model

Note that we can only carry out Bayesian inference when the posterior distribution is proper, i.e., the integral of the right-hand side in (45.10) over the parameter space is finite. Ge and Chen [9] proved that with the joint prior of $(\boldsymbol{\beta}, \boldsymbol{\lambda})$ specified in (45.9) and a uniform prior for $\boldsymbol{\beta}$, the posterior distribution (45.10) is proper, if conditions (i) $y_i > 0$, for $i = 1, \dots, n$, and (ii) $[v_i(\delta_{i1}, \dots, \delta_{ij}, \mathbf{x}'_i)]'$, $i = 1, \dots, n$ is of full column rank are satisfied. Condition (i) essentially requires that all event times are strictly positive. Condition (ii) requires that the corresponding matrix is of full rank and also implies that at least one event occurs in each interval, i.e., $\sum_{i=1}^n \delta_{ij} v_i > 0$, for $j = 1, \dots, J$.

Cox Proportional Hazards Regression Model

Define \mathbf{X}^* to be the matrix given by

$$\mathbf{X}^* = [v_i(\mathbf{x}_j - \mathbf{x}_i) : j \in \mathcal{R}(y_i), i = 1, \dots, n]'. \quad (45.12)$$

The necessary and sufficient conditions established in [4] for propriety of the posterior when an improper uniform prior is assumed for $\boldsymbol{\beta}$ are given by

- C1. The matrix \mathbf{X}^* is of full column rank and
- C2. There exists a positive vector $\boldsymbol{\nu}$ such that $\mathbf{X}^{*\prime} \boldsymbol{\nu} = \mathbf{0}$. (45.13)

A positive vector $\boldsymbol{\nu}$ means that each component of $\boldsymbol{\nu}$ is positive. Condition C2 can be checked by solving a linear programming problem [23].

Here we consider Example 1 again, which does not satisfy C1 and C2. Thus, the MPLE of $\boldsymbol{\beta}$ does not exist, and consequently, the posterior distribution is improper.

Example 1 (continuation) In this case, $\mathcal{R}(y_1) = \{1, 2, 3\}$ and \mathbf{X}^* in (45.12) has rows $(0, 0)$, $(1, -1)$, and $(0, 0)$, so that $\text{rank}(\mathbf{X}^*) = 1$ and condition C1 in (45.13) breaks down. The partial likelihood function in (45.6) is given by $L_p(\boldsymbol{\beta} | \mathcal{D}_{\text{obs}}) = \exp(\beta_2) / \{\exp(\beta_1) + 2 \exp(\beta_2)\}$. The maximum of $L_p(\boldsymbol{\beta} | \mathcal{D}_{\text{obs}})$ is attained when $\beta_1 - \beta_2 \rightarrow -\infty$.

45.3.3 Remedies for Posterior Propriety

If conditions in Sect. 45.3.2 for the piecewise constant hazards regression model and conditions in Sect. 45.3.2 for the Cox proportional hazards model are not satisfied, the posterior distribution under improper priors for $\boldsymbol{\beta}$ will be improper. It thus becomes infeasible to carry out Bayesian inference. Note that the posterior distribution is always proper under a

proper prior. Therefore, in order to guarantee the posterior propriety, a proper prior need to be assumed for $\boldsymbol{\beta}$. Below, we introduce one of the most popular proper priors for $\boldsymbol{\beta}$, namely, the Zellner's g -prior [30],

$$\boldsymbol{\beta} \sim N(\mathbf{0}, (g\tilde{\mathbf{X}}'\tilde{\mathbf{X}})^{-1}),$$

where $\tilde{\mathbf{X}}$ is the design matrix and g is either a constant or a hyperparameter, which is a parameter of a prior distribution. Note that a larger value of g corresponds to a more informative prior. More discussions about other proper priors for $\boldsymbol{\beta}$ are given in Sect. 45.5.1.

In Sect. 45.3.2, for the piecewise constant hazard regression model, we assume an improper Jeffreys-type prior for λ_j , for $j = 1, \dots, J$. However, if there are not many events in certain intervals, we need to assume a proper prior for the corresponding hazard parameter to guarantee the posterior propriety.

45.4 Analysis of the Test Data from a Tire Reliability Study

We consider the same test data set in [18] to study the time to failure of automobile tire due to tread and belt separation (TBS). Same as in [18], time to TBS failure was used as the response variable. Covariates considered include wedge gauge indicator (Wedge = 1 if wedge gauge is greater than the median and 0 otherwise), peel force indicator (Peel = 1 if peel force is greater than the median and 0 otherwise), the interaction between wedge gauge and peel force indicators (Wedge \times Peel), tire age (Tireage), interbelt gauge (Interbelt), end of belt #2 to buttress (Eb2b), and percent of carbon black (Crbnblk). Except for Wedge, Peel, and Wedge \times Peel, which are binary, all other covariates are continuous. The total number of tires used in the analysis was 34 and the number of TBS failure is 11. The continuous covariates were standardized for numerical stability.

The Cox proportional hazards model was fitted to study the effects of factors on time to TBS failure. The resulting MPLEs are shown in Table 45.3. We see from Table 45.3 that for Wedge \times Peel, the MPLE (Est) and the standard error (SE) were -19.44641 and 2997 , respectively (see also Fig. 45.2). These results indicate that the interaction term is not identifiable. One solution to the monotone likelihood problem from the frequentist point of view is to add the Firth's penalty to the likelihood function [13]. The detailed formulations of the Firth's penalty approach are given in Sect. 45.5.3. Table 45.4 presents the SAS outputs using the Firth's penalty. Wedge \times Peel is now identifiable with $\text{SE} = 2.69102$. Tireage with p -value = 0.0294 and Eb2b with p -value = 0.0356 were both significant.

Table 45.3 Output for the Cox proportional hazards regression model from SAS PHREG procedure—tire reliability study

Variable	DF	Parameter Estimate	Standard Error	Chi-square	Pr > ChiSq
Wedge	1	-0.79045	1.03396	0.5845	0.4446

To solve this problem from the Bayesian perspective, we first fit the tire data using the Cox proportional hazards regression model under various Zellner’s g -priors for β . In all the Bayesian computations, we used 10,000 Markov chain Monte Carlo (MCMC) samples, after a burn-in of 2000 iterations for each model to compute all posterior estimates, including posterior means, posterior standard deviations

(Standard Deviation), and 95% highest posterior density (HPD) intervals. All the analyses were done using SAS procedure PROC PHREG [24, Ch. 73]. The deviance information criterion (DIC) [26] was used to guide the choice of g in the Zellner’s g -prior. Based on the DIC criterion, the model with the smallest DIC value is the most optimal among all the models under consideration. As shown in Fig. 45.3, the value of DIC has an increasing trend as g increases from 0.001 to 0.1 with increment equals 0.001 and the value of the effective number of parameters (p_D) decreases as g increases. DIC attained the local minimum with DIC = 49.791 at $g = 0.001$ among all the models under consideration. Therefore, based on the DIC criteria, the model under the Zellner’s g -priors with $g = 0.001$ is the most optimal among all the models under consideration.

Table 45.5 shows the number of MCMC samples (N), the posterior mean, the posterior standard deviation, and 95% HPD intervals under the Zellner’s g -priors with $g = 0.001, 0.01, \text{ and } 0.1$. We took a posterior estimate to be “statistically significant at a significance level of 0.05” if the corresponding 95% HPD interval does not contain 0. The three separate rows under each coefficient are outputs for $g = 0.001, 0.01, \text{ and } 0.1$, respectively. Based on the posterior summaries in Table 45.5 for $g = 0.001$, Tireage with 95% HPD interval = (0.1801, 4.2824) and Eb2b with 95% HPD interval = (-2.6131, -0.3745) were significant. These results were similar to the results of the Firth’s penalty approach in Table 45.4. As shown in Table 45.5, posterior summaries were different under different Zellner’s g -priors. Eb2b was still significant for $g = 0.01$ and 0.1, while Tireage was not. We further note that the standard deviations of each parameter decreased as g increased.

Next, we fit the tire data using the piecewise constant hazards regression model. The Zellner’s g -priors with $g = 0.001, 0.01, \text{ and } 0.1$ were used for β , and the non-informative Jeffreys-type prior in Sect. 45.3.1 was assumed for λ . Due to the small number of events (TBS failure), we assume $J = 2$ intervals for the partition of the time axis to ensure that λ is identifiable. Under this joint prior, SAS PHREG procedure failed to provide output and reported “floating point overflow” error. We then ran the model using WinBUGS [19], which is another Bayesian software. The values of DIC (p_D) under the Zellner’s g -priors with $g = 0.001, 0.01, \text{ and } 0.1$ were 106.4 ($p_D = 8.5$), 106.7 ($p_D = 8.4$), 106.6 ($p_D = 6.6$), respectively. Based on the DIC criterion, the Zellner’s g -priors with $g = 0.001$ is still the most optimal among all the three priors under consideration. Note that the values of DIC from the piecewise constant hazards regression and Cox proportional hazards models are not comparable since the two models do not have the same number of terms.

Posterior summaries under the Zellner’s g -prior with $g = 0.001, 0.01, \text{ and } 0.1$ are presented in Table 45.6. Note that

WinBUGS reports 95% credible intervals based on quantiles rather than 95% HPD intervals. Similar to the HPD intervals, a posterior estimate is considered “statistically significant at a significance level of 0.05” if the corresponding 95% credible interval does not contain 0. As shown in Table 45.6 for $g = 0.001$, Eb2b was significant with 95% credible

interval = (-2.916, -0.471). Similar to the Cox proportional hazards model, posterior summaries of the piecewise constant hazard model were not robust under different Zellner’s g -priors. Eb2b was still significant for $g = 0.01$ and 0.1 , and the standard deviations of each parameter decreased as g increased.

45.5 Discussion

45.5.1 Alternative Prior Distributions

In addition to Zellner's g -priors, there are several other alternative proper priors to guarantee the posterior propriety under the monotone (partial) likelihood problem.

Jeffreys-Type Prior Recall that the posterior distribution for β is given by (45.11). Let $|\cdot|$ denote determinant. If we take

$$\pi(\beta) \propto |\mathbf{I}(\beta)|^{1/2} \quad (45.14)$$

in (45.11), the proposal by Heinze and Schemper [13] has a Bayesian interpretation under the Jeffreys-type prior for β . They also noted that the penalty function $|\mathbf{I}(\beta)|^{1/2}$ in the penalized likelihood function of the Cox proportional hazards model, which is $L_p^*(\beta|\mathcal{D}_{\text{obs}}) = L_p(\beta|\mathcal{D}_{\text{obs}})|\mathbf{I}(\beta)|^{1/2}$, is exactly the Jeffreys-type prior. If condition C1 in (45.13) holds, then $\pi(\beta)$ is proper, and thus the posterior distribution is proper because $L_p(\beta|\mathcal{D}_{\text{obs}})$ is bounded.

Shifted Jeffreys-Type Prior Let β_M be a mode of the prior distribution in (45.14). By adding β_M to β , we get a shifted Jeffreys-type prior given by $\pi_s(\beta) \propto |\mathbf{I}(\beta + \beta_M)|^{1/2}$, so that its mode is shifted to $\beta = \mathbf{0}$. Using $\pi_s(\beta)$, a different posterior $\pi_s(\beta|\mathcal{D}_{\text{obs}})$ is obtained from (45.11). The simulation study in [29] empirically suggests that the shifted Jeffreys-type prior may potentially reduce biases in MPLEs and posterior estimates of the regression coefficients.

Jeffreys-Type Prior Based on the First Risk Set Let $y_{(1)}, \dots, y_{(n)}$ denote the observed times arranged in ascending order associated with $\mathbf{x}_{(1)}, \dots, \mathbf{x}_{(n)}$ and $\nu_{(1)}, \dots, \nu_{(n)}$. Let $\pi_f(\beta)$ denote another variation of the Jeffreys-type prior, which only depends on the first risk set $\mathcal{R}(y_{i_0})$, where $i_0 = \min\{i \in \{1, \dots, n\} : \nu_{(i)} = 1\}$. Let $\mathbf{X}_{(i_0)}^*$ be the submatrix of \mathbf{X}^* corresponding to the first risk set. If $\mathbf{X}_{(i_0)}^*$ is of full column rank, then $\pi_f(\beta)$ exists and is proper. One benefit of this prior is the computing time. Using the first risk set to build the prior saves computation time especially for data sets with a large number of subjects and covariates.

Furthermore, constructing the prior based on the first risk set will not lose much information [29].

log-F Prior Almeida et al. [1] proposed the log-F($l_1/2, l_2/2$) as a solution for the monotone (partial) likelihood issue, where l_1 and l_2 are the degrees of freedom of the F distribution.

Different priors may result in different posterior summaries, interpretations, and degrees of difficulty in implementations, which deserves further research.

45.5.2 Bayesian Model Comparison

SAS and WinBUGS only produce DIC values for Bayesian model comparison. There are several other model selection criteria for Bayesian analysis, including the logarithm of the pseudomarginal likelihood (LPML) [15], the Watanabe-Akaike information criterion (WAIC) [28], and the Bayes factor [10], among others. However, it is still unknown whether a “better” prior may be selected under these criteria compared to DIC in the presence of monotone likelihoods.

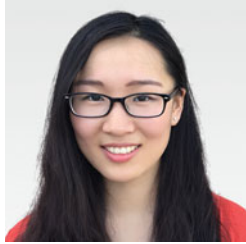

45.5.3 Software

The solution to the monotone likelihood problem proposed by Heinze and Schemper [13] is built on the idea of penalization investigated by Firth [8]. For recent accounts on the role of penalization for coping with the monotone likelihood problem, see [11] and [1]. SAS, SPLUS, and R codes for inference in the Cox proportional hazards model using the penalized partial likelihood function were implemented by Heinze and Ploner [12] and Ploner and Heinze [20]. The MPLE of β is a solution to the estimating equation $U(\beta) = \mathbf{0}$, where $U(\beta) = \partial \log L_p(\beta | \mathcal{D}_{\text{obs}}) / \partial \beta$ and $L_p(\beta | \mathcal{D}_{\text{obs}})$ is as in (45.6). In the approach by Heinze and Schemper [13], the estimate $\hat{\beta}^*$ is obtained by solving the equation $U^*(\beta) = \mathbf{0}$, where $U^*(\beta) = U(\beta) + \text{trace}\{I(\beta)^{-1} \partial I(\beta) / \partial \beta\} / 2$, with $I(\beta)$ denoting minus the Hessian matrix of $\log L_p(\beta | \mathcal{D}_{\text{obs}})$. The second term of $U^*(\beta)$ acts as a penalty. Bayesian approaches discussed in Sect. 45.3 can also be implemented using other softwares such as R [22], JAGS [21], and Stan [3].

Abstract

This chapter reviews multivariate modeling using copulas with illustrative applications in engineering such as multivariate process control and degradation analysis. A copula separates the dependence structure of a multivariate distribution from its marginal distributions. Properties and statistical inferences of copula-based multivariate models are discussed in detail. Applications in engineering are illustrated via examples of bivariate process control and degradation analysis, using existing data in the literature. An R package `copula` facilitates developments and applications of copula-based methods. The major change

from the last version (Yan 2006) is the update on the R package `copula` (Hofert et al. 2018).

Section 46.1 provides the background and motivation of multivariate modeling with copulas. Most multivariate statistical methods are based on the multivariate normal distribution, which cannot meet the practical needs to fit non-normal multivariate data. Copula-based multivariate distributions offer much more flexibility in modeling various non-normal data. They have been widely used in insurance, finance, risk management, and medical research. This chapter focuses on their applications in engineering.

Section 46.2 introduces the concept of copulas and its connection to multivariate distributions. The most important result about copulas is Sklar's (1959) theorem which shows that any continuous multivariate distribution has a canonical representation by a unique copula and all its marginal distributions. Scale-invariant dependence measures for two variables, such as Kendall's tau and Spearman's rho, are completely determined by their copula. The extremes of these two concordance measures, -1 and 1 , are obtained under perfect dependence, corresponding to the Fréchet-Hoeffding lower and upper bounds of copulas, respectively. A general algorithm to simulate random vectors from a copula is also presented.

Section 46.3 introduces two commonly used classes of copulas: elliptical copulas and Archimedean copulas. Elliptical copulas are copulas of elliptical distributions. Two most widely used elliptical copulas, the normal copula and the t copula, are discussed. Archimedean copulas are constructed without referring to distribution functions and random variables. Three popular Archimedean families, Clayton copula, Frank copula, and Gumbel copula, each having a mixture representation with a known frailty distribution, are discussed. Simulation algorithms are also presented.

Section 46.4 presents the maximum likelihood inference of copula-based multivariate distributions given the data. Three likelihood approaches are introduced.

e-mail: jun.yan@uconn.edu

The exact maximum likelihood approach estimates the marginal and copula parameters simultaneously by maximizing the exact parametric likelihood. The inference functions for margins approach is a two-step approach, which estimates the marginal parameters separately for each margin in a first step and then estimates the copula parameters given the the marginal parameters. The canonical maximum likelihood approach is for copula parameters only, using uniform pseudo-observations obtained from transforming all the margins by their empirical distribution functions.

Section 46.5 presents two novel engineering applications. The first example is a bivariate process control problem, where the marginal normality seems appropriate, but joint normality is suspicious. A Clayton copula provides better fit to the data than a normal copula. Through simulation, the upper control limit of Hotelling's T^2 chart based on normality is shown to be misleading when the true copula is a Clayton copula. The second example is a degradation analysis, where all the margins are skewed and heavy-tailed. A multivariate gamma distribution with normal copula fits the data much better than a multivariate normal distribution.

Section 46.6 concludes and points to references about other aspects of copula-based multivariate modeling that are not discussed in this chapter.

46.1 Introduction

Multivariate methods are needed wherever independence cannot be assumed among the variables under investigation. Multivariate data are encountered in real life much more often than univariate data. This is especially true nowadays with the rapid growth of data-acquisition technology. For example, a quality control engineer may have simultaneous surveillance of several related quality characteristics or process variables; a reliability analyst may measure the amount of degradation for a certain product repeatedly over time. Because of the dependence among the multiple quality characteristics and repeated measurements, univariate methods are invalid or inefficient. Multivariate methods that can account for the multivariate dependence are needed.

Classic multivariate statistical methods are based on the multivariate normal distribution. Under multivariate normality, an elegant set of multivariate techniques, such as principal

component analysis and factor analysis, has become standard tools and been successful in a variety of application fields. These methods have become so popular that often times they are applied without a careful check about the multivariate normal assumption. Non-normality can occur in different ways. First, the marginal distribution of some variables may not be normal. For instance, in the degradation analysis in Sect. 46.5, the error rates of magnetic-optic disks at all time points are skewed and heavy-tailed and hence cannot be adequately modeled by normal distributions. Second, even if all the marginal distributions are normal, jointly these variables may not be multivariate normal. For instance, in the bivariate process control problem in Sect. 46.5, marginal normality seems appropriate, but joint normality is suspicious. In both examples, multivariate distributions more flexible than the multivariate normal are needed.

Non-normal multivariate distributions constructed from copulas have proved very useful in recent years in many applications. A copula is a multivariate distribution function whose marginals are all uniforms over the unit interval. It is well-known that any continuous random variable can be transformed to a uniform random variable over the unit interval by its probability integral transformation. Therefore, a copula can be used to “couple” different margins together and construct new multivariate distributions. This method separates a multivariate distribution into two components, all the marginals and a copula, providing a very flexible framework in multivariate modeling. Comprehensive book references on this subject are Nelsen [39] and Joe [25]. For widely accessible introductions, see, for example, Genest and MacKay [17] and Fisher [11].

Copula-based models have gained much attention in various fields. Actuaries have used copulas in modeling dependent mortality and losses [13–15]. Financial and risk analysts have used copulas in asset allocation, credit scoring, default risk modeling, derivative pricing, and risk management [1, 3, 7]. Biostatisticians have used copulas in modeling correlated event times and competing risks [9, 49]. The aim of this chapter is to provide a review of multivariate modeling with copulas and to show that it can be extensively used in engineering applications.

The chapter is organized as follows. Section 46.2 presents the formal definition of copulas and construction of multivariate distribution with copulas. Section 46.3 presents details about two commonly used classes of copulas: elliptical copulas and Archimedean copulas. Section 46.4 presents likelihood-based statistical inferences for copula-based multivariate modeling. Section 46.5 presents two engineering applications, multivariate process control, and degradation analysis. Section 46.6 concludes and suggests future research directions. Implementations have been made easy by the open source software package `copula` [22] for the R project [41].

46.2 Copulas and Multivariate Distributions

46.2.1 Copulas

Consider a random vector $(U_1, \dots, U_p)^\top$, where each margin U_i , $i = 1, \dots, p$, is a uniform random variable over the unit interval. Suppose the joint cumulative distribution function (CDF) of $(U_1, \dots, U_p)^\top$ is

$$C(u_1, \dots, u_p) = \Pr(U_1 \leq u_1, \dots, U_p \leq u_p). \quad (46.1)$$

Then, function C is called a p -dimensional copula. As Embrechts et al. [7] noted, this definition of a copula masks some of the problems when constructing copulas using other techniques, by not explicitly specifying what properties a function must have to be a multivariate distribution function; for a more rigorous definition, see, for example, Nelsen [39]. However, it is “operational” and very intuitive. For example, one immediately obtains with this definition that for any p -dimensional copula C , $p \geq 3$, each $k \leq p$ margin of C is a k -dimensional copula and that independence leads to a product copula:

$$\Pi_p(u_1, \dots, u_p) = \prod_{i=1}^p u_i. \quad (46.2)$$

Every continuous multivariate distribution function defines a copula. Consider a continuous random vector $(X_1, \dots, X_p)^\top$ with joint CDF $F(x_1, \dots, x_p)$. Let F_i , $i = 1, \dots, p$, be the marginal CDF of X_i . Then, $U_i = F_i(X_i)$ is a uniform random variable over the unit interval. One can define a copula C as

$$C(u_1, \dots, u_p) = F\{F_1^{-1}(u_1), \dots, F_p^{-1}(u_p)\}. \quad (46.3)$$

The elliptical copulas in Sect. 46.3.1 are constructed this way. Another important class of copulas, Archimedean copulas, is constructed differently; see Sect. 46.3.2.

A copula (46.1) can be used to construct multivariate distributions with arbitrary margins. Suppose that it is desired that the i th margin X_i has marginal CDF G_i . A multivariate distribution function G can be defined via a copula C as

$$G(x_1, \dots, x_p) = C\{G_1(x_1), \dots, G_p(x_p)\}. \quad (46.4)$$

This multivariate distribution will have the desired marginal distributions.

Clearly, there is a close connection between copulas and multivariate distributions. It is natural to investigate the converse of (46.4). That is, for a given multivariate distribution function G , does there always exist a copula C such

that (46.4) holds? If so, is this C unique? These questions are answered by Sklar’s (1959) Theorem in the next subsection.

46.2.2 Copulas to Multivariate Distributions

Sklar’s Theorem is the most important result about copulas. The bivariate version of the theorem was established by Sklar [45] almost a half century ago in the probability metrics literature. The proof in the general p -dimensional case is more involved and can be found in Sklar [44]. A formal statement of the theorem is as follows [39, p.41].

Theorem 1 *Let F be a p -dimensional distribution function with margins F_1, \dots, F_p . Then there exists a p -dimensional copula C such that for all x in the domain of F ,*

$$F(x_1, \dots, x_p) = C\{F_1(x_1), \dots, F_p(x_p)\}. \quad (46.5)$$

If F_1, \dots, F_p are all continuous, the C is unique; otherwise, C is uniquely determined on $\text{Ran } F_1 \times \dots \times \text{Ran } F_p$, where $\text{Ran } H$ is the range of H . Conversely, if C is a p -dimensional copula and F_1, \dots, F_p are distribution functions, then the function F defined by (46.5) is a p -dimensional distribution function with marginal distributions F_1, \dots, F_p .

Sklar’s Theorem ensures that a continuous multivariate distribution can be separated into two components: univariate margins and multivariate dependence, where the dependence structure is represented by a copula. The dependence structure of a multivariate distribution can be analyzed separately from its margins. It is sufficient to study the dependence structure of a multivariate distribution by focusing on its copula.

The probability density function (PDF) of the CDF F in (46.5) can be found from the PDF of C and F_1, \dots, F_p . The PDF c of the copula C in (46.1) is

$$c(u_1, \dots, u_p) = \frac{\partial^p C(u_1, \dots, u_p)}{\partial u_1 \dots \partial u_p}. \quad (46.6)$$

When the density c is known, the density f of the multivariate distribution F in (46.5) is

$$f(x_1, \dots, x_p) = c\{F_1(x_1), \dots, F_p(x_p)\} \prod_{i=1}^p f_i(x_i), \quad (46.7)$$

where f_i is the density function of the distribution F_i . Expression (46.7) is called the canonical representation of a multivariate PDF, which can be used to construct likelihood for observed data.

46.2.3 Concordance Measures

The copula of two random variables completely determines any dependence measures that are scale-invariant, that is, measures remain unchanged under monotone increasing transformations of the random variables. The construction of the multivariate distribution (46.5) implies that the copula function C is invariant under monotone increasing transformations of its margins. Therefore, scale-invariant dependence measures can be expressed in terms of the copulas of the random variables.

Concordance measures of dependence are based on a form of dependence known as concordance. The most widely used concordance measures are Kendall's tau and Spearman's rho. Both of them can be defined by introducing a concordance function between two continuous random vectors (X_1, X_2) and (X'_1, X'_2) with possibly different joint distributions G and H but with common margins F_1 and F_2 . This concordance function Q is defined as

$$Q = \Pr\{(X_1 - X'_1)(X_2 - X'_2) > 0\} - \Pr\{(X_1 - X'_1)(X_2 - X'_2) < 0\}, \quad (46.8)$$

which is the difference between probability of concordance and dis-concordance of (X_1, X_2) and (X'_1, X'_2) . It can be shown that

$$Q = Q(C_G, C_H) = 4 \int_0^1 \int_0^1 C_G(u, v) dC_H(u, v) - 1, \quad (46.9)$$

where C_G and C_H are the copulas of G and H , respectively.

For a bivariate random vector (X_1, X_2) with copula C , Kendall's tau is defined as $Q(C, C)$, interpreted as the difference between the probability of concordance and dis-concordance of two independent and identically distributed observations. Therefore, we have

$$\tau = 4 \int_0^1 \int_0^1 C(u_1, u_2) dC(u_1, u_2) - 1, \quad (46.10)$$

where the range of τ can be shown to be $[-1, 1]$. Spearman's rho, on the other hand, is defined as $3Q(C, \Pi)$, where Π is the product copula obtained under independence. That is,

$$\rho = 12 \int_0^1 \int_0^1 u_1 u_2 dC(u_1, u_2) - 3. \quad (46.11)$$

The constant 3 scales this measure into the range of $[-1, 1]$ [see, e.g., 39, p.129]. Spearman's rho is proportional to the difference between the probability of concordance and dis-concordance of two vectors: both have the same margins, but one has copula C , while the other has the product copula Π . It is straightforward to show that Spearman's rho equals

to Pearson's product-moment correlation coefficient for the probability integral transformed variables $U_1 = F_1(X)$ and $U_2 = F_2(Y)$:

$$\begin{aligned} \rho &= 12E(U_1 U_2) - 3 = \frac{E(U_1 U_2) - 1/4}{1/12} \\ &= \frac{E(U_1 U_2) - E(U_1)E(U_2)}{\sqrt{\text{Var}(U_1) \text{Var}(U_2)}}. \end{aligned} \quad (46.12)$$

There are other dependence measures based on copulas. For example, tail dependence is a very important measure in studying the dependence between extreme events. Details can be found in Joe [25].

46.2.4 Fréchet-Hoeffding Bounds

Important bounds are defined for copulas and multivariate distributions. These bounds are called the Fréchet-Hoeffding Bounds, named after the pioneering work of Fréchet and Hoeffding, who independently published their work on this in 1935 and 1940, respectively [42]. Define functions M_p and W_p on $[0, 1]^p$ as follows:

$$\begin{aligned} M_p(u_1, \dots, u_p) &= \min(u_1, \dots, u_p), \\ W_p(u_1, \dots, u_p) &= \max(u_1 + \dots + u_p - n + 1, 0). \end{aligned}$$

Then for every copula C ,

$$W_p(u_1, \dots, u_p) \leq C(u_1, \dots, u_p) \leq M_p(u_1, \dots, u_p). \quad (46.13)$$

These bounds are general bounds, regardless of whether the margins are continuous or not. Function M_p is always a p -dimensional copula for $p \geq 2$. Function W_p is a copula only for $p = 2$; for $p \geq 3$, although not a copula, it is still the best possible lower bound since for any $u = (u_1, \dots, u_p) \in [0, 1]^p$, there exists a copula C (which depends on u) such that $C(u) = W_p(u)$. In the bivariate case, these bounds correspond to perfect negative dependence and perfect positive dependence, respectively. Within a given family of copulas, they may or may not be attained [see, e.g., 39, Table 4.1]. For $p = 2$, Fig. 46.1 shows the perspective plots of the Fréchet-Hoeffding bounds copulas and the product copula.

Intuitively, perfect dependence should lead to extremes of concordance measures. It can be shown that for continuous random vector (X_1, X_2) with copula C , $\tau = -1$ (or $\rho = -1$) is equivalent to $C = W_2$ and $\tau = 1$ (or $\rho = 1$) is equivalent to $C = M_2$; see [8] for a proof.

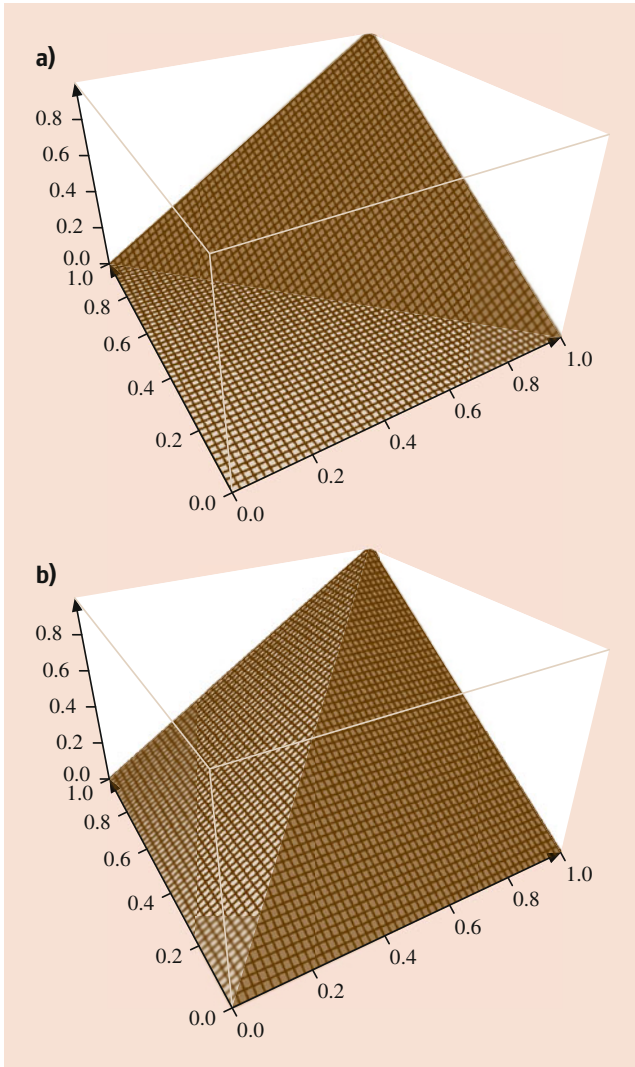

Fig. 46.1 Perspective plots of the Fréchet-Hoeffding bounds. (a) lower bound; (b) upper bound

46.2.5 Simulation

Random number generation from a copula is very important in statistical practice. Consider the p -dimensional copula in (46.1). Let $C_k(u_1, \dots, u_k) = C(u_1, \dots, u_k, 1, \dots, 1)$ for $k = 2, \dots, p - 1$. The conditional CDF of U_k given $U_1 = u_1, \dots, U_{k-1} = u_{k-1}$ is

$$C_k(u_k|u_1, \dots, u_{k-1}) = \frac{\partial^{k-1} C_k(u_1, \dots, u_k)}{\partial u_1 \dots \partial u_{k-1}} \cdot \frac{\partial^{k-1} C_{k-1}(u_1, \dots, u_{k-1})}{\partial u_1 \dots \partial u_{k-1}}. \quad (46.14)$$

Algorithm 1 is a general algorithm to generate a realization (u_1, \dots, u_p) from C via a sequence of conditioning. When the

Algorithm 1 Generating a random vector from a copula

1. Generate u_1 from a uniform over $[0, 1]$.
2. For $k = 2, \dots, p$, generate u_k from $C_k(\cdot|u_1, \dots, u_{k-1})$.

expression of $C_k(\cdot|u_1, \dots, u_{k-1})$ is available, a root finding routine is generally needed in generating u_k using the inverse CDF method. With realizations from C , one can easily generate realizations from the multivariate distribution (46.4) by applying the inverse CDF method at each margin.

46.3 Some Commonly Used Copulas

We introduce two commonly used copula classes in this section: elliptical copulas and Archimedean copulas. A third class of copulas, extreme value copulas, is very useful in multivariate extreme value theory but is omitted here to limit the scope of this chapter; more details about extreme value copulas can be found in Joe [25].

46.3.1 Elliptical Copulas

Elliptical copulas are copulas of elliptical distributions. A multivariate elliptical distribution of random vector (X_1, \dots, X_p) centered at zero has density of the form $\phi(t) = \psi(t^T \Sigma t)$, where $t \in R^p$ and Σ is a $p \times p$ dispersion matrix, which can be parameterized such that $\Sigma_{ij} = \text{Cov}(X_i, X_j)$ [10]. Let R_{ij} and τ_{ij} be Pearson's linear correlation coefficient and Kendall's tau between X_i and X_j , respectively. For an elliptical distribution, they are connected through

$$\tau_{ij} = \frac{2}{\pi} \arcsin(R_{ij}). \quad (46.15)$$

This relationship makes elliptical copulas very attractive in applications since the Kendall's tau matrix, similar to the correlation matrix, can offer a full range dependence structures. Tractable properties similar to those of multivariate normal make another attractiveness of elliptical copulas. The most popular elliptical distributions are multivariate normal and multivariate t , providing two popular copulas: normal copula and t copula.

The normal copula has been widely used in financial applications for its tractable calculus [1, 46]. Consider the joint CDF Φ_Σ of a multivariate normal distribution with correlation matrix Σ . Let Φ be the CDF of a standard normal variable. A normal copula with dispersion matrix Σ is defined as

$$C(u_1, \dots, u_p; \Sigma) = \Phi_\Sigma(\Phi^{-1}(u_1), \dots, \Phi^{-1}(u_p)). \quad (46.16)$$

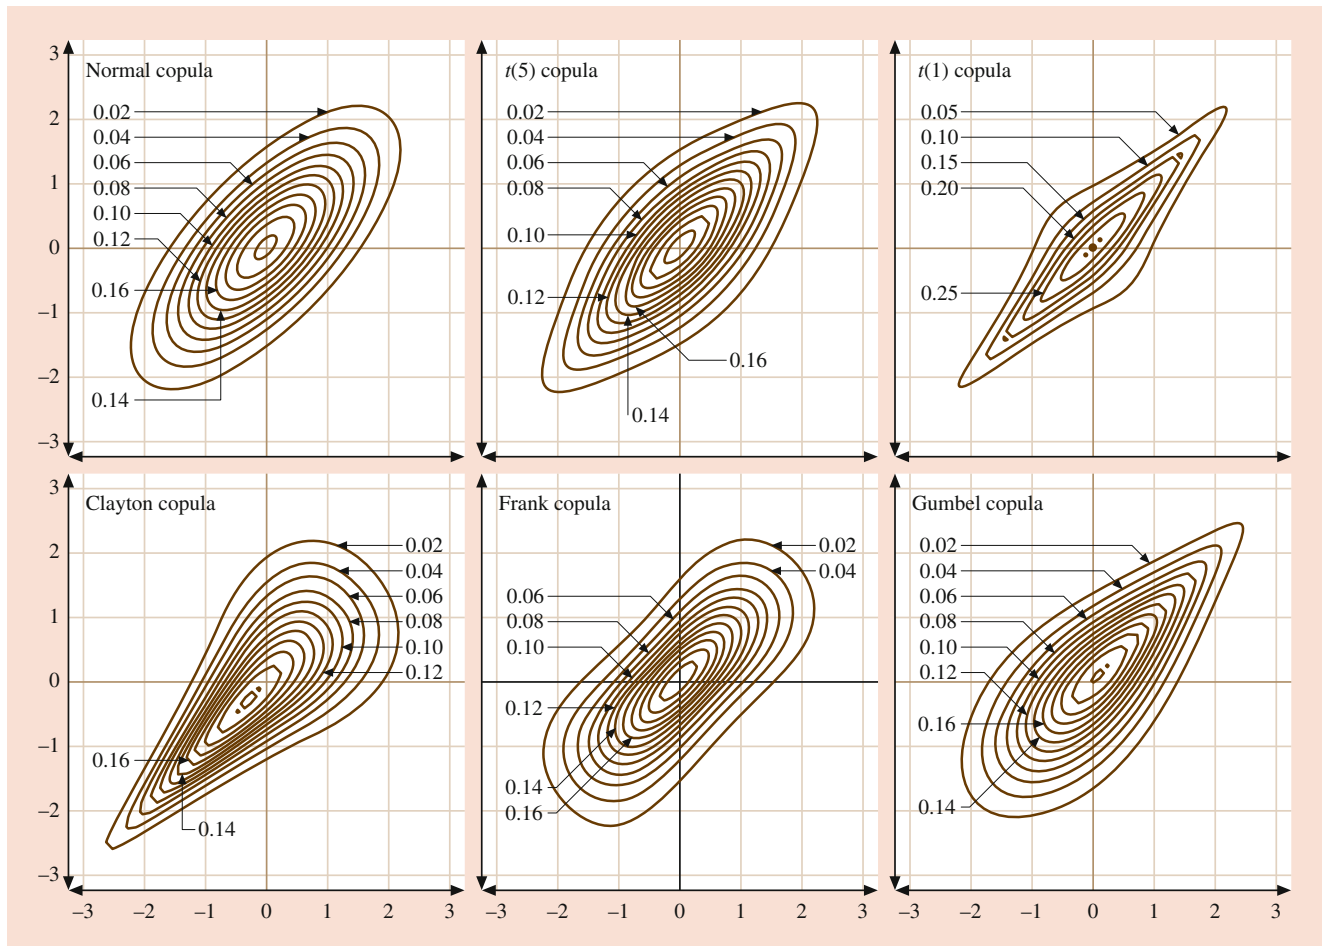

Fig. 46.2 Contours of bivariate distributions with the same marginals but different copulas. Both marginal distributions are standard normal

Functions Φ , Φ^{-1} , and Φ_{Σ} are available in any reasonably good statistical softwares, which makes their application widely accessible.

The t copula can be constructed similarly [6]. Consider the joint CDF $T_{\Sigma, \nu}$ of the standardized multivariate Student's t distribution with correlation matrix Σ and degrees of freedom ν . Let $F_{t_{\nu}}$ be the CDF of univariate t distribution with ν degrees of freedom. A t copula with dispersion matrix Σ and degrees of freedom parameter ν is defined as

$$C(u_1, \dots, u_p; \Sigma, \nu) = T_{\Sigma, \nu}(F_{t_{\nu}}^{-1}(u_1), \dots, F_{t_{\nu}}^{-1}(u_p)). \tag{46.17}$$

These copulas can be used to construct multivariate distributions using (46.5). Note that a normal copula with normal marginals is the same as a multivariate normal distribution. However, a t copula with t margins is not necessarily a multivariate t distribution. A multivariate t distribution must have the same degrees of freedom at all the margins. In contrast, a t copula with t margins can have different degrees

of freedom at different margins. It offers a lot more flexibility in modeling multivariate heavy-tailed data.

Figure 46.2 shows the density contours of bivariate distributions with same marginals but different copulas. These distributions all have standard normal as both margins, and their values of Kendall's tau are all 0.5. The three plots in the first row of Fig. 46.2 are for normal copula, t copula with 5 degrees of freedom, and t copula with 1 degree of freedom (or Cauchy copula). These densities are computed with (46.7). Note that a normal copula can be viewed as t copula with degrees of freedom being infinity. Figure 46.2 illustrates that the dependence at tails gets stronger as the degrees of freedom decrease.

Simulation from normal copulas and t copulas are straightforward if random number generators for multivariate normal and t are available. In R, package `mvtnorm` [18] provides CDF, PDF, and random number generation for multivariate normal and multivariate t distributions. These facilities are used in the implementation of package `copula` [22]. Figure 46.3 shows 1000 points from the corresponding bivariate distributions in Fig. 46.2.

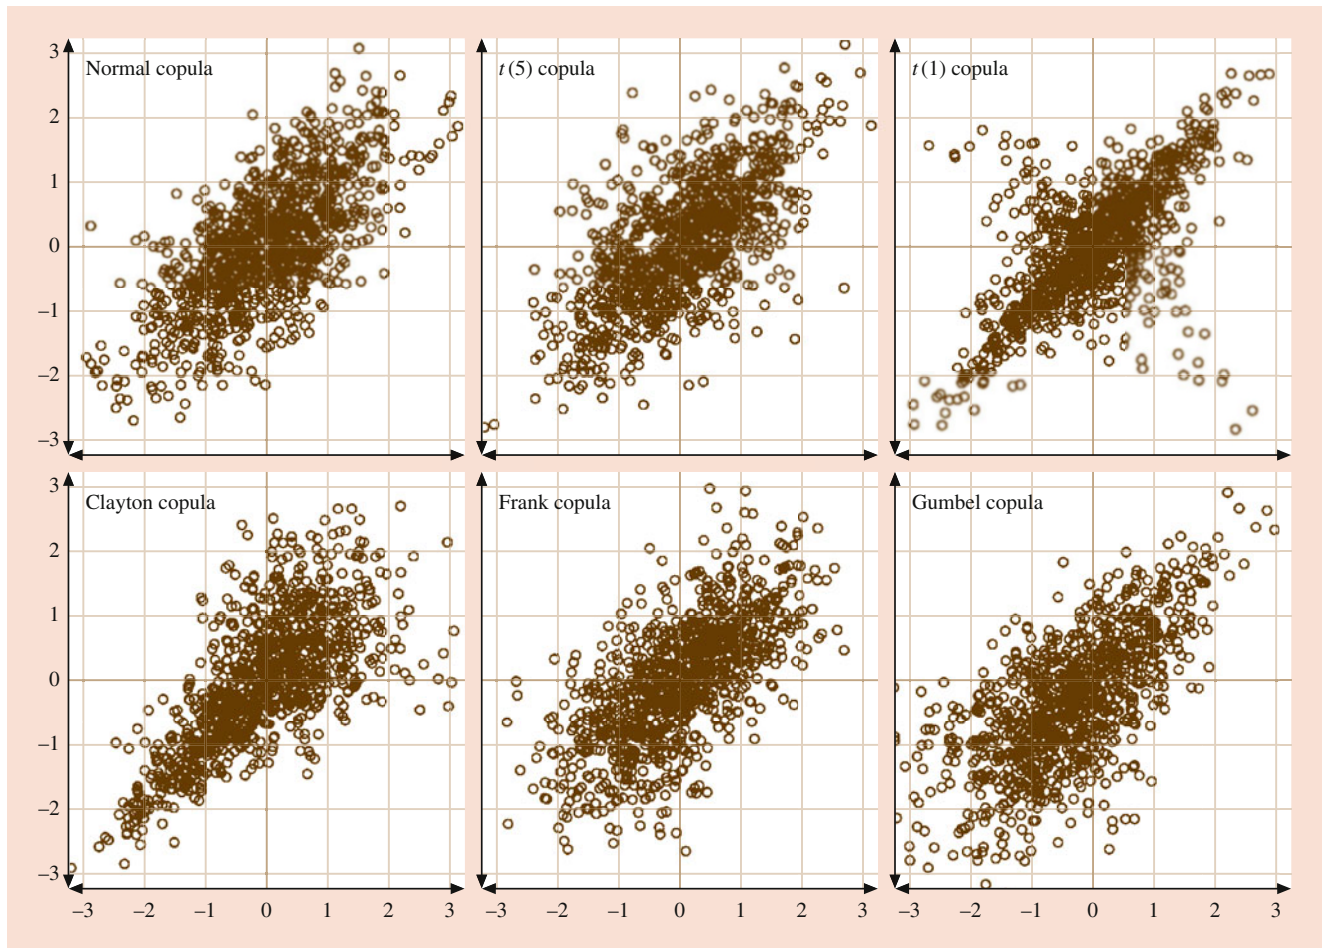

Fig. 46.3 1000 random points from bivariate distributions with the same marginals but different copulas. Both marginal distributions are standard normal

One caveat about elliptical copulas originates from the fact that not all elliptical distributions are marginally consistent [27]. Multivariate normal and t distributions have this property. For example, the d -dimensional marginal distribution for any p -dimensional normal distribution remains the same for all $p \geq d$. This property does not hold for some elliptical distributions such as the exponential power family, which has important practical consequences of the corresponding elliptical copulas [50]. See Example 3.1.9 of [22] for an illustration.

46.3.2 Archimedean Copulas

Archimedean copulas are constructed via a completely different route without referring to distribution functions or random variables. A key component in this way of construction is a complete monotonic function. A function $g(t)$ is completely monotonic on an interval J if it is continuous there and has derivatives of all orders which alternate in sign, that is,

$$(-1)^k \frac{d}{dt^k} \varphi(t) \geq 0, \quad k = 1, 2, \dots, \quad (46.18)$$

for all t in the interior of J . Let φ be a continuous strictly decreasing function from $[0, 1]$ to $[0, \infty]$ such that $\varphi(0) = \infty$ and $\varphi(1) = 0$, and let φ^{-1} be the inverse of φ . A function defined by

$$C(u_1, \dots, u_p) = \varphi^{-1} \{ \varphi(u_1) + \dots + \varphi(u_p) \} \quad (46.19)$$

is a p -dimensional copula for all $p \geq 2$ if and only if φ^{-1} is completely monotonic over $[0, \infty)$ [see, e.g., 39, Theorem 4.6.2]. The copula C in (46.19) is called an Archimedean copula. The name “Archimedean” for these copulas comes from a property of the unit cube and copula C which is an analog of the Archimedean axiom for positive real numbers [see 39, p.98 for more details]. The function φ is called the generator of the copula. A generator uniquely (up to a scalar multiple) determines an Archimedean copula.

In the bivariate case, an Archimedean copula may be obtained with weaker conditions on the generator φ and its pseudo-inverse $\varphi^{[-1]}$:

$$C(u_1, u_2) = \max[\varphi^{[-1]} \{\varphi(u_1) + \varphi(u_2)\}, 0], \quad (46.20)$$

where the generator φ is a function with two continuous derivatives such that $\varphi(1) = 0$, $\varphi'(u) < 0$, $\varphi''(u) > 0$ for all $u \in [0, 1]$, and $\varphi^{[-1]}$ is the pseudo-inverse of φ defined as

$$\varphi^{[-1]}(v) = \begin{cases} \varphi^{-1}(v) & 0 \leq v \leq \varphi(0), \\ 0 & \varphi(0) \leq v \leq \infty. \end{cases}$$

The generator φ is called a strict generator if $\varphi(0) = \infty$, in which case $\varphi^{[-1]} = \varphi$. [17] give proofs to some basic properties of bivariate copulas.

The generator φ plays an important role in the properties of an Archimedean copulas. It can be shown that the Kendall's tau for an Archimedean copula with generator φ is

$$\tau = 4 \int_0^1 \int_0^1 \frac{\varphi(v)}{\varphi'(v)} dv + 1. \quad (46.21)$$

This relationship can be used to construct estimating equations that equate the sample Kendall's tau to the theoretical value from the assumed parametric copula family.

Due to the exchangeable structure in (46.19), the associations among all variables are exchangeable too. As a consequence, an Archimedean copula cannot accommodate negative association unless $p = 2$. For Archimedean copulas with positive associations, there is a mixture representation due to Marshall and Olkin [34]. Suppose that conditional on a positive latent random variable called frailty, γ , the distribution of U_i is $F_i(U_i|\gamma) = U_i^\gamma$, $i = 1, \dots, p$, and U_1, \dots, U_p are independent. Then the copula C of U_1, \dots, U_p is

$$C(u_1, \dots, u_p) = E \left(\prod_{i=1}^p u_i^\gamma \right), \quad (46.22)$$

where the expectation is taken with respect to the distribution of γ , F_γ . Recall that the Laplace transform of γ is

$$\mathcal{L}(s) = E_\gamma(e^{-s\gamma}) = \int_0^\infty e^{-sx} dF_\gamma(x).$$

Laplace transform has well-defined inverse \mathcal{L}^{-1} . [34] show that the copula in (46.22) is

$$C(u_1, \dots, u_p) = \mathcal{L}(\mathcal{L}^{-1}(u_1) + \dots + \mathcal{L}^{-1}(u_p)). \quad (46.23)$$

This result suggests that an Archimedean copula can be constructed using the inverse of a Laplace transform as the generator.

Table 46.1 summarizes three commonly used one-parameter Archimedean copulas. A comprehensive list of one-parameter bivariate Archimedean copulas and their properties can be found in Table 4.1 of [39]. The three copulas in Table 46.1 all have inverse transforms of some positive random variables as their generators. The Clayton copula was introduced by Clayton [4] in modeling correlated survival times with a gamma frailty. The Frank copula first appeared in Frank [12]. It can be shown that the inverse of its generator is the Laplace transform of a log series random variables defined on positive integers. The Gumbel copula traces back to Gumbel [21]. Hougaard [24] uses a positive stable random variable to derive the multivariate distribution based on Gumbel copula.

Density contours of bivariate distributions constructed from these three Archimedean copulas are presented in the second row of Fig. 46.2. Both margins of these distributions are still standard normals. The parameters of these copulas are chosen such that the value of Kendall's tau is 0.5. The density of an Archimedean copula can be found by differentiating the copula as in (46.6). When the dimension p is high, the differentiation procedure can be tedious. Symbolic calculus softwares can be used for this purpose. From Fig. 46.2, one observes that the Frank copula has symmetric dependence. The dependence of the Clayton copula-based distribution is stronger in the lower-left region than in the upper-right region. In contrast, the dependence of the Gumbel copula-based distribution is stronger in the upper-right region than in the lower-left region.

Simulation from a general Archimedean can be done using the general Algorithm 1 in Sect. 46.2. When the inverse of the generator is known to be the Laplace transform of some positive random variable, an algorithm based on (46.23) is summarized in Algorithm 2 [14]. This algorithm is very easy to implement, given that a random number generator of the frailty is available. Gamma variable generator is available in most softwares. Algorithms for generating positive stable and log series variables can be found in Chambers et al. [2] and Kemp [28], respectively. For bivariate case, the general algorithm 1 can be simplified, avoiding numerical root finding. These algorithms have been implemented in package `copula` [22]. The lower panel of Fig. 46.3 shows 1000

Table 46.1 Some one-parameter (α) archimedean copulas

Family	Generator $\varphi(t)$	Frailty distribution	Laplace transformation of frailty $\mathcal{L}(s) = \varphi^{-1}(s)$
Clayton (1978)	$t^{-\alpha} - 1$	Gamma	$(1 + s)^{-1/\alpha}$
Frank (1979)	$\ln \frac{e^{\alpha t} - 1}{e^\alpha - 1}$	Log series	$\alpha^{-1} \ln(1 + e^s(e^\alpha - 1))$
Gumbel (1960)	$(-\ln t)^\alpha$	Positive stable	$\exp(-s^{1/\alpha})$

Algorithm 2 Generating a random vector from an Archimedean copula with a known frailty distribution

1. Generate a latent variable γ whose Laplace transformation \mathcal{L} is the inverse generator function φ^{-1} .
2. Generate independent uniform observations $v_1, \dots, v_p, i = 1, \dots, p$.
3. Output $u_i = \mathcal{L}(-\gamma^{-1} \log v_i), i = 1, \dots, p$.

random points generated from the corresponding bivariate distributions with Archimedean copulas in Fig. 46.2.

46.4 Statistical Inference

This section presents the maximum likelihood (ML) estimation for multivariate distributions constructed from copulas. Other methods, such as moment methods and nonparametric methods, are less developed for copula-based models and hence omitted.

Suppose that we observe a random sample of size n from a multivariate distribution (46.5):

$$(X_{i1}, \dots, X_{ip})^\top, \quad i = 1, \dots, n.$$

The parameter of interest is $\theta = (\beta^\top, \alpha^\top)^\top$, where β is the marginal parameter vector for the marginal distributions $F_i, i = 1, \dots, p$, and α is the association parameter vector for the copula C . Regression models for the marginal variables can be incorporated easily by assuming that the residuals follows a multivariate distribution (46.5).

46.4.1 Exact Maximum Likelihood

The exact log-likelihood $l(\theta)$ of the parameter vector θ can be expressed from (46.7):

$$l(\theta) = \sum_{i=1}^n \log c(F_1(X_{i1}; \beta), \dots, F_p(X_{ip}; \beta); \alpha) + \sum_{i=1}^n \sum_{j=1}^p \log f_j(X_{ij}; \beta). \tag{46.24}$$

The ML estimator of θ is

$$\hat{\theta}_{ML} = \arg \max_{\theta \in \Theta} l(\theta),$$

where Θ is the parameter space.

Under the usual regularity conditions for the asymptotic ML theory, the ML estimator $\hat{\theta}_{ML}$ is consistent and asymptotically efficient, with limiting distribution

$$\sqrt{n}(\hat{\theta}_{ML} - \theta_0) \rightarrow N(0, I^{-1}(\theta_0))$$

where θ_0 is the true parameter value and I is the Fisher information matrix. The asymptotic variance matrix $I^{-1}(\theta_0)$ can be estimated consistently by an empirical variance matrix of the influence functions evaluated at $\hat{\theta}_{ML}$.

In the `copula` package, a multivariate distribution constructed with a copula can be constructed with function `mvdc()`. Its log-likelihood can be computed with function `loglikMvdc()`. The maximum likelihood estimates and their standard errors are returned from function `fitMvdc()`.

The maximization of $l(\theta)$ in (46.24) may be a difficult task, especially when the dimension is high and/or the number of parameters is large. The separation of the margins and copula in (46.24) suggests that one may estimate the marginal parameters and association parameters in two steps, leading the method in the next subsection.

46.4.2 Inference Functions for Margins (IFM)

The estimation method of IFM was proposed by Joe and Xu [26]. This method estimates the marginal parameters β in a first step by

$$\hat{\beta} = \arg \max_{\beta} \sum_{i=1}^n \sum_{j=1}^p \log f_j(X_{ij}; \beta), \tag{46.25}$$

and then estimates the association parameters α given $\hat{\beta}$ by

$$\hat{\alpha} = \arg \max_{\alpha} \sum_{i=1}^n \log c(F_1(X_{i1}; \hat{\beta}), \dots, F_p(X_{ip}; \hat{\beta}); \alpha). \tag{46.26}$$

When each marginal distribution F_j has its own parameters β_j so that $\beta = (\beta_1^\top, \dots, \beta_p^\top)^\top$, the first step consists of an ML estimation for each margin $j = 1, \dots, p$:

$$\hat{\beta}_j = \arg \max_{\beta_j} \sum_{i=1}^n \log f_j(X_{ij}; \beta_j). \tag{46.27}$$

In this case, each maximization task has a very small number of parameters, greatly reducing the computational difficulty. This approach is called the two-stage parametric ML method by Shih and Louis [43] in a censored data setting.

The IFM estimator from (46.25) and (46.26), $\hat{\theta}_{IFM}$, is in general different from the ML estimate $\hat{\theta}_{ML}$. The limiting distribution of $\hat{\theta}_{IFM}$ is

$$\sqrt{n}(\hat{\theta}_{IFM} - \theta_0) \rightarrow N(0, G^{-1}(\theta_0))$$

where G is the Godambe information matrix [20]. This matrix has a sandwich form as from the usual robust estimation with estimating functions. Detailed expressions can be found in Joe [25]. Using pseudo-observations from the fitted probability integral transformation with $\hat{\beta}$ from (46.25), function `fitCopula()` called with `method = 'ml'` in the `copula` package returns point estimate of $\hat{\alpha}$ in (46.26). The returned standard error, however, should be ignored as the observations of the copula in the fitting are estimated instead of observed.

Compared to the ML estimator, the IFM estimator has advantages in numerical computations and is asymptotically efficient. Even in finite samples, it is highly efficient relative to the exact ML estimator [25]. The IFM estimate can be used as starting values in an exact ML estimation.

46.4.3 Canonical Maximum Likelihood (CML)

When the association is of explicit interest, parameter α can be estimated with the CML method without specifying the marginal distribution. This approach uses the empirical CDF of each marginal distribution to transform the observations $(X_{i1}, \dots, X_{ip})^\top$ into pseudo-observations with uniform margins $(U_{i1}, \dots, U_{ip})^\top$ and then estimates α as

$$\hat{\alpha}_{\text{CML}} = \arg \max_{\alpha} \sum_{i=1}^n \log c(U_{i1}, \dots, U_{ip}; \alpha). \quad (46.28)$$

The CML estimator $\hat{\alpha}_{\text{CML}}$ is consistent, asymptotically normal, and fully efficient at independence [16,43]. Function `fitCopula()` called with `method = 'mpl'`, which stands for maximum pseudo-likelihood, in the `copula` package returns point estimate $\hat{\alpha}_{\text{CML}}$ in (46.28) with valid standard errors.

46.5 Engineering Applications

Two engineering applications of copulas are considered in this section: multivariate process control and degradation analysis. An important third application is the modeling of multivariate failure times which may be censored. We focus on complete data applications in this chapter. In the example of multivariate process control, marginal normality seems appropriate, but joint normality is suspicious. In the example of degradation analysis, the margins are right-skewed and have long tails. We use a gamma distribution for each margin and a normal copula for the association.

46.5.1 Multivariate Process Control

In quality management, multiple process characteristics necessitate multivariate method for process control. There are three major control charts used in practice: Hotelling's T^2 , multivariate cumulative sum (MCUSUM), and multivariate exponentially weighted moving average (MEWMA); see Lowry and Montgomery [32] for a review. The most popular multivariate control chart is the T^2 chart, which has a long history since Hotelling [23]. Mason and Young [35] give details on how to use it with industrial applications. This method assumes that the multiple characteristics under surveillances are jointly normally distributed. The control limit of the chart is based on the sampling distribution of statistic T^2 , which can be shown to have an F distribution. When the multivariate normal assumption does not hold, due to either univariate or multivariate non-normality, T^2 control chart based on multivariate normality can be inaccurate and misleading.

Copula-based multivariate distributions open a new avenue for the statistical methods of multivariate process control. The parametric form of the multivariate distribution can be determined from a large amount of historical in-control data. Given a sample of observations when the process is in control, one can estimate the parameters and propose a statistic that measures the deviation from the target. The exact distribution of this statistic is generally unknown, and the control limit needs to be obtained from bootstrap; see for example Liu and Tang [31].

As an illustration, consider the example of bivariate process control in [33]. The data consists of 30 pairs of bivariate measurements from an exhaust manifold used on a Chrysler 5.21 engine in a given model year. They were collected from a machine capability study performed on the machine builder's floor. The sample correlation coefficient is 0.44. The left panel of Fig. 46.4 shows the scatter plot of the 30 observations. Normal assumption for each margin seems fine from the normal Q-Q plots (not shown). However, the joint distribution may not be a bivariate normal. The scatter plot suggests that the association may be stronger in the lower end than in the higher end of the data. This nonsymmetric association cannot be captured by a symmetric copula, such as those elliptical copula and Frank copula in Fig. 46.2. A better fit of the data may be obtained from a Clayton copula, which allows the bivariate dependence to be stronger at the left tail than at the right tail. The center panel of Fig. 46.4 shows the contours of the ML bivariate normal fit. The right panel of Fig. 46.4 shows the contours of the ML bivariate fit with normal margins and the Clayton copula. The maximized log-likelihood of the two models is 307.64 and 309.87, respectively. A formal test of the difference, which is beyond the scope of this chapter, can be done by comparing

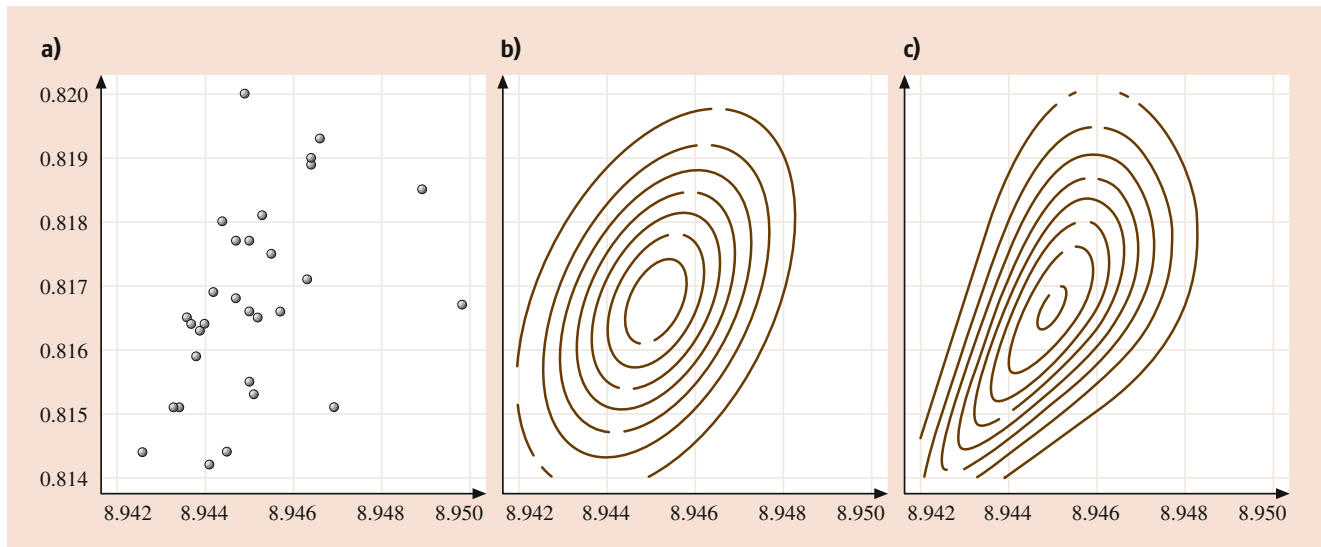

Fig. 46.4 Bivariate process characteristics and parametric fits. (a) scatter plot of the data; (b) contours of bivariate normal fit; (c) contours of bivariate fit with normal margins and Clayton copula

non-nested models without knowing the true model based on Kullback-Leibler information [48].

The T^2 control chart of Lu and Rudy [33] is a phase II chart for single observations to detect any departure of the underlying process from the standard values. Suppose that we observe a random sample of p -dimensional multivariate observations with sample size m . Let \bar{X}_m and S_m be the sample mean vector and sample covariance matrix, respectively. For a future p -dimension multivariate observation X , the T^2 is defined as

$$T^2 = (X - \bar{X}_m)^\top S_m^{-1} (X - \bar{X}_m). \quad (46.29)$$

Under joint normality, it can be shown that the exact distribution of

$$\frac{m^2 - mp}{p(m + 1)(m - 1)} T^2$$

is F with degrees of freedom p and $m - p$. The exact upper control limit for T^2 with level α is then

$$UCL_\alpha = \frac{p(m + 1)(m - 1)}{m^2 - mp} F_{1-\alpha; p, m-p}, \quad (46.30)$$

where $F_{1-\alpha; p, m-p}$ is the $100(1 - \alpha)$ percentile of an F distribution with p and $m - p$ degrees of freedom. In this example, $m = 30$, $p = 2$. The exact upper control limit for T^2 with level α is then

$$\begin{aligned} UCL_\alpha &= 2(30 + 1)(30 - 1)/[30^2 - 2(30)]F_{1-\alpha; 2, 28} \\ &= 2.14F_{1-\alpha; 2, 28}. \end{aligned}$$

With $\alpha = 0.9973$, the control limit $UCL = 15.75$.

When the true copula is a Clayton copula but is misspecified as a normal copula, the control limit in (46.30) can be inaccurate and hence misleading. By comparing the contours of a normal copula model with those of a Clayton copula model in Fig. 46.2, one can conjecture that if the true copula is a Clayton copula, and then $\Pr(T^2 > UCL_\alpha)$ will be greater than its nominal level α , because the bivariate density with Clayton copula is more concentrated on the lower-left part of the plot than the bivariate normal density. In other words, in order to maintain the control level α , one needs to increase the UCL of the T^2 chart. This difference obviously depends on the sample size m and the association parameter of the true Clayton copula. For a given sample size m and a Kendall's τ value, which determines the association strength of a Clayton copula, the control limit of T^2 can be obtained by simulation. Table 46.2 compares the 90%, 95%, 99%, and 99.73% percentiles of T^2 when the true copula is normal and when the true copula is Clayton. The percentiles under Clayton copulas are obtained from 100,000 simulations. The true Clayton copulas are parameterized to give Kendall's τ values 0.2, 0.4, 0.6, and 0.8. From Table 46.2, one observes that the simulated percentiles of T^2 are greater than those based on the F distribution under the normal assumption. The control region based on normal assumption is smaller than expected, which will result in investigating the process more often than necessary when the process is actually in control. The difference increases with the strength of the association.

This example illustrates that a non-normal joint distribution may have important influence on the control limit of the widely used T^2 chart, even when both the margins are normals. The T^2 statistic still measures the deviance from the target, but its distribution is unknown under the non-normal

Table 46.2 Comparison of T^2 percentiles when the true copula is normal and when the true copula is Clayton with various Kendall's τ . The percentiles under Clayton copulas are obtained from 100,000 simulations

Percentiles	Normal Copula	Clayton copula			
		$\tau = 0.2$	$\tau = 0.4$	$\tau = 0.6$	$\tau = 0.8$
90%	5.357	5.373	5.416	5.590	5.868
95%	7.150	7.253	7.468	8.061	9.396
99%	11.672	12.220	13.080	15.764	23.526
99.73%	15.754	16.821	18.611	24.173	41.123

Fig. 46.5 Error rates ($\times 10^5$) of 16 magneto-optic data storage disks measured every 500 hours

model. A comprehensive investigation of multivariate process control using copula is a future research direction.

46.5.2 Degradation Analysis

Performance degradation data has repeated measures over time for each test unit [see, e.g., 36, chapter 13]. These repeated measures on the same unit are correlated. There is a voluminous statistical literature on analysis of repeated measurements [see, for example, 5]. Analysis of such data has been implemented in popular statistical softwares, for example, PROC MIXED of the SAS system [30] and the nlme package [40] for R and Splus. Continuous response variables are generally assumed to be normally distributed, and multivariate normal distribution is used in likelihood-based approaches. The following example shows that a multivariate gamma distribution with normal copula can provide much better fit to the data than a multivariate normal distribution.

Degradation data on block error rates of 16 magneto-optic data storage disks are collected every 500 hours for 2000 hours at 80°C and 85% relative humidity [38]. Figure 46.5 shows these error rates at all five time points. A degradation analysis often needs to fit a curve for the degradation trend

Table 46.3 IFM fit for all the margins using normal and gamma distributions, both parameterized by mean and standard deviation. Presented results are log-likelihood (Loglik), estimated mean, and estimated standard deviation (StdDev) for each margin under each model

Time in 500 h	Normal margins			Gamma margins		
	Loglik	Mean	StdDev	Loglik	Mean	StdDev
0	-0.484	0.565	0.062	2.568	0.565	0.054
1	-0.526	0.617	0.063	2.538	0.617	0.054
2	-2.271	0.709	0.070	-0.125	0.709	0.064
3	-4.441	0.870	0.080	-3.269	0.870	0.078
4	-6.996	1.012	0.094	-5.205	1.012	0.087

in order to do predictions at unobserved time points. Before choosing a curve to fit, we first do exploratory data analysis using the two-step IFM method to look into parametric modeling for each margin and for copula separately.

Separate parametric fit for each margin is the first step of the IFM approach in Sect. 46.4. Two parametric models for each margin are used: normal and gamma. To make the parameters comparable across models, the gamma distribution is parameterized by its mean μ and standard deviation σ , giving density function:

$$f(x; \mu, \sigma) = \frac{1}{\Gamma(\alpha)\beta^\alpha} x^{\alpha-1} e^{-\frac{x}{\beta}}, \quad (46.31)$$

where $\alpha = \mu^2/\sigma^2$ and $\beta = \sigma^2/\mu$. Table 46.3 summarizes the separate parametric fit for each margins using normal and gamma distributions. For all the margins, the gamma distribution fit yields higher log-likelihood than the normal distribution fit. The estimated mean from both models is the same for the first three digits after the decimal point. The estimated standard deviation is noticeably lower in the gamma model, especially at earlier time points where the data are more skewed and heavier tailed. These estimates are consistent with the descriptive statistics of each time point, suggesting that the mean error rate is increasing over time, and their standard errors is increasing with the mean level.

Given the parametric fit for each margins, we can explore copula fitting in the second step of IFM. Due to the small number of observations, we choose single parameter normal copulas with three dispersion structures: AR(1), exchangeable, and Toeplitz. In particular, with $p = 5$, the dispersion matrices with parameter ρ under these structures are, respectively,

$$\begin{pmatrix} 1 & \rho & \rho^2 & \rho^3 & \rho^4 \\ \rho & 1 & \rho & \rho^2 & \rho^3 \\ \rho^2 & \rho & 1 & \rho^2 & \rho^2 \\ \rho^3 & \rho^2 & \rho & 1 & \rho \\ \rho^4 & \rho^3 & \rho^2 & \rho & 1 \end{pmatrix}, \quad \begin{pmatrix} 1 & \rho & \rho & \rho & \rho \\ \rho & 1 & \rho & \rho & \rho \\ \rho & \rho & 1 & \rho & \rho \\ \rho & \rho & \rho & 1 & \rho \\ \rho & \rho & \rho & \rho & 1 \end{pmatrix}, \quad \text{and} \quad \begin{pmatrix} 1 & \rho & & & \\ \rho & 1 & \rho & & \\ & \rho & 1 & \rho & \\ & & \rho & 1 & \rho \\ & & & \rho & 1 \end{pmatrix}. \quad (46.32)$$

Table 46.4 IFM and CML fit for single parameter normal copulas with dispersion structures: AR(1), exchangeable, and Toeplitz

Dispersion Structure	IFM Fit				CML Fit	
	Normal margins		Gamma margins		Empirical margins	
	Loglik	$\hat{\rho}$	Loglik	$\hat{\rho}$	Loglik	$\hat{\rho}$
AR(1)	39.954	0.917	66.350	0.892	10.380	0.964
Exchangeable	38.618	0.868	62.627	0.791	9.791	0.942
Toeplitz	23.335	0.544	39.975	0.540	5.957	0.568

Table 46.4 summarizes the log-likelihood and the estimated association parameter ρ for the given estimated margins in Table 46.3. Note that the log-likelihood values are not comparable across models with different margins because the data being used in the estimation are different. They are comparable when the margins are modeled the same. For both normal margins and gamma margins, the AR(1) structure gives the highest log-likelihood value. The estimated parameter is about 0.9, indicating high dependence among repeated measurements.

Table 46.4 also presents the normal copulas estimation using the CML method. No parametric distribution is assumed for each margin. The empirical distribution is used to transform the observations of each margin into uniform variables in $[0, 1]$, which are then used in (46.28). The CML fit also shows that the AR(1) structure gives the highest log-likelihood and that the within disk dependence is high. Based on these exploratory analysis, the AR(1) structure is used for the dispersion matrix of normal copula in an exact ML analysis.

We now present the exact ML estimation of a degradation model. For the sake of simplicity, we use a linear function of time to model the mean $\mu(t)$ and a linear function of $\mu(t)$ to model the logarithm of the standard deviation $\sigma(t)$. That is,

$$\mu(t) = \phi_0 + \phi_1 t, \tag{46.33}$$

$$\log \sigma(t) = \psi_0 + \psi_1 [\mu(t) - 1.0]. \tag{46.34}$$

where $\phi_0, \phi_1, \psi_0,$ and ψ_1 are parameters and the function of $\log \sigma(t)$ is centered at 1.0 for easier predictions of the variance at higher error rates. Two parametric models are considered for the repeated error rates: (1) multivariate normal and (2) multivariate gamma via a normal copula. Note that the two models both uses the normal copula. The marginal distributions of the two models at time t are both parameterized by mean $\mu(t)$ and standard deviation $\sigma(t)$ for comparison purpose. Similar parameterization has been used in Lambert and Vandenhende [29] and Frees and Wang [15].

Table 46.5 summarizes the maximum likelihood estimate of the parameters and their standard errors for both models. These estimates for both marginal parameters and the copula parameter are virtually the same or very close to each other. However, the standard errors of these estimates are noticeably smaller in the multivariate gamma model. The maximized

Table 46.5 Maximum likelihood results to the disk error rate data. Parameter estimates, standard errors and log-likelihood are provided for both the multivariate normal model and the multivariate gamma model with a normal copula. The second entry of each cell is the corresponding standard error

Model	Marginal parameters				Copula Parameter	Loglik
	Mean		StdDev.			
	ϕ_0	ϕ_1	ψ_0	ψ_1	ρ	
Normal	0.564	0.099	-0.849	1.439	0.899	34.719
	0.057	0.019	0.262	0.557	0.034	
Gamma	0.564	0.101	-0.986	1.383	0.900	48.863
	0.051	0.015	0.185	0.442	0.033	

Fig. 46.6 Predictive density of disk error rate at 2500 h. The solid line is from the gamma model; the dashed line is from the normal model

log-likelihood from the gamma model is much higher than that from the normal model. Given that both models have the same number of parameters, the multivariate gamma distribution fits the data much better.

The difference between the two models can also be illustrated by their predictive density of the error rate at 2500 h. Figure 46.6 presents the densities of the error rate at 2500 h using the estimated mean $\mu(2500)$ and $\sigma(2500)$ obtained with $\hat{\phi}_0, \hat{\phi}_1, \hat{\psi}_0,$ and $\hat{\psi}_1$. The normal model gives mean 1.058 and standard deviation 0.465, while the gamma model gives mean 1.070 and standard deviation 0.411. Although the mean values are close, the gamma model gives small standard deviation. It captures the skewness and long tail of the data.

46.6 Conclusion

This chapter reviews multivariate modeling with copulas and provides novel applications in engineering. Multivariate distribution construction using copulas and their statistical inferences are discussed in detail. Engineering applications are illustrated via examples of bivariate process control and degradation analysis, using existing data in the literature. Copulas offer a flexible modeling strategy that separates the dependence structure from the marginal distributions. Multivariate distributions constructed with copula apply to a much wider range of multivariate scenarios than the traditionally assumed multivariate normal distribution. A publicly available R package `copula` [22] facilitates methods development applications.

Some important topics about copulas are not discussed in this chapter. Survival function is of great concern in failure time data analysis. Similar to (46.5), a multivariate survival function can be constructed from via a copula with

$$S(x_1, \dots, x_p) = C\{S_1(x_1), \dots, S_p(x_p)\},$$

where S is the joint survival function and $S_i(t) = 1 - F(t)$ is the i th marginal survival function, $i = 1, \dots, p$. In this setting C is called a survival copula. Censoring presents an extra difficulty for multivariate failure time data analysis. Georges et al. [19] gives an excellent review on multivariate survival modeling with copulas. This chapter has focused on parametric copula models. Standard inferences of the maximum likelihood method can be applied under the usual regularity conditions. However, which copula to choose and how well it fits the data are important practical problems. Diagnostic tools, particularly graphical tools, can be very useful. See Hofert et al. [22] for a recent review.

Copulas have had a long history in the probability literature [42]. Recent development and application in insurance, finance, and biomedical research have been successful. With this chapter, it is hoped to encourage engineering researchers and practitioners to stimulate more advancement on copulas and seek more applications. Indeed, more engineering applications of copulas have appeared since the first version of this chapter [51], including multivariate process control [e.g., 47] and degradation analysis [e.g., 37], among others. Compared to other fields such as finance and hydrology, however, there seem to be potential to take fuller advantage of copulas in engineering applications.

Abstract

In this chapter the methodology of risk assessment and decision making in the field of environmental security is analyzed in view of complex novel threats and challenges connected with development of important multiscale tendencies of global climate and environmental changes, globalization, decentralization, and social transformation. To provide a methodological basis for increasing the effectiveness of environmental security management, a number of tasks were analyzed. A nonparametric two-stage method of multi-source data coupling and spatial–temporal regularization is proposed and discussed. Next, an approach to multiscale local and global model integration based on the modified

ensemble transform Kalman filtration procedure is proposed. An approach to a risk assessment based on the nonparametric kernel analysis of coherent complex measures of multidimensional multivariate distributions is then proposed. A decision making approach in the field of environmental risks analysis using satellite data and multi-model data is also considered and discussed. A number of important algorithms is described. Finally, the capabilities, limitations, and perspectives of the proposed methods and algorithms are discussed.

47.1 Introduction

The modern global community is facing complex novel threats and challenges connected with development of important multiscale tendencies of global climate and environmental changes, globalization, decentralization, and social transformation [1, 2]. Development of these tendencies not only generates new types of nexus, nonlinear interdependencies, and risks such as systems or chain risks, but also limits the applicability of traditional approaches to risk assessment [3, 4].

On the one hand, our understanding of multiscale and multiphysics catastrophic drivers is becoming more deep and comprehensive, which allows us to estimate a propagation of dangerous processes more accurately and correctly. as

Also, using modern GIS technologies and satellite observation leads to the increasing correctness of an estimation of the damage – spatial and temporal distribution of the infrastructure, houses, and other assets [4].

However, the number of resulting errors and, especially, uncertainties, is still high, and this substantially limits our ability to estimate risks. It is possible to say that the usual approach to analysis of risks in complex socio-environmental systems no longer leads to the correct assessment of losses, and requires application of significant fitness functions in every case. Studies show that the accuracy, correctness, reliability, and applicability of risk assessments vary widely depending on the locality.

This situation requires new tasks in the field of socio-environmental security to be formulated, and a new approach to operating with new comprehensive multisource data to be developed [5].

To provide a methodological basis for relatively reliable public safety from environmental dangers caused by natural or technological disasters, to support the state of human–environment dynamics, which includes restoration of the environment damaged by negative human behavior, to support the cycling of natural resources to products, to waste, to natural resources, to maintain the physical surroundings of society for its needs, aiming at the protection of society from social instability due to environmental degradation [5], it is necessary to propose a complex method to estimate the complex environmental risks and decision making, taking into account diverse multisource information.

Implementation of nonparametric methods for the analysis of complex multiscale, multicomponent, and multiphysics systems is widespread practice to obtain quantitative assessments of many important parameters, including risks [6]. In the context of novel threats, the key question is the methodology of application of these methods in view of the diversity of data sources.

Different data available have a different nature and require different approaches to be included in the decision-making process. Data from statistics, and from remote and direct observations and measurements should be combined, regularized, and also interpreted, verified, and calibrated using the wide range of local and global natural and data-assembling models, which should be harmonized (Fig. 47.1). This whole mass of data may be a basis for risk assessment and decision-making approaches in the field of socio-environmental security.

This methodology requires the development of interlinked approaches to multisource data analysis and regularization, to multiscale model integration, to multidriver risk assessment, and to decision making in complex multiphysics systems. In this chapter, such approaches will be considered.

47.2 Method of Nonparametric Regularization of Multisource Data Distributions for the Analysis of Security and Risk Parameters

The experience of study of the genesis, expansion, distribution of disasters, as well as the methods of assessment of the impact of the disasters to the socio-ecological systems, can lead to several important conclusions [7].

Analysis (including mapping) of the spatial and temporal distributions of varied types of disasters and data obtained from different sources is a very difficult task, and the direct comparison of these distributions is not entirely the correct method of analysis, first, because the long-term trends in changes in the distribution of certain types of drivers of disasters and their spatial and temporal scales obey different laws and do not coincide [8]. In most usual cases, for the assessment of socio-ecological system resilience, it is necessary to assess the overall danger from all types of natural (as well as from some types of technological) disaster. This requires the various driving forces, data from varied sources with different spatial and temporal scales, to be analyzed, and, thus, the different distributions of physical and economic parameters. This situation necessitates the determination of the measure of statistical distributions of available data (observations, measurements, archives, etc.), to the different spatial and temporal distributions of data.

Second, available data (statistics, archival records) usually have significant corrections, modifications, and errors. Thus, the data should be spatially and temporally regularized to reduce nonlinear uncertainties and errors.

To solve these problems – to obtain statistically reliable distributions of the disaster parameters per area unit during a certain period of time – a nonparametric data regularization algorithm may be proposed.

From the viewpoint of statistics, the proposed method may be presented as the following [8].

Correct statistical analysis requires the set of data x_i with controlled reliability, which reflects the distribution of investigated parameters over the study area during the whole observation period (taking into account variances in reliability of observation and archive data x_t). The set of observation data x_t ($x_t \in R^m$) consists of multisource data: historical records, archives, observations, measurements, etc., including data with sufficient reliability x_j ($x_j \in R^m$), where $j = 1, \dots, N$. The set x_t also includes observed and detected satellite indicators. The problem of the determination of controlled quality and reliability of the spatial–temporal distribution of the investigated parameters x_i might be solved within the framework of tasks of multivariate random processes analysis and multidimensional processes regularization [9].

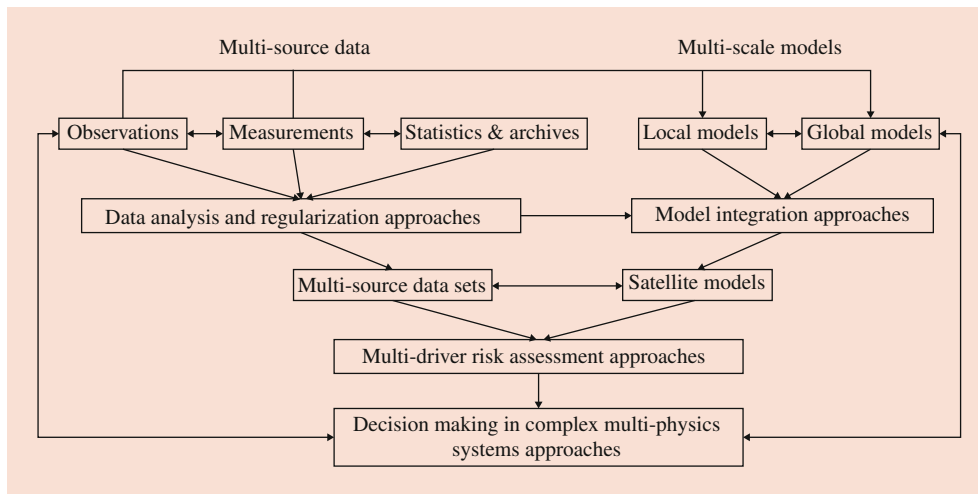

Fig. 47.1 Methodology of nonparametric methods implemented in tasks of socio-environmental security

Required regularization may be provided in different ways. If we are able to formulate a stable hypothesis on the distribution of the reliability of regional archives data within the framework of the defined problem we may be able to propose a relatively simple way of determining investigated parameters distributions $x_t^{(x,y)}$ toward distributions on measured sites x_t^m based on [10]:

$$x_t^{(x,y)} = \sum_{m=1}^n w_{x,y}(\tilde{x}_t^m) x_t^m, \quad (47.1)$$

where the weighting coefficients $w_{x,y}(\tilde{x}_t^m)$ are determined through the minimum task as:

$$\min \left\{ \sum_{m=1}^n \sum_{x_t^m \in R^m} w_{x,y}(\tilde{x}_t^m) \left(1 - \frac{x_t^m}{\tilde{x}_t^m} \right)^2 \right\}, \quad (47.2)$$

according to Cowpertwait [11]. Here, m is the number of records/points of measurements or observations; n is the number of observation series; x_t^m is the distribution of observation data; R^m is the set (aggregate collection) of observations; and \tilde{x}_t^m is the mean distribution of the measured parameters. This is the simple way of obtaining a regular spatial distribution of analyzed parameters over the study area, to which we can apply further analysis, in particular, temporal regularization.

A further regularization step should take into account both the observation distribution of temporal nonlinearity (caused by the imperfection of the available statistics) and the features of temporal–spatial heterogeneity of data distribution caused by the systemic complexity of the studied phenomena – natural and technological disasters. According to Mudelsee et al., Lee et al., and Villez et al. [12–14], the kernel-based

nonlinear approaches are quite effective for the analysis of such types of distributions.

Let us formulate the following task: using the method of data regularization, reduce the data of observations, measurements, and archive records received at random points, at random times, with uncertain accuracy regarding the true (most probable) state of the studied system.

The proposed two-step nonparametric regularization method is based on modified kernel principal component analysis (KPCA) [15–17].

First, it is necessary to find a set X , which closely corresponds to all available data distributions. If there are no additional assumptions about X , this task may be presented as the distribution of data in the discrete space H using the mapping function $\Phi: X \rightarrow H, x \mapsto \Phi(x)$. In particular, on the Hilbert space, this function will be presented as $\Phi: X \rightarrow \mathfrak{R}^X, x \mapsto K(\cdot, x)$. The correspondence of the resulting distribution of the input data will be determined by the point product of this space, which can be defined using the appropriate function: $K: X \times X \rightarrow \mathfrak{R}, (x, x') \mapsto K(x, x')$, called the kernel function, and all $x, x' \in X, K(x, x') = \langle \Phi(x), \Phi(x') \rangle_H$.

In the most usual cases the multisource data may be presented as the Gaussian random process with distribution $f: X \rightarrow \mathfrak{R}$, with mean $m: X \rightarrow \mathfrak{R}$, and with the covariation function $\mathbf{K}: X \times X \rightarrow \mathfrak{R}$. In this case $m(\mathbf{x}) = E[f(\mathbf{x})]$, and $\mathbf{K}(\mathbf{x}, \mathbf{x}') = E[(f(\mathbf{x}) - m(\mathbf{x}))(f(\mathbf{x}') - m(\mathbf{x}'))]$. A covariation matrix will determine a distribution of the vector of output, regularized data $f_x = (f(x_1), \dots, f(x_n))^T \approx N(\mathbf{0}, \mathbf{K}_{xx})$, which is the multivariate Gaussian distribution. In this case, covariation will define a form of the data distribution; thus, for the Gaussian processes a covariation will play the role of the kernel function.

Therefore, the task of regularization may be presented through the covariation matrix C as:

$$\min_{f \in H} \frac{1}{2} \|f\|_H^2 + C \sum_{i=1}^n \max \{0, \max (\Delta (x'_i, x') - (f(x_i, x'_i) - f(x_i, x')))\}, \tag{47.3}$$

where $f(\cdot, \cdot) = \sum_{i=1}^N \sum_{x \in X} \alpha_{ix} K((\cdot, \cdot), (x_i, x'))$.

If principal components algorithms (PCAs) will be used, the task of solving the system of equations:

$$C v_k = \lambda_k v_k, \tag{47.4}$$

should be formulated. The decomposition of eigenvalues of the empirical matrix of covariance:

$$C = E[(x - E(x))(x - E(x))^T], \tag{47.5}$$

should be executed. In the general case of Gaussian processes this solution may be presented as:

$$C v_k = \frac{1}{n} \sum_{i=1}^n \Phi(x_i) \Phi(x_i)^T v_k = \lambda_k v_k, \tag{47.6}$$

where $v_k = \sum_{i=1}^n \alpha_{ki} \Phi(x)$, $K\alpha = \lambda\alpha$, and values x for any principal component k may be calculated as:

$$(v_k, \Phi(x)) = \sum_{i=1}^n \alpha_{ki} K(x, x_i). \tag{47.7}$$

Thus, within the framework of this approach the algorithm of nonlinear regularization might be described as the following rule:

$$x_i = \sum_{i=1}^N \alpha_i^k \tilde{k}_t(x_i, x_i). \tag{47.8}$$

In this equation, the coefficients α selected according to the optimal balance of the relative validation function and the covariance matrix, for example, as [13]:

$$C^F v = \frac{1}{N} \sum_{j=1}^N \Phi(x_j) \Phi(x_j)^T \cdot \sum_{i=1}^N \alpha_i \Phi(x_i), \tag{47.9}$$

where the nonlinear mapping function of input data distribution Φ is determined as [15]:

$$\sum_{k=1}^N \Phi(x_k) = 0, \tag{47.10}$$

and \tilde{k}_t indicates the mean values of the kernel matrix $\mathbf{K} \in R^N$ ($[\mathbf{K}]_{ij} = [k(x_i, x_j)]$). The vector components of the matrix are determined as $\mathbf{k}_t \in R^N$; $[\mathbf{k}_t]_j = [k_t(\mathbf{x}_t, \mathbf{x}_j)]$. The matrix is calculated according to the modified rule of Cowpertwait and Mudelsee et al. [11, 12] as:

$$\mathbf{k}_t(\mathbf{x}_i, \mathbf{x}_t) = \left\langle \rho_{j,t}^{x_j} (1 - \rho_{j,i})^{x_j} \right\rangle, \tag{47.11}$$

where ρ indicates empirical parameters, selected according to the classification model of study phenomena [14].

Using the described algorithm it is possible to obtain regularized spatial-temporal distribution of the investigated parameters over the whole observation period with rectified reliability [12]. These distributions of multisource data should be used for the further modeling of risks.

It may be noted that the obtained regularized distributions can also be interpreted as the average for the observation interval probability of disaster occurrence in a certain area of the study territory.

47.3 Multimodel Data Utilization in Risk Assessment Tasks: On the Method of Local Model Integration into Global Models

The task of refinement of large-scale scenarios based on global models using local modeling should be considered. This task is fundamentally different from so-called regionalization of climatic, ecological, or runoff models. The task of the regionalization of models in the traditional sense is usually reduced to the “downscaling” tasks, or to the change (usually a decrease) in the spatial and temporal dimensions of the distributions obtained from the models. The proposed approach includes refinement of calculations based on the use of additional data sets not included in the standard model (typically, global models include 5–10% of the available measurements in the research area, which is obviously not sufficient for the calculation of local forecasts).

The principal complexity of this problem lies in the fact that climatic model parameters are usually calculated in the so-called geo-space, or, by definition, in the quasi-two-dimensional space of the earth’s surface characterized by closure, positive curvature (convexity), quasi-fractality, and anisotropy in geophysical fields (for example, in the gravitational, magnetic field of the Earth). Geospatial location is determined by spherical (latitude and longitude) or rectangular coordinates. The anisotropy of the geo-space is expressed in the unevenness of the horizontal and vertical directions (vertical movement is fairly complicated), and results in the sphericity of the Earth’s structure, as well as latitudinal

and longitudinal directions, the manifestation of which is latitudinal zonation. This determines the specific topology of data allocations for model calculations. In this situation, the results of observations are the sets of data obtained at certain points, and thus, although they are geo-referred, they do not necessarily correspond to all basic postulates that follow from the definition of geo-space.

From a mathematical viewpoint, the problem is to include the observation data (a priori stochastic data, which must be described by completely different methods and which are not necessarily complete) into the set of calculation data with the given topology (into the model data calculated on geo-space). In the general case, solving this task should solve the topological problem of bringing the topology of one set (with a given topology) with the number of sets of random data with an a priori indefinite topology.

In our case, the topology of the set of model data is given by the definition of geo-space, although the topology of sets of observational data is a priori not defined [18]. Based on the general theory of obtaining and analyzing data from experiments [9], we can analyze the data of current meteorological measurements in terms of the theory of Hilbert spaces, in which limited and unrestricted operators, and random elements and operators are defined, and thus the elements of linear and convex programming are determined. Thus, in our case, the use of the theory of finite-dimensional Hilbert spaces for the analysis of meteorological measurement data distributions may allow us to obtain results that will enable us to determine the topology of the corresponding sets and integrate data into sets with the topology, defined in the geo-space.

The representation of observations in Hilbert spaces allows us to stay within the framework of the so-called local simulation and thus avoid the need to determine boundary conditions dependent on the data structure [19]. In the future, this frees us from the need to harmonize the boundary conditions of two different types of data. Thus, the mathematical problem is reduced to finding the correct method for integrating meteorological observations, in the general case presented in the Hilbert random spaces, and simulation data presented as uniform normalized sets of data defined in the geo-space with the given topology.

Figuratively, this task can be represented as the gluing of patches of arbitrary shape and size on the surface of a round ball. In this case, the patches must be adjusted to each other, the total area of the patches is much smaller than area of the ball, the patches can have any shape and topology, and the ball has a finite elasticity, i.e., it can never change the positive curvature. The method proposed in this section is that the patches are pre-smoothed, their edges are cut and fitted to each other, after which they are consistently glued to the surface of the ball.

Thus, we propose to embed into the model the additional data not used during the construction of the model, and recalculate the necessary parameters on a grid that meets the needs of local simulation and is based on available data. This means that, unlike traditional downscaling, the proposed approach is based not on the results of simulation and on the properties of the resulting sets (with a substantially limited spatial and temporal resolution), but on the data of regional measurements. Therefore, the local data become decisive for the regionalization of the model in this approach, which is a fundamental difference.

Thus, the problem is divided into the problem of reducing the method of observing analysis and obtaining data measurement distributions, and the task of integrating the obtained reduced data into the model distributions with subsequent calculation of parameters on a reduced grid.

When we solve the problem of specifying the model on the sets of observational data presented as the Hilbert spaces in part of the reduction of the method of observation analysis, we will consider sets of data $\xi(x_{ij})$, measured within the framework of the method presented by linear operators $A_0 \rightarrow A$. To refine A , with sufficiently known (known and/or controlled epistemic reliability) signal $f'(x_{ij})$, represented by a random vector with a known covariance operator $F \in (\mathfrak{R} \rightarrow \mathfrak{R})$, $Fx = Ef(x, f)$, $x \in \mathfrak{R}$, we will be measuring the sets of variables [9]:

$$\xi' = Af' + v', \quad (47.12)$$

where v is a random element of a Hilbert space $\tilde{\mathfrak{R}}$ with a correlation operator $\Sigma x = Ev(x, v)$, $x \in \tilde{\mathfrak{R}}$, $Ev = 0$, which determines the error, or a “noise” – the measure of aleatoric uncertainty of measurements; ξ' indicates measurements refined with the model ξ ; E indicates mathematical expectation; A indicates the methodology, or the “model of measurements” are random linear operators (such that, $A \in B\mathfrak{R} \rightarrow \tilde{\mathfrak{R}}$, $x \in \mathfrak{R}$, $y \in \mathfrak{R}$, whereas the function $f(Ax, y) = f(x, A^*y)$) defines the method of data transformation.

If we introduce any measurable set M ($M \subset \tilde{\mathfrak{R}} \text{ B } \mathfrak{R}$), on which we define a random vector η , that describes the distribution of regularized data with a certain reliability, then in relation to it the problem of determining the methodology for integrating observation data into a general model, that is, refinement (reduction) operators, can be defined as [20]:

$$A_\eta = E(A|\eta), J_\eta = \left(E((A - A_\eta) * F(A - A_\eta) * |\eta) \right). \quad (47.13)$$

Here, F is a covariance data operator; J is the operator of uncertainty.

In this case, the task of reducing the data distributions can be formulated as:

$$\begin{aligned} E \left(\inf \left\{ E \left(\|R'\xi - Uf\|^2 | \eta \right) R' \in \left(\mathfrak{N} \rightarrow U \right) \right\} \right) \\ = E \left(E \left(\|R_\eta \xi - Uf\|^2 | \eta \right) \right) = E \|R_\eta \xi - Uf\|^2, \end{aligned} \tag{47.14}$$

where U is the orthogonal projector to the subspace \mathfrak{N} . Thus, we are talking about the determination of a random operator $R' = R_\eta$, which corresponds to the condition (47.20):

$$\begin{aligned} \inf \left\{ E \left(\|R'\xi - Uf\|^2 | \eta \right) R' \in \left(\mathfrak{N} \rightarrow U \right) \right\} \\ = E \left(\|R_\eta \xi - Uf\|^2 | \eta \right). \end{aligned} \tag{47.15}$$

After solving this problem, we obtain mutually coherent distributions of observation data with coordinated boundaries, based on the results of the analysis of data from individual measurements. The resulting sets, represented on Hilbert spaces, can be integrated (reduced) into the global models of any complexity with current topological properties.

Thus, at the first stage, the problem is reduced to the determination of regularized distributions of observation data. In addition, it should be noted that the problem of estimating the uncertainties of the distributions obtained is still urgent.

The task of obtaining the sets of statistically reliable distributions that are regularized in space and time of required indicators from the observed data (for example, from meteorological stations) in the research area can be solved using the proposed [14] algorithm for nonlinear spatial–temporal data regularization based on the analysis of the main components with the modified method of the smoothing nonlinear kernel function, kernel principal component analysis (KPCA) [8]. Using the proposed algorithm we obtain a regularized spatial–temporal distribution of the characteristics of the investigated parameters throughout the observation period with smooth reliability, taking into account all sources of observation [8, 14].

In accordance with the above general approach, the task is to integrate a plurality of data presented in the form of Hilbert spaces with given linear transformation operators to a set of data with a given topology (a set of model decisions).

Thus, based on the results of data analysis within the framework of the described method, we obtain a set of normalized distributions $\xi_t = A_t f(x_t) + v_t$, where t is the time (defined as the modeling step for a plurality of model data and as a measure of the data set). In the future, it can be proposed to jointly analyze the modeling and observation data in the modified ensemble transform Kalman filter (ETKF) modification method [21].

In this case, we assume that the vectors of the true state of the system x at time k are determined in accordance with the general law:

$$x_t = F_t x_{t-1} + B_t u_t + w_t, \tag{47.16}$$

where F_t is the matrix of the evolution of the system, or the simulated effects on the vector x_{t-1} at the moment $t - 1$; B_t is the matrix of controls, measured by the effects u_t on vector x ; w_t is a random process with the covariant matrix Q_t . In this way, we introduce the description of the model distributions F_x and the observation data B_t .

Let us determine the extrapolation value of the vector of the true state of the system by evaluating the state vector in the previous step:

$$\hat{x}_{t|t-1} = F_t \hat{x}_{t-1|t-1} + B_t u_{t-1}. \tag{47.17}$$

For this extrapolation value of the vector of the true state one can determine the general form of the covariance matrix:

$$P_{t|t-1} = F_t P_{t-1|t-1} F_t^T + Q_{t-1}. \tag{47.18}$$

The difference between the estimated (extrapolation) value of the vector of the true state of the system and that obtained at the appropriate simulation step can be estimated as:

$$\Delta \hat{x}_t = \xi_t - A_t \hat{x}_{t|t-1}, \tag{47.19}$$

a covariance matrix of deviation:

$$S_t = A_t P_{t|t-1} A_t^T + R_t. \tag{47.20}$$

Then, based on the covariance matrices of extrapolation to the state vector and the measurements, we introduce a matrix of optimal coefficients of the Kalman amplification:

$$K_t = P_{t|t-1} A_t^T S_t^{-1}. \tag{47.21}$$

Using this, we will adjust the extrapolation values of the vector of the true state of the system:

$$\hat{x}_{t|t} = \hat{x}_{t|t-1} + K_t \Delta \hat{x}_t. \tag{47.22}$$

Also, we introduce a geo-referred filter for the distribution of the vector of the state x_{ij} , which will depend on geographically bound j , i and in the general case, this will not depend on the time t :

$$(x_{ij})_t = (x_{ij})_t^\alpha = (x_{ij})_t \alpha_{ij}. \tag{47.23}$$

Here, the coefficients α are chosen according to the introduced KPCA algorithm [13], according to the rule of estimat-

ing the optimal balance of the mutual validation function and the covariance matrix:

$$C^F v = \frac{1}{N} \sum_{j=1}^N \Phi(x_j) \Phi(x_j)^T \cdot \sum_{i=1}^N \alpha_i \Phi(x_i), \quad (47.24)$$

where the nonlinear function of the data distribution Φ corresponds to conditions $\sum_{k=1}^N \Phi(x_k) = 0$, and \tilde{k}_t is the average value of kernel matrix $\mathbf{K} \in R^N$ ($[\mathbf{K}]_{ij} = [k(\mathbf{x}_i, \mathbf{x}_j)]$). This matrix consists of kernel vectors $\mathbf{k}_t \in R^N$, $[\mathbf{k}_i]_j = [k_t(\mathbf{x}_i, \mathbf{x}_j)]$, and is calculated according to modified rule $\mathbf{k}_t(\mathbf{x}_i, \mathbf{x}_t) = \left\langle \rho_{j,i}^{x_j} (1 - \rho_{j,i}^{x_j}) \right\rangle$, where ρ indicates empirical coefficients, selected from the model of the studied phenomena [8].

If we apply this filter and remember to reconcile the sets of data, we can offer the form of the covariance matrix P^a to analyze the actual errors based on the form of the covariance matrix of the extrapolated value of the state vector of the P^f system and the matrix of covariance of the observational data R :

$$P^a = P^f - P^f A^T (A P^f A^T + R)^{-1} A P^f. \quad (47.25)$$

Thus, we obtain a tool for optimizing the calculation of the matrix of optimal coefficients of the Kalman amplification and, accordingly, correction of the extrapolation values of the vector of the true state of the system with regard to the aggregate data of modeling and observations.

After completing the data integration procedure, we can calculate the necessary parameters by the algorithm [8]:

$$x_t^{(ij)} = \sum_{m=1}^n w_{ij}(\tilde{x}_t^m) x_t^m, \quad (47.26)$$

where $w_{ij}(\tilde{x}_t^m)$ is the weighting coefficient, determined by the rule [8, 13]:

$$\min \left\{ \sum_{m=1}^n \sum_{x_t^m \in R^m} w_{ij}(\tilde{x}_t^m) \left(1 - \frac{x_t^m}{\tilde{x}_t^m} \right)^2 \right\}. \quad (47.27)$$

In this equation, m is the number of experiments conducted; n is the number of data sources; x_t^m is the distribution of the results of observations; R^m is the set of data; \tilde{x}_t^m is the corrected extrapolation values of the vector of the true state of the system by aggregate modeling and observational data.

Therefore, we obtain a regular spatial distribution of measurable characteristics in the local study area, both as a result of model calculations, and taking into account regional measurements on a grid that corresponds to the distribution of data, that is, it has a much better resolution than the usual model.

47.4 Approach to the Risk Assessment as the Analysis of Coherent Complex Measures of Multidimensional Multivariate Distributions

The key question of the assessment is the quantification of risk in cases of multidimensional multivariate variables. This case requires a correct assessment of all parts of the loss function. The set of corresponding probabilities p , that is, the sets of quantiles q corresponding to the distribution p should be analyzed and estimated. The distribution function can be continuous (and in this case the function $q(p)$ under the conditions of continuous distribution of p should be analyzed), or discrete (and in this case we obtain a set of N separate values $q(p)$ for each p). In cases where the distributions of the measured quantities and the distributions of the corresponding probabilities p are not known and cannot be represented as linear normal distributions (in most real cases), nonparametric estimation methods should be used.

Nonparametric methods are aimed at risk assessment without applying rigorous assumptions about the properties of the distributions studied. That is, instead of the input of distribution parameters, we estimate the risk by empirical distributions, which stem from the properties of the distributions of data. In relation to parametric methods, nonparametric methods can prevent the risk of a false a priori estimation of distribution, which leads to large errors in the final risk measurements. Nonparametric methods are based on the assumption that the closest values are distributed in the same way as the previous data; thus, we can predict the evolution of the system using the latest data (represented by empirical distributions). The usefulness of nonparametric methods in practice depends on the observance of this assumption in different situations. As practice shows, in most cases this assumption is fulfilled and, thus, nonparametric methods work well. On the other hand, if this assumption is not fulfilled, especially at the boundaries of distributions, nonparametric methods may have sensitive uncertainties, in particular, if distributions have extremes.

Typically, quantile values are derived from histograms of empirical data distributions, which are regularized and specified in various ways. In particular, it is possible to regularize the histograms using kernel methods, which are the most complex of modern nonparametric methods for estimating distributions, and allow smoothing of the toothed histograms without introducing rigorous assumptions about the properties of data distributions.

It is also possible to extend the range of nonparametric estimation methods by including not only empirical statistics known from observations, but also additional data, in particular, artificially constructed distributions. For example, it is possible to construct a separate hypothetical scenario

based on individual data, with a certain probability of its implementation, and to apply a nonparametric method of joint assessment of the empirical (“historical”) and hypothetical (“nonhistorical”) scenario. Inclusion of the consideration of additional, for example, hypothetical distributions, allows us to overcome the main disadvantage of nonparametric estimation methods – their complete dependence on the sets of empirical data and, thus, the weakness in determining extremes. An important tool for studying the mutual dependencies of sets of distributions is the copula function. In Frees and Valdez [22] a general description of the use of copula functions for quantitative risk assessment is presented. These methods are described in more detail in Cherubini et al. [23].

For the assessment of long-term multidimensional interrelations in multivariate distributions, based on the results of the data analysis, it is suggested that the copula might be used in an elliptic form [23]. In particular, based on the analysis of the obtained data, for the further analysis of risks and the definition of strategies for minimization of disaster losses, use of a multidimensional probability distribution function can be proposed that takes into account the identified multivariate internal dependencies in the structure of disaster distributions in the best possible manner.

If the observation distribution can be described by random vector (X_1, X_2, \dots, X_n) with mutual distribution function $F_{X_1}(x_1) F_{X_2}(x_2), \dots, F_{X_n}(x_n)$ and marginal distribution functions $F_{X_1}(x_1) F_{X_2}(x_2), \dots, F_{X_n}(x_n)$, on the hypercube $[0, 1]^n$ a distribution function C with the uniform marginal distributions on the segment $[0, 1]$ can be defined, and the condition $F_{X_1, X_2, \dots, X_n}(x_1, x_2, \dots, x_n) = C(F_{X_1}(x_1), \dots, F_{X_n}(x_n))$ will be fulfilled.

Application of the regularization algorithms allowed the distributions satisfying the stated conditions to be obtained; in addition, the distribution functions F_{X_i} may be presented as continuous for all $i = 1, 2, \dots, n$, and, thus, the distribution function C , which is called the copula, will be defined unambiguously. For our case, the copula can be represented as:

$$C_{v,c}(u_1, u_2, \dots, u_n) = \frac{v\sqrt{|\mathbf{c}|} (v\pi)^n}{v+n} \cdot \frac{\prod_{n=1}^N \frac{(1+\frac{1}{n})^{\frac{v+n}{2}}}{1+\frac{v+n}{2n}}}{\prod_{n=1}^N \frac{(1+\frac{1}{n})^{\frac{v}{2}}}{1+\frac{v}{2n}}} \cdot \int_{\mathbf{x}_1}^{(u_1)} \dots \int_{\mathbf{x}_n}^{(u_n)} \left(1 + \frac{\mathbf{x}_i^{(x,y)}}{\mathbf{c}\mathbf{v}}\right) d\mathbf{x}_i^{(x,y)}, \tag{47.28}$$

where \mathbf{c} is the correlation matrix obtained from analysis of regularized data.

The possibility of the application of this type of copulas to describe the dependencies between the disaster risks is confirmed by studies in the field of finance and insurance,

in particular, Bradley and Taqqu and Rachev et al. [24, 25]. Thus, the proposed formula can be considered with a particular case of the general approach to risk assessment described in Rachev et al. [25].

In this form, we get the opportunity to determine the long-term trends of the interconnected processes and phenomena represented by stochastic observational data [26, 27].

However, one should take into account the fact that the risks in complex cases of describing large multicomponent, multiphysics systems at certain time intervals cannot be adequately described by linear superpositions of scalar correlations [28]. Here, it is necessary to use more complex dependencies, which reflect the complex interconnections in the system, and take into account the spatial-temporal heterogeneity and uncertainty inherent in the studied phenomena.

For analysis of the studied phenomena in intervals, in which its behavior differs essentially from normal, we propose using the following copula [29]:

$$C(u_1, u_2) = \exp\left(-V\left(-\frac{1}{\log u_1}, -\frac{1}{\log u_2}\right)\right), \tag{47.29}$$

$$V(x, y) = \int_0^1 \max\left(\frac{\omega}{x}, \frac{1-\omega}{y}\right) dH(\omega), \tag{47.30}$$

where:

$$H(\omega) = \begin{cases} 0, & \omega < 0; \\ 1/2(\omega(1-\omega))^{-1-\alpha}(\omega^{-\alpha}(1-\omega)^{-\alpha})^{\frac{1}{\alpha-2}} d\omega, & 0 \leq \omega < 1; \\ 1, & \omega \geq 1 \end{cases} \tag{47.31}$$

For analysis of interdependent (or weakly dependent) phenomena, for example, hydrological disasters, we can use the form $0 \leq \omega < 1$.

This formalization allows a better understanding of the interdependencies between climatic parameters and disaster distribution on a regional scale, and additionally allows regularization algorithms for reducing uncertainty to be integrated [30].

For further analysis of risk behavior measurement dependent on number of climatic, ecological, etc., independent heterogeneous parameters, we propose another algorithm. This method is based on the approach to coupled nonparametric analysis of multidimensional, multivariate distributions by kernel copulas [31]. Using this approach it is possible to reduce uncertainties and errors connected with differences in measurement intervals, and to smooth gaps in data distribution [32].

If $K_{u,h}(x)$ is the kernel vector for $u \in [0;1]$ on interval $h > 0$ we can propose accordingly [31]:

$$K_{u,h}(x) = \frac{K(x) (a_2(u, h) - a_1(u, h) x)}{a_0(u, h) a_2(u, h) - a_1^2(u, h)}, \quad (47.32)$$

$$a_l(u, h) = \int_{\frac{u-1}{h}}^{\frac{u}{h}} t^l K(t) dt, \quad l = 0, 1, 2. \quad (47.33)$$

Also, in this case the functions $G_{u,h}(t)$ and $T_{u,h}$:

$$G_{u,h}(t) = \int_{-\infty}^t K_{u,h}(x) dx, \quad (47.34)$$

$$T_{u,h} = G_{u,h}\left(\frac{u-1}{h}\right) \quad (47.35)$$

can be defined.

The distribution function of the complex parameter will be determined by distribution functions of studied parameters X_1, X_2, \dots, X_n using copula C:

$$F(x_1, x_2, \dots, x_n) = C(F_1(X_1), F_2(X_2), \dots, F_n(X_n)). \quad (47.36)$$

Distribution of extremes of the studied parameters will be described by distribution functions $F_i(x)$ corresponding to threshold $x_i > u_i$ as:

$$\hat{F}_i(x) = 1 - \frac{N_{u_i}}{n} \left(1 + \hat{\xi}_i \frac{x - u_i}{\hat{\beta}_i}\right)^{-\frac{1}{\hat{\xi}_i}}, \quad i = 1, 2, \quad (47.37)$$

where ξ indicates the smoothing parameter, and β indicates interdependence parameter ($\beta \in [0,1]$; $\beta = 0$ for independent distributions, and $\beta = 1$ for absolutely dependent distributions).

In this case, the optimal kernel copula estimator may be presented as [8, 33]:

$$\hat{C}(u, v) = n^{-1} \sum_{i=1}^n G_{u,h}\left(\frac{u - \hat{F}_1(X_{i1})}{h}\right) G_{u,h}\left(\frac{v - \hat{F}_2(X_{i2})}{h}\right) - (uT_{u,h} + vT_{u,h} + T_{u,h}T_{v,h}). \quad (47.38)$$

For example, for the area studied in northwestern part of Ukraine, on the base of multiyear statistics an “optimal correlator” between air temperature and disaster frequency was determined: “reduced max temperature” [8]:

$$T_{red} = \left(1 - \frac{\frac{1}{N} \sum_{n=1}^N T_n}{T_{max}}\right) \left(1 - \frac{1}{T_{max} - \frac{1}{N} \sum_{n=1}^N T_{max}}\right). \quad (47.39)$$

Here, N is the number of meteorological measurements, T_n is the measured air temperature, T_{max} is the maximum registered air temperature. This parameter allows more accurate interrelations between the long-term change of climatic indicators and the frequency of hydrological and climatic disasters to be calculated. The approach proposed is more correct relative to the analysis with traditional variables. Depending on the time interval, the multicomponent correlation obtained allows increased accuracy of the assessment of disaster frequency up to 22% [8]. This is an essential value for mid- and long-term regional forecasting.

47.5 Notes on Decision-Making Approaches in Environmental Risk Analysis Using Satellite Data

Despite a well-developed theory, risk assessment remains a complex task with deep uncertainties in many important cases. Especially in such complex cases as socio-environmental tasks, when we are dealing with complex multicomponent and multiphysics systems heterogeneously distributed in time and space.

In the general sense, the risk of R causing damage or potential losses L as a result of disaster occurring with probability p can be estimated as:

$$R_i = L_i p(L_i). \quad (47.40)$$

Or for all assemblage of events $i \in I$ on the interval I : $R = \sum_i L_i p(L_i)$.

In the integral form [34] it is possible to present:

$$R(x, t) = \int f_i(x, \omega) P(x, d\theta), \quad i = 1, \dots, m, \quad (47.41)$$

where $f(x, \omega)$, and $P(x, \omega)$ indicates stochastic functions and random distributions of probable events, which lead to a negative impact. Thus, in the general case, the risk is described as a superposition of several random processes.

In the general case, the definition of the functions $f(x, \omega)$ and $P(x, \omega)$ is a very complex task, which requires the introduction of additional conditions and restrictions. But

application of satellite observations and modeling can help to determine these functions.

Let us interpret the components of the equation of risk $f(x, \omega)$ as a function of propagation of the natural process, which produces hazardous effects on the components of the natural and anthropogenic environment in the considered area, and $P(x, \omega)$ as a function of the impact of individual components and objects of natural and anthropogenic environment in the considered territory under the influence of dangerous influences, according to Ermoliev et al. and Pflug and Werner [34, 35].

Under such an assumption, the risk assessment in each individual case can be reduced to two general cases. In the first case, we accept the impact function of the distribution of vulnerable components over the observation area (for example, vulnerable infrastructure, ecosystem component, etc., obtained from satellite observation), in a certain way ranked by the disaster statistics, and focus on the analysis, and on the verification of the set of features derived from the problem-oriented model of the drivers of a dangerous process.

Otherwise, we confine ourselves to the general definition of the properties of the propagation function, and concentrating on the analysis of the impact function, and on the statistical properties of the distribution of indicators of influence that we can observe. Depending on the specific problem being solved, the first, second path, or a combined approach can be used.

Regarding the methods of integrated information gathering, it should be noted that during the last 40 years, remote sensing and especially satellite observation methods have demonstrated explosive progress, including significant development of its methodology [36, 37]. As long as the basic methodological idea is now based on models of signal formation, the monitoring methods are based on the models of individual indicators, and control of natural processes is based on the analysis of sets of indicators [36, 38]. Our understanding of ecosystem structure and functioning is now more comprehensive and accurate: the complex nexus between the processes and phenomena can be analyzed, the feedback in an multi-agent environment can be simulated, and the integrated dynamics of the processes can be modeled to predict the behavior of multicomponent systems [39]. In this context, the remote sensing methods play a role as a source of information about the behavior of important variables of the used interlinked models. Therefore, remote sensing is now the tool not only for monitoring but also for predictions and forecasts.

Therefore, further evolution of our ecological knowledge, and the development of remote sensing technologies, require further development of the methodology of remote sensing applications, including new methods of data processing and

interpretation, a new foundation for the selection of the sets of interrelated indicators, based on the new ecological models [40]. Utilization of new kinds of indicators may also require new approaches to risk assessment, based on advanced methodology. In particular, this kind of approach should not be based on assessments of mean values and their deviations [41], but should be focused on optimal decision making in a complex multicomponent and multiphysics environment.

Let us consider a formal task. To solve the task of remote sensing data utilization in a multimodel approach to risk assessment for decision making in a complex multicomponent and multiphysics environment as a formal representation, we first need to consider the problem of the models' application to the selection of the optimal set of remote sensing indicators [8].

The initial stage includes the process of forecast generation, which is based on the set of initial a priori assumptions, observed or measured values [42], described as a vector $x = (x^1, x^2, \dots, x^s)$.

The further step is the modeling: model recalculation of these values into a group of core hydrological, biophysical, and climatological series (with $F(x, \varepsilon, y) = 0$, $(x, \varepsilon) \rightarrow y$), collected in a vector y . Next, based on the information from the pair (x, y) , we calculate values for a list of parameters, grouped into what is referred to as the vector of satellite indicator-based models: $z = (z^1, z^2, \dots, z^s)$ (with $z^s = g^s(x, y)$, $(x, y) \rightarrow z^s$).

As a result of the integrated modeling we obtain parameters summarized in the triplet (x, y, z) . This combined vector is a starting point for the modeling of socio-economic, socio-ecological, and risk parameters, as presented in Fig. 47.2 [42].

Usually, we consider a group of S satellite data-based models, labeled $s \in \{1, 2, \dots, s\}$. Each of these equations is such that the endogenous variables z^s can be obtained as an explicit mapping of the core variables $z^s = g^s(x, y)$.

Therefore, the satellite model might be conceptually presented by the time-series (x, y, z) , which will determine the behavior of z_t^s , with a residual term μ_t^s :

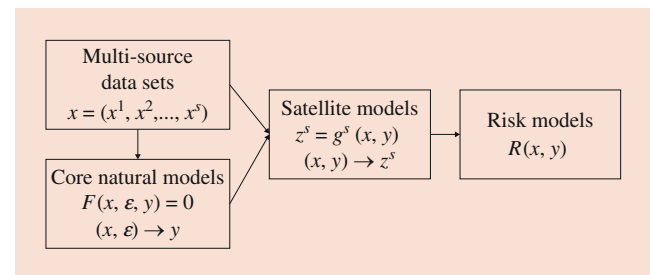

Fig. 47.2 Approach to decision making and risk assessment using multi-source and multimodel data in tasks of socio-environmental security

$$z_t^s = f(x_t, x_{t-1}, \dots, x_{t-L}, y_t, y_{t-1}, \dots, y_{t-L}, z_{t-T}^s, \mu_t^s). \quad (47.42)$$

This presentation of the satellite model in the simple unidirectional time-series form has neither interactions with other variables nor any feedback between z_t^s and the core initial a priori assumptions [40]. Among the wide range of satellite data-based models, the time-series models are well known and widely used, for example, in the form of autoregressive moving average models including, for example, autoregressive lags and/or moving-average components. To find the most usable model of the data-generating process for a given risk metric Z_t a number of standard methodologies may be applied:

$$Z_t = c + \sum_{l=0}^N \beta_l X_{t-l} + \sum_{l=0}^P \rho_l Y_{t-l} + \sum_{l=1}^L \partial_l Z_{t-l} + \sum_{k=0}^K \theta_k \varepsilon_{t-k}. \quad (47.43)$$

In this equation Z_t is a satellite variable vector, X_t is a vector of initial core variables, Y_t is a row vector of the layer of core parameters, ε_t is the stochastic error, and c , β , ρ , and ∂ are the unknown parameters.

It should be noted that in some cases, the approach is sensitive to the used method: for example, using autoregressive methods in the model may lead to a decrease in the impact of the core drivers on the target variables [43]. Therefore, depending on risk metric Z_t and on the type of core and supplementary variable the varied form of Eq. (47.43) may be applied. In particular, for the analysis of climate-related risk an approach based on copula utilization may be used [8].

In the modern paradigm of earth sciences complex risk analysis requires involvement of statistics from a combination of ecology, climatology, hydrogeology, hydrology, and geo-statistics to produce a correct analysis of the statistical properties of the estimated model [8, 42]. Therefore, a variable selection for identification of core drivers of the dynamic behavior of the studied socio-ecological risk variable is a key aspect of satellite model development [8, 42].

It should also be noted that the sensitivity of the approach to the method is varied on different time and spatial scales. For example, despite impressive results of recent years and good fitting of the existing data, models based on data mining, machine learning, or neural networks often fail in long-term forecasts, because they are not able to follow a changing external environment because they lack a theoretical basis. At the same time, because machine learning in environmental security can be interpreted as a nonparametric method of assessment of the high dimensional systems, the proposed approach may also be utilized as a way of adapting the machine-learning methods to separate tasks. It makes sense to assume that the best analytical and prediction approaches

should be based on a combination of statistics and physical models, and should combine geo-ecological models with statistical optimization [42]. Besides, models built this way have the additional benefit of ease of interpretation.

To develop a satellite model the optimal exogenous drivers X_t , Y_t should be selected from a set of all potential drivers in Eq. (47.43). Potential drivers can usually be defined based on relevant theory or a priori assumptions and identified by calibration measurements. Application of calibration measurements ensures that the most robust model for the tested variables is obtained. The selected drivers should be statistically significant and have the known distribution parameters; to obtain a required distribution a regularization procedure should be applied [8, 42]. The conditional dynamic forecasts of Z_t can be generated based on the selection and estimation of the satellite model, taking into account the sets of final parameter estimates and the forecasts of the core variables from the first stage. The validation of the final model on the number of samples is the final estimation step. The final models selected by the search procedure are reviewed for consistency with initial assumptions.

Thus, the problem is the selection of variables for each model type $(x, \varepsilon) \rightarrow y$, the search for the relevant type of formal relationship $(x, y) \rightarrow z^s$ between the physical and observable variable parameter, and the development of the total distribution for each type of risk investigated [42]. Directed modeling should solve this problem. The problem of regularization of the initial distribution of variables should be considered separately [42].

Therefore, using the proposed method the sets of parameters can be obtained, describing the state of the system analyzed. Further, based on the obtained parameter distributions, it is possible to estimate a distribution of risk and make management decisions.

Let us consider a task on the methodology of risk assessment, based on the optimal decisions, and based on the obtained sets of indicators [41]. First of all, it should be noted that in the formal task of risk assessment and management, the reduction or non-increase of losses should be used as a quantitative parameter of control. At the same time, the variables affecting the characteristics of the management or decision-making system can be both controlled and unmanageable. In this situation the controlled variables should be described as the parameters of decision making in the context of the influence of input data on the behavior of unmanageable variables. The full cycle of collecting, processing, interpretation of information about the system studied, the decision making, and the analysis of the system's response to decisions may be considered within the framework of the "information-response" formalization. The "information-response" formalization can be presented as follows [9]. Let us define as presumably stochastic $I(x, y, z)$ input information obtained from measurements, observations,

and model forecasts; $H_I(i|\theta)$ is the probability distribution function, where θ is a state of the studied object or system. Because the state of the system cannot be determined with certainty, the appropriate probability distribution $p(\theta)$ and distribution $H_I(i|\theta)$, which describe a priori incompleteness of information available on the studied system, should be defined.

Let us define as the decision function $d(I)$ a formalized response to incoming information, presented as the making and implementation of management decisions. Let us also define losses as $l(d(I), \theta)$ under conditions of a constant state of the studied systems θ , or with a defined change in this state. The expected losses associated with the expansion of dangerous processes, connected to the management decisions based on the information received, described by the decision function d , can be presented as [44]:

$$\begin{aligned} R(I, d) &= R\left[H_I(\bullet), d\right] \\ &= \iint l(d(i), \theta) dH_I(i|\theta) p(\theta) d\theta. \end{aligned} \quad (47.44)$$

To minimize this risk the optimal Bayes decision function d^* can be applied:

$$R(I(z^s), d^*) = \min_{d(i)} \iint l(d(i), \theta(x, y)) dH_I(i|\theta) p(\theta) d\theta. \quad (47.45)$$

Thus, it is formally shown that the risk can be reduced to a simple decision function. At the same time it is important that the minimization of losses requires a completeness of information on the studied system. In other words, all states θ should be determined, for each of which a solution $\{a\}$ can be defined, which form a set of possible decisions A .

Let us further consider the realization that the set of data i^* , which consists of information obtained from direct measurements, observations, and model forecasts, optimizes the decision function d^* , and can be applied to minimize risk. This set of data nominally makes information (I) formally completed (I^*). Formally, we can assume that the information is nominally full if there is a separate realization of information I or a single state of the studied system that meets all of the set of data; or, formally speaking: $I^* \equiv I$ if there exists a function $\phi(i)$, that when $H_I(i|\theta) \neq 0$, $\theta = \phi(i)$. In the case analyzed it means that the set of models $(x, \varepsilon) \rightarrow y$ operated the sets of parameters $(x, y) \rightarrow z^s$, controlled by certain technological tools within the framework of a sustainable methodology of measurement, should be developed. Taking into account the above-described models, these requirements correspond to the satellite models z_i^s .

Basing on the requirement for information completeness, an optimal decision function can be as follows:

$$d^*(i^*) = b, l(b, \phi(i^*)) = \min_a l(a, \phi(i^*)). \quad (47.46)$$

In this formal case, with an appropriately defined optimal decision function and nominally complete information, the risk function can be defined as:

$$R(I^*, d^*) = \int \min_{a \in A} l(a, \theta) p(\theta) d\theta. \quad (47.47)$$

Although it is important to remember that this approach is sensitive to the mutual completeness of information: for the analysis of behavior of the distribution of $H_I(i|\theta)$ and $p(\theta)$ and so to the determination of the realization of i^* of set I , the relevant models should be developed.

This formalization allows a wide range of optimal decision functions to be utilized: a stochastic [45], Bayesian [44], or fuzzy operator [46], depending on the task, data availability, and properties of their distributions can be applied.

The proposed approach is a complex of models and algorithms, which is aimed at the calculation of a unique set of parameters that should be obtained from observation systems, using determined tools for data processing and interpretation. Equation (47.47), based on an important nexus, allows the distributions of risk to be estimated and a basis for decision making to be developed too.

Speaking of modern methods of statistical analysis of multisource data in the tasks of environmental risk analysis, it should be noted that the modeling of geo-systems and the remote sensing interpretation methods should be an integral part of the risk assessment systems. We need to increase our level of knowledge in the field of earth sciences, as well to increase requirements in the area of decision making, because new challenges define new methodological frameworks. The approach proposed is based on the methodology that allows the problem definition of using the satellite observations in tasks of socio-ecological security to be expanded. In particular, in addition to traditional statistical analysis directed at change detection, it is possible to predict a state of the studied systems, basing on the models of geo-systems. These capabilities certainly expand the scope and sphere of the application or approach, and could positively affect the reliability of the results obtained through the use of different sources of data. Also important is that the proposed methodology includes feedback between management decisions and the system state, and it is formally postulated that risks depend on the decision made and on past, current, and planned management impacts on the system. Therefore, such a complex of methods and algorithms, combined into common methodology, could positive affect the

effectiveness of management decisions and the quality of risk assessment [41].

47.6 Conclusions and Discussion

A nonparametric, multistage algorithmic procedure for the statistical analysis of observational, measurement, and statistics data, which allows regularized distributions to be obtained in units invariant to the nature of the data, is proposed and discussed in this chapter. It allows input datasets for risk modeling to be obtained, and at the same time the different types of emergencies to be analyzed, irrespective of their origin, despite the different time and spatial scales that are inherent to driving forces and processes that generate danger.

In addition, the fundamentals of the regionalization of climate change models based on regularized regional observations are proposed through the integration of local meteorological observations into global climate models based on the Kalman filtration method. This approach allows multi-scale modeling to be utilized, with multisource data in risk assessment tasks.

Thus, it can be argued that a methodological basis for assessing the long-term risks of disasters associated with climate and environmental change has been proposed. That is, a methodology for the estimation of long-term socio-ecological risks based on integrated monitoring is proposed, and an approach to mathematical modeling of the environment using satellite data is given. This approach can be used as a methodological basis for decision making in the field of socio-ecological security.

At the same time, some important limitations should be mentioned.

The proposed method of multistage analysis of disaster parameters, based on the KPCA algorithm has certain limitations arising from the nature of the algorithm used.

First, the method relates to the so-called local modeling methods [19], and thus to the family of nonparametric estimation methods based on the properties of the studied data distributions, and do not require the inclusion of additional conditions, a priori distribution parameters, etc. In general, local models, unlike “global” balance models, do not require the implementation of conservation laws [19], or at least, their simultaneous execution.

This allows the freedom of choosing the boundary conditions, not imposing additional complex constraints, and using the entire set of observational data.

At the same time there is another problem. The conservation laws are based on the assumption of the homogeneity of time, and by abandoning the laws of conservation, we lose the time scale, which can be significant for scenario calculations. This problem can be solved by including an artificial timeline for each (or for certain sets) distribution and modeling case,

or, as in our algorithm, by entering time as a universal measure of random sets of observational data. In this way, we are removing the general problem. Regularization of varied sets of heterogeneous data can be correctly performed using the proposed path.

However, when analyzing the distribution of extreme indices in relation to the changes in the mean value, the problem of time arises again in a different form. Using time as a universal measure does not allow distributions of mean and extreme indicators to be analyzed independently in time. That is, within the framework of the presented form of the proposed algorithm it is impossible to accurately determine the short-term gradients of extreme values under the monotonic behavior of the mean.

In practice, this means that effective analysis of the extreme parameters as the driving forces of disasters using the proposed algorithm is possible, usually on a long and on a medium scale. For short-term intervals, increasing the reliability is possible only by improving the spatial resolution of the method.

For the short-term (from several days to several weeks) estimates, the method should be modified, in particular, through verification by local measurement (from a methodological point of view – through the involvement of a quasi-independent set of data with a definite time scale).

The mentioned limitations should be taken into account in application of the proposed method.

Thus, although within the framework of the solved problem (construction of methodology for medium- and long-term risk assessments) the proposed method is quite suitable and is, according to individual indicators, better than existing analogs, it has limitations in its application in solving other types of tasks and requires some modifications.

Acknowledgments The authors are grateful to anonymous referees for constructive suggestions that resulted in important improvements to the chapter, to colleagues from the International Institute for Applied Systems Analysis (IIASA), from the American Statistical Association (ASA), American Meteorological Society (AMS), and from the International Association for Promoting Geoethics (IAPG) for their critical and constructive comments and suggestions. The authors express special thanks to the National Academy of Sciences of Ukraine for partial support of this study within the framework of the multilateral program “Integrated robust management of food-energy-water-land use nexus for sustainable development.”

of interest can be obtained using probabilistic prediction. Next, the reliability model based on the probabilistic modeling is introduced, where the safe-life model and the damage tolerance model are discussed in detail. The life prediction given a certain risk constraint and the time-dependent probability of failure estimation can be made using the developed method. Two examples are employed to demonstrate the overall method.

Keywords

Reliability · Probabilistic models · Safe-life · Damage tolerance · Probability of failure · Bayesian

Abstract

The chapter presents a systematical method for probabilistic analysis using safe-life and damage tolerance models. In particular, the reliability analysis incorporating those models are developed to provide a basic framework for the life prediction given risk constraints and the time-dependent probability of failure estimation. First, the probabilistic modeling is presented, and the uncertainties from model prediction and data are considered. The uncertainties are quantified and are encoded in the probability density functions of model parameters using probabilistic parameter estimation. The propagation of the characterized uncertainties to the result of quantity

48.1 Introduction

The design philosophies have undergone a paradigm shift over the past few decades. The investigation of the disintegration of de Havilland Comet commercial jet in flight in 1950s made it clear that the life estimate of fatigue critical structures are highly necessary. This requirement leads to the safe-life design method. The design practice started to change in the 1960s toward the fail-safe design, which essentially is a principle to provide redundant load paths as backups in the event of localized failure. The fail-safe design can be viewed as an extended version of the safe-life design. In safe-life approach, the fatigue life of a structure or a component is certified by testing data and analysis. A fundamental assumption in this approach is that the material has no initial flaw at the beginning of the service. Although the existence of material flaws depends on the scale at which the material is examined, it is usually determined at a scale that a standard inspection technique can be applied. For example, a turbine disk is considered flawless when no indication is found using the certified ultrasound inspection. An indication is defined as the echo amplitude along the sound path being larger

than a predefined threshold, e.g., 20% of the screen height. This predefined threshold is used to differentiate a small flaw from the backscattered noise components in the echo signal data caused by material grain boundaries. As a result, material flaws producing smaller echo amplitudes cannot be effectively identified from the inspection data. Indeed in certain circumstances, these flaws can be picked up using special techniques such as micro-CT in the lab environment; but time, cost, and environmental constraints restrict those special techniques being used in a more general setting. Damage tolerance design method, on the other hand, considers the material of a component or a structure has initial natural flaws at the beginning of the service. The failure of F-4 Phantom II due to the fracture of the fail-safe wing structure in 1973 signified that a structure could not be fully fail-safe without inspection. This failure event together with the following DC-10 commercial jet landing crash at Sioux city in 1989 promoted the development of damage tolerance analysis, and the development finally spawned the certification of damage tolerance for life-limiting components in aircraft structures and turbine engines [1, 2].

Reliability analysis entails the computation of the failure probability under various sources of uncertainties. For mechanical components whose major failure modes are dominated by fatigue and fracture, uncertainties can arise from materials, manufacturing, service conditions, and so on. Due to the inherent nature of those uncertainties, it is difficult to completely eliminate all uncertain sources. The propagation of uncertainties from input or sources to the output leads to uncertain results; therefore, uncertainty modeling and quantification play an important role in risk mitigation for critical engineering infrastructures. Although the nature of uncertainties has been discussed in many fields for a long time, from a pragmatic point of view, whether an uncertainty is aleatory (intrinsic) or epistemic (lack of knowledge) can be less interest to an engineering analysis as the uncertainty quantification is made through a mathematical modeling process [3]. The uncertainty due to the lack of knowledge is encoded in the discrete model space where using one or more alternative models becomes subjective. The uncertainty due to intrinsic randomness is encoded in the parameter space of a chosen model or a joint model parameter space when a set of competing models are available. Instead of enforcing a clear label for an uncertainty, it can be more beneficial to treat the overall uncertainty as the model uncertainty and parameter uncertainties associated with models in a hierarchical manner for the ease of quantification [4]. This chapter is focused on the safe-life and damage tolerance models in the context of uncertainties; in particular, the uncertainties are dealt with in a probabilistic inference framework.

48.2 Probabilistic Modeling

Following the convention random variables are denoted using capital letters, and their samples are denoted using lowercase letters. Denote Y_i as a proposition asserting that the i th data value is in the range of y_i and $y_i + dy_i$. Similarly denote Z_i and E_i as propositions asserting that the model prediction for the i th data value is in the range of z_i and $z_i + dz_i$ and that the i th error value is in the range of e_i and $e_i + de_i$, respectively. The actual data value y_i and model prediction z_i can be expressed as

$$y_i = z_i + e_i. \quad (48.1)$$

Denote the prediction value of a mathematical model M as $m(x_i|\theta)$ where x_i is the model independent variable and $\theta \in \Theta$ is the uncertain model parameter vector. Using $p(\cdot)$ to represent the probability distribution, the probability distributions for propositions Z_i and E_i are expressed, respectively, as

$$p(Z_i|M, \theta) = f_Z(z_i), \quad (48.2)$$

and

$$p(E_i|M, \theta) = f_E(e_i). \quad (48.3)$$

Given Z_i and E_i are independent the probability distribution for proposition Y_i can be expressed as

$$p(Y_i|M, \theta) = \int \int p(Z_i|M, \theta)p(E_i|M, \theta)p(Y_i|Z_i, E_i, M, \theta) dZ_i dE_i. \quad (48.4)$$

From Eq. (48.1)

$$p(Y_i|Z_i, E_i, M, \theta) = \delta(y_i - z_i - e_i). \quad (48.5)$$

Substitute Eq. (48.5) into Eq. (48.4) to obtain

$$p(Y_i|M, \theta) = \int f_Z(z_i)f_E(y_i - z_i)dz_i. \quad (48.6)$$

For a *deterministic model prediction*, $z_i = m(x_i|\theta)$ and $f_Z(z_i) = \delta(z_i - m(x_i|\theta))$. In this case Eq. (48.6) writes

$$\begin{aligned} p(Y_i|M, \theta) &= \int \delta(z_i - m(x_i|\theta))f_E(y_i - z_i)dz_i \\ &= f_E(y_i - m(x_i|\theta)). \end{aligned} \quad (48.7)$$

When the error term is a Gaussian variable, the above equation can be written as

$$p(Y_i|M, \theta) = \frac{1}{\sqrt{2\pi}\sigma_e} \exp \left\{ -\frac{[y_i - m(x_i|\theta)]^2}{2\sigma_e^2} \right\}, \quad (48.8)$$

where σ_e is the standard deviation of the error variable e_i .

For a *probabilistic model prediction* including a statistical error term ϵ_i such as $z_i = m(x_i|\theta) + \epsilon_i$, marginalizing

$$p(Z_i|M, \theta) = \int p(Z_i|\mathcal{E}_i, M, \theta)p(\mathcal{E}_i|M, \theta)d\mathcal{E}_i \quad (48.9)$$

over ϵ_i with $p(Z_i|\mathcal{E}_i, M, \theta) = \delta(z_i - m(x_i|\theta) - \epsilon_i)$ to obtain

$$\begin{aligned} p(Z_i|M, \theta) &= \int \delta(z_i - m(x_i|\theta) - \epsilon_i)f_{\mathcal{E}}(\epsilon_i)d\epsilon_i \\ &= f_{\mathcal{E}}(z_i - m(x_i|\theta)) = f_Z(z_i). \end{aligned} \quad (48.10)$$

Substitute $f_Z(z_i)$ in Eq. (48.6) with Eq. (48.10) and obtain

$$p(Y_i|M, \theta) = \int f_{\mathcal{E}}(z_i - m(x_i|\theta))f_E(y_i - z_i)dz_i, \quad (48.11)$$

which is the convolution of the two probability distributions. It is known that when the error terms are two independent Gaussian variables, the convolution is another Gaussian probability distribution that can be expressed as

$$p(Y_i|M, \theta) = \frac{1}{\sqrt{2\pi}\sqrt{\sigma_e^2 + \sigma_{\epsilon}^2}} \exp \left\{ -\frac{[y_i - m(x_i|\theta)]^2}{2(\sigma_e^2 + \sigma_{\epsilon}^2)} \right\}, \quad (48.12)$$

where σ_{ϵ} is the standard deviation of the statistical error variable ϵ_i .

In addition if the model independent variable x_i is also uncertain with a distribution function $p(X) = f_X(x_i)$ and given that the model $m(x_i|\theta)$ is monotonic and differentiable over the domain of x , it is seen that

$$f_Z(z_i) = f_X(x_i) \left| \frac{dx_i}{dz_i} \right| = f_X(m^{-1}(z_i|\theta)) \left| \frac{dm^{-1}(z_i|\theta)}{dz_i} \right|. \quad (48.13)$$

where $m^{-1}(\cdot)$ is the inverse function. Assume that X follows a normal distribution with a mean of \bar{x}_i and a standard deviation of σ_x , the uncertainty from variable x_i can then be integrated into Eq. (48.6) and obtain

$$\begin{aligned} p(Y_i|M, \theta) &= \frac{1}{\sqrt{2\pi}\sqrt{\sigma_e^2 + \sigma_{\epsilon}^2 + (J\sigma_x)^2}} \\ &\times \exp \left\{ -\frac{[y_i - m(\bar{x}_i|\theta)]^2}{2[\sigma_e^2 + \sigma_{\epsilon}^2 + (J\sigma_x)^2]} \right\}, \end{aligned} \quad (48.14)$$

where $J = \left| \frac{dm^{-1}(z_i|\theta)}{dz_i} \right|$ and \bar{x}_i is the mean value of x_i . For multidimensional independent variable x_i , the term $(J\sigma_x)^2$ in Eq. (48.14) should be replaced with $J\Sigma_x J^T$ where J is the Jacobian matrix and Σ_x is the covariance matrix of x_i .

It is worth mentioning that for a forward analysis, e.g., the analysis of uncertainty propagation from various sources to result y through the model $m(x|\theta)$, the separated qualifications using σ_e , σ_{ϵ} , σ_x or Σ_x , and so on can be explicitly included and used. For inverse problems, e.g., the estimation of the model parameter θ , the detailed uncertainty contributions from different sources are not known a priori; therefore, it can be convenient to consider using a total standard deviation $\sigma_t^2 \equiv \sigma_e^2 + \sigma_{\epsilon}^2 + (J\sigma_x)^2$ and rewrite Eq. (48.14) as

$$p(Y_i|M, \theta) = \frac{1}{\sqrt{2\pi}\sigma_t} \exp \left\{ -\frac{[y_i - m(\bar{x}_i|\theta)]^2}{2\sigma_t^2} \right\}. \quad (48.15)$$

48.2.1 Probabilistic Parameter Estimation – Inverse Problem

The probabilistic parameter estimation can be recast into a probabilistic inference problem. The Bayesian method is a rational approach to perform probabilistic inference using three pieces of information, namely, the prior, the likelihood function, and the data. The basis of the Bayesian method is nothing but the conditional probability and the product rule of probability. The posterior probability distribution function of the model parameter is expressed using the product of the prior and the likelihood as

$$p(M, \theta|Y_i) \propto p(M, \theta)p(Y_i|M, \theta). \quad (48.16)$$

The “proportional to” symbol \propto in the above equation indicates the actual posterior distribution is known up to an normalizing constant

$$p(Y_i) = \sum_{M \in \mathcal{M}} \int_{\theta \in \Theta_M} p(M, \theta)p(Y_i|M, \theta)d\theta, \quad (48.17)$$

where \mathcal{M} is a finite set of available models and Θ_M is the parameter space for θ under model M . The normalizing constant is of no particular interest when the posterior is evaluated using the Markov chain Monte Carlo (MCMC) sampling method with only one model M available. It is needed when multiple models M are compared in the context of Bayesian model assessment. As only one model is considered in this study, the symbol M is omitted hereafter for simplicity. In addition the variable σ_t is also an uncertain variable and is independent of the model parameter θ ; the joint posterior probability density function (PDF) writes

$$p(\theta, \sigma_i | Y) \propto p(\theta, \sigma_i) p(Y | \theta, \sigma_i). \quad (48.18)$$

Given no prior information on (θ, σ_i) , the Jeffreys' noninformative prior [5], i.e., $p(\theta, \sigma_i) \propto 1/\sigma_i$, can be used. In this case the posterior PDF for a total of n data points $Y = (Y_1, Y_2, \dots, Y_n)$ is expressed as

$$p(\theta, \sigma_i | Y) \propto \frac{1}{\sigma_i} \cdot \frac{1}{(\sqrt{2\pi}\sigma_i)^n} \exp \left\{ -\frac{\sum_{i=1}^n [y_i - m(\bar{x}_i | \theta)]^2}{2\sigma_i^2} \right\}. \quad (48.19)$$

The approximation of the above PDF can be made using samples obtained from MCMC simulations with the standard Metropolis-Hastings (MH) sampling strategy [6, 7]. An alternative approach is using asymptotic approximation. The widely used one is the Laplace method [8, 9]. The basic idea of the Laplace method is to use a multivariate normal distribution to approximate the posterior PDF of Eq. (48.19). Under the condition that the PDF has one mode and is approximately symmetric around the mode, the Laplace method can yield accurate results.

48.2.2 Probabilistic Prediction: Forward Problem

The basis for probabilistic prediction is centered on three pieces of information, namely, a mathematical model correlating the input (independent) variable and the output (dependent) variable, a probabilistic representation of the model parameters, and the input variable. Once the model is chosen and the parameter is characterized in a probabilistic manner, the next step is to propagate the uncertainty through the model to output and quantify the uncertainty in the output results.

A universal method for the purpose is to use Monte Carlo-based method. The idea is to draw many samples of the uncertain variables from its distributions. Each of the samples can be seen as a realization of the randomness, and the corresponding model output associated with that particular sample is a realization of one possible output, following a certain probability distribution. Given that the number of the samples is sufficiently large (in statistical sense), the resulting empirical distribution of the model output ensures a convergence to the true distribution. The mean and confidence intervals of the model prediction can trivially be obtained using the empirical distribution.

A subtle but crucial point that is often overlooked is the differentiation between the mean estimation confidence interval and the prediction confidence interval. Recall the uncertain parameters are (θ, σ_i) and the probabilistic model prediction is

$$y_j = m(\bar{x} | \theta_j) + e_j, \quad (48.20)$$

where θ_j is the j th sample, and e_j is a random sample drawn from the error distribution with a standard deviation of $\sigma_{i,j}$. When using MC estimators for evaluation, the mean confidence interval does not involve the generation of an error variable according to $\text{Norm}(0, \sigma_{i,j})$ in j th realization; however, the prediction confidence interval of an MC estimator requires the error variable. The difference is signified in examples in the next sections.

48.3 Reliability Model

The early and formal definition of the engineering "Reliability" can be found in NASA's report [10]: *the probability that a system, subsystem, component or part will perform its intended functions under defined conditions at a designated time for a specified operating period*. It is a probabilistic measure because of the existence of uncertainty. In practice, the reliability can also be characterized using mean time between failure (MTBF), failure rate, and the probability of failure (POF), depending on the fields of applications and the criteria for decision-making. The probability of failure is widely used in structural reliability analysis and is adopted here. To understand the probability of failure, it is necessary to define a failure criterion for the problem in consideration. The failure criterion is a subjective choice fully tied to the specific engineering applications. For example, a failure can be defined as the fracture of a component due to a crack propagation in one case, but it can also be defined as a fatigue crack being larger than a length far below the one causing a sudden fracture. In other cases, it can also be defined as when a flaw is identified in a part in service using nondestructive inspection. Once the failure criterion is chosen, the response of a model becomes a binary output of failure or success.

Given a failure criterion such that the event of $g(\phi) \leq g_0$ is considered as a failure where $g(\phi)$ is the model taking a parameter ϕ . The so-called response function is then defined as $h(\phi) = g(\phi) - g_0$. The failure criterion essentially divides the entire multidimensional parameter space into two domains, the failure domain and the success domain. The POF is the failure domain portion of the entire domain. Mathematically it is the integral over the failure domain of the performance function and is expressed as

$$P_f \equiv \Pr [h(\phi) \leq 0] = \int_{h(\phi) \leq 0} p(\phi) d\phi. \quad (48.21)$$

Using MC-based methods for POF evaluation, the MC estimator of POF is

$$\hat{P}_f \approx \frac{1}{N_{mc}} \sum_{i=1}^{N_{mc}} \mathbf{1}(\phi_i), \quad (48.22)$$

where $\mathbf{1}(\cdot)$ is the identity function taking the value according to

$$\mathbf{1}(\phi) = \begin{cases} 1 & h(\phi) \leq 0 \\ 0 & \text{otherwise} \end{cases}, \quad (48.23)$$

N_{mc} is the total number of MC samples, and ϕ_i is the i th MC sample of the parameter vector.

48.3.1 Safe-Life Model

The safe-life model for fatigue analysis is usually referred to the Basquin law [11] for stress-life (s - N) data or Manson-Coffin law [12, 13] for strain-life (ϵ - N) data and their variants, considering loading, environmental, work-hardening effects, and so on. The most simple yet useful one is the log-linear model, which presents the strain/stress and the fatigue life as a linear relationship in the log-transformed coordinates. For example, the log-transformed Manson-Coffin low-cycle fatigue life model reads

$$\log N = b_0 + b_1 \log (\Delta \epsilon / 2), \quad (48.24)$$

where N is the number of cycles to failure or fatigue life, $\Delta \epsilon$ is the strain range during one load cycle, and (b_0, b_1) are model parameters to be determined by testing data. For linearized models (log-transformed linear, piece-wise linear, and the combinations of the two), the conventional linear regression can directly be applied. The median curve of the fit, the confidence interval for the median curve, as well as the prediction interval given the input can all analytically be evaluated.

It is worth mentioning the difference between the confidence interval of the median curve and the prediction interval of the model is vital for reliability analysis. For prediction purposes, the latter one should be pursued. Figure 48.1 shows the life testing data, a log-linear model's mean fit, confidence interval of the mean, and the prediction confidence interval. Note that the independent variable of the model is plastic strain amplitude ($\Delta \epsilon_p / 2$) and the dependent variable is the number of cycles to failure (N). The dependent variable is plotted in x -axis only to follow the convention. It can be observed in Fig. 48.1 that the prediction confidence interval is much wider than the confidence interval of the mean. Figure 48.2 shows PDFs of the mean life and predicted life.

Cumulative Damage Models

The log-linear model or the more general linearized model can be used to calculate life (N) under a given strain range ($\Delta \epsilon$); however, a proper treatment is needed when different strain ranges are repeated as a block loading. The fatigue process can be virtually thought as a process of life consumption by each of the strain ranges ($\Delta \epsilon_i, i = 1, \dots, k$). The concept is shown in Fig. 48.3. For one cycle in the block with a strain

Fig. 48.1 Low-cycle fatigue testing data and the log-linear strain-life model. The life testing data (triangles) [14], the mean (solid line), the 95% confidence interval of the mean fit (dotted lines), and the 95% prediction confidence interval (dashed lines) are shown

Fig. 48.2 PDFs of the median and the predicted life for $\Delta \epsilon_p / 2 = 10^{-2}$. The life is transformed back to the linear coordinates

range of $\Delta \epsilon_i$, the total useful life is consumed by a fraction of $1/N_i$. Denote the number of cycles associated with the strain range of $\Delta \epsilon_i$ in the block as n_i . The consumed fraction of the total life per one block is $(n_1/N_1 + n_2/N_2 + \dots + n_k/N_k)$ and the total number of cycles in one block is $(n_1 + n_2 + \dots + n_k)$. The equivalent consumed fraction of the total life per one cycle is

$$\Delta d = \frac{\frac{n_1}{N_1} + \frac{n_2}{N_2} + \dots + \frac{n_k}{N_k}}{n_1 + n_2 + \dots + n_k} = \sum_i^k \frac{f_i}{N_i}, \quad (48.25)$$

where $f_i = n_i / \sum_{i=1}^k n_i$ is the percentage (or frequency) of $\Delta \epsilon_i$ in the series of load cycles and N_i is the fatigue life at strain range $\Delta \epsilon_i$. Consequently the equivalent life in terms of cycles writes

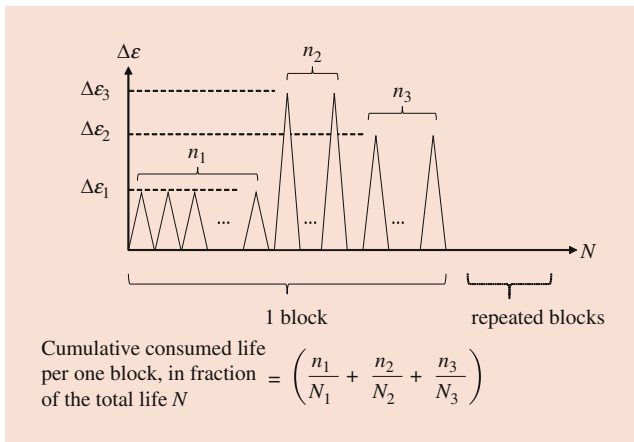

Fig. 48.3 Illustration of the repeated load block consisting of load cycles with different strain ranges

$$N_{eq} = \frac{1}{\Delta d} = \left[\sum_{i=1}^k \frac{f_i}{N_i} \right]^{-1}. \tag{48.26}$$

Equation (48.25) is the linear damage rule (Palmgren–Miner rule) originally suggested by Palmgren [15] and popularized by Miner [16]. It is later observed that the load sequence alters the accumulation and many variants accounting for the load sequence effects have been proposed. A comprehensive survey of cumulative damage models can be found in Ref. [17].

The aforementioned models describe the deterministic relationship between stress/strain range with the fatigue life, as well as the treatment for block loads. A probabilistic model can be established given a deterministic model and PDFs of the model parameters identified using experimental data. To demonstrate the probabilistic safe-life model with the linear damage rule, a repeated load block consisted of $\Delta\epsilon_1 = 5 \times 10^{-3}$ and $\Delta\epsilon_2 = 10^{-3}$ is considered. The frequency ratio is $n_1/n_2 = 1/3$. The log-linear model in Eq. (48.24) and a Gaussian likelihood with an unknown standard deviation σ_t are used. The Bayesian posterior of (b_0, b_1, σ_t) with a noninformative prior (i.e., $\propto 1/\sigma_t$) writes

$$p(b_0, b_1, \sigma_t) \propto \frac{1}{\sigma_t} \cdot \frac{1}{(\sqrt{2\pi}\sigma_t)^n} \times \exp \left\{ -\frac{\sum_{i=1}^n [\log \bar{N}_i - b_0 - b_1 \log(\Delta\bar{\epsilon}_i/2)]^2}{2\sigma_t^2} \right\}, \tag{48.27}$$

where $(\bar{\epsilon}_i, \bar{N}_i)$, $i = 1, \dots, n$ are experimental data. Here the data in Fig. 48.1 (solid triangles) are used. MCMC simulations are employed to draw samples from the Bayesian

posterior. The Metropolis-Hastings random walk [6, 7] is adopted with an initial values of (b_0, b_1, σ_t) set to be the linear regression mean $(-0.1, -1.42, 0.23)$. A total number of 10^7 samples are obtained and the results are shown in Fig. 48.4.

The prediction of the life under the given block load can be made with the MCMC samples. For each of the samples, a random realization can be obtained using Eq. (48.26) and Eq. (48.24). With all the MCMC samples, a total of 10^7 random realizations of the equivalent fatigue life are obtained. Based on the 10^7 realizations of the equivalent life, the empirical CDF of N_{eq} is obtained and presented in Fig. 48.5. Based on the empirical CDF of N_{eq} , the equivalent life under a probability of failure (POF) can be evaluated using the MC quantile estimator. For example, the fatigue life associated with a POF of 10^{-3} is the 0.001 quantile of the samples for N_{eq} . In addition, the asymptotic confidence interval for the MC quantile estimator can also be obtained using central limit theorem (CLT) as [19, 20]

$$N_{p,1-\alpha} = \hat{N}_p \pm z_{\alpha/2} \cdot \frac{\sqrt{p(1-p)}}{f(\hat{N}_p)\sqrt{N_{mc}}}, \tag{48.28}$$

where p is the probability (e.g., $p = 0.001$), \hat{N}_p is the MC estimation of p -quantile, N_{mc} is the number of samples, $f(\hat{N}_p)$ is the PDF of the life evaluated at \hat{N}_p , and $z_{\alpha/2} = \Phi^{-1}(1 - \alpha/2)$ and $\Phi^{-1}(\cdot)$ is the inverse CDF of the standard normal variable. For example, if a 95% = $1 - \alpha$ confidence interval is chosen, $\alpha = 0.05$ and $z_{\alpha/2} = 1.96$. It should be noted that the PDF $f(\cdot)$ is not known; therefore, a proper method to estimate $f(\hat{N}_p)$ should be used. Experiences have shown that the kernel density estimator (KDE) method reported in Ref. [18] can produce reliable and fast estimation using the samples.

It should be stressed that the confidence interval is associated with the MC estimator, reflecting the sampling uncertainty of the Monte Carlo method. For example, a 95% confidence interval loosely means that there is 95% chance that an individual MC estimation result of the POF falls in the interval. On one hand the plot in Fig. 48.6 allows for estimation of POF at a given time in terms of equivalent cycles; on the other, given a prescribed POF, the usable time in terms of equivalent cycles can be retrieved. For instance, if the requirement for reliability is $POF = 10^{-5}$, the 95% confidence interval of the allowable life in terms of equivalent cycles is 266~310. The fatigue life in safe-life design practice for many life-limiting parts such as turbine disks and shafts refers to the crack initiation life. As in these applications the goal is to avoid crack propagation stage for safety purposes; therefore, fatigue testing must be carefully designed to support the expectation. The criterion for initiation may vary depending on the applications. For turbine disks, and shafts, the crack initiation refers to an

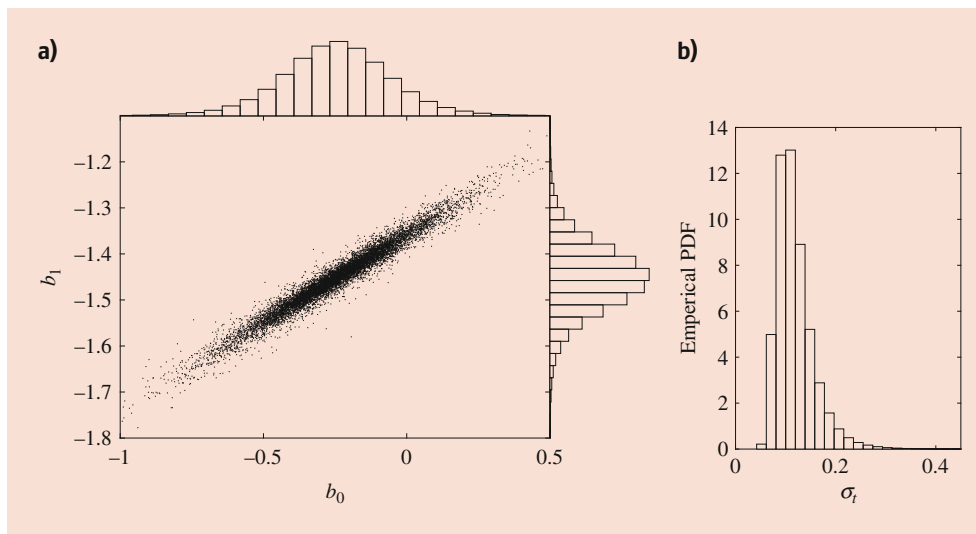

Fig. 48.4 MCMC samples drawn from Eq. (48.27). (a) Samples and histograms of model parameters b_0 and b_1 , and (b) histogram of the standard deviation σ_r in the Gaussian likelihood

Fig. 48.5 Prediction results of the equivalent life under the given block load. The density estimation result in solid line is made based on the fast kernel density estimation method in [18]

Fig. 48.6 Prediction results of the probability of failure (POF) under the given block load. Results are obtained using 10^7 MCMC samples. The median and confidence interval of the Monte Carlo (MC) estimator are shown

engineering crack size (0.38 mm radius) [21], which is tightly associated with the capacity of the nondestructive inspection for the parts. Conducting the fatigue testing of a specimen until it breaks is not unusual since such a termination of the testing is convenient; but this testing data includes both crack initiation life and crack propagation life and should be used with special care. Experiences have shown that for particular materials the crack propagation life is roughly 1/3 of the fracture life; therefore, the 2/3 of the fracture life can be used as a rough estimate for the crack initiation life. It is noted that this type of special treatment is not universal for all materials, but such a procedure does find its applications in safety-critical components [22, 23].

48.3.2 Damage Tolerance Model

Damage tolerance is the ability of the structure to resist failure due to the presence of flaws, cracks, or other damage, for a specified period of unrepaired usage. The size of the flaw is usually determined using the 90/95 probability of detection (POD) curve offered by the nondestructive testing (NDT) technique used in component manufacturing and in-service inspection. The size is also called 90/95 flaw size, indicating there is 95% confidence that at least 90% of all flaws of this size would be detected. For example, the recommended 90/95 flaw sizes of aircraft engine components are 0.035-inch diameter and 0.035 by 0.070 inches for embedded and

Fig. 48.7 The process of fatigue crack growth. The stable growth phase, also called Paris' regime, can be described by the log-linear Paris' equation. Here the actual values for ΔK and da/dN are just for illustration purposes

surface flaws, respectively [24]. For conservativeness a flaw is treated as a sharp fatigue crack with the worst orientation and shape with respect to the local stress field. The crack can propagate under cyclic loads to reach a critical size causing a sudden fracture. The total duration measured in the number of load cycles or equivalent operation hours is the fatigue crack growth life. The main focus of damage tolerance analysis is to evaluate the remaining useful life given an existing flaw. The fatigue crack growth is one of the major damage mechanisms for mechanical components; however, other damage mechanisms such as creep crack growth, corrosion, and wear are also commonly seen in realistic applications. The cyclic variation of stress intensity factor (SIF) is the main driving factor for fatigue crack growth. As shown in Fig. 48.7, the fatigue crack growth process can be divided into three phases. The widely used Paris' model establishes the log-linear relationship between the crack growth rate and the SIF range in the stable growth phase (Paris' regime) [25]:

$$\frac{da}{dN} = C (\Delta K)^m, \quad (48.29)$$

where a is the crack size, N is the number of load cycles, ΔK is the SIF variation during one load cycle, and C and m are model parameters. Take logarithm on both sides to obtain the log-linear model, allowing for linear regression on crack growth testing data.

For constant amplitude cyclic load, Paris' equation performs well in the stable phase of the crack growth. Realistic service load spectra contains variable amplitude load cycles, and the effect of a load spike can alter the crack growth rate significantly; therefore, the concept of ΔK_{eff} is proposed to include the effect of crack growth retardation [26–28]. The load ratio for constant amplitude load cycles also has

an impact on the fatigue crack growth rate over the entire stable phase of the crack growth and can be accounted for by introducing the load ratio parameter R into the Paris' equation [29–31]. For spectrum loading without load interactions or overload/underload effects, the cumulative damage rule in previous section can be applied:

$$\frac{da}{dN_{\text{eq}}} = \sum_{i=1}^k \omega_k \cdot C (\Delta K_k)^m, \quad (48.30)$$

where $\omega_k = n_i / \sum_{i=1}^k n_i$ is the frequency of k th cyclic stress range in the repeated load block, as illustrated in Fig. 48.3. To consider the load interaction and load ratio effects, appropriate variants of Paris' equation should be used.

In this chapter the Paris' equation is adopted for methodology demonstration without loss of generality. Figure 48.8 presents Virkler's [32] fatigue growth testing data on aluminum alloy in (a) and log-linear fitting on da/dN vs. ΔK in (b). To obtain the da/dN and ΔK , the following finite difference scheme is used [33]. $da_j = a_j - a_{j-1}$, $dN_j = N_j - N_{j-1}$, and $\Delta K_j = \sqrt{\pi \bar{a}_j} \Delta \sigma \cdot g(a, W)$. The index term $j = 2, \dots, q$ where q is the total number of a vs. N data points of a crack growth trajectory, W is the width of the specimen, $\Delta \sigma$ is the stress amplitude of the remote loading, $g(a, W)$ is the geometry correction factor, and $\bar{a}_j = (a_j + a_{j-1})/2$ is the average crack size of two adjacent measurement points. For a center through-thickness crack $g(a, W) = \sqrt{\sec(\pi \bar{a}_j/W)}$. More detailed geometry and loading information of the testing data can be found in Ref. [32].

Using Virkler's crack growth data, the parameters of Paris' equation are obtained using linear regression with da/dN vs. ΔK as a whole in log-transformed coordinates. The mean and covariance matrix of $(\ln C, m)$ are $\mu_p = [-26.155, 2.874]$, $\Sigma_p = \begin{bmatrix} 0.00235, & -0.00038 \\ -0.00038, & 0.000063 \end{bmatrix}$, respectively. The standard deviation of the error variable is $\sigma_t = 0.236$. It is known that in linear regression on $\ln(da/dN)$ vs. $\ln \Delta K$, the error variable is an addition term to the log-linear model. However, the error variable is transformed into an multiplication coefficient to the crack growth rate when the log-linear equation is transformed back to the regular coordinates for cycle-based integration of the crack growth trajectory. Consequently the analytical formulation of linear model prediction is only valid in the log-transformed space.

To perform the prediction for crack growth trajectory, the MC estimator is employed. A total number of 10^7 samples are drawn from the multivariate normal distribution with mean μ_p and covariance matrix Σ_p . For each of the samples the crack growth trajectory is evaluated, and the median prediction of the crack growth trajectory and median prediction confidence interval are estimated from the resulting 10^7 trajectories. For prediction confidence interval considering

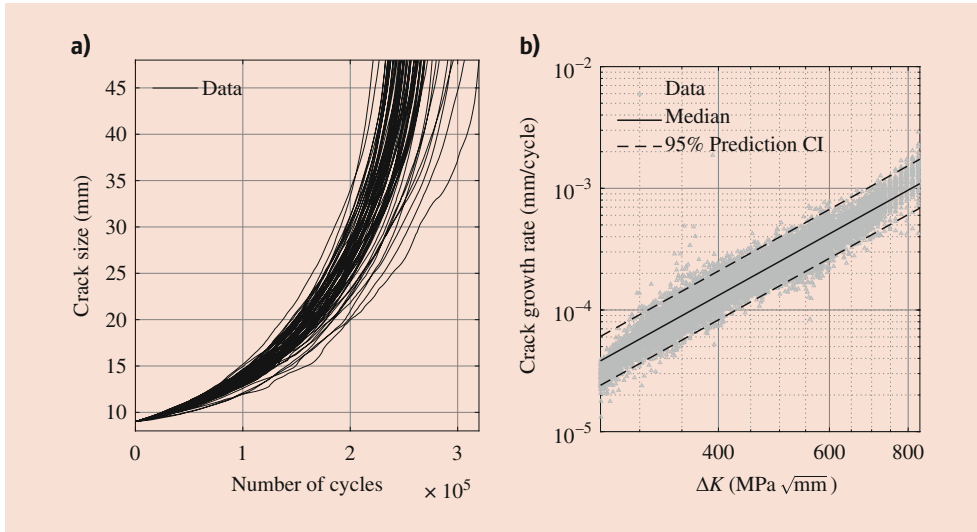

Fig. 48.8 Virkler’s fatigue testing data. (a) Crack size vs. number of cycles and (b) da/dN vs. ΔK and the log-linear fitting result. da/dN is obtained using discrete a vs. N data points associated with each of the crack growth trajectories in (a)

Fig. 48.9 Median and predicted crack growth trajectories for Virkler’s dataset

Fig. 48.10 Prediction results of the probability of failure (POF) using Virkler’s dataset. The failure is defined as the crack size being larger than 40 mm. Results are obtained using 10^7 MC samples. The median and confidence interval of the Monte Carlo estimator are shown

the modeling error, a number of 10^7 samples for the error variables are drawn from the Gaussian distribution with a zero mean and a standard deviation of σ_r . For each of the samples $(\ln C, m, \epsilon)$, the a multiplication coefficient $\exp(\epsilon)$ is applied to the right-hand side of Eq. (48.29), and the crack growth trajectory is evaluated. The prediction confidence interval is estimated using the resulting 10^7 prediction trajectories. Figure 48.9 presents the results obtained using the above MC estimator.

Given the definition of the failure event, e.g., the crack size being larger than 40 mm, the POF estimation is made using the MC estimator Eq. (48.22). Figure 48.10 shows the time-dependent POF results for Virkler’s dataset. The confidence interval of the MC estimator for rare event probabilities reads

$$\widehat{P}_{f,1-\alpha} = \widehat{P}_f \pm z_{\alpha/2} \sqrt{\text{Var}(\widehat{P}_f)}, \quad (48.31)$$

where $z_{\alpha/2}$ is defined as before in Eq. (48.28), \widehat{P}_f is given in Eq. (48.22), and $\text{Var}(\widehat{P}_f)$ is the variance of the MC estimator given by

$$\text{Var}(\widehat{P}_f) = \frac{1}{N_{mc} - 1} \left[\frac{1}{N_{mc}} \sum_{i=1}^{N_{mc}} \mathbf{1}(\phi_i)^2 - \widehat{P}_f^2 \right]. \quad (48.32)$$

The term $\mathbf{1}(\phi_i)$ is the identity function defined in Eq. (48.23), N_{mc} is total number of MC samples, and ϕ_i is the i th MC sample $(\ln C, m, \epsilon)$. It is worth mentioning that for rare event

probability estimations, a sufficient number of samples are required to yield a small relative error (RE) in the results. This is due to the fact that only when the number of sampling is large enough the tail region (small probability) of the distribution can be sufficiently sampled. A quick estimate for the required number of samples for rare event simulations can be made using the following equation [34]:

$$\text{RE}_{\text{mc}} \stackrel{\text{def}}{=} \frac{\text{Var}(\hat{P}_f)}{P_f} \approx \sqrt{\frac{1}{N_{\text{mc}} \cdot P_f}}. \quad (48.33)$$

For example, the MC estimator for a rare event with a probability of 10^{-5} needs a number of 10^7 to achieve a relative error about 10%.

48.4 Application

Shaft couplings are key components connecting different parts and transmitting torques in rotating machines such as power transmission systems and turbine engines. Among all the shaft couplings, Curvic couplings are widely used in aeroengines, heavy-duty gas turbines and coaxial drive systems due to its precise centering ability and excellent load carrying capacity. The failure of Curvic couplings can directly affect the overall structural integrity of a rotating machine. The startup and shutdown of the rotating machines form the mechanical load for Curvic couplings, and the repeated startup and shutdown form the cyclic fatigue load. As life-limiting parts in turbine machines, the assessment of the fatigue life and reliability of Curvic couplings must be carefully made to ensure the operation safety. The prediction of the fatigue life of Curvic couplings requires the material properties and loading information. Due to the complex geometry and the contact working condition of Curvic couplings, direct measurements of the loading information such as stress and strain in a realistic working condition is inaccessible. Finite element method (FEM) and/or boundary element method (BEM) have been used to evaluate the stress and strain profiles of Curvic couplings. Existing studies have shown that the state of contact surface can affect the overall stress and strain distribution around the contact surfaces of the contacting parts. To evaluate fatigue life and reliability of Curvic couplings, a full understanding of the stress and strain state of the coupling incorporating the manufacturing uncertainty is necessary. In addition, uncertainties from surface roughness and material must be scientifically quantified.

A full three-dimensional contact FE model of a Curvic coupling assembly in an aeroengine is employed for stress and strain analysis. Typical rotation and loading conditions are applied as boundary conditions, representing the realistic operation environments. The surface uncertainty introduced in the manufacturing process is modeled using the coefficient

of friction of contacting surfaces of the Curvic coupling, e.g., concave tooth/convex tooth. Transient analysis is performed to obtain the time-dependent stress and strain profile formed in a simplified duty cycle of the engine. A linear model is used to correlate the coefficient of friction and the maximum strain range in the duty cycle, and the variation of surface state can propagate to the variation of the maximum strain range at critical locations of the Curvic coupling. A probabilistic low-cycle fatigue model considering the surface effect is established by incorporating the surface parameter into the classical Manson-Coffin model.

48.4.1 Reliability and Life Prediction of a Curvic Coupling

The overall modeling process is presented in Fig. 48.11. The first component is to obtain the surface-dependent stress/strain results. The second component is the probabilistic life prediction module which considers the material uncertainty, surface uncertainty, numerical modeling uncertainty, and so on. The manufacturing-induced surface uncertainty is represented using the variation of the coefficient of friction (ρ) as shown in the figure. Using different values of the parameter ρ , the numerical analysis results of the Curvic coupling are obtained using transient contact FE models. Results are subsequently used to build the correlation model between the coefficient of friction (ρ) and the maximum cyclic strain/stress range ($\Delta\varepsilon$). This correlation is then incorporated into the probabilistic life prediction module for reliability and fatigue life estimation.

Stress and Strain States of Curvic Couplings Subject to Surface Uncertainty

The transient analysis of the assembly of a Curvic coupling is a complex modeling process. To perform an effective numerical analysis, the boundary conditions and the load cycle must be carefully set to represent the realistic working condition. Manufacturing uncertainties can effect on the overall efficiency, performance, and life of the engine, and it has become an important issue in the aircraft engine manufacturing industry [35]. Constrained by metal cutting conditions, the uncertainty in the process will affect the surface roughness of the components and further affect the friction coefficient of contact surface [36,37]. In particular, the surface uncertainty introduced in the manufacturing process is modeled using the coefficient of friction (ρ). The coefficient of friction can affect the contact model of the tooth-tooth contacting of the Curvic coupling. Consequently, the deformation of the contact teeth and the resulting strain and stress distributions over the teeth are altered. The transient analysis is performed for the Curvic coupling assembly with the following condition shown in Table 48.1. The configuration of the transient

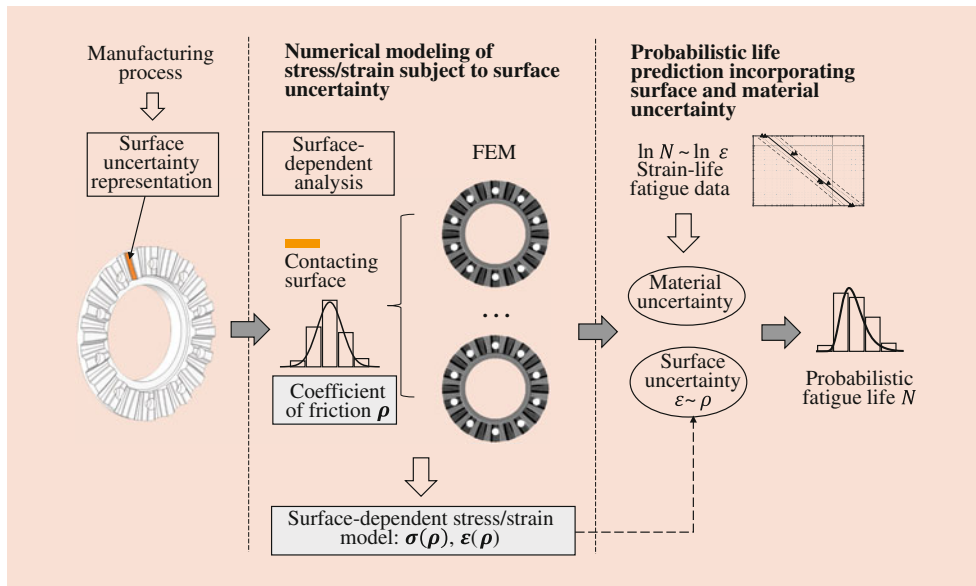

Fig. 48.11 The overall modeling process

analysis represents a simple startup-shutdown cycle of the rotor. In the time duration of 1–10 s, a linear ramp up of the rotational speed from 0 to 2094 rad/s is applied to realize the speed up process of the rotor. A constant moment is applied to the Curvic coupling to simulate the load. The ferritic steel alloy material CrMoV with a Young's modulus of 200 GPa, a Poisson's ratio of 0.3, and a density of $7.85 \times 10^3 \text{ kg/m}^3$ is used. To model the influence of the surface uncertainty on the stress and strain of the Curvic coupling, a set of discrete values for the coefficient of friction (ρ_i) are uniformly chosen in the range of [0, 0.3] with a step size of 0.05. For each of the values in (ρ_i), a transient contact FE analysis is performed using the finite element package ANSYS mechanical workbench. Ten-node quadratic tetrahedron elements are used in the mesh generation as shown in Fig. 48.12a. The average element length is 1.7 mm with program-controlled curvature adaption. A total of seven numerical cases are performed, and the results of the transient stresses and strains are obtained. The location where the strain range is maximized during 0–10s is considered as the fatigue critical region as shown in Fig. 48.12c. To consider the variation in all the contact pairs of the Curvic coupling, the maximum ranges for stress and strain in the repeated sectors shown in Fig. 48.12b are all obtained. The maximum ranges for stress and strain are obtained in one numerical analysis. The results of the maximum strain ranges are shown in Fig. 48.13 as scatter dots. For each ρ value shown in x-axis, a total of ten points from the repeated sectors are plotted. From the results shown in Fig. 48.13, the maximum strain range $\Delta\varepsilon$ and the coefficient of friction ρ show a linearity. Therefore, the following linear model can be built to correlate the coefficient of friction and the maximum strain range:

Table 48.1 The transient analysis setting for the Curvic coupling

Time	Rotational velocity (rad/s)	Moment ($N \times m$)
0	0	540
1	0	540
10	2094	540

$$\Delta\varepsilon = \beta_0 + \beta_1 \cdot \rho + \epsilon_\beta, \quad (48.34)$$

where β_0 and β_1 are fitting parameters and ϵ_β is the error term describing the difference between the model and the actual data. Using linear regression, the mean and covariance matrix of $\beta = [\beta_0, \beta_1]$ are obtained as

$$\mu_\beta = [1.9215 \times 10^{-3}, -4.7177 \times 10^{-4}], \quad (48.35)$$

and

$$\Sigma_\beta = \begin{bmatrix} 2.1768 \times 10^{-11} & -1.0047 \times 10^{-10} \\ -1.0047 \times 10^{-10} & 6.6978 \times 10^{-10} \end{bmatrix}, \quad (48.36)$$

respectively. The mean estimate of the standard deviation of the error term ϵ_β is $\sigma_{\epsilon_\beta} = 2.1653 \times 10^{-5}$. The fitting and prediction results are shown in Fig. 48.13.

Probabilistic LCF Life Prediction Incorporating Surface Uncertainty

A probabilistic low-cycle fatigue (LCF) model considering the surface uncertainty is proposed. The basic idea is to incorporate the surface state parameter ρ into the classical Manson-Coffin model in Eq. (48.24), so that the uncertainty

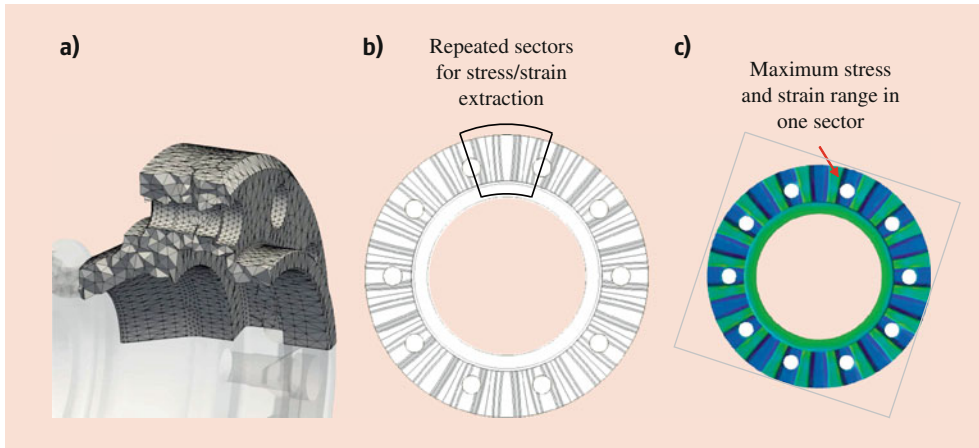

Fig. 48.12 The maximum stress/strain range at critical location in one of the ten repeated sectors. (a) Partial view of the finite element mesh, (b) the sketch of the Curvic coupling and the repeated sector, and (c) the

critical location in one sector where the maximum stress/strain range occurs in the representative load cycle in Table 48.1

Fig. 48.13 The maximum strain range and the linear model fitting and prediction results using Eq. (48.34)

from the surface state can propagate through the model to the final fatigue life prediction. The low-cycle fatigue testing data on CrMoV material reported in Ref. [38] are used to estimate the model parameters with Eq. (48.24), and the mean and covariance matrix of the parameter $b = [b_0, b_1]$ are

$$\mu_b = [5.358, -1.332], \quad (48.37)$$

and

$$\Sigma_b = \begin{bmatrix} 9.729 \times 10^{-3} & 6.394 \times 10^{-3} \\ 6.394 \times 10^{-3} & 6.718 \times 10^{-3} \end{bmatrix}, \quad (48.38)$$

respectively. The standard deviation of the error term is estimated as $\sigma_{e_b} = 0.148$. The low-cycle fatigue data and

Fig. 48.14 The fitting and prediction results on CrMoV low-cycle fatigue testing data (source [38]) using Manson-Coffin model

Manson-Coffin model fitting and predictions are shown in Fig. 48.14.

Substitute Eq. (48.34) into Eq. (48.24) to obtain the surface-dependent low-cycle fatigue life model:

$$\ln N = b_0 + b_1 \cdot \ln(\beta_0 + \beta_1 \cdot \rho + \epsilon_\beta) + e_b, \quad (48.39)$$

where ϵ_β and e_b are error terms due to surface uncertainty and material uncertainty, respectively. Given the PDFs of the six parameters $\theta = (b_0, b_1, \beta_0, \beta_1, \sigma_{\epsilon_\beta}, \sigma_{e_b})$, the probabilistic fatigue life prediction can be made using simulation-based methods such as Monte Carlo (MC) simulations and its variants. The variation of static friction of coefficient for steel and steel in greasy condition is between 0.11 and 0.23 [39]. Without loss of generality, the uniform distribution in the range of [0.10.25] is used for the friction of coefficient

Fig. 48.15 The empirical fatigue life distribution obtained using 1×10^8 MC simulations

parameter ρ . The parameter $b = [b_0, b_1]$ follows a bivariate normal distribution with a mean vector of Eq. (48.37) and a covariance matrix of Eq. (48.38), respectively. The parameter $\beta = [\beta_0, \beta_1]$ follows a bivariate normal distribution with a mean vector and a covariance matrix given in Eq. (48.35) and Eq. (48.36), respectively. The two Gaussian error terms ϵ and e have zero mean and standard deviations of $\sigma_{\epsilon_\beta} = 2.1653 \times 10^{-5}$ and $\sigma_{e_b} = 0.148$, respectively.

A total number of 1×10^8 MC samples of $\theta = [b_0, b_1, \beta_0, \beta_1, \epsilon_\beta, e_b]$ are drawn according the above distribution parameters. For each of the samples, a deterministic fatigue life can be obtained using Eq. (48.34). With all the samples, the empirical distribution based on the resulting 1×10^8 fatigue lives can be estimated. The results are shown in Fig. 48.15. The quantile of the fatigue life prediction can be used to estimate the failure probability. For example, the quantile point value $N_{q,MC}$ with $q = 10^{-6}$ is the estimate for probability $\Pr(N > N_q) = 10^{-6}$. In this case, the estimated fatigue life with $q = 10^{-6}$ is found to be 1.03×10^5 cycles.

Time-Dependent Reliability Under Surface and Material Uncertainty

Consider a simplified loading profile of the rotor consisted of the nominal speed and the overspeed. For simplicity, assume the overload increase the maximum strain range at critical locations by 12% due to overspeed, overheating, etc., and the overload corresponds to a ratio of 10% in the designed lifetime in terms of cycles. The load block is shown in Fig. 48.16. This case can be modeled using the aforementioned block-type of loading. In this case $f_j = (0.1, 0.9)$ and $\Delta\epsilon_j = (1.12\Delta\epsilon, \Delta\epsilon)$. Here the term $\Delta\epsilon$ is given by Eq. (48.34), and

Fig. 48.16 The load block consisting 10% of overspeed and 90% of normal speed

N_j is given by Eq. (48.39). Using the linear damage rule in Eq. (48.25), the total damage accumulated after t cycles is

$$\Delta d(\theta, t) = t \cdot \left[\sum_{j=1}^2 \frac{f_j}{N_j} \right]. \quad (48.40)$$

The failure event occurs when the consumed accumulation exceeds 1 or more conservatively, a number between 0 and 1. The limit state function which defines the hypersurface separating the failure domain and normal domain can be expressed as

$$h(\theta, t) = \Delta d(\theta, t) - 1. \quad (48.41)$$

A total of 1×10^8 MC samples of $\theta = [b_0, b_1, \beta_0, \beta_1, \epsilon_\beta, e_b]$ are drawn. For each of the samples, the identity function Eq. (48.23) is evaluated with the limit state function of Eq. (48.41), and the time-dependent POF can be estimated using MC estimator in Eq. (48.22). The confidence interval of the MC estimator of POF can be obtained using Eq. (48.31). Results of the time-dependent reliability estimations and the time-dependent failure rate in terms of failures per cycle are shown in Fig. 48.17a and b, respectively. The risk requirement for life-limiting parts in aeroengine is about 10^{-9} failure event per flight cycle according to the FAA regulation [1]; the estimated life under the requirement is 1.3×10^5 cycles.

48.5 Summary

The chapter presents probabilistic models for fatigue reliability analysis using safe-life and damage tolerance methods. Probabilistic modeling is developed to formulate a general uncertainty quantification framework. Uncertainties from different sources are encoded into the distributions of model parameters. An inverse problem is set up for parameter estimation using the Bayesian method. A subsequent forward uncertainty propagation using the estimated parameter distributions can be used for probabilistic prediction. The safe-life and damage tolerance methods are incorporated into

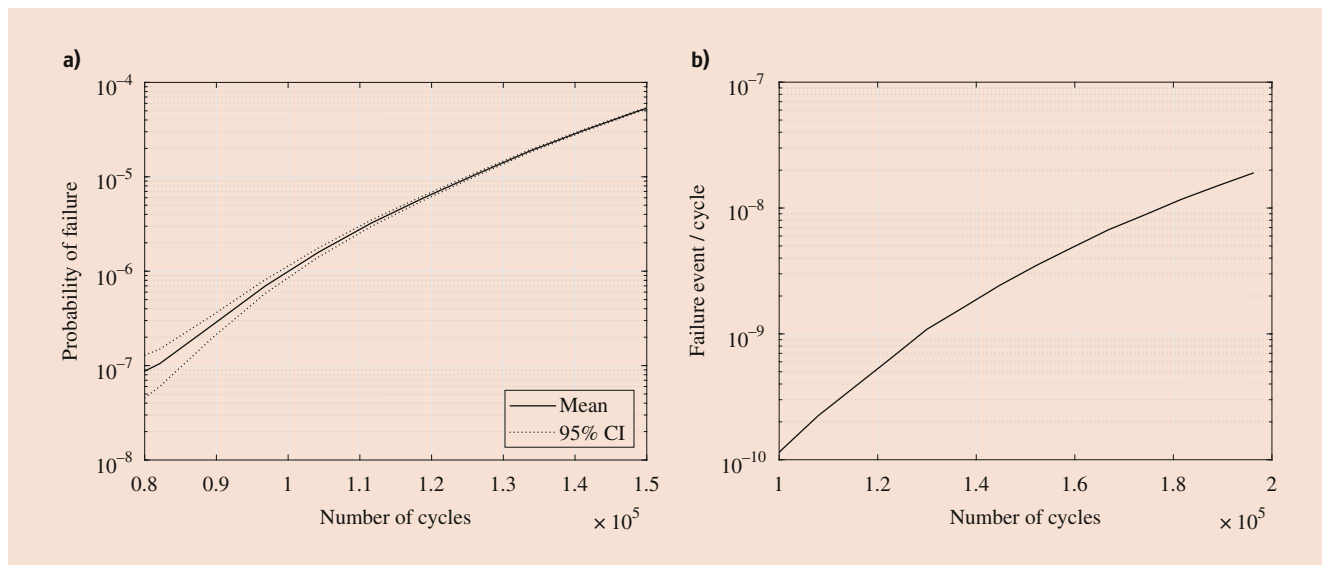

Fig. 48.17 (a) The time-dependent reliability in terms of probabilities of failure and (b) failure rate in terms of failures per cycle

the probabilistic framework for fatigue reliability analysis. The Monte Carlo estimators for reliability evaluations in terms of probability of failures are given. Two examples with realistic data are provided for demonstration. The difference between the median confidence interval and prediction confidence interval is signified using the examples.

The methods are applied to the reliability and low-cycle fatigue life prediction of a realistic Curvic coupling component in aeroengine. Contact surface uncertainty due to manufacturing and the inherent material uncertainty are considered. The coefficient of friction is used to represent different conditions of the surface state introduced by the manufacturing process. The strain and stress of Curvic couplings are evaluated using numerical models considering different contact surface coefficients of friction under working conditions. Based on the numerical results, a linear model is proposed to correlate the coefficient of friction and the resulting maximum principal strains at critical locations. Using the low-cycle fatigue model, a probabilistic life model incorporating the influence of surface roughness can be established to account for uncertainties from surface and material. Reliability and the fatigue life results are demonstrated.

using natural language processing to sentiment analysis for the consumer ambience and to buy/sell decision-making. The aim of this chapter is to present an approach to apply cognitive architecture in a multi-agent financial decision support system. On the basis of performed researches, it can be stated that cognitive architecture allows to increase the usability of the multi-agent system and consequently to improve the process of taking investment decisions. The ability to make automatic decisions is also of high importance here. For example, the cognitive agent can make real transactions (open/close short/long position) on the Forex market.

Abstract

The multi-criteria character associated with making decisions entails the need for analysis and evaluation of a large amount of information and drawing conclusions on the basis of such information. Since the process is time-consuming and practically impossible to be performed by a decision-maker in real time, it is necessary to use computer decision support systems, including multi-agent systems. To support financial decision-making, the cognitive technologies can be used. These technologies support

49.1 Introduction

The financial market is characterized by high variability of operating conditions [1]. Therefore, making financial decisions is a continuous process, associated with multi-criteria decisions nature. Subsequent decision situations occur chronologically in near real time and are always associated with risk.

The multi-criteria character associated with making decisions entails the need for analysis and evaluation of a large amount of information and drawing conclusions on the basis of such information. Since the process is time-consuming and practically impossible to be performed by a decision-maker (a human) in real time, it is necessary to use computer decision support systems, including multi-agent systems. These systems enable an automatic and quick way of finding information characterized by the appropriate value and drawing conclusions based on such data [2]. As a rule, each agent in the system uses a different method for financial

decision support, as well as can analyze different, often heterogeneous, data sources. A certain number of agents can, for example, make decisions using technical analysis, based on various types of indicators, which involves processing mainly structured data. Increasingly, however, agents make decisions using fundamental or behavioral analysis, which involves processing of expert or investor opinions. These opinions can be found, inter alia, on websites of brokerage houses, banks, or on social networks/blogs about financial matters. They are written mainly in a natural language, which is associated with the problem of processing unstructured data.

Parallely, there are observed changes in the financial industry related to the emergence of technology startup enterprises, which were previously outside of the financial sector. They are called “*Financial Technology*” or “*Fintech*” enterprises [3]. Mondal and Singh [3] state that key research issues for realizing innovations in the financial services include:

- Modeling and integrating large-scale and complex data from disparate and heterogeneous sources
- Putting a context around the data for context-aware reasoning and analytics purposes
- Cognitive analytics and semantic understanding and interpretation on the financial data
- Effective heuristics for detecting fraud
- Intelligent approaches for identifying cases of “creative accounting”
- Techniques for working with huge amounts of uncertain data from different modalities and identifying cross-connections and correlations

Dapp [4], in turn, states that current challenges in Fintech are related to using intelligent, cognitive, and self-learning technologies to support financial decisions-making processes. The authors have observed that new Fintech solutions are easily adopted by customers.

Cognitive technologies serve as tools for problem-solving that integrate such techniques, as machine learning, big data, data mining, computer vision systems, robotics, and natural language processing. Cognitive technologies can be used to support financial decision-making [5]. These technologies support using natural language processing (NLP) to sentiment analysis for the consumer ambience and to buy/sell decision-making [5]. Schumaker et al. [6] state that in order to support taking financial decisions, numerical and textual data should be processed parallely. For example, as a supplement of technical analysis (based on quotation numerical values) also the news (for example, from Tweeter) related to particular quotations should be automatically analyzed [7]. Jung et al. [8] and Alt et al. [9] address this problem

by applying a combined approach based on the technology acceptance theory and cognitive technology. Nowadays, machine learning, including deep learning, is mainly used to support taking financial decisions [10, 11]. They are useful for analyzing large volumes of numerical data. Thus, they are called cognitive tools in the explicit sense. However, a very big challenge is that they still are not enough for a computer system to learn a natural language and to understand the context of phenomena occurring in the environment as quickly and accurately as a several-year-old child [12, 13].

To resolve this problem, cognitive architectures, in the implicit sense (based on cognitive cycle), can be used. Generally speaking, the process of learning by humans is executed in the form of a cognitive cycle, from perception to purposeful actions. Many different artificial intelligence techniques are needed to support the cognitive cycle. Cognitive technologies must integrate them in a cognitive cycle of perception, learning, reasoning, and actions. This cycle is the key to designing modern intelligent systems [13]. The cognitive cycle consists of the following main stages [13]:

- Induction of new observations and generalizations of knowledge
- Abduction – the process of revising beliefs to modify theories
- Deduction, i.e., prediction
- Actions whose effects may confirm or refute the results of previous stages

The process of learning is also very important – chunks of knowledge are organized into theories – a set of consistent beliefs. The value of theory is high, if predictions based on this theory lead to successful actions. Learning is a permanent process of transforming data to theories. The cognitive cycle is a framework for accommodating multiple components of any kind [12, 13].

The aim of this chapter is to present an approach to apply cognitive architecture in a multi-agent financial decision support system (MAFDSS). This system is built using the framework Learning Intelligent Distribution Agent (LIDA) [14]. In this chapter, we consider the cognitive technology in the implicit sense (technologies based on cognitive sense consists of different artificial intelligence techniques).

The first part of the chapter presents the analysis of related works in the considered field. Issues related to cognitive technologies’ characteristics are presented in the second part. Next, the architecture of MAFDSS and functionalities of text analysis-based buy/sell decision agent are presented. The last part of the chapter presents the method of conducting and the results of a research experiment aimed at verifying the selected cognitive agents.

49.2 Related Works

There are different approaches to supporting financial decision-making process using multi-agent systems. Luo et al. [15] presents a multi-agent system for the stock trading framework, which consists of the following types of agents: the interface agent; the coordinator agent; the profiler agent; the monitoring agent; the communication agent; the risk management agent; the decision-making agent; the technical analysis agent; and the fundamental analysis agent. Such framework provides high performance of systems, but the authors draw attention to one main weakness – the coordinator agent is the critical component of this framework. The reason for this is that if this agent fails the whole system cannot work correctly.

Hafezi et al. [16] present a bat-neural network multi-agent system (BNNMAS), which aims to predict the stock prices. This framework uses four-layer genetic algorithm neural networks (GANN) and the generalized regression neural network (GRNN). Tan and Lim [17], in turn, introduced a hybrid intelligent system based on case-based reasoning (CBR) and the fuzzy ARTMAP (FAM) neural network model. This system supports investment decision-making process in manufacturing enterprises. The system stores cases of past investment projects in a database, characterized by a set of attributes indicated by human experts. The FAM network compares the attributes of a new project with attributes from past cases. Some similar projects are retrieved and adapted. The information from these projects can be used as an input to developing new investment projects.

Gottschlich and Hinz [18] present a system for supporting financial decision-making process based on collective wisdom. It allows for taking into consideration the crowd's recommendations for supporting investment decisions.

A numerical Pareto optimization method based on an evolutionary strategy has been presented by Xia [19] and Roosen et al. [20]. Barbosa and Belo [21] present a multi-agent approach based on a set of autonomous currency trading agents, using classification and regression models, a case-based reasoning system, and an expert system. Each agent supports a decision for different currency pairs. In order to decrease the level of risk the agents share monetary resources which have been used. Following such an approach to investments allows for achieving better results.

Some decision support systems related to financial crisis based on the investors' psychological behavior and rational reasoning are presented by Said et al. [22]. They focus on three main biases: overconfidence, loss aversion, and mimetic behavior. Authors state that for analyzing the financial crises, the interaction between rational and irrational behavior and the investor's psychology must be taken into consideration.

Chen et al. [23] present a hybrid multi-agent model developed based on mathematics and economics models. Here, more qualitative features are considered. The authors state that economic features, which cannot be modeled mathematically, can be difficult to be verified experimentally. Serrano [10] presents a random neural network in a deep learning cluster structure with learning based on a genetic algorithm, where information is transmitted in the combination of genes rather than the genes themselves. This approach has been applied and validated in Fintech; O'Hare and Davy present a solution based on classification of text opinions about financial markets using machine learning techniques. They use a multinomial naive Bayes (MNB) classifier and a support vector machine (SVM), for opinions' sentiment polarity classification [24]. Wang [25], in turn, presents an approach for supporting taking financial decisions based on the Matlab neural network time series tool. Sohangir et al. [11] applied several neural network models such as long short-term memory, doc2vec, and convolutional neural networks, to stock market opinions' analysis posted in StockTwits. Also, Li et al. [26] use convolution neural network (CNN) and two recurrent neural networks (RNNs) – the simple recurrent network (SRN) with traditional recurrent units and a long short-term memory (LSTM) with gating mechanisms, for analyzing opinions of investors. The machine learning approach is also used by Chan and Chong [27]. They develop two classifiers:

1. Making prediction of the right chunking point that lies between two adjacent phrases
2. Figuring out the appropriate syntactic structure for the chunks, such as noun phrases

Westerhoff [28] describes a system in which agents were divided into two groups – agents of the first group make decisions on the basis of methods of fundamental analysis, while agents of the second group make decisions on the basis of technical analysis. Paper [29] presents a multi-agent system that supports investing in the Forex exchange market and a method for assessing investment strategies of selected agents. Korczak et al. [30] conclude that different AI methods are used for supporting financial decision-making processes, including:

- Strong AI
- Deep learning
- Robotics
- Advanced brain-machine interfaces
- Trisynaptic models
- Circuit of the hippocampus
- Massive parallel processing
- Feedforward as well as feedback inhibition

In the process of document analysis, implemented also in multi-agent financial decision support systems, the following methods are used:

- Information retrieval
- Information extraction
- Text exploration
- Natural language processing [31]

The main purpose of information retrieval is to find an answer to a user's question among a collection of documents. Information extraction consists in identifying instances of a predefined class of events, their connections, and occurrences in written documents in the natural language [32]. The aim of text exploration is to learn the hidden information in the text using methods adapted to a large number of text data [33]. The natural language processing contains mechanisms that attempt to "understand" the context of the text. These methods do not include the term similarity values, but the following categories of text analysis are carried out [33]:

- The shallow analysis. It is referred to the analysis of the text, the effect of which is incomplete in relation to the deep analysis. Usually, the limitation is the recognition of nonrecursive or restricted recursion patterns that can be recognized with a high degree of certainty.
- Deep text analysis is the process of computer linguistic analysis of all possible interpretations and grammatical relations occurring in the natural text. Such a full analysis can be very complex.

In the process of text document analysis, semantic methods of knowledge representation, including semantic networks, are often used. Thanks to their application, a broadly understood knowledge representation is possible, in which it is important to draw attention to the interrelations between objects.

A very important problem is also the sentiment analysis related to other, than English, languages. Many tools for texts analysis in English are insufficient for other languages and it is needed to develop new, or to adjust existing tools to a given language, which is also a very important research and practical problem. For example, Ahmad et al. [7] develop the grid-based sentiment analysis method for Arabic and Chinese languages.

To sum up, in multi-agent systems supporting financial decision-making, the following methods are mainly used: technical analysis, fundamental analysis, and behavioral analysis. They are based on statistical methods and traditional data mining methods, such as regression analysis and decision trees and on training methods. Hassouna et al. [34] have showed limitations of statistical methods and traditional methods of data mining, such as:

- They do not explain the reasons for obtaining the value of retention and the relationship between factors that affect these values.
- Although they allow to define connections between variables and customer behavior, they do not allow to identify causal relationships between these variables. Decision trees can only be used in some cases to infer causation.
- Data mining models have a relatively short validity period. The application market, including mobile applications, faces new technologies every day. As a result, historical data becomes less valuable for prognosis.
- The level of analysis in data mining models reduces the ability to capture the heterogeneity of customer behavior.

In order to circumvent the disadvantages of traditional data mining techniques, the machine learning, including deep learning, models are currently used. However, these models also have limitations resulting from the following issues:

- Emergent character of ML – processing only numeric data. Many problems of the real world often also need symbolic data representation.
- The difficulties which use the hierarchical data (e.g., trees, thesauruses, and relations 1:M in databases) as input data model.
- The difficulties related to incomplete, contradictory data representation (e.g., "null" values).

In order to reduce the number of disadvantages of traditional data mining and deep learning methods, cognitive agents can be used in the multi-agent system supporting taking financial decisions. They perform cognitive and decision-making functions, which take place in the human brain, thanks to which they are able to analyze the real significance of observed phenomena and processes taking place, among others, on financial markets [12].

49.3 Recent Methods for Financial Decision Supporting

The methods for supporting financial decisions are generally divided into fundamental analysis, technical analysis, and behavioral analysis.

Using **fundamental analysis**, the investor is only interested in the issuer of the security and the economic environment in which they operate. By examining their financial condition, strengths, weaknesses, and development prospects, the investor answers the question whether it is worth investing in the issuer's securities [35]. A comprehensive examination of the issuer's condition is accompanied by an analysis of their macroeconomic environment, which allows to identify the entity which has the best opportunities

for future profit growth. Fundamental analysis is a form of capital market valuation involving the assessment of processes taking place in the macroeconomic environment of the stock exchange.

When choosing the most attractive companies, supporters of fundamental analysis refer, among others, to the following [35]:

- Audits of periodic statements and annual balance sheets of companies
- Analysis of the company's future profit forecasts
- Analysis of profits generated in a given period as well as incurred losses
- Examination of the development strategy chosen by the company

The investment selection process also applies to [36] the following:

- The general economic condition of the country
- The monetary policy implemented by the government and the central bank
- The analysis of the industry in which the company operates
- Strengths and weaknesses, opportunities, and risks which the company faces

It follows from the above that the fundamental analysis is used to determine the profitability of investments in company shares based on a comprehensive assessment of the company from the past. The conclusions are reached after analyzing the results of a minimum period of 3 years of the company's activity. To achieve a satisfactory result, the time projection of analyzing the company's results should be extended to 5 years.

The sense of fundamental analysis is not to identify good companies, but to select companies that are better than anyone can suppose or judge. Similarly, companies negatively perceived by the market can be excellent investment opportunities, if, of course, they are not as bad as it seems. Therefore, it is not enough to conduct a good fundamental analysis; one can only earn money when the conducted analysis is of higher quality than the analysis of the competition [36].

Opponents of fundamental analysis often question the possibility of including a large number of different types of risk in the company's valuation, such as interest rate risk related to the change in basic market interest rates, market currency risk, purchasing power risk – also known as inflation risk, political risk related to legislative and tax changes, etc. Fundamental analysis is not an ideal method, as it possesses various disadvantages which affect the results of investment decisions. Here are the most important of them [37]:

- The assumption that the company whose profits have risen so far will continue to strengthen; the profits of companies are not growing because they did so in the recent past, but because the companies are well managed, have better technology, and are well promoted.
- The assumption that the growth rate will be maintained at its current level.
- There are no fluctuations in economic life; expansions and recessions occur in the capitalist economy, the effects of which are felt by almost all enterprises.
- Failure to take account of the fact that market prices precede fundamental knowledge.

One of the major disadvantages of fundamental analysis is the assumption that the current trends disclosed in the financial reports will continue. In real economic life trends change, which makes forecasting much more difficult. The fundamental analysis consists of four stages: analysis of the macroeconomic environment, financial analysis, analysis of financial statements, and analysis of indicators. Let us, therefore, discuss their brief characteristics.

The initial stage of the fundamental analysis is to determine the state of the economic environment and its impact on investment decisions, i.e., the analysis of the macroeconomic environment. The concept of growth is central to this type of stock analysis, as the increase in profits and cash flow is considered the basic condition for the increase in dividends and share prices.

Macroeconomic analysis provides data used in industry and enterprise analysis, and allows forecasting interest rate levels and long-term trends in price and profit ratios. Analysts try to identify sectors of the economy that offer higher-than-average profit opportunities, and then relate this information to specific companies.

Economic cycles and related trends are crucial for the investor. The cyclicity of the stock market has been around since 1961 and has become a major disincentive to invest in the late 1970s and early 1980s [38].

Analysts who use fundamental analysis attach great importance to profits achieved by enterprises as well as to the analysis of the macroeconomic environment.

The macroeconomic analysis assesses the overall attractiveness of investing in a given stock market. This attractiveness depends on the economic and socioeconomic situation, as well as on the economic and monetary policy of the country in which the investor wants to invest, with a particular emphasis on the investment risk in the given country. Subsequently, a sectoral analysis is performed, which assesses the attractiveness of investing in companies belonging to a given sector of the economy. After choosing a sector, it is the turn of the analysis of companies belonging to a given sector. At the beginning, a situational analysis of the company is made

(against other companies in the sector), where nonfinancial aspects are assessed, e.g. [37]:

- Quality of management staff
- Modernity of production
- Company strategy
- Conducted marketing, etc.

It is clear that this stage of fundamental analysis is not easy for practical application by an individual novice investor. Such an investor should be recommended a “short-cut.” It involves studying ready-made analyses which are published in financial magazines or in financial columns of newspapers.

When choosing the most attractive companies, a special role in fundamental analysis is played by financial analysis, which is divided into three basic groups of investment techniques [38]:

1. Examination of the vertical and horizontal structure of the company’s balance sheet. This analysis includes determining the regularity of financing investment activities and the method of financing fixed assets, the method and regularity of financing current stocks, the company’s payment ability, and the ratio of receivables to liabilities. Therefore, the balance sheet division determines the dynamics and development opportunities of the company, while the horizontal layout checks its quality and market value.
2. Analysis of changes in the company’s foreign capital. The amount of foreign capital illustrates the degree of financial security that an entity possesses. It also informs about the amount of capital that will remain inside the entity after paying off its current liabilities. If the foreign capital is at a high level, this indicates a high investment risk and carries a possible danger to the company in the event of nonpayment of its obligations. The optimal situation is when foreign capital is at a relatively low level, which makes it possible to state that the given entity is in good financial condition and it is unlikely that its position among the competition will be violated.
3. Determining the company’s cash flow. This is the sum of profit and depreciation for individual tasks that have already been completed. This factor provides information on the sources and purpose of cash, as well as the type and method of financing the investment.

Technical analysis is not interested in the security issuer it deals with. Using this method, all that is needed is the current exchange rate and turnover, past data, and a reference point to calculate the indicators. It is not necessary to know the name of the security that is being analyzed in order to determine the optimal buying and selling times [39].

Technical analysis is based on three basic premises [40]:

1. The market discounts everything. Supporters of technical analysis claim that all factors that affect the price are already included in it. This is due to the belief that price behavior reflects changes in demand and supply relationships. In other words, the technical analyst assumes that one does not need to study the factors affecting the price of the instrument or investigate the reasons for the decreases or increases. The market knows everything and it shapes the price, which is why it is important to study charts and indicators for technical analysis to effectively forecast market behavior. This does not mean that technical analysts reject the claims that economic conditions are the cause of trends on the stock market. They simply believe that the market is easier to understand and predict by analyzing the record of its behavior, i.e., the charts.
2. Prices are subject to trends. When drawing price charts, the technical analyst tries to find a trend in them, i.e., the direction in which prices are moving. Recognizing the trend in its early phase allows to make a transaction that should bring profits (buy when the upward trend is created, sell when the downward trend appears). Analysts assume that the trend is more likely to continue than to reverse.
3. History repeats itself. The study of charts allows to find repetitive patterns (formations) by which prices move. This is due to the repetition of human behavior in certain situations. Knowing the most common patterns (formations), analysts try to find them in current quotations and on this basis forecast the future.

To sum up, the first premise claims that the market fully discounts all information that may affect the stock price, which means that testing prices alone is a self-sufficient approach. The second premise concerns the trend, one of the basic concepts of technical analysis. It claims that courses move in trends, and the task of technical analysis is to capture their changes. The third premise concerns market psychology and assumes that under similar conditions to the past, the market situation will be similar.

Therefore, a technical analyst is a person who studies the effects of market behavior (prices) and searches trends and formations that will help predict market behavior on historical charts. In their work, analysts support themselves with, among others, indicators which help them better understand price movements [41].

Thanks to this, it is possible to find the answer to three main questions that every investor asks [38]:

1. What to buy or sell?
2. When to buy?
3. When to sell?

Table 49.1 Technical analysis indicators [38, 41]

Tracking indicators trend	Oscillators	Mood indicators
They work best when prices are “in motion” but their signals are incorrect in the horizontal trend; they are lagging behind the trend, changing direction when reversed	They capture turning points in flat markets; however, their signals are premature when a new upward or downward trend begins; they are indicators that are concurrent with or even preceding a trend	Allow to study the “psychology of the masses”; these indicators may be leading or concurrent with the trend
Moving averages MACD MACD – histogram OBV – On Balance Volume A/D – accumulation/distribution	Stochastic ROC – rate of change Momentum RSI – Relative Strength Index Force Index CCI – Commodity Channel Index	New High-New Low Index Put-call ratio Bullish Consensus Commitments of Trade Advance/Decline Index Traders

Technical analysis, like fundamental analysis, is used to determine the right time to buy and sell shares. To make the investment as profitable as possible, a variety of tools are used in technical analysis in order to study phenomena occurring on the stock market. However, unlike the fundamental analysis, the whole process of assessing the amount of future investment profits proceeds in a slightly different way. In technical analysis, investors are guided in the stock market game mainly by historical data, which do not have their roots in reports, balance sheets, or profit and loss statements, but in data from the direct economic environment of a given company and what happens directly on capital market. These data are used by investors to construct stock market indicators, helpful in assessing the attractiveness of shares of selected companies. The first stock market indicators were created at the end of the nineteenth century, but their full boom can be considered only the period of the great bull market in the USA from the 1920s. Since then, their popularity has been established and continues to this day. The breakdown of indicators is presented in Table 49.1.

The behavioral trend is not intended to provide guidelines for rational behavior, as standard economic theory does, but to describe and explain the mechanisms that control people’s real decisions, mechanisms which stem from psychological and institutional factors [42]. Numerous theories serve this purpose, several of which are described below. The common basis for each of these theories is the assumption that people do not have perfect information or unlimited possibilities to process it; in the real world, information is incomplete, unclear, complicated, there may occur problems with its interpretation, and for practical reasons we are often unable to compare all possible selection options in each of the relevant aspects. For the abovementioned reasons, it cannot be said that people take optimal actions from the point of view of material rationality. Instead of striving to achieve maximum utility or profit, we are content only with their satisfactory level (satisfying behavior). In behavioral terms, the utility of the decision-maker is not treated as a permanent, coherent, and one-dimensional category [43]. On the contrary, several types are distinguished, among others:

- Decision-making utility, most often found in traditional economic approaches and referring to preferences that are disclosed by the buyer at the time of purchase
- Experienced utility, which relates to the perceived level of satisfaction

The literature mentions two research directions related to behavioral finance: analysis of market behavior on a macroeconomic scale, especially in the context of numerous market anomalies, and analysis of individual investors’ behavior in terms of systematic cognitive errors made by them in investment decisions.

Behavioral analysis usually employs the following [44]:

- Descriptive theory
- Predisposition effect
- Emotion changeability
- Cognitive distortions

Descriptive theory is the descriptive (i.e., based on the results of experiments) theory of decision-making in conditions of uncertainty, and it can be considered as the greatest contribution of psychological sciences to economics and finance. It is a model that somehow filled the gap between the idealistic theory of the expected utility of von Neumann and Morgenstern, and reality. The central assumption of the theory of perspective is that it is not the absolute level of wealth, but changes in its level (profit vs. loss) that are the carriers of perceived value. Another important assumption of this theory is decreasing sensitivity to losses. The last important feature of the human psyche affecting the shape of the function of value is the loss aversion, which is that losses hurt more than profits please, despite the fact that they are of the same absolute size. This means that the value function is steeper in the area of losses than in the area of profits [42].

The predisposition effect is manifested in the fact that shares in companies whose prices have risen are sold much faster by individual investors compared to shares in companies that have lost value. This is contrary to the classic theory of finance, according to which in making investment

decisions investors should be guided by expectations about future stock prices and not their price in the past. Moreover, the predisposition effect also negates two central assumptions of the portfolio theory: the tendency to diversify one's own investment portfolio and the investors' desire to sell shares in order to increase their own liquidity. In both situations, investors should sell those shares which possess the lowest expected returns. In addition, it would be advisable to sell shares of loss-making companies quickly, as this is the optimal solution from the tax point of view. Meanwhile, according to the predisposition effect, investors do the opposite, i.e., they are more willing to sell shares that have a higher expected rate of return [42].

Investing in the stock market is frequently associated with violent and variable emotions, which often have a significant impact on decisions taken, causing significant deviations from rational action. Making decisions on the capital market takes place in conditions of considerable uncertainty, because investors never know how the market will behave in a month, in a week, or even in an hour. Psychologists have long proven that the behavior of an individual is strongly dependent on their emotional state (8). Additionally, cognitive errors and distortions, which are usually a derivative of the impact of emotions, have a significant relationship with the limited rationality of the individual (9). Analyzing the impact of emotions and the psyche of investors on making decisions on capital market, one can get a real picture of investor behavior on the stock market. One of the most important manifestations of the impact of emotions on the investment process is that investors give in to the feelings of regret. Regret often accompanies investors after making a decision whose consequences have proved unfavorable for them. The theory of regret formulated by David Bell (10) assumes that the feeling of regret associated with making the wrong investment decision is stronger than the possible feeling of pride and satisfaction associated with making the right choice [43].

What follows is hasty selling of rising shares in order to secure oneself against the future decline in their prices. In addition, the regret caused by the loss on investing in a particular company is experienced more intensely than in the case of a loss at the level of the entire stock exchange, because that loss can be attributed by investors not to their own mistake, but to unpredictable market forces. The regularities described here affect the way investment portfolios are constructed by individual investors who choose their portfolio so that some of them provide a reduction in fear of potential loss, and some give hope for future profits. This is, therefore, contrary to Markovitz's portfolio theory, as investment portfolios in a behavioral perspective are not a set of analyzed and suitably diversified assets, but rather a mosaic of little correlated elements that reflect the investors' emotions rather than a rational assessment of the market's situation [44].

In addition to emotions, investors often undergo various cognitive distortions when making investment decisions. One of them is overconfidence. Investors are often so convinced of their outstanding investment capabilities that they undertake increasingly risky transactions, which often ends in very severe losses. An important manifestation of excessive self-confidence is unrealistic optimism, visible in making mistakes in the planning process. Its important aspect is the inability to learn from one's mistakes – even if earlier forecasts were excessively optimistic, most people believe that the next time their choice will prove to be correct, which can also be fatal in consequences for their state of ownership. Another cognitive distortion is the so-called mental accounting, which involves a separate and selective analysis of the various attributes of financial decisions. This leads to the fact that investors are not able to close the loss positions and invest funds from their shares in new ventures that resulted in losses, because such shares are treated as a separate mental account. Instead, many of them hope to change the trend and make up for the losses in the future, which often deepens these losses and causes a further decrease in the value of the entire investment portfolio [42].

Finally, analyzing cognitive distortions in the process of investment behavior, one should mention heuristics. These are practical rules of thumb, based on experience or even colloquial knowledge and used to make decisions without a thorough comparison of all available options (13). If an algorithm can be treated as an exact recipe for solving a problem, heuristics is usually only useful as a tip that may not necessarily bring the correct solution to the problem. Heuristic distortions are quite common in the process of making investment decisions on the stock exchange, where information buzz prompts investors to make decisions based on heuristics [44].

The financial decision support is always related to the risk. Depending on the group of factors posing a threat to the purpose of a given investment in capital assets, the following types of risk can be distinguished [8]:

1. Political risk. It is associated with political events and decisions taken in the country. Political decisions that can affect the capital market (negatively or positively) include, for example, the result of the election leading to a change in the ruling political option [45].
2. Risk related to the situation on the stock exchange market. It is associated with continuous movements of securities prices. Stock market analyses lead to the conclusion that prices are changing in line with trends. Changing the direction of the trend from growing to decreasing and vice versa causes a large uncertainty in investment because it is impossible to clearly indicate the point at which the trend will change [8].

3. Market risk. It manifests itself in fluctuations in market prices. It is associated primarily with changes in raw material prices, supply prices, product selling prices on the market, etc. [8].
4. Liquidity risk. It is associated with the difficulty of liquidating investments. Liquidity should be understood as the time necessary to convert assets (e.g., securities) into cash. The longer this time, the greater the liquidity risk [46].
5. Inflation risk. It is associated with a change in inflation rate. In conditions of high inflation, this may mean that investment income does not cover the increase in the cost of maintaining it [47].
6. Interest rate risk. To a large extent, it is a consequence of inflation risk. The level of return depends on the interest rate offered by banks on the market. An increase in the interest rate results in the outflow of capital from the stock exchange and placing it on bank accounts. Bank deposits are much less risky than investing on the stock exchange market. The consequence of this situation is a decrease in the rate of return on investment and vice versa, lowering interest rates by banks leads to an increase in the attractiveness of investing in securities. A special case of interest rate risk is the risk of a price change, often referred to as holding period risk. It is characteristic of the bond market and is associated with a situation in which the bond holder intends to sell it before the date of buyout [48].
7. Exchange rate risk. It occurs when the financial instrument in which one invests is denominated in a currency other than that of the investor. In this situation, the rate of return expressed in two different currencies is not the same. Therefore, if the investor buys a financial instrument in a foreign currency and the exchange rate depreciates, this is a favorable situation for the investor. When the exchange rate appreciates, the investor will lose because the nominal return on investment will decrease [49].
8. Default risk. It occurs when the issuer of a financial instrument fails to comply with the terms of the contract. If the investor buys bonds issued, for example, by a listed company, and the latter does not pay interest or fails to timely redeem the bonds, the investor will incur a loss [50].
9. Risk of reinvesting. It is related to a situation in which an investor's income from holding a financial instrument is reinvested at a different interest rate (e.g., due to changes in interest rates on the market) than the rate of return on a given financial instrument [51].
10. Risk of redemption on demand. It is related to futures and bonds. For example, if the investor has issued an American option for sale, which can be exercised at any time, the investor will incur a loss if the request to exercise this option occurs when the value of the instrument for which the option was written decreases.
11. Risk of interchangeability. It occurs in the case of instruments that can be converted into other instruments (in Poland, an example of such financial instruments are convertible bonds issued by the State Treasury). The risk is that the exchange may occur in conditions that are unfavorable to the investor [52].
12. Financial risk. It is a state of uncertainty that appears when financing investments with foreign capital. The use of debt capital leads to additional financial charges associated with servicing the loan. The financial risk is strongly influenced by interest rate fluctuations, which are quite difficult to predict [53].
13. Banking risk. Banks are the second group, apart from enterprises, using derivatives to minimize the risk of their activities, i.e., minimizing banking risk. Banking risk is associated with an extremely important role played by banks in the national economy. This role boils down to the three most important areas of the bank's activity, which are [54]:
 - Participation in the creation of money
 - Participation in the social division of labor
 - Allocating and transforming funds

The risk issues should be taken into consideration regardless of the method used to support financial decisions.

The presented methods for financial decision supporting are often implemented in agents' architectures in multi-agent systems. On the basis of decisions and data generated by several agents (each agent uses a different decision support method), it is possible to provide more sophisticated investment strategies. For example, the strategy can be built on the basis of expert opinions (based on, for example, fundamental, technical, or behavioral analysis). Such strategies can be realized by cognitive architectures characterized in the next part of the chapter.

49.4 Cognitive Architectures

49.4.1 Basic Issues

The cognitive architecture is defined as an organized structure of processes and knowledge trying to model itself on cognitive dependencies [55]. The primary stimulant for the creation of cognitive architectures was helping humans in complex situations, where the computer could be characterized by a much faster reaction time in a situation in which one should take into account many variables present in the current situation. If we take into account human capabilities, using the cognitive architectures can allow for mechanical support of the activities in which humans are limited [12].

Cognitive architectures are expected to be able to solve not only one problem using the designated method, but also to be able to analyze the problem from a broader perspective, using a wider range of solutions. In addition, they will be able to implement new solutions in a dynamically changing environment with the help of acquired experience and knowledge. The acquisition and use of acquired knowledge is special here. Thus, cognitive architectures should consist of the following [56]:

- Memory that will store knowledge.
- Adequate representation of the knowledge.
- Processing units whose task will be to extract, combine, and store available information; they are often called operators that perform functions that “cause something to happen”; from the point of view of architecture, it does not matter if these functions describe the physical world, the imaginary world (e.g., human mind/imagination), or any virtual world generated for the chosen architecture.

Common important features of cognitive architectures are: how their learning mechanisms are designed and how their memory is organized. A large variety can be found in how the role of memory is perceived in the various approaches to building architectures [12].

Learning mainly consists in the fact that the acquired knowledge will be remembered and the possibilities and situations in which it can be used are assigned. Effective design and use of this process is a significant step in building higher cognitive systems. The way in which memory is organized is related to how knowledge is represented [12].

If we focus on these two important features, we can divide architectures into three types [57]:

- Symbolic
- Emergent
- Hybrid

Figure 49.1 presents the examples of such architectures. Each type of cognitive architecture can be represented as a series of steps required by architecture to perform the desired action (cognitive cycle). Although the term cognitive cycle is used to describe most architectures, they differ in the type of activities performed at each stage. The way they are grouped depends on the type of information presented and processed, and not on the various possibilities, properties, and criteria for assessing a given architecture [57].

49.4.2 Symbolic Architecture

Symbolic architectures represent concepts using symbols that can be manipulated using a predefined set of

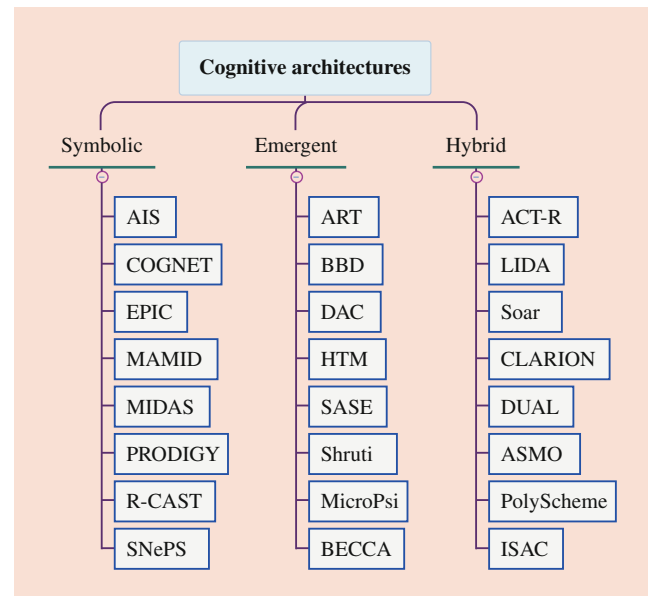

Fig. 49.1 Examples of cognitive architectures

instructions [57]. In most cases, this type of architecture uses centralized control of the flow of information from sensors to effectors. The executive functions related to the working memory are used here. In addition, knowledge stored in the semantic memory is used. This memory can be organized by means of production rules [12]. These rules are a very natural and intuitive representation of knowledge, therefore these are used by many practical solutions. Symbolic architectures stand out in planning and reasoning and they are able to cope with flexibility and resilience that enable us to cope with the changing environment and perceptual processing [57]. They work based on expert knowledge, after perceiving and identifying a problem. They are able to generate specific actions in line with assumed objectives of an action using their own knowledge.

Another organization of memory is graph representations, i.e., a structure consisting of vertices and edges that connect vertices. Usually, directed graphs are used where the edges immediately precede the vertices, and the vertices are direct successors of the edges. By transforming data into graphs, you can simplify the network to a large extent and create a clearer tool for solving problems [58].

Symbolic systems represent concepts using symbols that can be manipulated using a predefined set of instructions. Such instructions can be implemented as if-then rules applied to symbols representing facts known around the world (e.g., ACT-R, Soar, and other architecture of production rules).

The process of learning can be divided into an analytical (deductive) one and an inductive one. Analytical learning works on the principle of creating new facts based on agent’s knowledge. Inductive learning relies on finding the right

hypothesis among the observed data, which would agree or translate with already existing knowledge [12].

49.4.3 Emergent Architectures

An emergent architecture is not yet such an effective tool in solving problems, nor does it represent complex forms of knowledge like the symbolic architecture. This architecture sooner solves problems based on the interpretation of the observed data that reaches the system and the problems of perception. Neurobiological inspirations of emergent architectures appear in the form of connectionist and neural models. The network is composed of signal processing elements that represent specific memory traces, so one configuration is responsible for specific arousal in neural networks. Transitions between configurations are determined by connections between network nodes. In the neural model, based on the stimuli of several neurons (which individually fulfill specific functions), the system may interpret this configuration as a memory trace, e.g., of a specific object. There are associations between configurations, so that activation can pass to subsequent configurations of neurons. The actions occur between elements of the network. Changes take place in the entire network and new properties are developed [12].

The organization of memory in emergent architectures is carried out in two ways. One way is the global, distributed memory. All parameters occurring during the program operation have a direct impact on the achieved result. The other is local memory. The nodes of the network are activated by stimulation, so that only a few affect the final result [12].

Learning, in turn, is divided into an associative one and a competitive one. Associative learning transforms input data into simplified representations of output data, which can be divided into already known classes. The data are associated as objects, properties are matched to the possessed knowledge. Learning can be done under supervision, i.e., the data provided is compared to the expected network responses or by learning with the critic where the system is accounted from the few steps it has been able to perform (the result can be positive or negative). Competitive learning follows the “winner takes everything” principle, where the victorious element is the model for the next series of signals. The other elements are slowed down to simplify the signal flow [13].

This architecture solves the problems of system adaptation and learning by building parallel models, analogously to neural networks, in which the flow of information is initiated by signals from input nodes. However, the transparency of the system is low because it is no longer a set of symbolic entities, but it is distributed throughout the entire network. Hence, a logical inference in the traditional sense becomes problematic and unintuitive, which creates a new challenge to overcome for modern architectures [57].

49.4.4 Hybrid Architecture

The hybrid architecture combines the advantages of previous architectures, using effective planning and reasoning similar to the symbolic architecture, and good transformation of a large number of diverse data allowing the implementation of higher cognitive functions, similar to emergent architectures [12].

Memory organizations can be divided into a sprawled locale that includes a combination of local and distributed memory modules. The second division is symbolic-connectionist memory, which can be a combination of connectionist, dispersed, or local modules and symbolic modules [57].

Learning is divided into top-down or bottom-up domination. In top-down learning, the subsymbolic level determined by the lower level is taught by observing the dependencies from the received information from the higher (symbolic) level, where logical rules or other mechanisms of inference are operated. Teaching bottom-up mechanism works the opposite way. From the subsymbolic level, knowledge is transferred to the symbolic level in the form of formulated concepts [13].

Based of different types of architectures the cognitive agents are built.

49.4.5 Characteristic of Cognitive Agents

Cognitive agents internally regulate their goals based on their beliefs (like their decisions and plans). Goals and beliefs are a cognitive representation that can be internally generated, manipulated, and subject to reasoning [58, 59].

Most cognitive models try to model a certain type of cognitive process, e.g., perception, attention, memory, emotions, decision-making, choice of action, etc. or some narrow range within one of them. A much less frequent model at the level of systems (cognitive architecture) tries the full range of activities from incoming stimuli to outbound activities, along with the full range of cognitive processes between them [14].

Beliefs (knowledge possessed), expectations, goals, theories (coherent and explained set of beliefs, e.g., rules of production), plans, and intentions are representations used by cognitive agents. These representations affect the actions of themselves and other agents. A cognitive agent is defined in various ways in the literature, but the most common definition is that this type of agent is a computer program that [57]:

- Is capable of taking action in the environment in which it is located
- Can communicate directly with other agents

Table 49.2 Comparison of the cognitive and reactive agent

Cognitive agent	Reactive agent
Inference based on logic, ontologies, and knowledge	Inference based on the state of sensory inputs
Higher maintenance costs	Low maintenance costs
Self-sufficiency	Lack of self-sufficiency
Actions initiated by environmental stimuli	Actions depending on specific situations
Cognitive skills	Lack of cognitive skills
Learning	Functioning based on programmed methods, no learning opportunities

Source: own

- Is directed by a set of habits, tendencies that are specific goals, or an optimized function of benefits
- Has its own resources
- Is able to receive stimuli from its environment, but to a limited extent
- May have partial knowledge of this environment
- Has skills and can offer services
- Can reproduce, clone
- Displays behavior which urges it to strive to achieve goals taking into account available knowledge, resources and skills, and relying on the ability to receive stimuli from the perception and communication
- Can learn about the environment and learn by gaining experience

Therefore, it can be said that a cognitive agent is an intelligent program that not only requests based on the data received, takes specific actions to achieve the set goal (it can be, for example, supporting decision-making), but also, unlike a reactive agent, teaches while gaining experience. Table 49.2 presents the differences between cognitive agents and reactive agents.

It should be noted that the cognitive agent is self-sufficient, i.e., it can make its own decisions without human intervention (such agents are used, for example, in devices operating in space).

Higher costs of maintaining a cognitive agent are primarily associated with a greater demand for IT resources (hardware, software, and data resources).

In this chapter, attention will be paid to several types of cognitive agent architectures that we analyzed in our research:

- BOID
- Cougaar
- Soar
- SNePS
- LIDA

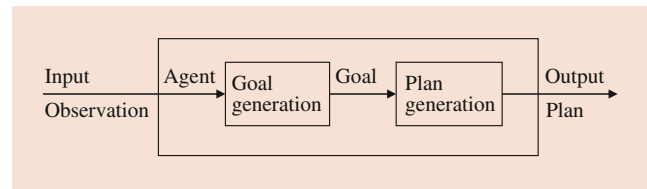

Fig. 49.2 Agent diagram in BOID architecture. (Source: own)

The first is the BOID architecture (beliefs, obligations, intentions, and desires).

Beliefs reflect the agent’s knowledge of the world around it, desires are defined as the states of the world – the potential goals of the agent, and its responsibilities are determined by tasks resulting from functioning in the group, while intentions reflect the agent’s real goals. The agent observes the environment and reacts appropriately to its changes using detectors and working mechanisms. Each object in the environment, called a component, is a process of input and output nature and operates based on rule systems that contain executable rule sets. The outputs represent the so-called “mental attitude” depending on the state of the inputs [59, 60].

Two modules are distinguished in this agent architecture (Fig. 49.2):

1. A goal-generation module that generates goals based on beliefs, desires, intentions, and responsibilities.
2. A plan-generation module that generates action sequences based on the generated goals.

In the case of agents supporting decision-making, goals and intentions are to help the decision-maker make decisions or to make the decisions independently (e.g., granting a loan and purchase shares), plans specify the actions to be taken to achieve the goal (e.g., read data and process it), beliefs express the decisions taken in the application process (for example, grant a loan and buy shares of given companies), while the obligations may specify that, for example, if a loan was granted to person 1, then the loan should also be granted to person 2 if he/she meets the same conditions as person 1 [61]. The BOID architecture is a symbolic architecture and can be used for financial decision supporting, but the frameworks of these architectures are too general and many of mechanisms for input data processing must be implemented by users.

Another cognitive architecture is Cougaar (cognitive agents architecture), which enables the creation of multi-agent systems using the Java programming language, developed by the ALPINE consortium for the DARPA (Defense Advanced Research Projects Agency). It consists of numerous layers of interactive applications – systems within systems [62]. This enables agents to be connected

in different communities [63]. For example, if we consider an enterprise, it may constitute a community, where the departments of the enterprise will be smaller communities located lower in the system hierarchy, while the counterparts of individual employees will be specific agent programs. In architecture, it is assumed that agents perform operations on so-called components (in other words, objects; for example, securities and currencies). The Cougaar architecture can therefore be used in the construction of multi-agent financial decision support systems, however it is a “black-box” and modification of software code (for example, to adapt to the field of the problem) is very difficult [64].

One of the more popular architectures is Soar (state, operator, and result). It is a general cognitive architecture for creating systems that exhibit intelligent behavior. Scientists, both in the fields of artificial intelligence and cognitive science, use Soar to perform a variety of tasks. It has been in use since 1983, evolving through a number of different versions. The creators of Soar have an ambitious plan to create a general artificial intelligence agent that will cope on many levels [65].

Plans for the functioning of Soar architecture provide for:

- Working on the full range of significant problems, open problems
- Using memory modules such as procedural, semantic, episodic, and iconic memory
- Use a full range of problem-solving methods
- Appropriate operation in an external environment
- Ability to solve tasks and implement them in the environment, combined with continuous learning about this process

Total rationality is a direction for the development of artificial intelligence. This means that the system, with the extensive knowledge it would have, would be able to take on any task it encounters. However, this goal is very difficult to achieve, so all attempts are now limited to an approximate version of rationality [65].

In Soar, decisions are made through current analysis and interpretation of sensory data provided to the agent. Working memory contains information needed to solve problems, often in the form of production rules or graphs, and all this is based on knowledge accumulated in long-term memory, e.g., semantic memory. Soar is characterized by functionality and efficiency. Functionality is that Soar has primitive cognitive skills that are needed to carry out tasks in accordance with the pattern of human reasoning. Among other things, it is able to make decisions based on reactions, understands the environment in which it works, plans, uses several forms of learning, and is aware of the situation. On the other hand, efficiency is based on the fact that it is able to take advantage

of the system’s advantages, such as efficient calculation of learned algorithms, has quick and easy access to saved experiences, is able to make decisions faster, and acquires and stores new knowledge.

In Soar there is a spatial visual system (SVS), independent from the system, which supports the interaction between connections needed for perception and motor control, and the symbolic representations of these relationships. In addition to internal support, SVS also supports the system externally. Thanks to this, the agent can use so-called mental images. They allow continuous interpretation of a dynamically changing environment. This is useful, e.g., in the use of car controls, with modern algorithms that interpret the planning of its path. Soar belongs to hybrid architecture; it uses both symbolic and nonsymbolic structure [66]. The working memory in the symbolic structure contains current and recent sensory data, the current goal, and interpretations of the situation in the context of implementation of this goal. Working memory acts as a buffer for long-term memory and motor function. The semantic memory contains information that illustrates the agent’s model of the external world, but it is downloaded to the working memory when it is needed. Newly created information in the learning process is delivered to the semantic memory, although one can implement the rules at the beginning of the agent’s creation. In the episodic memory, on the other hand, there are snapshots of the agent’s experience. This memory accumulates experience and allows one to use it to guide future behaviors and draw conclusions. Among numerous cognitive agent programs, this type of memory is not frequently employed, but it is extremely useful because it leads to maintaining greater consistency between experiences [66].

The procedural memory contains production rules. Specific situations are coded there, including descriptions as to how the system should deal with them. Processing units are operators which arise in working memory and propose solutions based on the current situation. They have their preferences, which are analyzed using established decision-making procedures. The agent determines whether the operator is suitable to participate in the cognitive cycle, and if not, it causes stagnation. This contributes to the fact that the operator enters the substate in which there may be more thought-out reasoning, task decomposition, changes in planning, and methods of finding solutions. The selected operator modifies working memory, e.g., by downloading from semantic or episodic memory, or by issuing external motor commands [65].

After selecting the operator, rules sensitive to his/her choice perform their actions by modifying the working memory. The action can be an internal step of reasoning, a query to SVS, downloading from episodic or semantic memory, or an external motor command. The operators in Soar conceptually correspond to the STRIPS operators; however, in

Soar the constituent parts of the operators (preconditions and actions) are broken down into individual rules to ensure the preconditions and conditional disjunctive actions. In addition, Soar has rules which are dependent on the tasks to assess the operator, ensuring contextual and precise control of operator selection and application [65]. The Soar can be used in multi-agent financial decision support systems, however it is characterized by high demand for hardware resources.

Another example of cognitive agent programs is SNePS – the Semantic Network Processing System. It is a system based on logical, framework, and network representations of knowledge, inference, and action. Semantic knowledge works on the principle of ordered direct graphs whose nodes represent entities and arches represent the relationship between two nodes [66]. The unit represented by node n reacts with the R arch with the unit represented by node m . In SNePS, a set of nodes in the program network and a set of logical conditions operate at the same time. When a problem arises that needs to be resolved, the entire SNePS operation is implemented at the node level, not at the arches. The relationships represented by arches can be understood as part of the structure of nodes that illustrate where certain activities originate. Each time information is added to the network, new connections are created that are implemented with the principle of operation of nodes and arches. New information is assigned to the appropriate relationship. Each autonomous representation is expressed as a node or condition. Each unit in the network is represented by a unique node. The program user can add such representations according to their needs [66].

There are four types of nodes [66]:

- Basic – they do not originate from arches, i.e., they do not start further action; it is assumed that the basic nodes represent, e.g., a unit: objects, classes, properties of entities; they can be ranked according to an equality or equivalence relationship; and it is also possible to specify the rules for using these nodes.
- Variables – additionally, they do not start an activity, but they represent any units or suggestions in a similar way as logical variables do.
- Molecular – they possess arches which extend from them and they can represent various solutions, including rules.
- Reference – they also possess arches coming out from them; they represent any sentences or units of any structure; and they are similar to open tasks in the predicate logic.

An important function of the SNePS program is the introduction of context functions. It is a structure consisting of three components [67]:

- A set of hypotheses, i.e., a set of nodes from which the context is composed; the hypotheses are defined in such a way that two contexts will not have the same set.
- A set of names, i.e., symbols that represent the context.
- A controller checking if a set of hypotheses for the structure of this context may be conflicting, in which case it returns TRUE.

The agent having the entire structure in the semantic network is supported by the SNIP: the SNePS inference package, which can be automatically applied. Whereas SNeRE: the SNePS rational engine is a package responsible for planning and taking action. Also available is the SNaLPS package: the SNePS natural language processing system, which efficiently analyses natural language [66].

SNePS agents are used for linguistic analysis, as they possess the ability to expand vocabulary and create text responses [12]. They also find their application as data managers. SNePS works in specific databases, where there are numerous connections between data tables and when the user can search and organize data in many ways. This is a more natural form of approach to working with data, because the system is able to better understand the relationships between them. Elements of such databases are represented by primary nodes, rows are represented by molecular nodes, and arches represent columns [66]. SNePS can be used in multi-agent decision support system, however its documentation is very weak.

In our research we use solution proposed by S. Franklin – the Learning Intelligent Distribution Agent (LIDA). Its architecture is shown in Fig. 49.3. A cognitive agent consists of the following modules [13]:

- Workspace
- Global workspace
- Sensory memory
- Perceptual memory
- Episodic memory
- Declarative memory
- Sensory and motor memory
- Selection of actions

LIDA is an agent that works at the system level. It receives many simultaneous incoming stimuli, and then internally processes them, which is completed by choosing and performing the appropriate action. The agent creates hypotheses, acts as a cognitive help in the thinking and understanding of individual cognitive activities and various executive processes. As a model, it tries to explain and predict the phenomena occurring in the environment. The basic function of the agent is to constantly answer the question: “What should I do next?” [13]. The agent’s operation is conditioned by the stimuli it receives from the external or internal environment.

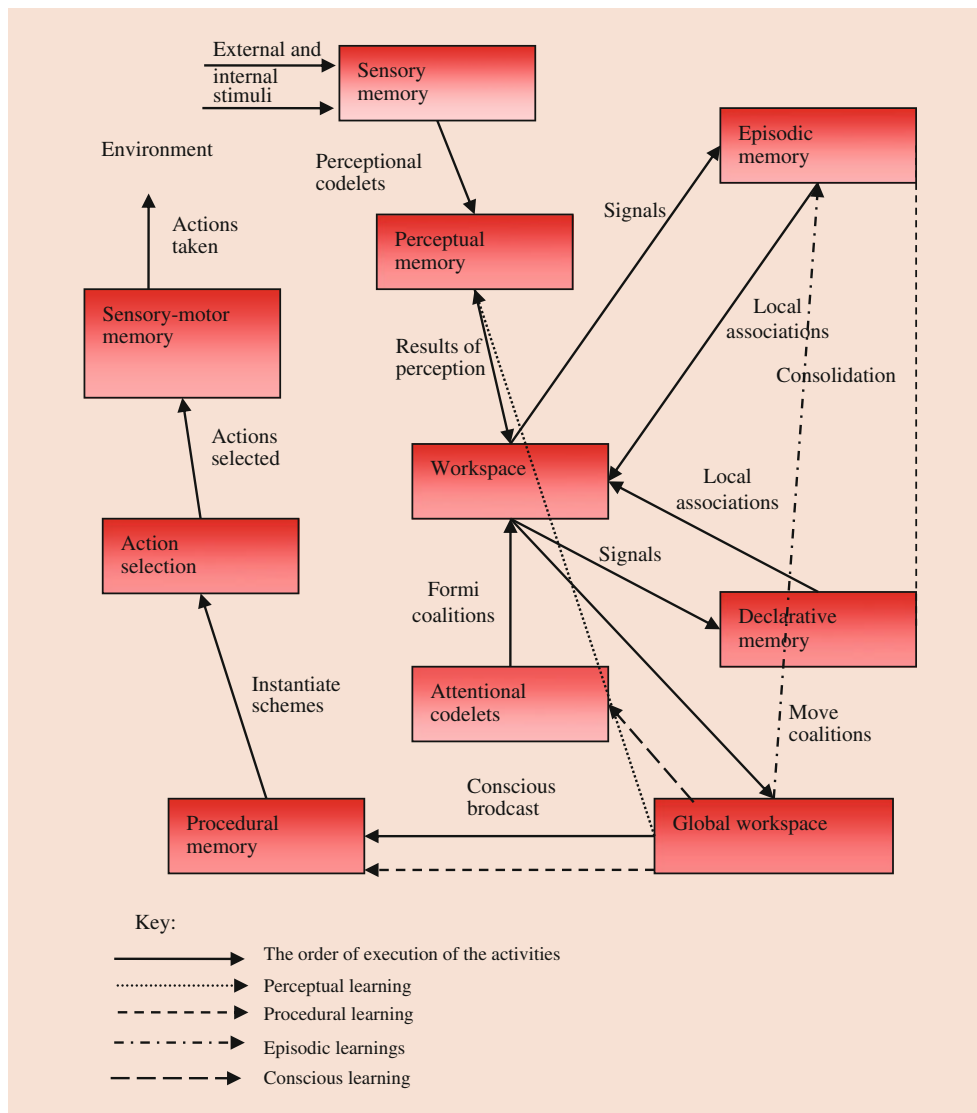

Fig. 49.3 The LIDA architecture

The key is that its reaction results from the cognitive cycle, which is the core of the agent's activities. The cycle consists of the higher-order cognitive processes, which include reflection, reasoning, problem-solving, planning, imagining, etc. It is divided into three phases [13]:

- The phase of perception and understanding – after receiving input data from, for example, motor sensors or agent's memories, it tries to understand the actual situation.
- The phase of consciousness – in this phase the content of this understanding is filtered, because the agent is interested in keeping only relevant information that it will be able to send to global workspace.
- The phase of action and learning – in this phase the system selects and then performs selected actions and learns in many memory mechanisms.

The LIDA cognitive cycle, presented in Fig. 49.1, begins with sensory stimuli, both external and internal, reaching the sensory memory, where early feature detectors are involved. Received data goes to perceptual memory. In the perceptual memory an association model is created, which aims to create perception and make it available to the workspace, which is constantly updated by sending signals to the perceptual, declarative, and episodic memory and receives local associations. The entire update happens in workspace by processing units called codelets. These small pieces of code perform a specific task when the expected conditions are met [13].

In the phase of consciousness, the codelets browse the content contained in the workspace and decide which of them should be introduced as a signal of consciousness delivered to global workspace. There, on the other hand, these data form coalitions, which, through competition, become

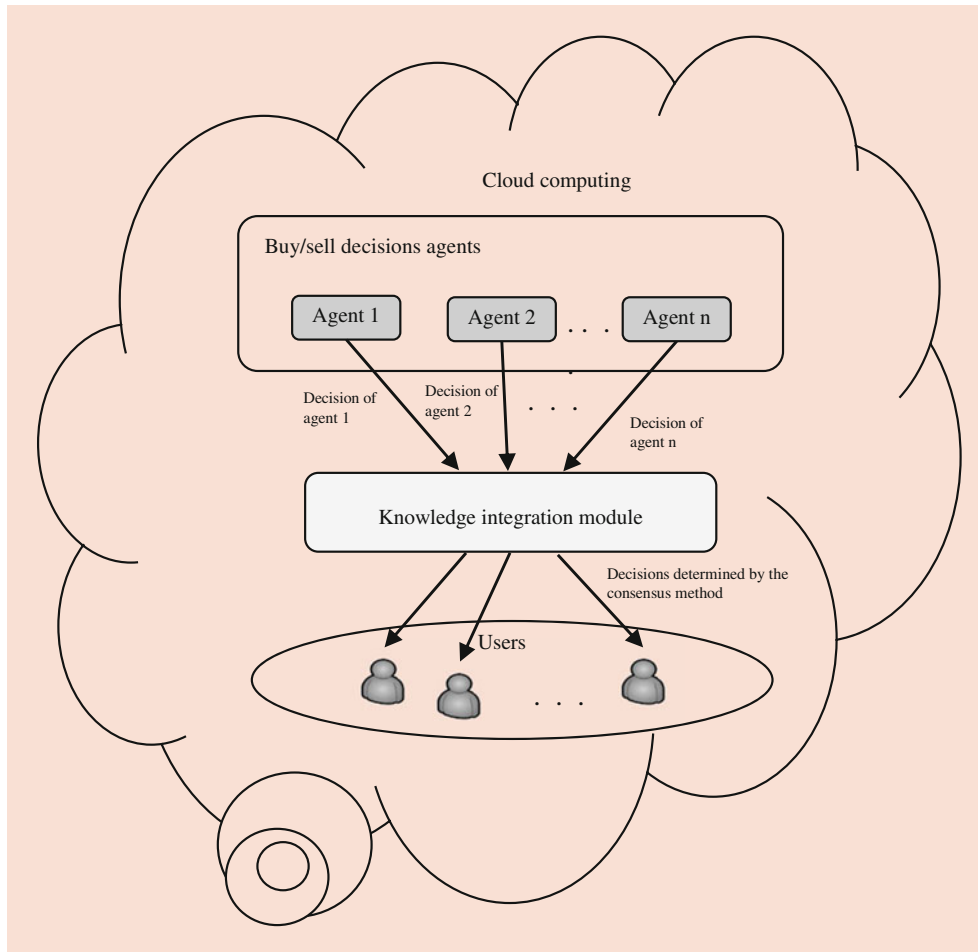

Fig. 49.4 Functional architecture of MAFDSS

selected as the right consciousness. The winning, most significant coalition has its own content transmitted globally. It becomes aware in the functional sense, completing the phase of attention of the cognitive cycle [68].

In the last, third phase of the cognitive cycle, almost every module can get the appropriate content of consciousness that matches its data structure for learning. For example, the procedural memory, which is responsible for “what to do when . . .” knowledge, uses information that in the future will facilitate an immediate response to over-stimuli. In the final stages of the cycle, the action selection module selects one action from the schemas provided to it, then it is sent to the sensory-motor memory to create or select an appropriate action plan that can then be performed. This action completes the cognitive cycle LIDA [69].

49.5 The Architecture and Functionality of MAFDSS

The purpose of MAFDSS is to support investing in financial markets by subcontracting the investor to buy/sell

decisions. The system consists of the following elements (Fig. 49.4):

- Agents making buy/sell decisions that process structured and unstructured knowledge.
- Knowledge integration module – operates using the consensus method; in this module, based on decisions generated by agents, a final decision is presented to the user. The issues related to this module has been presented by Hernes et al. [69, 70] and they are not a subject of this chapter.
- Users – people investing in the financial market.

The buy/sell decisions agents are divided into following groups:

- Technical analysis agents (they have been described, for example, by Korczak et al. [71])
- Fundamental analysis agents [72]
- Behavioral analysis agents [71]
- Deep learning agents [73]
- Text analysis agents

In this chapter, we focus on text analysis agents. The main aim of these agents is to offer advice on buy/sell decision based on expert or investors' opinions stored in cyberspace (e.g., portals, forums, and Tweeter).

The environment of the text analysis agent functioning is a set of text documents containing such opinions. The analysis of the opinion is carried out as follows:

1. On the basis of a training set (a set of opinions concerning a given market, e.g., Forex), a semantic network is created in the perceptual memory containing concepts (related to the product) and connections (associations) between them. The perceptual memory also stores synonyms and various types of words. In the perceptual memory of the LIDA agent, concepts are represented by nodes, while associations by links.
2. Sensory memory (containing strings) is passed in turn to individual opinions.
3. Opinion analysis is made by codelets (implemented in the form of Java programming language classes). They analyze the text according to the criteria defined by the configuration parameters (stored in the xml file). The values of parameters can be indicated by the user and used in a codelet software code. An example of a codelet configuration defining the sentiment of the opinion is presented in Fig. 49.5.

The task name parameter (in the LIDA codelet architecture is configured as a task, the task may also be to refresh the GUI content and it is not implemented by the codelet) means the codelet name. The task type parameter indicates the name of the Java class in which the codelet's program code is located, the parameter-named object specifies which words (or exceptions) are searched by the codelet in the sensory memory. The no-object parameter specifies which words (or expressions) cannot be in the text (for example, the opinion has buy

```
<task name="buy">
<tasktype> CodeletObjectDetector </tasktype>
<param name="object" type="string">sold out</param>
<param name="object" type="string">market</param>
<param name="noobject" type="string">bought
out</param>
<param name="distance" type="int">2</param>
<param name="node" type="string">buy</param>
</task>
```

Fig. 49.5 The example of the configuration of codelet

Fig. 49.6 The example of results of opinion analysis

- sentiment when the word “sold out” appears in the text, but the word “bought out” does not appear). The distance parameter specifies the maximum distance between the searched expression or expressions, the node parameter specifies which node has to be placed in the workspace in the case of finding the wanted items (or expression) [74–76].
4. The results of the analysis, in the form of a semantic network, are transferred to the working memory (the current situational model is created). Figure 49.6 shows an example of the results of the analysis of the following Product Opinion 1: “The market is sold out.” Nodes are marked with a large circle symbol, and links with the arrow symbol. The dots indicate levels of link activation (links can be determined with a certain level of probability).
 5. In the next step, the situational model is passed to the global workspace and the following action schemes are automatically selected from the procedural memory: “writing the results of the analysis of the opinion to the database” (noSQL database – analysis results – semantic network – are saved in the XML format) and “loading another opinion into sensory memory.” It is also possible to select the action “statistical analysis,” as a result of which the agent also indicates the features of the product that are most desirable by customers.

The next part of the chapter presents the results of performance evaluation of text analysis agent on the Forex market.

49.6 Research Experiment

The analysis of the efficiency of the developed method was carried out on data from the H4 range of quotations from the Forex. In order to make this analysis, a test was carried out in which the following assumptions were made:

1. The GBP/PLN pair quotations were used from three randomly selected periods:

- 17-04-2018 0:00 to 23-04-2018 23:59
 - 15-05-2018 0:00 to 21-05-2018 23:59
 - 28-05-2018 0:00 to 01-06-2018 23:59
2. The verification was based on the opinions of experts obtained from financial portals. These opinions were analyzed by the cognitive agent and on the basis of the analysis results, the agent determined which decisions should be taken in the periods considered (buy value 1, sell value -1 , leave unchanged value 0).
 3. It has been assumed that the unit of measure of effectiveness (relative measures) is pip (price change by one "point" on the Forex market is referred to as pips).
 4. Transaction costs are not taken into account.
 5. Money management – it was assumed that in each transaction, the investor engages 100% of his capital. The capital management strategy can be determined by the user. The efficiency analysis was carried out using the following measures (indicators):
 - Rate of return (ratio x_1)
 - Number of transaction
 - Gross profit (ratio x_2)
 - Gross loss (ratio x_3)
 - Total profit (ratio x_4)
 - Number of profitable transaction (ratio x_5)
 - Sharpe ratio (ratio x_6)

$$S = \frac{E(r) - E(f)}{|O(r)|} \times 100\% \quad (49.1)$$

where

$E(r)$ – the arithmetic average of the rate of return

$E(f)$ – the arithmetic average of the risk-free rate of return

$O(r)$ – standard deviation of return rates

- Average coefficient of variation (ratio x_7) is the ratio of the average deviation to the arithmetic mean multiplied by 100%:

$$V = \frac{s}{|E(r)|} \times 100\% \quad (49.2)$$

where

V – average coefficient of variation

s – deviation of the average rate of return

$E(r)$ – the arithmetic mean of the rate of return

6. The following performance evaluation function will be used [42]:

$$y = \left(a_1x_1 + a_2x_2 + a_3(1 - x_3) + a_4x_4 + a_5x_5 + a_6x_6 + a_7(1 - x_7) \right) \quad (49.3)$$

where x_i denotes normalized values of the indicators.

The results obtained on the basis of text analysis agent have been compared with the results of the fundamental analysis agent (based on fundamental analysis method – described in detail by Korczak et al. [72]), technical analysis agent (based on different technical analysis indicators – described in detail by Korczak et al. [71]), and buy-and-hold strategy (the investor makes a decision to buy at the beginning of the period, and the decision to sell at the end of the period). Table 49.3 presents the results of research experiment.

Analyzing the results, it can be stated that the values of particular ratios are characterized by a high dispersion. There is no agent which achieved the best values of particular ratios in all the periods. Taking into consideration a *rate of return*, the text analysis agent achieved the highest value in period 1 and 3. In period 2, the technical analysis agent achieved the highest value of this ratio. The B & H is characterized by the lowest values of *rate of return* in all periods. The technical analysis agent generates the highest number of transactions in each period. On the basis of values of *gross profit* and *gross loss* we can conclude that even if the overall *rate of return* in the given period is profitable, there are transactions generating losses. Taking into consideration the value of the *number of profitable transactions* it can be stated that this value was 50% or higher only in the case of the text analysis agent in all periods. The technical analysis agent generated the highest number of unprofitable transactions in relation to other agents. A large number of unprofitable transactions can lead to losses in investment capital even if the overall *rate of return* is profitable. Risk-based measures are very important – Sharpe ratio (the risk is lower if the ratio is higher) and average coefficient of volatility (the risk is lower if the ratio is lower). The text analysis agent and the fundamental analysis agent achieve the best values of these ratios. The transactions generated by these agents are less risky than transactions generated by the technical analysis agent.

The analysis of particular ratios by a user is a very time-consuming process. Therefore, the evaluation function is very helpful in this purpose. Taking into consideration this function, it can be stated that in period 1 and 3 the text analysis agent achieved the highest value, the fundamental agent was ranked higher in the second period. The B&H benchmark was ranked lowest in all the periods.

49.7 Conclusions

The application of a cognitive architecture in multi-agent systems supporting taking financial decisions allows performing it on the basis of natural language processing. Decisions generated by cognitive agent on the basis of opinions of

Table 49.3 Results of research experiment

Ratio	Text analysis agent			Fundamental analysis agent			Technical analysis agent			B & H		
	Period 1	Period 2	Period 3	Period 1	Period 2	Period 3	Period 1	Period 2	Period 3	Period 1	Period 2	Period 3
Rate of return [Pips]	-274	9345	2487	-675	8237	2389	-578	9373	2285	-1016	7246	1996
Number of transactions	4	7	5	3	6	6	11	16	9	1	1	1
Gross profit [Pips]	378	1273	378	429	2419	437	214	942	194	0	7246	1996
Gross loss [Pips]	-421	-438	-261	494	-685	-294	-396	-582	-146	-1016	0	0
Number of profitable transactions	2	5	4	1	5	4	4	10	5	0	1	1
Sharpe ratio	0.78	0.82	0.63	0.74	0.80	0.72	0.36	0.63	0.59	0.27	0.46	0.17
Average coefficient of volatility	0.28	0.36	0.32	0.31	0.28	0.42	0.47	0.43	0.58	-	-	-
Average rate of return per transaction	-68.5	1335.0	497.4	-225.0	1372.8	398.2	52.55	585.8	253.9	-1016	7246	1996
Value of evaluation function (y)	0.67	0.52	0.59	0.51	0.58	0.54	0.38	0.41	0.46	0.14	0.21	0.17

experts allow for achieving more satisfactory benefits in relation to, for example, the fundamental analysis agent or the technical analysis agent. It can result from the fact that experts build their opinions on the basis of different methods (including fundamental, behavioral, and technical analysis). Expert's opinions also consist of the market sentiment. It is highly probable that the "wisdom of the crowd" phenomena occurs also in this case.

To sum up, the cognitive architecture allows to increase the usability of the multi-agent system and consequently to improve the process of taking investment decisions. The ability to make automatic decisions is also of high importance here. For example, the cognitive agent can make real transactions (open/close short/long position) on the Forex market.

The further research works can be related, for example, to implementing deep text analysis method into the cognitive architecture and to developing an agent running on the basis of summarization of opinions of experts and users.

Acknowledgments The project is financed by the Ministry of Science and Higher Education in Poland under the program "Regional Initiative of Excellence" 2019–2022 project number 015/RID/2018/19 total funding amount 10 721 040,00 PLN.

Abstract

In the semiconductor industry, the study of reliability and the ability to predict temperature cycling fatigue life of electronic packaging are of significance. For that purpose, researchers and engineers frequently employ the finite element method (FEM) in their analyses. It is primarily a mechanics analysis tool that takes material properties, manufacturing processes, and environmental factors into consideration. Engineers also like to use FEM in their

design of electronic package, but frequently the term “reliability” they refer to only addresses the robustness of a particular design. It has little to do with probability and statistics. Meanwhile, in manufacturing factories of electronic products, including packaging, accelerated life testing (ALT) is carried out very often by quality engineers to find lives of a product in more severe environmental conditions than those of the field condition. Through regression analysis of the test result based on an empirical or semiempirical formula, the acceleration factor (AF) can be obtained for use in predicting service life of the product in field condition. Again, other than regression analysis, little probability and statistics are involved. By taking parameter uncertainties into consideration, this chapter demonstrates by an example that FEM, ALT, and AF can be combined to study the reliability of electronic packaging in which probability and statistics are applied.

50.1 Introduction

The development of semiconductor in the past few decades has changed dramatically the way we live. Today, the semiconductor industry is still prosperous, and its development trend is that semiconductors are designed and manufactured smaller and smaller with their performances become better and better. Along with the development of semiconductor industry, electronic packaging industry has also been thriving. The purpose of packaging is to connect together and enclose appropriately semiconductor chips, components,

printed circuit boards, and other assemblies and modules to guarantee the performance of electronic devices and protects them from mechanical damage, cooling, radio frequency noise emission, and electrostatic discharge. Various kinds of failure have to be avoided during the manufacturing and product life cycle of a package. To that purpose, the reliability of a packaged electronic device or equipment has to be assured, and related research is needed [1–4]. Unlike the design of semiconductor that relies primarily on electronic and electrical engineers, electronic packaging is a major discipline within the field of mechanical engineering, in particular mechanics [5]. Principles such as dynamics, stress analysis, heat transfer, and fluid mechanics are employed extensively in the design and analysis of electronic packaging. Thousands of researches have been carried out in the last few decades under the general term of “reliability of electronic packaging.” However, most researches have nothing to do with probability and statistics. Researchers just use the word “reliability” to address that their packaging designs and products manufactured are strong and robust enough to encounter environmental stresses, avoid failures, and possess lives that are long enough.

A major issue among those encountered in the design and manufacture of electronic packaging is the mismatch of thermal conductivity among materials used in a package [6]. It may result in stress concentration, fracture, or warpage that affects the performance and eventually causes failure of the package. The life of package may not meet the need as well. To overcome the problem, analysis has to be carried out in the design stage of a new electronic package. Advanced researches are also needed accompanying with the development of smaller and smaller semiconductors. A powerful tool used in the design of package as well as the research of “reliability of electronic packaging” is the finite element analysis (FEA), also called finite element method (FEM) or finite element modeling (FEM) [7]. Based on mechanics principles, the method has been developed for more than 50 years and is very much matured today. Commercial software packages can be found in the market. A software package of this kind usually covers analyses of solid mechanics (including stress, strain, displacement, etc.), fluid mechanics, heat transfer, temperature fatigue life, and many others. Modules in consideration of uncertainty have been included in a few software packages in recent years but in a rather primitive stage. One purpose of the present chapter is to propose and illustrate by examples a more complete mechanics analysis of electronic packaging that employs FEM and takes into account parameter uncertainties of materials as well as environmental factors. By doing so, statistical analysis can be connected to mechanics analysis, and the result is truly meaningful under the term of “reliability of electronic packaging.”

In fact, the idea of connecting mechanics analysis with statistical analysis arose by the leading author of this chapter more than 10 years ago. The reason was that several of his acquaintances had been doing researches on “reliability of electronic packaging,” but in fact, their research contents had little to do with reliability in terms of probability and statistics. The Weibull plots they drew and explained for experimental data might even be incorrect. The leading author of this chapter considered that if researchers argued FEM can describe accurately the mechanics behavior of a package as compared with experimental data, it can also be used in carrying out numerical simulation of mechanics behavior of the package. Actually, the term “mechanics simulation” or “numerical simulation” based on FEM has long been used by researchers of “reliability of electronic packaging,” but the simulation is in an average sense of everything that takes no consideration of uncertainty. The “reliability” those researchers address just reflects the strength and robustness of the package without any quantitative measure. The purpose of this chapter is to carry out mechanics-based numerical simulation of electronic packaging by FEM and take into account uncertainties of the manufacturing process, environmental factors, and material properties. It can be considered a kind of numerical experiment instead of true experiments or tests. The latter are usually very expensive if quantitative reliability measure and statistically meaningful sample size are asked for. The simulation would save greatly the expense, and its result would resemble experimental or test result if appropriate uncertainties are measured and statistically analyzed in advance and then incorporated into the simulation. Even under the same environmental condition, the simulation result will be a set of data caused by the considered uncertain factors but not a single-value data. It resembles a sample in a statistical experiment. Statistical analyses can then be employed to treat the data for drawing conclusion related to not only mechanics but also quantitative reliability of the electronic package. It would achieve truly the analysis of “reliability of electronic packaging.”

Most of the following contents are abstracted from the master thesis of the second author under direction of the leading author of this chapter. It presents to a certain extent the applicability of the above idea with special emphasis put on accelerated life testing (ALT) which is frequently practiced in the electronic industry. The organization is as follows. In Sect. 50.2, the background and research motivation are addressed. In Sect. 50.3, literature and related theories are reviewed briefly. In addition to the introduction of FEM and ALT, parameter uncertainty and reliability is emphasized. They make this study different from others. In Sect. 50.4, the configuration of electronic package and the analytical model used in this study are introduced. Verification of the model is also presented. In Sect. 50.5, both results of the reliability and

ALT analyses taking into account parameter uncertainties are addressed, and conclusion is drawn based on results of the analysis. In Sect. 50.6, a few comments are made to finally conclude this chapter.

50.2 Background and Research Motivation

With the rise in both demands and popularity of electronic products such as smart phones and personal computers, electronic packaging, being a vital component in these products, has become the topic of numerous researches. In order to keep up with the current trend of low cost, lightweight, highly efficient electronic products, many technological advances in electronic packaging have been made in the past few years, such as the replacement of lead wires with solder balls and different board configurations accustomed to different needs. To reduce sizes of the electronic product, the geometry of package has also evolved from single chip package (SCP), multichip package (MCP), system in package (SIP), system on package (SOP), package on package (POP), system on chip (SOC), and wafer-level chip-scale package (WLCSP) to the so-called 2.5D and 3D packaging such as the most updated fan-out wafer-level packaging (FOWLP) [1, 3]. These advances present many new challenges for manufacturers and engineers, with a special emphasis on the reliability of package, which influences the life of a finished product. One of the most popular electronic packaging configurations is the ball grid array (BGA), with rows of solder balls transmitting signals on a square or rectangular chip. Depending on the manufacturing process, it can further be classified as PBGA (plastic BGA), CBGA (ceramic BGA), CCBGA (ceramic column BGA), CSP (chip scale package or μ BGA), and TBGA (tape BGA). The BGA has advantages of being very efficient for its small size and is the configuration of choice in many products. The main reliability concern of BGAs is to prevent fracture of solder balls and prolong their temperature-cycling fatigue lives. It is an important issue and has been emphasized in electronic industry under the name of “reliability of electronic packaging” [5, 8].

From mechanics point of view, the differences between coefficients of thermal expansion (CTE) of the solder balls and their surroundings result in creep strain accumulation in solder balls when subjected to temperature-cycling conditions. This could cause failure at the interfaces between solder balls and their connected chip after a number of cycles. To prevent failures in advance, design engineers frequently employ finite element method (FEM) for prototyping and parameter optimization of packages in the electronic packaging industry. Researchers [9, 10] have also used FEM in conjunction with fatigue formulas such as Coffin-Manson equation [11, 12] to relate damage parameters accumulated

per cycle with fatigue life. These damage parameters include creep strain and strain energy.

From quality point of view, the life of an electronic product operated in a normal environmental condition, temperature in particular, has to be assured when it is manufactured. To that purpose, temperature-cycling fatigue life tests in factories are frequently required by purchasers. However, under a normal environmental or field condition, the number of cycles that leads to product failure is significantly large, making experiments time consuming, expensive, and often impractical. In order to obtain the reliability properties of a given BGA package in a short amount of time, engineers often carry out accelerated life testing (ALT) that tests the product in more severe environmental conditions and then employ empirical or semiempirical formulas (or ALT models in short) to estimate fatigue life of the package when it is operated in the normal or field condition [13]. However, ALT presents its own problems in that many experiments are required to curve-fit the coefficients of ALT models and the accumulated time and cost are substantial. Also, the accuracy of the empirical models is questionable and needs to be recorrelated for different packages with different solder materials.

This research plans to connect the above two types of engineers, i.e., design engineers and quality engineers, by combining FEA and ALT for studying the reliability of a BGA. The proposed analysis can take advantage of the speed and low cost of FEM, and use it as an experimental tool to correlate the coefficients of ALT models. Current FEM tools such as ANSYS have the ability to run a probabilistic design system (PDS)-based simulation, introducing random parameter variations into the FEM model. This approach could be used to simulate the manufacturing variations and natural variation in material properties that are present in real-world experiments, allowing FEM to be used as a substitute for ALT under different environmental conditions. With the ability to perform a large number of tests under different environmental conditions at relatively low costs, the proposed method could generate more relevant data to curve-fit existing ALT models and produce results that are more accurate and closer to real-life conditions.

50.2.1 Research Purpose

Traditional researches on the topic of “reliability of electronic packaging” are of deterministic nature; however, real-life conditions involve parameter uncertainties that result in the fatigue life being a random nature and having a distribution. This research combines traditional FEM approaches with probabilistic design system (PDS) to investigate the effects of parameter uncertainties on fatigue life distribution and reliability of lead-free plastic ball grid arrays (PBGA) under

different environmental conditions. This study also aims to improve the accuracy of current accelerated life testing (ALT) models such as the Norris-Landzberg (N-L) formula [13] by using the probabilistic FEM model as a substitute for real-life experiments. With a large number of individuals generated by PDS for each of the test samples, we can perform numerous ALTs without expensive cost, resulting in a cheap and efficient prediction method. Fatigue life distribution and reliability of PBGAs under different temperature cycling conditions as well as their corresponding statistics are emphasized in this chapter.

50.2.2 Research Procedure

The proposed method of fatigue life prediction combining finite element analysis (FEA), accelerated life testing (ALT), and probabilistic design system (PDS) is summarized in Fig. 50.1 in which the research procedures are divided into four parts. The first part is preparation and FEM model

verification. With experimental data collected from reference [14], we can replicate a full temperature-cycling test using FEM. Using the exact geometric dimensions and material properties, we construct a representative finite element model subject to boundary conditions and temperature cycling profiles of the said experiment. The cycles are performed several times in order for the equivalent creep strain per cycle to stabilize. The final results are recorded and applied to the modified Coffin-Manson equation which relates the damage parameter per cycle with fatigue life of the PBGA assembly. We then introduce parameter uncertainties into the FEM model using PDS, with 3% coefficient of variation [15, 16] on selected geometric dimensions and material properties. This simulates a real-life sample of 30 tests, and the fatigue life distributions are recorded and studied. The results are then verified with experimental data to ensure the FEM model is an accurate representation of the actual test vehicle and can be used for other temperature-cycling tests.

The second part is the traditional deterministic fatigue analysis. The study uses the verified FEM model and per-

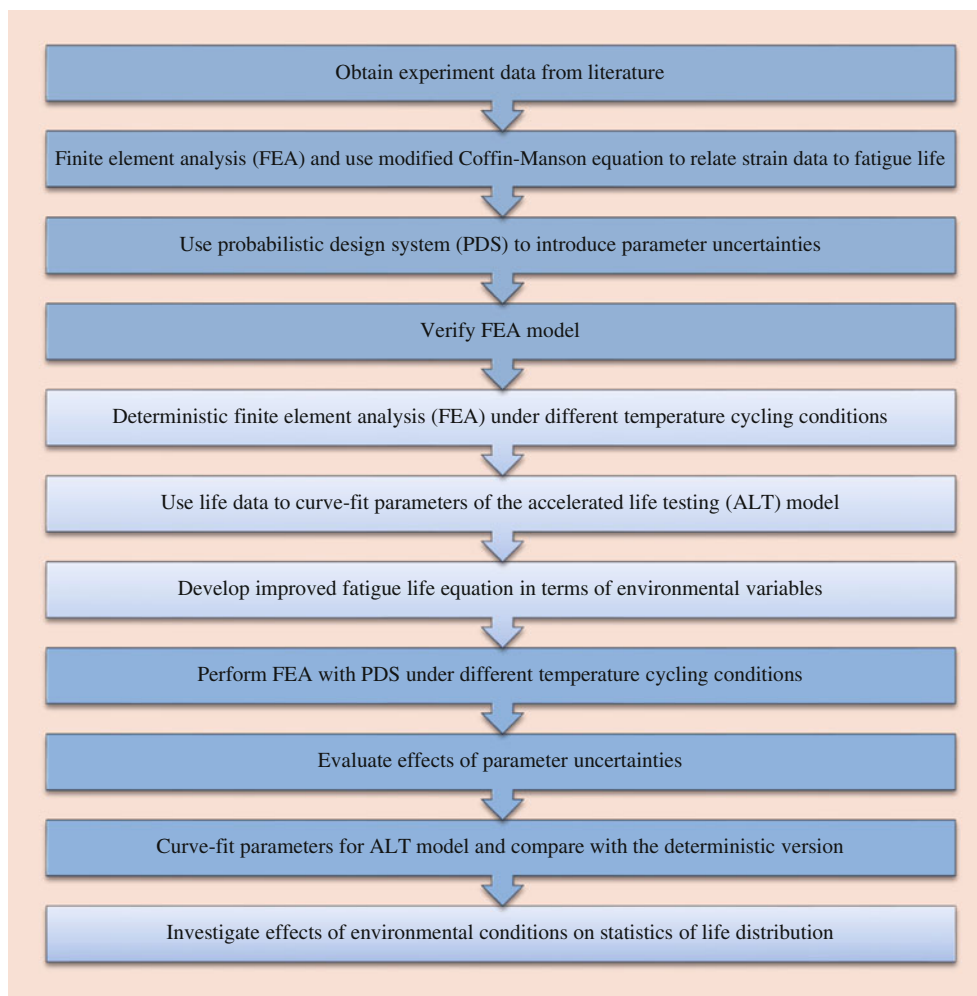

Fig. 50.1 Research procedure

forms various deterministic temperature cycling tests following JESD22-A104C of the JEDEC (Joint Electron Device Engineering Council) standards [17]. The fatigue life results are then used to curve-fit the N-L ALT empirical formula, and a deterministic version of the formula is devised. In the third part, we perform probabilistic FEM tests using PDS under each of the testing conditions. This creates samples of 30 per temperature-cycling condition resulting in a large set of data that we could use for further investigations, including the evaluation of the effect of each of the parameter uncertainties. A probabilistic N-L ALT formula is curve-fitted from the results, and its performance is compared with its deterministic counterpart. The fourth and final part of this chapter is to investigate the effect of environmental condition on the statistical quantities of fatigue life. The standard deviation, Weibull scale, shape, and threshold parameters are discussed in particular, and an attempt to summarize their behavior under different temperature loading is carried out.

While the above procedures were proposed and carried out by the second author of this chapter, it should be mentioned that they have been reorganized a little by the leading author in the following sections and subsections.

50.3 Fundamentals and Literature Review

This section gives an overview of fundamental theories used in this research and, in the meantime, reviews related works done by previous researchers on the subject of “reliability of electronic packaging.”

50.3.1 Cause of Failure

Temperature-cycling fatigue has always been a major source of failure in electronic components and products, and many researches have been carried out to investigate its contributing factors. Darveaux et al. [18] were among those earlier researchers who discovered that differences of coefficient of thermal expansion (CTE) among materials are the main cause of failure of electronic components and products under temperature-cycling conditions. They showed that a small amount of CTE difference is sufficient in producing instantaneous thermal strain, and the strain will accumulate under temperature-cycling conditions to cause failure eventually.

The above temperature-cycling fatigue failure generally arises from the propagation of a small crack in solder balls in which materials containing lead were frequently used before. Spurred by a 2003 European Union directive known as RoHS (Restriction of Hazardous Substances), lead-free materials have been required in recent years. In fact, as discovered by Kim et al. [19], lead-free solder has a lower crack propagation rate as compared to that with lead. The above situations

led to many more studies of reliability of electronic assemblies using solder material such as various configurations of Sn-Ag-Cu (SAC) solder. Among them, Meilunas et al. [20] have studied the reliability of both lead and lead-free solder joints under accelerated life tests. In their study, failures were determined and observed by X-ray, cross sectioning, and dye penetration, and the results showed that lead-free solders indeed have better performance against fatigue.

50.3.2 Finite Element Method (FEM)

Aside from actual temperature cycling fatigue tests, finite element method (FEM) has gained popularity for the simulation of mechanics behavior of electronic packages. A wide variety of assemblies has been the subject of research using FEM, notably Syed [21] who employed previous framework of SnPb modeling on SnAgCu solder alloys, with the intention of formulating a life prediction model that can be used in early design stages of chip development. Accumulated creep strain-based and creep strain density-based models were developed, but the prediction errors were up to 25% in certain cases. Pang and his associates [22] have done a collection of studies on lead-free solder with one particular example carried out by Che et al. [14] that focused on Sn-3.8Ag-0.7Cu solder joint electronic assemblies such as PBGA 316, PQFP208, PQFP176, and TSSOP48. The FEM as well as experiment were used to determine the mean time to failure (MTTF) and Weibull parameters against temperature cycles. The vehicle dimensions and material properties are the basis of this study and experimental data being a source of FEM verification.

To save computation time, submodeling techniques are commonly used in FEM. Lai and Wang [23] have once compared the calculation time between full and submodeling for flip-chip packages. They pointed out that computation time and cost can be saved using submodeling technique and found the solder ball on outer diagonal of the chip is the first to fail. Different types of reduced model have also been used to save computation time. They include slice model or strip model, quadrant model, and octant model with various degrees of accuracy and efficiency [24]. One thing we need to keep in mind while using reduced and submodeling techniques is whether they have the same failure location and mechanisms as the full model, otherwise the simplification will lead to errors and contradictions.

50.3.3 Fatigue Life Prediction

Fatigue is defined as the process of permanent deformation caused by continuously repeated loading. The loading is often of a cyclic nature and could be significantly smaller

than the yielding stress of the material. During the process of fatigue failure, the material properties gradually change, and cracks and creases are formed within the material. These imperfections tend to increase both in size and number as the cyclic loading continues, leading to total failure of the material or structure. In this chapter, we are concerned with the temperature fatigue failure of electronic packages, which is the result of thermal stress induced by temperature-cycling condition. These thermal stresses are caused by the mismatch of coefficient of thermal expansion at the interfaces of different material in the electronic package.

In the study of electronic packaging reliability, it is crucial to have a way to predict the fatigue life of components subject to temperature cycles. Many different fatigue life formulas have been developed and tested by researchers. One of the most widely used formulas is the Coffin-Manson equation, also called Coffin-Manson model [12, 13], which uses plastic strain amplitude as the damage parameter for correlating with fatigue life. The Coffin-Manson model is used mainly in the prediction of temperature cycling fatigue life of lead solders, but modification for use on lead-free solders has also produced reasonable results. Other models such as the Goldmann model [25] focuses on the relationship between fatigue life and geometry/material properties of the package, and Darveaux et al. [18] tackled the problem using energy-based methods, correlating inelastic strain energy density with fatigue life. Most of these models and methods are constructed using experimental data and are empirical or semiempirical formulas that have certain degrees of variation due to human and experimental errors. Further enhancements and modifications are needed.

In this study, the following modified Coffin-Manson fatigue life prediction formula is used:

$$N = \frac{1}{2} \left(\frac{\Delta\gamma}{2\varepsilon_f} \right)^{\frac{1}{C_f}} \quad (50.1)$$

where N is the fatigue life, ε_f is a ductility coefficient, C_f is the fatigue ductility exponent, and $\Delta\gamma$ is the shear strain range also called strain amplitude per loading cycle. The last quantity is related to the von Mises strain range $\Delta\varepsilon$ as follows

$$\Delta\gamma = \sqrt{3}\Delta\varepsilon \quad (50.2)$$

Since the shear strain range thus obtained is in an indirect manner, it is also called equivalent shear strain range or equivalent creep strain in short.

50.3.4 Accelerated Life Testing (ALT)

As mentioned before, another fatigue life prediction method used frequently in the electronics industry is accelerated life

testing (ALT). It tests electronic components including packages under harsh environmental conditions to obtain their failure times which are then correlated to components' lives under normal conditions through acceleration factor (AF) derived based on physical principles. Norris and Landzberg [13] used temperature cycling parameters such as cyclic frequency, maximum temperature, and temperature difference to deduce an empirical formula that calculates the AF between two different environmental conditions. The coefficients of the N-L formula or N-L model were curve-fitted using lead solders, but as lead-free solder gains popularity, investigations of the corresponding coefficients were carried out at later stages. These include Pan et al. [26], but with limited success as experimental results and predictions were found to have low correlation as those pointed out by Salmela et al. [27] and Zhang and Clech [28]. New models and modifications were proposed with new parameters added, such as the works of Dauksher [29] and Vasudevan and Fan [30], with a special emphasis on experimental confirmation. Jong et al. [31] discovered that the size of BGA package and other design parameters also have a profound effect on the AF, leading to an even more complicated model. For all above results, there is still a large discrepancy among researchers, which deserves further evaluation and improvements.

There are two major groups of accelerated life testing: One is to increase the operating frequency of the test subject, and the other to increase the intensity of the test loading. Raising the number of repetitive operation needs to be carried out carefully, if the frequency becomes too high, the operating environment may change and result in higher load intensity. On the other hand, while increasing experiment loading, one should keep in mind that the failure mode and mechanism should be consistent with normal loading for the experiment to be meaningful. For electronics, increasing environmental loading such as temperature or vibration is a common method to shorten the testing time. After obtaining life data from accelerated life testing, one can use the abovementioned acceleration factor (AF) to gain information of the test vehicle under normal operating condition. The definition of AF is the ratio between the fatigue lives of two environments, as shown below:

$$AF = \frac{N_1}{N_2} \quad (50.3)$$

where N_1 and N_2 are fatigue lives under two different environmental conditions. Frequently, N_1 is considered the life under normal or field condition, and N_2 the life under accelerated or more severe condition; the expression becomes

$$AF = \frac{N_{\text{field}}}{N_{\text{test}}} \quad (50.4)$$

It results in that AF is always greater than one.

Although ALT is frequently carried out in the electronics industry, it may not be known to researchers and/or engineers who employ FEM in the design and implementation of electronic packaging. Only a few researchers have made the connections. Among them, Norris and Landzberg are two pioneers who proposed the following Norris-Landzberg model [13]:

$$AF = \left(\frac{f_{\text{field}}}{f_{\text{test}}} \right)^m \left(\frac{\Delta T_{\text{test}}}{\Delta T_{\text{field}}} \right)^n \exp \left[\frac{E_a}{k} \left(\frac{1}{T_{\text{max,field}}} - \frac{1}{T_{\text{max,test}}} \right) \right] \quad (50.5)$$

where f represents cyclic frequency of temperature change, ΔT represents the temperature range of a cycle, T_{max} is the maximum temperature in a cycle, E_a is the activation energy, k is Boltzmann's constant, and m and n are empirical constants to be determined from test data. The model is also called N-L model in this study for simplicity. It should be noted that while a few parameters in the above expressions bear physical meanings, some are to be determined from test data. It is the nature of ALT-data treatment in real practices.

50.3.5 Parameter Uncertainty

As stated before, many engineers and researchers engaging in designs and/or researches related to “reliability of electronic packaging” placed their emphases on mechanics analysis of packages. They frequently employ FEM and empirical or semiempirical fatigue prediction formulas in their analyses. Although Weibull probability distribution has been adopted by a small amount of people in fitting experimental life data to obtain the mean or characteristic life of a package, the “reliability” they mentioned really has little to do with probability and statistics. The mechanics behavior most people addressed is also the average trend of a package. With regard to ALT employed frequently in factories of electronic products, although more life data than those from FEM are usually obtained, only the average life is considered in most analyses. The acceleration factor (AF) which engineers and/or researchers try to find from test result is also in an average sense in most cases. However, uncertainty exists in the real world, and if one wants the term “reliability of electronic packaging” to reflect quantitative reliability, one can take into account uncertainties of parameters in mechanics analysis. The major difference of this study from others is that FEM and ALT are employed at the same time and uncertainty is taken into consideration as well. By doing so, life distribution rather than life in its average sense can be obtained, and quantitative reliability can be addressed and predicted. If mechanics researchers assert their analyses based on FEM reflect the true behavior of electronic

packaging, FEM can be used for numerical simulation tool to obtain lives of a package subject to different environmental conditions. Moreover, if parameter uncertainty is considered, the simulation result will be life distribution rather than just a single-value life under a certain environmental condition. Using FEM as a tool to carry out numerical test in place of real ALT is another innovative part of this study.

Uncertainties may arise during both the design and manufacturing stages of electronic packaging. The effect of parameter uncertainty on the prediction of fatigue life of electronic assemblies has been studied and discussed previously. In a study carried out by Mercado and Sarihan [32] on plastic ball grid array (PBGA) assemblies, uncertainties of parameters including substrate thickness, solder height, and chip thickness were addressed and investigated using FEM. Perkins and Sitaraman [33] have also employed FEM to run a full factorial design of simulations (DOS) in which variations of parameters such as substrate size, CTE mismatch between components, substrate/board thickness, and joint pitch were discussed. In a later study, Wu and Barker [34] found the geometric variation caused by imperfections in the manufacturing process will result in discrete life distribution, but the effects of material properties are still open to further investigations.

In summary, both FEM and ALT can be used for fatigue life prediction of electronic components including packages when they are subject to a certain environmental condition, in particular temperature-cycling condition in this study. Parameter uncertainties would make the predicted life exhibit probability distribution which is related to quantitative reliability.

50.3.6 Probabilistic Design and Reliability

Traditional engineering analyses including FEM are performed under many different assumptions and simplifications concerning the dimensions and material properties. In the real world, uncertainties are present in all of these parameters, some of which may have significant effects on the evaluation results. It is therefore worth considering those effects. In fact, many software packages used in engineering design and/or analysis have developed probabilistic modules to treat uncertainties of parameters in recent years. However, they are usually in rather primitive stages. The module has been named “probabilistic design system” (PDS) in some commercial software packages. It works by assuming some parameters involved in the analysis follow normal distribution, randomly generating a large amount of sample points for each uncertain parameter, carrying out finite element analyses, handling the results by descriptive statistics, and discussing the effects of parameter uncertainties on the results. The present study follows similar procedures but treats the

simulation results in a more detailed manner. In particular, the results are related to quantitative reliability which has seldom been seen before. Since the simulation is also considered as numerical substitution of real ALT, its results are treated as those obtained from ALT. The overall concept is also new, at least to the writers.

Unlike traditional and deterministic FEM, parameter uncertainties cause an electronic package to have life distribution rather than a single-value life under the same environmental condition and in consideration of the same material properties. Under this circumstance, reliability analysis based on probability and statistics can be carried out to treat those simulated life data. Unfortunately, many engineers are not familiar with probability and statistics and can only perform mechanics analyses using traditional and deterministic FEM. A few of them sometimes use the following Weibull probability density function to fit experimental life data for the sake of comparing with their FEM results.

$$f(t) = \frac{\beta}{\theta} \left(\frac{t-\gamma}{\theta} \right)^{\beta-1} \exp \left[- \left(\frac{t-\gamma}{\theta} \right)^\beta \right], \quad (50.6)$$

$$\beta > 0, \theta > 0, \gamma \geq 0, t \geq 0.$$

in which t is the life or fatigue life of a package in this study, θ is a scale parameter which is also called characteristic life, β is the shape parameter, and γ is a threshold parameter. The mean and variance of the above distribution are

$$\mu = \gamma + \theta \Gamma \left(1 + \frac{1}{\beta} \right) \quad (50.7)$$

and

$$\sigma^2 = \theta^2 \left\{ \Gamma \left(1 + \frac{2}{\beta} \right) - \left[\Gamma \left(1 + \frac{1}{\beta} \right) \right]^2 \right\} \quad (50.8)$$

respectively, in which $\Gamma(\cdot)$ is the gamma function. The quantity of Eq. (50.7) is frequently called the mean time to failure (MTTF) in reliability engineering. The above three-parameter Weibull becomes two-parameter Weibull probability density function if the threshold parameter is 0. It is interesting to note that, other than normal probability distribution, Weibull probability distribution is frequently used in various engineering fields without knowing its reason by most users. The leading author of this chapter believes, other than its versatility in fitting all kinds of data, the fact that Weibull was trained to be an engineer and eventually became an outstanding professor makes the difference. In fact, Weibull distribution is also used frequently in treating test data of ALT. However, many engineers misinterpret the characteristic life as the mean life.

50.4 Modeling and Verification

This section will introduce configuration of the studied electronic package and its material properties. One emphasis is finite element modeling of the package and its verification. After the analytical result being verified, the FEM can then be used for performing numerical simulation of ALT, which will be addressed in the last part of this section.

50.4.1 Configuration and Finite Element Modeling

When running mechanics analysis concerning stress and strain under certain loading and boundary conditions, analytical methods are only applicable to subjects with simple geometries. However, engineering problems often involve real-life parts and components that are very complex and would be impossible to solve analytically. Therefore, a numerical analysis method that could break down the problems into smaller and manageable subproblems such as the finite element method (FEM) will be needed for such engineering needs. FEM divides an irregular geometry into many connected simple polygons to approximate the result of a certain loading by solving the relevant partial differential equations. In the electronic industry, FEM is often used as a tool to prototype chip design, since it can save time and money otherwise necessary for experiments and manufacturing. In this study, we utilized FEM to conduct our research on lead-free electronic assembly under temperature-cycling conditions to obtain the accumulated creep strain data needed for fatigue life prediction.

In order to execute the methodology proposed in this study, we first need to construct a finite element model that can be verified as an acceptable representation of real-life experiment. While many different types of lead-free electronic assemblies are in use today, it is essential to use a package that has experimental data available for calibration of our model. We chose the plastic ball grid array with 316 inputs/outputs (PBGA 316) presented in [14] as the basis of our model, and its results as our benchmark for accuracy confirmation. The schematic diagram of the package is shown in Fig. 50.2, and the layout of 316 solder balls is shown in Fig. 50.3. The bottom layer of the package is an FR4 PCB (printed circuit board) with solder balls on top of it. Above the solder balls lies a BT (bismaleimide triazine) substrate, and on top of the substrate is a mold with the die embedded in the center. The package has basically a square configuration, and its dimensions are summarized in Table 50.1.

The material properties are listed in Tables 50.2 and 50.3. Since we are dealing with creep behavior of electronic components under repeated temperature cycles, the material

properties that change with temperature have to be handled carefully with corresponding values entered at different stages of the analysis.

With regard to this package, although FEM can simulate a given environmental loading with accuracy, it is still near impossible to fully represent all of the physical processes that are present in a certain analysis, in the case of this study, the strain distribution of PBGA under temperature cycling. Therefore, it is essential that we make the following assumptions in our analysis using FEM: (1) The model is stress-free at room temperature (25 °C), and there are no residual stress caused by the manufacturing process. (2) The displacement on the symmetrical plane along the symmetric direction is 0. (3) The material properties of all of the components concerned are homogenous and isotropic. (4) All contact surfaces within the model are in full contact, and there are no impurities or voids inside the electronic packages. (5) Ignore the popcorn effect caused by humidity and temperature change. (6) Ignore heat conduction, convection, and radiation effects. (7) The inner parts of the model are of the same temperature as the outside temperature. That is to say, the system is under thermal equilibrium at all instants during the analysis and the thermal field only changes with time. It is interesting to point out that the above idealization through assumptions justifies to a certain degree that our later analysis taking into account uncertainties is meaningful.

Carrying out finite element analysis on a complex structure such as the PBGA array concerned in this study presents

itself with many difficulties. One of the obstacles to overcome is the long computational time required to evaluate the creep behavior of each of the 316 solder balls. With the need to repeat the analysis many times under different design parameters, the task quickly becomes unmanageable. It is therefore essential to make simplifications to the model to shorten the calculation time; fortunately, the symmetry of assembly means many different methods are available to improve the efficiency of the analysis. One of them is the so-called reduced modeling. It is a method used to take advantage of symmetry of the test subject. In the example of our study, the PBGA 316 assembly can be divided into different numbers of subsections. One popular method among researchers is the one quadrant reduced model [9] shown in Fig. 50.4. It is an effective method to obtain accurate result with a reasonable reduction in computational time, but with the amount of repetitions needed for this research, an even more efficient method is necessary. The slice model [31] shown in Fig. 50.5 is one such method, and it has been shown that the sacrifice in accuracy is within the acceptable range. Therefore, it is used as a basis of the rest of this study. The slice is split along the diagonal axis of the package and has the width of one-half of the pitch of the solder balls.

The technique of submodeling is also adopted in this study. It is a combination of reduced modeling and full modeling, in order to achieve better accuracy under a shorter amount of time [35]. While using the submodeling technique, the global model is usually meshed with a coarse mesh, giving a rough idea of the global displacement of the assembly. The data is then fed into various submodels at areas around

those focusing points such as the location of maximum stress or the point of failure. These submodels are meshed using a much finer mesh, as they are where maximum accuracy is desired. As opposed to the large global model, the smaller submodel will make fine meshes much less time consuming while producing satisfactory results, which is a reasonable compromise between accuracy and efficiency.

While using reduced modeling techniques such as the three-dimensional slice models, it is essential to apply the correct boundary and loading conditions in order to give an accurate representation of real-life testing. The conditions for our model follow that of the slice model found in literature [31]. We develop a 1/2 symmetric slice model along the diagonal of the package as that shown in Fig. 50.6 in which the origin is set at the bottom of the symmetric center, having x points to the long direction and y points upward. The boundary conditions of the reduced model are also shown in Fig. 50.6. It can be seen that all finite element nodes at the center and sliced surface of the package are set to be “symmetric” while those at the bottom are set to be “fixed.” The fixed condition means the displacement of those points in all directions are 0, preventing rigid body motion that would occur if being set otherwise, giving the model the freedom to deform and warp freely. On the surface at half of the ball pitch in the negative z -direction is where most difficulties are found, as it is neither a free surface nor a true symmetry plane. In order for this surface to move freely along the z -axis and to prevent out-of-plane stress, we assign it with generalized plane strain condition. The remaining surfaces not mentioned are all assumed to be free surfaces.

Fig. 50.4 One quadrant reduced model

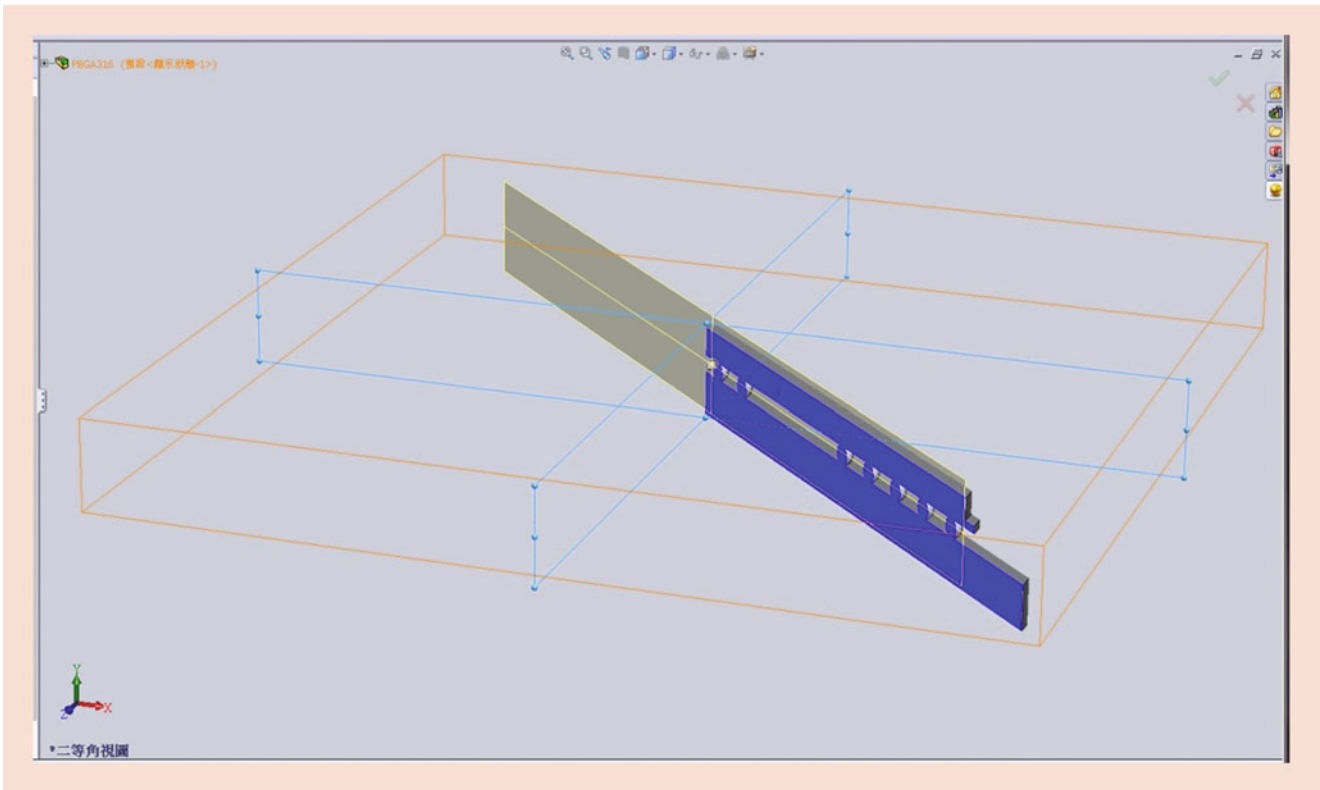

Fig. 50.5 Slice model

Fig. 50.6 Reduced finite element model of PBGA 316

The temperature-cycling conditions used in the finite element analysis follow those of JEDEC testing standard JESD22-A104C, a set of guidelines devised for testing of electronic reliability as a result of CTE mismatch between materials under different temperatures. Starting from room temperature, the loading conditions are described by four load steps: two dwells, one at the highest cycle temperature and one at the lowest, and two temperature ramps in between the dwells. The cycle can be represented visually using the graph shown in Fig. 50.7. In this study, since FEM is proposed as numerical substitution for ALT, six test conditions covering a wide variety of temperatures and cycle times as those shown in Table 50.4 are numerically studied. It should be noted that values in the last two columns of Table 50.4 can be used for converting fatigue life from cycles to hours. In later sections, these loading cycles will be used in FEM analysis to determine the AF of the PBGA 316 assembly once the model is verified by experiment results. For the time being, we chose Test A [14] as the basis of our comparison and verification.

During the finite element analysis, meshing is a crucial stage. Finer meshes result in more accurate result but are computationally expensive. In order to carry out a large set of simulation runs like our proposed method, it is important to strike the right balance for the size of the mesh. In this study, we examine different mesh density. Through many trial and errors with different meshing options, it has been found that the length of the simulation time mostly depends on the size

Fig. 50.7 Temperature profile of Test A

Table 50.4 Temperature-cycling conditions

Test condition	Temperature range (°C)	Ramp rate (°C/min)	Dwell time (min)	Cycle time (min/cycle)	Frequency (Cycle/day)
Test A	-40 ~ 125	11	15	60	24
Test B	0 ~ 100	6.67	15	60	24
Test C	-40 ~ 85	13.89	1	20	72
Test D	-40 ~ 150	9.5	10	60	24
Test E	-55 ~ 85	14	5	30	48
Test F	-55 ~ 150	14.64	1	30	48

of the mesh covering the solder balls, which is expected as the majority of the calculation resource is spent on modeling of the solder ball's creep behavior.

In order to evaluate the reliability of PBGA 316 assembly using FEM, we need to correlate the numerical result of FEM with experimental fatigue life of the package. As stated before, we can use the Coffin-Manson model for our life prediction, using maximum equivalent creep strain among all elements per cycle as the damage parameter.

50.4.2 Verification of FEM

The result of the above finite element analysis indicates the location of maximum equivalent creep strain occurs at the interface (with PCB) of the outmost solder ball in the central 4×4 cluster, which is consistent with literature data. A graph of the development of equivalent creep strain along with time is shown in Fig. 50.8. It is found that value of the equivalent creep strain per cycle stabilizes after three cycles. Therefore, the equivalent creep strain range after the fourth cycle is used in simulation afterward. The fatigue life of the assembly can then be found by applying the Coffin-Manson relationship of Eqs. (50.1) and (50.2), in which the fatigue ductility coefficient is taken to be 0.325 [16, 27, 36]. The value is found to be 2746 temperature cycles or 2746 h since a temperature cycle is 1 h (Fig. 50.7). The result is consistent with experimental data listed in Table 50.5 by Che et al. [14]. It is interesting to note that, although small samples are usually obtained (as that of Table 50.5 which is a small sample of 5), engineers like to fit their experimental or test data by Weibull probability distribution. However, they usually do not address quantitative reliability based on fitted distribution of the fatigue life and sometime misinterpret the characteristic life as the mean life. The test data thus fitted by Che et al. [14] has a Weibull slope $\beta = 7.69$ and a characteristic life $\theta = 2917$ corresponding to an MTTF of 2742 cycles calculated from Eq. (50.7). It is also interesting to note the five test lives in Table 50.5 exhibit a considerable scatter which is attributed to uncertainties of parameters mentioned previously and emphasized in this study.

Fig. 50.8 Development of equivalent creep strain

4	2972
5	3052
Average	2758

50.4.3 Probabilistic FEM and ALT

As stated before, ALT is frequently employed in the electronics industry, but owing to the long test-time and the expensive cost, its results under different environmental conditions are usually small samples from statistics point of view. If researchers and engineers assert their numerical analysis based on FEM can capture the mechanics behavior and predict the temperature-cycling fatigue life of electronic packaging accurately, the analysis can be used for substitution of ALT to save time and cost. Moreover, if parameter uncertainties involved in the analysis are considered, the result of FEM would not be a single-value fatigue life but a sample of fatigue life under a particular environmental condition. Thus, not only ALT under different environmental conditions can be substituted by numerical simulation based on FEM but also the results of fatigue lives exhibit distributions which are related to quantitative reliability and can be treated by any statistical methods. It can also bridge the gap between design engineers and reliability engineers.

It has been shown that uncertainties in geometric parameters and material properties have a significant effect on the temperature cycling fatigue life of electronic assemblies [33]. To construct an accurate simulation of real-life conditions in this study, we assume the radius and height of the solder ball, the thickness of the BT substrate, and Young's Moduli and CTEs of both the mold and the BT substrate in x , z plane are random variables having normal distribution. They are assumed to have mean values shown in Tables 50.1 and 50.2, and a 3% coefficient of variation in each of the assumed

Table 50.6 Simulation results

	Test A	Test B	Test C	Test D	Test E	Test F
Average (h)	2947	9216	12,522	1482	10,687	1501
Standard deviation (h)	571	1093	3981	292	2853	188

random parameters. A lot of simulations have been carried out, and some of the results will be reported in the following section.

50.5 Result of Analysis

As mentioned preciously, introducing parameter uncertainties into the analysis of FEM can form a methodology that generates a large set of temperature fatigue life data of a package but with less cost than that of real-life test. By doing so, the procedure is combined with ALT under different temperature-cycling environments, and the results can further be correlated to the acceleration factors (AFs). Also stated before, the temperature profiles used in this study follow the regulation of JESD22-A104C and are shown in Table 50.4. The choices of temperature profiles include the original condition used for verification purposes (Test A) and others that explore different maximum temperatures, different temperature differences, different cycling frequency, and even different dwell times and ramp times. The variety of these profiles gives more flexibility while constructing the ALT model, as many parameters could be considered while performing regression analyses for coefficients. The analysis (also called simulation) is performed on the PBGA 316 model for each of the six temperature profiles listed in Table 50.4. In the analysis, the maximum equivalent strain is found and applied to the Coffin-Manson relationship to produce fatigue life in cycles. It can be converted to life in hours if values of the last two columns in Table 50.4 are taken into consideration.

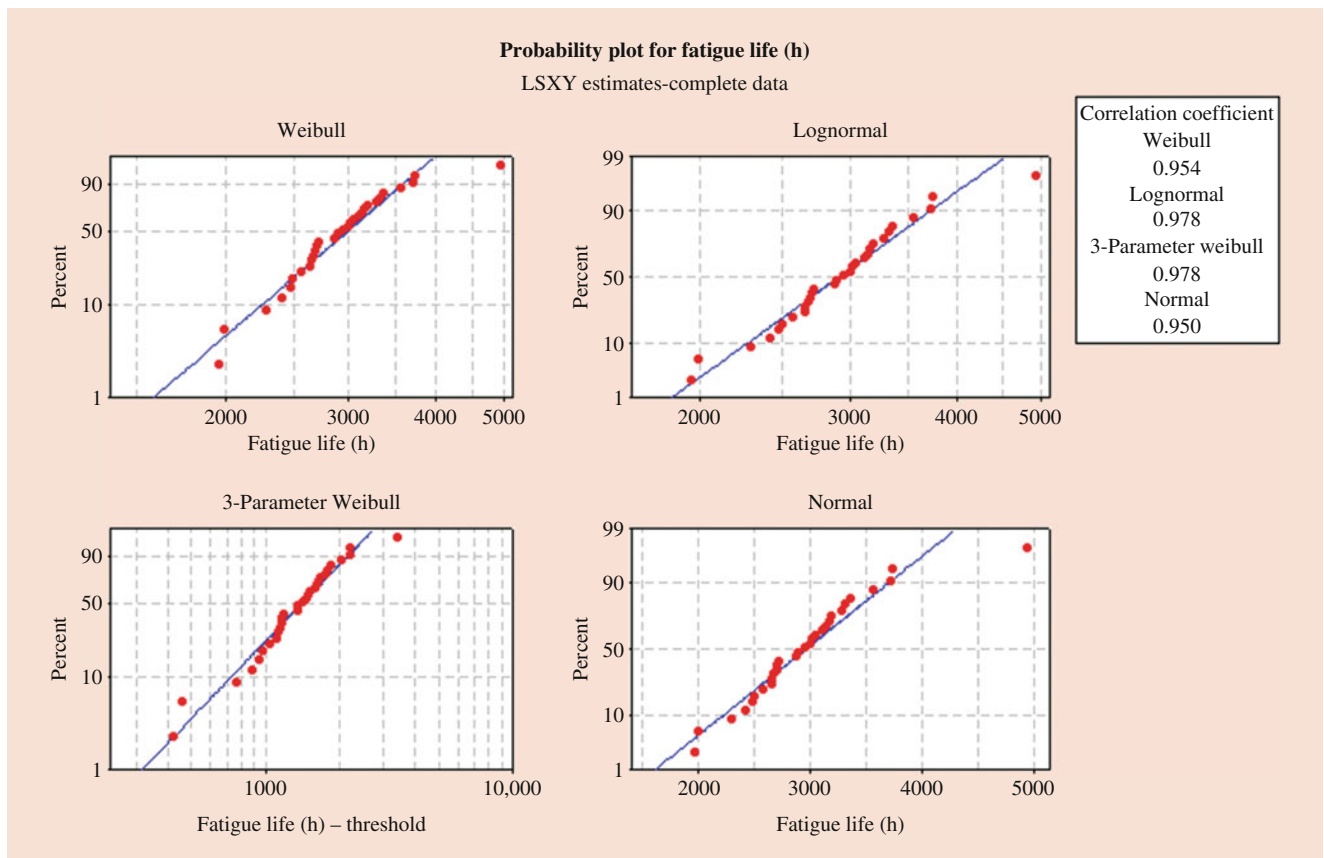

Some results of this study will be introduced in the following three subsections. The content of the first subsection is related to quantitative reliability, the second subsection emphasizes more on ALT, and the third subsection tries a preliminary study in combining the previous two.

50.5.1 Reliability of PBGA 316

In this study, the simulation is carried out 30 times for each of the six test conditions resulting in 180 fatigue life data in total. After being transformed into hours, the mean values and standard deviations of the results are shown in Table 50.6. The Pearson correlation coefficients between the fatigue life and each of the assumed random parameters are shown in Table 50.7. We can see from the table that all variables

Table 50.7 Pearson correlation coefficients of variables

Testcondition	Solder radius	Mold thickness	BT substrate thickness	Mold modulus	BT substrate modulus	Mold CTE	BT substrate CTE
Test A	0.104	-0.141	0.557	-0.016	0.383	0.146	0.323
Test B	0.445	-0.158	0.310	0.046	0.123	0.072	-0.089

Average	0.103	-0.164	0.250	-0.037	0.080	-0.067	0.109

**Fig. 50.9** Comparison among distributions (test A)

are moderately correlated to fatigue life of the assembly, with the thickness of the BT substrate showing the most obvious positive trend. This trend suggests that increasing the thickness of the BT substrate can extend the fatigue life of PBGA assemblies, the likely cause being a reduction of warpage with thicker substrates, which leads to a decrease in stress at the interfaces of the components. It is interesting to point out that this kind of observation coincides with conclusions made by other researchers based primarily on mechanics analysis and, in fact, it should be like this.

The probabilistic method proposed in this study results in multiple data for each test condition or temperature profile, which can be considered random fatigue life having a proba-

bility distribution. The distribution can be used for reliability evaluation and life prediction of the studied package such as the failure rate and mean time to failure (MTTF). As stated previously, traditional research often uses Weibull distribution as the default distribution for describing temperature fatigue life. However, it has been shown to not always be the case in real-life experiments. In our study, within concepts of Anderson-Darling test and the least squared method, we fit our life data-sets by normal, lognormal, Weibull, and 3-parameter Weibull distributions with correlation coefficient used as our indicator. It results in probability plots such as those shown in Fig. 50.9 for Test A. Probability plots for other tests conditions are neglected herein to save space. The

summarized result in Table 50.8 shows that 5 out of the 6 tests are best fitted with 3-parameter Weibull distribution, which is consistent with industry knowledge as the threshold term of 3-parameter Weibull distribution implies a range of time where no failure will occur. It is interesting to point out that results such as in Fig. 50.9 and Table 50.8 can be used for quantitative reliability evaluation of electronic packaging but much of the time ignored by engineers who just want to obtain characteristic life and/or MTTF of the package through fitting test data primarily by Weibull probability distribution. In our study, when we use 3-parameter Weibull distribution to describe all sets of data, the corresponding parameters are found and shown in Table 50.9, in which the MTTF and standard deviation of life of the package under each test condition are shown in the last two rows in hours. When comparing with those data in Table 50.6, the MTTFs are very close to mean values of the simulated data and the standard deviations are also within 10% difference from those simulated data except for Test B. One can also see that all shape parameters are larger than 1 indicating failure rate of the system increases with time, which is expected in an electronic assembly. The threshold parameter provides valuable information for manufacturers and engineers as the failure-free time can be used for guidelines for design and experimental purposes. The probability density function, reliability function, and failure rate function of the tested package can be plotted accordingly as those shown in Fig. 50.10 for Test A. The latter two quantities are frequently emphasized in reliability engineering.

50.5.2 ALT of PBGA 316

As mentioned before, a major difference of our study from others is that ALT is carried out numerically but not

experimentally. Although the concept of applying Norris-Landzberg model (or N-L model in brief) of Eq. (50.5) to find AF factor from the ALT result may not be new, the experimental or analytical data points are usually very few. Previous studies such as [27, 36] were based primarily on deterministic analyses with only a single data or an average data point considered for each of the temperature-cycling conditions. With the probabilistic approach, we have instead 30 data points for each temperature-cycling condition and a total of 180 data points, giving us more flexibility when performing regression analysis in search of parametric values such as m , n , and E_a/k in Eq. (50.5).

In our study, the temperature-cycling condition of Test A is considered the test condition in Eq. (50.5) with each of the other conditions being considered a particular field condition. After values of m , n , and E_a/k are evaluated, the package life under each field condition is estimated from the test condition and compared with FEM simulation result. As mentioned previously, the FEM simulation is proposed to substitute real ALT and can also be called numerical ALT.

Two different approaches are employed with regard to the regression analysis of those simulation data. The first approach uses all of the PDS data for curve fitting, with all 180 data points contributing in obtaining the unknown variables in the AF model of Eq. (50.5). The second approach uses average values of each of the conditions as the data set in the regression analysis. The latter still considers the effects of all 180 simulation results but is much simpler. The first approach results in $m = 0.36$, $n = 2.43$, and $E_a/k = 940.96$. We then set Test A as our test condition and consider the remaining 5 temperature-cycling conditions as different field conditions for verifying the accuracy of Eq. (50.5). Following what is usually done in real ALT and also for the sake of simplicity, only the mean value of the 30 data points for each condition is considered at this stage. The predicted temperature fatigue lives based on the simulation result of Test A and Eq. (50.5) are compared with simulation results of other tests, all in average sense. The prediction errors for each of the condition are calculated and shown in Table 50.10. Although the errors are comparably large, they are compatible with and even better than those found by Salmela and his associates when comparing their simulation result with test data [27, 36]. For the second approach, the best fitted parametric values are $m = 0.14$, $n = 1.04$, and

Table 50.8 Correlation coefficients for different distributions

Average			0.58%

$E_a/k = 3662.06$, and the prediction results become those shown in Table 50.11. Although the approach is simpler, the results are surprisingly better than those of the first approach. It needs further study to clarify the ambiguity.

50.5.3 Combination of Reliability and ALT for PBGA 316

It has been emphasized several times in the present chapter that traditional study on the topic of “reliability of electronic packaging” in fact has little to do with probability, statistics, and reliability. Although accelerated life testing (ALT)

has been carried out frequently in manufacturing factories of electronic products including packaging, the afterward analyses usually focus only on finding acceleration factor (AF) between the test condition and the field condition in an average sense. Other than regression analysis, no probability and statistics are involved in the analyses. If the finite element analysis is considered an appropriate method by researchers and engineers in studying “reliability of electronic packaging,” it can be extended to generate more data than those obtained from real test under a given condition by taking parameter uncertainties into consideration. Probability theory and statistical methods can then be applied to treat data

obtained through numerical simulation and draw conclusion other than that of the traditional analysis. The above two subsections present results in this study with one emphasizing in reliability of PBGA 316 and the other emphasizing in numerical ALT of PBGA 316 together with its afterward analysis. The present subsection tries to combine the above two topics.

In addition to evaluating parametric values and predicting the average life in practical ALT, we originally considered predicting the life distribution of the studied PBGA 316 under a specific temperature-cycling condition for results similar to those of Fig. 50.9. Since it is too complicated, we turn to predicting statistical properties of the life distribution. To make it simple in engineering applications, we assume the statistical property other than the mean value of life has the following linear relation with the environmental parameters:

$$S.P. = af + bT_{max} + c\Delta T + d \tag{50.9}$$

in which S. P. indicates the statistical property and the other parameters are defined in the statement after Eq. (50.5), with their meanings being seen in Fig. 50.7 and Table 50.4. Based on results of Tables 50.6 and 50.9, coefficients *a*, *b*, *c*, and *d* can be found by regression analysis, and the results are shown in Table 50.12. The corresponding prediction

values and errors (in parenthesis) are summarized in Table 50.13 and Fig. 50.11. From the results, we can see that the predictions of the threshold parameter of the 3-parameter Weibull distribution are quite accurate with an average error of less than 10%, showing that the linear regression method is applicable for this application. However, predictions for other parameters are not that good, and the method also deviates from the original purpose of ALT. Therefore, we seek for further improvements.

The practical ALT is intended for predicting life of an electronic product in a particular filed condition using life data of the product tested usually in more severely environmental conditions. However, as stated previously, only the average trend of life but not life distribution is considered. Since many life data have been generated through PDS of FEM, the present study tries to go a step further investigating the effect of temperature-cycling condition on life distribution of the studied PBGA 316. It is hoped that once life distributions under two or more test conditions are obtained, and their relation being established, the quantitative reliability of package under any other environmental conditions can be evaluated or estimated. This is in fact a problem of studying the relation between two degraded random processes and their corresponding lives, each under its own environmental condition. The problem is too complicated for engineers. Therefore, we focus on the AF of Eq. (50.5) based on Norris-Landzberg model and again consider Test A as our test condition and the others as field conditions. Only a few statistical properties are considered for simplicity. We want to find out whether the statistical properties are related to environmental conditions following Eq. (50.5). Using the data in Tables 50.6 and 50.9 and the AFs in the average sense, the respective results for *m*, *n*, and *E_a/k* are found and listed in Table 50.14. The prediction values and the errors (in parenthesis) concerning each of the statistical properties are summarized in Table 50.15 and Fig. 50.12. We can see that the shape parameter of the 3-parameter Weibull distribution shows the best prediction results with the average error less than 5%. This could mean the trend in failure rate of the assembly is highly dependent on the temperature-cycling condition and can be predicted with the

3-P Weibull threshold	1.13	1.32	5556.47

knowledge of the environmental parameters. It is interesting to see that while the linear regression method did a good job predicting the threshold parameter of the distribution, the AF of Eq. (50.5) did poorly and shows the inability of the N-L AF model to handle low-temperature cycling of Test C and Test E, each with a significantly higher error than the other tests. Aside from the shape parameter, the other predictions of statistical properties prove to be less than satisfying, which implies the environmental variables used for constructing the AF model may be unsuitable for these terms and further studies need to be carried out.

50.5.4 Conclusion of Analysis

The study proposes a method of fatigue life prediction of electronic assemblies that improves on previous models by implementing probabilistic concepts into FEM analysis.

Starting with the construction and verification of an FEM model, the method uses the model as an experimental tool instead of a design tool to perform accelerated life testing, bridging the gap between design engineers and test engineers. Working with the AF based on N-L model, the deterministic approach (which is not reported in this chapter) showed an inability to predict the fatigue lives of PBGA316 under lower temperature-cycling condition with a maximum temperature of 85 °C. With the introduction of parameter uncertainties in solder balls, mold, and BT substrate, a fatigue life distribution was found for each of the six environmental conditions. The height of the BT substrate has the most obvious influence on temperature-cycling fatigue life of the assembly, and it was found that the 3-parameter Weibull distribution can be used to describe the sets of data. The AF obtained using PDS showed a vast improvement over the deterministic model, with average errors less than 0.6% and the ability to handle lower temperature-cycling condition. Finally, while investigating the effect different temperature cycling conditions have on the distribution of thermal fatigue life, predictions of statistical properties such as standard variation and Weibull coefficients were carried out. It has been found that the threshold parameter of the 3-P Weibull distribution can be accurately obtained using a simple linear regression method, while the shape parameter of the 3-P Weibull distribution can be predicted using a modified AF based on A-L model. This implies the dependency of temperature-cycling fatigue life distribution on environment parameters including the maximum temperature, cycling frequency, and the temperature range in a temperature cycle.

Table 50.15 Predicted statistical properties from AF

Statistical property of life	Test A	Test B	Test C	Test D	Test E	Test F
Standard deviation	–	1295.88 (18.61%)	1432.76 (64.01%)	265.03 (9.18%)	1771.37 (37.91%)	191.96 (2.27%)

50.6 Final Comments

The application of FEM to study the quantitative reliability of electronic packaging caused by parameter uncertainties is meaningful and has been demonstrated in this study. The uncertainties may include material, process, and environmental factors since they all are parameters involved in the analysis of FEM. The environmental factors, in particular, are emphasized in practical ALTs in which one tries to find the relationship between lives of a product subjected to two or more different environmental conditions. Once the relationship is established, it can be used for predicting lives of the product subjected to various environmental conditions. The present study proposes to employ FEM as a kind of numerical ALT to substitute real ALT or part of real ALT in order to save test cost. It has been demonstrated the AF of ALT thus obtained can be used to predict the MTTF of the studied PBGA 316 subjected to a given temperature-

cycling condition rather accurately. However, for the purpose of reliability prediction, life distribution or higher-order statistics of life in addition to MTTF have to be found, and the relationship between life distributions or their statistical properties of two different environmental conditions has to be established. The demonstration in this study unfortunately is not very successful. One major reason is that engineers and/or engineering students are usually not very familiar with probability and statistics, which limits their analyses in that respect. It is believed that research can be carried out one step further in the future based on the concept proposed and demonstrated in the present study. The knowledge of probability and statistics is, of course, a plus to this kind of study.

It is interesting to point out that “uncertainty” addressed in this chapter has also been noticed in two recent articles by Wei et al. [37, 38]. Although the propagation of uncertainty is emphasized therein, it still justifies to a certain degree the concept of this chapter.

Accelerated life test (ALT) · Reliability test

Abstract

Accelerated life test (ALT) is a widely used method during product design with the aim to obtain reliability information on components and subsystems in a timely manner. Different types of ALTs provide different information about product and its failure mechanisms. To ensure that the ALTs can assess the product reliability accurately, quickly, and economically, designing efficient test plans is critically important. This chapter provides a limited discussion and description of the models and methods popularly used in ALT. The introduction describes the

51.1 Introduction

In reliability engineering, reliability tests are always used to assess the reliability indices and improve the design of products. To assess the reliability indices, it is mainly concerned with how to test or estimate them accurately, quickly, and economically. Determining a suitable statistical theory, method and technology for experiment design and data analysis is the key of conducting reliability tests, and it is often called statistical based reliability test (SRT). To improve the reliability of products, it mainly focuses on how the processes of design, material selection, manufacture, assemble, and application affect the storage, performance, and maintenance of the product. The key factor of achieving goals is the profound understanding of the performance evolution law of a particular product throughout the whole life cycle. This type of test has a higher requirement for engineering experience, and it is often called engineering based reliability test (ERT). Of course, this classification is only to emphasize the

Q. He (✉) · W.-H. Chen · J. Pan

 Hangzhou, China
 e-mail: heqingchuan@zstu.edu.cn; chenwh@zstu.edu.cn;
 panjun@zstu.edu.cn

different focus of the two types of tests. In practice, to carry out a SRT correctly, the engineering elements, such as usage conditions, failure mode, failure mechanism, test equipment, and cost limits, should be specified. In an ERT, there is also a large quantity of data that should be gathered and analyzed based on statistics.

In practice, ERT is often used in conjunction with SRT, and they play different roles in various stages of whole life cycle of a product. According to the testing purposes, the reliability test could be further classified into reliability growth test (RGT), reliability qualification test (RQT), reliability screening test (RST), reliability acceptance test (RAT), and reliability determination test (RDT). According to the relationship between the test stress and the normal work stress, the reliability test could be divided into traditional test and accelerated test (AT). The types of the major reliability tests are shown in Fig. 51.1 [1].

In general, as shown in Fig. 51.1, the major implemented reliability tests are RGT, RQT, RST, RAT, and RDT corresponding to the design, finalization of design, production, delivery, and use phases of the product whole life cycle. The RGT and RST belong to ERT. The RQT, RAT, and RDT belong with SRT. The statistical inference methods used in RQT and RAT are mainly the hypothesis test. They are often called reliability verification test (RVT). The statistical inference methods used in RDT are mainly the parameter estimation.

In the period when the subject of reliability just formed, products usually have low reliability and short lifespan, and the reliability test can be carried out by simulating the

actual usage conditions. However, with the improvement of product reliability, this type of test is difficult to induce product failure effectively and cannot obtain adequate failure data within acceptable test time and cost. To solve this problem, the AT method is developed: The sample is tested within an environment more severe than the sample would experience during normal operating conditions. Data is collected from high stress levels and also is used to predict the product life under the normal stress level and to improve the product. Among the ATs, the ERT mainly includes the accelerated RGT, the highly accelerated life test (HALT) and the highly accelerated stress screening test (HASS). The HALT and HASS are often referred to as the reliability enhancement test (RET). The SRT mainly includes the accelerated life test (ALT) and the accelerated degradation test (ADT). ALT is a widely used method for rapidly obtaining reliability information and evaluating the useful life of product in a relatively short period. To ensure that the reliability of products can be assessed accurately, quickly, and economically, designing an efficient plan is a critical step before conducting the ALT, and that requires the support of relevant statistical theories. With the promotion of the national strategy of civil-military integration, the ALT will be widely applied in the research and development (R&D) of products, and the ALT plan design theory will also face more challenges. Based on the overview and prospect on designing ALT plan given in [1], this chapter provides a limited discussion and description of the models and methods popularly used in ALT.

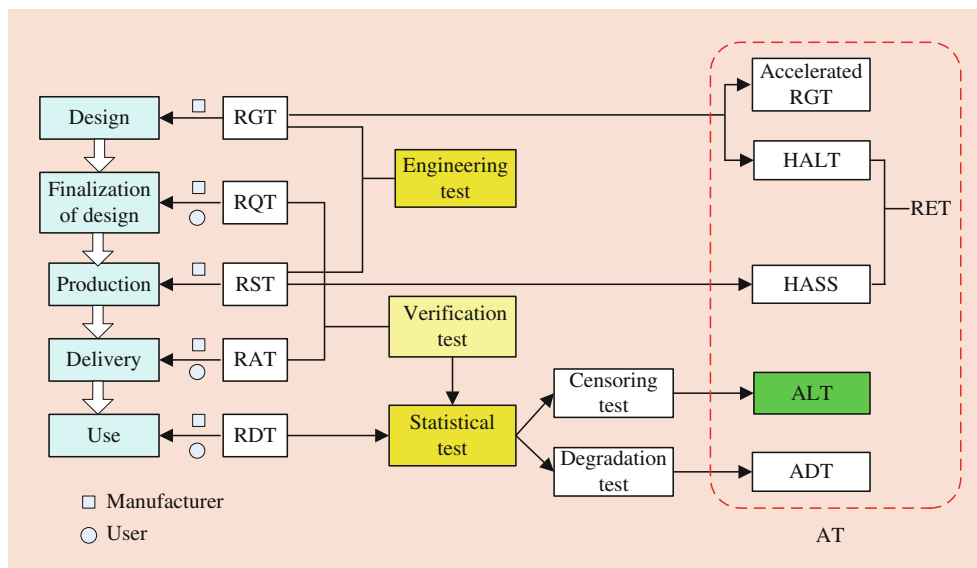

Fig. 51.1 Types, applications, and developments of reliability tests

51.2 Types of ALT

Different types of ALTs provide different information about product and its failure mechanisms. Generally, ALT experiments can be conducted using two approaches. The first is conducted by accelerating the use rate of the product at normal operating conditions such as switches and printers, and also home appliances such as refrigerator compressor and washing machines that are used only a fraction of time in one day. The manner in which the usage rate is increased depends on the product. For example, the median life of a switch for a light is 20 years (or 72,000 times), based on an assumed usage rate of ten times one day. If the switch is tested at 1200 h^{-1} , the median life is reduced to roughly 60 h. ALTs with increased usage rate attempt to simulate actual use. Therefore, the other environmental factors should be controlled to mimic actual use environments. If the usage rate is too high, it cannot have test items cool down between cycles of operation and thus can result in anomaly failure.

The second is conducted by subjecting a product to stresses severe-than-normal operating conditions to accelerate the failure. Depending on the nature of the product, life tests are accelerated by exposing the product to higher levels of accelerating variables such as temperature, pressure, and voltage. Thus, a sample at a high stress will generally fail more rapidly than it would have failed at low stress. With the premise that the failure modes and failure mechanisms are the same as those under normal stress, the samples are tested under stress levels higher than normal, and the lifetime of product under normal stress level can be estimated by extrapolating the life information of samples under high stress levels to normal level based on the life-stress relationship.

Different types of stress loadings can be considered when an ALT is conducted. Figure 51.2 shows four different types

of stress loading applied in ALTs, which are constant stress, step stress, progressive stress, and cyclic stress, respectively. The four loading schemes correspond to the constant stress ALT (CSALT), step stress ALT (SSALT), progressive stress ALT (PSALT), and cyclic stress ALT, respectively. The constant stress is time independent and also the most commonly used in engineering. The other three stress loading schemes is time dependent which means the stress level varies with time. Usually, time-dependent stress loadings can yield failures more quickly. In CSALT, samples are tested at constant, severer-than-normal operating conditions until either all samples fail or the test is terminated. In SSALT, the stress is increased at prespecified times or upon the occurrence of a fixed number of failures until either all the samples fail or the time period at the maximum stress level ends. In PSALT, the stress level is continuously increased as time goes on. In cyclic stress ALT, the stress level is periodically changed over time. The CSALT is applied to many products because it is easier to carry out, but need more samples and a long time at low stress levels to yield failure data. The SSALT, PSALT, and cyclic stress ALT could precipitate failures more rapidly. However, it is very difficult to model the life-stress relationship and, hence, to quantitatively predict the lifetime under normal usage conditions.

The ALT can be classified in other ways. Usually, two censoring schemes are widely used in ALT: time censoring (the type I censoring), where the number of actual failures is random upon the completion of test, and failure censoring (the type II censoring), where the total test duration is random at the end of test when certain number of failures is observed. These two kinds of censoring scheme correspond to the type I ALT and type II ALT. The two strategies of inspection performance of samples include continuous and periodic inspection, which can generate life data and group data, respectively. The number of accelerated stresses included single stress, two stresses, and multiple stresses. Usually,

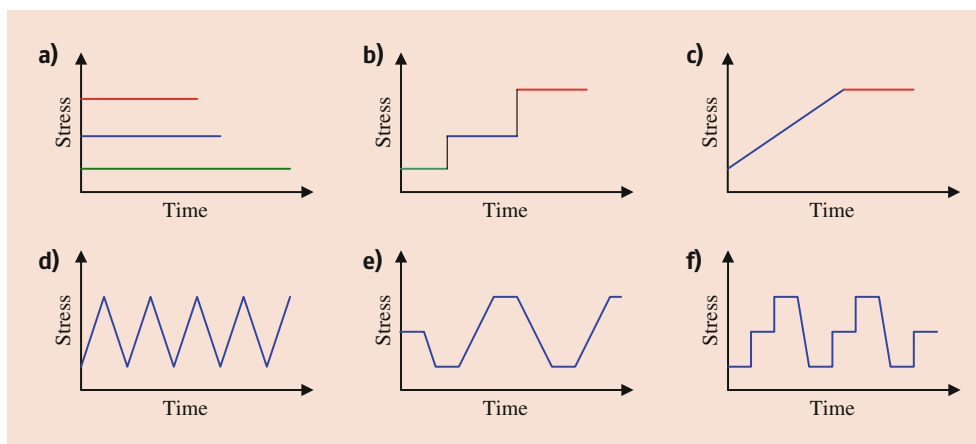

Fig. 51.2 Different types of accelerated stress loadings. (a) Constant stress. (b) Step stress. (c) Progressive stress. (d) Cyclic stress 1. (e) Cyclic stress 2. (f) Cyclic stress 3

the number of test stress is greater than or equal to three. They correspond to the single-stress ALT, two-stresses ALT, and multiple-stresses ALT, respectively. Comparing with the single-stresses ALT, the multiple-stresses ALT can simulate usage conditions better and can make the failure of products faster. With the rapid development of environment simulation technology, testing equipments used for multiple-stresses ALT are developed. All these equipments can load two or more environment stresses (such as the temperature and humidity, temperature and vibration, thermal and vacuum, and temperature and humidity and vibration) on products. Therefore, multiple-stresses ALTs begin to be used in engineering. For more details the reader is referred to Chap. ▶ 12 of Patrick and Andre [2].

51.3 Life Distribution

In reliability engineering, it is significant to determine which distribution best fits a set of data and to derive estimates of the distribution parameters. Let the symbol T denote lifetime for components, systems, etc. The cumulative distribution function (CDF) $F(t) = \Pr(T \leq t)$ is the probability of failure by time t . The probability density function (pdf) $f(t)$ is the derivative of the CDF. That is, $f(t) = dF(t)/dt$. Determining a probability distribution for lifetime means specifying either $F(t)$ or $f(t)$. The exponential, Weibull, and lognormal distributions are the most commonly used distributions in reliability engineering. For the other members of the family, the reader is referred to Chaps. ▶ 4 and ▶ 5 of Meeker and Escobar [3].

51.3.1 Exponential Distribution

The exponential distribution is a single-parameter distribution. If lifetime T has an exponential distribution its CDF and pdf are

$$F(t; \lambda) = 1 - \exp(-\lambda t),$$

$$f(t; \lambda) = \lambda \exp(-\lambda t), \quad t \geq 0$$

where λ is the constant hazard rate. The mean life or mean time to failure (MTTF) is $1/\lambda$.

The λ is a significant characteristic of the exponential distribution. It should be observed that λ has the same value and is independent of time. The exponential distribution is used for random failures. One salient feature is that the same proportion of parts fail relative to the number of parts remaining. Also, note that the exponential distribution is usually not appropriate because it assumes a constant λ .

Thus, the practitioner should be cautioned against using the exponential distribution, unless the underlying assumption of a constant λ can be justified.

51.3.2 Lognormal Distribution

Lifetime T is lognormally distributed if the logarithm of the T is normally distributed. When lifetime T has a lognormal distribution, its CDF and pdf are

$$F(t; \mu, \sigma) = \Phi_{\text{nor}}\left(\frac{\log(t) - \mu}{\sigma}\right),$$

$$f(t; \mu, \sigma) = \frac{1}{\sigma t} \phi_{\text{nor}}\left(\frac{\log(t) - \mu}{\sigma}\right), \quad t > 0$$

where Φ_{nor} and ϕ_{nor} are the standard normal CDF and pdf, respectively. In particular,

$$\phi_{\text{nor}(z)} = \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{z^2}{2}\right)$$

The parameters (μ, σ) are the mean and the standard deviation of $\log(T)$, respectively. The lognormal p quantile is $t_p = \exp[\mu + \Phi_{\text{nor}}^{-1}(p)\sigma]$. The lognormal distribution is used to model situations where large occurrences are concentrated at the tail (left) end of the range. It is based on the normal distribution, but is a more versatile distribution than the normal as it has a range of shapes, and therefore is often a better fit to reliability data, such as for products with wearout and fatigue characteristics.

51.3.3 Weibull Distribution

The Weibull distribution is developed in 1939 by Waloddi Weibull, who presented it in detail in 1951. If lifetime T has a Weibull distribution its CDF and pdf are

$$F(t; \eta, m) = 1 - \exp\left[-\left(\frac{t}{\eta}\right)^m\right],$$

$$f(t; \eta, m) = \frac{m}{\eta} \left(\frac{t}{\eta}\right)^{m-1} \exp\left[-\left(\frac{t}{\eta}\right)^m\right], \quad t > 0$$

where m is the shape parameter and η is the scale parameter. Note that η is approximately the 0.63 quantile of the Weibull distribution, or characteristic life. If, however, failures do not start at $t = 0$, but only after a finite time γ , then the CDF takes the form

$$F(t; \eta, m, \gamma) = 1 - \exp \left[- \left(\frac{t - \gamma}{\eta} \right)^m \right],$$

that is, a three-parameter distribution. The γ is called failure free time, location parameter, or minimum life.

The Weibull distribution is the most popular statistical distribution used in reliability engineering. It has the great advantage by adjusting the distribution parameters. It can be approximated to other distributions under special or limiting conditions. The Weibull distribution is widely used because a wide diversity of hazard rate curves can be modeled with it.

- If $m = 1$, the exponential reliability function (constant hazard rate) results with $\eta = \text{mean life } (1/\lambda)$ can be obtained. It is usually associated with useful life.
- If $m < 1$, a decreasing hazard rate reliability function can be obtained. It is usually associated with infant mortality, sometimes referred as early failures.
- If $m > 1$, an increasing hazard rate reliability function can be obtained. It is usually associated with wearout, corresponding to the end life of the product with closer inter-arrival failure times.
- When $m = 3.5$, for example, the distribution approximates to the normal distribution.
- If $m > 6$, it may reflect an accelerated rate of failures and fast wearout. Furthermore, it is time to doubt the accuracy of the analytical results.
- If $m > 10$, it is time to highly doubt the analytical results. Such a high β is fairly rare in practice.

The lognormal distribution and Weibull distribution are also called log-location-scale distributions. A random variable Y has a location-scale distribution if its CDF can be written as:

$$F(y; \mu, \sigma) = \text{Pr}(Y \leq y) = \Phi \left(\frac{y - \mu}{\sigma} \right),$$

where μ is a location parameter, σ is a scale parameter, and Φ does not depend on any unknown parameters. In many reliability applications, it is assumed that $\log(T)$ has a location-scale distribution. Then T is said to have a log-location-scale distribution.

51.4 Life-Stress Models

In reliability physics and engineering, the development and use of the acceleration factor (AF) and the life-stress relationship are vitally important to the theory of accelerated testing. The AF permits one to take time-to-failure data rapidly under accelerated test conditions, and then to extrapolate

the accelerated test results for a given set of operational conditions. The AF can be defined as given (51.1):

$$\text{AF} = \frac{t_{\text{normal}}}{t_{\text{acceleration}}} \quad (51.1)$$

where the t_{normal} and $t_{\text{acceleration}}$ are the time-to-failure data under normal operating conditions and accelerated stress conditions, respectively. Since t_{normal} may take many years to occur, then experimental determination of the AF is usually impractical. However, if one has proper life-stress relationship models then one can use these models to derive the AF.

A life-stress relationship can be one of the empirically derived relationship or a new one for the particular stress and application. It is applied to describe a life characteristic of the distribution from one stress level to another. The life characteristic can be any measure such as the mean, median, etc. For example, when considering the Weibull distribution, the scale parameter η is chosen to be the “life characteristic,” while m is assumed to remain constant across different stress levels. This assumption implies that the same failure mechanism is observed at different stresses. There are many life-stress models which have been used successfully in practice. Generally, the most commonly used life-stress relationship models include exponential model and power model.

51.4.1 Exponential Model

In this model, there is an exponential relationship between the life characteristic and the stress, which can be written as:

$$\text{Life} = A \times e^{-B \times \text{Stress}} \quad (51.2)$$

where A is an empirical constant and B can be a constant or function describing this relationship. Following are the most commonly used models involving stresses caused by temperature and humidity.

- Arrhenius Models

The Arrhenius equation is used to relate the rate of a chemical reaction R to temperature, which can be written as:

$$R(T) = \gamma_0 \exp \left(\frac{-E_a}{k_B \times T} \right) \quad (51.3)$$

where the γ_0 and the activation energy E_a are constants that depend on material properties, failure mechanism, and test methods; $k_B = 8.62 \times 10^{-5} \text{eV/K}$ is Boltzmann’s constant in units of electron volts per °C. The temperature $T = \text{temp } ^\circ\text{C} + 273.15$ is the temperature in Kelvin. Let T_{Field} and T_{test} be equal to absolute Kelvin temperatures at field

and test level, respectively. Then the Arrhenius acceleration factor can be written as:

$$AF = \exp \left\{ \frac{E_a}{k_B} \left(\frac{1}{T_{\text{Field}}} - \frac{1}{T_{\text{Test}}} \right) \right\}. \quad (51.4)$$

Based on (51.3), life is nonlinear in the single-stress variable temperature (T). Empirical observations suggested that the Arrhenius model has various applications, but it is most commonly used to estimate the acceleration factor for electronic component operating at a constant temperature. However, the nature of the failure mechanism may limit the range of temperature over which the Arrhenius relationship is adequate. The Arrhenius acceleration factor is also very sensitive to the value of E_a due to its exponential nature, therefore the accuracy of estimating E_a is very important. The E_a has a specific meaning as an atomic or material property. It simply becomes an empirical constant appropriate for use with a particular failure mechanism. There are no predetermined generic values of E_a for the specific failure mechanisms due to variation in parts characteristics. The only reliable way to obtain E_a is to conduct a series of acceleration tests.

- Eyring Model

The Eyring model is usually applied to combine the effect of more than one independent stress variables assuming no interactions between the stresses. A generic form of the Eyring equation can be written as:

$$\text{Life} = \exp \left\{ \frac{E_a}{k_B T} f_1(S_1) f_2(S_2) \right\} \quad (51.5)$$

where $f_1(S_1)$ and $f_2(S_2)$ are the factors for other applied stresses, such as temperature, humidity, voltage, current, vibration, and so on. A form of the Eyring model for the influence of voltage (V) in addition to temperature (T) is:

$$\text{Life} = AV^{-B} \exp \left\{ \frac{E_a}{k_B T} + \left(C + \frac{D}{T} \right) V \right\} \quad (51.6)$$

where A , B , C , and D are unknown parameters. Eyring also suggests the following generalized model, which considers the influences of temperature T and of further stresses S_i as:

$$AF = (T_2/T_1)^{-m} \exp \left\{ \frac{E_a}{k_B} \left(\frac{1}{T_{\text{Field}}} - \frac{1}{T_{\text{Test}}} \right) \right\} \exp \left\{ S_{\text{Field}} \left(C + \frac{D}{k_B T_{\text{Field}}} \right) - S_{\text{Test}} \left(C + \frac{D}{k_B T_{\text{Test}}} \right) \right\}. \quad (51.7)$$

See Meeker and Escobar [4] and the above references for more information on the Eyring model.

51.4.2 Power Model

A simple power relationship between the performance measure and the stress variable can be written as:

$$\text{Life} = A \times \text{Stress}^{-B} \quad (51.8)$$

where A is an empirical constant and B can be a constant or function describing this relationship. Following are the most commonly used power models involving stresses caused by temperature cycling, voltage, vibration, etc.

- Coffin-Manson Model

Models for mechanical failure, material fatigue, or material deformation are not forms of the Eyring model. These models typically have terms relating to cycles of stress or frequency of change in temperatures. The Coffin-Manson model is used successfully to model crack growth in solder and other metals due to repeated temperature cycling as equipment is turned on and off. It provides a relationship between life in thermal cycles, N_f , and plastic strain range $\Delta\gamma_p$, and says that the number of cycles to failure is

$$N_f(\Delta\gamma_p)^m = \text{Constant}, \quad (51.9)$$

where m is an empirical fatigue constant. During thermal cycling, the strain range caused by the mismatch of the coefficients of thermal expansion between solder and other materials is proportional to the cycling temperature excursion $\Delta T = T_{\text{Max}} - T_{\text{Min}}$. The acceleration factor can be approximated by:

$$AF = \left(\frac{\Delta T_{\text{Test}}}{\Delta T_{\text{Field}}} \right)^m \quad (51.10)$$

In the case of low cycle fatigue, the acceleration factor is typically used to the number of thermal cycles rather than the temperature exposure time. There are extensions of the Coffin-Manson model which account for the effect of temperature transition during thermal cycling.

- Voltage Acceleration Models

A simple model having only voltage V dependency takes the form:

$$AF = \left(\frac{V_{\text{Test}}}{V_{\text{Field}}} \right)^B \quad (51.11)$$

An alternative exponential voltage model takes the form of the following:

$$AF = \exp [B (V_{\text{Test}} - V_{\text{Field}})] \exp \left[\frac{E_a}{k_B} \left(\frac{1}{T_{\text{Field}}} - \frac{1}{T_{\text{Test}}} \right) \right] \quad (51.12)$$

where B is voltage acceleration parameter. Failure mechanisms of electronic components usually follow this relationship over most of their life for dependence on voltage.

- Vibration Acceleration Models

Most vibration models are based on the S-N curve. The relationship between peak stress σ and the number of cycles to failure N can be expressed as $N\sigma^b = \text{Constant}$ (high cycle fatigue). Assuming the linear relationship between the stress and acceleration G during vibration, the model takes the following form:

$$\text{Sinusoidal vibration : } AF = \left(\frac{G_{\text{Peak-Test}}}{G_{\text{Peak-Filed}}} \right)^b \quad (51.13)$$

$$\text{Random vibration : } AF = \left(\frac{G_{\text{Test}}}{G_{\text{Field}}} \right)^n \quad (51.14)$$

where b is the slope of the S-N line in the log-log scale and has different values for different materials. It is typical for sinusoidal vibration to measure life in vibration time or a number of cycles.

There are other models including the mix of exponential and power model or other physical laws, such as temperature-humidity model. Relative humidity is an environmental variable that can be combined with temperature to accelerate corrosion or other chemical reactions. As a special case of the Eyring model, Peck's equation is the most commonly used model to address the combined effect of temperature and humidity. The acceleration factor correlating product life in the field with test period can be expressed as:

$$AF = \left(\frac{RH_{\text{Test}}}{RH_{\text{Field}}} \right)^m \exp \left[\frac{E_a}{k_B} \left(\frac{1}{T_{\text{Field}}} - \frac{1}{T_{\text{Test}}} \right) \right] \quad (51.15)$$

where m is a constant, typically ranging between 2.0 and 4.0, and RH = relative humidity measured as percent. Usually, Peck's model can only be applied to wearout failure mechanisms, including electromigration, corrosion, dielectric breakdown, and dendritic growth. Another temperature-humidity model is Lawson model, which is based on the water absorption research:

$$AF = \exp \left[\frac{E_a}{k_B} \left(\frac{1}{T_{\text{Field}}} - \frac{1}{T_{\text{Test}}} \right) \right] \exp [b (RH_{\text{Test}}^2 - RH_{\text{Field}}^2)] \quad (51.16)$$

where b is an empirical humidity constant based on water absorption.

Example 51.1 An electrical insulator is rated for normal use at 12 V. Prior tests show this insulator can operate over 24 V and a life-stress exponent of the power model was found to be $B = 6$. How long must one run an ALT at 24 V to conduct an equivalent B_5 life if the B_5 life at 12 V is desired to be at least 20 years?

Let life $\text{Life} = A \times V^{-B}$ represent the life relationship, and applying (51.11) to calculate the acceleration factor due to voltage only:

$$AF = \left(\frac{24 \text{ V}}{12 \text{ V}} \right)^6 = 64$$

Thus

$$\begin{aligned} \text{Test time at 24 V} &= \frac{20 \text{ years}}{AF} = \frac{20 \text{ years} \times 8760 \text{ h/year}}{64} \\ &= 2737.5 \text{ h.} \end{aligned}$$

51.5 Statistical Analysis of ALT Data

An effective ALT conducted by using different types of stress loading, test stopping criteria, and performance inspection methods can produce different types of data such as failed and not failed (censored) data. Therefore, when dealing with the ALT data, appropriate data analysis methods must be used. Nelson and Meeker et al. are the pacesetters in discussing the method for statistical analysis of ALT data [2, 4]. Nelson and Meeker provide the basic analysis framework for ALT data. Although the ALT modes are extended, the statistical models are generalized and improved, and the framework has not yet been exceeded. In engineering, their researches and findings are widely used as important references in promoting the development of ALT design method. The most commonly used models and methods belong to the parametric statistics. The most widely used and advanced theory is the maximum likelihood estimation (MLE) theory for the location-scale distribution and the linear life-stress relationship. Nevertheless, the problems such as being difficult to determine the type of product life distribution and the lack of test data always bedevil the application of ALTs. See Meeker and Escobar [2] and Nelson [4, 6], and the above references for more information on statistical analysis of ALT data. There is also commercially available software designed to analyze ALT data. When sufficient data is available software packages such as ReliaSoft ALT can fit a statistical distribution to a life data set at each stress level and model the resulting life-stress relationship.

Generally, the first step in performing ALT data analysis is to determine an appropriate statistical distribution to de-

scribe lifetime at fixed levels of the accelerating variable(s). Typically, there is only one type of distribution used at all levels of stress. This implies that the failure mechanisms remain the same at different stress levels. The statistical model of CSALT includes the life distribution and the life-stress relationship. The statistical model of SSALT and PSALT includes the life distribution, the life-stress relationship, and also the equivalent principle of stress level transition. In studying the statistical theory of ALT, it began with supposing that the lifetime follows exponential distribution. From an engineering point of view, the ALT is primarily oriented to electronic products, and the exponential distribution is used widely as “standard distribution” in the reliability analysis. However, more engineers and applied statisticians find that it is more appropriate to describe the product life distribution as the function belong to the location-scale distribution (such as the Weibull distribution and lognormal distribution) than exponential distribution.

The process of finding the best statistical distribution is based on the failure data, goodness-of-fit tests, and engineering experience. Usually, probability plots are used to identify an appropriate distribution and to derive estimates of the distribution parameters. Probability plotting is a method for determining whether data conform to a hypothesized distribution. It in general involves a physical plot of the data on specially constructed probability plotting paper. The axes of probability plotting papers are transformed in such a way that the true CDF plots as a straight line. If the plotted data can be fitted by a straight line, the data fit the appropriate distribution. This approach can be easily implemented by hand under the given probability plotting paper. Nowadays computer software is used to assess the hypothesized distribution and determine the parameters of the underlying distribution by using MLE method or rank regression method. For example, probability plotting papers exist for all the major distribution,

such as normal, lognormal, Weibull, exponential, extreme value (see Reliasoft Weibull++ and Minitab 18).

Example 51.2 Assume that eight samples are tested. All of these items fail during the test after operating the following number of hours: 35, 40, 43, 47, 49, 54, 59, 63, 67, 74, 75, 77, 78, 86, 106, 108, 113, and 125. Find the best statistical distribution to describe lifetime of the product based on the observed failure data and determine the parameters.

Figure 51.3a, b show the Weibull distribution and lognormal distribution plotted with Minitab. In the two figures, the fitted line gives a good “eyeball fit” to the plotted data. It is very difficult to determine the best statistical distribution by using visual examination. However, the software employs more sophisticated mathematical methodology, and thus offers clear advantages by providing the capability to perform more accurate and versatile calculations and data plotting. See Fig. 51.3, the results (that is the value of AD and p) of the Anderson-Darling test show the lognormal distribution is a better one to describe lifetime of the product, and the location parameter μ is 4.213 and the scale parameter σ is 0.376.

The second step is to select (or create) a model to describe the relationship between the lifetime distributions and the accelerating variables. It is best to develop a model based on physical or chemical theory, empirical considerations, or both. Then, the pdf at the normal use stress level can be extrapolated based on the life-stress relationship and the characteristics of the distributions at each accelerated stress level. The life-stress relationships of single-stress, double-stresses, and multiple-stresses ALTs are single, binary, and multivariate functions, respectively. The number of stresses changes, and we must change the ALT plan design method with it. In practice, it is extremely difficult or impractical to

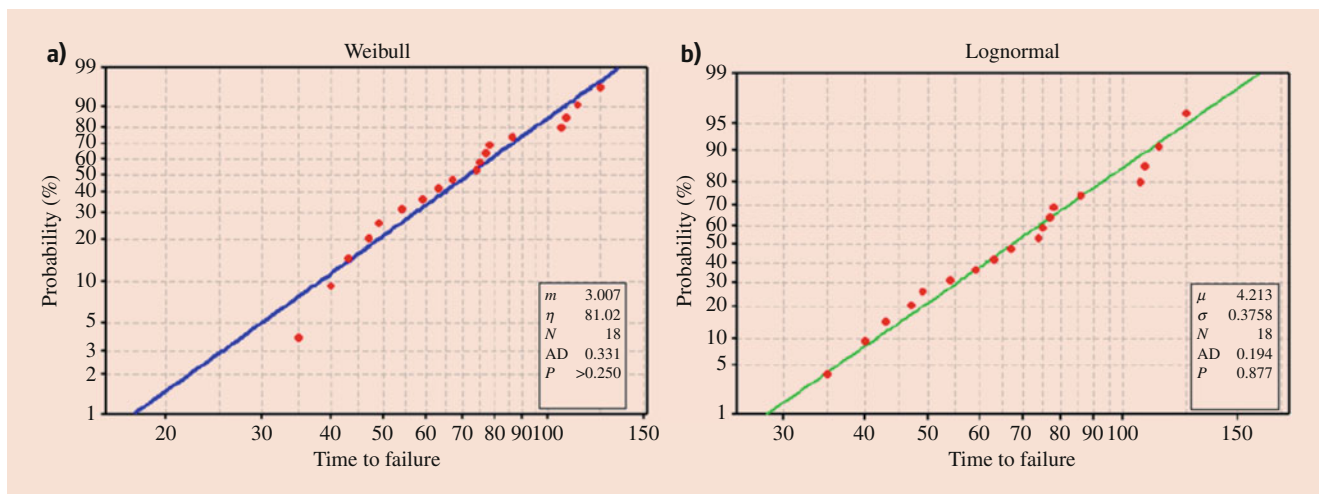

Fig. 51.3 Probability plotted with Minitab: (a) Weibull distribution plotted; (b) lognormal distribution plotted

verify acceleration relationships over the entire range of interest. Escobar and Meeker provide some basic guidelines for the use of acceleration models in reference [4]. Furthermore, for more details about time-to-failure modeling, the reader is referred to [6].

The next step is to assess statistical uncertainty in performing an ALT analysis. The statistical model and the statistical analysis method are the indispensable part for statistical analysis of ALT. The actual effectiveness of statistical inference is largely determined by whether the statistical model is suitable for engineering practices. Therefore, the statistical model should be tested before it is used in reliability assessment. The current theories provide methods for testing various life distributions. The verification on the life-stress relationship and the assumptions of cumulative damage is more concerned in engineering. The traditional theories on regression diagnosis are abundant, but few of them are applicable for censored data and non-normal distribution. In general, testing a model needs more sample sizes and stress levels than estimating model parameters. It is also difficult to validate the extrapolation effect of the model because of the long product life and high reliability. There needs to develop some new methods to deal with the uncertainty of the acceleration model. For more details about life data analysis process, the reader is referred to [1, 3, 5].

Example 51.3 To expedite product development of a capacitor, 45 capacitors are selected to conduct ALT. The capacitor is designed to operate at room temperatures up to 85 °C. The first group of 15 samples are tested at 1.4V₀ (V₀ is the

rated working voltage), second group at 1.6V₀, and third at 1.8V₀. The time-to-failure data obtained during this test are presented in Table 51.1.

The first step is to run life data analysis at each stress level and study how the accelerating variable affects the lifetime. For each level of the accelerating variable(s), plot the life data on probability paper for a suggested lifetime distribution. The distribution adequately describes the data if, for each individual condition, the points lie close to a straight line. ML is used to fit a line through the points at each level. A multiple probability plot shows fitted lines for all of the levels of the accelerating variable. This provides a convenient visual assessment of the assumption that all the samples have the same failure modes. If the assumption is reasonable, the lines will be approximately parallel.

Figure 51.4a, b show the Weibull and lognormal multiple probability plots, respectively. The points for each voltage stress level fall roughly along a straight line, and the lines appear to be reasonably parallel, but more parallel with the Weibull distribution. Thus, we confirm the consistency of the failure mechanisms at the three stress levels. It appears that both the Weibull and the lognormal distributions provide adequate descriptions of the ALT data. By comparison, the Weibull distribution is chosen as the life distribution. At each level of voltage stress, the Weibull distribution is fitted to the data, and estimates of η and m were computed by using the method of ML. Table 51.2 gives the ML estimates of η and m for each level of voltage stress obtained from Minitab.

Table 51.1 Accelerated test results for Example 51.3

Stress	Time to failure (h)
85 °C/1.4V ₀	89.3, 132.4, 276.3, 312.4, 346.6, 403.8, 476.8, 496.0, 682.4, 718.2, 897.4, 1008.3, 1036, 1094.5, 1136.0
85 °C/1.6V ₀	32.7, 34.8, 43.9, 57.2, 72.4, 99.5, 107.0, 123.7, 145.4, 180.1, 215.2, 235.5, 252.2, 280.0
85 °C/1.8V ₀	8.3, 9.6, 12.3, 17.5, 19.8, 24.0, 26.3, 36.2, 36.9, 45.5, 53.2, 63.6, 75.5, 76.3, 82.0

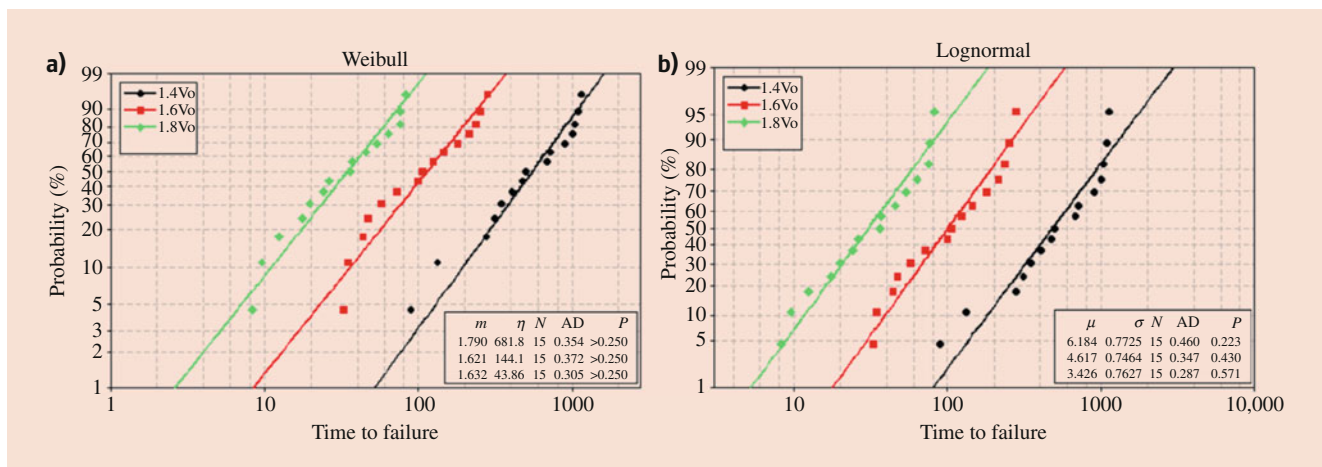

Fig. 51.4 Multiple probabilities plotted: (a) Weibull distribution plotted; (b) lognormal distribution plotted

The next step is to model a life-stress relationship. The inverse power relationship is widely used to relate the lifetime of a capacitor to voltage stress. Suppose that T (volt), the lifetime at volt, has a log-location-scale distribution with parameters (η, m) and that m does not depend on volt. Under the inverse power relationship, $\eta = \beta_0 + \beta_1 \ln(V)$. Fitting the model to data is accomplished by computing estimates for the parameters β_0 and β_1 . The result of fitting the inverse power relationship is

$$\hat{\eta}_0 = 1458 - 2571 \ln(V).$$

The estimate \hat{m} can be calculated by

$$\hat{m} = \frac{n_1 \hat{m}_1 + n_2 \hat{m}_2 + n_3 \hat{m}_3}{n_1 + n_2 + n_3} = 1.68$$

Then, the estimated rated lifetime at use conditions (85 °C/ V_0) can be estimated by

$$\hat{\eta} = 1458 - 2571 \ln(V_0) = 1458 \text{ h.}$$

And the reliability function at use conditions takes the form

$$R(t) = \exp \left[- \left(\frac{t}{\hat{\eta}_0} \right)^{\hat{m}} \right] = \exp \left[- \left(\frac{t}{1458} \right)^{1.68} \right].$$

Example 51.4 Consider the following times-to-failure data collected after testing 12 electronic devices at three different voltage stress levels and three temperature stress levels. On the i -th voltage stress level ($i = 1, 2, 3$) and the j -th temperature stress level ($j = 1, 2, 3$), the sample size n_{ij} is 8, the number of the failure data is r_{ij} , and the suspended time τ_{ij} is 10,000 h. Table 51.3 shows the time-to-failure data. As shown in Fig. 51.5, by using multiple probability plotting method, we found that the Weibull distribution is fitted to the

data at different stress levels. The estimates of η and m for each combination of voltage stress and temperature stress are obtained from Minitab. Suppose that the life-stress models are as follows:

$$\eta_{ij} = A \times V_i^{-C} \times \exp(B/T_j)$$

where the A , B , and C are unknown parameters. Find the reliability function at 120 V and 25 °C.

By using MLE, one can get the likelihood function as:

$$L = \prod_{i=1}^3 \prod_{j=1}^3 \frac{n_{ij}!}{(n_{ij} - r_{ij})!} \left\{ \prod_{k=1}^{r_{ij}} \frac{m t_{ij}^{m-1}}{\eta_{ij}^m} \exp \left[- \left(\frac{t_{(k)ij}}{\eta_{ij}} \right)^m \right] \right\} \times \exp \left[- \left(\frac{t_{(k)ij}}{\eta_{ij}} \right)^m \right]^{n_{ij} - r_{ij}}$$

Through maximizing $\ln L$, the maximum likelihood estimators of m , A , B , and C are the simultaneous solutions of four equations that are as follows:

$$\frac{\partial \ln L}{\partial m} = \sum_{i=1}^3 \sum_{j=1}^3 \left\{ \frac{r_{ij}}{m} + \sum_{k=1}^{r_{ij}} \ln t_{(k)ij} - r_{ij} \ln \eta_{ij} - \sum_{k=1}^{r_{ij}} \left(\frac{t_{(k)ij}}{\eta_{ij}} \right)^m \ln \frac{t_{(k)ij}}{\eta_{ij}} - (n_{ij} - r_{ij}) \left(\frac{\tau_{ij}}{\eta_{ij}} \right)^m \ln \frac{\tau_{ij}}{\eta_{ij}} \right\} = 0$$

$$\frac{\partial \ln L}{\partial A} = \sum_{i=1}^3 \sum_{j=1}^3 \frac{m}{A} \left\{ \sum_{k=1}^{r_{ij}} \left(\frac{t_{(k)ij}}{\eta_{ij}} \right)^m + (n_{ij} - r_{ij}) \left(\frac{\tau_{ij}}{\eta_{ij}} \right)^m - r_{ij} \right\} = 0$$

$$\frac{\partial \ln L}{\partial B} = \sum_{i=1}^3 \sum_{j=1}^3 \frac{m}{T_j} \left\{ \sum_{k=1}^{r_{ij}} \left(\frac{t_{(k)ij}}{\eta_{ij}} \right)^m + (n_{ij} - r_{ij}) \left(\frac{\tau_{ij}}{\eta_{ij}} \right)^m - r_{ij} \right\} = 0$$

Table 51.2 ML estimates for Example 51.3

V_i	1.4 V_0	1.6 V_0	1.8 V_0

8	Suspended at 10,000	2914.8	1963.1	9043.8	2532.7	1643.4	6368.0	1448.1	1010.1

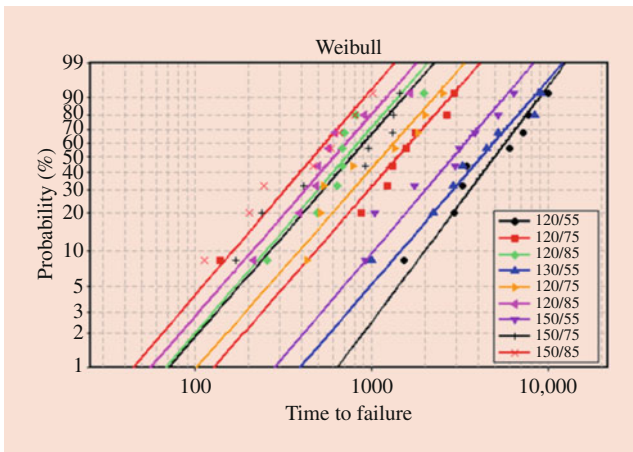

Fig. 51.5 Multiple Weibull distribution probability plotted

$$\frac{\partial \ln L}{\partial C} = \sum_{i=1}^3 \sum_{j=1}^3 m \ln V_i \left\{ r_{ij} - \sum_{k=1}^{r_{ij}} \left(\frac{t_{(k)ij}}{\eta_{ij}} \right)^m - (n_{ij} - r_{ij}) \left(\frac{\tau_{ij}}{\eta_{ij}} \right)^m \right\} = 0$$

Then, one can obtain that: $\hat{m} = 1.8$, $\hat{A} = 0.1$, $\hat{B} = 7543.3$ and $\hat{C} = 2.5$. The estimate lifetime at use conditions (120 V/25 °C) can be estimated by

$$\hat{\eta} = \hat{A} \times V^{-\hat{C}} \times \exp\left(\frac{\hat{B}}{T}\right) = 0.1 \times 120^{-2.5} \times \exp\left(\frac{7543.3}{273 + 25}\right) = 62418 \text{ h.}$$

And the reliability function at 120 V and 25 °C takes the form

$$R(t) = \exp\left[-\left(\frac{t}{\hat{\eta}}\right)^{\hat{m}}\right] = \exp\left[-\left(\frac{t}{62,418}\right)^{1.8}\right].$$

51.6 Design of ALT Plans

Finding an appropriate ALT method and an optimal test plan has become the common goal of all engineers. When designing an ALT plan, the type of stress loading, the number of stress levels and samples to be allocated to each stress level, censoring schemes, and also an applicable lifetime distribution and a life-stress models need to be first determined under many constraints, such as the limited test time, budget, and availability of resources. Designing optimal ALT plan should fit for the stress loading mode, ALT model, testing condition limitation, and design objective.

There are various optimization objectives and constraints such as V-optimization, D-optimization single objective,

multiple objectives, cost limits, and resource limits. By using V optimization, one can obtain the optimal plan by minimizing the asymptotic variance of the MLE of the p -th quantile of the product life distribution under normal stress. By using D optimization, one can obtain the optimal plan by maximizing the determinant of the Fisher information matrix of MLE. The most widely used researched ALT plan is the V-optimal continuous-inspection type I censoring CSALT plan with the location-scale distribution and linear life-stress relationship. For an overview of ALT design and planning, the reader is referred to [1, 7].

51.6.1 Method for Planning Single-Stress CSALTs

During planning ALTs, firstly suppose that [7]: (1) the logarithm life of product follows the Weibull distribution or lognormal distribution, and the CDF is $F(y; \mu, \sigma) = \Phi[(y - \mu)/\sigma]$, where μ is the location parameter, σ is the scale parameter, and $\Phi(\bullet)$ is the standard extreme value or the standard normal distribution. (2) The location parameter μ is a linear function of the standardized stress ξ ($0 \leq \xi \leq 1$), or the life-stress relationship is $\mu(\xi) = \gamma_0 + \gamma_1 \xi$, where $\gamma_1 < 0$. The Arrhenius model and the inverse power law model, which are the most widely used in engineering, both could be transformed into linear life-stress relationship. (3) The scale parameter σ is a constant and independent of ξ . (4) The failure time is statistically independent. (5) The type I censoring CSALT is considered, and the censoring time at each stress level is τ .

Assume that there are k stress levels, the sample size allocated to the i -th level ξ_i ($i = 1, 2, \dots, K$) is N_i , and also the lifetime of the j -th ($j = 1, 2, \dots, N_i$) samples on ξ_i is (t_{ij}, δ_{ij}) . If the sample fails, then $\delta_{ij} = 1$. If the sample is censored, then $\delta_{ij} = 0$ and $t_{ij} = \tau$. The log likelihood function of the MLE is

$$\ln L = \sum_{i=1}^K \sum_{j=1}^{N_i} \left\{ \delta_{ij} \ln f(t_{ij}; \mu(\xi_i), \sigma) + (1 - \delta_{ij}) \times \ln(1 - F(\tau; \mu(\xi_i), \sigma)) \right\} \tag{51.17}$$

where $f(t_{ij}; \mu(\xi_i), \sigma)$ is the pdf of the extreme value or normal distribution. The problem of designing optimal ALT plan could be also expressed as given in the following. Find the number of stress levels K^* , the stress level ξ_i^* , and the sample location ratio p_i^* that minimize the asymptotic variance of the MLE for the p -th quantile y_p of lifetime distribution under normal stress level under some constraint conditions. These conditions are mainly composed of the prior estimate values $\gamma_{0,e}$, $\gamma_{1,e}$, and σ_e of the model parameters γ_0 , γ_1 , and σ ,

respectively, and also the censoring time τ and the failure probability p under normal stress level.

However, the statistically optimal plan may not apply to practice. Nelson and Meeker et al. suggested a “compromise plan” with three or four stress levels can be used. The middle stress level can be used to test the life-stress relationship, prevent the test failures, and improve the plan robustness to the deviations of the statistical model and model parameters. Furthermore, Meeker also proposed the criterion that evaluates the ALT plan robustness to the deviations of the model parameters and product life distribution. The best plan of considering the estimation accuracy and robustness is the optimal compromise plan. This plan has three equally spaced test stresses and the sample location ratio of the middle stress level is 10% or 20%. The ratio at minimum stress level should be determined via optimization. This plan was also furtherly simplified by Meeker et al. to become the “4:2:1 plan,” which has three equally spaced levels and with the sample allocation ratio of 4:2:1 at the levels of lowest, the middle, and the highest stress.

51.6.2 Method for Planning Multiple-Stresses CSALTs

When the number of accelerated stresses is greater than 1, the life-stress relationship will turn into a binary or multivariate function. This leads to some problems, which are very different from planning single-stress ALTs. Escobar and Meeker carried out the earliest study on the theory and method of planning the optimal multiple constant stresses SALT for location-scale distribution. They used the assumptions given in Sect. 51.6.1, and generalized the life-stress relationship into a binary linear function $\mu(\xi_1, \xi_2) = \gamma_0 + \gamma_1\xi_1 + \gamma_2\xi_2$ (where $\gamma_i < 0$, $0 \leq \xi_i \leq 1$, and $i = 1, 2$), and then proved the following important conclusions. Firstly, the V-optimal MCSALT plan is not unique. Secondly, there is a type of V-optimal plan of which the stress level combinations $\xi_i^* = (\xi_{i1}^*, \xi_{i2}^*)$ ($i = 1, 2, \dots, K^*$) distribute on a straight line connecting the normal stress level (0, 0) and the highest stress level (1, 1). However, all parameters of the life-stress relationship cannot be determined by using these plans which are defined as optimal degenerated plan. Thirdly, each optimal degenerated plan corresponds to an infinite number of optimal nondegenerated plans. All parameters of the life-stress relationship can be determined by using the nondegenerated plans. The stress level combinations of optimal nondegenerated plans distribute on the life-stress relationship contour through the point $\xi_i^* = (\xi_{i1}^*, \xi_{i2}^*)$, and can be related with the stress level combinations of optimal degenerated plan by some equations.

Usually, the optimal plan is not just one. To get a determined plan one should restrict the arrangement mode of the

stress level combinations (called test points) in the feasible region of the test (called test region), and restrict the sample location ratio on test points. Escobar and Meeker proposed a method of obtaining the optimal nondegenerated plan (called splitting plan). Firstly, find the test point ξ_i^* and sample location ratios p_i^* by solving the optimization problem of single-stress ALT. And then find the two intersection points $\xi_{i,1}^*$ and $\xi_{i,2}^*$ of the life-stress relationship contour through the point ξ_i^* and the boundary of test region. The sample location ratio on $\xi_{i,1}^*$ and $\xi_{i,2}^*$ also should be inversely proportional to their distance to ξ_i^* . The splitting plan is the V-optimal plan, and is also the D-optimal plan among all V-optimal plans.

Furthermore, for a splitting plan, the number of test points and the difficulty of finding them increase with increasing in the number of stresses. In addition, the sample allocations at the test points are also reduced accordingly, and this will increase the risks of test failure. However, the degenerated plans are almost irrelevant to the dimension. The interaction effect between the stresses will also make the life-stress relationship to be a nonlinear function. In principle, with a little generalization, the splitting plan, orthogonal plan, and uniform plan are all applicable to the nonlinear life-stress relationship. However, a “chord method” for planning the V-optimal CSALT with time censoring and continuous inspection could be used to achieve a better plan [8]. For the problem of planning optimal MCSALT, whether the life-stress relationship is univariate or multivariate, linear or nonlinear, and whether the test region is rectangular or nonrectangular, the method could transform it into the problem of planning a single-stress ALT with linear life-stress relationship.

51.6.3 Design of SSALT Plans

Nelson firstly introduced the hypothesis of cumulative damage, which stated that the development of product damage under the same type of stress and failure mechanism was only related to the current state and current stress level, and was independent of the previous history of stress loading. Based on this hypothesis, Nelson established a rule of equivalent conversion between the life distributions and test times under different stress levels, and also proposed the theory and method of applying the step stress test to the SRT. In SSALT, the main method of estimating the model parameters is the MLE. The simple SSALT that has only two steps is generally used in practice. In addition, a three-step SSALT should be used to check whether the life-stress relationship is linear or not. The SSALT could save test costs although there is still no sufficient evidence to determine which is the best ALT mode among the CSALT and SSALT. When the total sample size and censoring time are the same, if only one test device is available, the SSALT can halved the test time by

comparing with CSALT. For more details about ALT design and planning, the reader is referred to [7, 9]. They give more detailed discussions of issues related to plan SSALT.

51.7 Some Pitfalls of Accelerated Testing

The aim of ALT is to obtain the reliability information of a product in a short period of time. There are numerous potential pitfalls in planning and conducting ALTs, as explained below.

In data analysis and interpretation stage, determining the appropriate accelerating variables and the associated life-stress relationship adequate for extrapolation are critical concerns. If the life-stress relationship does not reflect the actual failure processes, it is impossible to obtain inappropriate interpretations on the ALT data and assess the product reliability under the normal use conditions. Therefore, it is necessary to test the statistical model first before it is used in reliability assessment. The current theories provide methods for testing various common life distributions. However, from the aspect of engineering application, it is not easy to determine the life distribution and life-stress relationship of a specific product with competitive failure, because once there are more than one failure modes and failure causes, the data collection and the physical analysis on failure will become more difficult. The verification on the life-stress relationship and the assumptions of cumulative damage (for SSALT and PSALT) is more difficult. Testing a model needs more sample sizes and stress levels than estimating model parameters. For the ALT, it is difficult to directly validate the extrapolation effect of the model because of the long product life and high reliability. Furthermore, estimates and confidence intervals from ALTs also contain statistical uncertainty due to having only a limited amount of sample size and failure data. More extrapolation will exacerbate the problem. The Bayesian method and accelerated degradation test (ADT) can reduce the requirements on sample size to a certain extent, thus currently get more and more attention. Therefore, some new methods are needed to be dealt with the uncertainty of the acceleration model. Besides, for some products with complicated structures, their life distribution and life-stress relationship may be difficult to describe in a simple form.

When conducting ALT, the failure mechanisms at high levels of accelerating variables may not be the same as those at low levels. High levels of stresses may result in failure modes that are not representative of the field application or not occur in normal use of the product. Laboratory conditions are also not always similar to field conditions. There are more failures in the field than are predicted by analyzing the ALT data. During testing one only could do a periodic inspection that generates group data. Theoretically, there have special data analysis methods and optimal plan design for group data.

However, a systematic study on the accuracy of this method is not yet reported.

When planning ALT, different optimization criteria can be considered and different methods can be used for estimation of model parameters. However, each method has its inherent statistical properties and also, strictly speaking, no statistical model is exactly correct. Thus, the uncertainty reflected in the ALT plan need to be recognized. Furthermore, there is a lack of effective methods for planning ALTs of system-level products. For the system-level products, various problems, such as minimal sample size, competitive failure, complex stresses, and component relevance, often arise simultaneously, and there are some technical problems followed.

Note, the pitfalls during planning and conducting of ALTs must be considered. For more details about analysis of time-dependent accelerated testing, the reader is referred to [8, 10, 11]. In practice, pressure from management to reduce test time and cost can cause decisions that attempt to ignore these pitfalls. However, this will compromise the results of the ALT and result in misleading conclusions.

51.8 Summary

Reliability tests are always used to assess the reliability indices of product and improve products. ALT is a widely used method for rapidly obtaining reliability information and evaluating the useful life of the product in a relatively short period. In this chapter, we present a limited discussion and description of the models and methods popularly used in ALT, and also design of optimal test plans. Finally, we present some of the potential pitfalls the practitioner of ALT may face.

Abstract

One-shot device testing data arises from devices that can be used only once, for example, fire extinguishers, electro-explosive devices, and airbags in cars. In life tests, only the conditions of the tested devices at a specified time can be observed, instead of their actual lifetimes. Such data is therefore of either left- or right-censored. For these heavily censored data, there is an increasing need to develop innovative techniques for reliability analysis. In this chapter, we provide an overview of analyses of one-shot device testing data collected from accelerated life tests and discuss some statistical issues on the statistical estimation and inference as well as optimal designs of accelerated life tests for one-shot devices.

Keywords

One-shot device · Accelerated life tests · Constant-stress · Step-stress · Likelihood inference · Minimum density power divergence · Model selection · Model mis-specification · Multiple failure modes · Test plans

52.1 Introduction

One-shot device testing data analyses have recently received great attention in reliability studies. This chapter aims at providing the latest progress of statistical models and methods for analyzing one-shot device testing data collected from accelerated life tests. One-shot device testing data differs from typical data obtained by measuring lifetimes in standard life tests and poses a unique challenge in reliability analysis, due to a lack of lifetime information being collected from life tests. A one-shot device is a unit that is accompanied by

an irreversible chemical reaction or physical destruction and therefore no longer functions properly after use. As a result, the actual lifetime of a one-shot device cannot be obtained from life tests, and thus one-shot device testing data is binary; researchers can only observe either a success or failure at the inspection time as each device can be tested only once. The lifetime is either left- or right-censored. If successful tests occur, it implies that the lifetimes are beyond their inspection times, leading to right-censoring. On the contrary, the lifetimes are before their inspection times, leading to left-censoring, if failed tests appear. Examples of one-shot devices include explosive devices in stockpiles of military weapons, missiles, rockets, fire extinguishers, and vehicle airbags [3, 20, 48]. Shaked and Singpurwalla [39] proposed a Bayesian approach to assess submarine pressure hull damage. Hwang and Ke [22] developed an iterative procedure to evaluate the storage life and reliability of one-shot devices. Subsequently, Pan and Chu [37] studied one-shot devices in a series system.

One-shot devices are required to perform its function only once. Therefore, they are normally highly reliable and with longer lifetimes under normal operating conditions; however, it is very unlikely to observe many failures under normal operating conditions in a short time. To accurately estimate the reliability with a few or even no failures becomes very challenging. Recently, accelerated life tests (ALTs) are often applied to address this practical issue. In ALTs, devices are subject to stress levels higher than normal operating conditions to induce early failures. Consequently, more failures can be obtained in a short time. As there is no interest in estimating the reliability under the higher-than-normal stress levels, ALT models are then typically used to extrapolate the data obtained from the elevated stress levels to estimate the reliability under normal operating conditions. Since, ALTs are efficient in capturing valuable lifetime information within a limited time and therefore become a substantial element in a wide variety of reliability studies for many decades, including batteries [32], tantalum capacitors [42], and power modules [33]. One may refer to recent books with chapters on ALT models [5, 31, 36, 38] for details. There are many types of ALTs. Constant-stress ALTs (CSALTs) wherein each device is subject to only one pre-specified stress level are frequently used. On the other hand, step-stress ALTs (SSALTs) apply stress to devices in the way that stress levels will increase at pre-specified times step-by-step. These two types of ALTs have received great attention in literature.

The rest of this chapter is organized as follows. Section 52.2 presents literature reviews of one-shot device testing data analyses. Section 52.3 describes one-shot device testing data collected from CSALTs and statistical models that have been studied for one-shot device testing data. Section 52.4 considers the likelihood estimation and inference for one-shot device testing and discusses some statistical issues, including model mis-specification, model selection,

testing for proportional hazards rates, and designs of CSALTs for one-shot devices. Sections 52.5–52.7 discuss some latest developments of one-shot device testing data analyses. A robust estimator and hypothesis tests for one-shot device testing data, based on minimum density power divergence measures, are presented in Sect. 52.5. Sections 52.6 and 52.7 consider analyses for one-shot device testing data with multiple failure modes and one-shot device testing data collected from SSALTs, respectively.

52.2 Literature Reviews

This section provides an overview of one-shot device testing data analyses under ALTs. Under CSALTs, Fan et al. [19] compared three different priors in the Bayesian approach for making predictions on the reliability at a mission time and the mean lifetime of electro-explosive devices under normal operating conditions. Balakrishnan and Ling [6–9] subsequently developed expectation-maximization (EM) algorithms for likelihood estimation based on one-shot device testing data under exponential, Weibull, and gamma distributions. In addition, several confidence intervals for the mean lifetime and the reliability at a mission time under normal operating conditions have been studied. Balakrishnan et al. [14, 15] recently developed weighted minimum density power divergence estimators for one-shot device testing data under exponential and gamma distributions. Ling et al. [25] considered proportional hazards models for analyzing one-shot device testing data. Apart from the statistical estimation and inference, Balakrishnan and Ling [10] developed a procedure to obtain CSALT plans with budget constraints for one-shot devices. Ling and Balakrishnan [24] also studied model mis-specification effects on one-shot device testing data analyses between Weibull and gamma distributions and Balakrishnan and Chimitova [4] conducted comprehensive simulation studies to compare several goodness-of-fit tests for one-shot device testing data. In addition, Balakrishnan et al. [11–13] extended this line of work by introducing competing risks models to analyze one-shot device testing data with multiple failure modes. On the other hand, Ling [23] recently presented an EM algorithm for one-shot device testing data collected from SSALTs and also studied SSALT plans for one-shot devices with lifetimes following exponential distributions.

52.3 One-Shot Device Testing Data Under CSALTs and Models

Suppose that CSALTs with I test groups are considered. For $i = 1, 2, \dots, I$, in the i -th test group, K_i one-shot devices are subject to J types of accelerating factors (i.e., temperature, humidity, voltage, and pressure) at stress levels

Table 52.1 One-shot device testing data with multiple accelerating factors, various stress levels, and different inspection times

Test group	Stress levels	Inspection time	# of tested devices	# of failures
1	$(x_{11}, x_{12}, \dots, x_{1J})$	τ_1	K_1	n_1
2	$(x_{21}, x_{22}, \dots, x_{2J})$	τ_2	K_2	n_2
\vdots	\vdots	\vdots	\vdots	\vdots
I	$(x_{I1}, x_{I2}, \dots, x_{IJ})$	τ_I	K_I	n_I

$\mathbf{x}_i = (x_{i1}, x_{i2}, \dots, x_{iJ})$ and are inspected at time τ_i . The corresponding number of failures, n_i , is then recorded. The data thus observed can be summarized below in Table 52.1.

For notational convenience, we denote $\mathbf{z} = \{\tau_i, K_i, n_i, \mathbf{x}_i, i = 1, 2, \dots, I\}$ for the observed data and θ for the model parameters. Suppose the lifetime in the i -th test group has a distribution with the cumulative distribution function (cdf), $F(t; \Psi_i)$ with $\Psi_i = \Psi(\mathbf{x}_i; \theta)$. The observed likelihood function is then given by

$$L(\theta; \mathbf{z}) = C \prod_{i=1}^I [F(\tau_i; \Psi_i)]^{n_i} [R(\tau_i; \Psi_i)]^{K_i - n_i},$$

where $R(\tau_i; \Psi_i) = 1 - F(\tau_i; \Psi_i)$ and C is the normalizing constant. The data is used to determine some life characteristics of the devices under normal operating conditions, $\mathbf{x}_0 = (x_{01}, x_{02}, \dots, x_{0J})$, namely, the mean lifetime, μ , and the reliability at a mission time t , $R(t)$.

52.3.1 Exponential Models

Fan et al. [19], Balakrishnan and Ling [6, 7] studied one-shot device testing data under exponential distributions with single and multiple accelerating factors. Let E denote the lifetime that follows the exponential distribution. In the i -th test group, the cdf and the probability density function (pdf) of the exponential distributions with the rate parameter $\lambda_i > 0$ are given by

$$F_E(t; \lambda_i) = 1 - \exp(-\lambda_i t), \quad t > 0,$$

and

$$f_E(t; \lambda_i) = \frac{\partial F_E(t; \lambda_i)}{\partial t} = \lambda_i \exp(-\lambda_i t), \quad t > 0,$$

respectively. Its mean lifetime and reliability at a mission time t under normal operating conditions, $\mathbf{x}_0 = (x_{01}, x_{02}, \dots, x_{0J})$, are then given by

$$\mu_E = \int_0^\infty t f_E(t; \lambda_0) dt = \lambda_0^{-1},$$

and

$$R_E(t) = 1 - F_E(t; \lambda_0) = \exp(-\lambda_0 t),$$

respectively. As we need to extrapolate the data from the elevated stress levels, $\mathbf{x}_i = (x_{i1}, x_{i2}, \dots, x_{iJ})$, to the life characteristics of the devices under normal operating conditions, $\mathbf{x}_0 = (x_{01}, x_{02}, \dots, x_{0J})$, the parameter λ_i is related to the stress levels in a log-linear link function, with $x_{i0} = 1$, i.e.,

$$\ln(\lambda_i) = \sum_{j=0}^J e_j x_{ij}.$$

It is noting that many well-known stress-rate models, such as Arrhenius, inverse power law, and Eyring models, are all special cases of the log-linear link function, with appropriate transformations on the stress levels [44]. In this setting, the model parameters are $\theta_E = \{e_j, j = 0, 1, \dots, J\}$ to be estimated.

52.3.2 Weibull Models

As the exponential distributions enable us to model constant hazard rate only, Balakrishnan and Ling [8] further extended the work to Weibull distributions with multiple accelerating factors that vary both scale and shape parameters, because the Weibull distributions can model increasing, constant, and decreasing hazard rates and include the exponential distributions as a special case.

Let W denote the lifetime that follows the Weibull distribution. In the i -th test group, the cdf and the pdf of the Weibull distributions with the shape parameter $\eta_i > 0$ and the scale parameter $\beta_i > 0$ are given by

$$F_W(t; \eta_i, \beta_i) = 1 - \exp\left(-\left(\frac{t}{\beta_i}\right)^{\eta_i}\right), \quad t > 0,$$

and

$$\begin{aligned} f_W(t; \eta_i, \beta_i) &= \frac{\partial F_W(t; \eta_i, \beta_i)}{\partial t} \\ &= \frac{\eta_i}{\beta_i} \left(\frac{t}{\beta_i}\right)^{\eta_i - 1} \exp\left(-\left(\frac{t}{\beta_i}\right)^{\eta_i}\right), \quad t > 0, \end{aligned}$$

respectively. Its mean lifetime and reliability at a mission time t under normal operating conditions, $\mathbf{x}_0 = (x_{01}, x_{02}, \dots, x_{0J})$, are, respectively, given by

$$\mu_W = \int_0^\infty t f_W(t; \eta_0, \beta_0) dt = \beta_0 \Gamma\left(1 + \frac{1}{\eta_0}\right),$$

and

$$R_W(t) = 1 - F_W(t; \eta_0, \beta_0) = \exp\left(-\left(\frac{t}{\beta_0}\right)^{\eta_0}\right),$$

where $\Gamma(z) = \int_0^\infty x^{z-1} \exp(-x) dx$ is the gamma function. To extrapolate the data from the elevated stress levels, $\mathbf{x}_i = (x_{i1}, x_{i2}, \dots, x_{iJ})$, to the life characteristics of the devices under normal operating conditions, $\mathbf{x}_0 = (x_{01}, x_{02}, \dots, x_{0J})$, the parameters η_i and β_i are related to the stress levels in log-linear link functions, with $x_{i0} = 1$, i.e.,

$$\ln(\eta_i) = \sum_{j=0}^J r_j x_{ij}, \quad \text{and} \quad \ln(\beta_i) = \sum_{j=0}^J s_j x_{ij}.$$

Therefore, the model parameters are $\theta_W = \{r_j, s_j, j = 0, 1, \dots, J\}$ to be estimated.

52.3.3 Gamma Models

In addition to the Weibull distributions, gamma distributions can model increasing, constant, and decreasing hazard rates and include the exponential distributions as a special case. Balakrishnan and Ling [9] studied one-shot device testing data under gamma distributions with multiple accelerating factors that vary both scale and shape parameters.

Let G denote the lifetime that follows the gamma distribution. In the i -th test group, the cdf and the pdf of the gamma distributions with the shape parameter $\alpha_i > 0$ and the scale parameter $\beta_i > 0$ are, respectively, given by

$$F_G(t; \alpha_i, \beta_i) = \gamma\left(\alpha_i, \frac{t}{\beta_i}\right), \quad t > 0,$$

and

$$f_G(t; \alpha_i, \beta_i) = \frac{\partial F_G(t; \alpha_i, \beta_i)}{\partial t} = \frac{t^{\alpha_i-1}}{\Gamma(\alpha_i)\beta_i^{\alpha_i}} \exp\left(-\frac{t}{\beta_i}\right), \quad t > 0,$$

where $\gamma(z, s) = \int_0^s x^{z-1} \exp(-x) dx / \Gamma(z)$ is the lower incomplete gamma ratio. Its mean lifetime and reliability at a mission time t under normal operating conditions, $\mathbf{x}_0 = (x_{01}, x_{02}, \dots, x_{0J})$, are, respectively, given by

$$\mu_G = \int_0^\infty t f_G(t; \alpha_0, \beta_0) dt = \alpha_0 \beta_0,$$

and

$$R_G(t) = 1 - F_G(t; \alpha_0, \beta_0) = \Gamma\left(\alpha_0, \frac{t}{\beta_0}\right),$$

where $\Gamma(z, s) = 1 - \gamma(z, s)$ is the upper incomplete gamma ratio. Again, to extrapolate the data from the elevated stress levels, $\mathbf{x}_i = (x_{i1}, x_{i2}, \dots, x_{iJ})$, to the life characteristics of the devices under normal operating conditions, $\mathbf{x}_0 = (x_{01}, x_{02}, \dots, x_{0J})$, the parameters α_i and β_i are related to the stress levels in log-linear link functions, with $x_{i0} = 1$, i.e.,

$$\ln(\alpha_i) = \sum_{j=0}^J a_j x_{ij}, \quad \text{and} \quad \ln(\beta_i) = \sum_{j=0}^J b_j x_{ij}.$$

Therefore, the model parameters are $\theta_G = \{a_j, b_j, j = 0, 1, \dots, J\}$ to be estimated.

52.3.4 Generalized Gamma Models

Generalized gamma distribution that was introduced by Stacy [41] includes the preceding popular lifetime distributions. In this regard, we can consider this highly flexible distribution to analyze one-shot device testing data and used it to discriminate between the Weibull and the gamma distributions.

Let GG denote the lifetime that follows the generalized gamma distribution. In the i -th test group, the cdf and the pdf of the generalized gamma distributions with the shape parameters $\alpha_i > 0$, $\eta_i > 0$ and the scale parameter $\beta_i > 0$ are, respectively, given by

$$F_{GG}(t; \alpha_i, \eta_i, \beta_i) = \gamma\left(\alpha_i, \left(\frac{t}{\beta_i}\right)^{\eta_i}\right), \quad t > 0,$$

and

$$f_{GG}(t; \alpha_i, \eta_i, \beta_i) = \frac{\partial F_{GG}(t; \alpha_i, \eta_i, \beta_i)}{\partial t} = \frac{\eta_i t^{\eta_i \alpha_i - 1}}{\Gamma(\alpha_i) \beta_i^{\eta_i \alpha_i}} \exp\left(-\left(\frac{t}{\beta_i}\right)^{\eta_i}\right), \quad t > 0.$$

It is noting that the generalized gamma distribution becomes the Weibull distribution when $\alpha_i = 1$, while it becomes the gamma distribution when $\eta_i = 1$ and further reduces to the exponential distribution when $\alpha_i = \eta_i = 1$. Besides, its mean lifetime and reliability at a mission time t under normal operating conditions, $\mathbf{x}_0 = (x_{01}, x_{02}, \dots, x_{0J})$, are, respectively, given by

$$\mu_{GG} = \int_0^\infty t f_{GG}(t; \alpha_0, \eta_0, \beta_0) dt = \alpha_0 \Gamma\left(\beta_0 + \frac{1}{\eta_0}\right) / \Gamma(\beta_0),$$

and

$$R_{GG}(t) = 1 - F_{GG}(t; \alpha_0, \eta_0, \beta_0) = \Gamma \left(\alpha_0, \left(\frac{t}{\beta_0} \right)^{\eta_0} \right).$$

Once again, to extrapolate the data from the elevated stress levels, $\mathbf{x}_i = (x_{i1}, x_{i2}, \dots, x_{iJ})$, to the life characteristics of the devices under normal operating conditions, $\mathbf{x}_0 = (x_{01}, x_{02}, \dots, x_{0J})$, the parameters α_i , η_i and β_i are related to the stress levels in log-linear link functions, with $x_{i0} = 1$, i.e.,

$$\ln(\alpha_i) = \sum_{j=0}^J u_j x_{ij}, \quad \ln(\eta_i) = \sum_{j=0}^J v_j x_{ij}, \quad \text{and} \\ \ln(\beta_i) = \sum_{j=0}^J w_j x_{ij}.$$

Therefore, the model parameters are $\boldsymbol{\theta}_{GG} = \{u_j, v_j, w_j, j = 0, 1, \dots, J\}$ to be estimated.

52.3.5 Proportional Hazards Models

The former models are fully parametric models for one-shot device testing data. Ling et al. [25] proposed proportional hazards models that allow the hazard rate to change in a nonparametric way and require a link function to relate the stress levels to the lifetimes of the devices.

Under the proportional hazards assumption [16, 17], in the i -th test group, the cumulative hazard function at the inspection time τ_i is given by

$$H(\tau_i; v_i) = H_0(\tau_i) v_i,$$

where $H_0(\tau_i)$ is the baseline cumulative hazard function. This model is composed of two s -independent components. One component measures the influence of the stress factors, and the other measures the changes in the baseline. We now assume a log-linear link function to relate the stress levels to the lifetimes of the devices to obtain the cumulative hazard function as

$$H(\tau_i; v_i) = H_0(\tau_i) \exp \left(\sum_{j=1}^J h_j x_{ij} \right);$$

the corresponding reliability function is then

$$R_{PH}(\tau_i; v_i) = \exp(-H(\tau_i; v_i)) = \xi_i^{v_i} = \xi_i^{\exp(\sum_{j=1}^J h_j x_{ij})},$$

where $\xi_i = \exp(-H_0(\tau_i))$ is the baseline reliability at time τ_i and $x_{i0} = 1$. It is of interest to note that the baseline reliability

is decreasing in time and bounded between 0 and 1, that is, $0 < \xi_i < \xi_j < 1$ if $\tau_i > \tau_j$. Its reliability at a mission time τ_i under normal operating conditions, $\mathbf{x}_0 = (x_{01}, x_{02}, \dots, x_{0J})$, is then given by

$$R_{PH}(\tau_i) = R_{PH}(\tau_i; v_0) = \xi_i^{v_0}.$$

Therefore, the model parameters are $\boldsymbol{\theta}_{PH} = \{\xi_i, i = 1, 2, \dots, I, h_j, j = 1, 2, \dots, J\}$ to be estimated.

We now present a connection between the proportional hazards model and the Weibull distribution having proportional hazards rates. In CSALTs, if the lifetimes of devices subject to elevated stress levels \mathbf{x}_i follow the Weibull distribution with the scale parameter $\beta_i = \exp(\sum_{j=0}^J s_j x_{ij})$ and the same shape parameter, $\eta_0 = \eta_1 = \dots = \eta_I = \eta$, the reliability of the Weibull distribution is

$$R_W(t, \eta_i, \beta) = \exp \left(- \left(\frac{t}{\beta_i} \right)^\eta \right) \\ = \exp \left(- \left(t^\eta \exp \left(- \sum_{j=0}^J \eta s_j x_{ij} \right) \right) \right), \quad t > 0.$$

The Weibull distribution with the constant parameter is satisfied with the proportion hazards assumption, and then the baseline reliability and the coefficients of stress factors are given by

$$\xi_i = \exp(-\tau_i^\eta \exp(-\eta s_0)), \quad i = 1, 2, \dots, I,$$

and

$$h_j = -\eta s_j, \quad j = 1, 2, \dots, J.$$

52.4 Likelihood Inference

Likelihood inference on one-shot device testing data under several popular distributions in reliability studies has extensively been studied [6–9]. This section provides EM frameworks to find the maximum likelihood estimates (MLEs) of parameters of interest. Besides, several confidence intervals for the corresponding parameters are presented in this section. Some statistical issues on model mis-specification and model selection are also discussed. CSALT plans for one-shot devices are finally considered.

52.4.1 EM Algorithm

In one-shot device testing, no actual lifetime can be observed. Due to these highly censored data, EM algorithms were developed for estimating the model parameters under the

forementioned distributions. The EM algorithm [30] is an efficient and powerful technique for finding the MLEs of the model parameters in case of the presence of missing data. Thus, the EM technique is extensively employed in various fields. The EM algorithm simply involves two steps in each iteration: (1) expectation (E)-step: approximating the missing data and (2) maximization (M)-step: maximizing the corresponding likelihood function.

Suppose the lifetime follows a distribution with the pdf $f(t; \theta)$. In the EM algorithm, we first consider the log-likelihood function based on the complete data as follows:

$$\ell_c(\theta) = \sum_{i=1}^I \sum_{k=1}^{K_i} \ln(f(t_{ik}; \theta)).$$

In the m -th iteration, the objective then is to update the estimate θ that maximizes the function

$$Q(\theta, \theta^{(m)}) = E_{\theta^{(m)}}[\ell_c(\theta)|\mathbf{z}]$$

based on the current estimate $\theta^{(m)}$. The current estimate $\theta^{(m)}$ is replaced with the updated estimate $\theta^{(m+1)}$ in the M-step, and then the conditional expectation $Q(\theta, \theta^{(m+1)})$ can be obtained based on the updated estimate $\theta^{(m+1)}$ in the E-step. These two steps are repeated until convergence is achieved to a desired level of accuracy. It can be seen that we actually solve the incomplete data problem by first approximating the missing data and then using the approximated values to find the estimate of the parameter vector as the solution for the complete data problem.

However, for the maximization problem, a closed-form solution cannot be found. The EM algorithm based on the one-step Newton-Raphson method needs to be employed for this purpose. It requires the second-order derivatives of the log-likelihood function with respect to the model parameters. For the present situation, let us define

$$\mathbf{I} = \left[\frac{\partial Q(\theta, \theta^{(m)})}{\partial \theta} \right]_{\theta=\theta^{(m)}}$$

and

$$\mathbf{J} = - \left[\frac{\partial^2 Q(\theta, \theta^{(m)})}{\partial \theta \partial \theta'} \right]_{\theta=\theta^{(m)}}$$

Then, we have the updated estimates as

$$\theta^{(m+1)} = \mathbf{J}^{-1} \mathbf{I} + \theta^{(m)}.$$

In many cases, the primary interest may be on some lifetime characteristics, such as the mean lifetime and the reliability under normal operating conditions, which are functions

of the model parameters. Hence, one can plug in the MLEs of the model parameters into the corresponding functions and obtain readily the MLEs of the parameters of interest.

Let's look at the example of exponential distributions. The log-likelihood function based on the complete data is given by

$$\ell_c = \sum_{i=1}^I \left(K_i \sum_{j=0}^J e_j x_{ij} \right) - \sum_{i=1}^I \left(\left(\sum_{k=1}^{K_i} t_{ik} \right) \exp \left(\sum_{j=0}^J e_j x_{ij} \right) \right),$$

and the conditional expectation is

$$Q(\theta_E, \theta_E^{(m)}) = \sum_{i=1}^I \left(K_i \sum_{j=0}^J e_j x_{ij} \right) - \sum_{i=1}^I \left(K_i t_i^* \exp \left(\sum_{j=0}^J e_j x_{ij} \right) \right).$$

The first and second derivatives with respect to the model parameters to maximize the quantity $Q(\theta_E, \theta_E^{(m)})$ are then obtained as

$$\begin{aligned} \frac{\partial Q(\theta_E, \theta_E^{(m)})}{\partial e_j} &= \sum_{i=1}^I K_i x_{ij} \\ &- \sum_{i=1}^I \left(K_i x_{ij} t_i^* \exp \left(\sum_{j=0}^J e_j x_{ij} \right) \right), \quad j = 0, 1, \dots, J, \end{aligned}$$

and

$$\begin{aligned} \frac{\partial^2 Q(\theta_E, \theta_E^{(m)})}{\partial e_p \partial e_q} &= - \sum_{i=1}^I \left(K_i x_{ip} x_{iq} t_i^* \exp \left(\sum_{j=0}^J e_j x_{ij} \right) \right), \\ p, q &= 0, 1, \dots, J. \end{aligned}$$

Furthermore, the required conditional expectation in the E-step is straightforward:

$$t_i^* = E(t_{ik} | \mathbf{z}, \theta_E^{(m)}) = \frac{1}{\lambda_i^{(m)}} + \tau_i \left(1 - \frac{n_i}{K_i (1 - \exp(-\lambda_i^{(m)} \tau_i))} \right),$$

where $\lambda_i^{(m)} = \exp \left(\sum_{j=0}^J e_j^{(m)} x_{ij} \right)$.

Furthermore, when the MLEs of the model parameters $\hat{\theta}_E = (\hat{e}_0, \hat{e}_1, \dots, \hat{e}_J)$ are determined, we immediately have the MLEs of the mean lifetime and the reliability at a mission time t under normal operating conditions $\mathbf{x}_0 = (x_{01}, x_{02}, \dots, x_{0J})$, as

$$\hat{\mu}_E = \hat{\lambda}_0^{-1} = \exp \left(- \sum_{j=0}^J \hat{e}_j x_{0j} \right).$$

and

$$\widehat{R_E}(t) = \exp(-\hat{\lambda}_0 t) = \exp\left(-\exp\left(\sum_{j=0}^J \hat{e}_j x_{0j}\right) t\right),$$

respectively.

52.4.2 Confidence Intervals

Asymptotic Confidence Intervals

To construct confidence intervals for parameters of interest, asymptotic confidence intervals are commonly used when sample sizes are sufficiently large. This requires the asymptotic variance-covariance matrix of the MLEs of the model parameters. Under the EM framework, the missing information principle, discussed by Louis [28], is often employed for obtaining the observed information matrix of the MLEs of the model parameters. Balakrishnan and Ling [8] observed that, in case of the lifetimes being all censored, the observed information matrix obtained by the use of the missing information principle is equivalent to that obtained from the observed likelihood function. In one-shot device testing data, the observed information matrix of the MLEs is the negative of the second-order derivatives of the observed log-likelihood function with respect to the model parameters, i.e.,

$$\mathbf{I}_{obs} = -\left[\frac{\partial^2 \ln(L(\boldsymbol{\theta}; \mathbf{z}))}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}'}\right]_{\boldsymbol{\theta}=\hat{\boldsymbol{\theta}}}.$$

The asymptotic variance-covariance matrix of the MLEs of the model parameters is then the inverse of the observed information matrix, i.e.,

$$\hat{\mathbf{V}}_{\boldsymbol{\theta}} = \mathbf{I}_{obs}^{-1}.$$

In addition, the asymptotic variance of the MLE of a function of the model parameters, namely, the mean lifetime and the reliability, can be obtained by the delta method that requires the first-order derivatives of the corresponding function with respect to the model parameters. For example, the asymptotic variance of the MLE of a parameter of interest, ϕ , is

$$\hat{\mathbf{V}}_{\phi} = P' \hat{\mathbf{V}}_{\boldsymbol{\theta}} P,$$

where $P = \partial \phi / \partial \boldsymbol{\theta}$ is a vector of the first-order derivatives of ϕ with respect to $\boldsymbol{\theta}$.

Subsequently, the estimated standard error $\widehat{se}(\hat{\phi}) = \sqrt{\hat{\mathbf{V}}_{\phi}}$ is readily obtained. Consequently, the $100(1 - \delta)\%$ asymptotic confidence interval for ϕ is given by

$$\left(\hat{\phi} - z_{\frac{\delta}{2}} \widehat{se}(\hat{\phi}), \hat{\phi} + z_{\frac{\delta}{2}} \widehat{se}(\hat{\phi})\right),$$

where z_{δ} is the $100(1 - \delta)$ -th percentile of the standard normal distribution. Truncation on the bounds of the confidence intervals for the reliability and the mean lifetime of the devices may be needed, since the reliability has to lie between 0 and 1 and the mean lifetime has to be positive.

Jackknifed Confidence Intervals

The Jackknife method is a systematic re-sampling technique, omitting one observation at a time from the original sample, and can also be employed for constructing confidence intervals. In the case of one-shot device testing data, it is efficient to implement the Jackknife method because the calculation would not take too much time through the Jackknife technique.

Following the Jackknife method presented in [18], suppose the MLE $\hat{\phi}$ is obtained from the original data. For $i = 1, 2, \dots, I$, a device failed at τ_i is deleted from the data, and so both n_i and K_i are reduced by 1. Then, the MLE of ϕ based on the reduced data is obtained, and denoted by $\hat{\phi}_F^{(-i)}$. Similarly, for the cases when a device tested successfully at τ_i is deleted from the original data, the MLE of ϕ based on the reduced data (by reducing only K_i by 1) is also obtained and denoted by $\hat{\phi}_S^{(-i)}$. From this set of estimates, the bias of the MLE is given by

$$bias(\hat{\phi}) = -\frac{n-1}{n} \sum_{i=1}^I \left(n_i (\hat{\phi} - \hat{\phi}_F^{(-i)}) + (K_i - n_i) (\hat{\phi} - \hat{\phi}_S^{(-i)}) \right),$$

where $n = \sum_{i=1}^I K_i$. Hence, the Jackknife estimator of ϕ is simply

$$\hat{\phi}_{JK} = \hat{\phi} - bias(\hat{\phi}) = n\hat{\phi} - (n-1)\bar{\hat{\phi}},$$

where $\bar{\hat{\phi}} = \sum_{i=1}^I \left(n_i \hat{\phi}_F^{(-i)} + (K_i - n_i) \hat{\phi}_S^{(-i)} \right) / n$. In addition, its standard deviation can be calculated as

$$\widehat{se}_{JK}(\hat{\phi}) = \sqrt{\frac{n-1}{n} \sum_{i=1}^I \left\{ n_i (\hat{\phi}_F^{(-i)} - \bar{\hat{\phi}})^2 + (K_i - n_i) (\hat{\phi}_S^{(-i)} - \bar{\hat{\phi}})^2 \right\}}.$$

Hence, given the bias-corrected estimate $\hat{\phi}_{JK}$, the $100(1 - \delta)\%$ Jackknifed confidence interval for ϕ is then given by

$$\left(\hat{\phi}_{JK} - z_{\frac{\delta}{2}} \widehat{se}_{JK}(\hat{\phi}), \hat{\phi}_{JK} + z_{\frac{\delta}{2}} \widehat{se}_{JK}(\hat{\phi})\right).$$

As before, the Jackknifed confidence intervals for the mean lifetime and the reliability under normal operating conditions could be outside the range of their supports when the sample size is small. Therefore, we may have to do corrections on the confidence intervals, if necessary.

Parametric Bootstrap Confidence Intervals

Parametric bootstrap technique is an alternative to generate a set of estimates to construct confidence intervals for parameters of interest. By repeatedly performing bootstrap simulations, the corresponding distribution of the estimates can be approximated. The confidence intervals can then be constructed based on the empirical distribution of the estimates. The confidence intervals for a parameter of interest, ϕ , can be constructed by the parametric bootstrap method as follows:

1. Determine the MLE, $\hat{\theta}$, from the original data.
2. Obtain bootstrap samples $\{n_i^*, i = 1, 2, \dots, I\}$ based on $\hat{\theta}$ and $\{\tau_i, K_i, \mathbf{x}_i, i = 1, 2, \dots, I\}$
3. Determine the MLE of ϕ based on $\{n_i^*, i = 1, 2, \dots, I\}$, denoted by $\hat{\phi}_{BT}^b$
4. Repeat steps 2 and 3 B times to obtain the MLEs $\hat{\phi}_{BT}^b, b = 1, 2, \dots, B$
5. Sort the MLEs $\hat{\phi}_{BT}^b$ in an ascending order, denoted by $\hat{\phi}_{BT}^{[b]}, b = 1, 2, \dots, B$

Then, the $100(1 - \delta)\%$ parametric bootstrap confidence interval for ϕ is given by

$$\left(\hat{\phi}_{\lfloor \frac{\delta}{2}(B+1) \rfloor}^b, \hat{\phi}_{\lceil (1-\frac{\delta}{2})(B+1) \rceil}^b \right).$$

Here, the bootstrap confidence intervals do not require any correction.

Approximate Confidence Intervals

Hoyle [21] discussed various transformations for developing suitable confidence intervals in case of estimates with skewed distributions. When the sample size is small, the MLEs of the mean lifetime and the reliability may not possess normal distributions, and consequently the confidence intervals constructed directly by the asymptotic method may not maintain the nominal level of confidence. Here, we adopt the logit transformation [43] and have $\hat{f} = \ln(\hat{R}(t)/(1 - \hat{R}(t)))$ to be asymptotically normally distributed with the corresponding standard deviation, determined by the delta method, as

$$\widehat{se}(\hat{f}) = \frac{\widehat{se}(\hat{R}(t))}{\hat{R}(t)(1 - \hat{R}(t))},$$

where $\widehat{se}(\hat{R}(t))$ is the estimated standard error of $\hat{R}(t)$. From the $100(1 - \delta)\%$ confidence interval for f given by

$$\left(\hat{f} - z_{\frac{\delta}{2}} \widehat{se}(\hat{f}), \hat{f} + z_{\frac{\delta}{2}} \widehat{se}(\hat{f}) \right),$$

we can immediately obtain an approximate $100(1 - \delta)\%$ confidence interval for the reliability $R(t)$ to be

$$\left(\frac{\hat{R}(t)}{\hat{R}(t) + (1 - \hat{R}(t))S}, \frac{\hat{R}(t)}{\hat{R}(t) + (1 - \hat{R}(t))S^{-1}} \right),$$

where $S = \exp\left(z_{\frac{\delta}{2}} \widehat{se}(\hat{f})\right)$.

In a similar manner, the transformation approach can also be used to construct confidence intervals for the mean lifetime, which avoids having a negative lower bound for the mean lifetime. In this approach, we assume that $\ln(\hat{\mu})$ is asymptotically normally distributed with the corresponding standard deviation as $\widehat{se}(\ln(\hat{\mu})) = \widehat{se}(\hat{\mu})/\hat{\mu}$, where $\widehat{se}(\hat{\mu})$ is the estimated standard error of $\hat{\mu}$. This approach results in an approximate $100(1 - \delta)\%$ confidence interval for the mean lifetime μ as

$$\left(\hat{\mu} \exp\left(-\frac{z_{\frac{\delta}{2}} \widehat{se}(\hat{\mu})}{\hat{\mu}}\right), \hat{\mu} \exp\left(\frac{z_{\frac{\delta}{2}} \widehat{se}(\hat{\mu})}{\hat{\mu}}\right) \right).$$

It should be noted that the computational work for the estimated standard deviations of the reliability and the mean lifetime have been discussed earlier in Sect. 52.4.2.

52.4.3 Model Mis-Specification Analysis

Model-based methods have become a key part of reliability analysis. The gamma and Weibull distributions are quite similar as they can effectively model lifetimes with increasing, decreasing, and constant hazard rates. Besides, both these models include the exponential distributions as a special case. For these reasons, both these distributions are commonly used in reliability literature to model lifetime data. When the distribution is correctly chosen to fit one-shot device data, the MLEs possess less bias and smaller root mean square errors. In addition, the confidence intervals for parameters of interest are satisfactory in most cases. However, one has to be cautious about the improper fitting of distributions to data. In this regard, much attention has also been paid to model mis-specification analysis. This section examines the effects of model mis-specification on point estimation and likelihood inference.

Now, let us suppose the lifetimes of one-shot devices follow the gamma distributions but are wrongly assumed to have come from the Weibull distributions. Let θ_w^* be the quasi-MLE (QMLE) of the model parameters under the gamma distributions, given by (see [46])

$$\theta_w^* = \underset{\theta_w}{\operatorname{argmin}}(-\ln(L(\theta_w))).$$

To evaluate the effect of model mis-specification, let us denote the bias of the estimator of the parameter of interest ϕ_w under normal operating conditions \mathbf{x}_0 under the

Weibull distributions by $B_G(\hat{\phi}_W)$, which is equivalent to the parameter, ϕ_G , under the true gamma distributions. It can be expressed as

$$B_G(\hat{\phi}_W) = E[\hat{\phi}_W(\theta_W^*)] - \phi_G(\theta_G).$$

Then, the relative bias is given by

$$\kappa_G = \frac{B_G(\hat{\phi}_W)}{\phi_G(\theta_G)}.$$

Similarly, suppose the lifetimes of one-shot devices follow the Weibull distributions but are wrongly assumed to have come from the gamma distributions. Then, let θ_G^* be the QMLE of the model parameter under the Weibull distributions given by

$$\theta_G^* = \underset{\theta_G}{\operatorname{argmin}}(-\ln(L(\theta_G))).$$

Let $B_W(\hat{\phi}_G)$ denote the bias of the estimator of the parameter of interest ϕ_G under normal operating conditions \mathbf{x}_0 under the gamma distributions, which is equivalent to the parameter ϕ_W under the true Weibull distributions. It can be expressed as

$$B_W(\hat{\phi}_G) = E[\hat{\phi}_G(\theta_G^*)] - \phi_W(\theta_W).$$

Then, the relative bias is given by

$$\kappa_W = \frac{B_W(\hat{\phi}_G)}{\phi_W(\theta_W)}.$$

The model mis-specification issue on the likelihood inference was also investigated, when the distribution is wrongly specified. To measure the effect of model mis-specification, let $CP_G(\hat{\phi}_W)$ denote the coverage probability of the approximate confidence interval for a particular parameter of interest ϕ_W under the Weibull distributions, which is equivalent to ϕ_G under the true gamma distributions. It can be expressed as

$$CP_G(\hat{\phi}_W) = Pr(\phi_G \in (L_W, U_W)),$$

where L_W and U_W are the lower and upper bounds of the approximate confidence interval for ϕ_W , respectively. Similarly, let $CP_W(\hat{\phi}_G)$ denote the coverage probability of the approximate confidence interval for a particular parameter of interest ϕ_G under the gamma distributions, which is equivalent to ϕ_W under the true Weibull distributions. It can be expressed as

$$CP_W(\hat{\phi}_G) = Pr(\phi_W \in (L_G, U_G)),$$

where L_G and U_G are the lower and upper bounds of the approximate confidence interval for ϕ_G , respectively.

The numerical computations in [24] presented the relative bias of the estimators of the mean lifetime and the reliability for various settings and revealed that the estimation of the cdf for each test group is satisfactory even when the underlying distribution is mis-specified. The consequence of model mis-specification on point estimation is not serious when the normal operating conditions \mathbf{x}_0 are close to the elevated stress levels $\{\mathbf{x}_i, i = 1, 2, \dots, I\}$. However, due to the linkage between stress levels and lifetimes, the estimation of the mean lifetime and the reliability under \mathbf{x}_0 becomes imprecise, especially when the elevated stress levels are away from normal operating conditions. This observation suggests that having elevated stress levels near the normal operating conditions would minimize the effect of model mis-specification.

Furthermore, the performance of the approximate 95% confidence intervals for the mean lifetime and the reliability was examined. It was observed that the coverage probabilities under the true distributions maintain the nominal level. Also, these results showed that the model mis-specification is not serious only when the gamma distributions are mis-specified as the Weibull distributions in the case of small sample sizes. In general, the confidence intervals produce deflated coverage probabilities. Again, the consequence of model mis-specification on the likelihood inference is seen to be serious when the elevated stress levels are away from normal operating conditions, especially in the case of large sample sizes.

52.4.4 Model Selection

Due to the importance of system safety, it is of great interest in detecting if there is model mis-specification in the fitted model. Balakrishnan and Chimitova [4] compared several test statistics for testing the goodness-of-fit of assumed models: (1) a chi-square type statistic based on the difference between the empirical and expected numbers of failures at each inspection time, (2) Kolmogorov and (3) Cramer-von Mises-Smirnov type statistics based on the difference between the nonparametric MLE (NPMLE) of the lifetime distribution obtained from one-shot device testing data and the distribution specified under the null hypothesis, and (4) White type statistic comparing two estimators of the Fisher information.

Let R_i be the i -th residual for $i = 1, 2, \dots, I$. We define $n = \sum_{i=1}^I K_i$, $\hat{S}_0(t; \theta)$ as the baseline reliability function, $\hat{S}_n(t)$ as the NPMLE of the baseline reliability function, $n_i^* = K_i(1 - \hat{S}_n(R_i))$ as the empirical number of failures, and $\hat{n}_i = K_i(1 - \hat{S}_0(R_i; \hat{\theta}))$ as the expected number of failures.

The chi-square type statistic can be written as follows:

$$\chi_n^2 = \sum_{i=1}^I \frac{(n_i^* - \hat{n}_i)^2}{\hat{n}_i}.$$

It is clear that the values of the statistic strongly depend on the location of inspection times relative to the corresponding conditional distribution under test. It may happen that the value of the statistic will be small for some inappropriate distribution only because inspection times are located mainly in the right tail of the distribution. To avoid this problem, the weighted chi-square type statistic was introduced in the following form:

$$v\chi_n^2 = \sum_{i=1}^I \frac{v_{ij}(n_i^* - \hat{n}_i)^2}{\hat{n}_i},$$

where

$$v_{ij} = \frac{S_0(R_i; \hat{\theta})(1 - S_0(R_i; \hat{\theta}))}{\sum_{i=1}^I S_0(R_i; \hat{\theta})}.$$

The Kolmogorov type statistic is defined as

$$D_n = \sup_{0 < t < \infty} \left| \hat{S}_n(t) - S_0(t; \hat{\theta}_n) \right|.$$

The Cramer-von Mises-Smirnov type statistic is of the following form:

$$W_n^2 = \int_0^\infty \left(\hat{S}_n(t) - S_0(t; \hat{\theta}_n) \right)^2 dS_0(t; \hat{\theta}_n).$$

The White type statistic is based on the comparison of two estimators of the Fisher information matrix:

$$A_n(\hat{\theta}_n) = -\frac{1}{n} \sum_{i=1}^I \left[n_i \frac{\partial^2 \ln(1 - S_0(R_i; \hat{\theta}_n))}{\partial \lambda^2} + (K_i - n_i) \frac{\partial^2 \ln(S_0(R_i; \hat{\theta}_n))}{\partial \lambda^2} \right],$$

and

$$B_n(\hat{\theta}_n) = \frac{1}{n} \sum_{i=1}^I n_i \left(\frac{\partial \ln(1 - S_0(R_i; \hat{\theta}_n))}{\partial \lambda} \right) \left(\frac{\partial \ln(1 - S_0(R_i; \hat{\theta}_n))}{\partial \lambda} \right)' + \frac{1}{n} \sum_{i=1}^I (K_i - n_i) \left(\frac{\partial \ln(S_0(R_i; \hat{\theta}_n))}{\partial \lambda} \right) \left(\frac{\partial \ln(S_0(R_i; \hat{\theta}_n))}{\partial \lambda} \right)',$$

where λ is the vector of parameters of the baseline reliability function S_0 . The statistic is then defined as

$$V_n = \frac{|\det A_n(\hat{\theta}_n) - \det B_n(\hat{\theta}_n)|}{\det B_n(\hat{\theta}_n)}.$$

In addition, Ling and Balakrishnan [24] proposed two measures as specification tests for this purpose and then evaluated their performance. Akaike information criterion (AIC) (see [1, 2]) is commonly used to measure the relative quality of fits achieved by probability models for a given set of data. Let AIC_G and AIC_W denote the AIC values under the gamma and the Weibull distributions, respectively. For each probability distribution, there are $J + 1$ model parameters to be estimated for each of scale and shape parameters, and so AIC_G and AIC_W statistics are given by

$$AIC_G = 2(2J + 2) - 2 \ln(L(\hat{\theta}_G)) \quad \text{and}$$

$$AIC_W = 2(2J + 2) - 2 \ln(L(\hat{\theta}_W)).$$

When the assumed distribution does not fit the data, the logarithm of the likelihood value becomes small, and consequently the preferred model is the one with the smallest AIC value, and this is used for the purpose of model selection. Since the same number of parameters are in both gamma and Weibull distributions, the comparison of AIC values is exactly the same as the comparison of the log-likelihood values and also exactly the same as by the Bayesian information criterion (BIC). So, we can consider a specification test statistic as

$$D_{AIC} = AIC_G - AIC_W = 2(\ln(L(\hat{\theta}_W)) - \ln(L(\hat{\theta}_G))).$$

The gamma distributions are preferred when $D_{AIC} < 0$, while the Weibull distributions are preferred when $D_{AIC} > 0$.

Balakrishnan and Ling [8, 9] proposed a distance-based test statistic, which simply quantifies the distance between the observed and expected numbers of failures at each test group. Let M_G and M_W denote the values of the test statistic under the gamma and the Weibull distributions, respectively, which are given by

$$M_G = \max_i |n_i - K_i \hat{F}_G(\tau_i)| \quad \text{and} \quad M_W = \max_i |n_i - K_i \hat{F}_W(\tau_i)|.$$

So, when the assumed distribution does not fit the data well, we expect to observe a large value of the test statistic. We can then consider a specification test statistic as

$$D_M = M_G - M_W.$$

We can conclude that the gamma distributions are the preferred one when $D_M < 0$, while the Weibull distributions become the preferred one if $D_M > 0$.

We further define $(L, U) = (L_G, U_G)$ when $D_M < 0$ and $(L, U) = (L_W, U_W)$ when $D_M > 0$. When the specification test statistic D_M is implemented, the coverage probabilities of

the approximate confidence intervals for ϕ_G and ϕ_W can be expressed as

$$\begin{aligned} CP_G(\phi_G) &= Pr(\phi_G \in (L, U), D_M < 0) + Pr(\phi_G \in (L, U), D_M > 0) \\ &= Pr(\phi_G \in (L, U)|D_M < 0)P_G(D_M < 0) + Pr(\phi_G \in (L, U)|D_M > 0)P_G(D_M > 0), \end{aligned}$$

and

$$\begin{aligned} CP_W(\phi_W) &= Pr(\phi_W \in (L, U), D_M < 0) + Pr(\phi_W \in (L, U), D_M > 0) \\ &= Pr(\phi_W \in (L, U)|D_M < 0)P_W(D_M < 0) + Pr(\phi_W \in (L, U)|D_M > 0)P_W(D_M > 0), \end{aligned}$$

where $P_G(D_M < 0)$ represents the probability that the gamma distributions correctly selected and $P_W(D_M > 0)$ represents the probability that the Weibull distributions are correctly selected by the use of a specification test. Both $P_G(D_M < 0)$ and $P_W(D_M > 0)$ can be considered as the power of detection of mis-specified distributions by the specification test statistic. It is worth mentioning that the statistic D_M may be replaced by another specification statistic D_{AIC} .

A simulation study was carried out for evaluating the power of detection of model mis-specification for the AIC and the distance-based test statistic M for different settings. The obtained results revealed that the distance-based test statistic is slightly better than the AIC for detecting mis-specified distributions when the gamma distributions are the true one, while the AIC performs much better when the Weibull distributions are the true one. In practice, the true probability distributions are unknown; for this reason, the AIC is recommended as a specification test. Furthermore, the performance of the approximate 95% approximate confidence intervals for the mean lifetime and the reliability, with and without the use of a specification test, was evaluated. It was observed that, even when the coverage probabilities for mis-specified distributions are low in the case of large sample sizes, with the use of a specification test, the mis-specified distributions are unlikely to be selected as seen from the corresponding power values. Consequently, the coverage probabilities can be improved considerably and brought close to the nominal level, with the use of a model specification test.

On the other hand, likelihood ratio tests under generalized gamma distributions are useful for discriminating among those models. Firstly, we consider the likelihood ratio test for testing the null hypothesis $H_0 : v_j = 0, j = 0, 1, 2, \dots, J$ (gamma distributions) against the alternative hypothesis $H_1 : v$'s are not all equal to 0 (generalized gamma distributions). Under H_0 , the log-likelihood ratio test statistic is

$$LRT_G = -2(\ln(L(\hat{\theta}_G; \mathbf{z})) - \ln(L(\hat{\theta}_{GG}; \mathbf{z}))).$$

Similarly, we consider the likelihood ratio test for testing the null hypothesis $H_0 : u_j = 0, j = 0, 1, 2, \dots, J$ (Weibull distributions) against the alternative hypothesis $H_1 : u$'s are not all equal to 0 (generalized gamma distributions). Under H_0 , the log-likelihood ratio test statistic is

$$LRT_W = -2(\ln(L(\hat{\theta}_W; \mathbf{z})) - \ln(L(\hat{\theta}_{GG}; \mathbf{z}))).$$

The above null hypotheses are less likely to be true as the corresponding test statistic is large. Moreover, these test statistics are always positive and have an approximate chi-square distribution with degrees of freedom equal to $J + 1$ when the sample size is sufficiently large [47]. Therefore, we can compute the p-value to determine whether the gamma/Weibull distributions are appropriate to fit the observed data. For instance, if a p-value is less than 0.05, the corresponding distributions are not suggested to fit the data.

The performance of the likelihood ratio tests for choosing an appropriate model between the gamma and Weibull distributions to fit the observed data was determined in terms of percentages of rejection under the null hypothesis. The results showed that the likelihood ratio tests can successfully determine that Weibull distributions are inappropriate for fitting the data for all the considered sample sizes when the gamma distributions are the true one. Conversely, when the Weibull distributions are the correct one, the likelihood ratio tests performed satisfactory only when the sample size is sufficiently large. In conclusion, the Akaike information criterion and the distance-based test statistic and the likelihood ratio tests encountered the same challenge in one-shot device testing data.

52.4.5 Test of Proportional Hazard Rates

In the preceding section, the proportional hazards models have only the proportional hazards assumption and allow hazard rate to change in a nonparametric way. Here, a test for proportional hazards assumption based on one-shot device testing data is presented. Let us consider the distance-based test statistic [8, 9, 25]:

$$M = \max_i |n_i - \hat{n}_i|,$$

where $\hat{n}_i = K_i \hat{F}_{PH}(\tau_i)$ is the expected number of failures in the i -th test group under the proportional hazards models. The test statistic simply assesses the fit of the assumed models to the observed data, and so we would observe a large value of M when the assumed models are not good fit to the data.

Let $L_i = \lceil \hat{n}_i - M \rceil$ and $U_i = \lfloor \hat{n}_i + M \rfloor$. Under the proportional hazards models, we have $n_i \sim \text{Binomial}(K_i, \hat{F}_{PH}(\tau_i))$, and so, the corresponding exact p-value is given by

$$\text{p-value} = 1 - \prod_{i=1}^I \text{Pr}(L_i \leq n_i \leq U_i).$$

From the above expression, we can readily validate the proportional hazards assumption when the p-value is sufficiently large, i.e., p-value > 0.05 or 0.1, say.

52.4.6 Designs of CSALTs

Suppose that, in the i -th test group, K_i items are subject to J types of stress factors with higher-than-usual stress levels and inspected at v_i equally-spaced time points. Specifically, $K_{i,v}$ items are drawn and inspected at a specific time $\tau_{i,v}$, with $\sum_{v=1}^{v_i} K_{i,v} = K_i$. Then, $n_{i,v}$ failure items are collected from the inspection. Let us now assume that the lifetimes of devices in the i -th test group follow the Weibull distributions with scale parameter β_i and shape parameter η_i , wherein the scale and shape parameters are both related to the stress levels $\mathbf{x}_i = (x_{i1}, x_{i2}, \dots, x_{ij})$ through the log-linear link functions.

To design CSALTs for one-shot devices, Balakrishnan and Ling [10] considered the optimization problem of determining the inspection frequency, the number of inspections at each condition, and the allocation of the devices by minimizing the asymptotic variance of the MLE of the reliability at a

mission time under normal operating conditions, subject to a specified budget and a termination time.

Suppose the budget for conducting CSALTs for one-shot devices, the operation cost in the i -th test group, the cost of devices (including the purchase of and testing cost), and the termination time are C_{budget} , $C_{oper,i}$, C_{item} , and τ_{ter} , respectively. Given a test plan, ζ , that involves the inspection frequency, f , the number of inspections in the i -th test group, $v_i \geq 2$, and the allocation of devices, $K_{i,v}$, for $i = 1, 2, \dots, I, v = 1, 2, \dots, v_i$, it is assumed that the total cost of implementing the test plan is

$$TC(\zeta) = C_{item} \sum_{i=1}^I \sum_{v=1}^{v_i} K_{i,v} + \sum_{i=1}^I C_{oper,i} v_i f,$$

and

$$\max_i v_i f \leq \tau_{ter}.$$

Balakrishnan and Ling [10] presented a procedure of determining CSALT plans for one-shot devices.

52.5 Minimum Density Power Divergence Estimation

Balakrishnan et al. [14, 15] developed a new family of estimators, the minimum density power divergence estimators (MDPDEs), for one-shot device testing data under the exponential and gamma distributions. They revealed that some MDPDEs have a better behavior than the MLE in relation to robustness.

52.5.1 Minimum Density Power Divergence Estimators

Consider the theoretical probability vector

$$p(\theta) = [F(\tau_1; \theta), 1 - F(\tau_1; \theta), \dots, F(\tau_I; \theta), 1 - F(\tau_I; \theta)]',$$

and the observed probability vector

$$\hat{p} = \left[\frac{n_1}{K_1}, \frac{K_1 - n_1}{K_1}, \dots, \frac{n_I}{K_I}, \frac{K_I - n_I}{K_I} \right]'$$

The Kullback-Leibler divergence between the probability vectors is given by

$$\begin{aligned} d_{KL}(p(\theta), \hat{p}) &= \frac{1}{I} \sum_{i=1}^I \left(\frac{n_i}{K_i} \ln \left(\frac{n_i}{K_i F(\tau_i; \theta)} \right) + \frac{K_i - n_i}{K_i} \ln \left(\frac{K_i - n_i}{K_i (1 - F(\tau_i; \theta))} \right) \right) \\ &= \frac{1}{I} (s - \ln(L(\theta; \mathbf{z}))) \end{aligned}$$

with s being a constant not dependent on θ . Hence, the MLE of θ can also be defined as

$$\hat{\theta} = \arg \min_{\theta} d_{KL}(p(\theta), \hat{p}).$$

Suppose $y_{ik} \sim \text{Bernoulli}(\pi_i(\theta))$, where $\pi_i(\theta) = F(\tau_i; \theta)$. The MDPDEs with turning parameter $\omega \geq 0$ is given by

$$\hat{\theta}_{\omega} = \arg \min_{\theta} V(y_{ik}, \omega),$$

$$V(y_{ik}, \omega) = (\pi_i(\theta))^{\omega+1} + (1 - \pi_i(\theta))^{\omega+1} - \left(1 + \frac{1}{\omega}\right) ((\pi_i(\theta))^{y_{ik}} (1 - \pi_i(\theta))^{1-y_{ik}})^{\omega}.$$

Here, the term $\pi_i^{y_{ik}}(\theta)(1 - \pi_i(\theta))^{1-y_{ik}}$ plays the role of the density in our context. The divergence measure to be minimized can be simplified as

$$\begin{aligned} \frac{1}{I} \sum_{i=1}^I \sum_{k=1}^{K_i} V(y_{ik}, \omega) &= \sum_{i=1}^I (\pi_i(\theta))^{\omega+1} + (1 - \pi_i(\theta))^{\omega+1} \\ &\quad - \sum_{i=1}^I \left(1 + \frac{1}{\omega}\right) \left(\binom{n_i}{K_i} (\pi_i(\theta))^{\omega} + \binom{K_i - n_i}{K_i} (1 - \pi_i(\theta))^{\omega} \right). \end{aligned}$$

From the above expression, there is an alternative for $\hat{\theta}_{\omega}$, in which only a divergence measure between two probabilities is involved. Given two probability vectors $p(\theta)$ and \hat{p} , the

density power divergence (DPD) measure between $p(\theta)$ and \hat{p} , with tuning parameter ω , is given by

$$\begin{aligned} d_{\omega}(p(\theta), \hat{p}) &= \sum_{i=1}^I (\pi_i(\theta))^{\omega+1} + (1 - \pi_i(\theta))^{\omega+1} \\ &\quad - \sum_{i=1}^I \left(1 + \frac{1}{\omega}\right) \left(\binom{n_i}{K_i} (\pi_i(\theta))^{\omega} + \binom{K_i - n_i}{K_i} (1 - \pi_i(\theta))^{\omega} \right) \\ &\quad + \sum_{i=1}^I \left(\frac{1}{\omega}\right) \left(\binom{n_i}{K_i}^{\omega+1} + \binom{K_i - n_i}{K_i}^{\omega+1} \right). \end{aligned}$$

We observe that the last term $(n_i/K_i)^{\omega+1} + ((K_i - n_i)/K_i)^{\omega+1}$ does not have any role in the minimization of $d_{\omega}(\hat{p}, p(\theta))$, and the MDPDEs can alternatively be defined as

$$\hat{\theta}_{\omega} = \arg \min_{\theta} d_{\omega}(\hat{p}, p(\theta)).$$

For $\omega = 0$, we have

$$d_{\omega=0}(\hat{p}, p(\theta)) = \lim_{\omega \rightarrow 0^+} d_{\omega}(\hat{p}, p(\theta)) = d_{KL}(\hat{p}, p(\theta)).$$

This result implies that the MDPDEs contains the MLE as a particular case.

52.5.2 Wald-Type Tests

Balakrishnan et al. [14, 15] also presented Wald-type test statistics for testing different hypotheses concerning the parameter θ . Consider the composite null hypotheses of the type

$$m(\theta) = \mathbf{0}_r, \quad \text{and} \quad M(\theta) = \frac{\partial m(\theta)'}{\partial \theta}$$

with rank $M(\theta) = r$. The Wald-type test statistic is

$$W_n(\hat{\theta}_{\omega}) = nm(\hat{\theta}_{\omega})' \left(M(\hat{\theta}_{\omega})' \Sigma(\hat{\theta}_{\omega}) m(\hat{\theta}_{\omega}) \right)^{-1} m(\hat{\theta}_{\omega}),$$

One may refer to [14, 15] for the computation of $\Sigma(\hat{\theta}_{\omega})$ under the exponential and gamma distributions. Subsequently, at δ significance level, we decide to reject the null hypothesis when

$$W_n(\hat{\theta}_{\omega}) > \chi_{r, \delta}^2.$$

Besides, let

$$\ell_{\omega}(\theta_1, \theta_2) = m(\theta_1)' \left(M(\theta_2)' \Sigma_{\omega}(\theta_2) m(\theta_2) \right)^{-1} m(\theta_1),$$

and

$$\sigma_{W_n, \omega}(\theta^*) = \left. \frac{\partial \ell_\omega(\theta, \theta^*)}{\partial \theta'} \right|_{\theta=\theta^*} \Sigma_\omega(\theta^*) \left. \frac{\partial \ell_\omega(\theta, \theta^*)}{\partial \theta} \right|_{\theta=\theta^*}.$$

We can give an approximation of the power function of the Wald-type test statistic in θ^* to be

$$\begin{aligned} \pi_{W_n}(\theta^*) &= Pr\left(W_n(\hat{\theta}_\omega) > \chi_{r,\delta}^2\right) \\ &= 1 - \Phi_n\left(\frac{1}{\sigma_{W_n, \omega}(\theta^*)} \left(\frac{\chi_{r,\delta}^2}{\sqrt{n}} - \sqrt{n} \ell_\omega(\hat{\theta}_\omega, \theta^*)\right)\right), \end{aligned}$$

where $\Phi_n(x)$ tending uniformly to the standard normal distribution $\Phi(x)$.

They observed that the robustness of the MDPDE seems to increase with increasing ω ; their efficiency in case of pure data decreases slightly. Same happens with the Wald-type tests. A moderate value of ω is expected to provide the best trade-off for possibly contaminated data, but a data-driven choice of ω would be more convenient. A useful procedure for the data-based selection of ω was proposed by Warwick and Jones [45].

52.6 One-Shot Devices with Multiple Failure Modes

Modern devices are generally composed of multiple components, and it is common for devices to fail because of one of these components being failed. For instance, fire extinguishers contain liquid carbon dioxide, valves, safety fuses, and airbags contain crash sensors, inflators, and compressed gas. If the failed components can be found after tests, multivariate distributions can then be used to model the lifetime distribution of each type of components as well as the lifetime distribution of the devices.

52.6.1 Competing Risks Models for Independent Failure Models

Balakrishnan et al. [11–13] analyzed one-shot device testing data under competing risks models with the exponential and the Weibull distributions. CSALTs with I test groups for one-shot devices with M failure modes are set up as follows:

For $i = 1, 2, \dots, I$, in the i -th test group,

1. K_i devices are subject to elevated stress levels \mathbf{x}_i .
2. These devices are only inspected at time τ_i .
3. The number of devices with the m -th failure mode is denoted by n_{mi} , for $m = 1, 2, \dots, M$.

Let us now assume that there are only two failure modes and denote the random variable for the time to the m -th failure mode by T_{mik} , for $m = 1, 2, i = 1, 2, \dots, I$, and $k = 1, 2, \dots, K_i$, respectively. In this work, it is assumed that T_{mik} are independent of each other and that at most one failure mode can be observed in each device. Furthermore, Δ_{ik} is defined to be the indicator for the k -th device under in the i -th test group. If the device functions, we will set $\Delta_{ik} = 0$. However, if the device does not function, we will identify (by careful inspection) the specific failure mode. If the m -th failure mode is observed, we will denote this event by $\Delta_{ik} = m$, for $m = 1, 2$. Mathematically, the indicator Δ_{ik} is then defined as

$$\Delta_{ik} = \begin{cases} 0 & \text{if } \min(T_{1ik}, T_{2ik}) > \tau_i \\ 1 & \text{if } T_{1ik} < \min(T_{2ik}, \tau_i) \\ 2 & \text{if } T_{2ik} < \min(T_{1ik}, \tau_i) \end{cases}$$

and then δ_{ik} will be used for the realization of Δ_{ik} . Furthermore, we denote p_{0i} , p_{1i} , and p_{2i} for the reliability, the probability of observing the 1st failure mode, and the probability of observing the 2nd failure mode, respectively. Then, the likelihood function is given by

$$L(\theta; \mathbf{z}) = \prod_{i=1}^I \prod_{m=0}^2 (p_{mi}(\theta))^{n_{mi}},$$

where $n_{0i} = K_i - n_{1i} - n_{2i}$.

Balakrishnan et al. [11, 13] developed EM algorithms to find the MLEs of the model parameters, the mean lifetime, and the reliability under normal operating conditions. In addition, they measured the goodness-of-fit of the assumed model using a distance-based test statistic of the form

$$U = \max_i (|n_{0i} - \hat{n}_{0i}|, |n_{1i} - \hat{n}_{1i}|, |n_{2i} - \hat{n}_{2i}|),$$

where \hat{n}_{mi} is the expected numbers of n_{mi} based on the assumed model for $m = 0, 1, 2, i = 1, 2, \dots, I$. The statistic U quantifies the distance between the fitted model and the observed data. If the assumed model does not fit the data, the distance will be large. If the assumed model is true, $\{\hat{n}_{mi}, m = 0, 1, 2, i = 1, 2, \dots, I\}$, then follow the multinomial distribution with probabilities close to $\{p_{mi}, m = 0, 1, 2, i = 1, 2, \dots, I\}$. Consequently, the exact p -value of the test statistic U can be found as follows:

$$p\text{-value} = 1 - \prod_i \left(\sum_{n_{2i}=b_{2i}^u}^{b_{2i}^l} \sum_{n_{1i}=b_{1i}^u(n_{2i})}^{b_{1i}^l(n_{2i})} \frac{K_i!}{n_{0i}! n_{1i}! n_{2i}!} \hat{p}_{0i}^{n_{0i}} \hat{p}_{1i}^{n_{1i}} \hat{p}_{2i}^{n_{2i}} \right),$$

where $b_{1i}^l(n_{2i}) = \max(0, \lceil \hat{n}_{1i} - U \rceil, \lceil \hat{n}_{1i} + \hat{n}_{2i} - U \rceil - n_{2i})$, $b_{1i}^u(n_{2i}) = \min(K_i - n_{2i}, \lceil \hat{n}_{1i} + U \rceil, \lceil \hat{n}_{1i} + \hat{n}_{2i} + U \rceil - n_{2i})$, $b_{2i}^l = \max(0, \lceil \hat{n}_{2i} - U \rceil)$ and $b_{2i}^u = \min(K_i, \lceil \hat{n}_{2i} - U \rceil)$ for

$i = 1, 2, \dots, I$. If the exact p-value is smaller than the desired level, say, 0.05 or 0.1, then we may conclude that the assumed model does not fit the data well.

52.6.2 Copula Models for Correlated Failure Models

Subsequently, Ling et al. [26] considered two Archimedean copula models—the Gumbel-Hougaard copula and Frank copula—for analyzing one-shot device data with two correlated failure modes, to relax the independence assumption between two failure modes. The concept of copulas was first introduced by Sklar [40]. Copula models have been widely used to capture the dependence between random variables.

Consider one-shot devices with only two failure modes under CSALTs with I higher-than-normal stress levels, each of which is subject to an accelerating factor, and with ν inspection times. For $i = 1, 2, \dots, I, \nu = 1, 2, \dots, \nu, K_{i,\nu}$ devices are placed at stress level x_i and inspected at inspection time τ_ν . The numbers of devices without failures ($n_{i,\nu,0}$), with only the 1st failure mode ($n_{i,\nu,1}$), and with only the 2nd failure mode ($n_{i,\nu,2}$) are recorded. The one-shot device testing data collected at stress level x_i and at inspection time τ_ν can thus be summarized below in Table 52.2.

For notational convenience, $\mathbf{z} = \{x_i, \tau_j, K_{i,\nu}, n_{i,\nu,0}, n_{i,\nu,1}, n_{i,\nu,2}, i = 1, 2, \dots, I, \nu = 1, 2, \dots, \nu\}$ is denoted for the observed data. It is worth noting that both failure modes 1 and 2 may be observed at the inspection time and the number of devices with both failure modes is denoted as $n_{i,\nu,12}$, where $K_{i,\nu} = n_{i,\nu,0} + n_{i,\nu,1} + n_{i,\nu,2} + n_{i,\nu,12}$, for $i = 1, 2, \dots, I, \nu = 1, 2, \dots, \nu$. Moreover, the total number of devices with failure mode m is denoted as $N_{i,\nu,m} = n_{i,\nu,m} + n_{i,\nu,12}$, for $m = 1, 2$. In one-shot device testing data with two failure modes, let $T_{i,m}$ denote the time to the m -th failure mode at stress level x_i , where $i = 1, 2, \dots, I, m = 1, 2$. Suppose that $T_{i,m}$ has a distribution with the marginal probability distribution $F_{i,m}(t)$.

Gumbel-Hougaard copula that can characterize the positive dependence among random variables is one popular copula model with a range of applications. It is further assumed that the correlation between times to two failure modes changes over the stress levels, and under the Gumbel-

Table 52.2 Contingency table showing one-shot device testing data with two failure modes

Stress level x_i , Inspection time τ_ν			
Failure mode 2	Failure mode 1		Total
	Presence	Absence	
Presence	$n_{i,\nu,12}$	$n_{i,\nu,2}$	$N_{i,\nu,2}$
Absence	$n_{i,\nu,1}$	$n_{i,\nu,0}$	$K_{i,\nu} - N_{i,\nu,2}$
Total	$N_{i,\nu,1}$	$K_{i,\nu} - N_{i,\nu,1}$	$K_{i,\nu}$

Hougaard copula, $\ln(\alpha_i - 1)$ relates to stress level x_i in a linear form, namely,

$$y_i = \ln(\alpha_i - 1) = a_0 + a_1 x_i, \quad i = 1, 2, \dots, I.$$

Then, the joint cdf of $T_{i,1}$ and $T_{i,2}$ under the Gumbel-Hougaard copula can be written as

$$\begin{aligned} C_{\alpha_i}(t_1, t_2) &= P(T_{i,1} \leq t_1, T_{i,2} \leq t_2) \\ &= \exp\left(-\left[(-\log F_{i,1}(t_1))^{\alpha_i} + (-\log F_{i,2}(t_2))^{\alpha_i}\right]^{1/\alpha_i}\right). \end{aligned}$$

It is worth noting that Kendall’s tau, defined as the probability of concordance minus the probability of discordance of two random variables, is a measure of the degree of correspondence between two random variables. Kendall’s tau under the Gumbel-Hougaard copula can be expressed in terms of the dependence parameter as follows:

$$\Lambda_i = 1 - \frac{1}{\alpha_i}.$$

The Frank copula is another popular copula model because these copulas allow to model positive and negative dependence among random variables. Here, the dependence parameter is assumed to relate to stress level x_i in a linear form, namely,

$$y_i = \alpha_i = a_0 + a_1 x_i, \quad i = 1, 2, \dots, I.$$

Then, the joint cdf of $T_{i,1}$ and $T_{i,2}$ under the Frank copula is thus given by

$$\begin{aligned} C_{\alpha_i}(t_1, t_2) &= P(T_{i,1} \leq t_1, T_{i,2} \leq t_2) \\ &= -\frac{1}{\alpha_i} \ln\left(1 + \frac{(\exp(-\alpha_i F_{i,1}(t_1)) - 1)(\exp(-\alpha_i F_{i,2}(t_2)) - 1)}{(\exp(-\alpha_i) - 1)}\right). \end{aligned}$$

In addition, the Kendall’s tau can also be approximated by the dependence parameter as follows:

$$\Lambda_i \approx 1 - \frac{4}{\alpha_i} \left(1 - \frac{\pi^2}{6\alpha_i}\right).$$

The likelihood function of $\theta = (a_0, a_1)$ is then given by

$$L(\theta; \mathbf{z}) = \sum_{i=1}^I \sum_{v=1}^v n_{i,v,12} \ln(C_\theta(i, v)) + n_{i,v,1} \ln(\hat{F}_{i,1}(\tau_v) - C_\theta(i, v)) + n_{i,v,2} \ln(\hat{F}_{i,2}(\tau_v) - C_\theta(i, v)) + n_{i,v,0} \ln(1 - \hat{F}_{i,1}(\tau_v) - \hat{F}_{i,2}(\tau_v) + C_\theta(i, v)),$$

where $C_\theta(i, v) = C_{\alpha_i(\theta)}(\tau_v, \tau_v)$ and $\hat{F}_{i,m}(\tau_v) = N_{i,v,m}/K_{i,v}$.

It is observed that $\hat{F}_{i,s}(\tau_v) = C_\theta(i, v)$ when $\hat{F}_{i,m}(\tau_v) = 1$ for $s \neq m$, which leads to the term $\ln(\hat{F}_{i,s}(\tau_v) - C_\theta(i, v))$ in the log-likelihood function being undefined. To overcome this challenge, the replacement of 1 by $K_{i,v}(0.99^{(1/K_{i,v})})$ on $\hat{F}_{i,m}(\tau_v)$ is made as an adjustment. Similarly, for the Gumbel-Hougaard copula, $C_\theta(i, v)$ is undefined when $\hat{F}_{i,m}(\tau_v) = 0$, and thus the replacement of 0 by $K_{i,v}(1 - 0.99^{(1/K_{i,v})})$ on $\hat{F}_{i,m}(\tau_v)$ is also made as an adjustment. In short, an appropriate adjustment is required when either (i) $N_{i,v,m} = 0$ or (ii) $N_{i,v,m} = K_{i,v}$, for $m = 1, 2, i = 1, 2, \dots, I, v = 1, 2, \dots, v$.

Ling et al. [26] showed that one-shot devices with independent failure modes have shorter (longer) lifetimes than those with highly and positively (negatively) correlated failure modes. The Archimedean copula family contains a large variety of copulas that represent different dependence structures. Interested readers may refer to [34].

52.7 Step-Stress Accelerated Life Tests

Compared with CSALTs, in which each device is subject to only one pre-specific stress level, SSALTs wherein stress levels increase step-by-step over time [29] would require less samples and be more efficient and less costly to collect lifetime data. Thus, SSALTs have attracted great attention in literature. Ling [23] and Ling and Hu [27] studied simple SSALTs, which contain only two stress levels, under the exponential and the Weibull distributions.

Consider simple SSALTs wherein the stress levels changed only once from the test. Suppose that $0 < \tau_1 < \tau_2, 0 < K_1 < n$, and $x_1 < x_2$ and that all n devices are exposed to the same initial stress level x_1 . K_1 devices are selected to be tested at a pre-specified inspection time τ_1 , the number of failures n_1 are recorded. Then, the stress level increased to x_2 . All the remaining $K_2 = n - K_1$ devices are to be tested at another pre-specified inspection time τ_2 , and the number of failures n_2 are recorded. The one-shot device testing data thus observed can be summarized below in Table 52.3. Given one-shot device testing data, $\mathbf{z} = \{\tau_i, K_i, n_i, x_i, i = 1, 2\}$. In one-shot device testing data under simple SSALTs, the likelihood function is then given by

Table 52.3 One-shot device testing data under simple SSALTs

Stage	Inspection time	# of tested devices	# of failures	Stress level
1	τ_1	K_1	n_1	x_1
2	τ_2	K_2	n_2	x_2

$$L(\theta; \mathbf{z}) = \prod_{i=1}^2 (1 - R(\tau_i; \theta))^{n_i} (R(\tau_i; \theta))^{K_i - n_i}.$$

52.7.1 Exponential Models

Let T denote the lifetime of devices that follows the exponential distributions. Under the cumulative exposure model [35, 36], the cumulative hazard function, the reliability function, and the pdf are given by

$$H(t) = \begin{cases} \alpha_1 t, & 0 < t \leq \tau_1 \\ \alpha_1 \tau_1 + \alpha_2 (t - \tau_1), & t > \tau_1 \end{cases},$$

$$R(t) = \exp(-H(t)) = \begin{cases} \exp(-\alpha_1 t), & 0 < t \leq \tau_1 \\ \exp(-(\alpha_1 \tau_1 + \alpha_2 (t - \tau_1))), & t > \tau_1 \end{cases},$$

and

$$f(t) = -R'(t) = \begin{cases} \alpha_1 \exp(-\alpha_1 t), & 0 < t \leq \tau_1 \\ \alpha_2 \exp(-(\alpha_1 \tau_1 + \alpha_2 (t - \tau_1))), & t > \tau_1 \end{cases},$$

where $\alpha_1 > 0$ and $\alpha_2 > 0$ are the rate parameters at stages 1 and 2, respectively. We further assume that the rate parameters are related to the stress level in a log-linear form as

$$\alpha_i = \exp(a_0 + a_1 x_i).$$

Here, we denote $\theta_E = \{a_0, a_1\}$ as the model parameters to be estimated. Ling [23] developed an EM algorithm to find the MLEs of the model parameters. Furthermore, the mean lifetime under the normal operating condition x_0 is given by

$$\mu_E = \alpha_0^{-1} = \exp(-a_0 - a_1x_0).$$

In addition, let $\pi = K_1/n$, $A_i = R(\tau_i)^{-1} + (1 - R(\tau_i))^{-1}$ and $X_{ik} = \partial R(\tau_i)/\partial a_k$, $r_{kk} = A_2X_{2k}^2$, $r_{10} = A_2X_{21}X_{20}$, $s_{kk} = A_1X_{1k}^2 - A_2X_{2k}^2$, $s_{10} = A_1X_{11}X_{10} - A_2X_{21}X_{20}$. The estimated standard error of the mean lifetime under the normal operating condition is

$$\widehat{se}(\hat{\mu}_E) = \frac{(r_{11} - 2r_{10}x_0 + r_{00}x_0^2) + (s_{11} - 2s_{10}x_0 + s_{00}x_0^2)\pi}{n\alpha_0^2(r_{00}s_{11} + r_{11}s_{00} - 2r_{10}s_{10})\pi(1 - \pi)}.$$

It is noting that \hat{a}_0 and \hat{a}_1 are the MLEs of the model parameters of a_0 and a_1 , it follows that $\hat{\theta} \sim N_2(\theta, V_\theta)$, where

$$\theta = \begin{pmatrix} a_0 \\ a_1 \end{pmatrix} \quad \text{and} \quad V_\theta = \begin{pmatrix} \sigma_0^2 & \sigma_0\sigma_1\rho \\ \sigma_0\sigma_1\rho & \sigma_1^2 \end{pmatrix}.$$

Then, it can be easily seen that the logarithm of the estimated mean lifetime under the normal operating condition, $\log(\hat{\mu}_E) = \hat{a}_0 + \hat{a}_1x_0$, is asymptotically normal distributed.

52.7.2 Weibull Models

Subsequently, Ling and Hu [27] extended this work to the Weibull distributions with constant shape parameter and varying scale parameter. Again, under the cumulative exposure model, the cumulative hazard function and the reliability function are derived as

$$H(t) = \begin{cases} \left(\frac{t}{\alpha_1}\right)^{a_2}, & 0 < t \leq \tau_1 \\ \left(\frac{\tau_1}{\alpha_1} + \frac{t-\tau_1}{\alpha_2}\right)^{a_2}, & t > \tau_1 \end{cases},$$

and

$$R(t) = \exp(-H(t)) = \begin{cases} \exp\left(-\left(\frac{t}{\alpha_1}\right)^{a_2}\right), & 0 < t \leq \tau_1 \\ \exp\left(-\left(\frac{\tau_1}{\alpha_1} + \frac{t-\tau_1}{\alpha_2}\right)^{a_2}\right), & t > \tau_1 \end{cases},$$

where $\alpha_1 > 0$ and $\alpha_2 > 0$ are the scale parameters at the first and second stages, respectively, and $a_0 > 0$ is the common shape parameter. It is further assumed that the scale parameters relate to stress levels in a log-linear link function, i.e.,

$$\alpha_i = \exp(a_0 + a_1x_i).$$

Then, the reliability at a mission time t under the normal operating condition x_0 can be expressed as

$$\begin{aligned} R_0(t) &= \exp\left(-\left(\frac{t}{\alpha_0}\right)^{a_2}\right) \\ &= \exp(-\exp(-a_2(a_0 + a_1x_0 - \log(t))))). \end{aligned}$$

For notational convenience, we define $\theta_W = \{a_0, a_1, a_2\}$ as the model parameters to be estimated.

However, in this setting, the determinant of the 3×3 expected Fisher information matrix equals zero, implying that the matrix is singular and the inverse of the matrix does not exist. As a result, the asymptotic variance-covariance matrix of the MLEs of the model parameters cannot be obtained. Here, the matrix is singular because the model parameters $\mathbf{a} = \{a_0, a_1, a_2\}$ are not identifiable under the data structure presented in Table 52.3. SSALTs with more than two stress levels under Weibull distributions will be investigated.

52.7.3 Designs of Simple SSALTs

Ling [23] and Ling and Hu [27] presented procedures to decide the sample size and the inspection times for simple SSALTs, given the model parameters, the standard error, the stress levels, and the normal operating condition.

Consider simple SSALTs for one-shot devices under the exponential distributions; Ling [23] considered the optimal designs that minimize the standard error of the mean lifetime. The optimal proportion of devices inspected at τ_1 is

$$\pi_E = \arg \min_{0 < \pi < 1} \widehat{se}(\hat{\mu}_E) = \left(1 + \sqrt{\frac{A_1(X_{11} - X_{10}x_0)^2}{A_2(X_{21} - X_{20}x_0)^2}}\right)^{-1}.$$

Subsequently, Ling and Hu [27] considered simple SSALTs for one-shot devices under the Weibull distributions with constant shape parameter. Since the asymptotic variance-covariance matrix of the MLEs of the model parameters cannot be obtained, two scenarios were discussed: (1) a known shape parameter a_2 and (2) a known parameter about stress level a_1 .

If a_2 is known, then the optimal proportion of devices inspected at τ_1 is

$$\pi_{W1} = \left(1 + \left(\frac{X_{11}}{X_{21}}\right) \sqrt{\frac{A_1}{A_2}}\right)^{-1}.$$

It is worth noting that the percentage involves X_{21} , which relies on (x_1, τ_1, τ_2) , but is independent of the mission time t .

On the other hand, when the mean lifetimes, $E[T_i] < E[T_j]$, at two standardized stress levels, $0 < x_j < x_i < 1$, can be suggested by experts or obtained from previous similar studies, the parameter can also be obtained. Let T_m be the lifetime having the Weibull distributions with shape parameter a_2 and scale parameter $\alpha_m = \exp(a_0 + a_1x_m)$, where $m = \{i, j\}$. The mean lifetime is therefore given by

$$E[T_m] = \alpha_m \Gamma \left(1 + \frac{1}{a_2} \right),$$

where $\Gamma(\cdot)$ is the gamma function. It follows that

$$\log \left(\frac{E[T_i]}{E[T_j]} \right) = \log \left(\frac{\alpha_i}{\alpha_j} \right) = a_1(x_i - x_j).$$

Hence, the parameter about stress level can be expressed as

$$a_1 = \frac{\log(E[T_i]) - \log(E[T_j])}{x_i - x_j}.$$

It is therefore reasonable to fix a_1 as a known parameter. Hence, the optimal proportion of devices inspected at τ_1 is

$$\pi_{w2} = \left(1 + \left(\frac{a_2 X_{12} + d_2 X_{10}}{a_2 X_{22} + d_2 X_{20}} \right) \sqrt{\frac{A_1}{A_2}} \right)^{-1},$$

where $d_2 = \log(t) - a_0$.

In this setup, the proportion is not independent of the mission time t . Also, it is revealed that the asymptotic standard deviation is minimized when either $\pi_{w2} = 1$ or $\pi_{w2} = 0$. It thus suggested increasing the stress level once and all the devices are tested at the termination time. It is worth noting that stress levels affect the inspection times but have no effect on sample size. Most importantly, in this setup where the parameter about stress level a_1 is known, the sample size is relatively small, and the simulated standard deviation is relatively robust, compared to the preceding scenario where the shape parameter is known. It suggested that fixing the parameter about stress level is more preferable than fixing the shape parameter.

Abstract

The *Procrustes regression* model provides a statistical framework to assess the errors in image registration (in arbitrary dimensions) from “landmark” data. The same mathematics can be used to determine the errors in calculated motions of rigid bodies in Euclidean space.

Perhaps the scientifically most compelling example of rigid body motion is tectonic plates. Tectonic plates, to a first approximation, move as rigid bodies on the surface of the Earth. The estimation of the past configuration of the tectonic plates, and the *errors in these reconstructions*, is integral to the understanding of the past history of the Earth. Because tectonic plates are restricted to the surface of the Earth, the Procrustes regression model does not apply and the relevant model is called *spherical regression*.

The Procrustes and spherical regression models are mathematically simple and, because of this simplicity, beautiful theorems about the properties of their estimates can be proven. The previous chapter (Chang T, Image registration, rigid bodies, and unknown coordinate systems. In: Pham H (ed) Springer handbook of engineering statistics, Springer-Verlag, London, pp. 571–590, 2006) discusses many of these results. Using the spherical regression model, interesting insights into the properties of tectonic plate reconstructions are discussed in (Chang, J Geophys Res 92(B7):6319–6329, 1987; Chang, Int Stat Rev 61:299–316, 1993). We will not replicate these results here. Rather the focus of this chapter is the underlying mathematics used to establish the results. These problems are intrinsically geometric and the proper use of geometry is important to their understanding. We will explain these points.

This chapter is motivated by a request from a geophysics friend to explain, in as elementary fashion as feasible, the mathematics behind his work. This chapter will not replicate the formal proofs that appear elsewhere (see, for example, Chang, Ann Stat 14(3):907–924, 1986, Rivest, Ann Stat 17(1):307–317, 1989, or Chang and Ko,

T. Chang (✉)

 e-mail: Tcc8v@virginia.edu

Ann Stat 23(5):1823–1847, 1995). This chapter is aimed at the scientist who wants to understand on a heuristic level why the results are true, without reading mathematically complete proofs!

The type of data that is actually used to estimate plate reconstructions (experimentally determined “marine magnetic anomaly lineation” locations) is not of the form that is modeled in the spherical regression model. We discuss in Sect. 53.6 the type of data that is actually collected and how to analyze it using the mathematical principles we will discuss here. For the nongeophysicist, this section can be used as an example of the use of the mathematical principles of this chapter in a different and complex data setting.

Furthermore, although the rigid plate hypothesis is a simplification, one must first understand what types of reconstruction errors are consistent with rigid plates before deciding if the errors one is observing are in fact evidence of nonrigidity. Section 53.6 discusses some work of this type.

Essentially, this chapter is a case study in the use of tangent space approximations and some elementary ideas from differential geometry. Other authors have used similar geometrical approaches. For example, Rivest (J Biomech 38:1604–1611, 2005) and Oualkacha and Rivest (Biometrika 99:585–598, 2012) developed statistical methods for human motion studies derived from sensors placed on the human body as it moves. Chang and Rivest (Ann Stat 29(3):784–814, 2001) extended to Stiefel manifolds the work outlined here and in (Chang T, Image registration, rigid bodies, and unknown coordinate systems. In: Pham H (ed) Springer handbook of engineering statistics, Springer-Verlag, London, pp. 571–590, 2006) and used the results to reanalyze a data set on vector cardiograms. Patrangenaru has numerous papers (e.g., Mardia and Patrangenaru (Ann Stat 33(4):1666–1699, 2005)) developing statistical methods for comparing images when projective, rather than rigid, transformations are allowed. Indeed, the author believes that the engineering disciplines have multiple problems of a geometric nature and hopes that the approaches used here can be helpful in studying them.

This chapter has been written so that it can be read independently of the preceding chapter (Chang T, Image registration, rigid bodies, and unknown coordinate systems. In: Pham H (ed) Springer handbook of engineering statistics, Springer-Verlag, London, pp. 571–590, 2006).

53.1 The Spherical Regression and Procrustes Models

We will use R^k to denote k -dimensional Euclidean space. A vector $\mathbf{x} \in R^k$ will be thought of as a $k \times 1$ column vector. In particular, $\mathbf{x}^T \mathbf{y}$ is the dot product of \mathbf{x} and \mathbf{y} (using matrix notation) and the length $\|\mathbf{x}\|$ of \mathbf{x} is $\sqrt{\mathbf{x}^T \mathbf{x}}$.

Thus, the unit sphere, of dimension $k - 1$, in R^k will be

$$S^{k-1} = \Omega_k = \{\mathbf{x} \in R^k \mid \|\mathbf{x}\|^2 = \mathbf{x}^T \mathbf{x} = 1\}.$$

(The notation S^{k-1} emphasizes the dimension of the sphere, whereas the notation Ω_k emphasizes that each point in Ω_k is represented as a k -component vector.)

Although the spherical regression model, and its resulting theorems, can be developed in arbitrary dimensions k , $k = 3$ is the case of usual interest so that S^2 represents the Earth.

The spherical regression model posits fixed points $\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_n \in S^{k-1}$, homologous (“my nose is your nose”) random, and independent points $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n \in S^{k-1}$, so that

$$\mathbf{v}_i = \mathbf{A} \mathbf{u}_i + \text{error}. \quad (53.1)$$

\mathbf{A} represents a $k \times k$ matrix that satisfies the *orthogonality* condition

$$\mathbf{A}^T \mathbf{A} = \mathbf{I}_k = \mathbf{A} \mathbf{A}^T, \quad (53.2)$$

where \mathbf{I}_k represents the $k \times k$ identity matrix. This condition insures that each point $\mathbf{A} \mathbf{u}_i \in S^{k-1}$. It also insures a rigidity condition that

$$\|\mathbf{A} \mathbf{u}_i - \mathbf{A} \mathbf{u}_j\| = \|\mathbf{u}_i - \mathbf{u}_j\|. \quad (53.3)$$

Here the rigidity condition is described in terms of Euclidean space distance, but that is equivalent to a rigidity condition in great circle distance for points that lie on the sphere. The collection of such matrices \mathbf{A} is denoted $O(k)$ and referred to as the *orthogonal* matrices.

In the tectonic plate context, the \mathbf{u}_i are present day landmark points on one plate, \mathbf{v}_i are homologous landmark points on the opposing plate, and \mathbf{A}^T reconstructs the past position of the V-plate to the U-plate in a coordinate system fixed to the U-plate.

Usually it is impossible for a rigid body to be “pushed through the center of the Earth” and so there is an additional *orientation preserving* condition that the determinant of \mathbf{A} be 1. The collection of such matrices is denoted $SO(k)$ and referred to as the *special orthogonal* matrices. In particular, $SO(3)$ consists of the 3×3 rotation matrices. Each rotation in $SO(3)$ is defined by an axis, which can be an arbitrary unit vector in S^2 , and an angle of rotation.

The Procrustes regression model (without scale change) posits fixed points $\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_n \in R^k$ and random points $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n \in R^k$, so that each \mathbf{v}_i has a multivariate normal distribution with mean vector $\mathbf{A}\mathbf{u}_i + \mathbf{b}$ and variance covariance matrix $\sigma^2 \mathbf{I}_k$. \mathbf{A} , as before, represents a rotation matrix, and \mathbf{b} a translation vector. This model might apply, for example, if the $\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_n$ and $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n$ are homologous landmarks on two images, and the determination of \mathbf{A} and \mathbf{b} is commonly referred to as *image registration*.

For reasons of convenience in Sect. 53.5.1, we reparameterize the Procrustes model by letting $\boldsymbol{\alpha} = \mathbf{A}\bar{\mathbf{u}} + \mathbf{b}$. Then each \mathbf{v}_i has mean vector $\mathbf{A}(\mathbf{u}_i - \bar{\mathbf{u}}) + \boldsymbol{\alpha}$.

Speaking with unnecessary precision, the “error” in (53.1) is so that the density of each \mathbf{v} is, with respect to surface measure on S^{k-1} , proportional to $e^{\kappa \mathbf{v}^T \mathbf{A}\mathbf{u}}$. This is the “Fisher-von Mises” distribution $F(\mathbf{A}\mathbf{u}, \kappa)$. κ is the *concentration* parameter and $\mathbf{A}\mathbf{u}$ the *modal vector*.

More heuristically, we can write \mathbf{v} in its normal and tangential components

$$\mathbf{v} = (\mathbf{v}^T \mathbf{A}\mathbf{u}) \mathbf{A}\mathbf{u} + (\mathbf{v} - (\mathbf{v}^T \mathbf{A}\mathbf{u}) \mathbf{A}\mathbf{u}). \quad (53.4)$$

The tangential component $\mathbf{v} - (\mathbf{v}^T \mathbf{A}\mathbf{u}) \mathbf{A}\mathbf{u}$ is perpendicular to $\mathbf{A}\mathbf{u}$ and hence is tangent to S^{k-1} at $\mathbf{A}\mathbf{u}$. We will use $(\mathbf{A}\mathbf{u})^\perp$ to denote the collection of vectors perpendicular to $\mathbf{A}\mathbf{u}$. If the error is small, which occurs for large κ , $(\mathbf{v}^T \mathbf{A}\mathbf{u}) \mathbf{A}\mathbf{u}$ will be close to $\mathbf{A}\mathbf{u}$ and the tangential component $\mathbf{v} - (\mathbf{v}^T \mathbf{A}\mathbf{u}) \mathbf{A}\mathbf{u}$ will be closely approximated by a rotationally symmetric $k - 1$ dimensional multivariate normal distribution $N(\mathbf{0}, \kappa^{-1} \mathbf{I})$ with mean vector $\mathbf{0}$ and variance covariance matrix $\kappa^{-1} \mathbf{I}$. Here \mathbf{I} represents an identity matrix in $(\mathbf{A}\mathbf{u})^\perp$. Mathematically, it can be written as a $k \times k$ matrix as $\mathbf{I} = \mathbf{I}_k - (\mathbf{A}\mathbf{u})(\mathbf{A}\mathbf{u})^T$.

It is essential in what follows to understand that we are thinking of the hopefully small (that is large κ) error in \mathbf{v} from its “true” value $\mathbf{A}\mathbf{u}$ as a small vector (close to $\mathbf{0}$) in the tangent space $(\mathbf{A}\mathbf{u})^\perp$. Tangent space approximation is the essential mathematical tool being used in spherical regression theory. Thus, in what follows, we will let $\boldsymbol{\varepsilon} = \mathbf{v} - (\mathbf{v}^T \mathbf{A}\mathbf{u}) \mathbf{A}\mathbf{u}$ and rewrite (53.4) as

$$\mathbf{v} = \sqrt{1 - \boldsymbol{\varepsilon}^T \boldsymbol{\varepsilon}} \mathbf{A}\mathbf{u} + \boldsymbol{\varepsilon} \approx \mathbf{A}\mathbf{u} + \boldsymbol{\varepsilon} \quad (53.5)$$

where the error vector $\boldsymbol{\varepsilon}$ is normally distributed, in the tangent space $(\mathbf{A}\mathbf{u})^\perp$, with variance covariance matrix $\kappa^{-1} \mathbf{I}$. If κ is large, then $\boldsymbol{\varepsilon}^T \boldsymbol{\varepsilon}$ is small compared to $\boldsymbol{\varepsilon}$ and hence the approximation in (53.5). Indeed $\boldsymbol{\varepsilon}$ has order $\kappa^{-1/2}$ (denoted $O_p(\kappa^{-1/2})$ – the subscript p stands for *probability*), whereas $\boldsymbol{\varepsilon}^T \boldsymbol{\varepsilon}$ is $O_p(\kappa^{-1})$ so that as $\kappa \rightarrow \infty$, it is asymptotically negligible.

We note that the errors in magnetic anomaly lineation data are small compared to the radius of the Earth, so large κ approximation is appropriate.

53.2 Least Squares Estimation

In the spherical regression model, the least squares estimate $\hat{\mathbf{A}}$ of \mathbf{A} minimizes the objective function

$$\rho_2(\mathbf{A}) = \sum \| \mathbf{v}_i - \mathbf{A}\mathbf{u}_i \|^2 \quad (53.6)$$

and, in general, the L_p estimate minimizes $\rho_p(\mathbf{A}) = \sum \| \mathbf{v}_i - \mathbf{A}\mathbf{u}_i \|^p$. The least squares estimate is computationally easier, and indeed, there is an explicit formula for it in terms of the singular value decomposition of the 3×3 matrix $\sum \mathbf{u}_i \mathbf{v}_i^T$, see for example [1]. That being said, the L_1 estimate can be used if outliers are a potential issue, although numerical minimization is required.

In the Procrustes regression model, the least squares estimate $\hat{\mathbf{A}}$ of \mathbf{A} and $\hat{\boldsymbol{\alpha}}$ of $\boldsymbol{\alpha}$ minimize the objective function

$$\rho_2(\mathbf{A}, \boldsymbol{\alpha}) = \sum \| \mathbf{v}_i - \mathbf{A}(\mathbf{u}_i - \bar{\mathbf{u}}) - \boldsymbol{\alpha} \|^2 \quad (53.7)$$

Section 53.5 derives some asymptotic distributions of these least squares estimators. The first edition of this chapter [1] has more general results that include, for example, L_p estimators.

53.2.1 A Simple Example Derivation

Before deriving in Sect. 53.5, the distribution of $\hat{\mathbf{A}}$ (for the spherical regression problem) or for $\hat{\mathbf{A}}$ and $\hat{\boldsymbol{\alpha}}$ (for unscaled Procrustes regression), consider the following simpler problem of *location* estimation. Suppose $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n \in S^{k-1}$ are independently distributed $F(\boldsymbol{\mu}, \kappa)$ where $\boldsymbol{\mu} \in S^{k-1}$ is the modal (location) vector and κ is large. We want to figure out the distribution of the estimate $\hat{\boldsymbol{\mu}}$ that minimizes

$$\rho_2(\boldsymbol{\mu}) = \sum \| \mathbf{v}_i - \boldsymbol{\mu} \|^2. \quad (53.8)$$

Write, in a manner similar to (53.5),

$$\mathbf{v}_i \approx \boldsymbol{\mu} + \boldsymbol{\varepsilon}_i \quad (53.9)$$

$$\hat{\boldsymbol{\mu}} \approx \boldsymbol{\mu} + \mathbf{u} \quad (53.10)$$

where $\boldsymbol{\varepsilon}_i, \mathbf{u} \in \boldsymbol{\mu}^\perp$, that is, they are tangent to S^{k-1} at $\boldsymbol{\mu}$. Using the approximations (53.9) and (53.10), (53.8) becomes

$$\rho_2(\hat{\boldsymbol{\mu}}) \approx \sum \| \boldsymbol{\mu} + \boldsymbol{\varepsilon}_i - (\boldsymbol{\mu} + \mathbf{u}) \|^2 = \sum \| \boldsymbol{\varepsilon}_i - \mathbf{u} \|^2 \quad (53.11)$$

and \mathbf{u} minimizes (53.11). Since each $\boldsymbol{\varepsilon}_i$ is approximately distributed $N(\mathbf{0}, \kappa^{-1}\mathbf{I})$, $\mathbf{u} = n^{-1} \sum \boldsymbol{\varepsilon}_i$, and is approximately distributed $N(\mathbf{0}, (n\kappa)^{-1}\mathbf{I})$. Note that these distributional statements occur in the tangent space to S^{k-1} at $\boldsymbol{\mu}$, so that $\mathbf{I} = \mathbf{I}_k - \boldsymbol{\mu}\boldsymbol{\mu}^T$. Also note that we are actually computing the distribution of the deviation \mathbf{u} of $\hat{\boldsymbol{\mu}}$ from $\boldsymbol{\mu}$. Using standard statistical reasoning, this latter distribution is sufficient for both hypothesis tests and confidence regions on the parameter $\boldsymbol{\mu}$.

And, again, these are large κ asymptotic approximations. Technically they hold, in the limit, as $\kappa \rightarrow \infty$.

We also note that an explicit solution for $\hat{\boldsymbol{\mu}}$ is $\hat{\boldsymbol{\mu}} = \sum \mathbf{v}_i / \|\sum \mathbf{v}_i\|$ although this explicit solution is not used in the above.

53.3 Differential Manifolds

In the derivation of Sect. 53.2.1, S^{k-1} appears in two roles: It is both the data space, containing the data points $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n$, and the parameter space, containing the parameter $\boldsymbol{\mu}$ to be estimated. In both contexts, tangent space approximations are used: Using (53.9), the $\boldsymbol{\varepsilon}_i$ lies in the tangent space to the data space and in (53.10), \mathbf{u} lies in the tangent space of the parameter space.

In the spherical regression model, S^{k-1} is the data space, but $\text{SO}(k)$ is the parameter space. In the Procrustes model, R^k is the data space and the parameter space is $\text{SO}(k) \times R^k = \{(\mathbf{A}, \mathbf{b})\}$, where \mathbf{A} represents a rotation matrix and \mathbf{b} a translation vector. Thus, besides tangent space approximation to S^{k-1} , we need to understand how to make tangent space approximations to $\text{SO}(k)$. Tangent space approximations to $\text{SO}(k) \times R^k$ are a simple extension.

In addition, using (53.5) and reintroducing subscripts into it, each $\boldsymbol{\varepsilon}_i$ lies in the tangent space $(\mathbf{A}\mathbf{u}_i)^\perp$. So, we will need, for the data space at least, multiple tangent space approximations, one for each data point \mathbf{v}_i . This latest complication is intrinsic to regression problems.

Each element $\mathbf{A} \in \text{SO}(k)$ is a $k \times k$ matrix and has k^2 elements so we can easily represent $\text{SO}(k) \subseteq R^{k^2}$. In the mathematical lingo, S^{k-1} and $\text{SO}(k)$ are “embedded manifolds” in R^k and R^{k^2} , respectively. Differential geometry is the mathematical discipline that studies manifolds and the notion of tangent space is one of that discipline’s most fundamental constructs. Because our manifolds are naturally embedded in ambient Euclidean spaces, we can introduce the ideas we need without using the usual mathematical definitions in their most general and precise formulation.

In fact, in the history of differential geometry, the most important non-Euclidean geometry is the sphere S^2 . The sum of the angles in a spherical triangle (that is a triangle bounded by three great circle segments) always exceeds 180° and parallel lines do not exist. More relevantly, for our purposes, the sphere cannot be represented as a planar map without

tearing it somewhere. But small patches of the sphere can be represented using a map and we do so every day. In other words, the fact that the sphere closes in on itself is a global feature; locally we can think of it as a two dimensional plane with two cardinal directions (EW and NS).

A manifold of dimension p is, roughly speaking, a topological object that can locally be represented as a region of R^p .

For example, a polar projection centered at $\mathbf{u} \in S^{k-1}$ maps $\mathbf{h} \in \mathbf{u}^\perp$

$$\mathbf{h} \rightarrow \cos(\|\mathbf{h}\|)\mathbf{u} + \sin(\|\mathbf{h}\|)\|\mathbf{h}\|^{-1}\mathbf{h} \tag{53.12}$$

and this represents S^{k-1} locally at $\mathbf{u} \in S^{k-1}$ as the Euclidean space $\mathbf{u}^\perp \approx R^{k-1}$. (Note that for spaces, the symbol “ \approx ” in $\mathbf{u}^\perp \approx R^{k-1}$ is meant to convey that \mathbf{u}^\perp is a version of Euclidean $(k - 1)$ -dimensional space R^{k-1} , whereas for points, as in the Equations (53.5), (53.9), (53.10), and (53.11), it denotes approximation.) We say that S^{k-1} is a $(k - 1)$ -dimensional manifold, and it is embedded in R^k .

The matrix exponential function takes the skew symmetric $k \times k$ matrices

$$\text{Skew}(k) = \{\mathbf{H} | \mathbf{H} + \mathbf{H}^T = 0\}$$

onto $\text{SO}(k)$. It is defined by

$$\exp(\mathbf{H}) = \sum_{r=0}^{\infty} \frac{\mathbf{H}^r}{r!} \tag{53.13}$$

where \mathbf{H} is a $k \times k$ skew symmetric matrix. Notice that $\text{Skew}(k) \approx R^{k(k-1)/2}$.

For $k = 3$, and the 3-vector $\mathbf{t} = [t_1 \ t_2 \ t_3]^T$, let

$$\Phi(\mathbf{t}) = \exp\left(\begin{bmatrix} 0 & -t_3 & t_2 \\ t_3 & 0 & -t_1 \\ -t_2 & t_1 & 0 \end{bmatrix}\right) = \exp \mathbf{M}(\mathbf{t}) \tag{53.14}$$

where $\mathbf{M}(\mathbf{t})$ is defined by equation (53.14).

It can be shown that for the 3-vector \mathbf{t} , $\Phi(\mathbf{t})$ represents right hand rule rotation of $\|\mathbf{t}\|$ radians around the axis $\|\mathbf{t}\|^{-1}\mathbf{t}$. Thus, if \mathbf{t} is a small vector, $\Phi(\mathbf{t})$ will be a small rotation, that is, one close to \mathbf{I}_3 . Also note that if \mathbf{u} is of unit length $\Phi(2\pi\mathbf{u}) = \mathbf{I}_3$, so that Φ , and more generally $\exp(\mathbf{H})$, cannot globally represent $\text{SO}(k)$ as $\text{Skew}(k)$.

Nevertheless we can use (53.13) to define a manifold structure for $\text{SO}(k)$. For each $\mathbf{A} \in \text{SO}(k)$, let $\mathbf{A}\text{Skew}(k) = \{\mathbf{A}\mathbf{H} | \mathbf{H} \in \text{Skew}(k)\} \approx R^{k(k-1)/2}$.

$$\mathbf{A}\mathbf{H} \rightarrow \mathbf{A} \exp(\mathbf{H}) \tag{53.15}$$

represents the special orthogonal matrices close to \mathbf{A} as a portion of $\mathbf{A}\text{Skew}(k) \approx R^{k(k-1)/2}$. Thus, we can say that $\text{SO}(k)$ is a $k(k - 1)/2$ -dimensional manifold, and it is embedded in R^{k^2} .

53.4 Tangent Space Approximations

Let \mathcal{M} be a p -dimensional manifold embedded in some ambient Euclidean space R^N . If $c(t)$ is a curve in \mathcal{M} , that is, a function $R^1 \rightarrow \mathcal{M}$, it is a fortiori a curve in R^N . Thus, we can take derivatives $c'(t)$ and $c'(t)$ will be a vector in R^N . The vector $c'(0)$ is said to be a *tangent vector* to \mathcal{M} at $c(0) \in \mathcal{M}$. For a specific point $\mathbf{u} \in \mathcal{M}$, the *tangent space* to \mathcal{M} is the collection of all $c'(0)$ for curves with $c(0) = \mathbf{u}$.

For example, if $c(t)$ is a curve in $S^{k-1} \subseteq R^k$, we have for all t

$$c(t)^T c(t) = 1. \quad (53.16)$$

Differentiating (53.16) yields

$$0 = c'(t)^T c(t) + c(t)^T c'(t) = 2c'(t)^T c(t). \quad (53.17)$$

Specializing (53.17), to $t = 0$, we see that $c'(0) \in c(0)^\perp$. Conversely for $\mathbf{u} \in S^{k-1}$ and $\mathbf{h} \in \mathbf{u}^\perp$

$$c(t) = \cos(t \|\mathbf{h}\|) \mathbf{u} + \sin(t \|\mathbf{h}\|) \|\mathbf{h}\|^{-1} \mathbf{h}$$

is a curve in S^{k-1} with $c(0) = \mathbf{u}$ and $c'(0) = \mathbf{h}$.

In other words, the tangent space to S^{k-1} at \mathbf{u} is exactly \mathbf{u}^\perp .

Similarly, if $c(t)$ is a curve in $\text{SO}(k)$, and using (53.2)

$$c(t)^T c(t) = \mathbf{I}_k.$$

Hence,

$$\mathbf{0} = c(0)^T c'(0) + c'(0)^T c(0). \quad (53.18)$$

Let $\mathbf{A} = c(0)$ and $\mathbf{H} = \mathbf{A}^T c'(0)$. Rewriting (53.18)

$$\mathbf{0} = \mathbf{H} + \mathbf{H}^T$$

or $\mathbf{H} \in \text{Skew}(k)$ and $c'(0) = \mathbf{A}\mathbf{H} \in \mathbf{A}\text{Skew}(k)$. Conversely, if $\mathbf{H} \in \text{Skew}(k)$, (53.15) implies that $c(t) = \mathbf{A} \exp(t\mathbf{H})$ is a curve in $\text{SO}(k)$ with $c(0) = \mathbf{A}$ and $c'(0) = \mathbf{A}\mathbf{H}$.

In other words, the tangent space to $\text{SO}(k)$ at $\mathbf{A} \in \text{SO}(k)$ is exactly the collection of $k \times k$ matrices of the form $\mathbf{A}\text{Skew}(k)$.

53.4.1 The Lesson from Taylor Series

In (53.9) and (53.10), deviations in \mathbf{v}_i and $\hat{\boldsymbol{\mu}}$ from their “true” (without error) value $\boldsymbol{\mu}$ are expressed using tangent vectors $\boldsymbol{\varepsilon}_i$ and \mathbf{u} . The remainder of the proof focuses on the distributions of these tangent vectors.

The linear term of Taylor series

$$f(x) = f(x_0) + f'(x_0)(x - x_0) + \text{Remainder}$$

best approximates $f(x) - f(x_0)$, that is, the remainder is small, when x is close to x_0 . This means that when we can guarantee that \mathbf{v}_i and $\hat{\boldsymbol{\mu}}$ are close to $\boldsymbol{\mu}$, we should focus on their deviations from $\boldsymbol{\mu}$, as measured by $\boldsymbol{\varepsilon}_i$ and \mathbf{u} and not upon \mathbf{v}_i and $\hat{\boldsymbol{\mu}}$ directly.

Indeed, in neglecting terms of order $\|\boldsymbol{\varepsilon}_i\|^2$ and $\|\mathbf{u}\|^2$ when passing from $\|\mathbf{v}_i - \boldsymbol{\mu}\|$ in (53.11) to $\|\boldsymbol{\varepsilon}_i - \mathbf{u}\|$ in (53.6), we have applied Taylor linearization in both the data space and the parameter space. This is justifiable because as $\kappa \rightarrow \infty$, $\mathbf{v}_i \rightarrow \boldsymbol{\mu}$ and $\hat{\boldsymbol{\mu}} \rightarrow \boldsymbol{\mu}$, so that, in the limit, $\|\boldsymbol{\varepsilon}_i\|^2$ and $\|\mathbf{u}\|^2$ are asymptotically trivial.

In the plate tectonic context, the errors in tectonic plate data are on the order of 10 km and hence trivial relative to the radius of the Earth. This justifies a “local flat Earth approximation,” that is, Taylor linearization is justified in the data space.

Taylor linearization in the parameter space requires showing that $\hat{\boldsymbol{\mu}} \rightarrow \boldsymbol{\mu}$. This *large κ consistency* is usually very easy to establish unless the underlying statistical model has been badly specified.

Although statistical theory is rife with asymptotic approximations, most of them are *large sample* approximations; they are valid in the limit as the sample size $n \rightarrow \infty$. In this case, one only has consistency in the parameter space, and Taylor linearization in the data space is not available (one generally uses Central Limit type theorems instead). For this reason, the large sample results for spherical regression (see for example [4]) are not as clean as the corresponding large κ results (as in Rivest [5]).

53.4.2 The Map Maker’s Dilemma and Its Lessons

The approximations in (53.9) and (53.10) are essentially maps of tangent vectors $\boldsymbol{\varepsilon}_i$ and \mathbf{u} at $\boldsymbol{\mu}$ into points \mathbf{v}_i and $\hat{\boldsymbol{\mu}}$ on S^{k-1} .

An important property of non-Euclidean manifolds, such as S^{k-1} and $\text{SO}(k)$, is that any representation (map) of them as portion of Euclidean space distorts distances at least to some degree. Thus, any map of any portion of the Earth distorts distances somewhere. For example, the standard Mercator projection of the Earth is highly distorting in polar regions. Thus, when making a map of a region on the Earth, a map maker must choose a projection that makes the distortions as small as possible in the region of primary interest. So a map of Antarctica is not made using a standard Mercator projection, but rather using a polar projection (53.12) centered at the South pole.

A body is rigid when its internal distances are preserved as it moves. Thus, the problem of rigid body motion (or moving

coordinate systems) intrinsically involves distances, and any maps we use of S^{k-1} should, as best possible, preserve distances. Because v_i and $\hat{\boldsymbol{\mu}}$ are close to $\boldsymbol{\mu}$, we are called to use a polar projection of $\boldsymbol{\mu}^\perp$ onto S^{k-1} , that is, a polar projection centered at $\boldsymbol{\mu}$.

The polar projection (53.12) centered at $\mathbf{u} \in S^{k-1}$ takes $\mathbf{h} \in \mathbf{u}^\perp$ to

$$\mathbf{h} \rightarrow \cos(\|\mathbf{h}\|)\mathbf{u} + \sin(\|\mathbf{h}\|)\|\mathbf{h}\|^{-1}\mathbf{h} = \mathbf{u} + \mathbf{h} + \mathcal{O}(\|\mathbf{h}\|^2)$$

so that using (53.9) and (53.10) are asymptotically equivalent to using a polar projection centered at $\boldsymbol{\mu}$.

It can be shown that the map (53.15) of the tangent space $\mathbf{ASkew}(k)$ to $\text{SO}(k)$ at $\mathbf{A} \in \text{SO}(k)$ has similar distance properties as polar projection on S^{k-1} . (This requires somewhat more understanding of the geometry of $\text{SO}(k)$, but for $k = 3$, a more elementary explanation can be given, see the Appendix sections “Quaternion Representation of $\text{SO}(3)$ ” and “Combining Two Rotations Using Quaternionic Representation”.)

[3, 11] contain a striking example in $k = 3$ of the mess that can be made if statistical approaches are designed without proper use of geometry. In these chapters, the same basic Taylor linearization tool was used in both the messy and clean results. The difference between the messy and clean results is that the clean results (Eq. (53.35) below) were derived by linearizing $\text{SO}(3)$ using tangent space approximation and equation (53.15), whereas the messy results used a different commonly used mapping (axis latitude, axis longitude, angle of rotation) of $\text{SO}(3)$. This example is developed further in the Appendix.

Note that the map (53.15) relies on the group nature of $\text{SO}(k)$. In the terminology of statistical group models, using (53.15) yields “invariant” results and [11] also explains the importance of invariant inference in the geophysical context.

53.5 Asymptotic Analysis for Procrustes and Spherical Regressions in $k = 3$ Dimensions

In this section, we illustrate the use of Taylor linearization for least squares estimation in both the spherical regression and Procrustes models. The results we derive are special cases of those given in Theorem 31.4.4 (for Procrustes models) and Sect. 31.4.9 (for spherical regression models) of [1].

Use of Taylor linearization requires proof of *consistency*, that is that in the limit, the parameter estimates approach their true values. Consistency insures that in the limit, the nonlinear terms will be negligible relative to the linear terms. For the Procrustes model, we need that $\hat{\mathbf{A}} \rightarrow \mathbf{A}$ and $\hat{\boldsymbol{\alpha}} \rightarrow \boldsymbol{\alpha}$. We will perform our asymptotics as the sample size $n \rightarrow \infty$. Although we will not prove consistency, it can be shown that

$\hat{\mathbf{A}}$ and $\hat{\boldsymbol{\alpha}}$ are consistent except for the unreasonable geometry that $\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_n$ are all multiples of a single vector.

As discussed in Sect. 53.4.1, large sample asymptotics essentially linearizes the parameter space. For spherical regression, we will use large κ asymptotics to linearize both the data and the parameter space. Large sample asymptotics are available for spherical regressions (see [1]), but both their derivations and statements are more difficult (see [4]).

The parameter space for spherical regression on S^{k-1} is $\text{SO}(k)$. For Procrustes regression on R^k , it is $\text{SO}(k) \times R^k$. $\text{SO}(k)$ has dimension $k(k - 1)/2$ so to simplify matters we will restrict ourselves to the special case $k = 3$. This case is also the one of greatest physical interest.

53.5.1 Large Sample Asymptotics for the Procrustes Regression Model in R^3

In the example proof of Sect. 53.2.1, both the data space and the sample space were linearized using equations (53.9) and (53.10). For Procrustes regression, the data space is already linear and satisfies the model

$$v_i = \mathbf{A}(\mathbf{u}_i - \bar{\mathbf{u}}) + \boldsymbol{\alpha} + \boldsymbol{\varepsilon}_i \tag{53.19}$$

Let $(\hat{\mathbf{A}}, \hat{\boldsymbol{\alpha}})$ minimize (53.7) and write

$$\hat{\mathbf{A}} = \mathbf{A} \exp \mathbf{H} \approx \mathbf{A}(\mathbf{I} + \mathbf{H}) \quad \text{and} \quad \hat{\boldsymbol{\alpha}} = \boldsymbol{\alpha} + \mathbf{h}_\alpha \tag{53.20}$$

where in (53.20) the asymptotically trivial terms of order \mathbf{H}^2 and higher have been ignored

Equations (53.19) and (53.20) play an analogous role in the derivation of this section that (53.9) and (53.10) played in the derivation of Sect. 53.2.1: They are the expression of the deviations of the data v_i and the parameter estimates $(\hat{\mathbf{A}}, \hat{\boldsymbol{\alpha}})$ from their “true” values $\mathbf{A}(\mathbf{u}_i - \bar{\mathbf{u}}) + \boldsymbol{\alpha}$ and $(\mathbf{A}, \boldsymbol{\alpha})$. The data space R^k is its own tangent space and we are thinking of $\boldsymbol{\varepsilon}_i$ as a tangent vector to R^k at $\mathbf{A}(\mathbf{u}_i - \bar{\mathbf{u}}) + \boldsymbol{\alpha}$. $(\mathbf{A}\mathbf{H}, \mathbf{h}_\alpha)$ is a tangent vector to the parameter space $\text{SO}(k) \times R^k$ at $(\mathbf{A}, \boldsymbol{\alpha})$.

The distribution of \mathbf{H} will be in $k(k - 1)/2$ dimensions and the entries of \mathbf{H} are naturally double subscripted. This makes the derivation somewhat hard to follow, although its fundamental idea is almost as simple as the derivation in Sect. 53.2.1. To alleviate this problem partially, we will specialize to the case of physical interest $k = 3$.

Thus, as in equation (53.14), we write \mathbf{H} in the form $\mathbf{H} = \exp \mathbf{M}(\mathbf{h})$ and $\hat{\mathbf{A}} = \mathbf{A}\Phi(\mathbf{h})$ where $\mathbf{h} = [h_1 \ h_2 \ h_3]^T$ is a 3×1 column vector. We seek the asymptotic distribution of $(\mathbf{h}, \mathbf{h}_\alpha)$.

Recall that $\hat{\mathbf{A}}$ minimizes the objective function $\rho_2(\mathbf{A}, \boldsymbol{\alpha})$ of equation (53.7). Substituting (53.19) and (53.20) into (53.7), we arrive at

$$\begin{aligned}
\rho_2(\hat{\mathbf{A}}, \hat{\boldsymbol{\alpha}}) &\approx \sum \|\mathbf{A}(\mathbf{u}_i - \bar{\mathbf{u}}) + \boldsymbol{\alpha} + \boldsymbol{\varepsilon}_i \\
&\quad - \mathbf{A}(\mathbf{I} + \mathbf{H})(\mathbf{u}_i - \bar{\mathbf{u}}) - \boldsymbol{\alpha} - \mathbf{h}_\alpha\|^2 \\
&= \sum \|\boldsymbol{\varepsilon}_i - \mathbf{A}\mathbf{H}(\mathbf{u}_i - \bar{\mathbf{u}}) - \mathbf{h}_\alpha\|^2 \\
&= \sum \|\mathbf{A}^T \boldsymbol{\varepsilon}_i - \mathbf{H}(\mathbf{u}_i - \bar{\mathbf{u}}) - \mathbf{A}^T \mathbf{h}_\alpha\|^2
\end{aligned} \tag{53.21}$$

where the last equality follows from equations (53.2) and (53.3). Equation (53.21) plays the same role in the instant derivation as equation (53.11) plays in the derivation of Sect. 53.2.1.

Routine calculations show $\mathbf{H}\mathbf{t} = \mathbf{M}(\mathbf{h})\mathbf{t} = -\mathbf{M}(\mathbf{t})\mathbf{h} = -\mathbf{t} \times \mathbf{h}$, for any vector \mathbf{t} , where $\mathbf{t} \times \mathbf{h}$ denotes the vector cross product. Let $\mathbf{y}_i = \mathbf{A}^T \boldsymbol{\varepsilon}_i$. Since $\boldsymbol{\varepsilon}_i$ is distributed $N(\mathbf{0}, \sigma^2 \mathbf{I}_3)$ and using (53.2), \mathbf{y}_i is also distributed $N(\mathbf{0}, \sigma^2 \mathbf{I}_3)$. In other words, if the $3n \times 1$ vector \mathbf{y} is obtained by stacking $\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_n$, it satisfies the assumptions of the regression model

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}.$$

$\boldsymbol{\epsilon}$ is distributed $N(\mathbf{0}, \sigma^2 \mathbf{I}_{3n})$.

Here \mathbf{X} is the $3n \times 6$ matrix obtained by stacking vertically the 3×6 matrices $\mathbf{X}_i = \begin{bmatrix} -\mathbf{M}(\mathbf{u}_i - \bar{\mathbf{u}}) & \mathbf{A}^T \\ \mathbf{A} & \mathbf{0} \end{bmatrix}$, $i = 1, \dots, n$. $\boldsymbol{\beta}$ is a 6×1 vector whose “true” value is $\mathbf{0}$. The right hand side of (53.21) is the sum squares to be minimized by this regression. The minimum occurs at $\hat{\boldsymbol{\beta}} = (\mathbf{h}, \mathbf{h}_\alpha)$, where $\hat{\mathbf{A}} = \mathbf{A}\Phi(\mathbf{h})$ and $\hat{\boldsymbol{\alpha}} = \boldsymbol{\alpha} + \mathbf{h}_\alpha$.

Now

$$\mathbf{X}^T \mathbf{X} = \begin{bmatrix} \sum \mathbf{M}(\mathbf{u}_i - \bar{\mathbf{u}})^T \mathbf{M}(\mathbf{u}_i - \bar{\mathbf{u}}) & -\sum \mathbf{M}(\mathbf{u}_i - \bar{\mathbf{u}})^T \mathbf{A}^T \\ -\mathbf{A} \sum \mathbf{M}(\mathbf{u}_i - \bar{\mathbf{u}}) & n \mathbf{A} \mathbf{A}^T \end{bmatrix}.$$

For any vector \mathbf{t} , routine algebra shows $\mathbf{M}(\mathbf{t})^T \mathbf{M}(\mathbf{t}) = \|\mathbf{t}\|^2 \mathbf{I}_3 - \mathbf{t}\mathbf{t}^T$ and $\sum \mathbf{M}(\mathbf{u}_i - \bar{\mathbf{u}}) = \mathbf{M}(\sum (\mathbf{u}_i - \bar{\mathbf{u}})) = \mathbf{0}$. Let $\boldsymbol{\Sigma} = n^{-1} \sum (\mathbf{u}_i - \bar{\mathbf{u}})(\mathbf{u}_i - \bar{\mathbf{u}})^T$. Furthermore, $\sum \|\mathbf{u}_i - \bar{\mathbf{u}}\|^2 = \sum \text{Tr}((\mathbf{u}_i - \bar{\mathbf{u}})^T (\mathbf{u}_i - \bar{\mathbf{u}})) = \sum \text{Tr}((\mathbf{u}_i - \bar{\mathbf{u}})(\mathbf{u}_i - \bar{\mathbf{u}})^T) = n \text{Tr}(\boldsymbol{\Sigma})$. Then

$$\mathbf{X}^T \mathbf{X} = n \begin{bmatrix} \text{Tr}(\boldsymbol{\Sigma}) \mathbf{I}_3 - \boldsymbol{\Sigma} & \mathbf{0} \\ \mathbf{0} & \mathbf{I}_3 \end{bmatrix}.$$

Since $\hat{\boldsymbol{\beta}}$ has covariance matrix $\sigma^2 (\mathbf{X}^T \mathbf{X})^{-1}$, we have

- \mathbf{h} and \mathbf{h}_α are asymptotically independent.
- \mathbf{h} is asymptotically distributed $N(\mathbf{0}, n^{-1} \sigma^2 (\text{Tr}(\boldsymbol{\Sigma}) \mathbf{I}_3 - \boldsymbol{\Sigma})^{-1})$.
- \mathbf{h}_α is asymptotically normal $N(\mathbf{0}, n^{-1} \sigma^2 \mathbf{I}_3)$.

Section 31.4.6 of [1] has a numerical example using these results for a test on \mathbf{A} .

53.5.2 Large κ Asymptotic Analysis for the Spherical Regression Model on S^2

Large κ asymptotics for the spherical regression model were introduced by Rivest [5] and we follow his approach. Write as in (53.5)

$$\mathbf{v}_i \approx \mathbf{A}\mathbf{u}_i + \boldsymbol{\varepsilon}_i \tag{53.22}$$

where $\boldsymbol{\varepsilon}_i \in (\mathbf{A}\mathbf{u}_i)^\perp$ and as $\kappa \rightarrow \infty$, the distribution of $\boldsymbol{\varepsilon}_i$ approaches $N(\mathbf{0}, \kappa^{-1}(\mathbf{I}_k - (\mathbf{A}\mathbf{u}_i)(\mathbf{A}\mathbf{u}_i)^T))$. The vector $\mathbf{A}\mathbf{u}_i$ is an eigenvector of the matrix $\mathbf{I}_k - (\mathbf{A}\mathbf{u}_i)(\mathbf{A}\mathbf{u}_i)^T$ with eigenvalue 0. All vectors in $(\mathbf{A}\mathbf{u}_i)^\perp$ are eigenvectors of $\mathbf{I}_k - (\mathbf{A}\mathbf{u}_i)(\mathbf{A}\mathbf{u}_i)^T$ with eigenvalue 1. Thus, we have made explicit that each $\boldsymbol{\varepsilon}_i$ is constrained to lie to the tangent space $(\mathbf{A}\mathbf{u}_i)^\perp$. Let

$$\hat{\mathbf{A}} = \mathbf{A} \exp \mathbf{H} \approx \mathbf{A}(\mathbf{I} + \mathbf{H}). \tag{53.23}$$

Again, restricting to $k = 3$, write $\hat{\mathbf{A}} = \mathbf{A}\Phi(\mathbf{h})$ where $\mathbf{h} = [h_1 \ h_2 \ h_3]^T$ is a 3×1 column vector. We seek the asymptotic distribution of \mathbf{h} .

Substituting (53.22) and (53.23) into the objective function $\rho_2(\hat{\mathbf{A}})$ of equation (53.6), we arrive at

$$\begin{aligned}
\rho_2(\hat{\mathbf{A}}) &\approx \sum \|\mathbf{A}\mathbf{u}_i + \boldsymbol{\varepsilon}_i - \mathbf{A}(\mathbf{I} + \mathbf{H})\mathbf{u}_i\|^2 \\
&= \sum \|\mathbf{A}^T \boldsymbol{\varepsilon}_i - \mathbf{H}\mathbf{u}_i\|^2 = \sum \|\mathbf{A}^T \boldsymbol{\varepsilon}_i + \mathbf{M}(\mathbf{u}_i)\mathbf{h}\|^2.
\end{aligned} \tag{53.24}$$

Note that $\mathbf{A}^T \boldsymbol{\varepsilon}_i$ and $-\mathbf{M}(\mathbf{u}_i)\mathbf{h} = -\mathbf{u}_i \times \mathbf{h}$ are three component vectors, but both lie in $\mathbf{u}_i^\perp \approx R^2$. To use standard regression theory, we will reexpress them in terms of a basis of \mathbf{u}_i^\perp . Formally, for each i , pick unit length vectors $\mathbf{v}_i, \mathbf{w}_i$ so that $\mathbf{u}_i, \mathbf{v}_i, \mathbf{w}_i$ form a right hand rule orthonormal basis. In other words, $\mathbf{U}_i = [\mathbf{u}_i \ \mathbf{v}_i \ \mathbf{w}_i] \in SO(3)$ and

$$\mathbf{u}_i^T \mathbf{u}_i = \mathbf{v}_i^T \mathbf{v}_i = \mathbf{w}_i^T \mathbf{w}_i = 1 \tag{53.25}$$

$$\mathbf{u}_i^T \mathbf{v}_i = \mathbf{v}_i^T \mathbf{w}_i = \mathbf{w}_i^T \mathbf{u}_i = 0 \tag{53.26}$$

$$\mathbf{u}_i \mathbf{u}_i^T + \mathbf{v}_i \mathbf{v}_i^T + \mathbf{w}_i \mathbf{w}_i^T = \mathbf{I}_3. \tag{53.27}$$

(53.25) and (53.26) follow from $\mathbf{U}_i^T \mathbf{U}_i = \mathbf{I}_3$ and (53.27) from $\mathbf{U}_i \mathbf{U}_i^T = \mathbf{I}_3$.

Let \mathbf{V}_i be the 3×2 matrix whose columns are \mathbf{v}_i and \mathbf{w}_i and let $\tilde{\boldsymbol{\varepsilon}}_i = \mathbf{V}_i^T \mathbf{A}^T \boldsymbol{\varepsilon}_i$. $\tilde{\boldsymbol{\varepsilon}}_i$ is a 2-dimensional vector and its variance covariance matrix of $\tilde{\boldsymbol{\varepsilon}}_i$ is (for large κ)

$$\kappa^{-1} \mathbf{V}_i^T \mathbf{A}^T (\mathbf{I}_3 - (\mathbf{A}\mathbf{u}_i)(\mathbf{A}\mathbf{u}_i)^T) \mathbf{A} \mathbf{V}_i = \kappa^{-1} \mathbf{I}_2.$$

We have made generous use here of equations (53.25) and (53.26). Furthermore, (53.24) becomes

$$\rho_2(\hat{\mathbf{A}}) \approx \sum \|\tilde{\mathbf{e}}_i + \mathbf{V}_i^T \mathbf{M}(\mathbf{u}_i) \mathbf{h}\|^2.$$

Let \mathbf{X}_i be the 2×3 matrix with rows \mathbf{w}_i^T and $-\mathbf{v}_i^T$. It is well known that for three vectors $\mathbf{u}^T(\mathbf{v} \times \mathbf{w}) = \mathbf{w}^T(\mathbf{u} \times \mathbf{v})$ – this is called the “scalar triple product.” Therefore,

$$\begin{aligned} -\mathbf{V}_i^T \mathbf{M}(\mathbf{u}_i) \mathbf{h} &= \begin{bmatrix} -\mathbf{v}_i^T(\mathbf{u}_i \times \mathbf{h}) \\ -\mathbf{w}_i^T(\mathbf{u}_i \times \mathbf{h}) \end{bmatrix} = \begin{bmatrix} -\mathbf{h}^T(\mathbf{v}_i \times \mathbf{u}_i) \\ -\mathbf{h}^T(\mathbf{w}_i \times \mathbf{u}_i) \end{bmatrix} \\ &= \begin{bmatrix} \mathbf{h}^T \mathbf{w}_i \\ -\mathbf{h}^T \mathbf{v}_i \end{bmatrix} = \mathbf{X}_i \mathbf{h}. \end{aligned}$$

and

$$\rho_2(\hat{\mathbf{A}}) \approx \sum \|\tilde{\mathbf{e}}_i - \mathbf{X}_i \mathbf{h}\|^2 = \sum \|\mathbf{y}_i - \mathbf{X}_i \mathbf{h}\|^2 \quad (53.28)$$

where $\mathbf{y}_i = \tilde{\mathbf{e}}_i$, a 2×1 vector.

\mathbf{y}_i is distributed bivariate normal $N(\mathbf{X}_i \mathbf{0}, \kappa^{-1} \mathbf{I}_2)$. In other words, \mathbf{y}_i satisfies the assumptions of the regression model

$$\mathbf{y}_i = \mathbf{X}_i \boldsymbol{\beta} + \boldsymbol{\epsilon}_i$$

$$\boldsymbol{\epsilon}_i \text{ i.i.d. } N(\mathbf{0}, \kappa^{-1} \mathbf{I}_2)$$

where the “true” value of $\boldsymbol{\beta}$ is $\mathbf{0}$. The right hand side of (53.28) is the sum squares to be minimized by this regression, where $\hat{\mathbf{A}} = \mathbf{A} \Phi(\mathbf{h})$ and the minimum occurs at $\hat{\boldsymbol{\beta}} = \mathbf{h}$.

Let the $2n \times 3$ matrix \mathbf{X} be obtained by stacking $\mathbf{X}_1, \mathbf{X}_2, \dots, \mathbf{X}_n$ on top of each other. Then, using (53.27)

$$\mathbf{X}^T \mathbf{X} = \sum (\mathbf{w}_i \mathbf{w}_i^T + \mathbf{v}_i \mathbf{v}_i^T) = n(\mathbf{I}_3 - \boldsymbol{\Sigma})$$

where $\boldsymbol{\Sigma} = n^{-1} \sum \mathbf{u}_i \mathbf{u}_i^T$. Standard regression theory then indicates that the (asymptotic) distribution of \mathbf{h} is thus $N(\boldsymbol{\beta}, \sigma^2(\mathbf{X}^T \mathbf{X})^{-1})$ or, in this case, $N(\mathbf{0}, (n\kappa(\mathbf{I}_3 - \boldsymbol{\Sigma}))^{-1})$.

In summary, for example, to test $H_0 : \mathbf{A} = \mathbf{A}_0$, calculate the $\hat{\mathbf{A}}$ that minimizes (53.6). Find \mathbf{h} so that $\mathbf{A}_0^T \hat{\mathbf{A}} = \Phi(\mathbf{h})$ and compare $n\hat{\kappa} \mathbf{h}^T (\mathbf{I}_3 - \boldsymbol{\Sigma}) \mathbf{h}$ to a $3F_{3, 2n-3}$ distribution, that is, $n\hat{\kappa} \mathbf{h}^T (\mathbf{I}_3 - \boldsymbol{\Sigma}) \mathbf{h}/3$ is compared to an F-distribution with 3 and $2n - 3$ degrees of freedom. Alternatively, a confidence region for \mathbf{A} is $\{\hat{\mathbf{A}} \Phi(\mathbf{h}) \mid n\hat{\kappa} \mathbf{h}^T (\mathbf{I}_3 - \boldsymbol{\Sigma}) \mathbf{h} < 3F_{3, 2n-3, \alpha}\}$.

Note that in our approximating regression, from (53.28), $\rho_2(\hat{\mathbf{A}})$ plays the role of the error sum squares. So we can use the estimate $\hat{\kappa}^{-1} = \rho_2(\hat{\mathbf{A}}) / (2n - 3)$.

Finally we note that if $\boldsymbol{\Sigma} = \lambda_1 \mathbf{e}_1 \mathbf{e}_1^T + \lambda_2 \mathbf{e}_2 \mathbf{e}_2^T + \lambda_3 \mathbf{e}_3 \mathbf{e}_3^T$ is an eigendecomposition of $\boldsymbol{\Sigma}$, then $\lambda_1 + \lambda_2 + \lambda_3 = \text{Tr}(\boldsymbol{\Sigma}) = \text{Tr}(n^{-1} \sum \mathbf{u}_i \mathbf{u}_i^T) = n^{-1} \sum \text{Tr}(\mathbf{u}_i \mathbf{u}_i^T) = n^{-1} \sum \text{Tr}(\mathbf{u}_i^T \mathbf{u}_i) = 1$, using (53.25), and hence the eigenvalues of $\mathbf{I}_3 - \boldsymbol{\Sigma}$ are $\lambda_2 + \lambda_3, \lambda_1 + \lambda_3, \lambda_1 + \lambda_2$. Thus,

$$\begin{aligned} (\mathbf{I}_3 - \boldsymbol{\Sigma})^{-1} &= (\lambda_2 + \lambda_3)^{-1} \mathbf{e}_1 \mathbf{e}_1^T + (\lambda_1 + \lambda_3)^{-1} \mathbf{e}_2 \mathbf{e}_2^T \\ &\quad + (\lambda_1 + \lambda_2)^{-1} \mathbf{e}_3 \mathbf{e}_3^T. \end{aligned}$$

Theorem 31.4.4 and the results of Sect. 31.4.9 of [1] are expressed using this identity.

Ordering the eigenvalues and eigenvectors so that $\lambda_1 \geq \lambda_2 \geq \lambda_3$, \mathbf{e}_1 will be the center of the \mathbf{u}_i , and \mathbf{e}_3 will be perpendicular the great circle that best fits the \mathbf{u}_i . Then \mathbf{h} will have the greatest variability in the direction \mathbf{e}_1 and the least in the direction \mathbf{e}_3 . In the plate tectonic context, using heuristic reasoning, Stock and Molnar (see [12, 13]) predicted this behavior.

53.6 The Reconstruction of Tectonic Plate Motions from Magnetic Anomaly Lineations

Mathematically, the approach used in the derivations in Sects. 53.2.1, 53.5.1, and 53.5.2 was to use (first order) Taylor series approximations together with appropriately chosen tangent space approximations. The result was an approximating regression problem which is then analyzed using elementary least squares (regression) results. However, in Sect. 53.5.2, each \mathbf{v}_i has its own basepoint $\mathbf{A} \mathbf{u}_i$ for a tangent space approximation, and the resulting regression problem took place in multiple tangent spaces. Some matrix manipulation was necessary to “unify the basepoints” before applying standard regression results. This matrix manipulation, although tedious, is routine and masks the actually simple nature of the arguments in Sect. 53.5.2.

The spherical regression model assumes an idealized form of the data that, in fact, does not exist in plate tectonics. We discuss in this section the reconstruction of tectonic plate motions using experimentally measured locations on “marine magnetic anomaly lineations.” As we shall see the statistical justification for the proposed methodology closely follows the general outline of the previous paragraph. This discussion is based upon [14].

Marine magnetic anomaly lineation data is used to estimate the relative motion of two plates that are diverging at a mid-oceanic ridge. Molten lava is extruded at or near the ridge axis and hardens essentially immediately after extrusion. The new crustal material moves away from the ridge, carried by the plates, as if on diverging conveyer belts. If we could identify on each plate the material that was extruded at the same time, we would have two isochrons, one on each side of the ridge. The two paired isochrons would be congruent, each having the shape of the ridge at the common time of their extrusion. Since the two isochrons are congruent, there is a rotation \mathbf{A} so that if \mathbf{u} is a point on the U-plate isochron, then $\mathbf{A} \mathbf{u}$ would be (in the absence of

error) the homologous point on the V-plate isochron. Thus, if we could identify homologous pairs $(\mathbf{u}_i, \mathbf{v}_i)$, they could be used in a spherical regression to estimate \mathbf{A} and statistically assess the errors in the estimate. $\hat{\mathbf{A}}^T$ is said to reconstruct the past (at the common time of extrusion) position of the V-plate to the U-plate in a coordinate system fixed in the U-plate.

A very helpful figure due to Muller et al. [15] is available at https://commons.wikimedia.org/wiki/File:Age_of_oceanic_lithosphere.jpg.

It shows the mid-Atlantic ridge (solid black line) between South America and Africa. Regions of crustal material of the same color were extruded from the ridge in the same time interval and have the shape of the ridge at the common time of their extrusion. They occur in matching congruent pairs, one on each side of the ridge.

Careful examination of the shape of the mid-Atlantic ridge in Muller et al. [15] shows that it has a rather piecewise linear shape. The dominant direction of the segments of this piecewise linear shape is roughly parallel to the ridge. However, there are cross segments that are due to “fracture zones.” On the sea floor bottom, fracture zones look like valleys and can be detected by bathymetric measurement.

Figure 53.1 is a stylized diagram of a mid-oceanic ridge (solid black line) with two pairs of matching isochrons, dated 10 and 20 million years before present (mybp), one isochron of each pair on each side of the ridge. Two isochrons of the same age are congruent. However, the shape of the ridge does change with time, so isochrons of different ages are not necessarily congruent. A hypothetical homologous pair $(\mathbf{u}_1, \mathbf{v}_1)$ is also shown.

The cooling solid rock acquires a direction of magnetization that is determined by the location of the north magnetic pole at the time of cooling below the “blocking tempera-

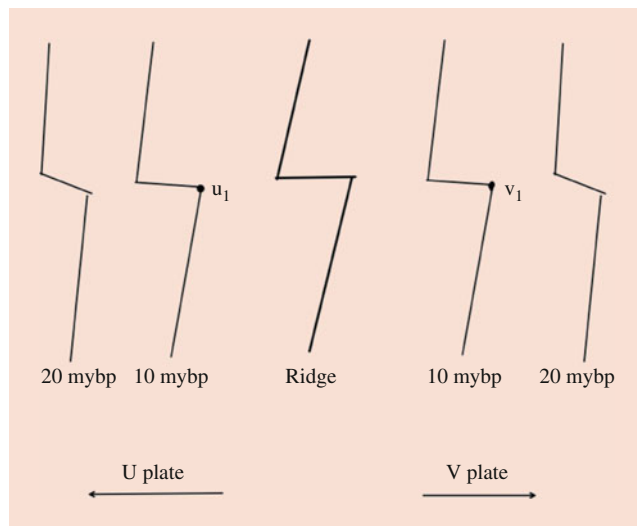

Fig. 53.1 Stylized diagram of a mid-oceanic ridge with two pairs of matching isochrons

ture of magnetization.” At specific times in the past, the “magnetic anomalies,” the north magnetic pole shifted to the geographic south. For example, the A6 anomaly occurred approximately 20 million years ago. Research vessels can measure the sea floor’s magnetic field as they cross the ocean. After subtracting the effects of the dominant magnetization (of the current magnetic field), a skilled geophysicist can determine when the vessel crossed the isochron of a specific magnetic anomaly. Thus, the data consists of identified locations of crossings of the magnetic anomaly lineation.

A research vessel is unlikely to collect crossing locations of opposing isochrons in homologous pairs. Thus, the spherical regression model does not apply.

53.6.1 The Hellinger Criterion to Fit Estimate a Reconstruction

Hellinger [16] proposed an approach for estimating \mathbf{A} . In the Hellinger framework, the isochrons are modeled as piecewise great circle segments. Let $\boldsymbol{\eta}_1, \boldsymbol{\eta}_2, \dots, \boldsymbol{\eta}_s$ denote the normal vectors to the great circle segments on the U-side isochron. Then $\mathbf{A}\boldsymbol{\eta}_1, \mathbf{A}\boldsymbol{\eta}_2, \dots, \mathbf{A}\boldsymbol{\eta}_s$ are the normal vectors to the great circle segments on the V-side isochron. Let $\mathbf{u}_{ij}, i = 1, \dots, s, j = 1, \dots, m_i$ denote the estimated crossings of the U-side isochron; here i indexes the isochron segment. Let $\mathbf{v}_{ik}, i = 1, \dots, s, k = 1, \dots, n_i$ denote the estimated crossings on the V-side isochron. The crossings on the U-side are not paired with those on the V-side so m_i and n_i are generally different. See Fig. 53.2.

The isochron crossings can be identified with differing levels of precision. Each magnetic anomaly has a characteristic squiggle that should be reflected in the magnetic record of the ship’s trajectory. The Hellinger methodology allows the scientist to assign uncertainty constants κ_{ij} and $\tilde{\kappa}_{ik}$ to each estimated crossing, based upon, for example, the difficulty of identifying the different characteristic squiggles. In essence, subject to an overall unknown “fudge factor” κ , $(\kappa \kappa_{ij})^{-1/2}$ represents the standard deviation of the error of \mathbf{u}_{ij} in the direction $\boldsymbol{\eta}_i$. $\tilde{\kappa}_{ik}$ has a similar interpretation.

Hellinger proposed to simultaneously estimate \mathbf{A} and the $\boldsymbol{\eta}_i$ by minimizing the objective function

$$r(\mathbf{A}, \boldsymbol{\eta}_1, \boldsymbol{\eta}_2, \dots, \boldsymbol{\eta}_s) = \sum_{i,j} \kappa_{ij} (\mathbf{u}_{ij}^T \boldsymbol{\eta}_i)^2 + \sum_{i,k} \tilde{\kappa}_{ik} (\mathbf{v}_{ik}^T \mathbf{A} \boldsymbol{\eta}_i)^2. \quad (53.29)$$

Notice that (53.29) is a weighted sum of the square distances from the identified crossings to the corresponding isochron segments.

Fig. 53.2 U-side and V-side isochrons with present day ridge (darkest). Section normal vectors $\eta_1, \eta_2, \eta_3, A\eta_1, A\eta_2, A\eta_3$. Ship trajectory (lightest line), crossings u_{11} (U-side segment 1), v_{32} (V-side segment 3)

53.6.2 Statistical Analysis of the Hellinger Estimate

We will use Taylor linearization together with tangent space approximations to $SO(3)$ and to S^2 at each u_{ij}, v_{ik} to build an approximating regression for which (53.29) is asymptotically equivalent to the regression's sum of squares.

The errors in this type of data are quite small, around 10 km, so large κ approximations are fully appropriate. Thus, we use separate local “flat Earth” approximations at each data point u_{ij}, v_{ik} . The total reach of the isochrons is quite extensive, so using a global flat Earth mapping (such as latitude and longitude) would introduce substantial distortion.

We assume that u_{ij}, v_{ik} are measurements of “true” locations $\alpha_{ij}, \tilde{\alpha}_{ik}$ with $\alpha_{ij}^T \eta_i = 0, \tilde{\alpha}_{ik}^T A\eta_i = 0$. Choose unit vectors $\beta_{ij}, \tilde{\beta}_{ik}$ so that $\alpha_{ij}, \beta_{ij}, \eta_i$ and $\tilde{\alpha}_{ik}, \tilde{\beta}_{ik}, A\eta_i$ form right-hand-rule-oriented orthonormal coordinate systems of R^3 . Let $\lambda_{ij}, \tilde{\lambda}_{ik}$ be fixed “tangential” error constants.

In the data space write the tangential approximations

$$\begin{aligned} u_{ij} &= (u_{ij}^T \alpha_{ij}) \alpha_{ij} + \epsilon_{ij} \approx \alpha_{ij} + \epsilon_{ij}, \\ v_{ik} &= (v_{ik}^T \tilde{\alpha}_{ik}) \tilde{\alpha}_{ik} + \tilde{\epsilon}_{ik} \approx \tilde{\alpha}_{ik} + \tilde{\epsilon}_{ik} \end{aligned} \quad (53.30)$$

where $\epsilon_{ij}^T \alpha_{ij} = 0, \tilde{\epsilon}_{ik}^T \tilde{\alpha}_{ik} = 0$. We assume that as $\kappa \rightarrow \infty$, the vectors $\epsilon_{ij} \in \alpha_{ij}^\perp$ have bivariate normal distributions with mean 0 and variance covariance matrices $(\kappa \kappa_{ij})^{-1} \eta_i \eta_i^T + (\kappa \lambda_{ij})^{-1} \beta_{ij} \beta_{ij}^T$. In essence, α_{ij}^\perp is spanned by η_i and β_{ij} and we are assuming that the component of ϵ_{ij}

in the direction η_i has variance $(\kappa \kappa_{ij})^{-1}$ and its component in the direction β_{ij} has variance $(\kappa \lambda_{ij})^{-1}$. Similar assumptions are made about the distribution of the $\tilde{\epsilon}_{ik} \in \tilde{\alpha}_{ik}^\perp$.

The parameters in this problem are $A \in SO(3)$ and the $\eta_i \in S^2$. Tangentially approximate their estimates by

$$\hat{\eta}_i \approx \eta_i + \xi_i, \quad \hat{A} = A\Phi(\mathbf{h}) \approx A(\mathbf{I} + \mathbf{H}) \quad (53.31)$$

where $\xi_i \in \eta_i^\perp$, \mathbf{H} is 3×3 skew symmetric whose components make up the 3-vector \mathbf{h} using the conventions of the previous section or equation (53.14). We seek the distribution of \mathbf{h} . Substituting (53.30) and (53.31), using $\eta_i^T \alpha_{ij} = 0, \eta_i^T A^T \tilde{\alpha}_{ik} = 0$, and ignoring lower order terms

$$\begin{aligned} r(\hat{A}, \hat{\eta}_1, \hat{\eta}_2, \dots, \hat{\eta}_s) &\approx \sum_{i,j} \kappa_{ij} (\alpha_{ij}^T \xi_i + \epsilon_{ij}^T \eta_i)^2 \\ &+ \sum_{i,k} \tilde{\kappa}_{ik} (\tilde{\alpha}_{ik}^T A \xi_i + \tilde{\alpha}_{ik}^T A \mathbf{H} \eta_i + \tilde{\epsilon}_{ik}^T A \eta_i)^2 \end{aligned} \quad (53.32)$$

Furthermore,

$$\begin{aligned} \tilde{\alpha}_{ik}^T A \mathbf{H} \eta_i &= (A^T \tilde{\alpha}_{ik})^T \mathbf{H} \eta_i = \mathbf{h}^T (\eta_i \times (A^T \tilde{\alpha}_{ik})) \\ &= \mathbf{h}^T (A^T \tilde{\beta}_{ik}) = (A^T \tilde{\beta}_{ik})^T \mathbf{h} \end{aligned}$$

By assumption $y_{ij} = \epsilon_{ij}^T \eta_i$ and $\tilde{y}_{ik} = \tilde{\epsilon}_{ik}^T A \eta_i$ are distributed (univariate) $N(0, (\kappa \kappa_{ij})^{-1})$ and $N(0, (\kappa \tilde{\kappa}_{ik})^{-1})$, respectively.

Thus (53.32) is the error sum squares of the weighted regression model

$$y_{ij} = -\alpha_{ij}^T \xi_i + \epsilon_{ij}$$

$$\tilde{y}_{ik} = -\tilde{\alpha}_{ik}^T A \xi_i - (A^T \tilde{\beta}_{ik})^T \mathbf{h} + \tilde{\epsilon}_{ik}.$$

Referring to the standard form of the regression model

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon},$$

design matrix \mathbf{X} has $\sum(m_i + n_i)$ rows, one for each crossing point. The vector $\boldsymbol{\beta}$ has $3 + 2s$ entries, 3 for \mathbf{h} and 2 for each ξ_i . It is actually an error vector so its “true” value is $\mathbf{0}$. The assigned uncertainties $\kappa_{ij}, \tilde{\kappa}_{ik}$ are the diagonal entries of the weight matrix \mathbf{W} .

In fact there is no \mathbf{y} vector and no fitted values of $\boldsymbol{\beta}$. But we can estimate its covariance matrix $\kappa^{-1}(\mathbf{X}^T \mathbf{W} \mathbf{X})^{-1}$ by estimating κ^{-1} from $r(\hat{A}, \hat{\eta}_1, \hat{\eta}_2, \dots, \hat{\eta}_s)$ that plays the role of the regression residual sum squares, and $\mathbf{X}^T \mathbf{W} \mathbf{X}$ from the data. That, together with the estimates $\hat{A}, \hat{\eta}_i$ obtained by minimizing (53.29), is sufficient for statistical procedures.

At this point it is easier to write a program to implement the procedure than to explain in detail what is actually done. [17] describes a package of programs for plate reconstructions.

Fig. 53.3 Stylized diagram of Indian Ocean triple junction, after Royer & Chang [18]. Stippled region is area of possible (slow) convergence between Australia and India

53.6.3 Additional Work Using Hellinger Estimates

Examining Muller et al. [15], one can see a triple junction of three diverging plate boundaries in the Indian Ocean. A stylized picture of the geometry of the triple junction (between Africa, Antarctica, and Australia) is shown in Fig. 53.3. The regression model of the previous section can be extended to analyze triple junctions.

In addition, if two plates do not share a diverging boundary, one can calculate their relative motion by combining rotations to a third plate with divergent boundaries to both plates: If \mathbf{A} takes the U-plate to the V-plate and \mathbf{B} takes the U-plate to the W-plate, then $\mathbf{C} = \mathbf{B}\mathbf{A}^T$ takes the V-plate to the W-plate and one can estimate, again through Taylor linearization, the errors in $\hat{\mathbf{C}} = \hat{\mathbf{B}}\hat{\mathbf{A}}^T$ from those of its constituent estimated rotations.

In particular, let $\hat{\mathbf{A}} = \mathbf{A}\Phi(\mathbf{h}_A)$, $\hat{\mathbf{B}} = \mathbf{B}\Phi(\mathbf{h}_B)$ and write $\hat{\mathbf{C}} = \mathbf{C}\Phi(\mathbf{h}_C)$. Then

$$\begin{aligned} \hat{\mathbf{C}} &= \hat{\mathbf{B}}\hat{\mathbf{A}}^T = \mathbf{B}\Phi(\mathbf{h}_B)(\mathbf{A}\Phi(\mathbf{h}_A))^T \\ &\approx \mathbf{B}(\mathbf{I}_3 + \mathbf{M}(\mathbf{h}_B))(\mathbf{I}_3 + \mathbf{M}(-\mathbf{h}_A))\mathbf{A}^T \\ &= \mathbf{B}(\mathbf{I}_3 + \mathbf{M}(\mathbf{h}_B))\mathbf{A}^T(\mathbf{I}_3 + \mathbf{M}(-\mathbf{A}\mathbf{h}_A)) \\ &= \mathbf{B}\mathbf{A}^T(\mathbf{I}_3 + \mathbf{M}(\mathbf{A}\mathbf{h}_B))(\mathbf{I}_3 + \mathbf{M}(-\mathbf{A}\mathbf{h}_A)) \\ &\approx \mathbf{C}(\mathbf{I}_3 + \mathbf{M}(\mathbf{A}(\mathbf{h}_B - \mathbf{h}_A))) \end{aligned} \quad (53.33)$$

Therefore,

$$\mathbf{h}_C \approx \mathbf{A}(\mathbf{h}_B - \mathbf{h}_A). \quad (53.34)$$

Since $\mathbf{h}_A, \mathbf{h}_B$ are both trivariate normal with mean $\mathbf{0}$ and are independent (since it is physically impossible for the same crossing to be on both boundaries), it suffices to estimate

$$\widehat{\text{Cov}}(\mathbf{h}_C) = \hat{\mathbf{A}}(\widehat{\text{Cov}}(\mathbf{h}_A) + \widehat{\text{Cov}}(\mathbf{h}_B))\hat{\mathbf{A}}^T \quad (53.35)$$

Statistical error analysis is needed to discern if small misfits in plate reconstructions are genuine or due to “statistical error.” Using these techniques, [18] determined that the Indo-Australian plate is actually two component plates with a relatively small converging internal movement. It is relevant to note that an area of increased seismic activity and seafloor undulations indicate where the boundary between India and Australia should be if the two component plates do not move rigidly together.

The rotation of India to Australia was estimated by combining the estimated rotations $\hat{\mathbf{A}}$ of Africa (U-plate) to India (V-plate) and $\hat{\mathbf{B}}$ of Africa to Australia (W-plate). The latter was constrained by the Indian Ocean triple junction. See again Fig. 53.3.

Now letting $\hat{\mathbf{C}} = \hat{\mathbf{B}}\hat{\mathbf{A}}^T$, one solves $\hat{\mathbf{C}} = \Phi(\mathbf{h}_C)$ for \mathbf{h}_C . Using (53.35) to estimate $\text{Cov}(\mathbf{h}_C)$. [18] found that $\mathbf{h}_C^T[\widehat{\text{Cov}}(\mathbf{h}_C)]^{-1}\mathbf{h}_C$ is significant compared to a χ_3^2 distribution and concluded that \mathbf{C} is not the identity, or equivalently, $\mathbf{A} \neq \mathbf{B}$.

Since then the Indo-Australian plate has been modeled as a composite plate with 4 component plates (Indian, Capricorn, Australian, and Macquarie), see for example DeMets, Gordon, and Royer [19]. In essence they propose modeling nonrigidities in a plate by using a collection of small component plates that move slowly relatively to each other and slower than the overall motion of the ambient larger plate. The same approach, and the software in [17], was used.

Once one is able to produce good approximating regressions, one can create spherical regression analogs of existing linear regression tools. For example, a straight forward use of weighted linear regression requires that all uncertainty constants $\kappa_{ij}, \tilde{\kappa}_{ik}$ be assigned with a common fudge factor κ . However, different fudge factors might be preferred, especially when working with multiple plate boundaries. This is essentially a spherical regression version of the classical Behrens-Fisher problem. Kirkwood [20] applied the solution of Johansen [21] for the analogous problem in the linear regression setting to solve the problem of multiple κ 's.

The Hellinger model assumes that the lineations are composed of great circle segments. As data becomes more numerous, this approximation can be called into question. Some preliminary work by H. Hendriks, R. Yang, and Chang assumed that the deviations of these segments from a great

circle can be modeled as a Brownian bridge. This work is incomplete, but the author believes that curved segment model is a problem that should soon be addressed.

53.7 Summary

In geometric statistical problems, the parameter is often a manifold. When employing Taylor series methods to study the asymptotic behavior of parameter estimates, it is necessary to map (reparameterize) the manifold into Euclidean space. Rather than reparameterizing the manifold globally, it is often better to use a local parameterization from a tangent space approximation.

When the data is also non-Euclidean, a data transformation of the data space to globally turn it into Euclidean space is usually inappropriate. Rather, when the errors in the data are small relative to the curvature of the data space, “local flat Earth” approximations are appropriate and, in this case, tangent space approximations to the data space are called for. With “local flat Earth” approximation, an approximating linear regression can often be found and the problem can be studied using standard regression methodology.

This chapter has described the underlying mathematical constructs and applied this process to four problems of increasing complexity.

Acknowledgments The author wishes to acknowledge the encouragement of Prof. Sang-mook Lee, a geophysics professor at Seoul National University. Prof. Lee admonished the author that it is his “scientific duty” to explain, in as elementary manner as possible, the mathematics underlying his work. His dedication to science and his cheerfulness inspire all who have met him. This chapter has been written to honor him.

Appendix

In this section, we outline the derivation of the formula for the errors in the estimate $\hat{\mathbf{C}} = \hat{\mathbf{B}}\hat{\mathbf{A}}^T$ of a combined rotation $\mathbf{C} = \mathbf{B}\mathbf{A}^T$ using the commonly used parameterization (axis latitude, axis longitude, angle of rotation), or (λ, θ, ρ) , of a rotation matrix in $\text{SO}(3)$. In other words, we derive the analogue to (53.35) using (λ, θ, ρ) and restrict ourselves to the case $k = 3$.

This parameterization is geometrically unnatural. We will see that, as mentioned in Sect. 53.4.2, ignoring the geometry of $\text{SO}(3)$ leads to a far messier version of (53.35).

Quaternion Representation of $\text{SO}(3)$

To work in the parameters (λ, θ, ρ) of a rotation, it is easier to use the quaternion representation of a rotation rather than its matrix representation.

The quaternions are a four dimensional extension of the real numbers in the same sense that the complex numbers are a two-dimensional extension of the reals. In particular, the quaternions are $\mathbb{Q} = \{\mathbf{q} = q_0 + q_1\mathbf{i} + q_2\mathbf{j} + q_3\mathbf{k} \mid q_0, q_1, q_2, q_3 \in \mathbb{R}\}$. \mathbf{i}, \mathbf{j} , and \mathbf{k} are special quaternions that play a similar role in \mathbb{Q} to the role of i in the complex numbers.

Multiplication in \mathbb{Q} is defined by the rules

$$\begin{aligned} i^2 = j^2 = k^2 = -1, \quad ij = -ji = k, \quad jk = -kj = i, \\ ki = -ik = j. \end{aligned} \quad (53.36)$$

\mathbb{Q} satisfies all the usual rules of algebra except that, as apparent in (53.36), multiplication is not commutative.

If $\mathbf{q} = q_0 + q_1\mathbf{i} + q_2\mathbf{j} + q_3\mathbf{k} \in \mathbb{Q}$, its “conjugate” is $\bar{\mathbf{q}} = q_0 - q_1\mathbf{i} - q_2\mathbf{j} - q_3\mathbf{k}$. Thus, the unit sphere $S^3 \subset \mathbb{R}^4$ can be represented as the set of “unit length quaternions,” that is, those quaternions $\mathbf{q} = q_0 + q_1\mathbf{i} + q_2\mathbf{j} + q_3\mathbf{k}$ that satisfy

$$\mathbf{q}\bar{\mathbf{q}} = \bar{\mathbf{q}}\mathbf{q} = q_0^2 + q_1^2 + q_2^2 + q_3^2 = 1.$$

Indeed it is easily checked that the Euclidean \mathbb{R}^4 dot product between quaternions \mathbf{q}_1 and \mathbf{q}_2 is $(\bar{\mathbf{q}}_1\mathbf{q}_2 + \bar{\mathbf{q}}_2\mathbf{q}_1) / 2$. Note also that $\bar{\mathbf{q}}_1\bar{\mathbf{q}}_2 = \bar{\mathbf{q}}_2\bar{\mathbf{q}}_1$.

So if a rotation \mathbf{A} has axis latitude, axis longitude, and angle of rotation (λ, θ, ρ) , its quaternion representation is

$$\mathbf{q} = \cos \frac{\rho}{2} + \sin \frac{\rho}{2} (\sin \lambda \cos \theta \mathbf{i} + \sin \lambda \sin \theta \mathbf{j} + \cos \lambda \mathbf{k}). \quad (53.37)$$

The “pure quaternions” can be identified as $\mathbb{R}^3 \approx \{\tilde{\mathbf{x}} = x_1\mathbf{i} + x_2\mathbf{j} + x_3\mathbf{k}\}$. In this way, we see that $\sin(\lambda)$

$\cos(\theta)\mathbf{i} + \sin(\lambda)\sin(\theta)\mathbf{j} + \cos(\lambda)\mathbf{k}$ is the pure quaternion representation of the axis of \mathbf{A} .

In general, if $\mathbf{x} \in \mathbf{R}^3$ is represented as a 3×1 vector, then we will denote its representation as a pure quaternion by $\tilde{\mathbf{x}}$. It can easily be verified that the pure quaternion representation of \mathbf{Ax} is $q\tilde{\mathbf{x}}\bar{q}$.

It is clear that q is a unit length quaternion and that q and $-q$ represent the same rotation. Mathematically we say that $\text{SO}(3)$ is “doubly covered” by S^3 .

This double covering of $\text{SO}(3)$ by S^3 is a disguised form of the long known “Cayley-Klein” parameters. For $q = q_0 + q_1\mathbf{i} + q_2\mathbf{j} + q_3\mathbf{k}$, let

$$\mathbf{H}(q) = \begin{bmatrix} q_0 - q_3i & -q_2 - q_1i \\ q_2 - q_1i & q_0 + q_3i \end{bmatrix}. \quad (53.38)$$

It is easily checked that $\det(\mathbf{H}(q)) = 1$ and that $\mathbf{H}(q)\overline{\mathbf{H}(q)}^T = \mathbf{I}_2$. The collection of 2×2 complex matrices \mathbf{A} that satisfy $\det(\mathbf{A}) = 1$ and $\mathbf{A}\bar{\mathbf{A}}^T = \mathbf{I}_2$ is called the “special unitary” group, denoted by $\text{SU}(2)$ and (53.38) identifies S^3 with $\text{SU}(2)$. Thus, $\mathbf{H}(q) \rightarrow \mathbf{A}$ defines a double covering of $\text{SO}(3)$ by $\text{SU}(2)$. For a more classical description of the Cayley-Klein parameters, see, for example, Goldstein [22].

Combining Two Rotations Using Quaternionic Representation

The tangent vectors to S^3 at 1, considered as a unit length quaternion and hence an element of S^3 , are the pure quaternions. Hence, the tangent vectors at $q \in S^3$ have the form $q\tilde{\mathbf{x}}$ where $\tilde{\mathbf{x}}$ is pure quaternion. Hence, we write

$$q_A \approx q + q_A\tilde{\mathbf{x}}_A \quad (53.39)$$

where $\tilde{\mathbf{x}}_A$ is pure quaternion.

If $\mathbf{C} = \mathbf{BA}^T$, then $q_C = q_B\bar{q}_A$. Thus,

$$\begin{aligned} q_C + q_C\tilde{\mathbf{x}}_C &\approx q_C\tilde{\mathbf{x}}_C \approx q_B\bar{q}_A\tilde{\mathbf{x}}_C \approx (q_B + q_B\tilde{\mathbf{x}}_B)(\bar{q}_A - \tilde{\mathbf{x}}_A\bar{q}_A) \\ &\approx q_B\bar{q}_A + q_B\tilde{\mathbf{x}}_B\bar{q}_A - q_B\tilde{\mathbf{x}}_A\bar{q}_A \end{aligned}$$

$$\tilde{\mathbf{x}}_C \approx \bar{q}_C(q_B\tilde{\mathbf{x}}_B\bar{q}_A - q_B\tilde{\mathbf{x}}_A\bar{q}_A) = q_A(\tilde{\mathbf{x}}_B - \tilde{\mathbf{x}}_A)\bar{q}_A. \quad (53.40)$$

(53.40) is the quaternionic version of (53.34). Indeed, by carefully following all the identifications in section “Quaternion Representation of $\text{SO}(3)$ ”, it can be shown that if we also write $\hat{\mathbf{A}} = \mathbf{A}\Phi(\mathbf{h}_A)$, then the 3-vector representation of $\tilde{\mathbf{x}}_A$ is $\mathbf{x}_A = \mathbf{h}_A/2$, and hence (53.40) would follow from (53.34).

Combining Two Rotations Using Axis Latitude, Longitude, and Angle of Rotation

We now compute the change of variables from $[\hat{\lambda} - \lambda \hat{\theta} - \theta \hat{\rho} - \rho]^T$ to \mathbf{x} . We will apply the Taylor approximations $\sin\left(\frac{\rho}{2}\right) \approx \sin\left(\frac{\rho}{2}\right) + \cos\left(\frac{\rho}{2}\right)(\hat{\rho} - \rho)/2$ and $\cos\left(\frac{\rho}{2}\right) \approx \cos\left(\frac{\rho}{2}\right) - \sin\left(\frac{\rho}{2}\right)(\hat{\rho} - \rho)/2$ and similar approximations for λ, θ in (53.37) to arrive at

$$\begin{aligned} \hat{q} &\approx q - \sin\frac{\rho}{2}\frac{(\hat{\rho}-\rho)}{2} \\ &\quad + \cos\frac{\rho}{2}\frac{(\hat{\rho}-\rho)}{2}(\sin\lambda\cos\theta\mathbf{i} + \sin\lambda\sin\theta\mathbf{j} + \cos\lambda\mathbf{k}) \\ &\quad + \sin\frac{\rho}{2}\cos\lambda(\hat{\lambda} - \lambda)(\cos\theta\mathbf{i} + \sin\theta\mathbf{j}) \\ &\quad + \sin\frac{\rho}{2}\sin\lambda(-\sin\theta\mathbf{i} + \cos\theta\mathbf{j})(\hat{\theta} - \theta) \\ &\quad - \sin\frac{\rho}{2}\sin\lambda(\hat{\lambda} - \lambda)\mathbf{k}. \end{aligned}$$

So

$$\hat{q} - q \approx \begin{bmatrix} \sin\frac{\rho}{2}(\cos\lambda\cos\theta\mathbf{i} + \cos\lambda\sin\theta\mathbf{j} - \sin\lambda\mathbf{k}) \\ \sin\frac{\rho}{2}(-\sin\lambda\sin\theta\mathbf{i} + \sin\lambda\cos\theta\mathbf{j}) \\ -\frac{1}{2}\sin\frac{\rho}{2} + \frac{1}{2}\cos\frac{\rho}{2}(\sin\lambda\cos\theta\mathbf{i} + \sin\lambda\sin\theta\mathbf{j} + \cos\lambda\mathbf{k}) \end{bmatrix}^T \begin{bmatrix} \hat{\lambda} - \lambda \\ \hat{\theta} - \theta \\ \hat{\rho} - \rho \end{bmatrix}$$

and, after substituting (53.37) and substantial simplification,

$$\tilde{\mathbf{x}} = \bar{q}(\hat{q} - q) \approx \begin{bmatrix} F_{11}\mathbf{i} + F_{21}\mathbf{j} + F_{31}\mathbf{k} \\ F_{12}\mathbf{i} + F_{22}\mathbf{j} + F_{32}\mathbf{k} \\ F_{13}\mathbf{i} + F_{23}\mathbf{j} + F_{33}\mathbf{k} \end{bmatrix}^T \begin{bmatrix} \hat{\lambda} - \lambda \\ \hat{\theta} - \theta \\ \hat{\rho} - \rho \end{bmatrix} \quad (53.41)$$

where

$$F_{11} = \sin\frac{\rho}{2}\left(\cos\frac{\rho}{2}\cos\lambda\cos\theta + \sin\frac{\rho}{2}\sin\theta\right)$$

$$F_{21} = \sin\frac{\rho}{2}\left(\cos\frac{\rho}{2}\cos\lambda\sin\theta - \sin\frac{\rho}{2}\cos\theta\right)$$

$$F_{31} = -\sin\frac{\rho}{2}\cos\frac{\rho}{2}\sin\lambda$$

$$F_{12} = -\sin\frac{\rho}{2}\sin\lambda\left(\cos\frac{\rho}{2}\sin\theta - \sin\frac{\rho}{2}\cos\lambda\cos\theta\right)$$

$$F_{22} = \sin\frac{\rho}{2}\sin\lambda\cos\theta\left(\cos\frac{\rho}{2} + \sin\frac{\rho}{2}\cos\lambda\right)$$

$$\begin{aligned}
 F_{32} &= -\left(\sin \frac{\rho}{2} \sin \lambda\right)^2 \\
 F_{13} &= \frac{1}{2} \sin \lambda \cos \theta \\
 F_{23} &= \frac{1}{2} \sin \lambda \sin \theta \\
 F_{33} &= \frac{1}{2} \cos \lambda.
 \end{aligned} \tag{53.42}$$

Rewriting (53.41) in real vector-matrix form

$$\mathbf{x} = \mathbf{F}(\lambda, \theta, \rho) \begin{bmatrix} \hat{\lambda} - \lambda \\ \hat{\theta} - \theta \\ \hat{\rho} - \rho \end{bmatrix}$$

where $\mathbf{F}(\lambda, \theta, \rho)$ is the 3×3 matrix with real entries F_{ij} .

Recall that the pure quaternion representation of \mathbf{Ax} is $q\tilde{x}\bar{q}$. Thus, using (53.40)

$$\mathbf{x}_C \approx \mathbf{A}(\mathbf{x}_B - \mathbf{x}_A)$$

$$\begin{aligned}
 \mathbf{F}(\lambda_C, \theta_C, \rho_C) \begin{bmatrix} \widehat{\lambda}_C - \lambda_C \\ \widehat{\theta}_C - \theta_C \\ \widehat{\rho}_C - \rho_C \end{bmatrix} &\approx \mathbf{A} \left(\mathbf{F}(\lambda_B, \theta_B, \rho_B) \begin{bmatrix} \widehat{\lambda}_B - \lambda_B \\ \widehat{\theta}_B - \theta_B \\ \widehat{\rho}_B - \rho_B \end{bmatrix} \right. \\
 &\left. - \mathbf{F}(\lambda_A, \theta_A, \rho_A) \begin{bmatrix} \widehat{\lambda}_A - \lambda_A \\ \widehat{\theta}_A - \theta_A \\ \widehat{\rho}_A - \rho_A \end{bmatrix} \right).
 \end{aligned}$$

It follows that

$$\begin{aligned}
 \widehat{\mathbf{Cov}} \left(\begin{bmatrix} \widehat{\lambda}_C - \lambda_C \\ \widehat{\theta}_C - \theta_C \\ \widehat{\rho}_C - \rho_C \end{bmatrix} \right) &= \mathbf{G} \widehat{\mathbf{Cov}} \left(\begin{bmatrix} \widehat{\lambda}_B - \lambda_B \\ \widehat{\theta}_B - \theta_B \\ \widehat{\rho}_B - \rho_B \end{bmatrix} \right) \mathbf{G}^T \\
 &+ \mathbf{H} \widehat{\mathbf{Cov}} \left(\begin{bmatrix} \widehat{\lambda}_A - \lambda_A \\ \widehat{\theta}_A - \theta_A \\ \widehat{\rho}_A - \rho_A \end{bmatrix} \right) \mathbf{H}^T
 \end{aligned} \tag{53.43}$$

where

$$\mathbf{G} = \mathbf{F}(\widehat{\lambda}_C, \widehat{\theta}_C, \widehat{\rho}_C)^{-1} \hat{\mathbf{A}} \mathbf{F}(\widehat{\lambda}_B, \widehat{\theta}_B, \widehat{\rho}_B)$$

$$\mathbf{H} = \mathbf{F}(\widehat{\lambda}_C, \widehat{\theta}_C, \widehat{\rho}_C)^{-1} \hat{\mathbf{A}} \mathbf{F}(\widehat{\lambda}_A, \widehat{\theta}_A, \widehat{\rho}_A) \tag{53.44}$$

(53.42)–(53.44) constitute the analogy to (53.35) when the matrix exponential parameterization (53.23) of $\text{SO}(3)$ is replaced by axis latitude, longitude, and angle of rotation.

The Map Maker’s Dilemma (Revisited)

As discussed near equation (53.5), and similar approximations (53.9) and (53.10), when using $\mathbf{e} \in (\mathbf{Au})^\perp$ to represent the deviation $\mathbf{v} \in S^2$ from its “true value” $\mathbf{Au} \in S^2$, we are essentially using a polar projection, centered at \mathbf{Au} , $R^2 \approx (\mathbf{Au})^\perp \rightarrow S^2$. Any map from $R^2 \rightarrow S^2$ is distorting somewhere, but when \mathbf{v} is close to \mathbf{Au} , the distortions in this polar projection will be small.

A parameterization of S^2 by two parameters is essentially a map $R^2 \rightarrow S^2$. The commonly used map (latitude, longitude) is highly distorting near the north and south poles and hence would not be appropriate to represent \mathbf{v} when \mathbf{Au} has a latitude much different from 0° .

Thinking temporarily of the unit quaternions S^3 instead of $\text{SO}(3)$, equation (53.39) represents a point $q_{\hat{A}} \in S^3$, that is, close to $q_A \in S^3$ by a tangent vector $q_A \tilde{x}_A \in q_A^\perp$. Essentially we are mapping S^3 using a polar projection centered at q_A . Hopefully $q_{\hat{A}}$ will be close to q_A and the distortions introduced by the polar projection will be small. Indeed these distortions are asymptotically trivial.

Because of the close relationship of S^3 to $\text{SO}(3)$, the same observations apply to using h_A to represent $\hat{\mathbf{A}}$ as in $\hat{\mathbf{A}} = \mathbf{A}\Phi(h_A)$.

The map $R^3 \rightarrow \text{SO}(3)$ using axis latitude, longitude, and angle of rotation also introduces distortions and these distortions can certainly exist in the area of interest, that is, rotations close to \mathbf{A} . (53.42)–(53.44) are considerably more complicated than (53.35) and this is due to the unfortunate matrices $\mathbf{F}(\lambda, \theta, \rho)$ whose sole functions are to correct the distortions introduced by an inappropriate parameterization of $\text{SO}(3)$.

start from the random utility maximization (RUM) theory and present its basic usage in binary and multinomial choice scenarios. We also present the random regret minimization (RRM) theory and relative advantage maximization (RAM) theory. Some extensions of the RUM are also presented, including the nested logit model that allows dependencies among alternatives and mixed logit model that considers the individual heterogeneity. We illustrate the usage and interpretation of these models through a numeric case study.

Abstract

Human behavior models, especially the choice models, have been developed and widely used in both research and practice for decades. They help explain human behaviors by modeling the choices made by each individual. Successful applications of these models require good understandings of the properties and the assumptions of the models. This chapter summarizes some commonly used discrete choice models in engineering area. Different assumptions toward the mechanism of choice-making behaviors lead to different types of choice models. We

54.1 Introduction

Human behavior modeling has drawn increasing attention for its potential in various realms such as economics, marketing, and engineering. A better understanding on individual preferences and human choice-making behavior may lead to more satisfactory, targeted, and efficient services. Because of this, researchers have never stopped trying to develop models to explain and predict human behavior in different circumstances in the last decades [21, 33, 34]. In this chapter, we focus on the choice-making behaviors that predominate many kinds of human behaviors according to Glasser's choice theory psychology [22]. Many models have been developed and implemented to model choice-making behaviors with different assumptions. One of the most widely accepted models, the discrete choice modeling, is used to describe and predict the probability of selecting a choice from a finite choice set in a probabilistic fashion, based on the Random Utility Maximization (RUM) principle [28]. RUM model requires a preference order over all choices of the finite

alternative set, which means that an axiom of “transitivity” should be satisfied. This means, for example, if alternative A is weakly preferred to alternative B, and B to C, then A is weakly preferred to C. If the preference order fails to meet the requirement of “transitivity,” the utility function in RUM model may not exist, and the choice behavior cannot be formulated following the RUM principle [32].

This specification to represent the utility of an alternative is usually called “context-independent” in studies, assuming that the utility of an alternative is invariant no matter whether other alternatives are present or not [4, 8]. However, this may not be the case when individuals are making choices. Imagine that Susan is considering going for a walk around a lake which is about 2 miles away from her home. She may prefer driving to the lake comparing with taking public transit there. When the two alternatives are taking public transit and biking, she may choose to take the public transit. However, when she is asked to either drive or bike, she would choose to bike. These kinds of non-transitive, circular orderings are pretty common in reality, which means that the traditional RUM model may not be applicable here [32].

Therefore, “context-dependent” models, such as RAM and RRM model where the transitivity on an alternative set may not be bounded, arise. The basic idea of RAM, the relative advantage maximization model, is to add the relative advantage of an alternative into its utility function as a context-dependent component to be maximized [26, 44]. The main hypothesis of RRM, the random regret minimization model, is that people are seeking to minimize the negative emotions when making decisions [14, 16, 26]. One may also regard the context-dependent specification as that people are not absolutely rational but with bounded rationality. This is because that people are bounded by the time and other resources required for their utilization in the face of the urgency and importance of the particular choice problem at hand. Several studies have shown the success of these models in applications.

The purpose of this chapter is to review the important models and techniques that can be used to model and predict user’s choice-making behaviors. For example, with these models, personalized travel choice recommendation systems can promote alternatives that are more likely to be accepted by an individual, helping him/her make plans for travel or triggering desired travel behavioral changes. We will also summarize properties and limitations of each model. This chapter is organized as follows: we start from traditional discrete choice model with RUM specification, including binary logit model, multinomial logit model, nested logit model, and mixed logit model. Then the RRM model is presented, followed by the RAM model. After that, we present a numerical study, in which we apply three models to a single dataset and illustrate how they compare with each other. Toward the end of the chapter, we will also discuss some

other models, such as machine learning methods, the hidden Markov model, and Bayesian statistics that have been useful in recommendation systems.

54.2 The Problem of Discrete Choice Modeling

Transportation is also an area in which discrete choice models are commonly used, since many travel-related choices such as travel mode and destination are discrete, qualitative, and finite [11, 39].

For discrete choice model, there are several requirements for the choice set [39]:

1. The choice set must be a finite set, which means there should be a finite number of alternatives.
2. The choice set includes all possible alternatives the system can offer to a user, and the user will choose an alternative from the set.
3. The alternatives in the choice set should be mutually exclusive, and the user chooses only one alternative from the set.

Discrete choice model considers that an individual’s choice behavior among a finite set of alternatives is influenced by a number of factors, including some socioeconomic and sociodemographic characteristics of the individual, the attributes of the alternatives in the choice set, and the external environments. These factors, together with a set of parameters quantifying the effects of these factors, collectively contribute to the utility that the individual obtains from choosing an alternative.

However, it is practically impossible to include all factors that could impact an individual’s choice in the utility function, since they are probably only partially observed, and it is unlikely that we could measure every factor perfectly and accurately. To count for these unobserved and immeasurable effects, the discrete choice model incorporates stochastic specifications, i.e., random utility terms. Possible causes of the randomness in user behaviors include the unobserved factors of the choices, the preference variation over people (heterogeneity), and correlation among choices in choice sets.

A systematic characterization and notations of the discrete choice problem are presented in Table 54.1. Given the depth of this problem, a range of models have been developed. For example, it is common that the utility function in discrete choice model is expressed in a linear form [9, 39]:

$$U_{ij} = \mathbf{x}_{ij}\boldsymbol{\beta}_i + \epsilon_{ij} = \mathbf{V}_{ij} + \epsilon_{ij} \quad (54.1)$$

where \mathbf{x}_{ij} is a vector of all factors from different categories (as mentioned above) of alternative j for individual i , $\boldsymbol{\beta}_i$ is a

Table 54.1 Table of notations

Notation	Meanings
i	Individual i
j, k	Alternative j , alternative k
m	m th attribute of an alternative
J	Total number of alternatives in a choice set
U_{ij}	Utility of alternative j for individual i
\mathbf{x}_{ij}	Vector of attributes of alternative j for individual i
$\boldsymbol{\beta}_i$	Vector of parameters/preferences of individual i corresponding to all attributes
ϵ	Random term drawn from a certain distribution
V_{ij}	Systematic utility of alternative j for individual i
P_{ij}	Probability for individual i choosing alternative j
y_0	The choice made to alternative 0 in a binary choice. If $y_0 = 1$, the individual accept alternative 0; if not, $y_0 = 0$
ΔV_{01}	Difference between V_0 and V_1
$\mathbf{x}_{1,0}$	Vector of attribute differences between \mathbf{x}_1 and \mathbf{x}_0
$G(\cdot), G(\boldsymbol{\beta} \boldsymbol{\theta})$	A certain type of distribution, with $\boldsymbol{\theta}$ as a set of parameters that could describe the distribution

Notations used in the chapter

vector of parameters that quantify the effects of these factors, and ϵ_{ij} is the random utility term. Here, V_{ij} is the systematic utility, and ϵ_{ij} is the random utility. In what follows, we will introduce a range of models, including the RUM, RAM, and RRM models.

54.3 Random Utility Maximization (RUM) Theory

According to the random utility maximization (RUM) model, individual i chooses the alternative j over all other alternatives because that choice provides the highest utility/benefits she/he could obtain, reflecting a rational behavior of the indi-

vidual. In other words, the probability for him/her to select alternative j over alternative k from a set J is [11, 39]:

$$\begin{aligned} P_{ij} &\equiv P(\text{Individual } i \text{ choosing alternative } j) \\ &= P(U_{ij} \geq U_{ik}) \quad \forall j \neq k \in (1, 2, \dots, J). \end{aligned} \quad (54.2)$$

This is the overall framework, and in what follows we introduce two specific models that expand on this premise.

54.3.1 Binomial Choice Model

Binomial choice model is for circumstances when there are only two alternatives (denoted as alternative 0 and 1). The logit model and probit model are two common examples of binomial choice model. The two models have different assumptions on the random term in Eq. 54.1.

Logit model assumes that the random term ϵ_j in Eq. 54.1 is an i.i.d. (independent and identically distributed) extreme value that follows a Gumbel distribution [39]. Suppose that the utilities of the two alternatives are U_0 and U_1 , respectively. By substituting Eq. 54.1 into Eq. 54.2, we could have the following equation:

$$\begin{aligned} P_0 &= P(U_0 \geq U_1) \\ &= P(V_0 + \epsilon_0 \geq V_1 + \epsilon_1) \\ &= P(V_0 - V_1 \geq \epsilon_1 - \epsilon_0). \end{aligned} \quad (54.3)$$

Since the logit model assumes that the $\epsilon_0 \sim \text{Gumbel}(a_0, b)$ and $\epsilon_1 \sim \text{Gumbel}(a_1, b)$, their difference $\epsilon_1 - \epsilon_0 \sim \text{Logistic}(a_1 - a_0, b)$ follows a logistic distribution [39]. From Eq. 54.3 we could see that the probability for an individual to choose alternative 0 depends only on the difference in utilities between the two alternatives, not on the absolute level of utilities. Thus, we further derive that

$$\begin{aligned} P_0 &= P(V_0 - V_1 \geq \epsilon_1 - \epsilon_0) \\ &= P(\Delta V_{01} \geq \epsilon) \quad (\text{Let } V_0 - V_1 = \Delta V_{01}, \text{ and } \epsilon_1 - \epsilon_0 = \epsilon) \\ &= P(\epsilon \leq \Delta V_{01}) \\ &= \text{logit}^{-1}(\Delta V_{01}) \end{aligned} \quad (54.4)$$

Different from the logic model, the probit model assumes that the random term ϵ_j in Eq. 54.1 follows a standard normal distribution. The two curves shown in Fig. 54.1 represent the two cumulative distribution functions of the two types of the random utility term.

It can be seen that using the Gumbel distribution for the errors (and hence the logistic distribution for the error

differences) is nearly the same as assuming that the errors are independently normal [39]. The difference is that the two tails of the Gumbel distribution are slightly fatter than those of a normal distribution, which means that the Gumbel distribution allows more aberrant behaviors than the normal one. However, the difference is usually indistinguishable empirically [39].

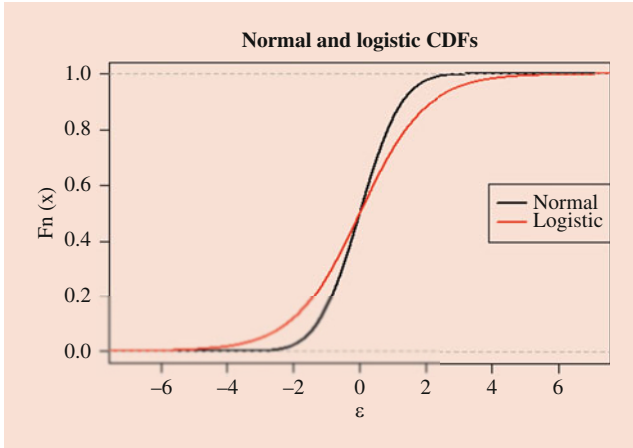

Fig. 54.1 CDFs for norm distribution and logistic distribution

With logistic model specification, the probability for an individual to choose alternative 0 is

$$P_0 = P(y_0 = 1) = \frac{\exp(V_0)}{\exp(V_0) + \exp(V_1)} = \frac{1}{1 + \exp(V_1 - V_0)} \tag{54.5}$$

In the above equation, $V_0 = \beta_0 \mathbf{x}_0$ and $V_1 = \beta_1 \mathbf{x}_1$ are the constant parts of the utilities of the two alternatives. From the equation we could have another property of the discrete choice model: the sum of the probability of all alternatives will equal 1, i.e., $P(y_0 = 1) + P(y_1 = 1) = 1$.

To interpret the estimates of the model, we need to talk about the concept of odds. This term is used to describe the probability of an event (or the probability of a nonevent). For the binary choice model, the odds are

$$\begin{aligned} Odds_{y_0=1} &= \frac{P(y_0 = 1)}{P(y_0 = 0)} = \frac{P(y_0 = 1)}{1 - P(y_0 = 1)} \\ &= \exp(V_1 - V_0) = \exp(\mathbf{x}_{1,0} \boldsymbol{\beta}) \end{aligned} \tag{54.6}$$

where $\mathbf{x}_{1,0}$ is the vector of attribute differences between \mathbf{x}_1 and \mathbf{x}_0 . Take log on both sides; the equation could further be written as

$$\ln(Odds_{y_0=1}) = \mathbf{x}_{1,0} \boldsymbol{\beta} \tag{54.7}$$

We could see the coefficients in a simple logistic model in terms of the log odds. For example, the coefficient β_a in $\boldsymbol{\beta}$ implies that a one-unit change in x_a in $\mathbf{x}_{1,0}$ results in a β_a -unit change in the log of the odds.

The estimation of the binomial logit model uses the maximum likelihood estimation (MLE), with which the estimated parameters for $\boldsymbol{\beta}$ have the greatest likelihood/probability to obtain the observed choices.

We use an example to illustrate the estimation method. Assuming that we have M observed binary choice behaviors $(y_1, \mathbf{x}_1), (y_2, \mathbf{x}_2), \dots, (y_M, \mathbf{x}_M)$ for an individual, we would like to predict his/her choice-making behavior with a binary logit model. For each observation m , assume that $P(y_m = 1) = \frac{\exp(\mathbf{x}_m \boldsymbol{\beta})}{1 + \exp(\mathbf{x}_m \boldsymbol{\beta})}$, and $P(y_m = 0) = 1 - \frac{\exp(\mathbf{x}_m \boldsymbol{\beta})}{1 + \exp(\mathbf{x}_m \boldsymbol{\beta})}$. The likelihood function could be formulated as

$$L(y|\mathbf{x}; \boldsymbol{\beta}) = \prod_{m \in \mathcal{M}_+} \frac{\exp(\mathbf{x}_m \boldsymbol{\beta})}{1 + \exp(\mathbf{x}_m \boldsymbol{\beta})} \prod_{m \in \mathcal{M}_-} \left[1 - \frac{\exp(\mathbf{x}_m \boldsymbol{\beta})}{1 + \exp(\mathbf{x}_m \boldsymbol{\beta})} \right] \tag{54.8}$$

where \mathcal{M}^+ refers to the observations for which $y_m = 1$ and \mathcal{M}^- to the observations for which $y_m = 0$.

The log likelihood function for the example is

$$\begin{aligned} \ln L(y|\mathbf{x}; \boldsymbol{\beta}) &= \sum_{m=1}^M \left\{ y_m \ln \frac{\exp(\mathbf{x}_m \boldsymbol{\beta})}{1 + \exp(\mathbf{x}_m \boldsymbol{\beta})} + (1 - y_m) \left[1 - \ln \frac{\exp(\mathbf{x}_m \boldsymbol{\beta})}{1 + \exp(\mathbf{x}_m \boldsymbol{\beta})} \right] \right\} \\ &= \sum_{m=1}^M \{ y_m [\mathbf{x}_m \boldsymbol{\beta} - \ln(1 + \exp(\mathbf{x}_m \boldsymbol{\beta}))] - (1 - y_m) \ln(1 + \exp(\mathbf{x}_m \boldsymbol{\beta})) \} \end{aligned} \tag{54.9}$$

The MLE of $\boldsymbol{\beta}$ maximizes the log likelihood function of Eq. 54.9.

54.3.2 Multinomial Logit Model

When there are J alternatives ($J > 2$) in the choice set, the multinomial logit model (MNL) casts the problem as a set of $J - 1$ independent binomial choice problems. A “reference” alternative is assigned before the regression such that other $J - 1$ alternatives can compare against it, one at a time. The same applies to the binomial logit model, as one of the

alternative is “reference” and the other is comparing against it. In MNL, any one of the alternative in the choice set could be set as the reference. However, if a reference alternative is decided, it may not be changed in the whole modeling process. Notice that though different reference alternative may return different estimates of the parameter vector $\boldsymbol{\beta}$, it is shown that the models are mathematically equivalent.

Similar to binary choice model, the choice probability for individual i to choose alternative k is formulated as

$$P_k = P(y_k = 1) = \frac{\exp(V_k)}{\sum_{j \in \{1,2,\dots,J\}} \exp(V_j)} \tag{54.10}$$

For a multinomial logit model, a set of parameters will be estimated for each alternative j comparing with the reference alternative. The interpretation of the parameters estimated is the same as the interpretation of the parameters in a binary logit model, where the two alternatives are the alternative j and the reference.

54.4 The Random Regret Minimization (RRM) Model

Random regret minimization (RRM) model differs from RUM model in terms of the decision-making principle. Rather than assuming that an individual is choosing the alternative that could provide the highest utility/benefit, the main hypothesis in RRM model is that the individual will choose the alternative such that the “emotion of regret” associated with the choice is minimized [13–16]. The “emotion of regret” refers to the negative emotion of loss brought by the non-chosen alternatives. This might happen when some attributes of the chosen alternative are worse than those of the non-chosen alternatives. For example, Susan may choose to drive to the lake finally. Though she believes that driving is the best choice among the three alternatives she is considering (drive, take public transit, bike), she still has a feeling of loss when considering that the cost of biking is much lower than driving or biking is healthier for herself. The “emotion of regret” is related to the advantages of the non-chosen alternatives. Here, an alternative has “advantage” on an attribute means that, regardless of other attributes, the attribute of this alternative is more attractive comparing with the same attribute of another alternative.

Different from an RUM model where transitivity is required for the utility of all the alternatives, here the “regret” of an alternative in an RRM model makes references to the values of the same attribute of other alternatives presented for comparison. This means that “regret” is not a concept with transitivity (remember that the concept of “utility” in the RUM model has transitivity) and can be different when the presented alternatives change.

The RRM model can be used to analyze and model a wide variety of choice behaviors. For example, in transportation, it has been applied to departure time choices, route choices, mode-destination choices, etc. Though RUM model may also work in these scenarios, RRM model may be able to handle some other problems that could not be explained by RUM model. A well-known example is the “compromise effect” that could be observed in human decision-making process: individuals tend to choose an alternative that is moderately good on all factors, avoiding extreme alternatives (including both extremely good or extremely poor) [13, 25]. This seemingly irrational behavior could not be well captured by

RUM models but could be reasonably interpreted by an RRM model.

Since the two types of model hold different assumptions toward the underlying mechanism of choice-making behavior, they provide valuable perspectives and implications. Because of this, RRM model may serve as a supplement to individual choice behavior modeling toolbox.

54.4.1 RRM Model Specification

According to [12], it is hypothesized that the regret associated with alternative k , due to a comparison with a competing alternative j based on a particular attribute m , equals zero in case alternative k scores equal or better than j on attribute m . Otherwise, the regret associated with the attribute comparison is a nondecreasing function of the difference in attribute value.

For example, assume that individual i is facing a choice among alternatives j , k , and l . The attributes related to the choice-making process is x_m and x_n : $j = \{x_{mj}, x_{nj}\}$, $k = \{x_{mk}, x_{nk}\}$, $l = \{x_{ml}, x_{nl}\}$. Each alternative is associated with a measure of random regret RR_j , RR_k , and RR_l . When individual i is making choices, he/she minimizes this random regret, which means that he/she chooses the choice $\arg_v \min_{v=j,k,l} \{RR_v\}$.

The classical RRM model proposed by Chorus et al. is given by the following equation [12, 14, 16]:

$$RR_{ki} = \sum_{j \neq k} \sum_m \ln(1 + \exp(\beta_m [x_{jmi} - x_{kmi}])) + \epsilon_{ki} \quad (54.11)$$

where i represents individual i , m represents the m th attribute, and j represents an competing alternative j .

Equation 54.11 shows that for individual i , when he/she considers selecting alternative k , the “regret” is the sum of all binary regrets associated with the binary comparisons between alternative k and its competitor alternatives j ($j \neq k$). For each binary comparison, the binary regrets are the sum of the differences between all attributes m of an alternative j and the alternative k .

The authors who propose RRM model also show that [13]:

1. The marginal regret converges to β_m when $x_{jm} - x_{km}$ becomes sufficiently large. The overall regret is increasing with the increasing number of attributes on which alternative k is outperformed, as well as with the increasing number of alternatives by which alternative k is outperformed and the increasing importance of the attribute β_m .
2. The marginal regret with respect to attribute m when considering alternative k approaches zero when $x_{jm} - x_{km} < 0$, i.e., when the chosen alternative k outperforms

the competing alternative j ($j \neq k$). Hence, the RRM model postulates that when a decision-maker considers alternative k as compared to alternative j he or she experiences (almost) no regret with regard to attribute m when in alternative k the m 's attribute performs considerably better. This is consistent with our intuition that regrets may arise only when alternative k is outperformed by the competing alternative j on attribute m .

The random error term ϵ_{ki} in Eq. 54.11 is assumed to be i.i.d. type I extreme value similar to RUM model. By letting the variance of the Gumbel distribution be $\pi^2/6$, the error term could be “integrated out,” and the system regret (no random term) is

$$R_{ki} = \sum_{j \neq k} \sum_m \ln(1 + \exp(\beta_m [x_{jmi} - x_{kmi}])) \quad (54.12)$$

Referring to [13, 14, 16], since minimization of random regret is equivalent to maximization of minus random regret, and given the symmetrical nature of the i.i.d. errors, the choice probabilities can be taken on the well-known MNL form. Thus, with Eq. 54.12, the choice probability associated with alternative k equals

$$P_{ki} = \frac{\exp(-R_{ki})}{\sum_{j=1,2,\dots,J} \exp(-R_{ji})} \quad (54.13)$$

Similar to RUM model, the parameters of RRM model can also be estimated with its likelihood function, given its properties of the smoothness, differentiability, and globally concaveness. A book on RRM and related tutorials can be found in [13], and some sample codes can also be found in [40].

54.4.2 Some Variants of RRM

Some variants of the RRM model have also been developed, such as the μ RRM and PRRM models. These models can be supplements of the classical RRM model [8, 41].

The μ RRM model is a generalization of the classical RRM model. Since the size of the estimated taste parameters (β s) may significantly impact the extent to which losses (regrets) loom larger than equivalent gains (rejoices), the μ RRM model accommodates for different shapes of the attribute level regret functions by adding a scale parameter μ to adjust the size of the estimated taste parameters:

$$RR_k^{\mu RRM} = \sum_{j \neq k} \sum_m \ln \left(1 + \exp \left(\frac{\beta_m}{\mu} [x_{jm} - x_{km}] \right) \right) + \epsilon_k$$

$$- \epsilon_{ki} \sim i.i.d. \text{ EV}(0, \mu) \quad (54.14)$$

Notice that the scale parameter μ is also to be estimated. When μ is estimated to be 1, then the μ RRM becomes the classical RRM. When μ is close to zero, the PRRM model is obtained, which postulates the strongest regret minimization behavior which is possible within the RRM modeling paradigm [8, 41].

54.5 The Relative Advantage Maximization (RAM) Model

Relative advantage maximization model, abbreviated as “RAM” model, is another context-dependent model that could be used to describe and predict user choice behaviors and is able to explain the “compromise effect” [26]. Similar to RRM model, RAM model also compares each attribute of the chosen alternative with the same attribute of the competing alternatives.

In RAM model, the “disadvantage” of an individual i 's choosing alternative k over a competing alternative j with respect to attribute m is equivalent to the concept of “regret” in RRM model. Thus, denoted by D_{mkji} , the disadvantage is formulated in the same form as the RRM model:

$$D_{mkji} = \ln(1 + \exp[\beta_m (x_{mji} - x_{mki})]) \quad (54.15)$$

The key difference between RAM model and RRM model is that RAM model takes both the “disadvantage” and “advantage” of an alternative into account. The “disadvantage” and “advantage” are assumed to be symmetric in RAM model [26]. This means that the advantage for an individual i to choose alternative k over j with respect to attribute m (denoted as A_{mkji}) equals the corresponding disadvantage for individual i to choose alternative j over k with respect to the same attribute m :

$$A_{mkji} = D_{mjki} = \ln(1 + \exp[\beta_m (x_{mji} - x_{mki})]) \quad (54.16)$$

Notice that the subscripts of A_{mkji} and D_{mjki} in Eq. 54.16 is different. The disadvantage D_{mkji} for an individual i to choose alternative k over j with respect to attribute m corresponding to A_{mkji} can be written as $D_{mkji} = \ln(1 + \exp[\beta_m (x_{mki} - x_{mji})])$. Please notice the difference between this equation and Eq. 54.16.

Also, Eq. 54.16 is only for a single attribute m . We could add up all the attributes, and the total advantage and disadvantage for individual i to choose alternative k over j over all attributes are as follows [8]:

$$A_{kji} = \sum_m A_{mkji}$$

$$D_{kji} = \sum_m D_{mkji} \quad (54.17)$$

RAM model defines the term “relative advantage” (RA) of alternative k over competing alternative j as a ratio of k 's advantage (over j) over the sum of advantages and disadvantages (over j). Mathematically, the relative advantage of the individual i to choose alternative k over j is:

$$RA_{kji} = \frac{A_{kji}}{A_{kji} + D_{kji}} \quad (54.18)$$

RAM model also integrates the definition of the systematic utility in MNL together with its concept of relative advantage, such that both context-independent preferences and context-dependent preferences play roles in the model. The systematic utility for individual i to choose an alternative k could then be written as a linear combination of the systematic utility term in MNL and the relative advantage term defined in previous:

$$V_{ki}^{RAM} = \beta_m + \sum_m \beta_m x_{mki} + \sum_{j \neq k} RA_{kji} \quad (54.19)$$

Here x_{mki} is the context-independent attribute m for individual i to choose an alternative k .

54.6 Extensions to More Complicated Choice Sets

In this section, we mention a few models that illustrate some interesting ideas to tackle complicated choice sets, i.e., when the assumptions about the choice set presented in Sect. 54.2 are not met. The discrete choice models we have discussed so far could address many choice behavior problems in applications. However, some limitations exist. For instance, the model may fail to work when alternatives are not independent from each other. One assumption for RUM models is that there is no correlation in unobserved factors over alternatives, which is known as the “independence of irrelevant alternatives” (IIA) property. In other words, IIA assumption says that when individuals are making choices among a set of alternatives, the probabilities for them to choose A over B should not be impacted by whether another alternative C is present or not [2,5,29]. It could be easily noticed that this lack of correlation among alternatives are not always be realistic. Thus, some models, such as nested logit model which allow correlation over alternatives in a certain way, were developed. Another problem is that the standard logit model's “taste” coefficients, i.e., β 's, are fixed, which means the β 's are the same for everyone. To allow each individual to have different β , mixed logit model, which assumes that the β is a random variable following a certain distribution, was developed. In what follows, we discuss two models, the nested logit model, and the mixed logit model, where both are extensions of the RUM model.

54.6.1 Nested Logit Model

Nested logit model is used to deal with choice problems where there are nonzero correlations across alternatives, i.e., the IIA is violated [42]. In other words, nested logit model is based on the idea that some alternatives may be joined in several groups (called nests). The error terms may present some correlation in the same nest, whereas error terms of different nests are still uncorrelated. In this way, nested logit model allows for nonzero correlation between unobserved components of choices within a nest and maintains zero correlation across nests.

After a nested logit model groups together alternatives that are similar into a nest, each nest with multiple alternatives in turn is considered as a new composite alternative, which competes with the rest of alternatives (other alternatives that are not in the nests and other nests) available to the individual. Notice that for a nested logit model, there can be several nests in a choice set, and each alternative can be in no more than one nest.

Whether to use nested logit model and how to group alternatives if necessary may require an IIA test. For example, the IIA test in R software tests the probability ratio of any two alternatives, seeing whether the results obtained on the estimation with all the alternatives and only on a subset of the alternatives are consistent. Illustrating this in a mathematical way: assume that there are N alternatives in a choice set \mathcal{C} . \mathcal{C}' is subset of \mathcal{C} , which only includes two alternatives j and k . The IIA test in R is to see whether $\frac{P(y=k, k \in \mathcal{C})}{P(y=j, j \in \mathcal{C})}$ equals to $\frac{P(y=k, k \in \mathcal{C}')}{P(y=j, j \in \mathcal{C}')}$.

Let's use an example to explain the specification of the nested logit model, as shown in Fig. 54.2: there are three alternatives available at the beginning, car, light rail, and bus. If there is no other conditions and we simply use MNL, we may have a conclusion that each of the alternatives has the same probability to be chosen (33.3%). However, this may

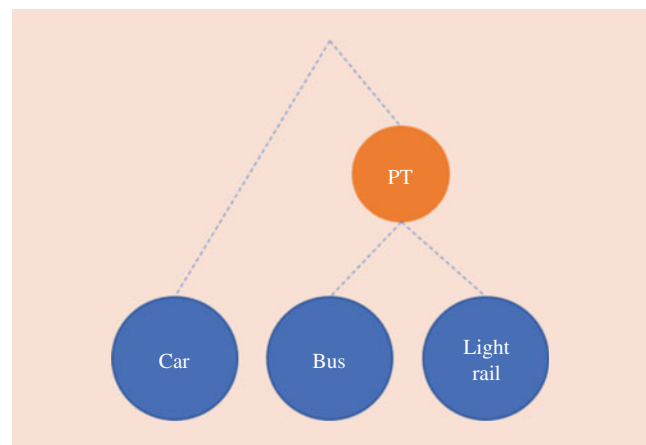

Fig. 54.2 Nested alternative

not be the case as the bus and light rail are both public transit (PT) and can be correlated. Nested logit model groups these two alternatives into a composite alternative PT, and then the available alternatives become Car and PT.

With nests identified, nested logit model estimates the probabilities of each alternative hierarchically:

1. Lower level: estimate a multinomial logit model for the alternatives in each nest.
2. Higher level: estimate a multinomial logit model consisting of all composite alternatives and alternatives which are non-nested.

To use a composite alternative to represent all the alternatives in the nest when building the higher level MNL, the utility of the composite alternative needs to include two components: (1) the expected maximum utility (EMU) of the lower level alternatives in the nest and (2) the vector of attributes which are common to all members of the nest. The probability that an alternative in a nest is chosen is computed as the product of the marginal probability of choosing the composite alternative and the conditional probability of choosing the alternative among all alternatives in the nest.

In the example shown in Fig. 54.2, bus and light rail are nested and a composite alternative PT is generated. Then the lower level, the PT nest, would be modeled by a binary logit model:

$$P(y_{bus} = 1|PT) = \frac{\exp(W_{bus})}{\exp(W_{rail}) + \exp(W_{bus})} \quad (54.20)$$

$$P(y_{rail} = 1|PT) = 1 - P(y_{bus} = 1)$$

where the utilities W_{bus} and W_{rail} contain only those attributes which are not the same to both alternatives.

The higher level would be modeled by another binary logit model:

$$P(y_j = 1) = \frac{\exp(V_j)}{\exp(V_{car}) + \exp(V_{PT})} \quad j \in (car, PT) \quad (54.21)$$

In Eq. 54.21, the utility V_{car} contains all the attributes of the car alternative. The utility V_{PT} , as we stated before, have two components:

$$V_{PT} = \beta_{EMU}W_{EMU} + \beta_{PT}x_{PT} \quad (54.22)$$

Here W_{EMU} is the expected maximum utility (EMU) of the alternatives in the nest of PT, $W_{EMU} = \ln[\exp(W_{bus}) + \exp(W_{metro})]$, x_{PT} is the vector of attributes that are taken out to estimate the binary logit model at the lower level binary model in the nest, and β_{EMU} and β_{PT} are parameters to be estimated.

54.6.2 Mixed Logit Model

Different from previous models where the parameters β in the utility function are all constant values (though the utility function has a random term ϵ), the mixed logit model allows parameters β become random variables obeying a certain distribution:

$$U_{ij} = \sum_k \beta_{ik}x_k + \epsilon_j \quad (54.23)$$

$$\beta_k \sim G(\beta|\theta)$$

Here, $G(\cdot)$ represents the density function of a certain type of distribution, with θ as a set of parameters that could describe the distribution. With this specification, the model aims to model the heterogeneity due to personal preferences. Because that each β in the utility model is a distribution rather than a constant value, the calculations of the utility of each alternatives and the probability become integral processes. That means that the choice probability of alternative j ($j = 1, 2, \dots, J$) being chosen is

$$P(y_j = 1) = \int \frac{\exp(V_j(\beta))}{\sum_{k=1}^J \exp(V_k(\beta))} G(\beta|\theta) d\beta \quad (54.24)$$

It could be noticed that the standard logit model is a special case of the mixed logit model: if the distribution $G(\beta|\theta)$ is only defined at a fixed value a , i.e., $G(\beta|\theta) = 1$ when $\beta = a$ and $G(\beta|\theta) = 0$ when $\beta \neq a$, the choice probability in Eq. 54.24 then becomes the one used in the logit model. Actually, it has been proved [30] that a mixed logit model can approximate to any degree of accuracy any true random utility model of discrete choice, given an appropriate specification of the variables and the distribution of coefficients.

The distribution $G(\beta|\theta)$ can also be discrete. Assume that β could take M distinct values, b_1, b_2, \dots, b_M . The probability for β to be value b_m , $m \in (1, 2, \dots, M)$ is $P(\beta = b_m) = p_m$. In this case, the choice probability for individual i to choose alternative j is

$$P(y_j = 1) = \sum_{m=1}^M p_m \frac{\exp(V_j(b_m))}{\sum_{k=1}^J \exp(V_k(b_m))} \quad (54.25)$$

One possible challenge for researchers is that there is a need to specify a certain type of distribution for each β if he/she plan to use a mixed logit model. Normal distribution is widely used in applications. The lognormal distribution is proved to be useful when a parameter is known to have the same sign for every individual according to domain knowledge. Uniform and triangle distributions have the advantage of being bounded on both sides, thus avoiding having too large parameters and causing unexpected problems. A more comprehensive summary could be found in [39].

54.7 Numerical Study

In this section, we use an example data to show how the three models, multinomial logit model, mixed logit model, and RRM, could be used. We implement the models in R 3.6.2.

54.7.1 General Description

The dataset we use in this section is a revealed preference (RP) dataset about shopping location choices, with 1503 shopping choices from 1074 individuals among five different alternatives. Each alternative has three attributes: “floor space groceries” (FSG), “floor space other” (FSO), and “travel time” (TT) indicating the availability of the shopping location for an individual. More details of the dataset could be found in [3].

The original dataset has 1503 rows, with each row representing a specific choice scenario and the choice made by the individual. We first convert the raw data into a new dataset whose format may be used in discrete choice models. For example, the first row of the original dataset is

In Table 54.2, attribute “ID” is the id of an individual; “FSG.1,” “FSO.1,” and “TT.1” are the three attributes of alternative 1. There are 5 alternatives, so there are 15 attributes in total. The last column “CHOICE” is the choice made by the individual.

First, we need to convert each row of the original dataset into a format as following:

We could see that the single record in Table 54.3 is converted into five rows, each representing an “true/false” binary choice for an alternative. After conversion, the original dataset with 1503 rows and 17 variables becomes a new dataset with 7515 rows and 7 attributes.

MNL

We apply a multinomial logit model (MNL) first to the dataset using the “mlogit” package in R with the following utility functions [19, 38]. Here the parameters apply to all alternatives (i.e., we do not include alternative-specific parameters for each variable):

$$U_{ji} = \beta_{FSG}FSG_{ji} + \beta_{FSO}FSO_{ji} + \beta_{TT}TT_{ji} + \epsilon_{ji} \quad (54.26)$$

Table 54.3 The converted dataset

ID	CHOICE	alt	FSG	FSO	TT	chid
1007	TRUE	1	1469	3123	594	1
1007	FALSE	2	60	26	0	1
1007	FALSE	3	309	2546	0	1
1007	FALSE	4	959	5877	0	1
1007	FALSE	5	1991	10068	0	1

Table 54.4 MNL model results

	Estimate	Std. Error	z-value	Pr(> z)
FSG	1.0595e-04	1.5040e-05	6.6889	2.248e-11***
FSO	1.1036e-05	2.2175e-06	4.9767	6.467e-07***
TT	-4.4843e-04	5.0021e-05	-8.9648	<2.2e-16***
				LL: -2305.2

*** Significant level of 0.05

The result of the multinomial logit model is shown in Table 54.4.

From Table 54.4 we could see that all the estimates are significant at 0.05 level. It is expected that the estimates for FSG and FSO are positive, and the estimate for TT is negative.

There are also various model structures for MNL. For example, we could estimate alternative-specific parameters (i.e., β s are different with different alternatives), add alternative-specific constants, or combine several alternatives together in the utility function. There are also different command that could be used other than “mlogit” in R. Readers who are interested in more details of the package may refer to its user manual.

Mixed Logit Model

With the same format of utility functions, in mixed logit model, we assume that the distribution patterns of the three attributes are all normal:

$$\begin{aligned}
 U_{ji} &= \beta_{FSG}FSG_{ji} + \beta_{FSO}FSO_{ji} + \beta_{TT}TT_{ji} + \epsilon_{ji} \\
 \beta_{FSG} &\sim N(b_{FSG}, sd_{FSG}^2) \\
 \beta_{FSO} &\sim N(b_{FSO}, sd_{FSO}^2) \\
 \beta_{TT} &\sim N(b_{TT}, sd_{TT}^2)
 \end{aligned} \quad (54.27)$$

In the results shown in Table 54.5, the estimates of the three variables are β_{FSG} , β_{FSO} , and β_{TT} in the utility functions. Meanwhile, they are also b_{FSG} , b_{FSO} , and b_{TT} that are parameters of the normal distribution. $sd.FSG$, $sd.FSO$, and $sd.TT$ are the three parameters of the standard deviations of the three distributions, respectively. As we could see, all the estimates are statistically significant at 0.05 level.

The results of the mixed logit model also include information about the random coefficients as shown in Table 54.6, including the ranges (min, mean, and max) and the quantiles (1st quantile, median, 3rd quantile) of the distributions.

RRM

In random regret minimization (RRM) model, instead of using utility functions to describe alternatives, we use regret functions:

$$R_{ji} = \sum_{k \neq j} \sum_m \ln(1 + \exp(\beta_m [x_{kmi} - x_{jmi}]))$$

$$j, k \in (1, 2, 3, 4, 5)$$

$$m \in (FSG, FSO, TT)$$
(54.28)

We use the ‘‘Apollo’’ package [40] written by Sander van Cranenburgh to implement the RRM model. We could see from Table 54.7 that except for the classical estimate, standard error, t-ratio (against 0), and p-value, there are several other columns showing the information of robust covariance estimators. Since the robust covariance estimators can tackle potential outliers in the dataset, they could be used to estimate the covariance of the real datasets or to perform outlier detection and discard/downweight some observations in the dataset. More information regarding the ‘‘Apollo’’ package and result interpretation could be seen in [24].

Results Comparison

Since the models do not have the same format, we do not compare the estimated β s. Instead, we summarize the log-likelihood (LL), AIC, BIC, and computational time for the three models.

From Table 54.8 we could see that the log-likelihoods (LL), AICs [1], and BICs [35] of MNL and RRM are close to each other, while RRM shows a little bit superior performance. AIC (Akaike information criterion) and BIC (Bayesian information criterion) are two estimators that deal with the trade-off between the goodness-of-fit and the simplicity of a model. Thus, they are commonly used for model selection. The formulation of AIC is

$$AIC = 2k - 2 \log(\hat{L})$$
(54.29)

where k represents the number of parameters to be estimated by the model and \hat{L} is the maximum value of the likelihood function of the model.

The formulation of BIC is a bit different from AIC:

$$BIC = \log(n)k - 2 \log(\hat{L})$$
(54.30)

where n represents the number of data points/observations/sample size.

From the comparison we could also see that mixed logit model may not be appropriate for this dataset. If we take a look at the standard deviation of the normal distribution of each variable, we could notice that the standard deviations are very large comparing with the estimates. This indicates that there is considerable heterogeneity among the individuals, or we did not choose a good distribution type to model the variability of the parameters among individuals.

54.8 Discussion

54.8.1 Limitations and Challenges

Various choice models have been proposed and applied in methodological studies and real-world applications. Though in this chapter we briefly discuss several commonly used models, there are variants of the models that are also promising, and there will be more emerging in the future to help understand, predict, and model user behavior. However, with all these models and successful implementations, there are still many questions unanswered.

Table 54.7 RRM

	Estimate	Std.err.	t.ratio	p-value	Robust std.err.	Robust t.ratio	Robust p-value
FSG	0.0680	0.0100	6.77	0.000	0.0170	3.99	0.000
FSO	0.0029	0.0011	2.79	0.005	0.0017	1.76	0.079
TT	-0.0155	0.0019	-8.35	0.000	0.0031	-4.99	0.000
							LL -2300.92

Significant level of 0.05

Table 54.8 Comparison of the three models

Model	LL	AIC	BIC	Time (s)
MNL	-2305.2	4616.494	4632.439	0
Mixed logit model	-7189.3	14390.63	14400.58	23
RRM	-2300.92	4607.841	4623.786	4

For the first, though current models with different assumptions provide various possible interpretations to choice behavior and show optimistic prediction results in existing studies, we are still not clear what circumstances are suitable for what models or which model is more accurate than other models, in a certain area of application. Moreover, to understand each model better, there might be more metrics that could be used to evaluate the performance of the models other than goodness-of-fit and prediction accuracy. We are still far away from the truth or the underlying mechanism of human choice behavior.

For the second, while most researchers have realized the importance of context dependency, there is still a lack of understanding of the influence of various types of the dependencies across space and over time. Since RRM and RAM were developed only recently (in relative sense), it is reasonable to expect more studies that will be focusing on related topics in the future.

As smart, personal devices are becoming essential items in our daily life, developments of user choice model face new challenges. A huge amount of products are bringing out individual services, in which individual preference learning and personal choice model are becoming important in implementations. However, data from an individual is often limited, both in sample size and in quality. Moreover, as the smart devices make it possible for the model to be updated in real time, the computational time of the individual choice model is required to be as short as possible to enable online applications. A more complicated learning and updating system should be designed for real-world implementation of the choice models.

Besides the models we discussed, there are also other methods that could be used to model choice behaviors, such as Hidden Markov Model, Bayesian network, or other dynamic models to estimate the state-dependent choice [6, 43, 45]. Strategies in machine learning also found useful

applications. For example, decision tree in artificial intelligence has been used to explore the underlying rules of travelers' switching decisions [37]. Recommendation systems that are frequently applied in e-commerce platforms may not be considered as choice models; the idea beneath may be inspirational especially when proposing personalized option menu for a user to choose [36].

54.8.2 Irrational Behavior

In previous models we assumed that individuals are rational or at least bounded-rational. This may not always be the case. Research in social science, psychology, and behaviors have proved that individuals have some irrational behaviors [7]. Take two famous protocols as examples:

1. Heuristic choice protocols hold that individual's choice mechanism relies on relatively little information and rule-of-thumb thinking. For example, when choosing between two alternatives, one recognized and the other not, an individual tends to choose the recognized one.
2. Social network choice protocol, which means that an individual is making choices who is not only subject to the considerations by himself/herself but also heavily impacted by other individuals who have close connection with him/her.

From these two protocols, we could see that individuals are often irrational. This provides another direction of individual choice model development, and some research have been putting efforts into it, e.g., [10]. For example, models with neural network architectures may help connect the irrational behavior with interpretable constraints and evolutionary rules [20], new assumptions to traditional normative models may provide better explanation to the mental activities when individuals are doing forced-choice tasks [31], and a new travel behavior model based on dual process may also reflect the seemingly irrational behaviors of drivers [18].

Abstract

Voting is an ancient method for a group such as a meeting or an electorate to make a collective decision or express an opinion after some discussions, deliberations, or election campaigns. Participants who give an option or choose a candidate are called voters; therefore, a simplest voting system consists certain number of qualified voters and

candidates. The most common application in weighted voting systems is, for example, the US Electoral College, where the number of electoral votes for each state is based upon its population. This chapter states the modeling of threshold weighted voting systems and the dynamic analysis of two terms including indecisive effect and known/unknown inputs. The system reliability models presented in the chapter are based on the assumptions that the system operates as two types of input values (0, 1) and three types of output values (0, 1, x) with three types of errors, and the components are unequally weighted and subject to three failure-modes (stuck-at-0, stuck-at-1, stuck-at- x). For any weighted voting system, a decision rule is required although different rules may result different system performance in terms of the system reliability. For instance, the current decision rule of US Electoral College is who wins the election obtaining at least 270 electoral votes, which results four former US presidents won the elections with less national populate votes than their opponents in history.

In general, the weighted voting system (WVS) consists of n units assigned with individual weights, each of which provides a binary decision (0 or 1) or abstains (x) from voting. A generic decision rule can be defined as the system output is 1 if the cumulative weight of all 1-opting units is at least a prespecified threshold τ of the cumulative weight of all nonabstaining units. If the indecisive effect is considered, weights of abstaining units can be added in the decision rule such as the system output is 1 if the cumulative weight of all 1-opting units is at least a prespecified threshold τ of the sum of all nonabstaining units and prespecified indecisive parameter θ of all abstaining units. The system fails if the generated output is not equal to its original input. Recent research results indicate that, under specified assumptions, multiple approaches can be used to quantify the reliability of the weighted voting system. This chapter demonstrates the development of decision rules and the evolution of approaches of generating reliability function. Some related works are addressed to provide a

55.1 Introduction

Weighted voting system (WVS) is one of the modern tools used in decision-making by assigning different powers to voters. A weighted voting system is characterized by three basic parts – *voters*, *weights*, and the *voting rule*. The voters can be considered as a group of n individuals, systems, or components (v_1, v_2, \dots, v_n) that each one can generate an independent decision. Each voter's weight w_i is the power of its individual decision counts. The rule is the minimum requirement of votes to make the final decision. Weighted voting is a comprehensive way of decision-making, and it has many significant applications in a wide range of systems including communication systems [1], financial systems [2], election systems [3], and medical systems [4]. Thus, more specific aspects and assumptions are naturally generated, which will be discussed briefly in the end of this chapter.

Two important aspects of *voters* include single voter's reliability and failure modes. Each voter plays an independent role in providing its own output, and its reliability is a value to quantify the probability of making correct output. Therewith, the fact of imperfect voter results in failure rate; however, different failure modes may result from wrong or absent output and input patterns. System design is then distinguished; therefore, system optimization is affected. *Levitin* [5] analyzed the optimization of systems consisting of voting units with limited availability and presented two ways to improve system reliability, where a method of taking information about units' availability into procedure for system optimization was approached. *Pham* and *Malon* [6] studied reliability optimal design of systems with competing failure modes. They achieved optimal parameterizations to provide maximum system reliability and minimum system cost. *Pham* [7] then studied reliability for dynamic configurations of systems with three failure modes. He presented the comparisons of reliability modeling function and optimal parameterization from two failure modes to three failure modes.

Unequal *weights* in multiunit systems are more frequently considered in many cases. The weight of each voter represents its decision counts in the whole system, especially assigning strategy is more careful when indecisive effect is considered. In classic models, weights of voters with no decision do not count; however, in modern models, indecisive

weights are considered and become obstacles of decision-making. Those obstacles can either be pros or cons, and there are typical adjustments in favor of goals from different cases. In 1976, *Lucas* [8] studied the relations between voting powers and weights, and he pointed out that not all inequalities could be canceled out by weighted voting and power was not trivial from one's strength as measured by the number of votes; therefore, his results motivated independent research on weights. *Levitin* [9] designed an asymmetric WVS in which each voting unit had two weights, where the weight was applied if the unit's decision was 0 and the second weight was applied if the unit's decision was 1. The idea of the asymmetry of unit weights allows the designer to take advantage of the knowledge of statistical asymmetry of voting units. *Aziz*, *Paterson*, and *Leech* [10] designed a WVS with a desirable distribution of power, where they presented an algorithm to compute an integer weight vector for target Banzhaf power indices.

The *Voting rule* is the fundamental law for a WVS to make the final decision. In classical models, electoral college, the voting rule is nothing but a threshold value. In modern models, voting rule consists of weights and parameters, human organizations; decision criterion is usually more complicated as many factors are involved in the final decision. *Nordmann* and *Pham* [11] built a dynamic system by considering weights along with threshold in the decision rule, where applicable assumptions were raised in case studies. *Levitin* [12] focused on threshold optimization; in such a procedure, he studied the method of finding threshold values to minimize the system cost. In 2014, *Posner* and *Sykes* [13] showed that all major voting systems were controversial in different ways which was resulted from the difficulty of designing a voting system that both allowed efficient decisions and protected the legitimate interests of voters. And they provided a new type of voting system, quadratic voting, which could resolve these problems theoretically but was unlikely to be implemented any time soon.

This chapter presents recent results on modeling reliability of voting systems consisting of n unequally weighted components with three failure modes in human organizations. The early work is initially studied by *Nordmann* and *Pham* in [11, 14] where the fundamental framework was constructed, and application gaps were also raised. Later, the modern research studied by *Xie* and *Pham* [15] improved methodology that a general recursive reliability function was presented. Recently, *Zhang* and *Pham* [16] have presented a weighted indecisive-voting system considering indecisive effect. The results illustrate ignored insights into system behavior in terms of parameterizations and reliability sensitivity in terms of input patterns. This chapter summaries these results and points out the motivation of some extended research on controlled voting when lacking prior information of inputs.

55.2 Weighted Threshold Voting System

Consider weighted voting systems model studied in [15]. The model descriptions and assumptions are given as follows. Specifically, we use human organization (HO) systems as a general illustrative example to represent the applied techniques of the generalized WVS.

55.2.1 Model Assumptions

- WVS is a decision-making system where a final decision is made based on any **given** input, *e. g.*, proposal in HO system, denoted by 1 (good) or 0 (bad).
- There are n voters in the WVS.
- All voters are statistically independent and nonidentical.
- Each voter makes a subdecision, and the final decision 1 (accept), 0 (reject), or x (no decision) is based on n subdecisions.
- For any voter v_i , an independent weight w_i is assigned.
- For any voter v_i , its probability of making correct subdecision is $p_{i,00}$ (reject bad proposal) and $p_{i,11}$ (accept good proposal).
- Each voter has probability of making wrong decision subject to three types of errors.
 1. Type 1: Accept the one should be rejected, $p_{i,01}$.
 2. Type 2: Reject the one should be accepted, $p_{i,10}$.
 3. Type 3: No decision on the one should be rejected, $p_{i,0x}$; no decision on the one should be accepted, $p_{i,1x}$.
- A decision rule is designed with a predefined value of threshold, τ , incorporating all subdecisions to generate the final decision.

55.2.2 Decision Rule

To illustrate how such systems fit into the framework of general models, Xie and Pham [15] described the problem in an HO system. Assume the proposal is the input of either acceptable and unacceptable and the information is implicitly contained in the material that each voter is going to review. Thus, via the disguised form, each voter gets an input either 1 (acceptable) or 0 (unacceptable). All voters are provided with the same input that depends on the actual proposal where a decision is to be made, and therefore produces a subdecision that is 1 (accept), 0 (reject), or x (indecisive). Ideally, the output from each voter should equal to its input; however, under the fact of imperfect voters, each voter is subject to errors described above.

Consider a weighted threshold voting system of n voters with the weight w_i for voter i , where I_1 is the index set of all voters with favorable outcomes for the system input, I_x is

the index set of all voters without any individual decision, and $\tau \in (0, 1]$ is the threshold value. The system collects all subdecisions from all voters and generates a joint system output based on the following decision rule [11, 14, 17]. The system output is “1” (acceptable) if and only if,

$$\sum_{i \in I_1} w_i \geq \tau \sum_{i \notin I_x} w_i \quad (55.1)$$

and it is “0” otherwise.

This model is a dynamic threshold weighted voting system subject to two failure modes as it does not consider weights for voters with no decision. Failure mode 1 means that the system accepts an input ought to be rejected, and failure mode 2 means that the system rejects an input ought to be accepted. Thus, the reliability of the system, R_{sys} , is that probability of the system making a correct decision for any given input.

$$R_{\text{sys}} = \Pr \{ \text{the system makes the correct decision} \}$$

Nordmann and Pham [11, 14] proposed this decision rule by developing a mathematical model with two restrictions on the scale of weights and the value of threshold, which resulted from the immense combinatorial complexity and thus cannot be applied directly to many real systems due to the complexity of computations. Simply, two restrictions on the generality of parameters in their model are the key obstacles from practical usage. Therefore, to formulate the model, an advanced methodology is induced. Later, Levitin [17] used this decision rule to estimate WVS reliability with universal generating function technique. Although his algorithm improved the calculation procedure, its functionality was still limited due to the intrinsic shortcomings of the algorithm until Xie and Pham [15].

55.2.3 Model Formulation

Xie and Pham [15] applied a simple recursive formula to calculate the reliability of the weighted voting systems without restrictions on both weights and threshold values. Define a random variable Z_i where $i = 1, 2, \dots, n$ as

$$Z_i = \begin{cases} 1 - \tau & \text{if } i \in I_1 \\ 0 & \text{if } i \in I_x \\ -\tau & \text{if } i \in I_0 \end{cases} \quad (55.2)$$

By rewriting Eq. (55.1), the system output is “1” if and only if,

$$\sum_{i \in I_1} w_i - \tau \sum_{i \notin I_x} w_i \geq 0 \quad (55.3)$$

To simplify Eq. (55.3) for clear interpretation, replace (55.2) into the second sum; it can be disaggregated and rearranged as follows,

$$\sum_{i \in I_1} (1 - \tau) w_i - \sum_{i \in I_0} \tau w_i \geq 0 \iff \sum_{i=1}^n w_i Z_i \geq 0 \tag{55.4}$$

Thus, each voter i contributes a positive value $(1 - \tau)w_i$ if it votes acceptance, and a negative value $-\tau w_i$ if it votes rejection toward to the final WVS score, where I_1 , I_0 , and I_x represent the index sets of voters with the corresponding decisions. Further, they define two probability functions.

$$Q_n(s) = \Pr\left(\sum_{i=1}^n w_i Z_i \geq s \mid P = 1\right)$$

$$\tilde{Q}_n(s) = \Pr\left(\sum_{i=1}^n w_i Z_i < s \mid P = 0\right)$$

Then, the probability of the system output $S = 1$ given the input $P = 1$ is,

$$Q_n(0) = \Pr\left(\sum_{i=1}^n w_i Z_i \geq 0 \mid P = 1\right) = \Pr(S = 1 \mid P = 1)$$

And the probability of the system output $S = 0$ given the input $P = 0$ is,

$$\tilde{Q}_n(0) = \Pr\left(\sum_{i=1}^n w_i Z_i < 0 \mid P = 0\right) = \Pr(S = 0 \mid P = 0)$$

Therefore, the reliability of such a weighted threshold voting system with n voters is,

$$R_{\text{sys}} = Q_n(0) \Pr(P = 1) + \tilde{Q}_n(0) \Pr(P = 0) \tag{55.5}$$

where $Q_n(s)$ and $\tilde{Q}_n(s)$ can be written in terms of recursive functions as follows:

For $n \geq 1$,

$$Q_1(s) = \begin{cases} 1 & \text{if } s \leq -\tau w_1 \\ p_{1,11} + p_{1,1x} & \text{if } -\tau w_1 < s \leq 0 \\ p_{1,11} & \text{if } 0 < s \leq (1 - \tau) w_1 \\ 0 & \text{if } s > (1 - \tau) w_1 \end{cases}$$

$$\tilde{Q}_1(s) = \begin{cases} 0 & \text{if } s \leq -\tau w_1 \\ p_{1,00} & \text{if } -\tau w_1 < s \leq 0 \\ p_{1,00} + p_{1,0x} & \text{if } 0 < s \leq (1 - \tau) w_1 \\ 1 & \text{if } s > (1 - \tau) w_1 \end{cases}$$

For $n \geq 2$,

$$Q_n(s) = Q_{n-1}(s_n^-) p_{n,11} + Q_{n-1}(s) p_{n,1x} + Q_{n-1}(s_n^+) p_{n,10}$$

$$\tilde{Q}_n(s) = \tilde{Q}_{n-1}(s_n^-) p_{n,11} + \tilde{Q}_{n-1}(s) p_{n,1x} + \tilde{Q}_{n-1}(s_n^+) p_{n,10}$$

where $s_n^- = s - (1 - \tau) w_n$ and $s_n^+ = s + \tau w_n$. Given $\Pr(P = 1) + \Pr(P = 0) = 1$, Eq. (55.5) indicates that the reliability value R_{sys} has the range $[R_{\text{sys}}^{\min}, R_{\text{sys}}^{\max}]$, where $R_{\text{sys}}^{\min} = \min\{Q_n(0), \tilde{Q}_n(0)\}$ and $R_{\text{sys}}^{\max} = \max\{Q_n(0), \tilde{Q}_n(0)\}$. The following numeric examples are illustrated to show how the system works.

55.2.4 Numeric Examples of System Reliability

Example 55.1 Suppose $\Pr(P = 1) = \Pr(P = 0) = 0.5$. Consider the following three extreme cases:

- (a) The output of the system is 1.
- (b) The output of the system is 0.
- (c) The output of the system is either 0 or 1 with equal probability.

For simplicity and without loss of generality, it is assumed that there is only one voter in the system, $n = 1$. In this case, the probability that the system output of 0 or 1 is $0.5(p_{1,00} + p_{1,10})$ or $0.5(p_{1,11} + p_{1,01})$, respectively. And therefore, the system reliability is $R_{\text{sys}} = 0.5(p_{1,00} + p_{1,1x} + p_{1,11})$.

In case (a), the system output is 1, which requires $0.5(p_{1,11} + p_{1,01}) = 1$. It implies that $p_{1,11} = p_{1,01} = 1$ and other $p_{1,vv'}$ should be 0, which leads the system reliability of case (a) is $R_{\text{sys}} = 0.5$. And the similar situation can be applied on case (b); thus, the system reliability of case (b) is also $R_{\text{sys}} = 0.5$. Note that the reliability of a system is defined as the probability of making a correct decision. If the input is either 0 or 1 with probability 0.5 of each, then the system will have an equal chance to make the right decision in either case (a) or (b), although the probability for case (a) or (b) happens at different time.

In case (c), the output of the system is either 0 or 1 with equal probability, so it implies that $0.5(p_{1,00} + p_{1,10}) = 0.5(p_{1,11} + p_{1,01}) = 0.5$. Thus, $p_{1,00} = 1 - p_{1,01} = p_{1,11} = 1 - p_{1,10}$ and $p_{1,0x} = p_{1,1x} = 0$, and the system reliability is $R_{\text{sys}} = p_{1,00} = 1 - p_{1,01} = p_{1,11} = 1 - p_{1,10}$, which may not necessary be 0.5. And $R_{\text{sys}} = 0.5$ only if $p_{1,00} = p_{1,01} = p_{1,11} = p_{1,10} = 0.5$.

Example 55.2 Suppose we have $n = 4$ voters in the HO system described above and the probability matrix of their judgement errors along with weights is distributed as follows.

$$p_{1,10} = 0.17, p_{1,1x} = 0.14, p_{1,01} = 0.15, p_{1,0x} = 0.10.$$

$$p_{2,10} = 0.14, p_{2,1x} = 0.10, p_{2,01} = 0.11, p_{2,0x} = 0.14$$

$$p_{3,10} = 0.11, p_{3,1x} = 0.12, p_{3,01} = 0.16, p_{3,0x} = 0.12$$

$$p_{4,10} = 0.15, p_{4,1x} = 0.12, p_{4,01} = 0.10, p_{4,0x} = 0.15$$

$$w_1 = 2.0, w_2 = 1.0, w_3 = 1.5, w_4 = 1.0$$

Given a low threshold value $\tau = 0.2$,

$$R_{\text{sys}}(\tau = 0.2) = \begin{cases} 0.9915 & \text{if } \Pr(P = 1) = 1 \\ 0.6567 & \text{if } \Pr(P = 0) = 1 \end{cases}$$

Given a medium threshold value $\tau = 0.5$,

$$R_{\text{sys}}(\tau = 0.5) = \begin{cases} 0.9214 & \text{if } \Pr(P = 1) = 1 \\ 0.9178 & \text{if } \Pr(P = 0) = 1 \end{cases}$$

Given a high threshold value $\tau = 0.8$,

$$R_{\text{sys}}(\tau = 0.8) = \begin{cases} 0.6549 & \text{if } \Pr(P = 1) = 1 \\ 0.9918 & \text{if } \Pr(P = 0) = 1 \end{cases}$$

To quantify the system performance, reliability is calculated under different cases of τ . System has inverse reacts under two extreme values of threshold when $\tau = \{0.2, 0.8\}$ under different types of inputs. However, the medium value of threshold $\tau = 0.5$ results a reliable system with equal performance under both types of inputs.

55.3 Reliability Analysis

55.3.1 Reliability Approximation

For practical reason, Xie and Pham [15] studied an approach of reliability approximation although C code is programed to calculate the reliability automatically if all necessary values are initialized, which aims to provide a quick check of the system reliability if the exact computation is not required.

The possible combinations of votes in a weighted voting system are defined in Eq. (55.1) on which the size of the sample space of the random variable $Y_n = \sum_{i=1}^n w_i Z_i$ is 3^n . Thus, without any further assumptions on both w_i and q_i , any algorithm for computing the system reliability involves up to 3^n terms, which will result computation difficulties. To solve this problem, they proposed an accurate large-sample approximation formula for evaluating the system reliability R_{sys} . The formula is developed based on the saddle point

approximation technique by Barnforff-Nielsen and Cox [18], and it works well for small size of samples. The computations of the proposed approach are straightforward for simple linear equations while techniques are needed for nonlinear equations when locating the saddle points. For any size n , the approximation values of R_{sys} can be calculated instantly in route.

Define a similar notation $Z_i^* = Z_i + \tau$, where Z_i is defined in Eq. (55.2). Given the input $P = 1$, the logarithm of the conditional moment generating function, $\sum_{i=1}^n w_i Z_i^*$, is defined as

$$K_n(u) = \sum_{i=1}^n \log(p_{1,11} e^{uw_i} + p_{1,1x} e^{u\tau w_i} + p_{1,10})$$

Then, the solution point $u = \hat{u}_n$, which solves the first derivative of $K_n'(u) = \tau \sum_{i=1}^n w_i$, is called a saddle point. Similarly, given the system input $P = 0$, the conditional moment generating function of $\sum_{i=1}^n w_i Z_i^*$ is denoted as,

$$\tilde{K}_n(u) = \sum_{i=1}^n \log(p_{1,01} e^{uw_i} + p_{1,0x} e^{u\tau w_i} + p_{1,00})$$

By solving the first derivative equation $\tilde{K}_n'(u) = \tau \sum_{i=1}^n w_i$, the saddle point \tilde{u}_n is located.

Now let $\hat{e}_n = \hat{u}_n * [K_n''(\hat{u}_n)]^{0.5}$ and $\hat{f}_n = \text{sign}(\hat{u}_n) * |\sqrt{2}[\hat{u}_n K_n'(\hat{u}_n) - K_n(\hat{u}_n)]^{0.5}|$, and $\tilde{e}_n = \tilde{u}_n * [K_n''(\tilde{u}_n)]^{0.5}$ and $\tilde{f}_n = \text{sign}(\tilde{u}_n) * |\sqrt{2}[\tilde{u}_n \tilde{K}_n'(\tilde{u}_n) - \tilde{K}_n(\tilde{u}_n)]^{0.5}|$. Suppose existing small positive constants $\varepsilon, \delta_1, \delta_2 > 0$ and a large positive number $M < \infty$, such that $\varepsilon < w_i < M$ and $\delta_1 < 1 - p_{1,vv'} < 1 - \delta_2$ for any $v \neq v'$. Therefore, the approximation results for $Q_n(0)$ and $\tilde{Q}_n(0)$ can be represented as follows.

$$Q_n(0) = \Pr\left(\sum_{i=1}^n w_i Z_i \geq 0 \mid P = 1\right) = 1 - \psi(\hat{e}_n) + \phi(\hat{e}_n) \left[\frac{1}{\hat{e}_n} - \frac{1}{\hat{f}_n} + O(n^{-1.5}) \right]$$

$$\tilde{Q}_n(0) = \Pr\left(\sum_{i=1}^n w_i Z_i < 0 \mid P = 0\right) = \psi(\hat{e}_n) - \phi(\hat{e}_n) \left[\frac{1}{\hat{e}_n} - \frac{1}{\hat{f}_n} + O(n^{-1.5}) \right]$$

where ψ and ϕ are the cumulative distribution function and the density function of a standard normal random variable, respectively, and the notation big $O(n^{-1.5})$ represents the remaining terms in the parenthesis which tend to 0 at a certain speed equal or faster than $n^{-1.5}$ as $n \rightarrow \infty$.

The error terms are at the rate of $O(n^{-1.5})$, and the R_{sys} is at most at the order of $O(n^{-1.5})$. When n is large, these approximations are extremely accurate.

55.3.2 Numeric Examples of System Reliability Approximation

Example 55.3 Table 55.1 illustrates the reliabilities calculated for a weighted voting system with $n = 5, 10, 15, 20, 25, 40, 100,$ and 300 voters. The parameters of the error probabilities are randomly resampled from the base set of 4 voters in Example 55.2. The second column is the calculated values of $Q_n(0)$ using the recursive formulas in subsection of Model Formulation, and the third column lists the approximation values of $Q_n(0)$ calculated using the recursive formulas in subsection of Reliability Approximation. The values in the fourth column are the calculated differences between the values in the second and third columns. The fifth, sixth, and seventh columns show the corresponding values related to $\tilde{Q}_n(0)$, respectively. And the last three columns are values related to the system reliability R_{sys} given $\Pr(P = 1) = 0.7$, where more favorable inputs are chosen in the illustrated examples.

C code takes less than a minute to finish each calculation up to $n = 20$. When $n = 25$, it takes about 3 hours to finish calculating the exact values of R_{sys} ; thus, they did not try it when $n > 25$. The accuracy increases as n grows bigger as expected, especially when $n \geq 20$.

From the calculations of differences between exact and approximated values, one can see that the approximation approach is a relatively good way to identify the system performance even if when the size is small. As expected, as n approaches to a big value, the approximation of the system reliability has no difference from the exact value. And this methodology is strongly recommended under certain constraints of budget controls or time-consuming issues in some policy-related systems.

55.3.3 Time-Dependent Reliability Function

To this end, no time limitation is set up for reliability evaluation; however, to make the model more applicable in practice, the requirement of a limited time for decision-making is appropriate. Along with voters' expertise, limited time will

affect the results of their decisions. Xie and Pham [15] assumed time-dependent functions on reliability and error rate for each voter; $p_{i,vv'}(t)$ is a function of time t , where t is the time up to a decision for any voter. That is, voters must make the decision before time t and the WVS will produce an output based on subdecisions from all voters. And this design can be extended to more general cases with some additional clarifications on model assumptions.

They considered a typical pattern which is proper in real cases, where the error probabilities $p_{i,vv'}(t)$ for any $v \neq v'$ are decreasing functions of t . That is, any voter is less reliable at the beginning as time is limited; however, the probability of all voters making wrong decisions would decrease after a certain time. If sufficient time is allowed, the probability of wrong decisions would reduce to a minimal level. Figure 55.1 illustrates an example of time-dependent functions for four different failure rates. The error probability decreases slowly from the maximum value and reaches to the minimum value after a certain period. The curves in Fig. 55.1 are from the following formula. For $t > 0$ where $v \neq v', v = 0, 1,$ and $v' = 0, 1, x$.

$$p_{i,vv'}(t) = p_{i,vv'}^{\min} + (1 + e^{-b_{i,vv'}}) \frac{(p_{i,vv'}^{\max} - p_{i,vv'}^{\min}) e^{-a_{i,vv'}t + b_{i,vv'}}}{1 + e^{-a_{i,vv'}t + b_{i,vv'}}} \quad (55.6)$$

where $a_{i,vv'} > 0$ decides the pace of $p_{i,vv'}(t)$ reduces as t increases, and $b_{i,vv'} > 0$ decides the location of the curve, and two constants $0 < p_{i,vv'}^{\min} < p_{i,vv'}^{\max} < 1$ for $v \neq v'$ are lower and upper bounds for $p_{i,vv'}(t)$ for the entire domain. When $p_{i,vv'}^{\min} = 0$ and $p_{i,vv'}^{\max} = e^{b_{i,vv'}} / (1 + e^{b_{i,vv'}})$, formula (55.6) becomes to the standard logistic function for sigmoid curves so that value of $p_{i,vv'}$ is between lower and upper bounds for all $t > 0$, and $p_{i,vv'}(0) = p_{i,vv'}^{\max}$.

The reliability of the threshold voting systems can be quantified under the time-dependent situation by defining $Q_{n,t}(s)$ and $\tilde{Q}_{n,t}(s)$ similarly as $Q_n(s)$ and $\tilde{Q}_n(s)$. Under such assumptions, $Q_{n,t}(0)$ and $\tilde{Q}_{n,t}(0)$ are nondecreasing which leads the time-dependent system reliability $R_{sys}(t)$ be nondecreasing of t . An example gives an intuitive vision of how it works on WVS.

Table 55.1 Comparison of exact and approximate system reliability

n	$Q_n(0)$			$\tilde{Q}_n(0)$			R_{sys}		
	Exact	Approx	Diff	Exact	Approx	Diff	Exact	Approx	Diff
5	0.9566	0.9733	-0.0167	0.9686	0.9497	0.0189	0.9602	0.9662	-0.0060

300	-	1	-	-	1	-	-	1	-

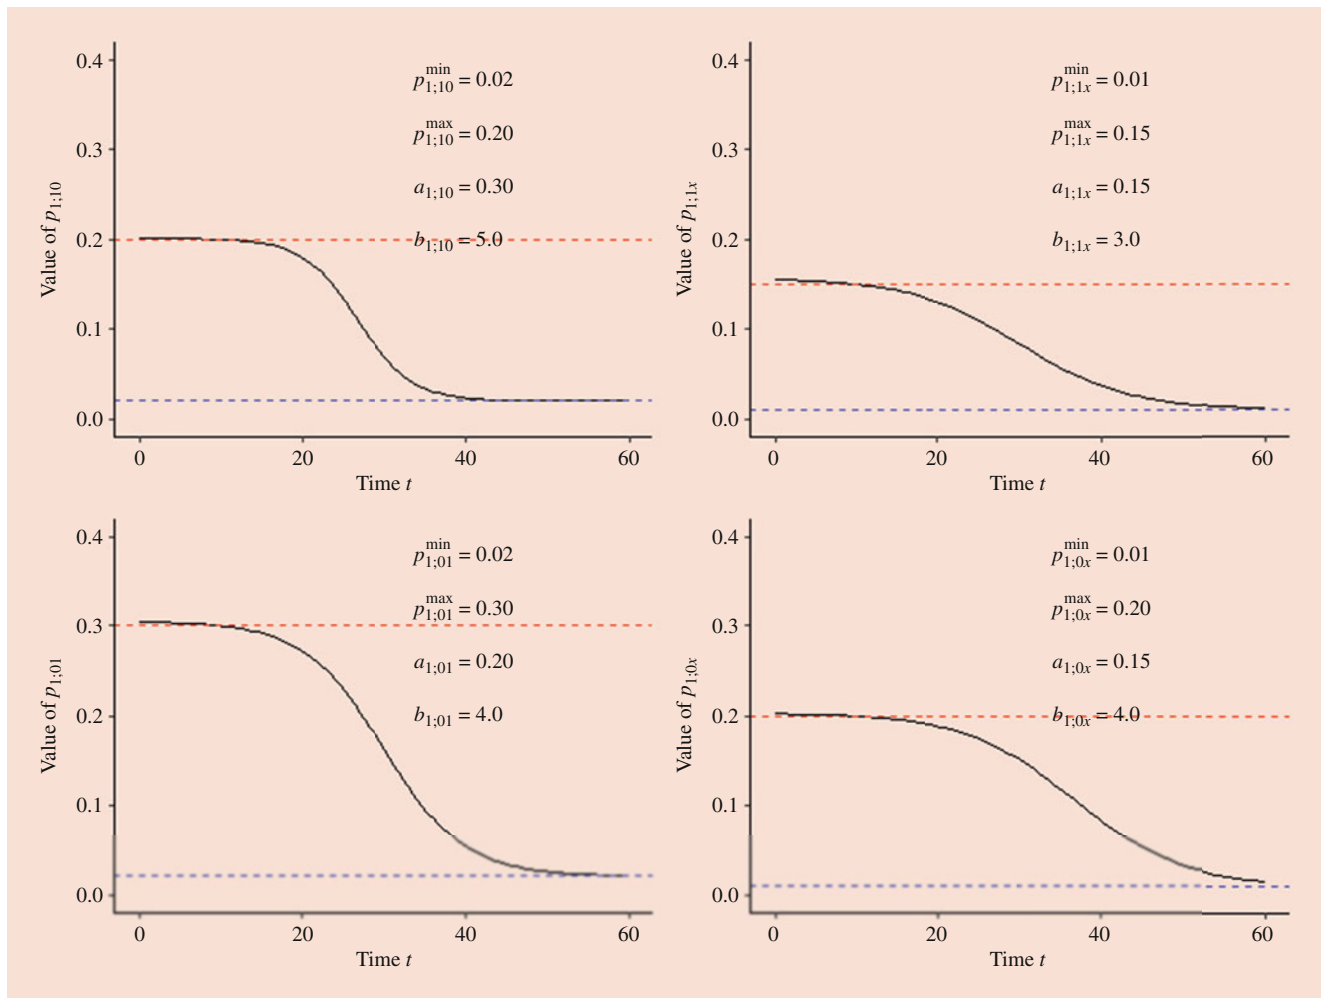

Fig. 55.1 Time-dependent functions of four failure rates

Example 55.4 Suppose a system has $n = 3$ voters. Assume their failure rates as functions of time t can be modeled in the form of (55.6), and the parameters are as follows,

Voter 1 : $(p_{1,10}^{\min}, p_{1,10}^{\max}) = (0.02, 0.20)$, $a_{1,10} = 0.30$, $b_{1,10} = 5.0$
 $(p_{1,1x}^{\min}, p_{1,1x}^{\max}) = (0.01, 0.15)$, $a_{1,1x} = 0.15$, $b_{1,1x} = 3.0$
 $(p_{1,01}^{\min}, p_{1,01}^{\max}) = (0.02, 0.30)$, $a_{1,01} = 0.20$, $b_{1,01} = 4.0$
 $(p_{1,0x}^{\min}, p_{1,0x}^{\max}) = (0.01, 0.20)$, $a_{1,0x} = 0.15$, $b_{1,0x} = 4.0$
 $w_1 = 2.0$

Voter 2 : $(p_{2,10}^{\min}, p_{2,10}^{\max}) = (0.00, 0.20)$, $a_{2,10} = 0.30$, $b_{2,10} = 4.5$
 $(p_{2,1x}^{\min}, p_{2,1x}^{\max}) = (0.01, 0.15)$, $a_{2,1x} = 0.15$, $b_{2,1x} = 2.3$
 $(p_{2,01}^{\min}, p_{2,01}^{\max}) = (0.01, 0.23)$, $a_{2,01} = 0.20$, $b_{2,01} = 4.5$
 $(p_{2,0x}^{\min}, p_{2,0x}^{\max}) = (0.00, 0.18)$, $a_{2,0x} = 0.15$, $b_{2,0x} = 5.0$
 $w_2 = 1.0$

Voter 3 : $(p_{3,10}^{\min}, p_{3,10}^{\max}) = (0.01, 0.20)$, $a_{3,10} = 0.25$, $b_{3,10} = 4.0$
 $(p_{3,1x}^{\min}, p_{3,1x}^{\max}) = (0.01, 0.10)$, $a_{3,1x} = 0.20$, $b_{3,1x} = 2.0$
 $(p_{3,01}^{\min}, p_{3,01}^{\max}) = (0.00, 0.10)$, $a_{3,01} = 0.15$, $b_{3,01} = 4.5$
 $(p_{3,0x}^{\min}, p_{3,0x}^{\max}) = (0.01, 0.20)$, $a_{3,0x} = 0.20$, $b_{3,0x} = 4.0$
 $w_3 = 1.5$

For three different options of threshold value $\tau = 0.3, 0.5$, and 0.7 , the time-dependent reliabilities $R_{\text{sys}}(t)$ at time t are calculated. Figure 55.2 shows six time-dependent reliability curves against time t . For simplicity, only two types of curves are provided. One curve is the reliability of input $P = 0$, and the other one is of input $P = 1$, respectively.

- In the first subplot with $\tau = 0.3$, the system reliability R_{sys} when $P = 1$ is always larger than $P = 0$, and its maximum value when $P = 1$ is clearly larger than $P = 0$.

Fig. 55.2 Time-dependent system reliability at time t under different τ

- In the second subplot with $\tau = 0.5$, the system reliability R_{sys} when $P = 1$ is most likely larger than when $P = 0$, and they both converge to 0.9992.
- In the third subplot with $\tau = 0.7$, the system reliability R_{sys} when $P = 1$ is always smaller than $P = 0$, and its maximum value when $P = 0$ is clearly larger than $P = 1$.

The system performance reacts differently at different values of τ . Smaller value results better performance given input $P = 1$, and larger value results higher reliable performance given input $P = 0$. To make the consistent system regardless of input patterns, medium value of τ is an option.

55.3.4 Optimal Stopping Time at Minimal Cost

It is impractical to process the system output for unlimited time; therefore, one of the primary goals is the budget control to make the model applicable. *Xie and Pham [15]* assumed that the error probabilities of each voter decrease as the time the voter spends on decision-making increases, which means that the system reliability is an increasing function of t . If t is limited, the system may not be reliable enough to guarantee the confidence for the decision. Thus, the motivation is to take the minimal time to generate an output with respect to higher reliability.

Linear Time-Dependent Cost Function

The goal is to determine the optimal stopping time to minimize the total cost by sacrificing limited amount of system

reliability. Define R_L as a prespecified least reliability value that the system is required to be achieved. Consider a simple linear time-dependent cost function,

$$LC(t) = c_1 (1 - R_t) + c_2 t \quad \text{such that } R_t \geq R_L \quad (55.7)$$

where c_1 is the cost associated with wrong decision and c_2 is the cost of unit time spent on decision process by all voters. In this case, both c_1 and c_2 are constants; however, they could also be time t dependent function as more complicated requirements may be considered in practice.

Denote $T = \operatorname{argmin}_{\{0 < t < \infty, R_t \geq R_L\}} LC(t)$ and T is the optimal stopping time that minimizes the cost $LC(t)$ subject to the constraint $R_t \geq R_L$ in limited time t . Then, define $t_0 = \inf \{t > 0 \mid R_t \geq R_L\}$ and t_0 is the minimum time to reach the prespecified value R_L . As R_t is a continuous and nondecreasing function of t , there exists an optimal time $T \in [t_0, t_0 + c_1 c_2^{-1} (1 - R_L)]$.

To obtain the numerical value of the optimal time T inside the interval $[t_0, t_0 + c_1 c_2^{-1} (1 - R_L)]$, one effective approach is to find the roots of the equation.

$$\left[\frac{d}{dt} LC(t) \right] \Big|_{t=T} = 0 \iff \left[\frac{d}{dt} R_t \right] \Big|_{t=T} = \frac{c_2}{c_1}$$

By solving it recursively from the *Newton-Raphson* algorithm, starting with an initial value $T^{(0)} \in [t_0, t_0 + c_1 c_2^{-1} (1 - R_L)]$, one can calculate the equation. For $k = 1, 2, \dots, m$.

Fig. 55.3 Liner cost function at time t under different τ

$$T^{(k)} = T^{(k-1)} + \left\{ \left[\frac{d}{dt} R_t \right] \Big|_{t=T^{(k-1)}} - \frac{c_2}{c_1} \right\} \left[\frac{d}{dt} R_t \right] \Big|_{t=T^{(k-1)}} \quad (55.8)$$

As the algorithm is numerically convergent, we normally can get a root, T^* , for Eq. (55.8). If $T^* \in [t_0, t_0 + c_1 c_2^{-1} (1 - R_L)]$ and $C(T^*) < C(t_0)$, we obtain $T = T^*$, otherwise, $T = t_0$.

Example 55.5 Continuous with Example 55.4. Suppose $c_1 = 90$ and $c_2 = 3$. Figure 55.3 plots the cost functions $LC(t)$ against t for the six cases illustrated in Fig. 55.2.

Assume the least reliability value required is $R_L = 0.95$.

- In the case of $\tau = 0.3$, the minimum time to achieve R_L is $t_0 = 41$ if the input $P = 0$ and $t_0 = 17$ if the input $P = 1$.
- In the case of $\tau = 0.5$, the minimum time to achieve R_L is $t_0 = 35$ if the input $P = 0$ and $t_0 = 26$ if the input $P = 1$.
- In the case of $\tau = 0.7$, the minimum time to achieve R_L is $t_0 = 24$ if the input $P = 0$ and $t_0 = 37$ if the input $P = 1$.

Thus, according to the optimal time $T \in [t_0, t_0 + c_1 c_2^{-1} (1 - R_L)]$,

- If $\tau = 0.3$, $T \in [41, 42.5]$ if the input $P = 0$ and $T \in [17, 18.5]$ if the input $P = 1$.
- If $\tau = 0.5$, $T \in [35, 36.5]$ if the input $P = 0$ and $T \in [26, 27.5]$ if the input $P = 1$.
- If $\tau = 0.7$, $T \in [24, 25.5]$ if the input $P = 0$ and $T \in [37, 38.5]$ if the input $P = 1$.

By checking the monotonicity of the optimal time interval for all six cases, the optimal time T is,

- If $\tau = 0.3$, $T = 41$ if the input $P = 0$ and $T = 17$ if the input $P = 1$.
- If $\tau = 0.5$, $T = 35$ if the input $P = 0$ and $T = 26$ if the input $P = 1$.
- If $\tau = 0.7$, $T = 24$ if the input $P = 0$ and $T = 37$ if the input $P = 1$.

In other words, for instance, given $\tau = 0.5$, the system cost $LC(t)$ will be minimal while still achieving system reliability at least $R_L = 0.95$ at the time $T = 35$ if the input $P = 0$ and at the time $T = 26$ if the input $P = 1$.

Higher-Order Time-Dependent Cost Function

Linear time-dependent cost function provides a simple typical case; beside time cost and punishment from wrong decision, there could be more cost such as labor cost and capital cost that depends on specific requirements. On the other hand, higher-order time-dependent cost function may also be applied on some situations when different costs are considered unequally weighted.

Consider a quadric time-dependent cost function with nonlinear cost on unit time,

$$HC(t) = c_3 (1 - R_t) + c_4 t^2 \quad \text{such that } R_t \geq R_L \quad (55.9)$$

where c_3 is the cost associated with wrong decision and c_4 is the cost of square of unit time by all voters. In this case, extra

time spent during the process of decision-making is more expensive to boost the cost out of the budget.

Similarly, define $T = \operatorname{argmin}_{\{0 < t < \infty, R_t \geq R_L\}} \text{HC}(t)$ be the optimal stopping time that minimizes the cost $\text{HC}(t)$ subject to the constraint $R_t \geq R_L$ in limited time t . Then, $t_0 = \inf \{R_t \geq R_L | t > 0\}$ is the minimum time to reach the prespecified value R_L . As R_t is a continuous and nondecreasing function of t , one can find an optimal time $T \in \left[\sqrt{t_0}, \sqrt{t_0 + c_3 c_4^{-1} (1 - R_L)} \right]$.

To obtain the optimal time T inside the interval $\left[\sqrt{t_0}, \sqrt{t_0 + c_3 c_4^{-1} (1 - R_L)} \right]$, the same approach yields the following equation.

$$\left[\frac{d}{dt^2} \text{HC}(t) \right] \Big|_{t=T} = 0 \iff \left[\frac{d}{dt^2} R_t \right] \Big|_{t=T} = \frac{2c_4}{c_3}$$

Applying *Newton-Raphson* algorithm with an initial value $T^{(0)} \in \left[\sqrt{t_0}, \sqrt{t_0 + c_3 c_4^{-1} (1 - R_L)} \right]$, one can calculate the equation. For $k = 1, 2, \dots, m$.

$$T^{(k)} = T^{(k-1)} + \left\{ \left[\frac{d}{dt^2} R_t \right] \Big|_{t=T^{(k-1)}} - \frac{2c_4}{c_3} \right\} \left[\frac{d}{dt^2} R_t \right] \Big|_{t=T^{(k-1)}}$$

Then, if $T^* \in \left[\sqrt{t_0}, \sqrt{t_0 + c_3 c_4^{-1} (1 - R_L)} \right]$ and $C(T^*) < C(t_0)$, we obtain $T = T^*$, otherwise $T = t_0$.

Example 55.6 Continuous with Example 55.5. To better depict the difference from linear case, assume $c_3 = 90$ and $c_4 = 3$ equivalent to c_1 and c_2 . Figure 55.4 plots the cost functions $\text{HC}(t)$ against t for the six cases illustrated in Fig. 55.2. And the comparison can be illustrated clearly from Fig. 55.3.

Assume the least reliability value required is $R_L = 0.95$; as the time-dependent reliability function preserves, one can obtain the identical minimum time to achieve R_L for input $P = 0$ and $P = 1$, respectively.

- In the case of $\tau = 0.3$, the minimum time to achieve R_L is $t_0 = 41$ if the input $P = 0$ and $t_0 = 17$ if the input $P = 1$.
- In the case of $\tau = 0.5$, the minimum time to achieve R_L is $t_0 = 35$ if the input $P = 0$ and $t_0 = 26$ if the input $P = 1$.
- In the case of $\tau = 0.7$, the minimum time to achieve R_L is $t_0 = 24$ if the input $P = 0$ and $t_0 = 37$ if the input $P = 1$.

Thus, according to the optimal time $T \in \left[\sqrt{t_0}, \sqrt{t_0 + c_3 c_4^{-1} (1 - R_L)} \right]$,

- If $\tau = 0.3$, $T \in [6.40, 6.52]$ if the input $P = 0$ and $T \in [4.12, 4.30]$ if the input $P = 1$.
- If $\tau = 0.5$, $T \in [5.92, 6.04]$ if the input $P = 0$ and $T \in [5.09, 5.24]$ if the input $P = 1$.
- If $\tau = 0.7$, $T \in [4.90, 5.05]$ if the input $P = 0$ and $T \in [6.08, 6.21]$ if the input $P = 1$.

By checking the monotonicity of the optimal time interval for all six cases, the optimal time T is,

- If $\tau = 0.3$, $T = 6.40$ if the input $P = 0$ and $T = 4.12$ if the input $P = 1$.
- If $\tau = 0.5$, $T = 5.92$ if the input $P = 0$ and $T = 5.09$ if the input $P = 1$.
- If $\tau = 0.7$, $T = 4.90$ if the input $P = 0$ and $T = 6.08$ if the input $P = 1$.

As expected, cost of unit time in quadric formula reaches to a high level much faster than linear formula. It is much harder to keep the system reliable at this case since there is much less time in the process of decision-making. From the comparison of Examples 55.5 and 55.6, one can tell the budget control substantially influences decision-making.

55.4 Weighted Threshold Indecisive Voting System

Although the situation of no decision of any voter has been noticed in the basic model assumptions, the weighted voting system introduced in Sect. 55.3 uses a classic decision rule without considering indecisive effect, that is, weights of voters who have no decision do not get involved in calculations. This will likely cause bias even in some simple situations. For example, suppose an HO system with 10 voters makes the decision on a proposal. Eight voters have no decision, and the other two have decisions with one acceptance and one rejection. If the one-vote acceptance has higher weights than the one-vote rejection, the final decision is acceptance according to the classic decision rule. However, this may not be true as the summation of weights for 8 voters with no decision may be much larger, and the proper decision might be either rejection or reevaluation.

Zhang and Pham [16] studied a generalized weighted indecisive voting n -units system using a new decision rule considering indecisive effect, where the classic decision rule becomes the special case of the indecisive decision rule. They are trying to scale the effects of indecisiveness to the entire system performance in terms of system reliability. The numeric examples do the comparison between two decision rules and illustrate the sensitivities of the model.

Fig. 55.4 Quadric cost function at time t under different τ

55.4.1 Model Assumptions

The basic model assumptions are the same as ones defined in Sect. 55.3 except for the last one, the law of the decision rule. In this section, a decision rule is designed with two prespecified parameters of threshold and indecision (τ, θ) incorporating all subdecisions to generate the final decision. The additional indecision parameter, θ , is introduced in the decision rule as indecisive effect is considered. Note that θ has domain different than τ as θ can be zero, which makes the indecisive decision rule be the classic one described in Sect. 55.3.

55.4.2 Indecisive Decision Rule

The weights of indecisive voters are treated as obstacles of decision-making because no decision is likely to be considered a negative decision. Given any input, a decision should be made as acceptance if the input is favorable and vice versa. In such a case, no decision is more likely a nonfavorable decision, which may result a wrong final decision or reevaluation. Thus, given the input is 1 (favorable), the system output is 1 if and only if the follow equation is satisfied.

$$\sum_{i \in I_1} w_i \geq \tau \left(\sum_{i \notin I_x} w_i + \theta \sum_{i \in I_x} w_i \right) \quad (55.9)$$

Total weights of each voter who votes 1 in the left-hand side need to exceed partial of the total weights where the indecisive weights are drained out accordingly. A parameter θ used to distinguish no decision from wrong decision is applied on the indecisive weights in the right-hand side. Note θ can be zero, which results the decision rule to be the classic one in Sect. 55.3.

55.4.3 Indecisive Model Formulation

To formulate the indecisive model, Zhang and Pham [16] regenerate the recursive function to avoid imposing restrictions [11, 14]. They used the same technic to define a random variable X_i where $i = 1, 2, \dots, n$ where indecisive index is newly introduced.

$$X_i = \begin{cases} 1 - \tau & \text{if } i \in I_1 \\ -\tau & \text{if } i \in I_x \\ -\tau\theta & \text{if } i \in I_0 \end{cases} \quad (55.10)$$

Rewriting Eq. (55.10), the system output is 1 (favorable) if and only if,

$$\sum_{i \in I_1} w_i - \tau \sum_{i \notin I_x} w_i - \tau\theta \sum_{i \in I_x} w_i \geq 0 \quad (55.11)$$

Simplifying (55.11) for a clear vision, the second sum can be disaggregated and then rearranged.

$$\sum_{i \in I_1} (1 - \tau) w_i - \sum_{i \in I_0} \tau w_i - \sum_{i \in I_x} \tau \theta w_i \geq 0 \tag{55.12}$$

$$\iff \sum_{i=1}^n w_i X_i \geq 0$$

Equation (55.12) clearly interprets contribution values of three types of individual decision, where the positive value $(1 - \tau)w_i$ of voter i accumulates if it votes acceptance, the negative value $-\tau w_i$ of voter i summed up if it votes rejection, and the negative value $-\tau \theta w_i$ of voter i is added together if it abstains. Then, two similar probability functions can be induced as follows.

$$Q_n(s) = \Pr\left(\sum_{i=1}^n w_i X_i \geq s \mid P = 1\right)$$

$$\tilde{Q}_n(s) = \Pr\left(\sum_{i=1}^n w_i X_i < s \mid P = 0\right)$$

Initializing variable $s = 0$, one obtains conditional probability functions,

$$Q_n(0) = \Pr\left(\sum_{i=1}^n w_i X_i \geq 0 \mid P = 1\right) = \Pr(S = 1 \mid P = 1)$$

$$\tilde{Q}_n(0) = \Pr\left(\sum_{i=1}^n w_i X_i < 0 \mid P = 0\right) = \Pr(S = 0 \mid P = 0)$$

Hence, the reliability of the weighted threshold indecisive voting system with n voters is,

$$R_{\text{sys}} = Q_n(0) \Pr(P = 1) + \tilde{Q}_n(0) \Pr(P = 0)$$

where $Q_n(s)$ and $\tilde{Q}_n(s)$ can be written in terms of recursive functions, and the restricted domains are different from the classic ones illustrated in Sect. 55.3. Simply, an indecisive parameter θ is considered showing as follows,

For $n \geq 1$,

$$Q_1(s) = \begin{cases} 1 & \text{if } s \leq -\tau w_1 \\ p_{1,11} + p_{1,1x} & \text{if } -\tau w_1 < s \leq -\tau \theta w_1 \\ p_{1,11} & \text{if } -\tau \theta w_1 < s \leq (1 - \tau) w_1 \\ 0 & \text{if } s > (1 - \tau) w_1 \end{cases}$$

$$\tilde{Q}_1(s) = \begin{cases} 0 & \text{if } s \leq -\tau w_1 \\ p_{1,00} & \text{if } -\tau w_1 < s \leq -\tau \theta w_1 \\ p_{1,00} + p_{1,0x} & \text{if } -\tau \theta w_1 < s \leq (1 - \tau) w_1 \\ 1 & \text{if } s > (1 - \tau) w_1 \end{cases}$$

For $n \geq 2$

$$Q_n(s) = Q_{n-1}(s_n^1) p_{n,11} + Q_{n-1}(s_n^x) p_{n,1x} + Q_{n-1}(s_n^0) p_{n,10}$$

$$\tilde{Q}_n(s) = \tilde{Q}_{n-1}(s_n^1) p_{n,11} + \tilde{Q}_{n-1}(s_n^x) p_{n,1x} + \tilde{Q}_{n-1}(s_n^0) p_{n,10}$$

where $s_n^1 = s - (1 - \tau) w_n$, $s_n^x = s + \tau w_n$, and $s_n^0 = s + \tau \theta w_n$. One more parameter from indecisive effect recursively makes the equations more complicated as the n goes up. Two examples are provided varying values for one parameter while another one is fixed, and it aims to provide a brief knowledge of an across relation between two parameters and a simple comparison between two decision rules.

55.4.4 Numerical Example of Indecisive System Reliability

Example 55.7 Consider a grant institution votes to fund good proposals and suppose the voting group has $n = 4$ members and probabilities of their judgment errors with assigned weights are given the same as in Example 55.2. Fix the indecisive parameter $\theta = 0$; the calculations from three values of $\tau = \{0.1, 0.5, 0.9\}$ are tabled, where weights are normalized. Note that $\theta = 0$ makes the indecisive decision rule identical in Sect. 55.3. This example shows how single parameter τ is affecting the system reliability.

In Table 55.2, system reliability under five different prior distributions of inputs P are calculated. Two extreme cases of threshold τ in third and fifth rows indicate inverse results, where the system is more reliable of favorable proposals when τ is extremely small and vice versa when τ is extremely high. From the calculations, the system guarantees the quality of proposals in the way that bad proposals are easily rejected, and good proposals seem to be accepted competitively. Figure 55.5 intuitively summaries the trend of performance in terms of system reliability.

The system reaches a steady state regardless of the quality of proposals when $\tau = 0.5$. The initialization of τ really depends on how much knowledge of the input is obtained. This example recalls the classic decision by setting $\theta = 0$ and extends the calculations by illustrating two more extreme cases of τ .

Example 55.8 (Extended Example 55.7) Calculations of three fixed values of $\tau = \{0.1, 0.5, 0.9\}$ while the values of θ vary. This example shows how cross effect influences the system reliability from both parameters.

- A higher value of θ downgrades R_{sys} given favorable proposals; however, it increases R_{sys} given nonfavorable proposals. Given τ , one can see larger variations of R_{sys} for

Table 55.2 System reliability with $\theta = 0$

Pr($P = 1$)	1.0	0.8	0.5	0.2	0.0
τ	R_{sys} with $\theta = 0$				
$\tau = 0.1$	0.9956	0.9108	0.7836	0.6564	0.5717
$\tau = 0.5$	0.9214	0.9207	0.9196	0.9186	0.9178
$\tau = 0.9$	0.5400	0.6311	0.7678	0.9045	0.9956

favorable proposals than nonfavorable ones with respect to θ .

- In practice, high penalties for indecisive decisions result in more competitive situations for favorable proposals. In

the meanwhile, this can easily prevent the acceptance from nonfavorable proposals since indecisive votes are likely treated as nonacceptable votes.

It turns out that indecisive effect is sensitive in types of inputs. Figure 55.6 visualizes Table 55.3 by showing the trend of performance via different initializations of θ in terms of system reliability under different distributions of inputs.

Fig. 55.5 Illustration of system performance in Table 2

- Higher probabilities of favorable proposals result in larger R_{sys} with smaller τ when θ is fixed, and with smaller θ if τ is fixed. The situation overturns with unfavorable proposals. Somehow, it indicates the sensitivity of the prior distribution of inputs.
- Both high values of τ when θ is fixed and high values of θ when τ is fixed make favorable proposals competitively acceptable and nonfavorable ones easily rejected. Thus, initializations of both parameters affect the system performance, and one has the independent theory to optimize the system associated with prespecified assumptions.
- Overall, the system is stable under $\tau = 0.5$ whenever θ changes, which provides a naive option when prior information of input is limited.

Fig. 55.6 Illustration of system performance in Table 55.3

Table 55.3 System reliability with $\tau = \{0.1, 0.5, 0.9\}$

$\Pr(P = 1)$	1.0	0.8	0.5	0.2	0.0
θ	R_{sys} with $\tau = 0.1$				
$\theta = 0.0$	0.9956	0.9108	0.7836	0.6564	0.5717
$\theta = 0.2$	0.9954	0.9107	0.7836	0.6566	0.5719
$\theta = 0.4$	0.9954	0.9107	0.7836	0.6566	0.5719
$\theta = 0.8$	0.9954	0.9107	0.7836	0.6566	0.5719
θ	R_{sys} with $\tau = 0.5$				
$\theta = 0.0$	0.9214	0.9207	0.9196	0.9186	0.9178
$\theta = 0.2$	0.9011	0.9078	0.9178	0.9279	0.9346
$\theta = 0.4$	0.8876	0.8977	0.9130	0.9282	0.9383
$\theta = 0.8$	0.8298	0.8537	0.8894	0.9251	0.9489
θ	R_{sys} with $\tau = 0.9$				
$\theta = 0.0$	0.5400	0.6311	0.7678	0.9045	0.9956
$\theta = 0.2$	0.4279	0.5421	0.7134	0.8846	0.9988
$\theta = 0.4$	0.3820	0.5054	0.6905	0.8756	0.9990
$\theta = 0.8$	0.2948	0.4358	0.6473	0.8587	0.9997

- Nonzero θ downgrades the overall system performance. It is straightforward when threshold τ is large by comparing values of intersection of x -axis representing input P .

In real applications, the threshold value is very substantial in deterministic optimization of the system performance. Given the size of the voters and the error probabilities of each voter with respect to each type of individual decision, cross effects from both parameters θ and τ bring complications in decision-making along with uncertain types of inputs. As discussed in Sect. 55.3, cost function is time-dependent; to have a better understanding of prior information of inputs, certain effort is required. However, a budget constraint would then change the optimization process as extra restrictions relocate the local optimal.

55.4.5 Sensitivity Analysis on WVS

Two major reasons drive the test of different combinations of (τ, θ) along with different qualities of voters. First, system reliability is used to quantify system reactions under certain policies and constraints including maximal system reliability or minimal budget cost, therefore, resulting in location detections of parameterization. Moreover, the decision process becomes less optimistic when the prior information is limited, which again relates to the assumptions of budget constraints. What is interesting is the mutual interactions between them and makes them become a closed loop. To loop out of the circle, sensitivity analysis may help to locate the equilibrium.

Fig. 55.7 Sensitivity on failure rate

Intrinsic Sensitivity

Example 55.9

(Sensitivity on Failure Rate of Voters) Recall Example 55.2 as a control case. Zhang and Pham [16] showed the 10% decrease/increase of all types of errors of each voter has limited influence on system reliability, which outstands the advantage of the model design. In this example, 50% decrease/increase of failure rate of each voter is applied on their model. Figure 55.7 plots the change of system reliability at $\theta = \{0.0, 0.4, 0.8\}$ with $\tau = 0.5$ while other variables are fixed. Table 55.4 compares two cases.

Different from 10% change of failure rate [16], 50% change of failure rate has significant distinctions in drop and raise failure rates.

- First, 50% drop/raise of $p_{i,vv'}$ (reliable/less reliable voters) results a 5–15%/5–10% increase/decrease in system reliability among all three cases.
- Moreover, the variation of system reliability in drop case is much bigger than in the raise case, which is different from 10% change of failure rate.
- The raise case has more advantages in real applications. Much less reliable voters result limited downgrade in system performance. And variations of the system reliability are small enough among three combinations of parameterizations.

Table 55.4 Reliability of different $p_{i,vv'}$ with $(\tau, \theta) = (0.5, 0.0)$

		R_{sys}		
$\Pr(P=1)$	Control	10% Drop $p_{i,vv'}$	10% Raise $p_{i,vv'}$	Change in %
0.0	0.9178	0.9339	0.9000	1.75 / -1.94
0.4	0.9193	0.9351	0.9017	1.72 / -1.91
0.8	0.9207	0.9363	0.9033	1.69 / -1.89
1.0	0.9214	0.9369	0.9041	1.68 / -1.88
		R_{sys}		
$\Pr(P=1)$	Control	50% drop $p_{i,vv'}$	50% raise $p_{i,vv'}$	Change in %
0.0	0.9178	0.9838	0.8571	7.19 / -6.61
0.4	0.9193	0.9835	0.8540	6.98 / -7.10
0.8	0.9207	0.9831	0.8508	6.78 / -7.59
1.0	0.9214	0.9829	0.8492	6.67 / -7.84

Table 55.4 exhibits the calculated numbers for both 10% and 50% cases with $(\tau, \theta) = (0.5, 0)$, which shows 5 times difference in voters' qualities results less than 5 times difference in system reliability. This may indicate the advantage of the system design.

Example 55.10

(Sensitivity on τ) Recall Example 55.2 as a control case. This example focuses on how τ affects the system by fixing all other variables and parameters. Five different values of $\tau = \{0.1, 0.3, 0.5, 0.7, 0.9\}$ are applied in calculations. Figure 55.8 plots three cases given $\theta = \{0.0, 0.4, 0.8\}$. First subplots of Fig. 55.8 represent the classic decision rule as indecisiveness is excluded with $\theta = 0$.

- When $\tau < 0.5$, system reliability R_{sys} has an increasing trend as the system is reliable given favorable proposals. When $\tau > 0.5$, system reliability R_{sys} has a decreasing trend as the system is less reliable given favorable proposals.
- $\tau = 0.5$ makes the system reach to a steady state given any inputs if indecisiveness is not considered ($\theta = 0$); however, this is not the case when indecisiveness is applied in decision rule as one can see in the second and third subplots of Fig. 55.8.
- Indecisiveness makes the system more sensitive in choices of threshold τ . The overall system performance is reliable as $\min_P R_{sys} > 0.5$ independent from the choices of τ in the first subplot of Fig. 55.8, but the system become less stable with large value of τ when $\theta \neq 0$.

Example 55.10

(Sensitivity on θ) Recall Example 55.2 as a control case. This example focuses on how θ affects the system by fixing all other variables and parameters. Five different values

of $\theta = \{0.1, 0.3, 0.5, 0.7, 0.9\}$ are applied in calculations. Figure 55.9 plots three cases given $\tau = \{0.1, 0.5, 0.9\}$. In this example, $\theta = 0$ is omitted as it studies θ influence. One can see the domination of τ as it determines how system is affected in terms of R_{sys} , although θ indeed has internal effects.

- When $\tau = 0.1$, all 5 lines representing different options of θ overlap together. θ has no influence at all. As the threshold is small, it makes indecisiveness small enough to lose power to play in the role. In fact, this also proves small threshold is less practical.
- As τ gets bigger, θ is brought back to the game. From both second and third subplots of Fig. 55.9, larger θ makes the system less reliable if τ is fixed. However, θ causes larger variations when τ is large; therewith, θ is sensitive on condition of τ .
- When $\tau = 0.5$, system is stable even with the missing information of inputs. Although the system is less sensitive on θ , it can still be a secondary factor in model modifications as τ is the dominant factor in decision rule.

Extrinsic Sensitivity

The indecisive effect can be applied when people have difficulties in making decisions. If more time t can be spent to collect more information, it may be helpful to make decisions. In fact, this is meaningful in social activities. Zhang and Pham [16] have done some jobs on this problem. Three extreme conditions are considered unless any specific motivation is specified. Without loss of generality, more information is assumed to decrease the probability of no decision $p_{i,vx}$ where $v = \{0, 1\}$ for voter i and $x \in v'$. However, one does not know if extra information contributes either positively or negatively. Therefore, it would be wise to assume that decreasing values have three different flows.

Fig. 55.8 Sensitivity on τ

- *Flow 1*: Decreasing values $\tilde{p}_{i,vx}$ from indecisive probabilities all contribute to probability of making correct decision, that is, $p_{i,00} = p_{i,00} + \tilde{p}_{i,0x}$ and $p_{i,11} = p_{i,11} + \tilde{p}_{i,1x}$.
- *Flow 2*: Decreasing values $\tilde{p}_{i,vx}$ from indecisive probabilities all contribute to probability of making wrong decision, that is, $p_{i,01} = p_{i,01} + \tilde{p}_{i,0x}$ and $p_{i,10} = p_{i,10} + \tilde{p}_{i,1x}$.
- *Flow 3*: Decreasing values $\tilde{p}_{i,vx}$ from indecisive probabilities contribute to probability of making correct and wrong decision with equal probability, that is, $p_{i,00} = p_{i,00} + 0.5\tilde{p}_{i,0x}$ and $p_{i,01} = p_{i,01} + 0.5\tilde{p}_{i,0x}$ if input $P = 0$, and $p_{i,10} = p_{i,10} + 0.5\tilde{p}_{i,1x}$ and $p_{i,11} = p_{i,11} + 0.5\tilde{p}_{i,1x}$ if input $P = 1$.

Example 55.11

(Sensitivity on time T) After certain effort made by time T , voters' probability of indecision drops to half of the original level, $\tilde{p}_{i,vx} = 0.5p_{i,vx}$, where $p_{i,vx}$ is from Example 55.2 as a control experiment. To minimize the side effect from initialization of two parameters, $\tau = 0.5$ is applied. Figure 55.10 depicts R_{sys} for all three flows under three cases of $\theta = \{0.1, 0.5, 0.9\}$.

- The solid black curve on each subplot represents the control experiment for all three cases. Flow 1 and flow 2 represent two extreme conditions which define the upper and lower bounds for the black curve.
- The lower bound, flow 2, is the worst condition that indicates the waste of the effort as system becomes less reliable. In fact, this is less likely to happen.
- The ideal condition of flow 1 indicates certain effort is worthy as system reliability improves quite a bit, and flow 3 is showing some credits of the effort from the third subplots.
- This example indeed gives confidence on effort of lowering indecisive effect, and applying some risk management will likely control the direction above flow 3 and reach to flow 1 as possible.

One can also consider this problem associated with cost control as the discussion in Sect. 55.3. In this example, a constant function after time T is studied. However, one can still apply a time-dependent function if restrictions only allow $t < T$ spent on effort as it is more practical in real applications.

Fig. 55.9 Sensitivity on θ

55.5 Other Related Works

55.5.1 Model-Related Studies

Based on the framework of weighted voting systems, some key components of WVS are studied. And those ideas and techniques are critical and creative to reach the goal of optimizations under various practical requirements.

Levitin [19] showed the additional reliability improvement achieved by grouping units in voting subsystems and tallying the weighted votes of such subsystems to make a final decision. He aimed to answer the question that if there was a way to make WVS more reliable without affecting the failure rate of individual voter, which could be achieved by grouping voters into several separate voting subsystems sharing the same decision rule. Each category was considered as a new united voter with new weights generated from each element of the category until final decision was made; therefore, the threshold value τ needed to be further determined into a group of threshold values with respect to each group. A specific algorithm was suggested that obtains the optimal element grouping as well as weights within each group, and its evaluation process was based on universal generating techniques. He concluded that unit grouping is most beneficial

when some units had very similar probabilities of making correct decisions to certain type of inputs.

Long et al. [20] studied the system reliability optimization of WVS with continuous states inputs, where they derived the analytical expression. For the reliability of the entire system under certain distribution assumptions. They pointed out the limitation of many existing models with inputs having very small state spaces. Furthermore, the number of different combinations of generated output rose dramatically with increased input states. Therewith, they provided an example to describe the configuration of a WVS consisting of n independent voters with continuous states input. To evaluate the effectiveness and accuracy of the model, they applied Monte Carlo Simulations to reach the randomization requirement to quantify the model. Some optimization problems with cost constraints were formulated based on continuous inputs, where they concluded that different types of voters resulted different allocations under various cost constraints.

Foroughi and Aouni [21] applied data envelopment analysis to show the drawbacks of the assignment of weights in the existing model and create an approach for determining a common set of weights of voters in a WVS. Weights obtained from inefficient voters and their sensitivity to the votes from the worst voters were major shortcomings needed to be overcome. They built a new model using only the

Fig. 55.10 Sensitivity on T

information about efficient voter and prevented selection of zero weights. Moreover, to enlarge the discrimination power and minimize the possibility of having multiple optimal solutions, some additional objective functions were used. Examples of a new generated two-objective function model are utilized as a combination of the new model they built with the existing model. They addressed some fundamental but significant works on weights of a WVS, which is crucial to quantify the system performance. More research needs to be done on determination of weights of voters, one of the key components of a WVS.

55.5.2 Application-Related Studies

Besides traditional applications of WVS on target detection, communication systems, and pattern recognition, WVS can be applied on more advanced modern applications as the characteristics of WVS are well established so far. Case studies such as works mentioned below are indicating accuracy and effectiveness of weighted voting systems.

Sun and Han [22] proposed a dynamic weighted voting based on knowledge discovery on multiple classifier systems to improve its performance. Principal components analysis was used for the feature extraction and decorrelation

to reduce the pattern dimensions. Then, the model of the new classifier fusion was built by introducing the algorithm step by step, and experimental results indicate the system performance of the classification can be improved; therefore, the proposed method in image classification is effective. They concluded two attractive characteristics including operation of base classifiers and auto-generation of mass function induced from interclass in different feature spaces. In such a way, weights assigned to each output of the base classifier were able to estimate by the separability of the training sample sets in relevant feature spaces, and all weights were able to be calculated by a modified heuristic fusion function and assigned randomly to each classifier varying with its output from mass functions.

Levitin [23] studied a WVS of units with nonsimultaneous outputs delivery, where the decision time of the entire system was dependent on the distribution of unit weights and on the value of threshold in decision rule. Decision-making on a WVS in practice usually had constraint of limited time; therefore, a measurement of its performance was considered as the expected system decision time. He formulated the problem of the optimal system equivalent to locate voters' weights and threshold that maximize the system reliability while providing the expected decision time less than a predetermined value. The algorithm based on universal generating function

for evaluating WVS reliability and expected decision time illustrated the existence of the trade-off between the system reliability and its rapidity.

Liu and Zhang [24] built a WVS model with two different kinds of unreliable links including type I of two states with reliable connection and complete failure and type II of three states with reliable connection, error, and failure. Outputs of voting units might not be properly transferred to a sink unit because of the unreliability of links between voting units and sink units. Wireless sensor network was applied in their model design and formulation. By illustrating examples, they studied the influence of a specified link's reliability and some system variables on reliability optimization on a WVS. Under type I links, the system was more reliable with the increase of link quality or the number of units. If type II links were applied, the effect from the change on the mean value of unit reliability was reduced with the increasing number of voting units. This work focused on a potential component of WVS that could be significant but easily ignored.

55.6 Conclusion and Future Research

In this chapter, the framework of weighted voting system with nonidentical voters subject to three types of failure rate is presented. For the weighted threshold voting system, three key components including *voters*, *weights*, and *decision rules* are introduced. Two decision rules are considered. One is a classic decision rule without indecisive effect, and the other one is an extended decision rule considering indecisive effect. System reliability is used to quantify the system performance of a WVS, and some approximation techniques are applied under certain purposes. Numeric examples are illustrated to better understand how WVS evaluate the whole process of decision-making. Sensitivity analysis is presented via different optimization problems with certain constraints. Last but not least, many related works that cannot be fully explained are also mentioned to give a brief but full picture of current results of WVS.

The results of indecisive effect along with recursive evaluation functions presented in this chapter are a recent research. Although sensitivity analysis shows its potential of widely usage in practice, some new problems are also induced such as the new indecisive parameter in decision rule and the types of inputs. Therefore, some extensions from current research may be treated as future research works.

- The optimization of system decisions with respect to decision rule under different assumptions on failure rate of each voter is mentioned by Sah [25], and it turns out that the size of voters is strongly related. As the modern decision rule introduced in this chapter is much more

complicated, it requires more research on optimization study from the size of voters.

- The indecisive parameter is usually dynamic rather than static in an HO system; the true distributed indecisive parameter will maintain the system performance in a high level. In the meanwhile, the accurate distribution of indecisive parameter has significant influence on model optimization. More research is needed to address those problems.
- Inputs are assumed to be known and played an extremely important role in computation process in this chapter. However, this does not conclude all cases. In real, a WVS is required to generate the decision based on unknown input, and the problem of how to design the WVS given unknown inputs to keep the system function as reliable remains unsolved; a control system may be a key to be combined in WVS. Also, the state of inputs is another question to investigate, for example, the correlation between indecisive effect and continuous/discrete inputs remains unknown. Certain works need to be done for these meaningful problems.

Abstract

This chapter deals with statistical problems involving *image registration* from landmark data, either in Euclidean 2-space R^2 or 3-space R^3 . In this problem, we have two images of the same object (such as satellite images taken at different times) or an image of a prototypical object and an actual object. It is desired to find the rotation, translation, and possibly scale change, which will best align the two images. Whereas many problems of this type are two-dimensional, it should be noted that medical imaging is often three dimensional.

After discussing several estimation techniques and their calculation, we discuss the relative efficiency of the various estimators. These results are important in choosing an optimal estimator. The relationship of the geometry of the landmarks to the statistical properties of the estimators is discussed. Finally we discuss diagnostics to determine which landmarks are most influential on the estimated registration. If the registration is unsatisfactory, these diagnostics can be used to determine which data points are most responsible and should be reexamined.

56.1 Unknown Coordinate Systems and Their Estimation

This chapter deals with statistical problems involving *image registration* from landmark data, either in Euclidean 2-space R^2 or 3-space R^3 . In this problem, we have two images of the same object (such as satellite images taken at different times) or an image of a prototypical object and an actual object. It is desired to find the rotation, translation, and possibly scale change, which will best align the two images. Whereas many problems of this type are two dimensional, it should be noted that medical imaging is often three-dimensional.

The same mathematics can be used to determine the errors in calculated motions of rigid bodies in Euclidean space, or in the determination of unknown Euclidean coordinates. The latter might occur, for example, if locations are measured relative to a moving object (“body coordinates”) and it is desired to reconcile these locations with respect to a fixed coordinate system (“space coordinates”).

This chapter focuses on image registrations. However, scientifically the most compelling example of rigid body motion is tectonic plates. To a first approximation, tectonic plates move as a rigid body on the unit sphere Ω_3 in R^3 . For this reason, we will also give results for Ω_3 and the unit circle Ω_2 . A separate chapter [8] in the present volume will focus primarily on tectonic plate reconstructions.

The chapter has six major sections.

After introducing some mathematical preliminaries, we introduce the concept of *M-estimators*, a generalization of least squares estimation. In least squares estimation, the registration that minimizes the sum of squares of the lengths of the deviations is chosen; in *M* estimation, the sum of squares of the lengths of the deviations is replaced by some other objective function. An important case is L_1 estimation, which minimizes the sum of the lengths of the deviations; L_1 estimation is often used when the possibility of outliers in the data is suspected.

The second section of this chapter deals with the calculation of least squares estimates. Then, in the third section, we introduce an iterative modification of the least squares algorithm to calculate other *M*-estimates. Note that minimization usually involves some form of differentiation and hence this section starts with a short introduction to the geometry of the group of rotations and differentiation in the rotation group. Many statistical techniques are based upon approximation by derivatives, and hence, a little understanding of geometry is necessary to understand the later statistical sections.

The fourth section discusses the statistical properties of *M*-estimates. A great deal of emphasis is placed upon the relationship between the geometric configuration of the landmarks and the statistical errors in the image registration. It is shown that these statistical errors are determined, up to a constant, by the geometry of the landmarks. The constant of

proportionality depends upon the objective function and the distribution of the errors in the data.

General statistical theory indicates that, if the data error distribution is (isotropic) multivariate normal, least squares estimation is optimal. An important result of this section is that, even in this case when least squares estimation is theoretically the most efficient, the use of L_1 estimation can guard against outliers with a very modest cost in efficiency. Here optimality and efficiency refer to the expected size of the statistical errors. In practice, data is often long-tailed and L_1 estimation yields *smaller* statistical errors than least squares estimation. This will be the case with the three-dimensional image registration example given here.

In the fifth section, we discuss diagnostics that can be used to determine which data points are most influential upon the registration. Thus, if the registration is unsatisfactory, these diagnostics can be used to determine which data points are most responsible and should be reexamined.

Finally, *Chang and Rivest* [1] discuss location and regression estimation in statistical group models and shows how some of the phenomenon discussed here can be shown to occur in a more general context. We discuss some of these results in a sixth section.

56.1.1 Problems of Unknown Coordinate Systems

Wahba [2] posed the following question. Suppose we have the directions of certain stars with respect to the unknown coordinate system of a satellite. How can we estimate the orientation of the satellite? Let \mathbf{A} be the unknown 3×3 matrix whose rows represent the axes of the satellite’s coordinate system with respect to a fixed and known (Earth) coordinate system. Furthermore, let \mathbf{u}_i be the directions of the stars with respect to the known coordinate systems, where each \mathbf{u}_i is written as a three-dimensional column vector with unit length. Similarly let \mathbf{v}_i be the directions of the stars with respect to the satellite’s coordinate system. Then

$$\mathbf{v}_i = \mathbf{A}\mathbf{u}_i + \text{error}. \quad (56.1)$$

In essence the question was to estimate \mathbf{A} . *Wahba* gave the least squares solution.

Chapman et al. [3] posed the same question in the following form. Suppose we have an object defined by a computer-aided design (CAD) program and a prototype is measured using a coordinate measuring machine (CMM). The orientations of lines on the object can be defined by unit vectors parallel to the lines and the orientations of planes can be defined by unit vectors normal to the planes. So we have unit vectors \mathbf{u}_i defined by the CAD program and the corresponding unit vectors \mathbf{v}_i as measured by the CMM. If \mathbf{A} is the coordinate

system of the CMM relative to the CAD program, then (56.1) holds.

Chapman et al. again used a least squares estimate $\hat{\mathbf{A}}$ of \mathbf{A} . The main question of interest, that is, the geometric integrity of the prototype, was then answered by analyzing the residuals of \mathbf{v}_i from $\hat{\mathbf{A}}\mathbf{u}_i$.

Since the \mathbf{u}_i and \mathbf{v}_i are of unit length, these two problems involve spherical data.

56.1.2 Image Registration

If we enlarge the inquiry to Euclidean space data, we arrive at the widely used *image registration* problem. Suppose $\mathbf{u}_i \in \mathbb{R}^p$ represent the locations of some landmarks in one image, and $\mathbf{v}_i \in \mathbb{R}^p$ the locations of corresponding landmarks in a second image of the same object. The usual applications occur with $p = 2, 3$. Under certain conditions, it might be reasonable to suppose that

$$\mathbf{v}_i = \mathbf{B}\mathbf{u}_i + \mathbf{b} + \text{error} \quad (56.2)$$

for an unknown $p \times p$ matrix \mathbf{B} and an unknown p -dimensional column vector \mathbf{b} . The matrix \mathbf{B} represents a coordinate change and the vector \mathbf{b} represents a translation of coordinates. The image registration problem is to estimate \mathbf{B} and \mathbf{b} .

The model (56.2) also arises in a slightly different context. Suppose we have landmarks \mathbf{u}_i on a prototypical face. For example, the \mathbf{u}_i might represent the locations of the nose, the two eyes, the base of the chin, etc. For the purpose of automated processing of a large number of facial images of different subjects, we might want to bring each facial image into alignment with the prototypical image using a transformation of the form (56.2) where the \mathbf{v}_i represents the same locations (nose, two eyes, base of chin, etc.) on the subject facial image.

In the absence of measurement error, one does not expect the landmarks on two faces to be related using a transformation of the form

$$\mathbf{v}_i = \mathbf{B}\mathbf{u}_i + \mathbf{b}. \quad (56.3)$$

The reader might be puzzled why a transformation of this form is under consideration. Statistical error, however, is not limited to measurement error. Statistical error incorporates all effects not included in the systematic portion of the model. In building a model of the form (56.2), we hope to separate out the most important relationship (56.3) between the landmarks \mathbf{u}_i on one object and the corresponding landmarks \mathbf{v}_i on the other object; the rest is placed in the statistical error.

Unlike the Wahba problem, the unknown (\mathbf{B}, \mathbf{b}) of the image registration problem, or the unknown \mathbf{A} in the *Chapman*

et al. problem, may not be of primary interest. Rather, they must be estimated as a preliminary step to more interesting problems. We will discuss herein the properties of various methods of estimating these unknowns. These properties will hopefully help the interested reader to choose a good estimation technique which will hopefully yield better results after this preliminary step is completed.

56.1.3 The Orthogonal and Special Orthogonal Matrices

Consider, for example, the dataset in Table 56.1 from *Chang* and *Ko* [4], which we will analyze repeatedly in what follows. This dataset consists of the digitized locations of 12 pairs of landmarks on the left and right hands of one of the authors. This is a $p = 3$ three-dimensional image registration problem. We might decide that, apart from the statistical error term, the shape of the two hands is the same; that is, the distance between two points on one hand is the same as the distance between the corresponding two points on the other hand.

This distance preserving condition translates mathematically to the equation $\mathbf{B}^T\mathbf{B} = \mathbf{I}_p$, the $p \times p$ -dimensional identity matrix. We outline a derivation of this well-known mathematical fact for the primary purpose of introducing the reader to the mathematical style of the remainder of this chapter. The distance between two p -dimensional column vectors \mathbf{v}_1 and \mathbf{v}_2 is

$$\|\mathbf{v}_2 - \mathbf{v}_1\| = \sqrt{(\mathbf{v}_2 - \mathbf{v}_1)^T(\mathbf{v}_2 - \mathbf{v}_1)}, \quad (56.4)$$

where the operations on the right-hand side of (56.4) are matrix multiplication and transposition. If the \mathbf{v}_i and \mathbf{u}_i are related by (56.3),

Table 56.1 12 digitized locations on the left and right hand

	Left hand u_i			Right hand v_i		
A	5.17	11.30	16.18	5.91	11.16	16.55
B	7.40	12.36	17.50	8.63	10.62	18.33
C	8.56	12.59	17.87	10.09	10.60	18.64
D	9.75	13.62	17.01	10.89	10.95	17.90
E	11.46	14.55	12.96	12.97	10.13	13.88
F	7.10	13.12	12.56	8.79	11.21	13.17
G	8.85	13.82	12.60	10.70	11.10	13.42
H	6.77	13.07	10.32	8.47	11.09	11.35
I	6.26	11.62	13.34	7.28	12.52	14.04
J	6.83	12.00	13.83	8.05	12.42	14.56
K	7.94	12.29	13.84	9.07	12.39	14.86
L	8.68	12.71	13.67	10.15	12.17	14.44

A top of little finger, *B* top of ring finger, *C* top of middle finger, *D* top of forefinger, *E* top of thumb, *F* gap between thumb and forefinger, *G* center of palm, *H* base of palm, *I* little finger knuckle, *J* ring finger knuckle, *K* middle finger knuckle, *L* forefinger knuckle

$$\begin{aligned} (\mathbf{v}_j - \mathbf{v}_i)^T (\mathbf{v}_j - \mathbf{v}_i) &= [\mathbf{B}(\mathbf{u}_j - \mathbf{u}_i)]^T [\mathbf{B}(\mathbf{u}_j - \mathbf{u}_i)] \\ &= (\mathbf{u}_j - \mathbf{u}_i)^T \mathbf{B}^T \mathbf{B} (\mathbf{u}_j - \mathbf{u}_i) \end{aligned}$$

Thus, if $\|\mathbf{v}_j - \mathbf{v}_i\| = \|\mathbf{u}_j - \mathbf{u}_i\|$ for all i and j , and if the \mathbf{u}_i do not all lie in a $(p - 1)$ -dimensional hyperplane of R^p ,

$$\mathbf{I}_p = \mathbf{B}^T \mathbf{B} = \mathbf{B} \mathbf{B}^T. \quad (56.5)$$

Note that the first equality of (56.5) implies that $\mathbf{B}^{-1} = \mathbf{B}^T$ and hence the second equality follows. Matrices which satisfy condition (56.5) are said to be *orthogonal*.

On the other hand, we might want to hypothesize that the two hands (again apart from statistical error) have the same shape except that one hand might be larger than the other. In this case, we are hypothesizing

$$\mathbf{B} = \gamma \mathbf{A} \quad (56.6)$$

where \mathbf{A} is orthogonal and γ is a positive real number.

In the Wahba and Chapman et al. problems, the rows of \mathbf{A} are known to be an orthonormal basis of R^3 . Since the (i, j) entry of $\mathbf{A} \mathbf{A}^T$ is the dot product of the i -th and j -th rows of \mathbf{A} , it follows that \mathbf{A} is orthogonal. However, more is known. Since the unknown coordinate system is known to be right-handed,

$$\mathbf{A}^T \mathbf{A} = \mathbf{I}_p, \quad \det(\mathbf{A}) = 1, \quad (56.7)$$

where $\det(\mathbf{A})$ is the determinant of the matrix \mathbf{A} . Such matrices are said to be *special orthogonal*.

In the hands data of Table 56.1, if we use the model (56.2) with condition (56.6), then \mathbf{A} will not be special orthogonal. This is because the left and right hands have different orientations. However, it is common in image registration problems to assume that condition (56.6) is true with \mathbf{A} assumed to be special orthogonal.

Following standard mathematical notation, we will use $O(p)$ to denote the $p \times p$ orthogonal matrices [i.e., the set of all matrices which satisfy (56.5)] and $SO(p)$ to denote the subset of $O(p)$ of special orthogonal matrices [i.e., the set of all matrices which satisfy (56.7)].

56.1.4 The Procrustes and Spherical Regression Models

In this chapter, we will be concerned with statistical methods which apply to the model (56.2) for Euclidean space data $\mathbf{u}_i, \mathbf{v}_i \in R^p$, for arbitrary p , where \mathbf{B} satisfies the condition (56.5) with \mathbf{B} constrained to be either orthogonal or special orthogonal. Following Goodall [5], we will call this model the *Procrustes* model.

We will also consider models of the form (56.1), where the p -vectors \mathbf{u}_i and \mathbf{v}_i are constrained to be of unit length, that is

$$\mathbf{u}_i, \mathbf{v}_i \in \Omega_p = S^{p-1} = \{\mathbf{x} \in R^p | \mathbf{x}^T \mathbf{x} = 1\}$$

and \mathbf{A} is constrained to be either orthogonal or special orthogonal. Following Chang [6], we will call this model the *spherical regression* model.

The statistical methodology for these two models can easily be described in parallel. In general, we will focus on the Procrustes model, while giving the modifications that apply to the spherical regression model.

56.1.5 Least Squares, L_1 , and M Estimation

In Sect. 56.2, we will derive the least squares estimate of \mathbf{A} , γ , \mathbf{b} for the Procrustes model. This estimate minimizes

$$\rho_2(\mathbf{A}, \gamma, \mathbf{b}) = \sum_i \|\mathbf{v}_i - \gamma \mathbf{A} \mathbf{u}_i - \mathbf{b}\|^2 \quad (56.8)$$

overall \mathbf{A} in either $O(p)$ or $SO(p)$, constants $\gamma > 0$, and p -vectors $\mathbf{b} \in R^p$. For the spherical regression model, the least squares estimate minimizes

$$\rho_2(\mathbf{A}) = \sum_i \|\mathbf{v}_i - \mathbf{A} \mathbf{u}_i\|^2 \quad (56.9)$$

$$= 2n - 2 \sum_i \mathbf{v}_i^T \mathbf{A} \mathbf{u}_i \quad (56.10)$$

overall \mathbf{A} in either $O(p)$ or $SO(p)$. For the second equality in (56.9), we have used that if $1 = \mathbf{v}^T \mathbf{v} = \mathbf{u}^T \mathbf{u}$, then

$$\begin{aligned} \|\mathbf{v} - \mathbf{A} \mathbf{u}\|^2 &= (\mathbf{v} - \mathbf{A} \mathbf{u})^T (\mathbf{v} - \mathbf{A} \mathbf{u}) \\ &= \mathbf{v}^T \mathbf{v} - \mathbf{v}^T \mathbf{A} \mathbf{u} - (\mathbf{A} \mathbf{u})^T \mathbf{v} + \mathbf{u}^T \mathbf{A}^T \mathbf{A} \mathbf{u} \\ &= 2 - 2\mathbf{v}^T \mathbf{A} \mathbf{u}. \end{aligned}$$

Least squares estimates have the advantage that an explicit closed-form solution for them is available. They have the disadvantage that they are very sensitive to *outliers*, that is, points $(\mathbf{u}_i, \mathbf{v}_i)$ for which the error term in (56.2) is unusually large. In the image registration problem, an outlier can arise in several contexts. It can be the result of a measurement error, or it can be the result of a misidentified landmark. Perhaps the image is not very clear, or the landmark (e.g., “point of the nose”) cannot be very precisely determined, or the landmark is obscured (by clouds or shrubs, etc.). Or perhaps there are places in the image where the image is not

really rigid, that is, the ideal match (56.3) does not apply very well. It is easy to conceive of a myriad of situations which might give rise to outliers.

L_1 estimators are often used to ameliorate the effects of outliers. These estimators minimize

$$\rho_1(\mathbf{A}, \gamma, \mathbf{b}) = \sum_i \|v_i - \gamma \mathbf{A}u_i - \mathbf{b}\|, \quad (56.11)$$

for the Procrustes model, or the sum of the distances along the surface of the sphere

$$\rho_1(\mathbf{A}) = \sum_i \arccos(v_i^T \mathbf{A}u_i) \quad (56.12)$$

for the spherical regression model. Unfortunately, an explicit closed-form solution for the L_1 estimate is not available and it must be calculated by numerical minimization. We will offer a few suggestions on approaches for numerical minimization in Sect. 56.3.5.

The least squares and L_1 estimators are special cases of the so-called M estimators. These estimators minimize an objective function of the form

$$\rho(\mathbf{A}, \gamma, \mathbf{b}) = \sum_i \rho_0(s_i), \quad (56.13)$$

where

$$s_i = \|v_i - \gamma \mathbf{A}u_i - \mathbf{b}\|$$

and ρ_0 is some increasing function. Intermediate between the least squares and L_1 estimate is the *Huber* estimate for which

$$\rho_0(s) = \begin{cases} (s/b)^2 & s < b \\ s/b & s \geq b \end{cases}$$

for some preset constant b . Or we can *Windsorize* the estimate

$$\rho_0(s) = \begin{cases} (s/b)^2 & s < b \\ 1 & s \geq b \end{cases}.$$

In the linear regression context, these and other objective functions are discussed in *Huber* [7].

For the spherical regression model, an M -estimator minimizes an objective function of the form

$$\rho(\mathbf{A}) = \sum_i \rho_0(t_i), \quad (56.14)$$

where

$$t_i = v_i^T \mathbf{A}u_i.$$

Notice that as v moves away from $\mathbf{A}u$ towards the antipodal point $-\mathbf{A}u$, $t = v^T \mathbf{A}u$ decreases from 1 to -1 . Thus, for the spherical case, $\rho_0(t)$ is chosen to be a decreasing function of t .

In Sect. 56.4 we will discuss the statistical properties of M -estimates. We will see how the geometry of the data translates into the error structure of the estimate. In the image registration problem, this information can be used, for example, to help select landmarks. General statistical theory indicates that under certain conditions (“normal distribution”) the least squares solution is optimal. However, if we were to use a L_1 estimate to guard against outliers, we would suffer a penalty of 13% for image registrations in two dimensions and only 8% for image registrations in three dimensions, even when least squares is theoretically optimal. We will make more precise in Sect. 56.4 how this *penalty* is defined. The important point to realize is that, especially for three-dimensional image registrations, L_1 estimators offer important protections against outliers in the data at very modest cost in the statistical efficiency of the estimator.

In Sect. 56.5, we will discuss diagnostics for the Procrustes and spherical regression models. If the image registration is not satisfactory, this section will give tools to determine which of the landmarks is causing the unsatisfactory registration. It will follow, for example, that landmarks that greatly influence \mathbf{A} will have negligible influence on γ and vice versa.

56.2 Least Squares Estimation

56.2.1 Group Properties of $O(p)$ and $SO(p)$

It is important to note that $O(p)$ and $SO(p)$ are groups in the mathematical sense. That is, if $\mathbf{A}, \mathbf{B} \in O(p)$, then

$$(\mathbf{AB})^T (\mathbf{AB}) = \mathbf{B}^T \mathbf{A}^T \mathbf{A} \mathbf{B} = \mathbf{B}^T \mathbf{I}_p \mathbf{B} = \mathbf{I}_p$$

since both \mathbf{A} and \mathbf{B} satisfy (56.5). Thus, $\mathbf{AB} \in O(p)$. Similarly if $\mathbf{A} \in O(p)$, then (56.5) implies that $\mathbf{A}^{-1} = \mathbf{A}^T \in O(p)$. This implies that $O(p)$ is a group. Furthermore, if $\det(\mathbf{A}) = \det(\mathbf{B}) = 1$, then $\det(\mathbf{AB}) = \det(\mathbf{A})\det(\mathbf{B}) = 1$ and $\det(\mathbf{A}^{-1}) = 1/\det(\mathbf{A}) = 1$. In summary, we have

$$\begin{aligned} \text{If } \mathbf{A}, \mathbf{B} \in O(p), \quad \text{then } \mathbf{AB} \in O(p) \\ \text{and } \mathbf{A}^{-1} = \mathbf{A}^T \in O(p) \\ \text{If } \mathbf{A}, \mathbf{B} \in SO(p), \quad \text{then } \mathbf{AB} \in SO(p) \\ \text{and } \mathbf{A}^{-1} = \mathbf{A}^T \in SO(p). \end{aligned} \quad (56.15)$$

Notice also that, if \mathbf{A} satisfies (56.5), then $1 = \det(\mathbf{A}^T \mathbf{A}) = [\det(\mathbf{A})]^2$ so that $\det(\mathbf{A}) = 1, -1$.

56.2.2 Singular Value Decomposition

Given a $p \times q$ matrix \mathbf{X} its *singular value decomposition* is

$$\mathbf{X} = \mathbf{O}_1 \mathbf{\Lambda} \mathbf{O}_2^T \quad (56.16)$$

where $\mathbf{O}_1 \in O(p)$, $\mathbf{O}_2 \in O(q)$ and $\mathbf{\Lambda}$ is $p \times q$. If $p \leq q$, $\mathbf{\Lambda}$ has block form

$$\mathbf{\Lambda} = \begin{bmatrix} \text{diag}(\lambda_1, \dots, \lambda_p) & \mathbf{0}_{(p, q-p)} \end{bmatrix}$$

Here $\text{diag}(\lambda_1, \dots, \lambda_p)$ is a diagonal matrix with entries $\lambda_1 \geq \dots \geq \lambda_p$ and $\mathbf{0}_{(p, q-p)}$ is a $p \times (q - p)$ matrix with all zeros. If $q \leq p$

$$\mathbf{\Lambda} = \begin{pmatrix} \text{diag}(\lambda_1, \dots, \lambda_q) \\ \mathbf{0}_{(p-q, q)} \end{pmatrix}.$$

Most mathematical software packages now include the singular value decomposition. However, it can be computed using a package which only computes eigen-decompositions of symmetric matrices. Suppose temporarily $p \leq q$. Since $\mathbf{X}\mathbf{X}^T$ is a symmetric nonnegative definite matrix, its eigen-decomposition has the form

$$\mathbf{X}\mathbf{X}^T = \mathbf{O}_1 \mathbf{\Lambda}_1 \mathbf{O}_1^T$$

where $\mathbf{O}_1 \in O(p)$ and $\mathbf{\Lambda}_1 = \text{diag}(\lambda_1^2, \dots, \lambda_p^2)$ with $\lambda_1 \geq \dots \geq \lambda_p \geq 0$. The columns of \mathbf{O}_1 are the eigenvectors of $\mathbf{X}\mathbf{X}^T$ and $\lambda_1^2, \dots, \lambda_p^2$ are the corresponding eigenvalues. Suppose $\lambda_p > 0$ and let $\tilde{\mathbf{O}}_2 = \mathbf{X}^T \mathbf{O}_1 \mathbf{\Lambda}_1^{-1/2}$. $\tilde{\mathbf{O}}_2$ is $q \times p$, but

$$\begin{aligned} \tilde{\mathbf{O}}_2^T \tilde{\mathbf{O}}_2 &= \mathbf{\Lambda}_1^{-1/2} \mathbf{O}_1^T \mathbf{X}\mathbf{X}^T \mathbf{O}_1 \mathbf{\Lambda}_1^{-1/2} \\ &= \mathbf{\Lambda}_1^{-1/2} \mathbf{O}_1^T \mathbf{O}_1 \mathbf{\Lambda}_1 \mathbf{O}_1^T \mathbf{O}_1 \mathbf{\Lambda}_1^{-1/2} \\ &= \mathbf{\Lambda}_1^{-1/2} \mathbf{\Lambda}_1 \mathbf{\Lambda}_1^{-1/2} = \mathbf{I}_p, \end{aligned}$$

so that the columns of $\tilde{\mathbf{O}}_2$ are orthonormal. Furthermore

$$\mathbf{O}_1 \mathbf{\Lambda}_1^{1/2} \tilde{\mathbf{O}}_2^T = \mathbf{O}_1 \mathbf{\Lambda}_1^{1/2} \mathbf{\Lambda}_1^{-1/2} \mathbf{O}_1^T \mathbf{X} = \mathbf{X}.$$

Filling $\mathbf{\Lambda}_1^{1/2}$ with $q - p$ columns of zeros, and completing the columns of $\tilde{\mathbf{O}}_2$ to an orthonormal basis of R^q yields the decomposition (56.16).

Extensions to the cases when $\lambda_p = 0$ or when $q \leq p$ will not be difficult for the careful reader.

56.2.3 Least Squares Estimation in the Procrustes Model

The least squares estimation of the Procrustes model (56.2) has long been known (see, for example, Goodall [5]). Let

$\bar{\mathbf{u}} = n^{-1} \sum_i \mathbf{u}_i$, where n is the number of pairs $(\mathbf{u}_i, \mathbf{v}_i)$ and let $\bar{\mathbf{v}}$ be similarly defined. Define the $p \times p$ matrix \mathbf{X} by

$$\mathbf{X} = \sum_i (\mathbf{u}_i - \bar{\mathbf{u}}) (\mathbf{v}_i - \bar{\mathbf{v}})^T.$$

Then

$$\begin{aligned} \rho_2(\mathbf{A}, \gamma, \mathbf{b}) &= \sum_i \|\mathbf{v}_i - \gamma \mathbf{A} \mathbf{u}_i - \mathbf{b}\|^2 \\ &= \sum_i \left\| \mathbf{v}_i - \bar{\mathbf{v}} - \gamma \mathbf{A} (\mathbf{u}_i - \bar{\mathbf{u}}) - [\mathbf{b} - (\bar{\mathbf{v}} - \gamma \mathbf{A} \bar{\mathbf{u}})] \right\|^2 \\ &= \sum_i \|\mathbf{v}_i - \bar{\mathbf{v}}\|^2 \\ &\quad - \gamma \sum_i (\mathbf{u}_i - \bar{\mathbf{u}})^T \mathbf{A}^T (\mathbf{v}_i - \bar{\mathbf{v}}) \\ &\quad - \gamma \sum_i (\mathbf{v}_i - \bar{\mathbf{v}})^T \mathbf{A} (\mathbf{u}_i - \bar{\mathbf{u}}) \\ &\quad + \gamma^2 \sum_i \|\mathbf{u}_i - \bar{\mathbf{u}}\|^2 \\ &\quad + n \|\mathbf{b} - (\bar{\mathbf{v}} - \gamma \mathbf{A} \bar{\mathbf{u}})\|^2. \end{aligned}$$

All the other cross-product terms sum to zero. Now

$$\begin{aligned} \sum_i (\mathbf{v}_i - \bar{\mathbf{v}})^T \mathbf{A} (\mathbf{u}_i - \bar{\mathbf{u}}) &= \sum_i \text{Tr} [(\mathbf{v}_i - \bar{\mathbf{v}})^T \mathbf{A} (\mathbf{u}_i - \bar{\mathbf{u}})] \\ &= \sum_i \text{Tr} [\mathbf{A} (\mathbf{u}_i - \bar{\mathbf{u}}) (\mathbf{v}_i - \bar{\mathbf{v}})^T] = \text{Tr}(\mathbf{A}\mathbf{X}) \end{aligned}$$

and

$$\begin{aligned} \sum_i (\mathbf{u}_i - \bar{\mathbf{u}})^T \mathbf{A}^T (\mathbf{v}_i - \bar{\mathbf{v}}) &= \sum_i (\mathbf{v}_i - \bar{\mathbf{v}})^T \mathbf{A} (\mathbf{u}_i - \bar{\mathbf{u}}) = \text{Tr}(\mathbf{A}\mathbf{X}). \end{aligned}$$

Therefore

$$\begin{aligned} \rho_2(\mathbf{A}, \gamma, \mathbf{b}) &= \sum_i \|\mathbf{v}_i - \bar{\mathbf{v}}\|^2 - 2\gamma \text{Tr}(\mathbf{A}\mathbf{X}) \\ &\quad + \gamma^2 \sum_i \|\mathbf{u}_i - \bar{\mathbf{u}}\|^2 \\ &\quad + n \|\mathbf{b} - (\bar{\mathbf{v}} - \gamma \mathbf{A} \bar{\mathbf{u}})\|^2. \end{aligned} \quad (56.17)$$

Substituting (56.16),

$$\begin{aligned} \text{Tr}(\mathbf{A}\mathbf{X}) &= \text{Tr}(\mathbf{A} \mathbf{O}_1 \mathbf{\Lambda} \mathbf{O}_2^T) = \text{Tr}(\mathbf{O}_2^T \mathbf{A} \mathbf{O}_1 \mathbf{\Lambda}) \\ &= \sum_i \lambda_i e_{ii}, \end{aligned}$$

where e_{ii} are the diagonal entries of $\mathbf{O}_2^T \mathbf{A} \mathbf{O}_1 \in O(p)$. Now $|e_{ii}| \leq 1$ and hence $\text{Tr}(\mathbf{A}\mathbf{X})$ is maximized when $e_{ii} = 1$ or, equivalently, when $\mathbf{O}_2^T \mathbf{A} \mathbf{O}_1 = \mathbf{I}_p$. This implies $\mathbf{A} = \mathbf{O}_2 \mathbf{O}_1^T$.

Thus, if $(\hat{\mathbf{A}}, \hat{\gamma}, \hat{\mathbf{b}})$ minimizes (56.17),

$$\begin{aligned}\hat{\mathbf{A}} &= \mathbf{O}_2 \mathbf{O}_1^T, \\ \hat{\gamma} &= (\sum_i \|\mathbf{u}_i - \bar{\mathbf{u}}\|^2)^{-1} \text{Tr}(\hat{\mathbf{A}}\mathbf{X}) \\ &= (\sum_i \|\mathbf{u}_i - \bar{\mathbf{u}}\|^2)^{-1} \sum_i \lambda_i, \\ \hat{\mathbf{b}} &= \bar{\mathbf{v}} - \hat{\gamma} \hat{\mathbf{A}} \bar{\mathbf{u}}.\end{aligned}\quad (56.18)$$

If \mathbf{A} is constrained to lie in $SO(p)$, we use a modified singular value decomposition. Let $\mathbf{X} = \tilde{\mathbf{O}}_1 \tilde{\mathbf{\Lambda}} \tilde{\mathbf{O}}_2$ be the (usual) singular value decomposition of \mathbf{X} and let

$$\mathbf{E} = \text{diag}(1, \dots, 1, -1) \quad (56.19)$$

be the identity matrix with its last entry changed to -1 . Let $\mathbf{O}_1 = \tilde{\mathbf{O}}_1 \mathbf{E}^{\delta_1}$ where $\delta_1 = 0$ if $\tilde{\mathbf{O}}_1 \in SO(p)$ and $\delta_1 = 1$ otherwise.

Similarly define δ_2 and \mathbf{O}_2 . Finally write $\mathbf{A} = \tilde{\mathbf{\Lambda}} \mathbf{E}^{\delta_1 + \delta_2}$. Then (56.16) is valid with $\mathbf{O}_1, \mathbf{O}_2 \in SO(p)$ and $\lambda_1 \geq \dots \geq \lambda_{p-1} \geq |\lambda_p|$.

This is the modified singular value decomposition.

The least squares estimates, subject to the constraint $\hat{\mathbf{A}} \in SO(p)$, is still given by (56.18) when a modified singular value decomposition is used for \mathbf{X} .

56.2.4 Example: Least Squares Estimates for the Hands Data

Consider, for example, the hands data in Table 56.1. For this data

$$\begin{aligned}\bar{\mathbf{u}} &= \begin{bmatrix} 7.8975 \\ 12.7542 \\ 14.3067 \end{bmatrix}, \quad \bar{\mathbf{v}} = \begin{bmatrix} 9.2500 \\ 11.3633 \\ 15.0950 \end{bmatrix}, \\ \mathbf{X} &= \left(\begin{bmatrix} 5.17 \\ 11.30 \\ 16.18 \end{bmatrix} - \bar{\mathbf{u}} \right) \left(\begin{bmatrix} 5.91 \\ 11.16 \\ 16.55 \end{bmatrix} - \bar{\mathbf{v}} \right)^T + \dots + \\ &\quad \left(\begin{bmatrix} 8.68 \\ 12.71 \\ 13.67 \end{bmatrix} - \bar{\mathbf{u}} \right) \left(\begin{bmatrix} 10.15 \\ 12.17 \\ 14.44 \end{bmatrix} - \bar{\mathbf{v}} \right)^T \\ &= \begin{bmatrix} 34.0963 & -6.9083 & 3.5769 \\ 17.3778 & -4.9028 & -5.6605 \\ -2.3940 & -5.7387 & 57.8598 \end{bmatrix}.\end{aligned}$$

The singular value decomposition $\mathbf{X} = \mathbf{O}_1 \mathbf{\Lambda} \mathbf{O}_2^T$ is given by

$$\mathbf{O}_1 = \begin{bmatrix} 0.0465 & -0.8896 & -0.4544 \\ -0.1012 & -0.4567 & 0.8838 \\ 0.9938 & -0.0048 & 0.1112 \end{bmatrix}$$

$$\mathbf{O}_2 = \begin{bmatrix} -0.0436 & -0.9764 & -0.2114 \\ -0.0944 & 0.2147 & -0.9721 \\ 0.9946 & -0.0224 & -0.1015 \end{bmatrix}$$

$$\mathbf{\Lambda} = \text{diag}(58.5564 \quad 39.1810 \quad 1.8855)$$

Hence (56.18) yields

$$\hat{\mathbf{A}} = \begin{bmatrix} 0.9627 & 0.2635 & -0.0621 \\ 0.2463 & -0.9477 & -0.2030 \\ 0.1123 & -0.1801 & 0.9722 \end{bmatrix}$$

$$\hat{\gamma} = 0.9925$$

$$\hat{\mathbf{b}} = [-0.7488 \quad 24.3115 \quad 2.6196]^T. \quad (56.20)$$

Notice that $\det(\hat{\mathbf{A}}) = -1$, so $\hat{\mathbf{A}} \notin SO(3)$. We expect this result since, as previously remarked, the left and right hands have different orientations. The value of $\hat{\gamma}$ is somewhat puzzling since the subject is right-handed and one would expect; therefore, $\gamma > 1$. Although, as we will see in Sect. 56.4, the difference between $\hat{\gamma}$ and 1 is not significant, a better estimate would have been achieved if the L_1 objective function (56.11) were numerically minimized instead. In this case $\hat{\gamma} = 1.0086$. Our analysis will show that the hands dataset has an outlier and we see here an example of the superior resistance of L_1 estimates to outliers.

56.2.5 Least Squares Estimation in the Spherical Regression Model

Least squares estimation for the spherical regression model is similar to least squares estimation in the Procrustes model. Let $\mathbf{X} = \sum_i \mathbf{u}_i \mathbf{v}_i^T$ and define $\mathbf{O}_1, \mathbf{O}_2 \in O(p)$ using a singular value decomposition of \mathbf{X} . Then $\hat{\mathbf{A}} = \mathbf{O}_2 \mathbf{O}_1^T$. If, on the other hand, it is desired to constrain $\hat{\mathbf{A}}$ to $SO(p)$, one defines $\mathbf{O}_1, \mathbf{O}_2 \in SO(p)$ using a modified singular value decomposition and, again, $\hat{\mathbf{A}} = \mathbf{O}_2 \mathbf{O}_1^T$.

56.3 Parameterizing $O(p)$ and $SO(p)$

To develop the statistical properties of $\hat{\mathbf{A}}$, it is necessary to rewrite $O(p)$ and $SO(p)$ into a smaller number of parameters.

56.3.1 $SO(p)$ for $p = 2$

For $p = 2$,

$$SO(2) = \left\{ \Phi_2(h) = \begin{pmatrix} \cos(h) & -\sin(h) \\ \sin(h) & \cos(h) \end{pmatrix} \mid h \in \mathbb{R}^1 \right\}. \quad (56.21)$$

Physically $\Phi_2(h)$ represents a rotation of \mathbb{R}^2 by an angle of h radians. Since $\Phi_2(h) = \Phi_2(h + 2\pi)$, $SO(2)$ is geometrically a circle.

Since each element of $SO(2)$ has four entries, it is tempting to think of $SO(2)$ as four-dimensional. However, as (56.21) makes clear, $SO(2)$ can be described by one parameter $h \in \mathbb{R}^1$. Thus, $SO(2)$ is really one-dimensional. Suppose we were constrained to live on a circle Ω_2 (instead of the sphere Ω_3). At each point on Ω_2 we can only travel to our left or to our right, and, if our travels were limited, it would appear as if we only had one-dimensional travel. Mathematicians describe this situation by saying that $SO(2)$ is a one-dimensional *manifold*. Manifolds, and their importance to geometric statistical problems, are further discussed in the accompanying chapter [8].

Notice also $\Phi_2(0) = \mathbf{I}_2$ and that, if h is small, then $\Phi_2(h)$ is close to \mathbf{I}_2 . Thus, if h is small, $\Phi_2(h)\mathbf{x}$ is close to \mathbf{x} for all $\mathbf{x} \in \mathbb{R}^2$. As we shall see, this simple observation is key to understanding our approach to the statistical properties of $\hat{\mathbf{A}}$.

56.3.2 $SO(p)$ for $p = 3$

$SO(3)$ can be described as the collection of all rotations in \mathbb{R}^3 . That is,

$$SO(3) = \{ \Phi_3(\mathbf{h}) \mid \mathbf{h} \in \mathbb{R}^3 \} \quad (56.22)$$

where $\Phi_3(\mathbf{h})$ is right-hand rule rotation of $\|\mathbf{h}\|$ radians around the axis $\|\mathbf{h}\|^{-1}\mathbf{h}$. Writing $\theta = \|\mathbf{h}\|$ and $\boldsymbol{\xi} = \|\mathbf{h}\|^{-1}\mathbf{h}$, so that $\boldsymbol{\xi}$ is a unit-length three-dimensional vector, it can be shown that

$$\begin{aligned} \Phi_3(\mathbf{h}) = \Phi_3(\theta\boldsymbol{\xi}) &= \cos(\theta) \mathbf{I}_3 + \sin(\theta) M_3(\boldsymbol{\xi}) \\ &+ (1 - \cos(\theta)) \boldsymbol{\xi}\boldsymbol{\xi}^T \end{aligned} \quad (56.23)$$

Where

$$M_3(\boldsymbol{\xi}) = M_3 \begin{pmatrix} \xi_1 \\ \xi_2 \\ \xi_3 \end{pmatrix} = \begin{pmatrix} 0 & -\xi_3 & \xi_2 \\ \xi_3 & 0 & -\xi_1 \\ -\xi_2 & \xi_1 & 0 \end{pmatrix}.$$

Thus, although each $\mathbf{A} \in SO(3)$ has nine entries, $SO(3)$ is actually a three-dimensional manifold.

Again we notice that $\Phi_3(\mathbf{0}) = \mathbf{I}_3$ and that if $\|\mathbf{h}\|$ is small then $\Phi_3(\mathbf{h})\mathbf{x}$ is close to \mathbf{x} for all $\mathbf{x} \in \mathbb{R}^3$.

For future use, we note that if $\mathbf{C} \in SO(3)$, then the axis $\boldsymbol{\xi}$ of the rotation represented by \mathbf{C} satisfies $\mathbf{C}\boldsymbol{\xi} = \boldsymbol{\xi}$. Thus, $\boldsymbol{\xi}$ is the eigenvector associated to the eigenvalue 1 of \mathbf{C} . By re-representing \mathbf{C} in an orthonormal basis which includes $\boldsymbol{\xi}$, one can show that the angle of rotation θ of the rotation represented by \mathbf{C} satisfies $1 + 2\cos(\theta) = \text{Tr}(\mathbf{C})$. Thus, if $\boldsymbol{\xi}$ and θ are calculated in this way, $\Phi_3(\theta\boldsymbol{\xi}) = \mathbf{C}$.

56.3.3 $SO(p)$ and $O(p)$, for General p , and the Matrix Exponential Map

For general p , let \mathbf{H} be a $p \times p$ skew-symmetric matrix; that is

$$\mathbf{H}^T = -\mathbf{H}.$$

We define the matrix exponential map by

$$\exp(\mathbf{H}) = \sum_{k=0}^{k=\infty} \frac{\mathbf{H}^k}{k!}.$$

It can be shown that the skew-symmetry condition implies that $\exp(\mathbf{H})[\exp(\mathbf{H})]^T = \mathbf{I}_p$ and indeed

$$SO(p) = \{ \exp(\mathbf{H}) \mid \mathbf{H} \text{ is skew symmetric} \} \quad (56.24)$$

A skew-symmetric matrix must have zeros on its main diagonal and its entries below the main diagonal are determined by its entries above the main diagonal. Thus, the skew-symmetric $p \times p$ matrices have $p(p-1)/2$ independent entries, and hence, $SO(p)$ is a manifold of dimension $p(p-1)/2$.

Let $\mathbf{0}$ be a $p \times p$ matrix of zeros. Then

$$\exp(\mathbf{0}) = \mathbf{I}_p. \quad (56.25)$$

Thus, if the entries of \mathbf{H} are small (in absolute value), then $\exp(\mathbf{H})$ will be close to the identity matrix.

For $p = 3$, it can be shown, by using (56.23), that $\Phi_3(\mathbf{h}) = \exp[M_3(\mathbf{h})]$ for $\mathbf{h} \in \mathbb{R}^3$. Similarly we define for $h \in \mathbb{R}^1$ the skew-symmetric matrix

$$M_2(h) = \begin{pmatrix} 0 & -h \\ h & 0 \end{pmatrix}$$

and it follows that $\Phi_2(h) = \exp[M_2(h)]$. Thus, (56.21) and (56.22) are indeed special cases of (56.24).

$O(p)$ has two connected components; one is $SO(p)$ and the other is

$$SO(p)E = \{ \mathbf{A}\mathbf{E} \mid \mathbf{A} \in SO(p) \},$$

where E has been previously defined in (56.19). Notice that E is a reflection of R^p through the $(p - 1)$ -dimensional hyperplane perpendicular to the last coordinate vector. Indeed all reflections of R^p are in $O(p)$.

56.3.4 Distribution and Calculation of M -Estimates

So, heuristically speaking, suppose we have estimates $(\hat{\mathbf{A}}, \hat{\gamma}, \hat{\mathbf{b}})$ which minimize an objective function of the form (56.13). What values of the unknown parameters $(\mathbf{A}, \gamma, \mathbf{b})$ should we consider as reasonable given the data? The obvious answer, which is fully consistent with the usual practices of statistics, is those $(\mathbf{A}, \gamma, \mathbf{b})$ which do not excessively degrade the fit of the best-fit parameters $(\hat{\mathbf{A}}, \hat{\gamma}, \hat{\mathbf{b}})$; that is, those $(\mathbf{A}, \gamma, \mathbf{b})$ for which

$$\rho(\mathbf{A}, \gamma, \mathbf{b}) - \rho(\hat{\mathbf{A}}, \hat{\gamma}, \hat{\mathbf{b}}) = \sum_i \left[\rho_0(\|v_i - \gamma \mathbf{A} u_i - \mathbf{b}\|) - \rho_0(\|v_i - \hat{\gamma} \hat{\mathbf{A}} u_i - \hat{\mathbf{b}}\|) \right]$$

is not too large.

Recall that, for $p = 3$, if \mathbf{h} is small, then $\Phi_3(\mathbf{h})\mathbf{u}_i$ will be close to \mathbf{u}_i . This suggests writing

$$\hat{\mathbf{A}} = \mathbf{A} \Phi_3(\hat{\mathbf{h}}), \quad (56.26)$$

where $\hat{\mathbf{h}} \in R^3$. Then $\mathbf{A} \mathbf{u}_i = \hat{\mathbf{A}} \Phi_3(-\hat{\mathbf{h}})\mathbf{u}_i$ will be close to $\hat{\mathbf{A}} \mathbf{u}_i$ when $\hat{\mathbf{h}}$ is small. Rather than focus on the distribution of $\hat{\mathbf{A}}$, we will focus on the distribution of the *deviation* of $\hat{\mathbf{A}}$ from \mathbf{A} as measured by the (hopefully) small vector $\hat{\mathbf{h}}$.

Similarly, for $p = 2$, we will write

$$\hat{\mathbf{A}} = \mathbf{A} \Phi_2(\hat{\mathbf{h}}), \quad (56.27)$$

where $\hat{\mathbf{h}} \in R^1$. For general p , one writes

$$\hat{\mathbf{A}} = \mathbf{A} \exp(\hat{\mathbf{H}}), \quad (56.28)$$

where $\hat{\mathbf{H}}$ is $p \times p$ skew-symmetric.

The most elementary procedures in statistics are based upon the fact

If X_1, \dots, X_n are independent and each X_i is distributed $N(\mu, \sigma^2)$, then \bar{X} is distributed $N(\mu, \sigma^2/n)$.

An equivalent result is

If X_1, \dots, X_n are independent and each X_i is distributed $N(\mu, \sigma^2)$, then $\bar{X} - \mu$ is distributed $N(0, \sigma^2/n)$.

In the latter form, we have an estimator (in this case \bar{X}) and the distribution of the *deviation* $\hat{h} = \bar{X} - \mu$ of the estimator from the unknown parameter μ . This is sufficient for both confidence intervals and hypothesis testing and is analogous to what we propose to do in Sect. 56.4.

Similarly, in what follows, we will focus on the distributions of $\hat{h}, \hat{\mathbf{h}}$ or $\hat{\mathbf{H}}$ (depending upon whether $p = 2, 3$, or general) instead of directly giving the distributions of $\hat{\mathbf{A}}$. The reasons for doing so are rooted in the geometry of $SO(p)$ and are explained in greater detail in Sects. 53.3 and 53.4 of the accompanying chapter [8].

56.3.5 Numerical Calculation of M -Estimates for the Procrustes Model

We use here the geometric insights into $SO(p)$ to propose a method of minimizing the objective function (56.13) for the Procrustes model. The simplifications necessary to minimize the objective function (56.14) for the spherical regression model should be reasonably clear.

In what follows, it will be convenient to rewrite the Procrustes model

$$v_i = \gamma \mathbf{A} u_i + \mathbf{b} + \text{error}$$

in the equivalent form

$$v_i = \gamma \mathbf{A} (u_i - \bar{u}) + \beta + \text{error}, \quad (56.29)$$

where $\beta = \gamma \mathbf{A} \bar{u} + \mathbf{b}$.

Let $\psi(s) = \rho'_0(s)$. Differentiating (56.13) with respect to γ and β , we get that the M -estimates $(\hat{\mathbf{A}}, \hat{\gamma}, \hat{\beta})$ must satisfy

$$0 = \sum_i \psi(s_i) s_i^{-1} \left[v_i - \hat{\gamma} \hat{\mathbf{A}} (u_i - \bar{u}) - \hat{\beta} \right]^T \hat{\mathbf{A}} (u_i - \bar{u}) \quad (56.30)$$

$$0 = \sum_i \psi(s_i) s_i^{-1} \left[v_i - \hat{\gamma} \hat{\mathbf{A}} (u_i - \bar{u}) - \hat{\beta} \right]^T \quad (56.31)$$

where $s_i = \|v_i - \hat{\gamma} \hat{\mathbf{A}} (u_i - \bar{u}) - \hat{\beta}\|$.

To differentiate (56.13) with respect to \mathbf{A} , we note that, if \mathbf{H} is any skew-symmetric matrix, and using (56.25),

$$\begin{aligned} 0 &= \frac{d}{dt} \Big|_{t=0} \left\{ \sum_i \rho_0 \left(\|v_i - \hat{\gamma} \hat{\mathbf{A}} \exp(t\mathbf{H})(u_i - \bar{u}) - \hat{\beta}\| \right) \right\} \\ &= -\hat{\gamma} \sum_i \psi(s_i) s_i^{-1} \left[v_i - \hat{\gamma} \hat{\mathbf{A}} (u_i - \bar{u}) - \hat{\beta} \right]^T \hat{\mathbf{A}} \mathbf{H} (u_i - \bar{u}) \\ &= -\hat{\gamma} \text{Tr}(\tilde{\mathbf{X}} \hat{\mathbf{A}} \mathbf{H}), \end{aligned}$$

where

$$\tilde{\mathbf{X}} = \sum_i \psi(s_i) s_i^{-1} (\mathbf{u}_i - \bar{\mathbf{u}}) \left[\mathbf{v}_i - \hat{\gamma} \hat{\mathbf{A}} (\mathbf{u}_i - \bar{\mathbf{u}}) - \hat{\boldsymbol{\beta}} \right]^T.$$

Since \mathbf{H} is any skew-symmetric matrix, $\tilde{\mathbf{X}}\hat{\mathbf{A}}$ is symmetric. Equivalently if

$$\mathbf{X} = \sum_i \psi(s_i) s_i^{-1} (\mathbf{u}_i - \bar{\mathbf{u}}) (\mathbf{v}_i - \hat{\boldsymbol{\beta}})^T \quad (56.32)$$

then $\mathbf{X}\hat{\mathbf{A}}$ is symmetric.

Equations (56.32), (56.30), and (56.31) lead to the following iterative minimization algorithm. Start with the least squares solution given in Sect. 56.2.3 and use these estimates to calculate s_i . Using these s_i and the current guess for $\hat{\mathbf{A}}$, solve (56.30) and (56.31) to update the guesses for $\hat{\gamma}$ and $\hat{\boldsymbol{\beta}}$. Now writing $\mathbf{X} = \mathbf{O}_1 \mathbf{\Lambda} \mathbf{O}_2^T$ for the singular value decomposition of \mathbf{X} , the next guess for $\hat{\mathbf{A}}$ is $\mathbf{O}_2 \mathbf{O}_1^T$. This yields a minimum in $O(p)$. If minimization in $\text{SO}(p)$ is desired, a modified singular value decomposition is used for \mathbf{X} instead. Having updated the guesses for $(\hat{\mathbf{A}}, \hat{\gamma}, \hat{\boldsymbol{\beta}})$, we now iterate.

For example, consider the hands data of Table 56.1. We calculate the L_1 estimate for which $\psi(s) = 1$. Starting with the least squares estimates in (56.20), we convert $\hat{\mathbf{b}}$ to

$$\hat{\boldsymbol{\beta}} = \hat{\gamma} \hat{\mathbf{A}} \bar{\mathbf{u}} + \hat{\mathbf{b}} = (9.2500 \ 11.3633 \ 15.0950)^T \quad (56.33)$$

We use these least squares estimate as an initial guess; a single iteration of the minimization algorithm yields the updated guess

$$\hat{\mathbf{A}} = \begin{pmatrix} 0.9569 & 0.2823 & -0.0690 \\ 0.2614 & -0.9399 & -0.2199 \\ 0.1269 & -0.1924 & 0.9731 \end{pmatrix},$$

$$\hat{\gamma} = 1.0015,$$

$$\hat{\boldsymbol{\beta}} = (9.2835 \ 11.4092 \ 15.0851)^T.$$

Convergence is achieved after around a dozen iterations. We arrive at the L_1 estimates

$$\hat{\mathbf{A}} = \begin{pmatrix} 0.9418 & 0.3274 & -0.0760 \\ 0.3045 & -0.9268 & -0.2200 \\ 0.1425 & -0.1840 & 0.9725 \end{pmatrix},$$

$$\hat{\gamma} = 1.0086, \quad (56.34)$$

$$\hat{\boldsymbol{\beta}} = (9.2850 \ 11.4255 \ 15.0883)^T.$$

56.4 Statistical Properties of M -Estimates

56.4.1 The Σ Matrix and the Geometry of the \mathbf{u}_i

Let Σ be the $p \times p$ matrix

$$\Sigma = n^{-1} \sum_i (\mathbf{u}_i - \bar{\mathbf{u}}) (\mathbf{u}_i - \bar{\mathbf{u}})^T$$

Σ is nonnegative definite symmetric and hence its eigenvalues are real and its eigenvectors form an orthonormal basis of R^p . We can use this eigen-decomposition of Σ to summarize the geometry of the point \mathbf{u}_i . More specifically, let $\lambda_1 \geq \dots \geq \lambda_p \geq 0$ be the eigenvalues of Σ with corresponding eigenvectors $\mathbf{e}_1, \dots, \mathbf{e}_p$. Then \mathbf{e}_1 points in the direction of the greatest variation in the \mathbf{u}_i , and \mathbf{e}_p in the direction of the least variation.

56.4.2 Example: Σ for the Hands Data

For example, for the data of Table 56.1,

$$\bar{\mathbf{u}} = \begin{pmatrix} 7.8975 \\ 12.7542 \\ 14.3067 \end{pmatrix}$$

$$\begin{aligned} \Sigma &= \frac{1}{12} \left\{ \left[\begin{pmatrix} 5.17 \\ 11.30 \\ 16.18 \end{pmatrix} - \bar{\mathbf{u}} \right] \left[\begin{pmatrix} 5.17 \\ 11.30 \\ 16.18 \end{pmatrix} - \bar{\mathbf{u}} \right]^T + \dots + \right. \\ &\quad \left. \left[\begin{pmatrix} 8.68 \\ 12.71 \\ 13.67 \end{pmatrix} - \bar{\mathbf{u}} \right] \left[\begin{pmatrix} 8.68 \\ 12.71 \\ 13.67 \end{pmatrix} - \bar{\mathbf{u}} \right]^T \right\} \\ &= \begin{pmatrix} 2.6249 & 1.2525 & 0.1424 \\ 1.2525 & 0.8095 & -0.5552 \\ 0.1424 & -0.5552 & 4.9306 \end{pmatrix} \end{aligned}$$

$$\lambda_1 = 5.004, \quad \lambda_2 = 3.255, \quad \lambda_3 = 0.1054,$$

$$\mathbf{e}_1 = \begin{pmatrix} -0.0115 \\ -0.1346 \\ 0.9908 \end{pmatrix}, \quad \mathbf{e}_2 = \begin{pmatrix} -0.8942 \\ -0.4420 \\ -0.0704 \end{pmatrix},$$

$$\mathbf{e}_3 = \begin{pmatrix} -0.4474 \\ 0.8869 \\ 0.1152 \end{pmatrix}$$

Examining the data of Table 56.1, one sees that $\bar{\mathbf{u}}$ is close to point G, the center of the left palm. Examining

the displacement of G to C, top of the middle finger, it is evident that left hand was close to vertically oriented. This is the direction \mathbf{e}_1 . Examining the displacement of G to E, the top of the thumb, it appears that the left thumb was pointed in roughly the direction of the x -axis. This is the direction of $-\mathbf{e}_2$. Thus, the left hand was roughly parallel to the x - z plane. The normal vector to the plane of the left hand is thus approximately parallel to the y -axis. This is the direction of \mathbf{e}_3 . Notice that λ_3 is much smaller than λ_1 or λ_2 , indicating that the thickness of the hand is much smaller than its length or breadth.

56.4.3 Statistical Assumptions for the Procrustes Model

Before giving the statistical properties of $(\hat{\mathbf{A}}, \hat{\gamma}, \hat{\mathbf{b}})$, it is necessary to make explicit the statistical assumptions of the Procrustes model (56.2). These assumptions are:

- $\mathbf{u}_1, \dots, \mathbf{u}_n \in R^p$ are fixed (nonrandom) vectors.
- $\mathbf{v}_1, \dots, \mathbf{v}_n \in R^p$ are independent random vectors.
- The distribution of \mathbf{v}_i is of the form $f_0(s_i)$, where $s_i = \|\mathbf{v}_i - \gamma \mathbf{A} \mathbf{u}_i - \mathbf{b}\|$. Here $(\mathbf{A}, \gamma, \mathbf{b})$ are unknown, $\mathbf{A} \in \text{SO}(p)$ or $\text{O}(p)$, γ is a positive real constant, and $\mathbf{b} \in R^p$.

The most obvious example of a suitable distribution f_0 is

$$f_0(s) = (2\pi\sigma^2)^{-p/2} e^{-\frac{s^2}{2\sigma^2}} \quad (56.35)$$

for a fixed constant σ^2 . In what follows, we will not need to know the value of σ^2 . In fact, we will not even need to know the form of f_0 , only that the distribution of \mathbf{v}_i depends only upon its distance s_i from $\gamma \mathbf{A} \mathbf{u}_i + \mathbf{b}$.

The distribution (56.35) is a multivariate normal distribution with mean vector $\gamma \mathbf{A} \mathbf{u}_i + \mathbf{b}$ and covariance matrix $\sigma^2 \mathbf{I}_p$. Equivalently, the p components of \mathbf{v}_i are independent and each has variance σ^2 . If the components of \mathbf{v}_i were to have different variances, then the distribution of \mathbf{v}_i would not satisfy the Procrustes model assumptions.

In essence we assume that \mathbf{v}_i is isotropically (i.e., that all directions are the same) distributed around its mean vector.

56.4.4 Theorem (Distribution of $(\hat{\mathbf{A}}, \hat{\gamma}, \hat{\mathbf{b}})$ for the Procrustes Model)

Suppose $(\hat{\mathbf{A}}, \hat{\gamma}, \hat{\mathbf{b}})$ minimize an objective function of the form (56.13). Let $\boldsymbol{\beta} = \gamma \mathbf{A} \bar{\mathbf{u}} + \mathbf{b}$ and $\hat{\boldsymbol{\beta}} = \hat{\gamma} \hat{\mathbf{A}} \bar{\mathbf{u}} + \hat{\mathbf{b}}$. Then

- $\hat{\mathbf{A}}, \hat{\gamma}$, and $\hat{\boldsymbol{\beta}}$ are independent.
- $\hat{\boldsymbol{\beta}}$ is distributed multivariate normal with mean $\boldsymbol{\beta}$ and covariance matrix $\frac{k}{n} \mathbf{I}_p$.
- If $p = 2$, write $\hat{\mathbf{A}} = \mathbf{A} \Phi_2(\hat{\mathbf{h}})$, for $\hat{\mathbf{h}} \in R^1$. Then $\hat{\mathbf{h}}$ is normally distributed with mean 0 and variance $\frac{k}{n \text{Tr}(\boldsymbol{\Sigma})}$.
- If $p = 3$, write $\hat{\mathbf{A}} = \mathbf{A} \Phi_3(\hat{\mathbf{h}})$, for $\hat{\mathbf{h}} \in R^3$. Let $\boldsymbol{\Sigma} = \lambda_1 \mathbf{e}_1 \mathbf{e}_1^T + \lambda_2 \mathbf{e}_2 \mathbf{e}_2^T + \lambda_3 \mathbf{e}_3 \mathbf{e}_3^T$ be the spectral decomposition of $\boldsymbol{\Sigma}$. Then $\hat{\mathbf{h}}$ is distributed trivariate normal with mean 0 and covariance matrix

$$\frac{k}{n} [(\lambda_2 + \lambda_3)^{-1} \mathbf{e}_1 \mathbf{e}_1^T + (\lambda_3 + \lambda_1)^{-1} \mathbf{e}_2 \mathbf{e}_2^T + (\lambda_1 + \lambda_2)^{-1} \mathbf{e}_3 \mathbf{e}_3^T].$$

- For general p , write $\hat{\mathbf{A}} = \mathbf{A} \exp(\hat{\mathbf{H}})$, where $\hat{\mathbf{H}}$ is $p \times p$ skew-symmetric. Then $\hat{\mathbf{H}}$ has a multivariate normal density proportional to $\exp\left[-\frac{n}{2k} \text{Tr}(\hat{\mathbf{H}} \boldsymbol{\Sigma} \hat{\mathbf{H}})\right]$.
- $\hat{\gamma}$ is normally distributed with mean γ and variance $\frac{k}{n \text{Tr}(\boldsymbol{\Sigma})}$.

These results are asymptotic, that is, they are large-sample approximate distributions.

The constant k is defined to be

$$k = \frac{pE[\psi(s)^2]}{E^2[\psi'(s) + (p-1)\psi(s)s^{-1}]}, \quad (56.36)$$

where $\psi(s) = \rho'_0(s)$. Thus, k can be estimated from the sample by

$$\hat{k} = \frac{np \sum_i \psi(s_i)^2}{\left\{ \sum_i [\psi'(s_i) + (p-1)\psi(s_i)s_i^{-1}] \right\}^2}, \quad (56.37)$$

where $s_i = \|\mathbf{v}_i - \hat{\gamma} \hat{\mathbf{A}} \mathbf{u}_i - \hat{\mathbf{b}}\|$.

Theorem 56.4.4 is proven in Chang and Ko [4]. (In [4], s is defined to be $s = \|\mathbf{v} - \hat{\gamma} \hat{\mathbf{A}} \mathbf{u} - \hat{\mathbf{b}}\|^2$ and this causes the formulas (56.36) and (56.37) to be written somewhat differently there.)

56.4.5 Example: A Test of $\gamma = 1$

For the hands data, the least squares estimates were given in Example 56.2.4. Table 56.2 gives the calculation of the s_i . Substituting $p = 3$, $\rho_0(s) = s^2$, $\psi(s) = 2s$ into (56.37), $\hat{k} = (3n)^{-1} \sum_i s_i^2 = 0.0860$.

To test if the two hands are the same size, we test $\gamma = 1$. Using Example 56.4.2, $\text{Tr}(\boldsymbol{\Sigma}) = 8.365$. Hence, the variance of $\hat{\gamma}$ is 0.000860 and its standard error is 0.0293. Since $\hat{\gamma} = 0.9925$, we see that $\hat{\gamma}$ is not significantly different from 1.

Table 56.2 Calculation of residual lengths for data from Table 56.1

	Predicted \hat{v}_i			Residual			s_i
	$\hat{\gamma} \hat{\mathbf{A}} \mathbf{u}_i + \hat{\mathbf{b}}$			$\mathbf{v}_i - \hat{\mathbf{v}}_i$			$\ \mathbf{v}_i - \hat{\mathbf{v}}_i\ $
A	6.148	11.687	16.868	-0.238	-0.527	-0.318	0.660
B	8.475	10.969	18.207	0.155	-0.349	0.123	0.401
C	9.620	10.962	18.654	0.470	-0.362	-0.014	0.593
D	11.080	10.457	17.769	-0.190	0.493	0.131	0.544
E	13.206	10.816	13.865	-0.236	-0.686	0.015	0.726
F	8.691	11.176	13.247	0.099	0.034	-0.077	0.129
G	10.544	10.938	13.355	0.156	0.162	0.065	0.234
H	8.501	11.594	11.046	-0.031	-0.504	0.304	0.589
I	7.449	12.225	14.178	-0.169	0.295	-0.138	0.367
J	8.062	11.908	14.649	-0.012	0.512	-0.089	0.520
K	9.198	11.904	14.730	-0.128	0.486	0.130	0.519
L	10.026	11.724	14.573	0.125	0.446	-0.133	0.481

The L_1 estimate of γ is 1.0086. To calculate the standard error of this estimate, we use $\rho_0(s) = s$ and $\psi(s) = 1$. Hence, for the L_1 estimate, (56.37) yields $\hat{k} = 0.75(n^{-1} \sum_i s_i^{-1})^{-2}$. After recomputing the s_i using L_1 estimates of $(\mathbf{A}, \gamma, \mathbf{b})$, we obtain $\hat{k} = 0.023$. Thus, the L_1 estimate of γ has a standard error of 0.0150 and this estimate is also not significantly different from 1.

Apparently, the two hands have the same size.

General statistical theory implies that if the \mathbf{v}_i were really normally distributed, the least squares estimates would be the most efficient. In other words, least squares estimates should have the smallest standard errors. Evidently this is not true for the hands data and it appears that this data is not, in fact, normally distributed.

56.4.6 Example: A Test on A

As discussed in Sect. 56.4.2, the eigenvector \mathbf{e}_3 of $\boldsymbol{\Sigma}$ is perpendicular to the plane of the left palm. It might be of interest to test if the two hands have the same orientation; that is, after reflecting the left hand in the plane perpendicular to \mathbf{e}_3 , do the fingers and thumb of the two hands point in the same directions. We formulate this hypothesis as \mathbf{H}_0 : $\mathbf{A} = \mathbf{R}_{\mathbf{e}_3}$ where $\mathbf{R}_{\mathbf{e}_3}$ is the matrix of the reflection in plane perpendicular to \mathbf{e}_3 .

$$\begin{aligned} \mathbf{R}_{\mathbf{e}_3} &= \mathbf{I}_3 - 2\mathbf{e}_3\mathbf{e}_3^T \\ &= \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} - 2 \begin{pmatrix} -0.4474 \\ 0.8869 \\ 0.1152 \end{pmatrix} \begin{pmatrix} -0.4474 & 0.8869 & 0.1152 \end{pmatrix}^T \\ &= \begin{pmatrix} 0.5996 & 0.7936 & 0.1031 \\ 0.7936 & -0.5731 & -0.2044 \\ 0.1031 & -0.2044 & 0.9734 \end{pmatrix}, \end{aligned}$$

$\hat{\mathbf{h}}$ is defined by

$$\begin{aligned} \Phi_3(\hat{\mathbf{h}}) &= \mathbf{R}_{\mathbf{e}_3}^T \hat{\mathbf{A}} \\ &= \begin{pmatrix} 0.7843 & -0.6127 & -0.0976 \\ 0.5999 & 0.7890 & -0.1327 \\ 0.1583 & 0.0455 & 0.9863 \end{pmatrix}, \end{aligned} \quad (56.38)$$

where $\hat{\mathbf{A}}$ was calculated in Sect. 56.2.4.

To solve for $\hat{\mathbf{h}}$, we use the results at the end of Sect. 56.3.2. The matrix of (56.38) has an eigenvector of $\boldsymbol{\xi} = (0.1395 \ -0.2003 \ 0.9494)^T$ corresponding to the eigenvalue of 1. Its angle of rotation is given by

$$\theta = \arccos \left[0.5 \text{Tr} \left(\mathbf{R}_{\mathbf{e}_3}^T \hat{\mathbf{A}} \right) - 0.5 \right] = 0.6764.$$

Thus, $\hat{\mathbf{h}} = \theta \boldsymbol{\xi} = (0.0944 \ -0.1355 \ 0.6422)^T$.

By Theorem 56.4.4, if H_0 is true, $\hat{\mathbf{h}}$ is trivariate normally distributed with mean $\mathbf{0}$ and covariance matrix

$$\frac{k}{n} \left[(\lambda_2 + \lambda_3)^{-1} \mathbf{e}_1 \mathbf{e}_1^T + (\lambda_3 + \lambda_1)^{-1} \mathbf{e}_2 \mathbf{e}_2^T + (\lambda_1 + \lambda_2)^{-1} \mathbf{e}_3 \mathbf{e}_3^T \right].$$

The constant k was estimated in Sect. 56.4.5 and the λ_i and \mathbf{e}_i were calculated in Sect. 56.4.2. Using these calculations, the covariance matrix of $\hat{\mathbf{h}}$ is estimated to be

$$\widehat{\text{Cov}}(\hat{\mathbf{h}}) = \begin{pmatrix} 0.001296 & 0.0002134 & 0.00001923 \\ 0.0002134 & 0.0009951 & -0.0001520 \\ 0.00001923 & -0.0001520 & 0.002112 \end{pmatrix}$$

Under the null hypothesis

$$\chi^2 = \hat{\mathbf{h}}^T \widehat{\text{Cov}}(\hat{\mathbf{h}})^{-1} \hat{\mathbf{h}} = 213$$

has an approximate χ^2 distribution with three degrees of freedom.

We emphatically conclude that, after reflecting the left hand, the orientations of the two hands are not the same.

56.4.7 Asymptotic Relative Efficiency of Least Squares and L_1 Estimates

Examining Theorem 56.4.4, we see that the covariance of the M -estimate $(\hat{\mathbf{A}}, \hat{\gamma}, \hat{\mathbf{b}})$ is determined, up to a constant k , by the geometry of the \mathbf{u}_i , as summarized by the matrix Σ . Only the constant k , see (56.36), depends upon the probability distribution of the \mathbf{v}_i and the objective function (56.13) that $(\hat{\mathbf{A}}, \hat{\gamma}, \hat{\mathbf{b}})$ minimize. Furthermore, a sample estimate of k , see (56.37) is available which does not require knowledge of the distribution of the \mathbf{v}_i .

Let $k(f_0, L_2)$ denote the constant k as defined in (56.36) when the underlying density is of the form f_0 and least squares (L_2) estimation is used, and $k(f_0, L_1)$ the corresponding value when L_1 estimation is used. The ratio $\text{ARE}(L_1, L_2; f_0) = k(f_0, L_2)/k(f_0, L_1)$ is called the *asymptotic relative efficiency* of the L_1 to the least squares estimators at the density f_0 .

We see that

$$\text{ARE}(L_1, L_2; f_0) = \frac{\text{Variance of least squares estimator}}{\text{Variance of } L_1 \text{ estimator}}, \quad (56.39)$$

where we recognize that both variances are matrices, but the two variance matrices are multiples of each other.

If f_0 is a p -dimensional normal density (56.35), it can be shown from (56.36) that

$$\text{ARE}(L_1, L_2; N_p) = \frac{2\Gamma^2[(p+1)/2]}{p\Gamma^2(p/2)}. \quad (56.40)$$

We have used N_p in (56.40) to denote the p -dimensional normal density function.

The Γ function in (56.40) has the properties

$$\begin{aligned} \Gamma(1) &= 1 & \Gamma(0.5) &= \sqrt{\pi} \\ \Gamma(q+1) &= q\Gamma(q). \end{aligned}$$

Thus, when $p = 2, 3$

$$\begin{aligned} \text{ARE}(L_1, L_2; N_2) &= \frac{\pi}{4} = 0.785, \\ \text{ARE}(L_1, L_2; N_3) &= \frac{8}{3\pi} = 0.849. \end{aligned} \quad (56.41)$$

$\text{ARE}(L_1, L_2; N_p)$ increases to 1 as $p \rightarrow \infty$.

When the underlying distribution is normal, statistical theory indicates that least squares procedures are optimal, that

is, they have the smallest variance. Using (56.39) and (56.41), we see that for $p = 3$, even when the data is normal, the use of L_1 methods results in only an 8% penalty in standard error. And L_1 methods offer superior resistance to outliers.

Indeed, as we saw in Example 56.4.5, the standard error of the L_1 estimator was *smaller* than the standard error of the least squares estimator. Evidently the hands dataset is long-tailed, that is, it has more outliers than would be expected with normal data.

56.4.8 The Geometry of the Landmarks and the Errors in $\hat{\mathbf{A}}$

In this section, we will constrain our discussion to the case $p = 3$.

Suppose we write the estimate $\hat{\mathbf{A}}$ in the form

$$\hat{\mathbf{A}} = \mathbf{A}\Phi_3(\hat{\mathbf{h}}). \quad (56.42)$$

$\Phi_3(\hat{\mathbf{h}})$ is a (hopefully) small rotation which expresses the deviation of the estimate $\hat{\mathbf{A}}$ from the true value \mathbf{A} .

Recall that $\Phi_3(\hat{\mathbf{h}})$ is a rotation of $\|\hat{\mathbf{h}}\|$ radians around the axis $\|\hat{\mathbf{h}}\|^{-1}\hat{\mathbf{h}}$.

In particular $\Phi_3(\hat{\mathbf{h}})^{-1} = \Phi_3(-\hat{\mathbf{h}})$ and

$$\mathbf{A} = \hat{\mathbf{A}}\Phi_3(-\hat{\mathbf{h}}).$$

According to Theorem 56.4.4, the covariance matrix of $\hat{\mathbf{h}}$ has the form

$$\begin{aligned} \text{Cov}(\hat{\mathbf{h}}) &= \frac{k}{n} [(\lambda_2 + \lambda_3)^{-1} \mathbf{e}_1 \mathbf{e}_1^T + (\lambda_3 + \lambda_1)^{-1} \mathbf{e}_2 \mathbf{e}_2^T \\ &\quad + (\lambda_1 + \lambda_2)^{-1} \mathbf{e}_3 \mathbf{e}_3^T], \end{aligned} \quad (56.43)$$

where $\lambda_1 \geq \lambda_2 \geq \lambda_3$ are the eigenvalues of Σ with corresponding eigenvectors $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$. Since $\hat{\mathbf{h}}$ is normally distributed

$$\chi^2 = \hat{\mathbf{h}}^T \left[\text{Cov}(\hat{\mathbf{h}})^{-1} \right] \hat{\mathbf{h}}$$

is distributed χ^2 with three degrees of freedom.

Thus, a confidence region for \mathbf{A} is of the form

$$\left\{ \hat{\mathbf{A}}\Phi_3(-\hat{\mathbf{h}}) \mid \hat{\mathbf{h}}^T \left[\text{Cov}(\hat{\mathbf{h}})^{-1} \right] \hat{\mathbf{h}} < \chi_{3,\alpha}^2 \right\}, \quad (56.44)$$

where $\chi_{3,\alpha}^2$ is the appropriate critical point of a χ_3^2 distribution.

Let $\theta = \|\hat{\mathbf{h}}\|$ and $\boldsymbol{\xi} = -\|\hat{\mathbf{h}}\|^{-1}\hat{\mathbf{h}}$ so that $\hat{\mathbf{h}} = -\theta\boldsymbol{\xi}$.

Thus, $\Phi_3(\hat{\mathbf{h}})$ is a rotation of θ radians around the axis $\boldsymbol{\xi}$.

Substituting (56.43) into the confidence region (56.44), we can re-express this confidence region as

$$\left\{ \hat{\mathbf{A}} \Phi_3(\theta\boldsymbol{\xi}) \mid \theta^2 \frac{n}{k} \left[(\lambda_2 + \lambda_3) (\boldsymbol{\xi}^T \mathbf{e}_1)^2 + (\lambda_3 + \lambda_1) (\boldsymbol{\xi}^T \mathbf{e}_2)^2 + (\lambda_1 + \lambda_2) (\boldsymbol{\xi}^T \mathbf{e}_3)^2 \right] < \chi_{3,\alpha}^2 \right\}. \quad (56.45)$$

Now

$$\lambda_2 + \lambda_3 \leq \lambda_3 + \lambda_1 \leq \lambda_1 + \lambda_2.$$

Thus, the confidence region (56.45) constrains θ the most (i.e., the limits on θ are the smallest) when $\boldsymbol{\xi}$ points in the direction \mathbf{e}_3 . It bounds θ the least when $\boldsymbol{\xi}$ points in the direction \mathbf{e}_1 .

Recall also that \mathbf{e}_1 is the direction of the greatest variation in the \mathbf{u}_i and \mathbf{e}_3 the direction of the least variation.

For the hands data of Table 56.1, \mathbf{e}_1 points in the direction of the length of the left hand and \mathbf{e}_3 in the normal direction to the palm.

Thus, the angle θ of the small rotation $\Phi_3(\theta\boldsymbol{\xi})$ is the most constrained when its axis $\boldsymbol{\xi}$ points in the direction of the least variation in the \mathbf{u}_i . θ is least constrained when $\boldsymbol{\xi}$ points in the direction of the greatest variation of the \mathbf{u}_i .

For the hands data, if $\hat{\mathbf{h}}$ is in the direction of \mathbf{e}_1 , the length of the hand, it represents a small rotation at the elbow with the wrist held rigid. The variance of the deviation rotation $\hat{\mathbf{h}}$ in the direction \mathbf{e}_1 is $(\lambda_2 + \lambda_3)^{-1} = 0.298$. If $\hat{\mathbf{h}}$ points in the direction of \mathbf{e}_2 , the width of the hand, it represents a forwards and backwards rotation at the wrist; the variance of $\hat{\mathbf{h}}$ in this direction is $(\lambda_3 + \lambda_1)^{-1} = 0.196$. Finally if $\hat{\mathbf{h}}$ points in the direction of \mathbf{e}_3 , the normal vector to the hand, it represents a somewhat awkward sideways rotation at the wrist (this rotation is represented in Fig. 56.1b); the variance of $\hat{\mathbf{h}}$ in this direction is $(\lambda_1 + \lambda_2)^{-1} = 0.121$. If the variability of the component of $\hat{\mathbf{h}}$ in the direction of a rotation at the elbow is unacceptably large, we could increase λ_3 , in effect to create, if possible, landmarks which effectively thicken the palm.

A heuristic derivation of this result is due to *Stock and Molnar* [9, 10]. It appeared in the geophysical literature and is considered a major development in our understanding of the uncertainties in tectonic plate reconstructions. We will present their argument below, suitably modified for the image registration context.

It is convenient to rewrite the model, as in Theorem 56.4.4, in the form (56.29). If we substitute $\mathbf{A} = \hat{\mathbf{A}}\Phi_3(\theta\boldsymbol{\xi})$, we see that \mathbf{A} first perturbs the $\mathbf{u}_i - \bar{\mathbf{u}}$ by the small rotation $\Phi_3(\theta\boldsymbol{\xi})$ and then applies the best fitting orthogonal matrix $\hat{\mathbf{A}}$.

Fig. 56.1 (a) A hand with axes \mathbf{e}_1 , \mathbf{e}_2 ; axis \mathbf{e}_3 points out of paper. X marks the center point $\bar{\mathbf{u}}$. The distances $d(C, \mathbf{e}_3)$ and $d(E, \mathbf{e}_1)$ are the lengths of the indicated line segments. (b) The effect of a rotation of angle θ around the axis \mathbf{e}_3 . The point C moves a distance of approximately $d(C, \mathbf{e}_3)\theta$. Under a rotation of θ around \mathbf{e}_1 (not shown), the point E moves a distance of approximately $d(E, \mathbf{e}_1)\theta$. Notice that $d(E, \mathbf{e}_1) < d(C, \mathbf{e}_3)$, and, indeed, the landmarks \mathbf{u}_i tend to be closer to \mathbf{e}_1 than to \mathbf{e}_3 . It follows that a rotation of θ around \mathbf{e}_3 will move the figure more than a rotation of θ around \mathbf{e}_1 .

Let $d(\mathbf{u}_i, \boldsymbol{\xi})$ be the distance of the landmark \mathbf{u}_i to the line through the center point $\bar{\mathbf{u}}$ and in the direction of the axis $\boldsymbol{\xi}$. Refer to Fig. 56.1. Since the landmarks vary most in the direction \mathbf{e}_1 and least in the direction \mathbf{e}_3 , the distances $d(\mathbf{u}_i, \mathbf{e}_3)$ will tend to be biggest and the distances $d(\mathbf{u}_i, \mathbf{e}_1)$ smallest.

A point \mathbf{x} will move a distance of approximately $d(\mathbf{x}, \boldsymbol{\xi})\theta$ under a rotation of angle θ around the axis $\boldsymbol{\xi}$. It follows that a rotation of angle θ will most move the landmarks \mathbf{u}_i if the axis is \mathbf{e}_3 . It will move the landmarks \mathbf{u}_i least if the axis is \mathbf{e}_1 . In other words, for a fixed θ , the small rotation $\Phi_3(\theta\boldsymbol{\xi})$ will most degrade the best fit, provided by $\hat{\mathbf{A}}$, if $\boldsymbol{\xi} = \mathbf{e}_3$; it will least degrade the best fit if $\boldsymbol{\xi} = \mathbf{e}_1$.

An orthogonal transformation $\mathbf{A} = \hat{\mathbf{A}}\Phi_3(\theta\boldsymbol{\xi})$ is considered a possible transformation if it does not degrade the best fit by too much. It follows that θ is most constrained if $\boldsymbol{\xi} = \mathbf{e}_3$, the direction of the least variation in the landmarks \mathbf{u}_i , and is least constrained if $\boldsymbol{\xi} = \mathbf{e}_1$, the direction of greatest variation in the landmarks \mathbf{u}_i .

Suppose instead we were to write the estimate $\hat{\mathbf{A}}$ in the form

$$\begin{aligned} \hat{\mathbf{A}} &= \Phi_3(\hat{\mathbf{h}}_v) \mathbf{A}, \\ \mathbf{A} &= \Phi_3(-\hat{\mathbf{h}}_v) \hat{\mathbf{A}}. \end{aligned} \quad (56.46)$$

Then (56.43) is replaced by

$$\begin{aligned} \text{Cov}(\hat{\mathbf{h}}_v) &= \frac{k}{n} [(\lambda_2 + \lambda_3)^{-1} (\mathbf{A}\mathbf{e}_1) (\mathbf{A}\mathbf{e}_1)^T \\ &\quad + (\lambda_3 + \lambda_1)^{-1} (\mathbf{A}\mathbf{e}_2) (\mathbf{A}\mathbf{e}_2)^T \\ &\quad + (\lambda_1 + \lambda_2)^{-1} (\mathbf{A}\mathbf{e}_3) (\mathbf{A}\mathbf{e}_3)^T]. \end{aligned}$$

The same reasoning then expresses the errors of $\hat{\mathbf{h}}_v$, and hence of $\hat{\mathbf{A}}$, in terms of the geometry of the landmarks \mathbf{v}_i . In other words, for the hands data, using the definition (56.46) expresses the errors of $\hat{\mathbf{A}}$ in terms of the orientation of the right hand.

56.4.9 Statistical Properties of M -Estimates for Spherical Regressions

The statistical assumptions of the spherical regression model (56.1) are:

- $\mathbf{u}_1, \dots, \mathbf{u}_n \in \Omega_p$ are fixed (nonrandom) vectors.
- $\mathbf{v}_1, \dots, \mathbf{v}_n \in \Omega_p$ are independent random vectors.
- The distribution of \mathbf{v}_i is of the form $f_0(t_i)$ where $t_i = \mathbf{v}_i^T \mathbf{A} \mathbf{u}_i$. Here $\mathbf{A} \in \text{SO}(p)$ or $O(p)$ is unknown.

A commonly used distribution for spherical data $\mathbf{x} \in \Omega_p$ is the distribution whose density (with respect to surface measure, or uniform measure, on Ω_p) is

$$f(\mathbf{x}; \boldsymbol{\theta}) = c(\kappa) \exp(\kappa \mathbf{x}^T \boldsymbol{\theta}). \quad (56.47)$$

This distribution has two parameters: a positive real constant κ which is commonly called the *concentration parameter* and $\boldsymbol{\theta} \in \Omega_p$. It is easily seen that $f(\mathbf{x})$ is maximized over $\mathbf{x} \in \Omega_p$ at $\boldsymbol{\theta}$ and hence $\boldsymbol{\theta}$ is usually referred to as the *modal vector*; $c(\kappa)$ is a normalizing constant.

If $\kappa = 0$, (56.47) is a uniform density on Ω_p . On the other hand as $\kappa \rightarrow \infty$, the density (56.47) approaches that of a multivariate normal distribution in $p - 1$ dimensions with a covariance matrix of $\kappa^{-1} \mathbf{I}_{p-1}$. Thus, intuitively we can think of κ as σ^{-2} , that is, think of κ as the inverse variance. As $\kappa \rightarrow \infty$, (56.47) approaches a singular multivariate normal distribution supported on the $(p - 1)$ -dimensional subspace $\boldsymbol{\theta}^\perp \subset R^p$. As a singular multivariate, normal distribution in R^p its covariance matrix is $\kappa^{-1} (\mathbf{I}_p - \boldsymbol{\theta} \boldsymbol{\theta}^T)$.

For the circle Ω_1 , (56.47) is due to von Mises. For general Ω_p , it is due (independently) to Fisher and to Langevin. More properties of the Fisher–von Mises–Langevin distribution can be found in Watson [11] or in Fisher et al. [12].

The distribution of an M -estimator $\hat{\mathbf{A}}$ which minimizes an objective function of the form (56.14) is similar to the distribution given in Theorem 56.4.4:

- If $p = 2$, write $\hat{\mathbf{A}} = \mathbf{A} \Phi_2(\hat{\mathbf{h}})$, for $\hat{\mathbf{h}} \in R^1$. Then $\hat{\mathbf{h}}$ is normally distributed with mean 0 and variance $\frac{k}{n}$.

- If $p = 3$, write $\hat{\mathbf{A}} = \mathbf{A} \Phi_3(\hat{\mathbf{h}})$, for $\hat{\mathbf{h}} \in R^3$. Let $\boldsymbol{\Sigma} = \lambda_1 \mathbf{e}_1 \mathbf{e}_1^T + \lambda_2 \mathbf{e}_2 \mathbf{e}_2^T + \lambda_3 \mathbf{e}_3 \mathbf{e}_3^T$ be the spectral decomposition of $\boldsymbol{\Sigma}$. Then $\hat{\mathbf{h}}$ is distributed trivariate normal with mean $\mathbf{0}$ and covariance matrix

$$\begin{aligned} \frac{k}{n} [(\lambda_2 + \lambda_3)^{-1} \mathbf{e}_1 \mathbf{e}_1^T + (\lambda_3 + \lambda_1)^{-1} \mathbf{e}_2 \mathbf{e}_2^T \\ + (\lambda_1 + \lambda_2)^{-1} \mathbf{e}_3 \mathbf{e}_3^T]. \end{aligned}$$

- For general p , write $\hat{\mathbf{A}} = \mathbf{A} \exp(\hat{\mathbf{H}})$, where $\hat{\mathbf{H}}$ is $p \times p$ skew-symmetric. Then $\hat{\mathbf{H}}$ has a multivariate normal density proportional to $\exp\left[-\frac{n}{2k} \text{Tr}(\hat{\mathbf{H}}^T \boldsymbol{\Sigma} \hat{\mathbf{H}})\right]$.

Let $\psi(t) = -\rho'_0(t)$. (The sign of ψ has been chosen to make $\psi(t)$ nonnegative, since ρ_0 is a decreasing function of t .) The constant k and its sample estimate \hat{k} are given by

$$\begin{aligned} k &= \frac{(p-1)E[\psi(t)^2(1-t^2)]}{E^2[(p-1)\psi(t)t - \psi'(t)(1-t^2)]}, \\ \hat{k} &= \frac{n(p-1)\sum_i \psi(t_i)^2(1-t_i^2)}{\left\{\sum_i [(p-1)\psi(t_i)t_i - \psi'(t_i)(1-t_i^2)]\right\}^2}. \end{aligned} \quad (56.48)$$

For the spherical case, the matrix $\boldsymbol{\Sigma} = \sum_i \mathbf{u}_i \mathbf{u}_i^T$. Its dominant eigenvector \mathbf{e}_1 points in the direction of the center of the \mathbf{u}_i . The \mathbf{e}_2 is the vector perpendicular to \mathbf{e}_1 so that the two-dimensional plane spanned by \mathbf{e}_1 and \mathbf{e}_2 (and the origin) best fits the \mathbf{u}_i . This continues until $\mathbf{e}_1, \dots, \mathbf{e}_{p-1}$ is the $(p - 1)$ -dimensional hyperplane, among the collection of all $(p - 1)$ -dimensional hyperplanes that best fits the data. This latter hyperplane is, of course, the hyperplane perpendicular to \mathbf{e}_p . Except for this slight reinterpretation of the geometric meaning of the \mathbf{e}_i , our previous comments about the relationship of the uncertainties in $\hat{\mathbf{h}}$ to the geometry of the \mathbf{u} -points, as summarized by the eigen-decomposition of $\boldsymbol{\Sigma}$, remain valid. Indeed the original Stock and Molnar insights about the uncertainties of tectonic plate reconstructions were actually in the spherical data context.

Thus, as before, the uncertainties in $\hat{\mathbf{A}}$ are determined up to the constant k by the geometry of the \mathbf{u} -points. Only the constant k depends upon the underlying data distribution f_0 or upon the objective function ρ . We can define the asymptotic relative efficiency as in Sect. 56.4.7 without change. Its interpretation (56.39) also remains valid.

Equation (56.48) implies that we can, as before, define the asymptotic efficiency of the L_1 estimator relative to the least squares estimator, at the density f_0 , as $\text{ARE}(L_1, L_2; f_0) = k(f_0, L_2)/k(f_0, L_1)$. The interpretation (56.39) remains valid. The constants $k(f_0, L_2)$ and $k(f_0, L_1)$ come from (56.48) using the underlying density f_0 under consideration and $\rho_0(t) = 2 - 2t$ [refer to (56.9)], $\psi(t) = 2$, for the least squares case, or $\rho_0(t) = \arccos(t)$, $\psi(t) = (1 - t^2)^{\frac{1}{2}}$, for the L_1 case. If f_0 is the Fisher–von Mises–Langevin density (56.47) on Ω_p (which we will denote by $F_{\kappa,p}$ in the following)

Fig. 56.2 Asymptotic efficiency of L_1 estimators relative to least squares estimators for Fisher–von Mises–Langevin distributions on Ω_p as a function of κ for (a) $p = 2$ and (b) $p = 3$. Horizontal lines are asymptotic limits as $\kappa \rightarrow \infty$.

$$\begin{aligned} \text{ARE}(L_1, L_2; F_{\kappa,p}) &= \frac{\left[\int_{-1}^1 e^{\kappa t} (1-t^2)^{(p-2)/2} dt \right]^2}{\left[\int_{-1}^1 e^{\kappa t} (1-t^2)^{(p-1)/2} dt \right]^2} \frac{1}{\left[\int_{-1}^1 e^{\kappa t} (1-t^2)^{(p-3)/2} dt \right]} \end{aligned} \tag{56.49}$$

As $\kappa \rightarrow \infty$, the limit of (56.49) is

$$\begin{aligned} \lim_{\kappa \rightarrow \infty} \text{ARE}(L_1, L_2; F_{\kappa,p}) &= \frac{2\Gamma^2(p/2)}{(p-1)\Gamma^2[(p-1)/2]} \end{aligned} \tag{56.50}$$

Comparing (56.40) with (56.50), we see that (56.50) is the same as (56.40) with p replaced by $p - 1$. This is as expected because, as noted above, for large κ the Fisher–von Mises–Langevin distribution approaches a $(p - 1)$ -dimensional multivariate normal distribution. Figure 56.2 gives a graph of $\text{ARE}(L_1, L_2; F_{\kappa,p})$ for $p = 2, 3$.

In particular for $p = 3$, $\text{ARE}(L_1, L_2; F_{\kappa,3}) \rightarrow \pi/4$. For the Fisher–von–Mises–Langevin distribution, least squares methods are optimal. Nevertheless, in standard error terms, the penalty for using L_1 methods is at most 13%.

56.5 Diagnostics

We discuss in this section influence function diagnostics for the Procrustes model. Suppose the registration provided by the estimates $(\hat{\mathbf{A}}, \hat{\gamma}, \hat{\mathbf{b}})$ is unsatisfactory. These diagnostics

will determine which points are influential for the estimated orthogonal matrix $\hat{\mathbf{A}}$, which points are influential for the estimated scale change $\hat{\gamma}$, and which are influential for the estimated translation $\hat{\mathbf{b}}$.

56.5.1 Influence Diagnostics in Simple Linear Regression

As background discussion, we consider first the simple linear regression model

$$y_i = \alpha + \beta x_i + \text{error}, \tag{56.51}$$

where $x_i, y_i \in R^1$. For simplicity, we will assume $\sum_i x_i = 0$. This can be accomplished by a centering transformation similar to that used in (56.29).

For the model (56.51), the least squares estimates are

$$\begin{aligned} \hat{\alpha} &= \bar{y}, \\ \hat{\beta} &= \left(\sum_i x_i^2 \right)^{-1} \left(\sum_i x_i y_i \right). \end{aligned} \tag{56.52}$$

Suppose we delete the i -th observation (x_i, y_i) and recompute the estimates (56.52). The resulting estimates would be [see Cook and Weisberg [13], (Sect. 3.4.6)]

$$\begin{aligned} \hat{\alpha}_{(i)} &= \hat{\alpha} - (1 - v_{ii})^{-1} \frac{e_i}{n}, \\ \hat{\beta}_{(i)} &= \hat{\beta} - (1 - v_{ii})^{-1} \frac{x_i e_i}{\sum_k x_k^2}, \end{aligned} \tag{56.53}$$

where

$$e_i = y_i - \hat{\alpha} - \hat{\beta} x_i$$

is the residual, and

$$v_{ii} = \frac{1}{n} + \frac{x_i^2}{\sum_k x_k^2}$$

is the i -th diagonal entry of the so-called *hat* matrix. It can be shown that

$$\begin{aligned} 0 \leq v_{ii} &\leq 1, \\ \sum_i v_{ii} &= 2. \end{aligned} \tag{56.54}$$

If $|x_i|$ is big, $1 - v_{ii}$ can be close to zero, although because of (56.54), if n is large, this will usually not be the case. Ignoring the factor of $(1 - v_{ii})^{-1}$, it follows from (56.53) that deletion of (x_i, y_i) will be influential for $\hat{\alpha}$ when the magnitude of the residual $|e_i|$ is big. Deletion of (x_i, y_i) will be influential for $\hat{\beta}$ when both $|x_i|$ and $|e_i|$ are big. Points with large values of $|x_i|$ [typically, due to (56.54), $|x_i| > \frac{4}{n}$] are

called *high-leverage* points, whereas points with large values of $|e_i|$ are called *outliers*. (Recall we have centered the data so that $\bar{x} = 0$.)

Thus, influence on $\hat{\alpha}$ and on $\hat{\beta}$ is different. Outliers are influential for $\hat{\alpha}$, whereas influence for $\hat{\beta}$ is a combination of being an outlier and having high leverage. For the model (56.51) with the least squares estimators, the *influence function* works out to be

$$\text{IF}[\hat{\alpha}; (x_i, y_i)] = \frac{y_i - \alpha - \beta x_i}{n}, \quad (56.55)$$

$$\text{IF}[\hat{\beta}; (x_i, y_i)] = \frac{x_i (y_i - \alpha - \beta x_i)}{\sum_k x_k^2}, \quad (56.56)$$

where α and β are the “true” population values in the model (56.51). We will not give a formal definition of the influence function here, but refer the reader to *Cook and Weisberg [13]* for a more comprehensive discussion of the influence function in the regression model.

It should be noted that to actually calculate (56.55) and (56.56) from a sample, it is necessary to estimate α and β . Thus, even though in the left-hand sides of (56.55) and (56.56), $\hat{\alpha}$ and $\hat{\beta}$ are least squares estimates, we should substitute in the right-hand sides of (56.55) and (56.56) better estimates, if available, of α and β . There is no contradiction in using L_1 estimates to estimate the influence function of the least squares estimators.

56.5.2 Influence Diagnostics for the Procrustes Model

Chang and Ko [4] calculated the *standardized influence functions* (SIF) for M -estimates (56.13) in the Procrustes model (56.29). (The influence functions of the estimates $\hat{\mathbf{A}}$ and $\hat{\beta}$ are vectors; the standardization calculates their square length in some metric.) Using their notation

$$\left\| \text{SIF}[\hat{\beta}; (\mathbf{u}_i, \mathbf{v}_i)] \right\|^2 = k_I \psi(s_i)^2, \quad (56.57)$$

where $s_i = \|\mathbf{v}_i - \gamma \mathbf{A}(\mathbf{u}_i - \bar{\mathbf{u}}) - \beta\|$ and $\psi(s) = \rho'_0(s)$. Therefore

- The influence of $(\mathbf{u}_i, \mathbf{v}_i)$ on the estimate $\hat{\beta}$ of the translation parameter depends only upon the length s_i of the residual.

This behavior is similar to that of simple linear regression (56.55). The constant k_I is given by

$$k_I = \frac{pE[g'(s)^2]}{E^2[\psi'(s) + (p-1)\psi(s)s^{-1}]},$$

where $g(s) = \log f_0(s)$ and $f_0(s)$ is defined in Sect. 56.4.3.

For the scale parameter γ , let $\Sigma = n^{-1} \sum_i (\mathbf{u}_i - \bar{\mathbf{u}})(\mathbf{u}_i - \bar{\mathbf{u}})^T$. Then

$$\left\| \text{SIF}[\hat{\gamma}; (\mathbf{u}_i, \mathbf{v}_i)] \right\|^2 = \frac{k_I \psi(s_i)^2}{\text{Tr}(\Sigma)} [\mathbf{w}_i^T \mathbf{A}(\mathbf{u}_i - \bar{\mathbf{u}})]^2. \quad (56.58)$$

Here

$$\mathbf{w}_i = [\mathbf{v}_i - \gamma \mathbf{A}(\mathbf{u}_i - \bar{\mathbf{u}}) - \beta] / s_i.$$

Notice that $\mathbf{v}_i - \gamma \mathbf{A}(\mathbf{u}_i - \bar{\mathbf{u}}) - \beta$ is the residual of the i -th data point and s_i is its length. Thus, \mathbf{w}_i is a unit-length vector in the direction of the i -th data point residual. We conclude

- For a given length s_i of residual, a point $(\mathbf{u}_i, \mathbf{v}_i)$ will be influential for the estimate $\hat{\gamma}$ of the scale parameter if \mathbf{u}_i is far from the center $\bar{\mathbf{u}}$ of the data and if its residual is parallel to $\mathbf{A}(\mathbf{u}_i - \bar{\mathbf{u}})$.

For simplicity, we restrict the formulas of influence on the estimate of the orthogonal matrix \mathbf{A} to the cases $p = 2, 3$. For $p = 2$,

$$\left\| \text{SIF}[\hat{\mathbf{A}}; (\mathbf{u}_i, \mathbf{v}_i)] \right\|^2 = \frac{k_I \psi(s_i)^2}{\text{Tr}(\Sigma)} \|\mathbf{w}_i \times [\mathbf{A}(\mathbf{u}_i - \bar{\mathbf{u}})]\|^2 \quad (56.59)$$

The product on the right-hand side of (56.59) is the vector “cross” product. Therefore

- For $p = 2$, for a given length s_i of residual, a point $(\mathbf{u}_i, \mathbf{v}_i)$ will be influential for the estimate $\hat{\mathbf{A}}$ of the orthogonal matrix if \mathbf{u}_i is far from the center $\bar{\mathbf{u}}$ of the data and if its residual is perpendicular to $\mathbf{A}(\mathbf{u}_i - \bar{\mathbf{u}})$. Thus, points that are influential for $\hat{\mathbf{A}}$ will not be influential for $\hat{\gamma}$, and vice versa. Indeed

$$\begin{aligned} \left\| \text{SIF}[\hat{\gamma}; (\mathbf{u}_i, \mathbf{v}_i)] \right\|^2 + \left\| \text{SIF}[\hat{\mathbf{A}}; (\mathbf{u}_i, \mathbf{v}_i)] \right\|^2 \\ = \frac{k_I \psi(s_i)^2}{\text{Tr}(\Sigma)} \|\mathbf{u}_i - \bar{\mathbf{u}}\|^2. \end{aligned}$$

For $p = 3$, let $\lambda_1 \geq \lambda_2 \geq \lambda_3$ be the eigenvalues of Σ and let $\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3$ be the corresponding eigenvectors. Write

$$\mathbf{w}_i \times \left(\mathbf{A} \frac{\mathbf{u}_i - \bar{\mathbf{u}}}{\|\mathbf{u}_i - \bar{\mathbf{u}}\|} \right) = x_1 \mathbf{A} \mathbf{e}_1 + x_2 \mathbf{A} \mathbf{e}_2 + x_3 \mathbf{A} \mathbf{e}_3.$$

Then

$$\begin{aligned} \left\| \text{SIF}[\hat{\mathbf{A}}; (\mathbf{u}_i, \mathbf{v}_i)] \right\|^2 &= k_I \psi(s_i)^2 \|\mathbf{u}_i - \bar{\mathbf{u}}\|^2 \\ &\left(\frac{x_1^2}{\lambda_2 + \lambda_3} + \frac{x_2^2}{\lambda_3 + \lambda_1} + \frac{x_3^2}{\lambda_1 + \lambda_2} \right) \end{aligned} \quad (56.60)$$

It follows

- For $p = 3$, for a given length s_i of residual and distance $\|\mathbf{u}_i - \bar{\mathbf{u}}\|$ of \mathbf{u}_i from the center of the data, a point $(\mathbf{u}_i, \mathbf{v}_i)$ will be maximally influential for the estimate $\hat{\mathbf{A}}$ of the orthogonal matrix if both $\mathbf{u}_i - \bar{\mathbf{u}}$ is perpendicular to the dominant eigenvector \mathbf{e}_1 of Σ and the residual

$$\mathbf{w}_i = \pm \mathbf{A} \left(\frac{\mathbf{u}_i - \bar{\mathbf{u}}}{\|\mathbf{u}_i - \bar{\mathbf{u}}\|} \times \mathbf{e}_1 \right).$$

- The influence of $(\mathbf{u}_i, \mathbf{v}_i)$ on $\hat{\mathbf{A}}$ will be zero if

$$\mathbf{w}_i = \pm \hat{\mathbf{A}} \left(\frac{\mathbf{u}_i - \bar{\mathbf{u}}}{\|\mathbf{u}_i - \bar{\mathbf{u}}\|} \right).$$

- The maximum influence of the data on the estimate $\hat{\mathbf{A}}$ of the orthogonal matrix can be minimized for fixed $\text{Tr}(\Sigma)$ by making $\lambda_1 = \lambda_2 = \lambda_3$. Thus, the optimal choice of landmarks would make the landmarks spherically symmetric around the center point $\bar{\mathbf{u}}$.

56.5.3 Example: Influence for the Hands Data

For the Procrustes model (56.29) and the hands data, we compare here the influence statistics for the least squares estimates $(\hat{\mathbf{A}}_2, \hat{\gamma}_2, \hat{\beta}_2)$ [given in (56.20) and (56.33)] to those for the L_1 estimates $(\hat{\mathbf{A}}_1, \hat{\gamma}_1, \hat{\beta}_1)$ [in (56.34)]. These estimates correspond to $\psi_2(s) = s$ and $\psi_1(s) = 1$, respectively. In the right-hand sides of (56.57), (56.58), and (56.60), we substituted $\mathbf{v}_i - \hat{\gamma}_1 \hat{\mathbf{A}}_1 (\mathbf{u}_i - \bar{\mathbf{u}}) - \hat{\beta}_1$ to calculate the influence functions for both the L_1 and least squares estimates. Similarly the \mathbf{w}_i were calculated using the L_1 estimates. Furthermore, when (56.57), (56.58), and (56.60) were calculated for the i -th observation $(\mathbf{u}_i, \mathbf{v}_i)$, \mathbf{u}_i was not used to calculate Σ .

Using (56.57),

$$\begin{aligned} \left\| \text{SIF} \left[\hat{\beta}_2; (\mathbf{u}_i, \mathbf{v}_i) \right] \right\|^2 &\propto s_i^2, \\ \left\| \text{SIF} \left[\hat{\beta}_1; (\mathbf{u}_i, \mathbf{v}_i) \right] \right\|^2 &\propto 1, \end{aligned}$$

so that E (top of thumb), followed by H (base of palm), are the most influential for $\hat{\beta}_2$. All points are equally influential for $\hat{\beta}_1$.

In what follows we will be interested in determining which data points are most influential for which estimates. In other words, we will be interested in the relative values of $\|\text{SIF}\|^2$. Thus, for each estimator, we renormalized the values of $\|\text{SIF}\|^2$ so that their sum (over the 12 data points) equals 1. The results, together with the values of s_i , are shown in Fig. 56.3.

We have from (56.58) and (56.60)

$$\begin{aligned} \left\| \text{SIF} \left[\hat{\gamma}_2; (\mathbf{u}_i, \mathbf{v}_i) \right] \right\|^2 &\propto s_i^2 \left[\mathbf{w}_i^T \mathbf{A} (\mathbf{u}_i - \bar{\mathbf{u}}) \right]^2, \\ \left\| \text{SIF} \left[\hat{\gamma}_1; (\mathbf{u}_i, \mathbf{v}_i) \right] \right\|^2 &\propto \left[\mathbf{w}_i^T \mathbf{A} (\mathbf{u}_i - \bar{\mathbf{u}}) \right]^2, \\ \left\| \text{SIF} \left[\hat{\mathbf{A}}_2; (\mathbf{u}_i, \mathbf{v}_i) \right] \right\|^2 &\propto s_i^2 \|\mathbf{u}_i - \bar{\mathbf{u}}\|^2 \\ &\quad \left(\frac{x_1^2}{\lambda_2 + \lambda_3} + \frac{x_2^2}{\lambda_3 + \lambda_1} + \frac{x_3^2}{\lambda_1 + \lambda_2} \right), \\ \left\| \text{SIF} \left[\hat{\mathbf{A}}_1; (\mathbf{u}_i, \mathbf{v}_i) \right] \right\|^2 &\propto \|\mathbf{u}_i - \bar{\mathbf{u}}\|^2 \\ &\quad \left(\frac{x_1^2}{\lambda_2 + \lambda_3} + \frac{x_2^2}{\lambda_3 + \lambda_1} + \frac{x_3^2}{\lambda_1 + \lambda_2} \right), \\ \mathbf{w}_i \times \left[\hat{\mathbf{A}}_1 \frac{\mathbf{u}_i - \bar{\mathbf{u}}}{\|\mathbf{u}_i - \bar{\mathbf{u}}\|} \right] &= x_1 \hat{\mathbf{A}}_1 \mathbf{e}_1 + x_2 \hat{\mathbf{A}}_1 \mathbf{e}_2 + x_3 \hat{\mathbf{A}}_1 \mathbf{e}_3. \end{aligned}$$

Examining Fig. 56.3, we see that point E is by far the most influential point for $\hat{\mathbf{A}}$. Its relative influence however can be somewhat diminished by using L_1 estimates. The value of $\|\mathbf{u}_E - \bar{\mathbf{u}}\|$ is also the largest of the $\|\mathbf{u}_i - \bar{\mathbf{u}}\|$. It turns out that $\mathbf{u}_E - \bar{\mathbf{u}}$ makes an angle of 13° with \mathbf{e}_2 and that the unit length \mathbf{w}_E makes an angle of 12° with $\hat{\mathbf{A}}_1 \mathbf{e}_3$. Thus, x_1 will be relatively big and x_2, x_3 relatively small. This accounts for the strong influence of point E on both estimates of \mathbf{A} . Notice that s_E and $\|\mathbf{u}_E - \bar{\mathbf{u}}\|$ are sufficiently big that, despite the directions of \mathbf{w}_E and $\hat{\mathbf{A}}_1 (\mathbf{u}_E - \bar{\mathbf{u}})$, E is still fairly influential for $\hat{\gamma}_2$. However, its influence on $\hat{\gamma}_1$, which does not depend upon s_E , is quite small.

The point H (base of the palm) is the most influential point for $\hat{\gamma}$. H is perhaps the least well-defined point so that it is

Fig. 56.3 Relative influence of hands data points on least squares (upper case) and L_1 estimates (lower case) of γ and \mathbf{A}

not surprising that its residual length s_H is relatively big. It also defines the length of the hand, so that its influence on $\hat{\gamma}$ is not surprising. Indeed if H were completely deleted, $\hat{\gamma}_2$ would change from 0.9925 to 1.0110 and $\hat{\gamma}_1$ changes from 1.0086 to 1.0262.

One might think that C (top of the middle finger) would also be influential for $\hat{\gamma}$. In a coordinate system of the eigenvectors of Σ ,

$$\mathbf{u}_H - \bar{\mathbf{u}} = [-3.98 \ 1.15 \ 0.33]^T$$

$$\mathbf{u}_C - \bar{\mathbf{u}} = [3.55 \ -0.77 \ -0.03]^T$$

so that $\mathbf{u}_H - \bar{\mathbf{u}} \approx -(\mathbf{u}_C - \bar{\mathbf{u}})$. It is useful here to remember that \mathbf{e}_1 is approximately in the direction of the length of the left hand. Furthermore, s_C and s_H are reasonably close.

However, Fig. 56.3 indicates that C has negligible influence on both estimates of γ . Indeed if C were completely deleted, $\hat{\gamma}_2$ would only change from 0.9925 to 0.9895 and $\hat{\gamma}_1$ change from 1.0086 to 1.0047. These changes are much smaller than those caused by the deletion of H.

The difference is that $\hat{\mathbf{A}}_1(\mathbf{u}_C - \bar{\mathbf{u}})$ makes an angle of 88° with \mathbf{w}_C . In other words, $\hat{\mathbf{A}}_1(\mathbf{u}_C - \bar{\mathbf{u}})$ and \mathbf{w}_C are very close to perpendicular. (Perhaps the close to perpendicularity of the residual at C to $\hat{\mathbf{A}}_1(\mathbf{u}_C - \bar{\mathbf{u}})$ is to be expected. The uncertainty in locating C is roughly tangential to the middle finger tip.) Hence, the influence of C on $\hat{\gamma}$ is negligible.

On the other hand, $\hat{\mathbf{A}}_1(\mathbf{u}_H - \bar{\mathbf{u}})$ makes an angle of 124° with \mathbf{w}_H . This accounts for the greater influence of H.

Thus, if the registration between the two hands is unsatisfactory in either the translation or rotation parameters, point E should be inspected. If it is unsatisfactory in the scale change, point H should be checked.

56.6 Location Problems and the Relationship to Regression Problems

Chang and Rivest [1] discuss the relationship between location and regression problems in a more general context. Their paper explains certain phenomenon that arises in the regression type problems explored in this chapter.

56.6.1 Location Problems Associated with Spherical and Procrustes Regressions

Ko and Chang [14] derive the large sample distribution of M -estimates for location problems on the sphere Ω_p . They assume

- $\mathbf{v}_1, \dots, \mathbf{v}_n \in \Omega_p$ are independent random vectors.
- The distribution of \mathbf{v}_i is of the form $f_0(t_i)$ where $t_i = \mathbf{v}_i^T \boldsymbol{\theta}$ for some (unknown) $\boldsymbol{\theta} \in \Omega_p$.

The relationship of these assumptions to those of the spherical regression model given in Sect. 56.4.9 is clear.

A M -estimate $\hat{\boldsymbol{\theta}}$ for $\boldsymbol{\theta}$ minimizes an objection function of the form $\rho(\boldsymbol{\theta}) = \sum_i \rho_0(t_i)$. Write $\hat{\boldsymbol{\theta}}$ in the form

$$\hat{\boldsymbol{\theta}} = \cos(\|\mathbf{h}\|) \boldsymbol{\theta} + \sin(\|\mathbf{h}\|) \|\mathbf{h}\|^{-1} \mathbf{h} \quad (56.61)$$

where $\mathbf{h} \in \boldsymbol{\theta}^\perp$, the vectors in R^p orthogonal to $\boldsymbol{\theta}$. We note that $\boldsymbol{\theta}^\perp$ consists of the vectors tangent to Ω_p at $\boldsymbol{\theta}$ and that the accompanying chapter [8] develops more completely the use of tangent space approximations in geometric statistics. It is also explained there that (56.61) is the spherical analog to the use of Φ_2, Φ_3 and the exponential map in $\text{SO}(p)$.

[14] establishes that the large sample distribution of \mathbf{h} is multivariate normal with mean $\mathbf{0}$ and covariance matrix $\frac{k}{n}(\mathbf{I}_p - \boldsymbol{\theta}\boldsymbol{\theta}^T)$ where k and its estimate \hat{k} are given in (56.48). Thus, all the previous comments about asymptotic relative efficiencies in the spherical regression model also hold for spherical location models. We note that, unlike the standard linear model, the spherical location model is not a special case of the spherical regression model.

The analogous location problem for Procrustes regression is

- $\mathbf{v}_1, \dots, \mathbf{v}_n \in R^p$ are independent random vectors.
- The distribution of \mathbf{v}_i is of the form $f_0(s_i)$, where $s_i = \|\mathbf{v}_i - \mathbf{b}\|$. Here $\mathbf{b} \in R^p$ is unknown.

The estimate $\hat{\mathbf{b}}$ minimizes the objective function $\rho(\mathbf{b}) = \sum_i \rho_0(s_i)$. Standard M -estimation theory (see for example Huber [7]) establishes that the asymptotic distribution of $\hat{\mathbf{b}} - \mathbf{b}$ is multivariate normal with mean $\mathbf{0}$ and covariance matrix $\frac{k}{n}\mathbf{I}_p$. Here k and its estimate are given by equations (56.36) and (56.37). Hence, the previous comments about relative efficiency in the Procrustes regression model also hold for these location models.

56.6.2 Location and Regression Problems in Statistical Group Models

As discussed in Sect. 56.2.1 $G = \text{SO}(p)$ is a group in the mathematical sense. (For the sake of simplicity, we will not discuss $\text{O}(p)$.) The sphere $X = \Omega_p$ is a G -space. That is, there is a map $G \times X \rightarrow X$ and one usually denotes by $g \cdot x$ the image of $(g, x) \in G \times X$ under this map. In the case of $\text{SO}(p)$ and Ω_p , this map is

$$\mathbf{A} \cdot \mathbf{x} = \mathbf{A}\mathbf{x}. \quad (56.62)$$

Here the left hand side of (56.62) is to be interpreted, analogously to $g \cdot x$, using standard G -space notation and the right hand side of (56.62) is interpreted as matrix multiplication.

G -spaces require compatibility with the group operations

$$(g_1 * g_2) \cdot x = g_1 \cdot (g_2 \cdot x)$$

$$1 \cdot x = x.$$

Here “ $*$ ” is the group multiplication and “1” is its identity element.

Ω_p has a G -invariant inner product $\langle x, y \rangle = \langle g \cdot x, g \cdot y \rangle$. In particular

$$\langle \mathbf{x}, \mathbf{y} \rangle = \mathbf{x}^T \mathbf{y} = (\mathbf{A}\mathbf{x})^T (\mathbf{A}\mathbf{y}) = \langle \mathbf{A} \cdot \mathbf{x}, \mathbf{A} \cdot \mathbf{y} \rangle.$$

Notice also that under the location model in Sect. 56.6.1, the distribution of \mathbf{v}_i depends only upon $\langle \mathbf{v}_i, \theta \rangle = \mathbf{v}_i^T \theta$.

$G = \{(\mathbf{A}, \gamma, \mathbf{b})\}$ is also a group and $X = \mathbb{R}^p$ a G -space. However, Euclidean dot product is not G -invariant and, for this reason, we will use $G = \{(\mathbf{A}, \mathbf{b})\}$. This group is called the *special Euclidean* motions and denoted by $SE(p)$. Now Euclidean dot product is G -invariant; the location model in Section 56.6.1 depends only upon this inner product.

Given a G -space X and a G -invariant inner product $\langle x, y \rangle$, suppose

- $y_1, \dots, y_n \in X$ are independent random vectors.
- The distribution of \mathbf{y}_i is of the form $f_0(t_i)$, where $t_i = \langle \mathbf{y}_i, \theta \rangle$ for some unknown $\theta \in X$.

This is a location problem.

The associated regression model assumes

- $x_1, \dots, x_n \in X$ are fixed (nonrandom) vectors.
- $y_1, \dots, y_n \in X$ are independent random vectors.
- The distribution of \mathbf{y}_i is of the form $f_0(t_i)$, where $t_i = \langle \mathbf{y}_i, g \cdot x_i \rangle$ for some unknown $g \in G$.

Consider M -estimates $\hat{\theta}$ in the location problem and \hat{g} in the regression problem that minimize an objective function of the form $\sum_i \rho_0(t_i)$. *Chang and Rivest [1]* show how the large sample distribution of \hat{g} in the regression problem can be calculated from the distribution of its sibling $\hat{\theta}$ in the location problem. These results depend heavily on the tangent space approximations discussed in the accompanying chapter [8]. In particular, if a certain tangent space representation is irreducible (in the mathematical group representation sense), and appropriate Euclidean parameterizations of G and X are used

- The asymptotic covariance of \hat{g} breaks up as a product of a constant that depends only upon ρ_0 and f_0 and a matrix that depends only upon x_1, \dots, x_n .

- The asymptotic relative efficiencies between the location and regression models will be equal.

Thus, *Chang and Rivest [1]* explain some of the relationships between the Procrustes and spherical regression models and the corresponding location problems discussed in Section 56.6.1.

- Weight mapping crossover (WMX), 650, 651
- Weighted batch mean (WBM) method, 203
- Weighted Marshall-Olkin bivariate exponential distribution, 742
- Weighted threshold indecisive voting system
 - indecisive decision rule, 1099
 - indecisive model formulation, 1099
 - model assumptions, 1099
 - numerical example, 1100–1102
 - sensitivity analysis, 1102–1104
- Weighted threshold voting system
 - decision rule, 1091
 - in detection, communication and recognition, 1106
 - examples of system reliability, 1092–1093
 - future research, 1107
 - model assumptions, 1091
 - model formulation, 1091–1092
 - reliability analysis, 1093
- White-box testing, 437
- White type statistic, 1048
- Whöler curve, 56
- Widely applicable information criterion (WAIC), 782
- Wiener process, 524
- Wilcoxon rank sum test, 622
- Wilcoxon rank test, 577
- Wireless sensor network, 1107
- Working memory, 993

- X**
- XGBoost, 873
- XLMiner, 809

- Y**
- Yield modeling, 812
- Young inequality, 692
- Yule-Walker formula, 861

- Z**
- Zellner's *g*-prior, 925
- Zero-defect process, 262, 266, 271
- Zero-inflated models, 269
- Zero-inflated Poisson (ZIP) distribution, 266
 - CUSUM chart for, 267
 - EWMA chart for, 267–268
 - Shewhart chart for, 266–267
- Zero-inflation Poisson model, 266
- Zero-truncated Poisson distribution, 267
