A well-known issue of Educational Technology Research & Development in 1994 addressed the question of whether and to what extent media influence learning. Two opposing perspectives were presented in that issue by Richard Clark and Robert Kozma, both of whom have also contributed to this Handbook. One way to think about this Handbook, along with the three previous editions, is to recall that media debate and think about how research and practice have since evolved. We dedicate this Handbook to all the scholars who have contributed so much to explorations and investigations of how technology has and continues to influence the practice of learning and instruction. Many of those who have contributed so much to our understanding of educational technology have since passed away, including such luminaries as Robert Gagné, Robert Glaser, and William Winn among a list much too long to include here. We are deeply indebted to the contributions that so many have made to what we know and have yet to learn about how best to support and facilitate learning.

Foreword

Information and Communication Technologies in Education

In *Learning with Personal Computers* Alfred Bork (1987) promised a revolution in schooling due to the increasing availability of microcomputers. Twenty-five years later, on average, almost every person in economically developed countries is now blessed with one or more computers. However, the revolution that Bork imagined does not yet show definite signs of materializing soon. Upon reflection, we can say that most of us were, in the 1980s, perhaps a bit too optimistic about what information and communications technologies (ICT) could do to promote and improve education. Many are now trying to discern what added value ICT can contribute to the education enterprise, in addition to increasing the convenience of instruction and to motivating students to engage with activities that all too often are trivial. Skeptics have expressed doubts about the utility of technology in the classroom; some argue in favor of maintaining the traditional model of instruction that is exclusively reliant on teachers, print-based textbooks, and blackboards (perhaps a dry-erase whiteboard for the more progressive Luddites).

Increasing numbers of educators and scholars recognize that no technology can automatically benefit education in any significant way. Many realize that it is not about the technology after all—it is about what is done with technology to promote students' learning. When a new technology emerges, what really counts is the educational potential or learning opportunities provided to students, which are often obscured by the novelty of an innovative device. Scholars and teachers have the responsibility to discover and then to reveal those learning opportunities along with the associated potential to transform educational practice.

There is a growing and significant body of research that explores in detail and in depth the impact of new technologies on students' learning. Much of this new research is covered in this *Handbook*, which reviews research about the ways in which technology can significantly impact learning and create profound interactions between and among learners, teachers, and resources. This work is only a small part of a larger picture of ICT in the twenty-first century. The work reviewed in this *Handbook* provides one small glimpse of the revolution that is unfolding (albeit much later than Bork imagined).

There are many kinds of technologies used in present-day schools, some of which were developed specifically for the school context. Examples of commonly used educational technologies include classroom response systems, search engines, word processors, projectors, and interactive whiteboards. All of these and other technologies serve a wide variety of other non-school-based purposes. Most of these technologies were not invented for learning or teaching; however, their application to non-school settings, for which many of them were developed, is different from their use in school settings. For example, consider the word processor. Word processing facilitates the productive work of business by creating the correspondence necessary to conduct affairs. Specific features of the word processor were designed to make such business use both easy and effective. However, when one places a word processor in a classroom context, the use and purpose are not the same at all. Preparing teachers to help primary and secondary school students to make effective use of a word processor is quite different from training an administrator to help clerks and office assistants make effective use of the word processor in a particular office setting.

How shall we treat different uses of the same technology? How can we realize the educational potential of technologies taken for granted in the workplace? A definition of educational technology might emphasize the significant pedagogical or learning uses that technology serves; such a definition acknowledges the principle that uses and training for use should fit the specific purpose. This *Handbook* focuses on these educational uses and purposes.

Of the millions of teachers, educators, and scholars around the world, only a small number are engaged in research concerning the use of ICT in education. One result of this trend is a contrast between developers and educators who may ultimately use the new technologies. Developers create and laud the features of emerging devices and innovative technologies, while educators who want to teach with those technologies may become confused and frustrated with new technologies. It is rare that the two groups exchange views and experiences, and learn from each other. For many teachers, new educational technologies and facilities can cause some discomfort or even feel threatening due to their lack of adequate preparation in effective pedagogical use and integration into teaching and learning. There has been much research on the application of technology in education, as is evident in this *Handbook*. The chapter on TPACK (technological pedagogical and content knowledge) is a case in point. There is almost always initial resistance to a new technology, and the cost effectiveness of new technologies remains controversial (see Chapter 9 in this *Handbook*). Suggestions by technologists for educational application can be general and too distant from actual classroom use; thus these recommendations all too often fall short of the actual needs of teachers. As a result, too many teachers fail to embrace and use the new technologies in constructive ways with their own students.

An encouraging indication of change is this fourth edition of the *Handbook*, which includes a new section that is subject-specific and explores technologies in different disciplines. The first and last sections of the *Handbook* also offer a range of perspectives on technology integration that are aimed at practical use and widespread application.

Educational Communication Technology (ICT for Education)

Educational communication technology is a very dynamic area of research and application; new products can become out of date within a matter of months. The popular press often disseminates stories that dwell on the novelty rather than on the practicality of a new technology. Decision makers and those responsible for procurement are presented with a dilemma regarding acquisition of newer, forward-looking but riskier technologies as opposed to the reliable, older but more mature technologies. As is shown by the many chapters pertaining to emerging technologies, innovations ranging from cloud-based technologies to tablet applications are undoubtedly worthy of our attention due to their educational potential. However, the maturity of a technology and its connection and compatibility with existing technologies and expertise present significant challenges. When venturing to deploy a new technology, there are usually many unknown factors and some risk (Spector, 2012). When a new technology is profoundly different from previous technologies, or when the application of the technology dramatically changes practices, there are bound to be a multitude of unexpected problems.

In addition to the constant change of educational technologies, there is another challenge—namely differences between theory and practice, along with differences between the natural sciences and the humanities. A new educational technology that works well in support of learning physics may not work as well in support of learning philosophy, and vice versa. Moreover, the relevant learning theories and paradigms might be quite different in different areas of application. Effective technology integration requires sensitivity to the potential of various technologies as well as a profound understanding of specific disciplines and associated pedagogical practices. In too many cases, educators adopt without hesitation a new technology only to see it fail in practical use. As a community of professional practitioners, we are slowly coming to the realization that new tools need to be tested in the real and somewhat uncontrolled and chaotic circumstances in which everyday learning and instruction occur. Educational technology researchers and developers should carefully observe, assess, and identify the adaptability and success of the new technologies in light of actual teaching and learning; furthermore, all must keep in mind the opportunities, the benefits, the constraints, and the risks. Compulsive and hasty adoption of a new technology will very likely result in another cycle of sweet expectation followed by bitter disappointment.

Another important issue is the boundary between the two academic disciplines of educational technology and computer science. They are distinct from each other; however, a typical program of educational technology often offers many courses that are also found in a computer science curriculum. A closer scrutiny, however, reveals that educational technology courses are quite different from apparently similar courses in a computer science department. A recent IEEE-sponsored report recommends a very specific, cross-disciplinary curriculum for advanced learning technologists that could, if adopted, reduce the tensions between computer science and educational technology as separate and competing disciplines (Hartley, Kinshuk, Koper, Okamoto, & Spector, 2010). As things now stand, educational technology graduates find themselves at a disadvantage in the job market in comparison with a computer science graduate who appears equally well qualified. This state of affairs affects the growth of the discipline adversely. To avoid this waste of resources and dashed expectations, the discipline of educational technology needs to enhance its own reputation as a separate and credible area of expertise, which is what Hartley and colleagues (2010) encourage. That is to say, advanced learning technology graduates need to command abilities and skills that neither computer scientists nor education degree holders possess. However, they should be able to communicate and collaborate with both computer scientists and professional educators. In short, there is a need for a careful scrutiny of the field and a re-delineation of its academic scope and theoretical systems, along the lines of the Hartley et al. (2010) report, which identified the following domains of competence for educational technologists:

1. Knowledge competence—includes those competences concerned with demonstrating knowledge and understanding of learning theories, of different types of advanced learning technologies, technology-based pedagogies, and associated research and development.
2. Process competence—focuses on skills in making effective use of tools and technologies to promote learning in the twenty-first century; a variety of tools ranging from those which support virtual learning environments to those which pertain to simulation and gaming are mentioned.
3. Application process—concerns the application of advanced learning technologies in practice and actual educational settings, including the full range of life-cycle issues from analysis and planning to implementation and evaluation.
4. Personal and social competence—emphasizes the need to support and develop social and collaboration skills while developing autonomous and independent learning skills vital to lifelong learning in the information age.
5. Innovative and creative competence—recognizes that technologies will continue to change and that there is a need to be flexible and creative in making effective use of new technologies; becoming effective change agents within the education system is an important competence domain for instructional technologists and information scientists.

Growth of the Discipline

Since its establishment, the discipline of educational technology has been through several paradigm shifts and grown remarkably. Informed by theories and concepts from many other disciplines, including education, computer science, psychology, cognitive science, and communications, educational technology has acquired academic respectability. However, some have expressed doubts about the field, raising the issue of educational technology borrowing from other disciplines without creating a coherent and unique discipline of its own. In rebuttal, educational technologists argue that adoption and integration are not merely effortless borrowing tasks; rather, technology integration is a dynamic, innovative, and productive process—a *transdisciplinary* process, as Hideaki Koizumi (2004) put it. According to that Japanese scholar, educational neuroscience is a product of such a transdisciplinary process. The growth of the discipline of educational technology has been a product of a similar transdisciplinary process (see Richey, Klein, & Tracey, 2010). It is through this transdisciplinary process that the discipline of educational technology has made many unique contributions to both theory and practice. The work on cognitive load theory is a recent example of the transdisciplinary nature of educational technology (see, for example, van Merriënboer & Ayres, 2005).

There is a need to reconstruct the theoretical framework for educational technology, and there is an associated need to reconceptualize its academic scope and purpose. Supporting learners and the learning process with appropriate technologies is the fundamental belief of educational technology. Therefore, the design, development and application of technologies capable of such a role should be within the sphere of this discipline, where learning and technology intersect, and numerous other disciplines mingle in creative ways. In this theater of interaction and hybridization, there is both chemistry and synergy, and participants from diverse academic backgrounds and researchers of various segments of educational technology cooperate productively. However, due to their differences in training, skills, and values, these experts view technologies with different lens and may study problems from different perspectives and interest themselves in different dimensions of the same problem. How can they work together optimally?

No doubt, their cooperation needs to be based on the common ground designated by the shared ultimate goal of assisting learning. More is needed; however, mechanisms should be created and deployed to merge horizons and promote synergy among experts from different disciplines, thus removing academic biases, increasing their appreciation of each other's paradigms and interests, and locating the possible points for connection and cooperation. The fourth edition of this AECT (Association for Educational Communications and Technology) *Handbook* represents a creative realization of such an effort.

Global Differences

In addition to overcoming the aforementioned problems, we, as professional practitioners, need to do more if we want the desired educational technology revolution to unfold on a large, global scale. We have yet to scale the formidable barriers created by global differences, which are seen in both economic development as well as in social-cultural interests and habits.

First, economic inequalities have caused disparities in educational investment between countries and regions. Even within one country, especially some large and diverse ones, there can also be seen the full spectrum of differences in educational investment and accrued educational benefits. Underdeveloped countries and regions may acquire educational equipment and facilities by virtue of inter-governmental assistance, NGO (non-governmental organizations) donations and aid, and so on, addressing part of the significant physical digital divide. Nevertheless, these facilities are not usually updated and upgraded in a regular and timely manner as they would be in developed economies. More disconcerting is the gap in human resources and expertise—the non-physical digital divide. Technical expertise that is pedagogically informed is in short supply, making the Hartley et al. (2010) report even more pertinent.

Second, schools and their administration are often constrained as much as enabled by their particular social and cultural settings, which can differ radically because of racial, ethnic, or religious distinctions. Differences in local traditions, community characteristics, and special academic/educational interest can also be determining factors in enabling or inhibiting effective use of educational technology. Consequently there exists a wide range of teaching beliefs;

major disagreements about pedagogy and educational technology may even be found among teachers employed by the same school. Such discrepancies in culture and values can result in conflicting attitudes towards technology. In extreme cases, an educational technology may become an object of distrust or even ridicule. Compared with the hardware gap and infrastructure challenges, social and cultural inequalities are more subtle and difficult to manage.

In spite of those global differences, multinational organizations, especially network technology businesses and other information technology leaders are promoting their new educational technologies and relevant products. One result of this trend is that new technologies are confronted with a huge array of economic, social, cultural, and educational settings. As a result, the performance of the same educational technology can vary from one context to another; we have such failures to replicate findings in the research literature. This phenomenon is not unlike the legendary orange in an old Chinese saying: Grown south of the Huai River, it is sweet; grown north of the river, it tastes bitter and sour. If educational technology researchers and practitioners do not take into account local situations and customize technologies and educational practices accordingly, the promised revolution in schooling due to emerging educational technologies will never take place.

To sum up, there are significant challenges to the effective pedagogical use of technologies and development of new educational technologies based on the following four conclusions:

1. Technological advancement is an endless enterprise, but technological improvement does not necessarily translate into proportionate improvements in educational effect and impact on students' learning.
2. In different economic, social, and cultural environments, the same technology may perform differently.
3. The accelerated development in technology makes more acute the shortage of instructor knowledge about the effective use of technologies; good teachers who are well prepared are always in short supply.
4. Extensive and intensive involvement of teachers and pedagogically knowledgeable instructional designers is essential for progress in educational technology. There is little that educational technology can contribute to improve formal or informal student learning without this critical involvement.

We look forward to the day when a large number of elementary and secondary school teachers become readers and/or authors of the future editions of this *Handbook*; that will be a positive sign that educational technology is penetrating deep into classrooms and adding the synergy to launch the long-awaited revolution. Therefore, let us focus our efforts and work collaboratively across multiple disciplines so that this day may come sooner rather than later. Together we can make a difference.

Shanghai, China Youqun Ren

Preface

As has been the case with the three previous editions of the *Handbook of Research on Educational Communications and Technology*, this volume has taken about 3 years to develop. The content is new and does not duplicate anything in the previous editions of the Handbook, all of which is available online at no cost to members of the Association for Educational Communications and Technology (AECT; see http://www.aect.org). We have a new publisher, Springer, who has agreed to do the same for this fourth edition. Springer has been most helpful in the development of this volume by making a customized version of Editorial Manager available to support submissions, reviews, and editing.

As we did with the third edition, we asked for guidance from AECT members and other professionals with regard to how best to develop the content and structure of the *Handbook*. We learned that *Handbook* users are typically doctoral students and other researchers new to a particular topic or area of research. They value a short and cogent summary of research in a focused area and especially appreciate the extensive reference sections and the indication of core references (marked with a preceding asterisk and located at the end of each chapter). Those whom we contacted in the first year of this effort also indicated a desire to see more research emphasized in additional areas. In general, there was a desire for short, focused research reviews, long and extensive references, and a discussion about research that could or should be conducted in the future. We provided all of our authors with this guidance, and we believe that they have done an excellent job in providing *Handbook* users with what they want.

Together with a large number of respondents to queries about the Handbook, including one specifically targeting AECT members, we initially developed more than 120 potential chapters. We asked the professional and academic communities to provide an extended abstract and core references for chapters that they would agree to author. The coeditors then examined the various proposals and settled on just over a 100 potential chapters. As the process evolved and potential authors were asked to deliver draft chapters, the list was narrowed to about 87. For a variety of reasons, several authors withdrew or were dropped and we ended up with 75 chapters, divided into nine sections, compared with 56 chapters in six sections in the third edition.

We retained the Foundations section but of course included completely new content with more emphasis on research as had been requested by those we asked for input. In addition to two new chapters on research, there are chapters on neuroimaging and motivation as these are both regarded as foundation areas that can and should inform instructional design and educational technology research. Ethics, human performance technology, and TPACK (technological, pedagogical, and content knowledge) are also treated in the Foundations section.

Section 2 treats qualitative and quantitative tools and methods separately and includes chapters on design-based research, action research, and program evaluation not previously addressed in the Handbook. There is an extensive section on assessment and evaluation with many new topics addressed, including stealth assessment, cost-benefit analysis, and model-based assessments.

Section 4 includes a chapter specifically addressing cultural issues per the advice we received in the initial response to our queries of what to include. Many of the same emerging trends one finds in the New Media Consortium's *Horizon Report* (http://www.nmc.org/publications) and *A Roadmap for Educational Technology* jointly published by the Computing Research Association and the Computing Community Consortium, and the National Science Foundation (available online at http://www.cra.org/ccc/docs/groe/GROE%20Roadmap%20for%20Education%20Technology%20Final%20Report.pdf) are evident in this section—see, for example, Chaps. 35, 36, and 38.

Section 5 represents an entirely new section developed in response to the feedback we received about previous Handbooks. While we were not successful in recruiting as many chapters in this section as we had planned, readers will find very informative chapters on technology in science education, medical training, mathematics, engineering, visual arts, social studies and visual arts.

While Section 7 has been included in previous editions, all the chapters in this section are new for this edition. In addition to new treatments of instructional design models and technology-based instruction, there are topics not previously addressed such as change agency, governmental policies, and curricula for training instructional designers.

The second part of the *Handbook* contains three sections that address respectively emerging technologies, technology integration, and the future of educational technology research. Section 7 is the most extensive section of the *Handbook*, and was designed specifically in response to the feedback we received early in the process. Again we used technologies cited in the NMC *Horizon Report* and in *A Roadmap for Educational Technology* to guide input for this section. Readers will find e-books, pedagogical agents, adaptive technologies, augmented realities, and research on many other new and emerging technologies treated in this section.

Because so many scholars have commented on the ability to make effective use of new and emerging technologies, we decided to specifically address the issue of Technology Integration in a separate section in this edition of the *Handbook*. We included chapters on measuring technology readiness skills and generational differences as well as issues specific to different contexts (formal learning in schools, medical education, multicultural settings, etc.).

The final section of the *Handbook* is entitled A Look Forward and is intended as a precursor for further research. This is another new section of the *Handbook* and is meant as a kind of book-end section to go with the Foundations section. Issues involving the philosophy of science, teacher education, and prospects in developing countries are addressed, among others.

As with the third edition, we made every effort to include research from around the world as this *Handbook* has become an internationally acclaimed standard in the field of educational technology research. The third edition has now been translated into Chinese by a team of university scholars in China led by Ren Youqun. Since he is one of a very few individuals who have read every chapter in the previous edition of the *Handbook*, and because he leads an impressive group of researchers at East China Normal University, we invited him to contribute the Foreword to the fourth edition. We then invited Joost Lowyck who wrote the Foreword to the third edition and who was also familiar with all of that content to write the first chapter in this edition. His chapter provides an historical overview of educational technology aimed at bridging educational theory and practice. Lowyck provides five principles relevant to that enterprise: (1) evolutions in society and education have influenced the selection and use of learning theories and technologies; (2) learning theories and technologies are situated in a somewhat vague conceptual field; (3) learning theories and technologies are connected and intertwined with information processing and knowledge acquisition; (4) educational technologies have shifted learner support from program or instructor control toward more shared and learner control, and (5) learning theories and findings represent a fuzzy mixture of principles and applications. The reader will find an insightful discussion to accompany these five principles. In addition, the editors have taken up these principles in the epilogue and concluding chapter of the Handbook.

We hope that the efforts of the authors, reviewers, editors, and so many others in bringing this Handbook to the educational technology research community will prove useful and result in ongoing productive research. Our final word—enjoy.

Acknowledgements

This fourth edition of the *Handbook of Research on Educational Communications and Technology* would not have been possible without the (a) contributions of the distinguished authors who willingly and patiently contributed their knowledge and expertise in providing the content, (b) the dedication and diligence of the qualified reviewers who provided valuable and insightful feedback to the authors, (c) the strong and continuing sponsorship of the Association for Educational Communications and Technology (AECT), and (d) the responsive and engaged support of Springer's senior editor, Melissa James, and her publishing staff, especially Radhika Srinivas. Gloria Natividad at UNT assisted with the glossary and other aspects of manuscript preparation. Springer made it possible to use the online Editorial Manager (EM) system for the submissions, reviews and editing. Springer created a custom tailored EM site to support the *Handbook*. Many authors and reviewers were familiar with EM through experiences with *Educational Technology Research and Development* or *Instructional Science*; this proved to be a welcome improvement in managing *Handbook* development.

Many others have contributed to this edition of the *Handbook*, including participants at AECT sessions and respondents to queries the editors presented at various venues in the last 3 years. As is the case with any major publication, it is impossible to cite all those who contributed along the way. The order of the editors does not reflect the quantity or quality of contribution; all editors shared equally in the development of the *Handbook*. We are most grateful for having had the opportunity to edit this fourth edition of the *Handbook* and appreciative of all those who helped make it possible.

Section I

Foundations

J. Michael Spector and M. David Merrill

This first section of the *Handbook* is focused on the foundations that inform educational technology research and development. The purpose of this section is to provide a research-based overview of the foundations of educational technology pertinent to the twenty-first century scholarship and practice. The intent is not to repeat anything explicitly covered in the three previous editions of the *Handbook* (Jonassen, 2004; Jonassen, Harris, & Driscoll, 2001; Spector, Merrill, van Merriënboer, & Driscoll, 2008), all of which are available online at no cost to members of the Association of Educational Communications and Technology (see http://www.aect.org) which sponsors the *Handbook*.

The emphasis in this section is on research linked to new and emerging educational technologies, including the relationships between theories, models, frameworks, perspectives, approaches, and principles. This section should provide those new to this area of research with a comprehensive understanding of the many different areas and perspectives that influence and inform research and scholarship in educational technology.

The section begins with Joost Lowyck's historical overview of educational technology and the interrelationships between theory, technology, research, and practice. The historical overview is followed by two chapters focused on research paradigms (van Merriënboer and de Bruin) and research perspectives (Morrison and Ross); taken together, these two chapters represent the complexity and diversity of views that inform educational technology research. The fourth chapter in this introductory section by Foshay, Villachica, and Stepich elaborates the relationships between human performance technology and instructional design.

J.M. Spector (✉)
University of North Texas, Denton, TX, USA
e-mail: mike.spector@unt.edu

M.D. Merrill
Utah State University, Logan, UT, USA

The first four chapters that provide readers with the breadth of views pertaining to educational technology research are followed by five chapters that explore specific foundation areas not addressed in previous editions of the *Handbook*. Chapter 5 by Antoneko, van Gog, and Paas is focused on the implications of neuroscience for educational research. Chapter 6 by Kim and Pekrun addresses research on emotions and motivation that are pertinent to learning, performance, and the design of instruction. Chapter 7 by Branch provides an overview of instructional design models that often are the point of departure for the design of research studies. Chapter 8 by Warren, Lee, and Najmi provides readers with an update of how recent technologies have influenced the design of instruction and educational technology research. Chapter 9 by Koehler, Mishra, Kereluik, Shin, and Graham reviews research in the recently defined area of technological, pedagogical, and content knowledge (TPACK).

These nine chapters represent the breadth and depth of the broad area of educational technology research. By no means do these few chapters exhaust the full breadth of this complex area. The chapters to follow in subsequent sections should make clear that these first few chapters only tap the depth of research in this area. The final section of the *Handbook* (the epilogue) represents the editors' attempt to suggest that this large *Handbook* only touches a few important research areas—there is much we have yet to understand and there are new and emerging technologies that will surely change what researchers and practitioners do.

While all of the chapters in this *Handbook* are new and do not appear in previous editions, several chapters have been added specifically at the request of *Handbook* users. The final chapter by Moore and Ellsworth in this introductory section is one of those—it addresses the important area of ethics and standards educational technology research and practice. A code to guide instructional practice can be found in Spector, Ohrazda, Van Schaack, and Wiley (2005), and AECT has an ethics code, so it is fitting and appropriate that this topic should be included in the Foundations section of the *Handbook*.

Bridging Learning Theories and Technology-Enhanced Environments: A Critical Appraisal of Its History

1

Joost Lowyck

Abstract

In education, retrospection is often used as a method for better understanding emerging trends as documented in many books and articles. In this chapter, the focus is not on a broad description of the history of educational technology but on the interplay between learning theories and technologies. However, neither learning theories nor tools are monolithic phenomena. They are composed of multiple attributes, and they refer to many aspects and facets which render the history of educational technology highly complex. Moreover, evolution in both theory and technology reflects no clear successive breaks or discrete developments—rather, waves of growth and accumulation. When looking closer at learning and technology, it becomes clear that many interactions occur. These interactions will be documented following continuous development after World War II. We do not follow a strict timeline but cluster the critical appraisal in the following observations: (1) evolutions in society and education have influenced the selection and use of learning theories and technologies; (2) learning theories and technologies are situated in a somewhat vague conceptual field; (3) learning theories and technologies are connected and intertwined by information processing and knowledge acquisition; (4) educational technologies shifted learner support from program or instructor control toward more shared and learner control; and (5) learning theories and findings represent a fuzzy mixture of principles and applications. The history reflects an evolution from individual toward community learning, from content-driven learning toward process-driven approaches, from isolated media toward integrated use, from presentation media toward interactive media, from learning settings dependent on place and time toward ubiquitous learning, and from fixed tools toward handheld devices. These developments increasingly confront learners with complexity and challenge their responsibility to become active participants in a learning society.

Keywords

Learning theories • Educational technology • Technology

Introduction

According to Gagné (1974) the main question of educational technology is: How can "things of learning" best be employed to promote learning? In most discussions of technology implementation, learning issues remain relatively tacit (Bransford, Brophy, & Williams, 2000). Searching the relationship between learning theories and technologies is at first

J. Lowyck (✉)
Centre for Instructional Psychology and Technology (CIP & T), The Education and Training Research Group, Leuven University, Dekenstraat 2, Box 3773, B-3000 Leuven, Belgium
e-mail: joost.lowyck@ppw.kuleuven.be

J.M. Spector et al. (eds.), *Handbook of Research on Educational Communications and Technology*,
DOI 10.1007/978-1-4614-3185-5_1, © Springer Science+Business Media New York 2014

glance an attractive endeavor given its possible relevance for both educational theory and practice. However, dealing with this issue is quite complex. Indeed, a number of questions arise about the relationship of learning theory and technology, sometimes called a marriage (Perkins, 1991; Salomon & Ben-Zvi, 2006). Do learning theories refer to hybrid constructs or are they rather eclectic containers of more modest models or even common sense practice? How should technology be conceptualized? If a link exists between learning and technology, what is the nature of the relationship? Can we best label developments in the knowledge-base of learning and technology as paradigm shifts (Koschmann, 1996), sequential events (Sloan, 1973), or waves (Toffler, 1980)?

In this chapter we will not reiterate broad accounts of evolutions in educational technology (see amongst others De Corte, Verschaffel, & Lowyck, 1996; Januszewski, 1996; Kozma, 1991; Mayer, 2010; Molenda, 2008; Reiser & Gagné, 1983; Saettler, 2004). We start the quest for linking learning theories and technologies at the moment explicit learning theory enters educational technology. The critical appraisal of the link between learning theories and technologies is structured around the following observations to reduce complexity and fuzziness in that interdisciplinary field: (1) evolutions in society and education have influenced the selection and use of learning theories and technologies; (2) learning theories and technologies are situated in a somewhat vague conceptual field; (3) learning theories and technologies are connected and intertwined by information processing and knowledge acquisition; (4) educational technologies shifted learner support from program or instructor control toward more shared and learner control; and (5) learning theories and findings represent a fuzzy mixture of principles and applications.

Observation 1: Evolutions in Society and Education Have Influenced the Selection and Use of Learning Theories and Technologies

Educational technology influenced in many and often centrifugal ways educational innovation as part of societal development. Successive behaviorist, cognitive, constructivist, and socio-constructivist approaches to learning and the concomitant use of technologies suggest a clear, straightforward contribution to education based on the internal dynamics of that field. However, one may wonder why in the 1960s and 1970s behavioral learning theory, but no others, was selected as the focus of educational technology. Examples of more cognitively oriented theories available at that time are the work of Bartlett (1958) on "Thinking, an experimental and social study," of Bruner (1961) on "The act of discovery," of de Groot (1965, originally published in 1946) on "Thought and choice in chess," of Dewey (1910) on "How to think," of Piaget (1952) on "The origins of intelligence in children," and of Vygotsky (1962, originally published in 1934) on "Thought and language." These theories inspired school curricula and teaching methods but not technology use. Even though Newell and Simon (1972) contend that the appearance of modern computers at the end of World War II gave researchers the courage to return to complex cognitive performances, there was no relationship between early cognitive research and technology for education.

It is clear that more than learning science controls the selection and use of peculiar learning theories and tools. This points to the impact of society on educational technologies in that learning theories are selected to support the technology implementation society drives us to employ (Boyd, 1988). Indeed, society holds strong expectations to solve learning problems with technology. Expectations function as macro-hypotheses that are progressively shaped and falsified during implementation, often resulting in more difficulties and less productivity than initially expected. One waits for the next, more powerful learning theory or tool (Lowyck, 2008).

The influence of the *Zeitgeist* can be illustrated with some examples. At first, audiovisual tools were expected to bring reality into the stuffy classroom and to bridge the gap between school and the world outside the classroom. Mass media (radio, film and television) were proclaimed to refresh education with real-world information presented just-in-time (Dale, 1953; Saettler, 2004). The audiovisual movement was grounded on communication theories that model the flow of interaction between sender and receiver, regulating the transport of information (Kozma, 1991; Levie & Dickie, 1973; Saettler, 2004; Tosti & Ball, 1969). While this movement nicely illustrates the impact of societal expectations on education, no explicit learning theory provided a foundation, so it is not part of our critical appraisal of linking learning theories and technology.

At the end of the 1950s in the aftermath of the Sputnik-shock, Western societies aimed at improving education quality especially in mathematics and science to compensate for the supposed failure of the progressive education movement and teachers' deficient classroom behaviors (Skinner, 1968). In line with the *back-to-basics* movement (Boyd, 1988), curricula were revised and proper, programmed design and delivery of subject-matter was expected to contribute to educational quality based on a genuine science of instruction (Glaser, 1965; Lockee, Larson, Burton, & Moore, 2008). In a similar vein, democratization of education was aimed at giving increased access to education responding to the post-war baby boom which led youngsters in a prosperous economic period to mass education. This, however, raised concerns about individual development though interpreted in multiple ways by Rousseau-inspired romantics to more mechanistically oriented empirical behaviorists (Grittner, 1975). Computer-assisted instruction (CAI) claimed to realize individualization which brought Suppes (1969) to expect that computers could offer individualized instruction, once possible for only a few members of the aristocracy, to all students at all levels of abilities. However, the limited capacity of computers and reductionist instructional design at that time hindered the full implementation of individualization.

In the late 1970s, increasing use of personal computers in professional settings responding to the challenges of an information society created a new argument for the integration of computers in education and emphasis on acquiring computer skills (Dillemans, Lowyck, Van der Perre, Claeys, & Elen, 1998; Mandinach, 2009). This is why policy-makers in most Western countries launched extensive national programs to introduce new technologies in schools (Kozma, 2003). Learning to program computers, for example, was seen as a main task for education in a growing technology-rich society. Teachers and other computer savvy practitioners built instructional materials based on common sense knowledge of classroom teaching and content delivery with simple question-answer-feedback loops, vaguely inspired by behavioral principles (Saettler, 2004). This led to a proliferation of small and isolated CAI-programs, mostly in algorithmic subject-matter domains with little theoretical underpinnings or fundamental goals to achieve (McDonald & Gibbons, 2009). The interplay between behaviorist learning theory and technology ultimately resulted in inflexible and didactic instruction (Shute & Psotka, 1996).

During the 1980s, a cognitive orientation in education was strongly supported by Western governments struggling with increasing worldwide competition in commerce, industry, science and technology. Enhancing learners' common understandings of complex issues, deep learning and complex skillfulness instead of mere subject-matter delivery was perceived as a strategic approach to societal survival (NCEE, 1983; Sawyer, 2006). This shift resulted in more complex forms of cognitive behavior embedded in school curricula, increasing interest in the role of knowledge in human behavior, and an interactionist view of learning and thinking (Resnick, 1981). The ambition to tune education by means of technology to complex changes in society gave birth to a new wave of investments in research and development not only in supplying funds and resources for equipment and network connectivity (Jones, 2003). Many computer microworlds, cognitive tools and instructional programs were produced at research centers, universities and enterprises (Duffy, Lowyck, & Jonassen, 1993). However, most of these computer-based educational systems were not widely adopted or embraced. This was due to both the *not-invented-here syndrome* and the increasing cost of commercial products (Boyd, 1988; Jonassen, 1992).

Intensive electronic networking, and social media reflect more recent changes in society that are expected to add value through a common purpose and deliberate collaborative action in a community of learners and practitioners (Center for Technology in Learning, SRI, 1994). Increasing miniaturization, integrated functionalities, and wireless use comprise a communication hyperspace in a global world that call for new ways of technology use in education. This is why socio-constructivist theories and technology-supported communities of learning and practice have become dominant, at least as a frame of reference within the community of educational technologists.

Summary

Evolutions of learning theories and technologies show internal and autonomous dynamics that lead toward mutual fertilization. Pressure in Western countries to survive in a scientifically and economically changing, competitive world activates governmental initiatives to support technology in schools through financial support and stimulation of research and development. However, policy makers often formulate unrealistic expectations due to lacking knowledge of the multidimensionality of technological solutions for education. Commercial organizations respond to societal demands with little concern about efficiency, effectiveness and relevance of educational products and processes, an observation that brings researchers to request grounded evaluation (Clark, 1983; Salomon, 2002). Schools and educational institutions are involved in lasting and difficult processes of innovation through technologies that impact all organization components (curricula, personnel, finances, infrastructure, etc.), while teachers and learners are challenged to cultivate new competencies, unlearn dysfunctional behaviors and conceptualizations, and build new perspectives on technologies for learning.

Observation 2: Learning Theories and Technologies Are Situated in a Somewhat Vague Conceptual Field

Exploring links between learning theories and technology is dependent on agreed upon conceptual frameworks and concepts within research traditions. Each field of study is filled with ill-defined concepts and terminology that is inconsistently used and leads toward different starting positions. A basic science of learning starts from the insight that little is known and that much has to be discovered, while applied science and technology focus on what is known and applicable in practice (Glaser, 1962). Despite continuous efforts to calibrate conceptual issues (Januszewski & Persichitte, 2008; Reiser & Ely, 1997), and unlike the natural sciences, concepts in the behavioral sciences are rarely standardized

(Halliday & Hasan, 1985). That concepts are used in various ways becomes especially problematic when central theoretical importance is involved (Prenzel & Mandl, 1993).

Learning Theories

Learning as a relatively permanent change in motor, cognitive and psychodynamic behavior that occurs as a direct result of experience is shared by all learning theories. Despite this largely accepted definition, "learning theory" remains a broad term with many perspectives "ranging from fundamental exploratory research, to applied research, to technological development, through the specification of work-a-day methods of practice" (Glaser, 1965, p. 1). Conceptual confusion originates partly from an over-generalization of successive ways of thought that are perceived as the way things are. Observable behavior, mind, information processing, sociocultural theories, genetics and brain research are changes that signal scientific progress but the tendency to over-generalize is often driven by other than scientific considerations (Bredo, 2006). Given the intrinsic limitations of educational research, no single theory encompasses all aspects of learning and learners (Gage, 1972). Consequently, various theories that emerged as researchers focused on different kinds of learning only represent a limited part of the knowledge-base of psychology as a discipline (Bransford et al., 2006). In addition, learning theories do not constitute a monolithic, coherent system but each school of thought represents a collection of distinct theories that are loosely connected (Burton, Moore, & Magliaro, 1996; Dede, 2008) a fact that led to the balkanization into smaller communities with different research traditions and largely incommensurable views of learning (Koschmann, 1996). While behavioral theory and early information processing theory use definitions that are instrumental to experimental research, socio-constructivist theory is complex, eclectic, and multifaceted (Lowyck & Elen, 1993). A possible solution is to take a pragmatic position defining learning theories as an interrelated set of facts, propositions, rules, and principles that has been shown to be reliable in many situations (Spector, 2008). Though this may be helpful to avoid conceptual fuzziness, it seems hard to define valid and precise criteria to differentiate between evidence-based and common sense knowledge in an educational context.

Technology

Educational technology holds a double meaning: (a) application of scientific know-how, and (b) tools or equipment (Glaser, 1965; Molenda, 2008; Reiser & Gagné, 1983). AECT (the Association for Educational Communications and Technology; http://www/aect.org) refers to the "disciplined application of scientific principles and theoretical knowledge to enhance human learning and performance" (Spector et al., 2008, p. 820), which is very close to instructional design as defined by Gagné (1974) as a "body of technical knowledge about the systematic design and conduct of education, based upon scientific research" (p. 3). Technology as the mere application of research findings was highlighted in the years of programmed instruction with procedures for behavioral modification to reach terminal behaviors (Glaser, 1965). Along with an increasing variety of learning theories, different genres of technology-based learning environments covered different functions of educational technology, including intelligent tutoring systems, interactive simulations and games, animated pedagogical agents, virtual environments, and computer-supported collaborative learning systems (Mayer, 2010).

Others focus on the physical aspects of technology via which instruction is presented to the learners. McDonald and Gibbons (2009) refer to this as the *tools approach* which holds the expectation that using technological tools will affect learning outcomes. This led to various gimmicks being introduced in schools as extras not necessarily well aligned with the teaching-learning process (Husèn, 1967). Machines on their own will not bring about any change (Stolurow & Davis, 1965). This statement is close to Clark's (1983) view that method, not media, determines effectiveness. This claim also pertains to the comparison of computer-based environments (e.g., desktop simulation and virtual reality simulation) (Mayer, 2010). The question, however, is not if tools can contribute to learning but how instructional materials in various forms can enhance learning and allow the manipulation of the properties of instruction that impact learning (Lumsdaine, 1963). This reflects the position of Kozma (2000) who emphasizes a nexus of media and method. Indeed, technology allows for methods that would not otherwise be possible, such as interactive multimedia simulations that support the ability to act on the environment and not simply observe it (Winn, 2002) or hypermedia that challenge cognitive flexibility while crisscrossing the information landscape (Spiro, Feltovich, Jacobson, & Coulson, 1992). In times when information and communication technologies deeply penetrate society, the dichotomy between applied science and tools technology has been in favor of synergy. Educational technology involves a broad variety of modalities, tools, and strategies for learning (Ross, Morrisson, & Lowther, 2010).

Linking Learning Theories and Technology

Given the complexity and diversity of conceptualization, it seems difficult to find a direct link between learning theories and technology. Firstly, the relationship is asymmetric; it is common to consider learning theories as leading and technology as following (Salomon & Perkins, 1996). Secondly, although the psychology of learning is a critical foundation area (Spector, 2008), in complex technological environments it shares a place with communication theory, general systems theory, and instructional-curriculum theory (Richey, 1986). In fact, not only learning but organizational issues as well are important in technological environments, with a focus on the availability, accessibility and acceptability of educational resources (Lane, 2008). An analysis of articles in journals on educational psychology between 2003 and 2007 shows that only 5.6 % of the articles addressed the links between learning theory and technology (Nolen, 2009, as cited in Ross et al., 2010).

Summary

Learning theories, technology and their interlinking fields are dependent on specific research traditions, historical artifacts, idiosyncratic frameworks, technology-based functionalities and pragmatics, which necessarily leads to divergence. Calibration of concepts and conceptual frameworks is not merely a philosophical issue but it is critical for cumulative knowledge building. Not surprisingly, rapid changes in learning theories and technologies generate new terminology. However, increased efforts to refine conceptual frameworks for valid theory building are needed to support cumulative domain knowledge in the field of educational technology. Given the conceptual complexity, the expectation that a clear link between learning theories and technology can be built based on agreed upon definitions is in vain. Consequently, a solution has to be found in a more pragmatic approach with a smaller unit of analysis, where (partial) learning theories, models, and principles are connected to specific technological tools in order to overcome conceptual overload.

Observation 3: Learning Theories and Technologies Are Connected and Intertwined by Information Processing and Knowledge Acquisition

Different learning theories and epistemologies (e.g., objectivism and constructivism), lead to various conceptions of information processing and knowledge acquisition that influence technology use. Given the central function of education to help learners acquire declarative, procedural and conditional knowledge, learning theories and technologies are fellow travelers.

Behaviorist Theory and Subject-Matter Decomposition

In the behaviorist tradition, knowing is an accumulation of associations and components of skills that prescribes simpler tasks as prerequisites for more complex ones (Greeno, Collins, & Resnick, 1996). The stimulus-response theory in which knowledge is defined as a learner's collection of specific responses to stimuli that are represented in behavioral objectives is basic in programmed instruction and CAI. Logical presentation of content, requirement of overt responses, and presentation of immediate knowledge of correctness are common characteristics. Subject-matter is decomposed into small units with carefully arranged sequences aimed at specified terminal behaviors (Shrock, 1995). Terminal behaviors are defined as understanding concept formation, concept utilization, and reasoning through variations of the stimulus context (Glaser, 1962), not through direct access to thinking or knowledge organization. Researchers and designers massively invested in refining and shaping the initial principles of content framing and sequencing (Lockee, Moore, & Burton, 2004; Tennyson, 2010).

A frequently cited example of a system based on behaviorist learning theory, is programmed logic for automatic teaching operation (PLATO), a mainframe-based, integrated system of hardware and software with well-designed instructional materials displayed on special terminals connected through satellite links. The PLATO system started in the early 1960s; didactic as well as communication functions were gradually expanded (Molenda, 2008; Saettler, 2004), leading to over 15,000 h of instructional materials available in a variety of disciplines (Simons & de Laat, 2006). Despite its continuous adaptation and extension, PLATO as a closed system had to compete with a steady innovation of subject-matter and didactic approaches in curricula, a paradigm shift toward a cognitive interpretation of learning environments, and a knowledge-building epistemology. Besides evolutions in education, financial issues played an important role since CAI was significantly more expensive than conventional instruction and no return on investment was realized (Saettler, 2004).

Information Processing Theory and Problem-Solving Tasks

Gagné (1974) dates the transition from behaviorist learning toward cognitive theory at the moment learning is conceived of as a matter of students' information processing. Cognitive theory is largely rooted in objectivist epistemology, but unlike the behaviorists, cognitive psychologists emphasize the individual's processing of information and how knowledge is stored and retrieved (Winn, 2004). A human information processing system consists of a sensory register, short-term (working) memory and long-term-memory (Simon, 1978). Information moves through stages in the cognitive system with processes and mental representations that operate at each step (Brown, 1978; Glaser, 1991). Mental processes mediate what is selected, processed, remembered, recalled and generalized (Hannafin & Hill, 2008).

Theory on information processing and problem solving emerged with the development of the digital computer after World War II (Newell & Simon, 1972; Simon, 1978) and is strongly related to content: “If content is a substantial determinant of human behavior—if in fact the message is a lot more message than the medium—then information processing theories have opportunities for describing human behavior veridically that are foreclosed to theories unable to cope with content (Newell & Simon, 1972, p. 11). All problem-solving behavior is framed by the information-processing system, the task environments and the problem space (Simon, 1978).

In a cognitive perspective, knowledge that supports understanding differs from information as disconnected facts and formulas (Bransford et al., 2000). There is a clear shift from information delivery toward student’s knowledge activation since the logical type of knowledge that was associated with a given discipline in a behaviorist approach is replaced by the psychological nature of meaningful knowledge held by learners (Shuell, 1992). Subject-matter is no more fragmented in small parts but organized around problems that activate learner’s prior declarative, procedural, and self-regulatory knowledge in an interconnected way to solve a given problem. Processing and transformation capabilities of computer micro-worlds allow learners to progress unto more advanced models, increasing the number of rules, qualifiers, constraints to be taken into account, and the range of problems that can be accommodated (Kozma, 1991; Seel, 2006). Computer simulations are compatible with a cognitive theory of learning since they present formalized models, elicit specific cognitive processes like hypothesis generation and testing, allow for learner activity in terms of model manipulation, and interact with the underlying domain model. Learners can execute actions like changing the values of input variables, observing the effects in output variables and make or test hypotheses based on the changes in values that foster conceptual change (de Jong, 1991; Winn, 2004).

Cognitive Theory and Knowledge Organization

Knowledge is a complex phenomenon involving such constructs as schema, mental models, symbol manipulation, knowledge construction, and conceptual change (Winn, 2004). Research in cognitive psychology revealed the centrality of knowledge in human performance including content, knowledge structure and context (Cooke, 1999). Knowledge in isolation (inert knowledge) is of little value but knowledge is powerful if highly organized and easily accessible (Greeno et al., 1996; Schraw, 2006). However, reduction of knowledge organization to neat hierarchies and sequences is an oversimplification of the knowledge people construct (Siemens, 2004; Winn, 1993). Indeed, each individual must possess extensive knowledge, organize knowledge into interconnected schemata and scripts, and use that knowledge to construct conceptual mental models of a given subject-matter domain that are used to solve problems and think critically (Schraw, 2006).

Knowledge organization has been supported by different cognitive tools, such as simulations (de Jong, 2010), concept mapping, and semantic networking embedded in computer tools that visually represent a cognitive structure with nodes and links (Jonassen & Reeves, 1996). In the early 1990s, several computer-based tools were developed (Kommers, Jonassen, & Mayes, 1992) challenging learners to analyze structural relationships among the subject-matter. “Learning tool” (Kozma, 1992), “TextVision” (Kommers & de Vries, 1992), and “SemNet” (Fisher, 1992) are examples of software packages that allow users to graphically represent concepts, define relationships and enter detailed textual and graphic information for each concept. However, a graphical representation of knowledge structure is limited both in mirroring knowledge complexity and accessing deep knowledge. The complexity of digging up and representing concepts, nodes and knowledge structures not only accounts for novices with limited domain knowledge but also for experts as has been evidenced by research on expert knowledge acquisition (Cooke, 1999).

Constructivist Theory and Knowledge Construction

Knowledge construction is a generative learning process (Wittrock, 1974). From a constructivist perspective, knowledge is not conceptualized as a body of information based on verified facts but, rather, as individually constructed by observation and experimentation. Knowledge acquisition is dynamic rather than static, multidimensional rather than linear, and systemic rather than systematic (Winn, 1993). The active interaction between an individual and the environment is mediated through cognitive structures of the individual (Jonassen, Mayes, & McAleese, 1993). The knowledge that each student constructs is not predictable from the individual pieces of information in the information landscape or the curriculum but emerges from the sum of the encounters and from the relations established by the student within the knowledge domain.

If the learner is seeking information to solve a problem or build a better understanding, then environments, such as hypertext retrieval systems, can support that need and engage the learner. Information retrieval is supported by the learner's ability to follow a particular path and make decisions about which links to follow within the hypertext information. In order to make learners able to amend the information in some way, many hypertext systems include functions to support the creation or editing of nodes and links and other functionalities (Jonassen, 1992). Learning from hypertext mostly is task driven, in contrast with free browsing. This is why cognitive flexibility that allows crisscrossing the information landscape is not well suited for novices in a given subject-matter domain (Spiro et al., 1992). Browsing in a domain for which no properly developed schemata have yet been constructed by the learner is not likely to lead to satisfactory knowledge acquisition at all (Jonassen et al., 1993).

Socio-constructivist Theory and Distributed Knowledge

The information-processing approach with cognition mainly conceived of as involving internal mental processes came under increasing criticism. The main objection was that knowledge can be viewed as distributed over individuals and their environments rather than as something self-sufficient to an individual. The notions of *distributed cognition* and *distributed knowledge* play an important role as human activity is affected by contextual affordances which include both people and cultural artifacts (Greeno et al., 1996; Hewitt & Scardamalia, 1998; Säljö, Eklund, & Mäkitalo, 2006). Glaser (1991) offers several arguments for integrating the social dimension within a cognitive perspective: (a) available knowledge is extended; (b) the loci of self-regulatory activity are multiplied; (c) learners can help each other in realizing a Vygotskian zone of proximal development; and (d) a social context helps in bringing thinking to an observable status.

The socio-constructivist perspective and the distributed character of knowledge have influenced computer use since about 1990. CSCL (computer supported collaborative learning) serves groups of learners who co-construct knowledge in a given subject-matter context and aim at goals that are externally provided. CSCL technology is used to present or stimulate a problem for study, helping to situate it in a real-world context, mediate communication within and across classrooms, provide archival storage for the products of group work, or enable learners to model their shared understanding of new concepts (Koschmann, 1996).

Computer-supported intentional learning environment (CSILE) and its extension Knowledge Forum are instances of CSCL that encourage structured collaborative knowledge-building instead of focusing on individual learning tasks (Scardamalia & Bereiter, 1994). Students communicate ideas and reflections, ask questions, exchange statements and continuously build up shared knowledge as input in a database. The computer system supports the knowledge organization of individual and community discourse. The target is real world knowledge that is constructed over time and not restricted to a single product or topic (Scardamalia, 2002; Siemens, 2004).

Summary

Conceptions of information processing and knowledge building change over time, depending on epistemological arguments and evolving learning theories. Different computer tools and systems have been designed to contribute to the supposed increase of education quality in terms of knowledge acquisition but most if not all are limited in curriculum coverage. The shift from programmed instructional materials as parts of the school curriculum toward student's individual and collective knowledge organization and knowledge construction tools paved the way for more real-world problems and knowledge. Evaluation studies clearly show that not only the use of cognitive tools but the link with underlying cognitive processes defines a system's or a tool's merits.

Observation 4: Educational Technologies Have Shifted Learner Support from Program or Instructor Control Toward More Shared and Learner Control

A basic tenet in the discussion of the interplay between technology and education is how technology might support individuals and groups to reach learning goals. Depending upon available learning theories and technological tools, different kinds of support have been inserted into instructional materials, programs, and technology enhanced learning environments, while open-ended learning environments suggest *freedom to learn*. This reveals a tension between structured learning support and a learner's self-management with technology.

Intelligent Computer-Assisted Learning and Intelligent Tutoring Systems

In the behaviorist tradition, computers integrate the activities of a display component, a response component and a feedback component of instruction (Gagné, 1974). It was expected that computer-assisted learning could realize maximal learning support through adaptive feedback. However, linear feedback often results in deficient individual support in traditional CAI programs. A solution is sought in the design of a new generation of programs called intelligent computer-assisted instruction (ICAI). They are instances of micro-adaptive instruction that aim at continuously tuning instruction to the needs of the individual learner with branching as a fundamental aspect of design (Wenger, 1987). ICAI systems are behavioristic since they only use the status of student's behavior to adapt instruction (Urban-Lurain, 1996). However, genuine feedback is hard to realize since the source of information is external to the student and takes place not during a learning activity but only after task completion (Butler & Winne, 1995). In addition, limited computer capacity in terms of memory and speed imposed severe restrictions to tune feedback to individual needs of students.

Fine-tuned adaptivity based on a student's cognitive status had to wait for intelligent tutoring systems (ITSs). A cognitively oriented tutoring system or ITS is not a static preprogrammed system but integrates computational models using artificial intelligence and cognitive science to generate interventions. These are generated based on data gathered from a database that includes the nature of errors and cognitive skills that are realized in the form of production rules (Shute & Psotka, 1996). The database is structured around (a) an expert or domain model, (b) a dynamic student model, (c) a tutor or teaching model, and (d) a communication model and user interface (De Corte et al., 1996; Larkin, 1991). Anderson (1983) developed his adaptive control of thought (ACT*) theory in which a learner's knowledge is tracked (knowledge tracing) in order to generate appropriate learning activities.

In ITSs two different lines of evolution can be observed. One is to refine ITSs in order to integrate new knowledge about learning and new programming techniques. The other is the acceptance of limitations since intelligent machines do not have the breadth of knowledge that permits human reasoning given the fuzziness of thinking and permeability of the boundaries among cognitive schemata (Winn, 2004). Progress has been made in ITS development mainly in knowledge-domains with a rule-based, logical structure, such as classical mechanics, geometric optics, economics, elementary algebra, grammar, and computer programming (Sleeman & Brown, 1982; Wenger, 1987). Further development of natural language processing (Graesser, Chipman, & King, 2008) allows the ITSs to make decisions based on qualitative data analysis (e.g., open-ended text responses or annotated concept maps) (Lee & Park, 2008). Implementations of such ITSs are found in (a) adaptive hypermedia systems (AHSs) which combine adaptive instructional systems and hypermedia-based systems (Brusilovsky, 2001; Lee & Park, 2008; Vandewaetere, 2011), (b) affective artificial intelligence in education (AIED) to detect and intelligently manage the affective dimension of the learner (Blanchard, Volfson, Hong, & Lajoie, 2009), (c) Web-based AHSs that adapt to the goals, interests, and knowledge of individual users (Brusilovsky, 2007), (d) intelligent simulation learning environments with advanced help, hints, explanations and tutoring facilities (de Jong, 1991), and (e) sophisticated online courses that incorporate intelligent tutoring systems (Larreamendy-Joerns & Leinhardt, 2006).

Notwithstanding large investments and refined adaptivity, the ITS movement was in decline. Firstly, ITSs can model procedural skill acquisition but they show limitations in simulating student's complex cognitive processes and situated activity. Secondly, computer-based tutoring systems resulted in many highly structured, directive systems due to the limitations of ITSs to simulate ill-structured or not-rule-based domains (Shute & Psotka, 1996). The consequence is that if computer simulation is impossible, then so is intelligent tutoring. This led Kintsch (1991) to launch the idea of "unintelligent" tutoring in which a tutor should not do all the planning and monitoring because these are activities that students must perform in order to learn. In this view, computers tools, though not artificially intelligent, can play a role to support mindful processes in students (Derry & Lajoie, 1993; Jonassen, 2003; Jonassen & Reeves, 1996; Salomon, Perkins, & Globerson, 1991).

Computer-Enhanced Learning Environments and Learner Support

Transition from instructional materials or programs to learning environments brings about a shift in the locus of control from system to learner which influences the role of system intelligence to support the learner (Chung & Reigeluth, 1992; van Joolingen, 1999). Locus of control can be classified as external (program control), internal (learner control) or shared (Corbalan, Kester, & van Merriënboer, 2008; Elen, 1995; Hannafin, 1984; Lawless & Brown, 1997). In contrast to ITSs as a mode of program-based guidance, learning environments allow learners to reify a learning process while maintaining task complexity (Bereiter & Scardamalia, 2006; Collins, 1996; Zucchermaglio, 1993). Learner control allows learners to make instructional decisions on support needed and content to be covered, choosing the estimated optimal level of difficulty, sequencing a learning path, regulating both the kind and speed of presentation, and defining the amount of information they want to process (Dalgarno, 2001; Merrill, 1984; Vandewaetere, 2011).

Multiple descriptions of constructivism suggest divergent ways to interpret and operationalize learner support. Discovery learning, problem-based learning, inquiry learning, experiential learning and constructivist learning are versions of open learning that leads to the perception that almost unlimited control can be given to students (Bednar, Cunningham, Duffy, & Perry, 1991; Honebein, Duffy, & Fishman, 1993; Kirschner, Sweller, & Clark, 2006). This view is rooted in the work of radical constructivists such as Papert (1980) who points to the paradox that new technologies, instead of creating opportunities for the exercise of qualitative thinking, tend to reinforce educational methods whose very existence reflect the limitation of the pre-computer period. In his view, based on his collaboration with Piaget, learning as self-discovery with Logo as a tool can occur without being taught. His strong constructivist position holds that "In the Logo environment … the child is in control: The child programs the computer. And in teaching the computer how to think, children embark on an exploration about how they themselves think" (p. 19). In his opinion, the acquisition and transfer of programming skills induced by Logo would happen to the pupils (De Corte, Verschaffel, Schrooten, & Olivié, 1993). Studies on that cognitive-effects hypothesis of Logo on children did not deliver positive results (De Corte, 1996). Most researchers share the viewpoint that systematic guidance and even direct instruction needs to be embedded in the program with ample room for exploration. In his reaction to the findings, Papert (1987) ascribes the criticism that Logo did not deliver what it promised to a technocentrist, rigourous model of research: "The finding as stated has no force whatsoever if you see Logo not as a treatment but as a cultural element—something that can be powerful when it is integrated into a culture but is simply isolated technical knowledge when it is not" (p. 24). This illustrates the lasting problem with constructivism and all its derivatives as an ideology as opposed to a learning theory. Even in a constructivist framework, students have goals to pursue (Clark, Kirschner, & Sweller, 2012; Winn, 1993), be they externally or internally generated.

More moderate conceptions of control can be found with learners as partners in distributed intelligence to enhance cognitive and metacognitive knowledge and strategies (Salomon et al., 1991). Examples of constructivist learning environments with explicit learner support are cognitive apprenticeship and situated cognition (Collins, Brown, & Newman, 1989), anchored instruction (Cognition and Technology Group at Vanderbilt, 1993), and simulation learning environments (de Jong, 1991). They contain advanced help, hints, modeling, coaching, fading, articulation, reflection, and exploration to support the process of increasing learner control. In order to counter helplessness in multimedia, standard pop-up help systems, animated guides or intelligent agents that monitor browsing patterns of learners are designed (Dalgarno, 2001).

Learner support has been realized in different computer-based learning contexts from which two are exemplified: (a) use of computer tools that originated outside education (De Corte et al., 1996; Duffy et al., 1993), and (b) dedicated tools embedded in the environment (e.g., pedagogical agents) (Clarebout, Elen, Johnson, & Shaw, 2002). Publicly available computer tools have been inserted into many learning environments (e.g., word processors, calculators, spreadsheets, database programs, drawing and composition programs) to free students from the intellectual burden of lower-level operations, present a familiar structure for performing a process, and trace states and processes so as to contribute to the quality of a student's thinking and learning (Jonassen, 1992). The supply of tools has been enlarged with WebQuests, simulations and games, micro-worlds, blogs, and wikis (Molenda, 2008), and social media (Säljö, 2010) that allow for high levels of interactivity, interactive data processing, symbol transformation, graphic rendering, information storage and retrieval, and communication (Dalgarno, 2001; Kozma, 2000; Mayer, 2010).

Animated pedagogical agents illustrate endeavors to embed learner support in interactive learning environments to enable the system to engage and motivate students by adapting support to individual students and providing students with nonverbal feedback (Johnson, Rickel, & Lester, 2000). Functionalities of learning support delivered by animated pedagogical agents include supplanting, scaffolding, demonstrating, modeling, coaching and testing, but metacognitive support is lacking (Clarebout et al., 2002). A possible explanation for the absence of metacognitive support is that the design of pedagogical agents stems from the ITS tradition with a strong focus on domain specific knowledge and single solution procedural tasks (Clarebout et al., 2002).

Open-Ended Computer Environments: Conditions to Be Met by Learners

Advances in computer technology and multimedia allow learning experiences with authentic, real-world problems in which learners have control over activities, tools and resources (Reiser, 2001). When constructivism is considered to be a learning theory, most authors interpret it as individuals who have to create their own new understandings (Resnick, 1989) though this does not necessarily imply unguided or minimally guided learning (Mayer, 2004; Winn, 1993). Learning environments are goal oriented, which makes learner's self-regulation and external support crucially dependent upon a student's ability. Student use of support in open learning environments is not an objective nor an external measure, but it is mediated by many characteristics and processes such as prior knowledge of subject matter, self-regulating capacity and perspectives on learning environments and support (Elen & Lowyck, 1998; Lowyck & Elen, 1994). High achievers who are knowledgeable about a subject-matter area can benefit from a high degree of learner control whereas learners who lack knowledge about the structure of the domain and metacognitive knowledge and strategies make poor choices (Collins, 1996). Initial schema development and knowledge acquisition normally must be guided more than advanced knowledge acquisition since a domain for which no properly developed schemata have yet been constructed is not likely to lead to satisfactory knowledge acquisition at all (Jonassen et al., 1993). Freedom of movement in hypermedia can cause inexperienced learners to get lost in hyperspace (Spiro et al. 1992). Functionalities of learning environments, including learner support, seem effective when learners are in tune with the intentions of the system and make use of available support (Winne, 2004). Students do not react to objective or nominal stimuli but to transformed, interpreted stimuli which commonly leads to a suboptimal use of instructional interventions (Lowyck, Lehtinen, & Elen, 2004). Students' perspectives on learning environments and their epistemological beliefs (Bromme, Pieschl, & Stahl, 2010) may affect outcomes. Gerjets and Hesse (2004) hypothesize that a multiplicity of factors besides the attributes of the learning environment may play a role (e.g., knowledge prerequisites, learning styles, learner preferences, motivational orientations, attitudes, epistemological beliefs, and instructional conceptions). This emphasizes the role of student's perspectives, perceptions and instructional cognition that mediate between a designed computer-enhanced environment and student's use of it.

Summary

Learner support in technology rich environments is crucial for learning. Depending upon learning theories and available technologies, different kinds of scaffolds have been designed. CAI only used linear sequences, a limitation that has been overcome in ICAI and ITSs. The advent of cognitive and socio-constructivist approaches shifted the focus from program control to learner and shared control. The complexity of theoretical frameworks and operational interventions results in many different support tools. The expectation that open-ended learning environments in and of themselves would result in learning is questionable. The zone of proximal development concept needs to be considered. A technological learning environment is not effective by itself; it has to be adopted by learners in line with their ability, self-management and perspectives on technological learning environments.

Observation 5: Learning Theories and Findings Represent a Fuzzy Mixture of Principles and Applications

The proposition that a science of learning is fundamental to educational technology has been broadly accepted but it is unclear how bridging both fields can be realized. There are, however, arguments to assert that a direct transfer of theory into practice can no longer be expected. Firstly, the nature of learning sciences and instructional technology reflects two separate endeavors with different conceptual frameworks, methods and goals, often labeled as fundamental versus applied which brings Glaser to contend that "the progress of basic science does not insure systematic and fruitful interplay between basic knowledge, applied research, and subsequent technology" (Glaser, 1962, p. 3). Learning theories build a descriptive knowledge base while educational technology needs theoretically valid prescriptions to optimize learning (Elen, 1995). Secondly, building a unified base of knowledge about learning seems unrealistic since successive learning theories show noncumulative characteristics (Elen & Clarebout, 2008) and new technologies have a tendency to get disconnected from findings obtained with older technologies (Hannafin & Young, 2008). Though learning theories as an emerging set of notions rather than as a set of empirical findings and microtheories can help us to understand complex systems (Calfee, 1981), they are mostly used as a source of verified instructional strategies, tactics and techniques. Behaviorism, for example, is grounded in experimental psychology that delivers laboratory findings, and early information processing theory is based on rich data about individual problem solving, both with high internal validity. Constructivism and socio-constructivism find their origins in externally valid ecological settings that reflect multiple perspectives, which renders theories complex, multifaceted and divergent. The former theories (behaviorism and cognitivism) resemble rivers flowing in a riverbed while the latter (constructivism and socio-constructivism) resemble a river delta spreading out into many channels.

Learning Theories, Findings, and Principles

Theories supply findings that are the starting point for applied research and the development of instructional principles and devices (Ertmer & Newby, 1993; Glaser, 1962). A principle or basic method reflects a relationship that is always true under appropriate conditions regardless of program or practice prescribed by a given theory or model (Merrill, 2002). A principle makes a statement about the outcomes instruction aims at, the conditions required, and the methods that can be used (Winn, 1993). Evolution of learning theories, findings, and principles reflect different transitions from theory into practice, ranging from convergent to divergent.

Behaviorist Learning Theories, Findings, and Principles

Behavioral theory focuses on basic laws of behavior modification. From experimental behaviorist learning theory it was expected that principles based on the analysis of simple performances tested in laboratory conditions could be extrapolated to complex forms of learning (Glaser & Bassok, 1989). Skinnerian operant or instrumental conditioning based on the relationship between stimuli that precede a response (antecedents), stimuli that follow a response (consequences) and the response (operant) itself has been broadly accepted in instructional technology (Winn, 2004). Reinforcement, contiguity and repetition are pivotal in the acquisition of behavior (Burton et al., 1996) which can easily be translated into behavioral control principles. These principles led to agreed upon specifications for instructional materials like analysis of terminal behaviors, content, objectives, criteria-referenced assessment, learner and behavior characteristics, sequencing of content from simple to complex, and frame composition (Andrews & Goodson, 1980; Ertmer & Newby, 1993; Lockee et al., 2004; Montague & Wulfeck, 1986, Tennyson, 2010, Winn, 1993). Programmed instruction and CAI are organized in small, easy steps to let the learner start from an initial skill level and gradually master a task while reducing prompting cues along the path to mastery. More evidence has been collected on the prompting aspect rather than the fading aspect (Lumsdaine, 1963).

Despite intensive and lasting efforts to implement behavioral principles in instructional environments, the narrow focus on links between stimulus and response led to a reductionist and fragmented perspective. However, criticism should not only be directed at the behavioral foundation but also at the poorly developed software (Cooper, 1993).

Cognitivist Learning Theories, Findings, and Principles

The invalid expectancy that stimulus-response can account for complex human behavior (Tennyson, 2010; Winn, 2004) challenged cognitive learning theory to open the black box of mental activities (Glaser, 1991). Stimulus-response as the unit of behavior is replaced by a cognitive interpretation with emphasis on planning and hierarchical organization of the mind. Early cognitive learning theories focus on problem-solving and information processing based on Miller's work on chunking and the limited capacity of working memory (Miller, 1956) and the TOTE unit "test-operate-test-exit" (Miller, Galanter, & Pribram, 1960). Though problem-solving and information processing are interconnected fields (Newell & Simon, 1972), findings are translated into separate principles for problem-solving and information processing.

Problem-solving theory was initially elaborated for processes of relatively well-structured puzzle-like problems in laboratory settings in which a given state, a goal state and allowable operators are clearly specified (Simon, 1978). This led to the following principled sequence: (a) input translation that produces a mental representation, (b) selection of a particular problem-solving method, (c) application of the selected method, (d) termination of the method execution, and (e) introduction of new problems (Newell & Simon, 1972). Studies on complex problem solving revealed some core instructional principles, such as (a) develop skills within specific domains rather than as general heuristics (domain-specific), (b) restrict problem-solving skills to a limited range of applicability (near-transfer principle), and (c) integrate different kinds of knowledge within guided problem-solving tasks (integration principle) (Mayer & Wittrock, 2006). These principles can be used in designing micro-worlds or simulations but they hold no indication how to link principles to tools. Translation of findings into principles and instructional technology is highly dependent on an instructional designer's decisions and available technologies.

Information processing systems describe how people perceive, store, integrate, retrieve, and use information. Findings from information processing theory mirror principles for educational technology. They focus on the load that performing a task causes to a learner's cognitive system (Mayer, 2010; Paas & van Merriënboer, 1994; van Merriënboer & Sweller, 2005). Cognitive load theory is based on assumptions about dual-coding (Paivio, 1986), limited working memory and chunking (Miller, 1956), and cognitive processing for meaningful learning (Mayer & Moreno, 2003). Examples of such principles are as follows: (a) if the visual channel is overloaded, move some essential processing from the visual to the auditory channel; (b) if both visual and auditory channels are overloaded, use segmenting and pre-training; (c) if one or two channels' overload is caused by extraneous material, use weeding and signaling, and if caused by confusing presentations, align and eliminate redundancy; (d) if one or both channels are overloaded by representational holding, synchronizing and individualizing are useful (Mayer & Moreno, 2003). These principles are close to the information processing theory and can be empirically tested (van Merriënboer & Sweller, 2005).

The cognitive orientation effectuated a shift from materials to be presented in an instructional system to students' goal-oriented and self-regulated processes and dialogue with the instructional design system (Cooper, 1993; Merrill, Kowalis, & Wilson, 1981; Merrill, Li, & Jones, 1990; Tennyson, 1992). This shift leads to more general principles to build cognitive learning environments, like activation of learner's involvement in the learning process through learner control, self-monitoring, revising techniques, cognitive task analysis procedures, use of cognitive strategies, and allowing students to link prior and new knowledge (Ertmer & Newby, 1993). In addition, theories and concomitant principles are dependent on evolutions in technology. While, for example, early attempts to implement cognitively oriented instruction in technology tools were inappropriate or ineffective, increased hardware speed and capacity allowed us to implement cognitive-based learning using hypertext, hypermedia, expert systems, and so on (Cooper, 1993).

(Socio-) constructivist Learning Theories, Findings, and Principles

Information processing adapts an objectivist epistemology and represents a mechanistic view of learning with ready recall of information and smooth execution of procedures (Perkins, 1991). Increasing complexity and situatedness of learning led to dissatisfaction with the computational view of cognition and the restriction of learning to internal mental representations. This leads to a constructivist perspective on learning as the creation of meaning based on experience-in-context (Bednar et al., 1991; Duffy et al., 1993). Constructivism as an umbrella term holds many perspectives and approaches, including situated cognition, realistic learning environments, social negotiation, multiple perspectives, and self-awareness of the knowledge-production processes (Driscoll, 2000). Any analysis of constructivism is difficult because there is a great range of ideas and a variety of theoretical positions and differences in perception of the instructional implications of this basic tenet. In addition, "the move away from the computational view brought about the move away from learning and cognition as the central focus of educational research in *any* form" (Winn, 2004, p. 80).

Principles deduced from constructive theories are numerous and divergent. Though characteristics of constructive learning as active, constructive, cumulative, collaborative, situated and goal directed are canonical (Bednar et al., 1991; De Corte, 2010; Shuell, 1988; Simons, 1993), any learning inherently shows this constructive character (Perkins, 1991). Given the divergence in interpretations of constructivism, ranging from radical to moderate (Lowyck & Elen, 1993), a lack of precision in defining principles for instructional interventions makes new prescriptions highly probabilistic (Winn, 1987). Nevertheless, scholars derived constructive principles to guide the design of so-called powerful learning environments. Driscoll (2000), for example, formulates these principles: (a) embed learning in complex, realistic and relevant environments; (b) provide for social negotiation as an integral part of learning; (c) support multiple perspectives and the use of multiple modes of representation; (d) encourage ownership in learning; and (e) nurture self-awareness of the knowledge construction process. Ertmer and Newby (1993) suggest these: (a) anchor learning in meaningful contexts; (b) actively use what is learned; (c) revisit content at different times, in rearranged contexts, for different purposes, and from different conceptual perspectives; (d) develop pattern-recognition skills presenting alternative ways of presenting problems; and (e) present new problems and situations that differ from the conditions of the initial instruction. Merrill (2002) elaborated *first principles* that focus on knowledge building and suggest that learning is promoted when: (a) learners are engaged in solving real-world problems; (b) existing knowledge is activated as a foundation for new knowledge; (c) new knowledge is demonstrated to the learner; (d) new knowledge is applied by the learner; and (e) new knowledge is integrated into the learner's world. These three examples illustrate that generalized principles reflect divergent findings which renders operational advisement almost impossible.

In contrast, the Jasper series (Cognition and Technology Group at Vanderbilt, 1993) use concrete operationalization of principles that involve video-based formats, narratives with realistic problems, generative formats, embedded data designs, problem complexity, pairs of related adventures, and links across the curriculum. These seem to be descriptions of specific types of interactive instructional material rather than theoretically derived and empirically validated prescriptive principles (Elen, 1995). The difficulty of detecting and formulating principles for building constructive learning reveals shortcomings in both theoretical precision and convergent modeling. Jonassen and Reeves (1996) suggest eliminating design principles and leaving design in the hands of learners who use technologies as cognitive tools for analyzing the world, accessing information, interpreting and organizing their personal knowledge, and representing what they know to others (i.e., learning by design or design-based learning). Technologies such as databases, spreadsheets, programming languages, visualization tools, micro-worlds, and many others can be used to support such learning. What is at issue is not constructivism as a theory but the learner's ability to cope with design complexity.

Socio-constructivism adheres to the viewpoint that human activity is influenced by affordances, artifacts, and other people (Hewitt & Scardamalia, 1998). In the broad framework of a sociocultural approach, human activities are seen as socially mediated (Dillenbourg, Baker, Blaye, & O'Malley, 1996; Lowyck & Pöysä, 2001). Socio-constructivism adds theoretical complexity while integrating learning, epistemological, sociological, anthropological, and educational theories (Koschmann, 2001). Winn (2002) offers the following principles for implementing the findings of socio-constructivism: (a) technology may sometimes be a necessary condition for the creation of learning communities but is never a sufficient condition; (b) simply creating an interactive learning environment is not sufficient to bring about learning; (c) practitioners should create a social context for learning in technology-based learning environments; (d) effective learning communities often include experts from outside education; (e) students should be encouraged, when appropriate, to create or modify the learning environment; and (f) partnerships among students, teachers, and researchers should be encouraged. However, these "should" statements are a source of inspiration rather than an account of outcomes of research. CSCL principles include these: (a) support educationally effective peer interactions; (b) integrate different forms of discourse; (c) focus students on communal problems of understanding; (c) promote awareness of participants' contributions; (e) encourage students to build on each other's work; and (f) emphasize the work on the community (Hewitt & Scardamalia, 1998). Again, these principles and suggestions for application of theoretical findings are framed in general terms rather than in concrete links between theory, findings, principles, and prescriptions.

Summary

Evolutions in learning theory are translated into findings and principles that possibly guide the design of technological tools. In most cases, it remains difficult if not impossible to detect a direct link between theory, and its operationalization into technological tools or environments. The transitions between theory, findings, principles, and concrete implementations are problematic. Different research findings lack documentation of the transition steps between descriptive and prescriptive knowledge, which also caused problems in building tools for automated instructional design (Spector, Polson, & Muraida, 1993). Most principles are formulated at a general level, which supposes translation into very concrete situations, environments and tools. Consequently, the expertise of designers, learners, and learner communities will define effectiveness and efficiency of these translation efforts.

Conclusion

The quest for understanding the links between learning and things of learning started from the rather optimistic expectation that a close and natural relationship could be documented. This expectation is suggested by the term "educational technology." However, in-depth scrutiny reveals high complexity in both conceptualization and realization. This led to the decision to represent the complexity in terms of a limited set of observations to guide a critical appraisal of the relationship between learning theories and technology. These observations are subjective, based on selected sources, and aim at further discussion. Within the limits of this approach, a few main conclusions can be drawn.

Firstly, learning theories and technology show internal and autonomous dynamics that lead toward mutual fertilization. Their relationship is interdependent though not parallel, and each can draw inspiration from the other. A tight empirical liaison, however, cannot be created. Ambitions of policy-makers, researchers, and practitioners to innovate education with new learning theories and powerful technologies, yielded a myriad of isolated products, projects, and environments that were expected to impact education, learning and learners in an effective and efficient way. The aim to build evidence-based knowledge about educational technology mostly got stuck in idiosyncratic, divergent, and nebulous frameworks. In contrast, interesting and worthwhile examples of links between learning theories and technology have been found at a more fine-grained level of interaction in which both learning principles and technological characteristics are documented. These seldom led to valid theoretical propositions that transcend the particularity of findings or settings.

Secondly, tuning learning theories to technology and vice versa requires consistency and stability. Both domains show intrinsic constraints that influence modes of interaction. On the one hand, learning theories can call for complex processes that cannot be realized due to the limited capacities of technology, as documented in the case of ITSs. On the other hand, powerful technologies can be used for lower-level learning goals, such as information delivery. In order to foster, the elaboration of a suitable conceptual framework that focuses on interaction variables is urgently needed.

Thirdly, the relationship between learning theories and technology is part of a complex educational system that calls for synergy at the macro-, meso-, and micro-level. In addition, several parts of the system influence the use of technology for learning, which makes learning theories one of several technology partners. Sociological, political, anthropological, epistemological, financial, economic, and organizational and other issues play an important role in an educational system. The question is if and to what degree an interdisciplinary approach supports educational technology theory and development. In the field of educational technology, isolation and balkanization of learning theories and technologies hinder development of a linking discipline.

Fourthly, both learning theories and technology are empty concepts when not connected to actors, such as instructional designers, teachers, and learners. Many aspects of human activity buffer the effectiveness and efficiency of educational technology. Deep understanding of learning theories and technology as well as their relationship is a condition to activate potential interplay and foster mutual fertilization. Teachers and learners need metacognitive instructional knowledge and motivation to tune their (mental) behaviors to the nominal stimuli of the environment or to guide their own process of learning in technology-enhanced learning environments. To put it in a slogan, teachers and learners are co-designers of their learning processes which affect knowledge-construction and management as well as products that result from collaboration in distributed knowledge environments.

Lastly the interplay between learning theories and technology needs a transition science. Learning theories deliver descriptive findings that fill the knowledge base of *knowing that*, while educational technology, if not considered as tools technology is a prescriptive field that defines *knowing how*, to use Ryle's (1949) terminology. Instructional design as a connecting field mediates between knowing that and knowing how. Strange enough, learning theories and technology become disconnected if instructional design does not consider evolutions in learning theories. This is why strong behaviorist principles that originated in early instructional design hindered adaptation of models and principles to more cognitive and constructivist approaches. Hopefully, evolutions in learning theories and technologies will lead to more coherence and synergy than has been illustrated with selections of the literature. This calls for a community that not only designs and develops products and environments but that invests in theory building through continuous refinement of *knowing that* and *knowing how* to bring about synergy in the complex and divergent field of educational technology.

We shall not cease from exploration
And the end of all our exploring
Will be to arrive where we started
T.S. Eliot, Four quartets

Research Paradigms and Perspectives on Learning

2

Jeroen J.G. van Merriënboer and Anique B.H. de Bruin

Abstract

What is the most important factor influencing human learning? Different instructional theories give very different answers to this question, because they take different perspectives on learning and thus focus on other desired learning outcomes, other methods affecting learning processes, and other conditions under which learning takes place. This chapter describes how eight prevailing research paradigms have influenced and still strongly influence theory development in the field of educational communications and technology. According to the perspective of Gestalt psychology, the most important factor influencing learning is insight and understanding; according to behaviorism and neo-behaviorism, it is reinforcement; according to developmental psychology, it is the learner's stage of cognitive development; according to cultural-historical theory, it is interaction with the world; according to information processing theory, it is active and deep processing of new information; according to cognitive symbolic theory, it is what the learner already knows; according to cognitive resource models, it is the limited processing capacity of the human mind, and according to social constructivism, it is the social construction of meaning. It is argued that research is typically done within one particular paradigm, but that researchers should be conscious of the fact that paradigms heavily affect their research methods and findings. Moreover, researchers should be open to alternative theories and paradigms because new developments often take place at the interface between paradigms.

Keywords

Research paradigm • Gestalt psychology • Behaviorism • Developmental psychology • Cultural-historical theory • Information processing theory • Symbolic cognitive theory • Cognitive resource theory • Social constructivist theory

Introduction

Instructional theories are concerned with instructional methods that affect learning. Learning refers to the act, process, or experience of gaining knowledge, skills, and attitudes and as such, learning is inherent to all human life. People learn by doing, by exploring, by listening, by reading books, by studying examples, by being rewarded, by discovering, by making and testing predictions, by trial-and-error, by teaching, by abstracting away from concrete experiences, by observing others, by solving problems, by analyzing information, by repetition, by questioning, by paraphrasing information,

by discussing, by seeing analogies, by making notes, and so forth and so forth. Learning is an extremely broad concept and this makes it hard to answer the question of what the main factors influencing learning are, and thus to identify instructional methods that optimize learning. Taking a particular perspective on learning helps to identify relevant factors. The main question that is answered in this chapter is this: "how do perspectives on learning and research paradigms help researchers in the field of educational communications and technology to develop instructional theories?"

The first section of this chapter takes a closer look at instructional theories which relate instructional methods to learning outcomes and also identify conditions that affect the relationships between methods and outcomes, such as characteristics of the learners, of the learning tasks or learning domain, and of the context in which learning takes place. Different instructional theories typically focus on different sets of desired outcomes, different methods, and different conditions under which learning takes place. The second section explains how the development of theories takes place within particular research paradigms. Eight prevailing paradigms in the field of educational communications and technology are discussed. Within the same paradigm, theories can be compared with each other and theories with the strongest explanatory power are likely to survive. In contrast, theories originating from different paradigms are very hard to compare with each other because they have little in common. Yet, a reconciliation of paradigms might be possible after deep revisions, leading to new developments and research lines. The third Discussion section examines implications for doing research in the field of educational communications and technology.

The Infinite Universe of Instructional Theories

Instructional theories relate instructional methods to each other and to learning processes and learning outcomes. The main elements of instructional theories are thus instructional methods, which specify what the instruction looks like, and instructional outcomes, which specify learning outcomes and processes associated with these instructional methods. A further common distinction is between descriptive instructional theories, which primarily explain the relationships between instructional methods and learning outcomes or processes, and instructional design theories, which prescribe the best instructional methods helping learners to reach desired outcomes (also called "prescriptive" theories). Most instructional theories distinguish different categories of instructional methods or deal with only one or a few of those categories. Reigeluth (1983), for example, makes a distinction between (a) organizational methods, which deal with the way in which instruction is arranged and sequenced, (b) delivery strategies, which are concerned with the media that are used to convey information to students, and (c) management strategies, which involve the decisions that help the learners to interact with the activities designed for learning.

Instructional *design* theories typically contain a taxonomy of learning outcomes, which makes it possible to classify the desired outcomes and then to select the most suitable instructional method or methods for helping learners to reach these outcomes. The taxonomies of Bloom and Gagné are still in wide use. In the cognitive domain, Bloom (1956) makes a distinction between knowledge, comprehension, application, analysis, synthesis, and evaluation and he describes suitable methods for teaching each of these outcomes. Gagné (1968) makes a distinction between five domains (perceptual-motor skills, attitudes, verbal information, cognitive strategies, and intellectual skills), and in the intellectual skills domain, he makes a further distinction among discrimination, concrete concepts, defined concepts, rules, and higher-order rules. Like Bloom, he describes instructional methods for helping learners to reach each of these outcomes. More recent instructional design models have further refined taxonomies of learning (e.g., Merrill's performance-content matrix, 1983) or, alternatively, focused on helping students learn highly integrated sets of qualitative different outcomes (i.e., *complex learning*, van Merriënboer, Clark, & de Croock, 2002; van Merriënboer, Kirschner, & Kester, 2003).

Although instructional theories deal with the relationships between instructional methods and learning processes and/or outcomes, it should be stressed that these are never straightforward relations. There are numerous conditions that affect the relationships between methods and outcomes. These conditions deal, for example, with the characteristics of the learners, with the nature of the learning domain or learning tasks, and with the context in which learning takes place. Relevant factors with regard to the learners are prior knowledge, general ability, age, limitations, and learning styles. For example, students with low prior knowledge learn more from studying examples than from solving the equivalent problems, but this pattern is reversed for students with high prior knowledge (Kalyuga, Ayres, Chandler, & Sweller, 2003). Relevant factors with regard to the learning domain or tasks are potential dangers, tools used, the epistemology of the domain, task complexity, and standards. For example, a safe task is better practiced on-the-job than in a simulated environment, but this pattern is reversed for a dangerous task. Finally, relevant factors with regard to the context are available time, money, equipment, culture, and setting (e.g., military, school, business). For example, inquiry methods may be superior to expository methods if ample instructional time is available, but this pattern is reversed with limited instructional time.

In the field of education, there are simply no instructional methods that either work or do not work regardless of conditions.

At best, there are some methods that help learners to reach particular learning outcomes under particular conditions. Berliner refers in his article *Educational research: The hardest science of all* (2002) to this problem as the *ubiquity of interactions*, leading to a combinatorial explosion of factors influencing learning. Consequently, the universe of instructional theories is practically infinite and each instructional theory can only try to describe a small fraction of this whole universe. This is where research paradigms come into play. Such paradigms help us to determine the limits of "our" fraction of the universe, and to develop families of competing instructional theories that can be sensibly compared with each other.

Paradigms and Perspectives on Learning

In his book *The structure of scientific revolutions*, Kuhn (1996) introduced the term paradigm to refer to a set of practices that define a scientific discipline or sub discipline. The practices refer, amongst others, to what is studied, the kind of research questions that are posed and how these are structured, how and with what tools studies are conducted, and how results are analyzed and interpreted. In short, a paradigm is a specific way of viewing reality, excluding alternative ways of viewing reality. Consequently, different paradigms are incommensurable, meaning that no meaningful comparison between them is possible without fundamental modification of the concepts that are an intrinsic part of the paradigms being compared. The same is true for the theories developed within a particular paradigm. Within the same paradigm, theories can compete with each other and the theory with the strongest explanatory power is likely to survive. But theories developed in different paradigms cannot be sensibly compared with each other without far-reaching modifications because they represent fundamentally different ways of looking at reality. Yet, a reconciliation of paradigms after necessary deep revisions may lead to a novel perspective on learning and new research lines.

The remainder of this section briefly discusses eight prevailing paradigms in the field of educational communications and technology and their central perspective on learning: Gestalt psychology, behaviorism and neo-behaviorism, developmental psychology, cultural-historical theory, information processing theory, symbolic cognitive theories, cognitive resource theories, and social constructivism.

Gestalt Psychology

Gestalt psychology originated in the early twentieth century in Germany, with Wertheimer, Koffka, and Kohler as most important representatives (Ash, 1998). The word "Gestalt" refers to the essence of an entity's complete form, and the phrase "the whole is greater than the sum of its parts" is often used when explaining Gestalt theory. Gestalt psychologists analyze perceptual and thinking processes as reorganizing or relating one aspect of a problem situation to another, which may result in structural understanding. This involves restructuring the elements of a problem situation in a new way so that a problem can be solved. In this process, it may be important to give hints to the problem solver to help him or her break out of old ways of organizing the situation (called "Einstellung"). The new way of looking at the problem is accompanied by "insight," the "magical flash" or "Aha-erlebnis" that occurs when the solution suddenly falls into place. Gestalt psychologists hold that positive transfer from one task to another is achieved by arranging learning situations so that a learner can gain insight into the problem to be solved. This type of learning is thought to be permanent and reorganized knowledge may yield deep understanding and thus transfer to new situations.

Luchins (1961) described the implications of Gestalt psychology, and in particular the work of his teacher Max Wertheimer, for the field of educational communications and technology. Wertheimer stressed the importance of thinking about problems as a whole and introduced the distinction between productive thinking, which is an unplanned response to situations and environmental interactions yielding insight and understanding, and reproductive thinking, which is solving a problem with previous experiences and what is already known. Productive thinking is seen as the most important goal of education (*see* Wertheimer, 1982). Central to Wertheimer's approach is that learners are conceptualized as active constructors of knowledge rather than passive recipients of information; they actively seek to make sense of the environment by imposing structure and order on stimuli encountered through direct perception and experience. In this view, instruction and teaching should help to "… illustrate clear-cut structures as well as various degrees of structurization; present hints as to the next step in proceeding; pace the learning; illustrate required elements; point to gaps in the learning process, and illustrate sensible, productive ways of dealing with a particular task in contrast to stupid ways" (Luchins, 1961, p. 27). If researchers working in the Gestalt tradition were asked what the most important factor influencing learning is, their answer would be: "*reaching insight and understanding through restructuring*."

Behaviorism and Neo-behaviorism

During the first part of the twentieth century, partly in parallel with the florescence of Gestalt psychology in Europe, the intellectual climate in the USA emphasized the individual's possibilities to develop and achieve great things (the American Dream).

The idea that behavior is malleable and education can foster excellence made learning one of the paramount concerns of American psychology. According to behaviorism, which was flourishing in those days, learning at all levels, be it a monkey learning to collect candy by pushing a lever, or a child in elementary school learning to subtract, is guided by a set of basic laws. Two of these main laws are termed classical conditioning and operant conditioning. Classical conditioning refers to the phenomenon that a neutral stimulus (a bell) can lead to an automatic response (salivation in a dog) after it is associated a number of times with a stimulus that in itself triggers the automatic response (food). Ivan Pavlov (1927), the discoverer of this phenomenon, termed this automatically learned association a conditioned reflex. In contrast, operant conditioning happens when the learner's behavior is stimulated (usually referred to as reinforced) by a positive outcome, or is punished by a negative outcome (Thorndike, 1911). Consider a cat inside a cage trying to get out. It shows all sorts of random behavior, for example, biting the bars, jumping up and down, and pushing a lever. The latter behavior opens the cage, but only after repeated execution of that behavior is there enough reinforcement for the cat to learn the association between the lever and the opening of the cage. Skinner (1938) insisted on a sharp distinction between classical conditioning and operant conditioning; in the former the conditioned response is set off automatically by an external stimulus, whereas in the latter behavior is voluntarily executed by the learner.

Behaviorists agreed that most of learning is guided by these relatively simple laws, and that cognitive processes played a minor role, if any role at all. They viewed the child's mind as a blank slate, and emphasized the all-decisive effect of the environment (Fontana, 1984). Reinforcement, and to a lesser extent punishment, shapes learning and should be used by educators to create desired behavior and prevent unwanted behavior. In the field of educational communications and technology, *programmed learning* was based on behaviorist insights (Skinner, 1968). It consists of small learning steps ("frames") that the learner goes through in a self-paced way. Each frame contains a segment of information and a question on which the learner will be provided feedback. Behaviorists' answer to the question what the most important factor influencing learning is, would simply be: "*Reinforcement!*"

Developmental Psychology

The most influential scientist in the history of developmental psychology still is Jean Piaget. He was the first to study what is now termed cognitive development, focusing on how children learn to understand the world and how their cognitive abilities expand during childhood. He was influenced by Gestalt psychology and its study of how structural understanding develops. His theory departed from the idea that cognitive development follows qualitatively different stages, each with its own distinctive characteristics. Until then, children were mainly viewed as miniature adults, but Piaget created room for the idea of a separate life phase. Piaget described four developmental stages, following a similar age line across individuals (Piaget & Inhelder, 1962). During the first stage, the sensorimotor stage (0–2 years), children learn through sensorimotor experiences, e.g., seeing, kicking, and hitting objects. Children learn to realize that their actions can influence the world, and by the end of this stage they have acquired the ability to mentally represent objects in their heads. Children in the preoperational stage (2–7 years) show an enormous increase in the ability to mentally represent objects, illustrated mostly by the development of language. The third stage, the concrete operational stage (7–11 years), is marked by an increased flexibility of these mental representations; children's thinking becomes more flexible, logical, and organized than before. A major milestone is solving the conservation task: Children understand that the amount of liquid in a glass does not change when poured from a tall glass into a short, wide glass. The final stage, the formal operational stage (11 years and beyond), is characterized by the development of abstract, scientific thinking. Whereas children in the concrete operational stage can reason about objects in the real world, formal operational children are able to do so about abstract situations.

When transferring insights from cognitive development to learning, it is clear that education should be adapted to the characteristics of the specific stage the learner is in. A one-year-old infant should be encouraged to physically stimulate his environment in order to learn. The pre-operational child, moreover, will only learn when confronted with real-life examples involving limited reasoning. The concrete operational child can be challenged with more complex examples, for instance, classifying objects according to a rule, as long as the examples are concrete and close to the child's experiences. Abstract reasoning is reserved for the formal-operational child. Piagetians emphasize active discovery learning, adapted to the child's developmental level. Developmental psychologists would argue that the most important factor influencing learning is: "*the cognitive-developmental stage the learner finds himself in*."

Cultural-Historical Theory

Cultural-historical theory is rooted in dialectical materialism, the official philosophy of Communism claiming that everything is material and that change takes place through the struggle of opposites (i.e., thesis-antithesis-synthesis). Lev Vygotsky (1978) is the founding father of cultural-historical theory in the 1920s. His theory focuses on human development as the interplay between the individual mind and society, as expressed in his famous statement "the mind grows through interaction with other minds." On a broader scale, cultural-historical theory stresses that human beings live and learn in an environment transformed by the activity of prior members of their species; the transformations from one generation to the next generation are the result of the human ability to create and use artifacts. Furthermore, cultural mediators such as words, signs, and symbols enable the development of higher mental functions in this transformative process. As a result, the specific knowledge gained by children in this process also represents the shared knowledge of a culture—a process known as *internalization*. A popular theory in the cultural-historical tradition is activity theory, which was founded by Leont'ev and further developed by Engeström (*see* Engeström, Miettinen, & Punamaki, 1999), who proposes a scheme of activity containing three interacting entities—the individual, the objects and tools, and the community.

With regard to educational communications and technologies, cultural-historical theories stress the importance of social interaction with the world. A central concept in this respect is Vygotsky's zone of proximal development. The basic idea is that children (and adult learners) learn by interacting with the world and with others, that is, by performing meaningful tasks. At the lower limit of the zone of proximal development are tasks that the learner can perform independently; at the upper limit of the zone are the tasks that the learner can only perform thanks to the support and guidance offered by others, such as a teacher, parent, or more experienced peer. Thus, the zone of proximal development captures the skills that are in the process of maturing, and learning is optimized if tasks are in this zone and can be accomplished only thanks to support and guidance provided by others. A closely related concept is scaffolding, meaning that the given support and guidance gradually decreases as learners acquire more knowledge and skills. Over the course of a learning process, a more-skilled person thus adjusts the amount of guidance to fit the learners' current performance. In the cultural-historical perspective, dialogue is an important tool in this process because spontaneous concepts of the learner are then confronted with the rational and more useful concepts of the teacher or a more experienced peer. If researchers in the cultural-historical paradigm were asked what the most important factor influencing learning is, their answer would be "*social interaction with the world and with others*."

Information Processing Theories

The analogy between the human mind and a computer is drawn from information processing theories, which were mainly developed in the 1950s and 1960s. Concepts that are still used daily in psychology, such as memory storage and retrieval, find their origin in the information processing approach to cognition (Broadbent, 1958; Neisser, 1967). Where behaviorism stressed the importance of the environment, the information processing approach puts a strong emphasis on the internal cognitive state of humans, and aimed to study the complexity of their cognitive processes. Information processing theorists viewed the human mind as an information processing device containing distinct components: A sensory register, a short-term memory, and a long-term memory. The sensory register is an extremely short-term buffer of information, long enough to determine (unconsciously) whether information should be passed on to short-term memory or, alternatively, be discarded. Short-term memory is comparable to the central processing unit of a computer, being all that is in the direct and immediate attention of the individual, limited in capacity and duration. Short-term memory integrates information from long-term memory and the current environment. Long-term memory refers to all the knowledge that is stored in the human brain for long-term use. Knowledge in long-term memory that is not currently used is inactive, but can be retrieved and manipulated in short-term memory when necessary.

The implications of information processing theories for education lie in the supposed three-component architecture of the human mind. Educators therefore need to take into account the computer-like structure of the human mind, not only receiving information, but actively processing it as well (Craik & Lockhart, 1972). Grouping information into meaningful parts (referred to as chunking) increases the chances of remembering the information and reduces short-term memory load. Moreover, instruction should focus on rehearsal of information in short-term memory to enable storage in long-term memory. When a learned procedure is rehearsed often enough, it becomes automatized and can be executed without effort. Finally, learners should be stimulated to actively retrieve information from long-term memory when necessary and use it in short-term memory. Information processing theorists would argue that the most important factor influencing learning is: "*the active mental processing of information*."

Symbolic Cognitive Theories

Symbolic cognitive theories build on the computer metaphor introduced by information processing theories, but describe knowledge in such a way that meaning is conveyed. A basic distinction is between models that describe declarative knowledge and models that describe procedural knowledge. Declarative knowledge refers to representations of the outside world and is typically modelled in semantic or propositional networks (Quillian, 1967), which may vary from plain facts, via simple schemas (e.g., concepts, principles), to highly complex schemas (e.g., conceptual or causal models of a complex domain). This notion reflects ideas from schema theory as introduced by Piaget (1975, original work 1929) and Bartlett (1932). Procedural knowledge refers to cognitive processes that operate on these representations; it is typically modelled in productions or cognitive rules (Anderson, 1993), which link particular conditions to cognitive or motor actions (IF condition THEN action). Symbolic cognitive theories make it possible to give a highly detailed description of to-be-learned knowledge in a process of Cognitive Task Analysis (CTA; Clark, Feldon, van Merriënboer, Yates, & Early, 2008) and to develop computer programs that model this knowledge.

An example of an instructional theory largely based on symbolic cognitive theories is van Merriënboer's four-component instructional design model (4C/ID; 1997, 2007). This model describes learning environments aimed at complex learning as built from four components: (1) learning tasks, which provide the backbone of an educational program, (2) supportive information, which provides the information helpful to perform nonroutine aspects of learning tasks (e.g., problem solving, reasoning), (3) procedural information, which provides the just-in-time information helpful to perform routine aspects of learning tasks, and (4) part-task practice, which helps to automate selected routine aspects of learning tasks. Components 1 and 2 are based on theories of schema construction or declarative learning, in particular, models of inductive learning (i.e., learning from different concrete experiences) for learning tasks, and models of elaboration (i.e., learning by connecting new information to what you already know) for supportive information. Components 3 and 4 are based on theories of schema automation or procedural learning, in particular, models of knowledge compilation (i.e., embedding new information in cognitive rules) for procedural information, and models of strengthening (i.e., automating cognitive rules by repetition) for part-task practice. A learning environment built from the four components thus promotes four simultaneous learning processes in a process of complex learning. Those learning processes will be more effective as the learner has more knowledge to begin with, and instructional methods that may be effective for learners with little prior knowledge will often be ineffective for learners with high prior knowledge (i.e., the "expertise reversal effect"; Kalyuga et al., 2003). If researchers working in the cognitive symbolic paradigm were asked what the most important factor influencing learning is, their answer would be similar to the well-known statement of Ausubel (Ausubel, Novak, & Hanesian, 1978): "*The most important factor influencing learning is what the learner already knows. Ascertain this and teach him accordingly*."

Cognitive Resource Theories

Like cognitive symbolic models, cognitive resource theories build on the computer metaphor of the human mind. But in contrast to symbolic cognitive models, resource models do not refer to semantic representations in memory that convey meaning but limit themselves to a specification of human cognitive architecture and, especially, the capacity of memory systems. Most resource models make a distinction between working memory and long-term memory to explain why available cognitive resources for learning and performance are limited. Whereas the capacity of long-term memory is virtually unlimited, working memory is very limited in duration and in capacity. Information stored in working memory and not rehearsed is lost within 30 s (Baddeley, 1992) and the capacity of working memory is limited to Miller's (1956) famous 7 ± 2 elements or, according to more recent findings, even 4 ± 1 element (Cowan, 2001). The interactions between working memory and long-term memory are even more important than the direct processing limitations of working memory itself (Sweller, 2004). The limitations of working memory only apply to new, yet to be learned information that has not been stored in long-term memory. When dealing with previously learned information stored in long-term memory, the limitations disappear because constructed schemas in long-term memory can be handled as one element in working memory.

In the field of instructional design, cognitive load theory (Sweller, van Merriënboer, & Paas, 1998; van Merriënboer & Sweller, 2005, 2010) is a popular theory based on cognitive resource theories. The main assumption is that effective instruction should limit extraneous or ineffective cognitive load on working memory, so that the available resources can be used for genuine learning, that is, the construction and automation of schemas in long-term memory. One process that causes a high extraneous cognitive load is, for example, conventional problem solving. For novice learners, problem solving is only possible thanks to means-ends analysis, which requires the student to consider differences between the goal state and the given state of the problem, and to search blindly for solution steps to reduce those differences. This process is exceptionally expensive in terms of working memory capacity and bears no relation to schema construction processes concerned with learning to recognize problem states and their associated solution steps. Problem solving and learning to solve problems are thus two very different and incompatible processes! For teaching problem solving, cognitive load researchers devised more effective problems formats such as goal-free problems (Ayres, 1993), worked-out examples (Renkl, 1997), and completion problems (Van Merriënboer, 1990). If researchers working in the cognitive resource paradigm were asked what the most important factor influencing learning is, their answer would be: "*The limited processing capacity of the human mind*."

Social Constructivist Theories

Social constructivism has its roots in developmental psychology (Jean Piaget, 1896–1980†), cultural-historical theory (Lev Vygotsky, 1896–1934†) and, to a somewhat lesser degree, Gestalt psychology (Max Wertheimer, 1880–1943†). Jean Piaget was the first to emphasize the constructive nature of the child's mind: The child actively attempts to construct understanding of the outside world. Wertheimer stressed the importance of productive thinking as a reconstructive act. Vygotsky, who was also influenced by Gestalt psychology, independently came to similar conclusions as Piaget with regard to the importance of constructivist action to promote learning (*see* Dockrell, Smith, & Tomlinson, 1997). Social constructivism deviates from Piaget's idea of constructivism, in that it stresses, like cultural-historical theory, the importance of *social* interaction to achieve understanding (Palincsar, 1998). It argues that knowledge and even our idea of reality arise through social relationships and interactions. That is, everything we know we have learned by communicating and interacting with others, either personally or through multimedia. The social constructivist is interested in how an individual learns as a result of these interactions. Radical constructivism (Von Glasersfeld, 1995) takes these ideas a few steps further, stating that all knowledge is created by the human mind and therefore it is impossible to know to what extent this corresponds to ontological (true) reality.

Social constructivism was developed in the 1990s and is very popular in education and educational research today. It is not surprising that it puts a strong focus on student discussion and learning through multimedia. Many popular educational formats such as problem-based learning and computer supported collaborative learning (CSCL) have their roots in social constructivism. According to social constructivism small or large group discussion increases student motivation, and builds a deeper understanding of what students are learning. It also provides support for self-regulation of learning, as students can test the quality of their knowledge on that of peer students. Jonassen (Jonassen, Carr, & Yueh, 1998) advocates the use of cognitive tools or mindtools from a social-constructivist perspective. Cognitive tools refer to computer tools that are designed to foster information gathering and learning. These include concept mapping software, spreadsheets, but also internet forums and Google. They are preferable for teacher-centered education as they actively engage the learner and improve students' sense of ownership of their knowledge. Social constructivist theory discourages the use of traditional lectures, because of the minimal opportunities for communication and discussion with the teacher and fellow students. According to social constructivism the most important factor influencing learning would be: "*The construction of meaning and knowledge through the interaction with others*."

Discussion and Conclusions

Instructional theories relate instructional methods to each other and to learning processes and learning outcomes. The relations between methods and outcomes are, however, never straightforward. There are numerous conditions that affect the relationships between methods and outcomes: This ubiquity of interactions leads to a combinatorial explosion of factors influencing learning. Consequently, the universe of instructional theories is practically infinite and each instructional theory is dealing with only a small fraction of the whole universe. Scientific paradigms determine which fraction of the universe theories developed within this paradigm are looking at. Eight dominant paradigms in the field of educational communications and technologies were discussed, each with their own perspective on learning and their own focus on one or more particular factors influencing learning. Gestalt psychology focuses on how learners reach *insight and understanding*; behaviorism and neo-behaviorism focus on the effects of *reinforcement* on learning; developmental psychology focuses on the *stage of cognitive development* of the learners; cultural-historical theory focuses on the learners' *interaction with the world*; information processing theory focuses on *active mental processing* by the learners; symbolic cognitive theories focus on the learners' *prior knowledge*; cognitive resource theories focus on the *limited processing capacity* of the human mind, and social constructivism focuses on the *social construction of meaning* by learners.

Because the paradigms and theories developed within these paradigms have little in common, it is often difficult if not impossible to compare them. The different ways of looking at reality may produce different results. For example, researchers working in the neo-behaviorist paradigm report consistent positive results of reinforcement on learning outcomes (e.g., Flora, 2004), while researchers working in the social constructivist paradigm also report negative effects because external reinforcements may harm intrinsic motivation (e.g., Sivan, 1986). Both claims are based on sound research but nevertheless reach different conclusions because research questions, methods, and interpretations of results are fundamentally different. This also makes it difficult to reconcile the different claims (but see Cameron & Pierce, 2002). In this respect, Berliner (2002) also refers to "decade by findings interactions," meaning that results may also be different depending on the period in which the research has been done. For example, in the 1960s sound research was done on differences in achievement motivation between boys and girls. Nowadays, these results are worthless because the feminist revolution has worked its way through society—changes in context have changed the results of the interaction under study.

Whereas different paradigms may have little in common, progress in one particular paradigm is often made by lending ideas from other paradigms. For example, Piaget's developmental psychology is influenced by ideas on structural understanding from Gestalt psychology; cognitive symbolic theories and cognitive resource models both build on information processing theory; cognitive symbolic theories acknowledge the importance of limited working memory and also include ideas from schema theory originally developed by Piaget (1929) and Bartlett (1932), and social constructivist theories include ideas from developmental psychology, cultural-historical theory, and Gestalt psychology. Especially some of the newer paradigms have borrowed from many of the older ones. The influential report *How people learn* (National Research Council, 2000) reflects much of the current thinking in these newer paradigms.

Research paradigms have clear implications for both research and design. Researchers in different paradigms do research on different things because they focus on different learning outcomes, methods, and conditions. Consequently, they will also focus on the design of different instructional measures, such as hints (Gestalt psychology), rewards (behaviorism), discovery learning (developmental psychology), dialogue (cultural historical theory), programmed instruction (information processing theory), learning by doing (symbolic cognitive theories), example-based learning (cognitive resource models), or collaborative knowledge building tools (social constructivism). Yet, although different ways of looking at reality may produce different results, they do not exclude the identification of basic principles in learning, just as a biologist doing research on ecosystems on Earth and an astronomer doing research on the climate on Mars might reach the same conclusions on conditions for life on a planet. Merrill's work on "first principles of instruction" (2002), for example, shows that five principles are quite common over different paradigms, including paradigms that are often contrasted with each other such as symbolic cognitive theories and social constructivist models. The first principles state that learning is promoted when learners: (1) work on meaningful problems, (2) activate previous experience, (3) observe what is to be learned, (4) apply what has been learned, and (5) integrate what has been learned into their everyday life.

What are the implications of the existence of different paradigms and perspectives on learning for doing research in the field of educational communications and technology? First, it should be clear that educational researchers should be conscious of the paradigm they are working in, including its opportunities and limitations. Second, within this paradigm, they should deliberately contribute to theory development because researchers without a theory are like wanderers in the desert and their research results will be blown away like sand. Third, researchers should always have an open mind for research based on competing theories and paradigms, because radically new ideas and perspectives will most likely develop at the interface between paradigms.

Research-Based Instructional Perspectives

3

Gary R. Morrison and Steven M. Ross

Abstract

Instructional technology research is broad both in terms of topics and explorations of basic and applied research. In this chapter, we examine various types of stimulus materials that instructional technology researchers have used to study different phenomena. Specifically, we discuss and illustrate how the choice of stimulus material (e.g., actual lesson content, pictures, prose, etc.) directly influences the internal validity (rigor) and external validity (generalizability) of the findings. While randomized experiments are considered the so-called gold standard (Slavin, Educational Researcher 37(1):5–14, 2008) of educational research, particularly for evaluating the effectiveness of instructional strategies, these studies may employ artificial or novel stimulus materials that can limit generalization of the results. Since one goal of instructional technology research is to provide evidence that allows the instructional designer to generate heuristics easily applicable (i.e., generalized) to new situations, studies with strong external validity should be highly desired. Similarly, there are also instances where initial studies need to be designed with high internal validity, sometimes at the sacrifice of external validity, to control for extraneous variables. Using selected studies as illustrative examples, this chapter examines how validity has been addressed in instructional technology research.

Research • Educational psychology • Educational technology • Stimulus materials • Internal validity • External validity

Introduction

The field of instructional technology began developing a rich knowledge base of research studies focusing on instructional technology with the start of *Audio-Visual Communications Review (AVCR)* in 1954. While the field has mostly avoided meaningless media comparison studies in recent years (Clark, 1983), the breadth of topics continues to grow. Our earlier analysis of research methodologies employed in articles published in AVCR, *Educational Communications and Technology Journal (ECTJ), and Educational Technology Research & Development (ETR&D)* (Ross & Morrison, 1996, 2004) found that the trends in the use of methodologies have changed over time. For example, time series studies dominated the first 10 years of AVCR publication, but have all but disappeared from ETR&D. In contrast, we have seen a steady increase of studies employing true experimental designs that was the dominant methodology from 1973 to 2001. More recently, we have examined the number

of studies classified as intervention research (Levin, 2004), that is, studies designed to compare two different instructional treatments such as immediate feedback compared to delayed feedback. We found a steady decline (Ross et al., 2008) in intervention studies in ETR&D similar to the trend in educational psychology journals (Hsieh et al., 2005).

In this chapter, we focus on how instructional technology researchers have designed the stimulus materials used in their studies to strengthen either the internal or external validity of findings. For readers who desire a more in-depth discussion of quantitative and qualitative methods, we suggest the various chapters in all four editions of this handbook. In the following section, we start with a brief discussion of internal and external validity issues in instructional technology research. Then, we examine the design of stimulus materials in studies with high internal validity and studies with high external validity. Last, we address the issue of generalization of results in instructional technology studies based on both the choice of stimulus materials and the degree to which the study participants mindfully engage with the material to be learned.

Validity Issues in Instructional Technology Research

Experimental research in education and psychology values studies establishing high internal validity to eliminate any unintended variables influencing the results (Ross & Morrison, 2004). According to Slavin (2008), researchers can further maximize high internal validity by using a randomized assignment of participants to treatments to eliminate systematic error. The quest for high internal validity orients researchers to design experiments in which treatment manipulations can be tightly controlled. In the process, using naturalistic conditions (e.g., real classrooms) becomes challenging, given the many extraneous sources of variance that are likely to operate in those contexts. For example, the extensive research conducted on verbal learning in the 1960s and 1970s largely involved associative learning tasks using simple words and nonsense syllables (Paivio, 1971; Underwood, 1996). With simplicity and artificiality comes greater opportunity for control of the variables.

This orientation directly supports the objectives of the basic educational psychology researcher whose interests lie in testing the generalized theory associated with treatment strategies, independent of the specific methods used in their administration. Educational technology researchers, however, are interested in the interaction of medium and method or instructional strategy, or simply the instructional strategy (Bernard et al., 2004; Bernard et al., 2009; Clark, 2001; Kozma, 1991, 1994; Ullmer, 1994). To learn about this interaction, realistic instruction rather than artificial or contrived instruction needs to be used. In other words, external validity becomes as important a concern as internal validity.

Discussing these issues brings to mind a manuscript that one of us was asked to review a number of years ago for publication in an educational research journal. The author's intent was to compare, using an experimental design, the effects on learning from programmed instruction and computer-based instruction (CBI). To avoid Clark's (1983) criticism of performing a media comparison, i.e., confounding media with instructional strategies, the author decided to make the two treatments as similar as possible in all characteristics except delivery mode. This task essentially involved replicating the exact programmed instruction design in the CBI condition. Not surprisingly, the findings showed no difference between treatments, a direct justification of Clark's position. But, unfortunately, this result (or one showing an actual treatment effect as well) would be meaningless for advancing theory or practice in educational technology. By stripping away the special attributes of a normal CBI lesson (e.g., interaction, sound, adaptive feedback, animation etc.), all that remained were alternative forms of programmed instruction and the unexciting finding, to use Clark's metaphor, that groceries delivered in different, but fundamentally similar ways still have the same nutritional value. Needless to say, this study, with its high internal validity but very low external validity, was evaluated as unsuitable for publication.

Stimulus Materials in Studies with High Internal Validity

Studies in instructional technology research that require high internal validity often focus on attributes of a medium such as on the legibility of projected materials (Adams, Rosemier, & Sleeman, 1965; Snowberg, 1973) or the design of CBI screens and materials (Acker & Klein, 1986; Grabinger, 1983; Morrison, Ross, Schultz, & O'Dell, 1989; Ross, Morrison, & Odell, 1988). Similarly, studies examining imagery (McManis, 1965; Noble, 1952) or exploring how individuals learn relationships from a diagram (Winn & Solomon, 1993) may use an experimental design with high internal validity to control for other variables. When designing these studies, the researchers must decide if internal or external validity is of greater importance. For example, consider the text in Fig. 3.1 which a researcher might use to investigate the emotional meaning of a particular typeface. In the first row, a real word is displayed in the two different

Fig. 3.1 Comparison of two types of stimulus materials

typefaces. If the participants indicated that the typeface on the left was light and elegant, reviewers might question the interpretation because of the word jewelry. Similarly, the word muscle printed in a bold, heavy font would also confound the interpretation of the meaning of the typeface. The second row uses nonsense words that have no meaning and allows the researcher to conclude that any meaning derived from the rating is due to the typeface. The first row of words has high external validity because of the use of real words; however, the words may influence the participants' rating of the typeface. The second row has high internal validity, but generalizing the results raise additional questions for application. Specifically, typefaces are rarely used in the absence of words and phrases having meaning. It thus seems highly probable that the emotional valances determined using nonsense words would vary (perhaps even considerably) when the same typefaces were employed with instructional text or popular literature.

Given these options, instructional technology researchers initially may decide to establish a theoretical construct (e.g., emotional connotation of type) by using the second row of stimuli. Thus, internal validity would be emphasized over external validity for this basic research study. After establishing the construct, they may design applied studies using materials with a high external validity to test the application of the construct in a more realistic context. In the following section, we illustrate these trade-offs by examining several studies that focus on media attributes and the type of stimulus materials they employed.

Using Artificial Materials in Studies of Media Variables

An example of a highly controlled study is one conducted by Snowberg (1973) examining the use of background colors in projected media. One of the concerns expressed by Snowberg was that the selection of colors as backgrounds for the slides offers almost limitless possibilities. To address this problem, Snowberg selected a range of color filters that allowed for replication. Additional neutral filters were combined with the color filters so that each background was of the same brightness or luminance, thus avoiding a difference between background colors. Ten letters for the stimulus materials were taken from a Snellen chart to create a chart similar to those used by optometrist to check visual acuity. By controlling the five colors, providing for brightness control, and using standardized letters; Snowberg was able to isolate the legibility of projected letters on various colored backgrounds. If real words were used, the participants could possibly have identified or guessed the word based on a few letters, thus reducing the number of possible answers. By using individual letters, the participant had to distinguish between letters such H, D, N, O, and C. This controlled study allowed the researcher to examine the media attribute, the effect of background color on letter legibility, while controlling for confounding variables.

While these recommendations provide seemingly useful guidelines for selecting backgrounds for the best legibility, other color background variations could provide more aesthetically pleasing colors and larger more readable text. That is, one would seldom need to use a small (minimal legibility) font with black text on a white background, which was found to be the minimally legible combination. Thus, replicating this basic design using realistic materials and other background colors would be a logical extension of Snowberg's study. For a typical classroom, you might not need maximum legibility, but rather acceptable readability and an aesthetically pleasing display. An applied research study might also determine that attentiveness is also contextually (e.g., schools' colors) or gender (e.g., pink vs. blue as a preference) linked. Nonetheless, Snowberg's findings are valuable for establishing basic legibility principles that are minimally contaminated by extraneous variables.

In another study of legibility, Adams et al. (1965) studied the legibility of typewritten fonts projected on a white background. They also used letters from a Snellen chart and created stimulus slides consisting of five different type sizes ranging from 3/32 to 8/32 of an inch. Participants were elementary school students who were asked to judge the slides from distances of 20, 25, 30, and 40 feet from the screen in a darkened room. Adams et al. concluded the two smaller type sizes should be avoided, particularly if the viewing distance was beyond 20 feet. Findings indicated that letters at least 6/32 to 8/32 of inch (about 14–18 points) should be used.

These two studies (Adams et al., 1965; Snowberg, 1973) address questions of legibility of projected visuals. Both focused on recognizing individual letters (legibility) rather than words (readability) (Craig & Bevington, 2006). The results establish the color combination or letter size with the best legibility. Similarly, both Snowberg (1973) and Adams et al. (1965) have identified the *smallest* font one should use. These studies raise the question of whether a study using realistic words and sentences would produce similar results, especially if it examined larger font sizes rather than the minimum specified. How this question is answered directly bears on the external validity of the original (basic research) findings. For example, a typical classroom would not have the lighting controls used by Snowberg (1973) for either projection or ambient light. Thus, assuming that the brighter ambient lighting in a typical classroom would reduce the contrast between the words and lettering, we might find that a larger font size is needed.

An extension of this research (Aslan, Watson, & Morrison, 2011) is a study in progress in which participants use a paired-comparison technique to select the PowerPoint slide design they most prefer. The slides were designed using 20-, 24-, 28-, and 32-point text with realistic material (bonsai art), but unrelated to the interests of the participants. The researchers were not interested in the smallest legible text, but rather an optimal-sized text. As the font size increases, the number of words and the length of each phrase on a line become shorter. Thus, the contextual support is also reduced (Ross & Morrison, 1989) when font size is increased. As an extension of the basic research studies reviewed, additional studies using realistic materials in natural settings are needed to find the balance between the smallest legible font and a readable font that provides adequate contextual support using aesthetically pleasing color combinations.

Using Artificial Materials to Study Learning

To control for prior knowledge, many studies examining serial learning and imagery have used nonsense words (McManis, 1965; Noble, 1952). Instructional technology researchers have adopted other approaches to control for internal validity in applied research. In a study of the effect of concrete-verbal and visual information on mental imagery, Clark (1978) selected abstract geometric figures for participants to reproduce. Participants were presented either (a) picture only, (b) printed instructions for creating the drawing, (c) audio only instructions, (d) audio with pictures, (e) audio and video of the instructor giving directions, or (f) audio instructions while showing the instructor. Participants then reproduced from memory the drawing described in the stimulus materials. The general hypothesis was that dual channel presentations would be more effective. By using abstract geometric figures that were the equivalent of nonsense words, Clark could increase internal validity by controlling for prior knowledge of the image.

When studying the effectiveness of objectives, overviews, or inserted questions, the stimulus materials require one or more pages of meaningful textual information so the participant can answer test questions. However, the meaningful text introduces a confounding variable that can threaten internal validity as the participants may have relevant prior knowledge. Consider the study by Hannafin, Phillips, Rieber, and Garhart (1987) who examined two different types of orienting strategies on learning. Participants received either a behavioral orienting strategy that directed them to focus on a specific name, place, or date; or a cognitive strategy that directed them to focus on a broader topic such as culture. The control group was advised simply to pay attention to the material. Given the nature of this study, careful consideration was needed for selection of the stimulus material. For example, if they were to select a chapter from a science textbook on the solar system, some students might have prior knowledge they could use to answer the items on the pretest. The use of nonsense words or even a foreign language as used in Ho's (1984) or Winn, Li, and Schill (1991) studies is not practical when students must learn from textual materials.

To reduce the threat to internal validity, Hannafin et al. (1987) used a fictitious story that included realistic scientific, cultural, political, and geographic elements to create a plausible story line. This contrived story allowed participants to apply intact scientific knowledge to a novel topic. Results indicated that the behavioral and cognitive strategies were more effective for factual learning while the control group showed superior performance for inferential learning. Two explanations of these results were offered. First, students revert to their own preferred approach for learning and ignore the recommended strategy. Second, the orienting activities were ineffective because the materials included sound design features that reduced the effectiveness or need for an orienting strategy. By using a fictitious, but realistic scenario Hannafin et al. were able to reduce the threat to internal validity from prior knowledge and increase the external validity by using contrived, but realistic appearing materials.

While artificial stimulus material allows the researcher to control for other variables such as prior knowledge, generalization of the results therefore is more limited. To the degree that instructional technology research is expected to inform practice, an impact that some researchers have questioned (Ross, Morrison, & Lowther, 2010), it would seem the use of realistic material in natural settings would be more valuable in using technology as a teaching and learning tool.

Stimulus Materials in Studies with High External Validity

Examples of progressing from highly controlled to more realistic application contexts come from CBI research. CBI tends to present information on individual screens with the learner having the capability to navigate between screens rather than scrolling through the instruction as one might do with electronic text.

From Basic to Applied Research: Contrasting Internal and External Validity

When an individual screen design (or frame) is used to present the stimulus material or the instruction, there is a limited number of characters or words the designer can include on a single frame much like we are limited to how many characters or words we can type on a single sheet of paper with 1 in. margins and 12 point Times Roman font. Grabinger (1983) was one of the first to study screen design layout for CBI. To control for confounding variables, Grabinger created stimulus screens consisting of x's and o's (e.g., XxxxoooxxxxooooXxxooooxxxoo) to control for any meaning the message might include that could influence the participants preference for the design. Participants were shown two different designs on identical monitors side-by-side and asked to indicate which one they preferred. Results were similar to those for printed instruction (Dair, 1967), indicating a preference for large amounts of white space and screens with sparse amounts of text.

Using Grabinger's (1983) research as a starting point, we conducted several studies to extend the original research to realistic materials. In the first study, Morrison et al. (1989) used realistic stimulus materials to test Grabinger's findings. Several authors in addition to Grabinger suggested the use of white space for CBI screen design as the designer was no longer constrained by properties of the printed page (Allessi & Trollip, 1985; Bork, 1987; Hooper & Hannafin, 1986). However, as the amount of white space increases on the screen, the amount of information decreases requiring the reader to read additional screens to obtain the same amount of information. The first study by Morrison et al. examined learner preferences for screen density when realistic instructional materials were used. A lesson from a unit on measures of central tendency was selected. To allow for replication and application, we used a measure of screen density that calculated the maximum number of characters that could be displayed on a screen and then divided the actual number of characters to arrive at a screen density percentage creating four different density levels. Two designs were shown one at a time in a random order for a total of six pairings.

The results indicated that participants preferred the 31% density screen over the others. It appears that participants desired greater contextual support when viewing realistic materials than when viewing artificial designs that lacked meaning. The Morrison et al. (1989) study extended Grabinger's work through the use of high external validity materials to test the assumptions in a realistic setting. Importantly, it supported somewhat different design principles, namely, that density reduction and contextual support need to be balanced to maximize readability.

Comparing Internal and External Validity in a Single Study

The results of the two previous studies raised additional questions. For example, as the density (i.e., number of words on the screen) increases, the number of screens needed to read the same materials decreases. At first glance, it would seem logical to have the participant review *all* the screens for each density level (one to four screens depending on the density level). However, if the participants tended to select the higher density screens, one might conclude it was the easier choice since they only had to review one or two screens. To determine if the number of screens viewed would influence the preference, two additional treatments were added. In the first treatment, participants *only* viewed the first screen for each density level. In the second treatment, participants were required to review all screens for a density level before making a choice. In this study, Ross, Morrison, and Schultz (1995) compared realistic materials, approximation to English (ATE) (nonsense words with same letter pattern as English), and nonsense notation (x's and o's) used by Grabinger (1983). The realistic materials were the same used by Morrison et al. (1989). Four different screen designs consisting of 53, 31, 26, and 22% density were employed, with each requiring 1, 2, 3, and 4 screens, respectively, to present the full content. The resulting design consisted of three types of text, four density levels, and two screen conditions (first screen only or all screens of the density level). The six comparisons of four density levels for a specific text type (realistic lesson, ATE, or nonsense) were presented in a random order and rated until all three text types were judged by each participant. Overall, the higher density screens were preferred for realistic materials while the lower density screens were preferred for the artificial text (ATE and nonsense). The results confirmed our hypotheses that students wanted more information on a single screen when viewing realistic materials, but preferred more white space when viewing nonrealistic or nonsense materials.

Using Realistic Learning Material to Increase External Validity

Tessmer and Driscoll (1986) investigated the effectiveness of a concept tree and narrative text for learning coordinate concepts with high school students taking physics. Stimulus materials that had multiple related concepts were needed for the study. It would have been extremely difficult to create fictitious stimulus materials of this complexity. Therefore, Tessmer and Driscoll selected a physics unit that the classroom teacher judged as unfamiliar to the students based on past performance. The stimulus materials were then created for each treatment based on realistic materials. The participants were given 20 min to read the treatment materials and then completed an immediate posttest followed by a delayed posttest. Participants in the concept tree treatment performed better on concept classification. Although using realistic material increased the risk that students' prior knowledge and experiences in the physics course would bias treatment effects, it significantly increased the external validity of the study and the implication that the concept tree could be a useful applied instructional strategy.

Another example of a study with high external validity is one conducted by Ross and Anand (1987) which used realistic instructional materials and personalized those materials for one treatment group. Participants were fifth- and sixth-grade students who received stimulus materials that taught the procedures for dividing by fractions. The abstract treatment group received examples and problems that referred to items as quantity, fluid, liquid, and so forth. The concrete treatment group received examples and problems that substituted hypothetical concrete referents such as Bill, Joe, English, artist, etc. In the personalized treatment group, personal information collected from a biographical survey was inserted into the examples and problems so the participant saw his or her name, best friends' names, birth date, pet's name, and favorite candy. Participants in all three treatments received the same examples and problems; only the context used for presenting the examples and problems was modified by substitution of words. The results indicated that students in the personalized treatment performed significantly better on the context subtest and transfer test. By using realistic materials, the researchers provided evidence of the potential effectiveness of the personalization strategy for applied classroom use.

More recent examples of the use of realistic materials include the use of an existing problem-based learning unit from science (Song & Grabowski, 2006), a math unit on addition subtraction developed by the researchers (Kopcha & Sullivan, 2008), and the use of two different math units of which one was a commercial product (Roschelle et al., 2009). By using experimental or quasi-experimental designs, these studies combine moderate to high levels of both internal and external validity.

Realistic Materials and Incentives: Are They Adequate?

As researchers, it is easy (and comforting) to assume that if we use realistic materials that are relevant to our participants, such as a unit on momentum for students in a physics class or a unit on writing objectives for pre-service teachers, they will put forth the same effort to learn as they would if studying for a class. Given this assumption and the contradictory results in the research literature on feedback, we decided to explore whether feedback strategies would operate differently under varied incentive conditions for learning (Morrison, Ross, Gopalakrishnan, & Casey, 1995).

The 246 participants in the feedback study were drawn from two pre-service teacher education courses (Morrison et al., 1995). The instructional materials were designed to be relevant to students' academic preparation by focusing on writing behavioral objectives, the three domains of objectives, and the taxonomy of behavioral objectives. Students from each of the two classes were randomly assigned to one of five feedback treatments including knowledge of correct response (KCR), delayed with immediate knowledge of response (e.g., correctness of answer), answer until correct (AUC), questions with no feedback, no questions or feedback. Participants from the first course were in the performance incentive group as they could use the score from the treatment to receive credit for a required unit on objectives. Participants in the second course were classified as the task incentive group as they received five bonus points for participating in the study. It was predicted that participants in the performance incentive group would show greater motivation to learn and mindfully use the feedback, particularly in the more complex (i.e., KCR and AUC) feedback treatments. This assumption was only partially supported. The performance incentive group did learn more and made greater use of the review opportunities after answering a question. However, differences between groups for selecting the option to review were not significant. When participants complete an artificial learning task as the task-incentive treatment, they may show little interest in mastering content or in using the instructional resources such as feedback. One concern for researchers is how to motivate them to go beyond surface processing of the content and engage in a deeper level of processing that produces meaningful learning (or at least emulates real-life learning processes). While the performance incentive (substitute study performance for a course assignment) in the above study did appear to motivate the performance-incentive group to perform well, it was not enough to promote a deeper level of processing or make extensive use of the feedback. Thus, generalizability to real-life instructional contexts, where there is greater accountability for achievement, may be limited.

Conclusion

In this chapter, we have examined the use of stimulus materials in instructional technology research. Depending on the purpose of the research, the stimulus materials can range from artificial using nonsense symbols, to contrived materials using real words or text, and ultimately to realistic using actual lesson content. The selection of the type of stimulus materials is determined primarily by the focus of the research—verifying basic laws and principles of learning using technology or evaluating the effectiveness of applied instructional strategies using technology. Underlying the particular focus and concomitant selection of stimulus materials is the researcher's emphasis on addressing different types of validity concerns. Basic research studies rely primarily on materials that foster high internal validity by controlling extraneous variables relating to the learner characteristics and the learning context. Applied studies place a greater emphasis on external validity to allow for generalization of the results to real-life learning contexts. It is this trade off that often requires researchers to begin a new area of inquiry with a study emphasizing high internal validity to isolate variables and phenomena. As a subsequent step, the laws and principles supported in the initial basic research are tested in realistic settings to determine their utility for different application contexts.

While the design of stimulus material directly influences the absolute and relative strengths of internal and external validity in a research study, the meaningfulness of the evidence obtained also depends on the degree to which the study participants mindfully engage with the instruction. That is, whether the material to be learned consists of nonsense symbols or material straight from the textbook currently being used, if participants' primary incentive is to earn extra credit points that are noncontingent on performance, both internal validity (i.e., appropriate treatment induction) and external validity (realistic learning conditions) are likely to be compromised. Instructional technology research needs to continue to focus on relevant and quality research that addresses issues relevant to the field and to education in general. Studies are needed that help practitioners solve practical problems. But unless the research designs employed establish sufficient rigor, the results may not accurately reflect the uses and impacts of the technology applications examined (Ross et al., 2010).

Cousins but Not Twins: Instructional Design and Human Performance Technology in the Workplace

4

Wellesley R. Foshay, Steven W. Villachica, and Donald A. Stepich

Abstract

Instructional design (ID) and human performance technology (HPT) stem from a common origin in systems thinking and behavioral psychology, but today the two fields employ different research bases, system foci, and methods. To contrast these fields, this chapter presents an idealized and abstracted discussion that examines the theoretical origins of the two fields, briefly describes their similarities, and focuses on their differences in terms of analytical frameworks and methods. We conclude that contemporary practice in most contexts combines elements of ID and HPT, particularly when working in cross-functional teams seeking to improve organizational performance. Practitioners of ID are likely to encounter HPT in their work, and they may be called upon to serve as part of a cross-functional team using HPT as a common conceptual framework.

Keywords

Educational technology • Human performance technology • Instructional design • Instructional designer • Performance-based training • Training

Introduction

While they share commonalities, instructional design (ID) and human performance technology (HPT) employ different research bases, system foci, and methods. Practitioners of ID are likely to encounter HPT in their work, and they may be called upon to serve as part of a cross-functional team using HPT as a common conceptual framework. Some ID professionals have successfully broadened their careers to include both training interventions (using ID) and non-training interventions (using an HPT framework and drawing from other fields). The relationship between the two is sufficiently close that some professional preparation programs in ID also offer HPT electives and concentrations. Other programs focus on HPT, with additional coursework in ID. For all these reasons, it is probably a good idea for ID professionals to have at least some awareness of HPT.

To contrast these fields, this chapter presents an idealized and abstracted discussion that examines the theoretical origins of the two fields, briefly describes their similarities, and focuses on their differences in terms of frameworks and methods. The chapter concludes with a description of a "savvy instructional designer" that combines elements of ID and HPT. To avoid presenting idiosyncratic comparisons as generalities, the chapter employs widely cited ("classic") references that provide a representative view of each field. The authors encourage readers to consult these references for more thorough introductions to HPT.

Origins of ID and HPT

Historical accounts of the origins of systematic ID in the 1960s typically attribute its roots to a combination of the then-dominant behavioral learning psychology, combined with the metaphorical inspiration of general systems theory. This resulted in the endless variations of the analysis-design-develop-implement-evaluate (ADDIE) model (Molenda, 2003), which IDs came to accept as both

- An analytical framework for systems thinking and design in training and education
- A project management structure for development, implementation, and maintenance

Drawing on educational psychology, educational technology, instructional technology, communications, and related fields, IDs now create instruction for a broad variety of populations in different settings. IDs may support populations in educational settings in K-12 schools, colleges, and universities. IDs may also support workplace populations in business, government, military, and nonprofit settings. Aguinis and Kraiger (2009) define "training" as a systematic approach to learning with the goal of improving individual, team, and organizational effectiveness. They maintain that development refers to the acquisition of new knowledge or skills for purposes of personal growth. As it is difficult to determine where one ends and the other begins, this chapter uses the term "training" to describe any instruction occurring in the workplace. Because there is as yet little documented application of HPT in school settings, this chapter examines ID and HPT in workplace settings and excludes educational settings.

ID and HPT share a common analytical framework drawn from operations research and common origins in behavioral psychology (Definition & Terminology Committee of AECT 2007). Historical accounts of ID often fail to mention that similar efforts at systems thinking and systematic development were taking place in a wide range of fields over the same time. Of particular interest are American industrial training specialists and industrial psychologists, who found useful a similar, ADDIE-like framework for systematic analysis and intervention to improve human performance in organizations (for an early example, *see* Gilbert 1996a, 1996b). According to Rummler (2007), the roots of HPT arose in the 1960s, with publications appearing in the 1970s. These publications include the work of early theorists such as Mager and Pipe (1970), Rummler (1972), Harless (1973), and Gilbert (1996a, 1996b). In time, leaders active in what is now the International Society for Performance Improvement (ISPI) came to refer to the many variations of this framework collectively as HPT (Van Tiem et al. 2004). Practitioners now refer to HPT using a variety of terms, including "workplace learning and performance improvement" (Beich, 2008). In addition to behavioral psychology and disciplines related to ID, HPT draws on additional disciplines ranging from organizational development to process improvement. Unlike the research base supporting ID, empirical research in HPT is largely limited to reporting cases studies consisting of various performance improvement solutions.

Contrasting ID and HPT

In workplace environments, ID and HPT practitioners can share a variety of goals, frameworks, methods, and evaluation strategies while differing in subtle but important ways. Four commonalities are apparent:

- *Evidence-based practices* emerge from application of relevant research, observation (reflective practice), and other credible sources of evidence.
- *Goals, standards, codes of ethics* have been established, associated with respective professional organizations (ASTD, n.d.; ISPI, 2002a). For HPT, two professional organizations have developed formal professional certification programs. The ISPI program produces Certified Performance Technologists (CPTs) based on its standards (ISPI, 2002b). The program from the American Society for Training and Development (ASTD) produces Certified Professionals in Learning and Performance certification (CPLPs) based on its competency model (ASTD, 2008).
- *Systemic and systematic approaches* are common to both fields of practice although they vary in scope, as discussed below.
- *Formative, summative, confirmative evaluation* are considered standard practice in both fields, though with some differences in measurement strategy, as discussed below.

While these commonalities are important, there are also important differences in frameworks and many nuances of method. Table 4.1 summarizes the major contrasts between ID and HPT within the context of the workplace. This section describes each of these important differences.

Frameworks

Research Base

Molenda (2010) traces the evolution of ID theory from roots in behavioral learning theory and cognitive psychology, beginning with Bruner and continuing through the four successive editions of Gagne's *Conditions of Learning* (1985), and on to current cognitive learning theory. He points out that this work rapidly matured from an early focus using programmed instruction and computer-based learning to a more generalizable framework for a technology of teaching which could be instantiated effectively in any medium—even classrooms using nothing beyond the familiar lesson plan and standard curriculum materials.

Table 4.1 A comparison of ID and HPT frameworks and methods

		ID	HPT
Frameworks	Research base	• IDs employ behaviorist, cognitive and constructivist approaches, with behaviorism largely eclipsed • Evolution includes ID theory, methodology, and project management	• HPT practitioners employ largely behavioral approaches, with exceptions lying in the use of cognitive psychology in the area of performance support for knowledge work • Evolution influenced by both ID and other non-training fields
	Systems view	• Instructional systems comprised of learners, objectives, methods, and evaluation (Morrison et al., 2007)	• Performance systems comprised of interacting components operating at multiple levels: individual, team, organization, enterprise, and society • Performance systems may include instructional subsystems
Methods	Core processes	• IDs use different variations of the ADDIE model to create instructional systems • IDs may choose to use rapid prototyping and participative design to decrease development time while improving quality	• HPT practitioners use the HPT model to close gaps between actual and desired performance • Aside from the development of performance support systems and eLearning, HPT practitioners typically do not employ rapid prototyping
	Performance analysis	• Analysis in ID presumes an instructional solution to a given problem or opportunity • Analysis activities include the specification of broad learning goals, learner characteristics and workplace contexts, learning hierarchies, and job tasks	• HPT practitioners begin with understanding the required performance and its organizational setting. They will analyze the organization and the larger environment. They will specify a gap between existing and desired performance and make sure the gap is worth closing before proceeding further
	Cause analysis	• In presuming an instructional solution to a given problem or opportunity, analysis in ID does not investigate causes of a performance gap • The closest that IDs get to cause analysis lies in determining whether learners should be able to use job aids during their training and in the workplace	• Having aligned a performance gap with organizational business goals and determined that the gap is worth closing HPT practitioners will conduct a cause analysis to identify environmental and individual sources of the performance gap • In conducting cause analyses, HPT practitioners use a troubleshooting sequence that investigates environmental sources of the gap before investigating knowledge and other sources of the gap lying in the personal repertory
		• Create effective learning as learning is good and more learning is better. In workplace settings, training serves this learning function	• Deliver workplace performance in ways that meet organizational missions and business goals. In workplace settings, HPTers will employ a solution-agnostic process to ensure they understand performance requirements and causes of performance gaps before they create solutions to close them
	Intervention selection	• Focuses on the selection of training media and perhaps job aids • Training is viewed as the default solution to any gap between actual and desired performance	• HPT practitioners match the interventions they select to the sources of a performance gap arising from a cause analysis • As interventions that address environmental sources of performance gaps tend to be less expensive and faster to create, HPT practitioners will use them in place of interventions that address the personal repertory when they can
	Measuring results	• If conducted, evaluation focuses on the extent to which the training delivered some sort of return on the organization's investment • Isolating effects of training is an important part of a credible evaluation report • Often conducted contrary to Kirkpatrick's and Phillip's guidance to start at higher levels and work backwards	• Isolating out the effects of training, within a larger HPT intervention, interests some HPT practitioners but not others • May use a Kirkpatrick/Phillips model if decision-makers are interested in the return on their investment in training, but will do so in the order these authors recommend, beginning with higher levels and working backward • Will use program evaluation approaches to investigate other questions decision-makers may have

Molenda also traces the development of ID methodology. He attributes its origins to the application of operations research to training development in the military, where the emphasis was on training as part of integrated operational systems, such as weapons systems. Thus, training was provided as part of a larger system that defense contractors delivered to the military. The methodology for this systems view of training was developed at Florida State University as the Instructional Systems Development (ISD) model. The methodology was in itself a systematic method for development of training, which embodied both

- *Project management* principles (such as a work flow using the ADDIE steps)
- *Design processes* intended to proceduralize the best available decision-making principles for application of the emerging technology of instruction

Thus, ISD was originally defined as both a *systems approach* to creating training and a *systematic approach* to managing training development projects. ISD also had the goal of *systematic design* by incorporating procedures for design of the training itself. IDs completed phases and activities that became project deliverables. These deliverables became inputs for subsequent phases and activities.

As HPT branched from ISD, the development of HPT theory followed a substantially different course. Rosenberg, Coscarelli, and Hutchison (1999) state that from ISD, HPT took the systems analysis framework, but it was substantially broadened: they attribute to Mager (1988) the point that "In the HPT suprasystem, instructional technology is a subsystem, and HPT is a subsystem in the overall management suprasystem" (Rosenberg et al., p. 25). Thus, while the focus of ISD was on the training (sub) system within the context of operational systems, the systems framework took HPT in a different direction: HPT's focus is on the entire organization's performance, and within that the performance of work groups and individuals. Work groups range in size from small teams to larger departments to global enterprises.

More recently, while learning theory evolved from a behavioral to a cognitive learning theory perspective, HPT has retained much more of a behavioral orientation (although the Rosenberg et al. discussion of the field's origins does include cognitive engineering). HPT practitioners creating custom software solutions that provide on-demand access to information, advice, tools, and learning also draw on cognitive psychology to create performance support systems. Creating systems that help knowledge workers recognize situations, make decisions, and solve problems, HPT practitioners may use cognitive task analysis to ensure that the user interfaces they create match both the mental models (i.e., "thoughtflow") and workflow that exemplary performers use to complete their job tasks (c.f. Villachica & Stone, 1999; Villachica, Stone, & Endicott, 2006).

The evolution of HPT methodology also diverged from ISD's systematic methodology. In HPT, attention was at first on the major analytical frameworks. Process models of the problem-solving process or the project management system of the sort contemplated by ISD came later, with the work of Mager and Pipe (1970), Rossett (1987), Rosenberg (1990), and Hutchinson (1990). It is probably fair to say that the defining focus of HPT has remained on the analytical frameworks, rather than on standardization of procedural methodology. For example, the standards which define ISPI's CPT are performance-based and do not require the use of any particular methodology (ISPI, 2002b).

The evolutionary trends of HPT development are substantially different from those influencing ID. As HPT practitioners view training as only one of many possible interventions to improve performance, the field has been influenced by a wide range of fields and the interventions they create. Rosenberg et al. (1999) include information technology, ergonomics and human factors, psychometrics, behavioral feedback systems, organizational development, and change management. Each of these fields has had its own influence on the evolution of theory and practice of HPT.

Systems View

The concept of a "system," is a cornerstone in both ID and HPT. Brethower (2006) defines a system as "a collection of elements and relationships held together by a purpose in common" (p. 124). As an example of a system, consider an automobile assembly plant. The plant is made up of a collection of elements (people, machinery, processes, etc.) combined to accomplish the purpose of producing finished automobiles that can be shipped to dealers throughout the world.

Starting with this cornerstone concept, a systems view has three essential characteristics (Anderson & Johnson, 1997; Brethower, 2006; Meadows, 2008):

- *It is holistic*. A systems view attempts to encompass all of the system's elements—both tangible elements (people, buildings, and machinery) and intangible elements (workflow processes, organizational culture, company policies, and safety regulations). However, the system is seen as more than the simple sum of its parts. For example, in the automobile assembly plant, the people cannot produce automobile without the machinery and the machinery cannot produce automobiles without the people.
- *It focuses primarily on the interactions among the elements rather than on the elements themselves*. The tangible and intangible elements of the system interact in ways that are complex, dynamic, and interdependent. Small changes in one element may ripple throughout the entire system, influencing all of the other elements. Elements of

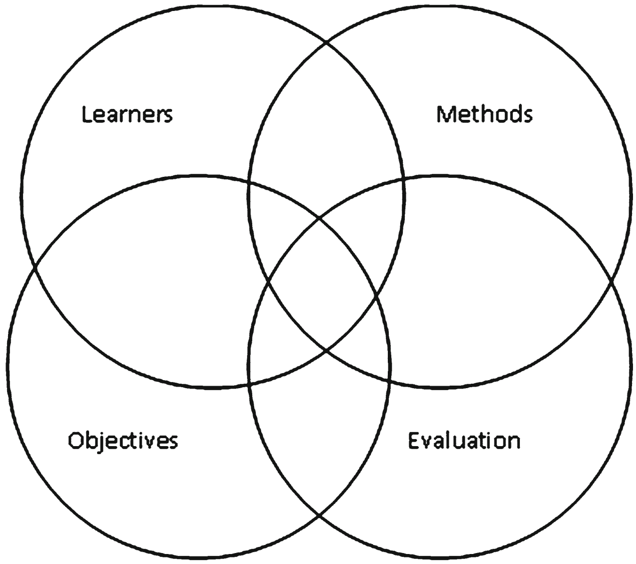

Fig. 4.1 Components of an instructional system (Morrison et al., 2007)

Table 4.2 Gilbert's (1996a, 1996b) behavior engineering model (BEM) (p. 88)

	Information	Instrumentation	Motivation
Environmental supports	*Data*: Information about expectations, guidance during performance, and feedback the extent to which performance met expectations	*Instruments*: Tools, time, and materials required to perform the task	*Incentives*: Financial and nonfinancial rewards for performing the task; consequences for nonperformance
Person's repertory of behavior	*Knowledge* (*and Skills*): The internalized know-how required to perform the task	*Capacity*: Innate physical, cognitive, and emotional capabilities required to perform the task	*Motives*: The interest and desire to perform the task

the system may interact in ways that produce unexpected consequences. For example, in the automobile assembly plant, a new piece of machinery will often result in changes in workflow processes, organizational culture, and safety regulations.

- *It views systems as "nested," with larger systems made up of smaller ones*. For example, one smaller system within the automobile assembly plant is the building, which is in turn, made up of smaller systems—lighting, heating, and ventilation. Conversely, the assembly plant itself is part of a larger system of the manufacturer, which is in turn part of an industry that is part of national and global economies.

Both ID and HPT begin with this systems view. However, they apply it to different systems. ID considers an "instructional system" while HPT considers a broader "performance system." Each system has the same three essential characteristics. However, the purpose and elements of the systems differ. The ID process creates an instructional system, the purpose of which is to promote the acquisition of specified knowledge or skills. Morrison, Ross, and Kemp (2007) present one view of an instructional system that consists of four interdependent elements (*see* Fig. 4.1):

- Learners—characteristics of the individuals who will participate in the instruction
- Objectives—the knowledge or skills the learners are to acquire
- Methods—the means that will be used to help the learners learn
- Evaluation—the means to be used to determine the extent to which learning has occurred

Other descriptions of instructional systems appear within Dick, Carey, and Carey's (2009) ID model, Smith and Ragan's (2005) ID model, Gagne's nine events of instruction (Gagne, Wager, Golas, & Keller, 2005), and Merrill's (2002) first principles of instruction. Each instructional system is made up of a different set of elements. Within in each system the elements interact to promote the acquisition of specified knowledge or skills. In contrast to ID's focus on instructional systems, HPT focuses on producing performance systems that promote the consistent performance of a specified job or task in ways that meet organizational expectations. Gilbert (reprinted in 1996a, 1996b) presents one view of a performance system comprised of six interdependent elements (*see* Table 4.2). According to Gilbert, worthy performance occurs when both environmental supports and a person's repertory of behavior work together to produce consistent performance that meets organizational expectations. This systemic view stresses multiple elements working at different levels in ways that produce competent human performance.

Other performance systems arising from HPT include Kaufman's (1983) organizational elements model, Langdon's (2000) language of work model, Marker's synchronized analysis model (2007), and Rummler's (2006) anatomy of performance model. Each performance system is made up of a different set of elements operating at levels of individuals, work groups, departments, enterprises, and even societies. But in each system the elements interact to promote the consistent performance of a specified job or task towards goals that organizations value.

Methods

Owing to similarities and differences in their frameworks, ID and HPT use a variety of similar methods but sometimes in different ways.

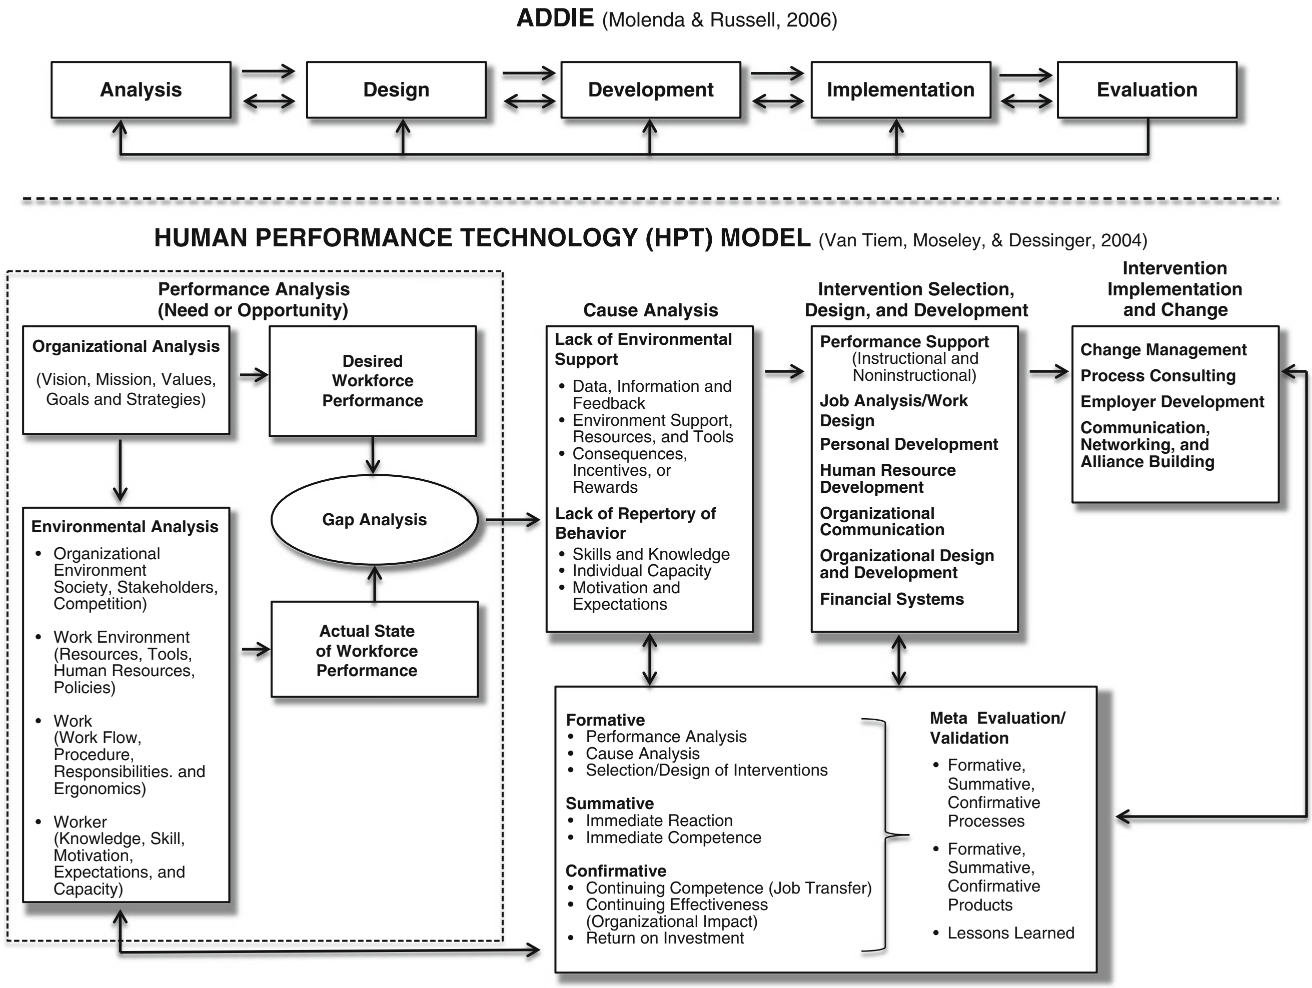

Fig. 4.2 A comparison of ADDIE and HPT models

Core Processes

As depicted in Fig. 4.2, both ADDIE and HPT are linear, systematic models. Both models help practitioners address complexity inherent in these efforts by ordering their phases and component activities. IDs and HPT practitioners completing these phases and activities produce deliverables that become inputs for subsequent phases and activities. Both models employ aspects of analysis, design, development, implementation, and evaluation. While both ADDIE and HPT embed evaluation throughout all phases, HPT can be heavier on analysis, with phases addressing both performance and cause analysis. HPT also specifies both implementation and change management. Where ADDIE separates Design and Development, HPT combines them. An ID creating training will complete all or part of the ADDIE phases. HPT practitioners creating performance improvement systems will complete all or part of the phases and activities comprising the HPT model, depending on the nature of the project they are working on. In both ID and HPT settings, senior project personnel typically complete aspects of analysis, design, and evaluation. Less experienced personnel often address development and implementation. Unfortunately, Both ID and HPT models commonly omit a maintenance phase. This omission makes it impossible to calculate trustworthy life cycle costs and benefits associated with these efforts.

As depicted in their models, both ADDIE and HPT employ linear, “waterfall” core processes, where the completion of one phase leads to the beginning of the next. The exception lies in evaluation, which provides feedback informing all of the phases in the model. ID has seen the emergence of prototyping-based models that employ iterative mock-ups created collaboratively with end users. Baek, Cagiltay, Boling, and Frick (2007) describe how rapid prototyping and participative design overcome the bureaucratic and linear nature of ADDIE, speeding up its otherwise slow design and development processes. Ross et al. (2007) mentions the role of prototyping in design research and natural work settings. Aside from a discussion of rapid application development (RAD) in creating performance support systems (Villachica et al., 2006), rapid prototyping and participative design do not appear in the most recent edition of the *HPT Handbook*.

Performance Analysis

One of the major contrasts between ID and HPT lies in the area of analysis. Typically in response to some formal or informal request for training, IDs completing the analysis phase of the ADDIE model specify broad learning goals as well as learner characteristics and workplace contexts. IDs may also specify learning hierarchies and job tasks during the analysis phase. IDs subsequently use the outputs of the analysis phase to form instructional objectives during the design phase. In contrast, HPT practitioners begin with a performance analysis targeted at specifying the nature of the problem or opportunity. The performance analysis consists of three different analytical activities: organizational analysis, environmental analysis, and gap analysis. This phase of the HPT model ensures practitioners align any gap between actual and desired workplace performance with the organization's missions and business goals at the levels of the organization, work, and worker. HPT practitioners will use a statement like this to describe the performance gap itself:

- What we want our (insert target population here) to do is (insert expected behavior here) at (insert expected measurement here)
- What our (insert target population here) are doing now is (insert existing behavior here) at (insert existing measurement here)

Use of this convention tends to clearly specify the performance problem as well as when it will be solved: when others in the organization meet the desired performance. During the performance analysis, HPT practitioners will also make sure the specified performance gap is worth closing.

Harless (1973) coined the term "front-end analysis" to refer to these activities, and he addressed what is now the performance analysis phase of the HPT model in the first of his 13 "smart questions":

1. Do we have a problem?
2. Do we have a human performance problem?
3. How will we know when the problem is solved?
4. What is the performance problem?
5. Should we allocate resources to solve it (p. 231)?

To answer these questions and complete the performance analysis, HPT practitioners will partner with clients, sponsors, and other stakeholders.

Cause Analysis

In focusing on knowledge, skills, and attitudes, IDs do not employ a cause analysis to investigate the sources of a performance gap. The closest they may get might be to determine whether learners meeting a particular objective might use a job aid (e.g., Mager, 1997; Morrison et al., 2007). In contrast, HPT uses a solution-neutral troubleshooting approach that refrains from specifying a treatment—whether it is training, other changes to environmental support, or other changes to the personal repertory—until the diagnosis of the performance gap is complete. Cause analysis focuses on identifying *all* possible environmental and personal sources of the performance gap, and HPT practitioners expect to see multiple, interacting sources of any given performance gap.

In diagnosing the sources of a gap, HPT practitioners will address potential sources arising from inadequate environmental support before those arising from an inadequacy in people's repertory of behavior. The reason lies in the concept of leverage (Chevalier, 2003, 2006; Gilbert, 1996a, 1996b). Environmental sources of performance gaps tend to be more common, anecdotally accounting (by a common "rule of thumb") for roughly 75 % of all performance gaps (Dean, 1997). HPT practitioners will consider a lack of skills and knowledge as the source of a given performance gap only *after* ruling out all environmental sources of a performance gap.

Intervention Selection

In ID, intervention selection focuses on the selection of training media and perhaps supplementing it with job aids as their default solution. In addition to many workplace executives, managers, and supervisors, IDs tend to presume that learning is good, and more learning is even better. This perception leads to the widespread belief that training is the default solution for any gap between actual and desired performance in the workplace. In contrast, HPT practitioners will investigate all potential sources of a performance gap and then use all potential means to close it (Molenda & Pershing, 2007; Rummler & Brache, 1990). In HPT, sources of performance gaps arising from the cause analysis lead to recommended interventions to close the performance gap. HPT practitioners refrain from recommending solutions (or interventions) until they have identified the source(s) of the performance gap. In specifying only those solutions that address corresponding sources of a performance gap, HPT is "solution agnostic." In selecting interventions associated with multiple causes of performance gaps, HPT practitioners are more likely to create, implement, and maintain solution systems, rather than isolated interventions.

As interventions fixing sources of performance gaps that lie in the environment tend to be faster and less expensive to create, implement, and maintain than those involved in changing behavioral repertories, HPT practitioners tend to view instructional interventions as among the most costly and least desirable of performance solutions. This perception is sharpened by Dean's (1997) anecdotal observation that only 10.5 % of performance gaps arise from a lack of required skills and knowledge, meaning that training that enables learners to acquire such skills is a special case of HPT, appropriate for closing a relatively small number of performance gaps.

Measuring Results

While both ID and HPT emphasize evaluation, the approaches most commonly used differ. In ID, the focus is on training. Perhaps the most commonly used analytical framework is Kirkpatrick's with Phillips' extensions (Kirkpatrick and Kirkpatrick, 2006). The purpose of the model is to demonstrate return on investment for training, using a 4- (or 5-) level analytical framework. However, the top levels of the model have been criticized as difficult to develop, and aimed at the wrong target: isolating the effects of training (Watkins, Leigh, Foshay, & Kaufman, 1998)—a goal of interest to trainers, but often not to the business. In fairness, we believe some of this difficulty comes from the experience of practitioners who often implement the model starting with the lowest level, rather than the highest, and thus find themselves focusing on outcomes which are of least importance. When this happens, the measures used can be highly misleading.

By contrast, the HPT approach resolves from the start the challenge of measuring important outcomes: the focus of front end analysis in HPT is on closing the performance gap with real business consequences to be measured in ways which are meaningful to the client (Moseley and Dessinger, 2010; Winiecki, 2006). There is no intent to isolate the impact of each performance improvement intervention, including training. Thus, development of meaningful business impact measures is not an added, artificial exercise; it is an inherent part of the initial problem definition (Brinkerhoff, 2006; Pershing, 2006). This approach has the added advantage of assuring the sponsorship to gather the data for the measures of results, because they are part of the business' normal work, and not an added, artificial step.

True Confessions: Limitations of the Preceding Comparisons

Thus far this chapter has presented only an abstracted comparison of the "classical" analytical frameworks used by ID and HPT. Both fields are undergoing constant evolution, drawing both on practitioners' reflections and advances in underlying theory. IDs and HPT practitioners constantly adapt these fields to meet their own, clients', and stakeholders' requirements. Accordingly, in any real-world ID or HPT project, the devil is in the details. The authors would like to explore two such issues of evolution and context here: the rise of a cross-disciplinary approach to design thinking and the emergence of savvy IDs who blend elements of ID and HPT in improving workplace performance.

The Rise of Design Thinking

Conversations about the nature of design in instructional systems development (e.g., Boling & Smith, 2007; Ertmer et al., 2008; Rowland, 1993; Silber, 2010) also involve conversations about the design process and design thinking (e.g., Brown, 2008; d.school, 2010; Lawson, 2006; Myerson, 2001). This broad conception of design cuts across

- Disciplines, including architecture, engineering, community planning
- Professions such as graphic design, product design interior design, and textile design (Lawson, 2006)

Jonassen (2004) maintains that design involves ill-structured problem solving in the face of vague goal statements and few constraints. There are multiple, undefined criteria, with no right or wrong way of solving the problem, only better and worse ones.

Elements of design thinking are beginning to make inroads into both ID and HPT. As depicted in Table 4.3, Baek et al. (2007) apply them in their discussion of user-centered design in ID. Villachica and Stone (1998, 2010) have discussed elements of design thinking in creating both instruction and performance support systems based on the use of Martin's (1991) RAD. Readers wishing additional information on this topic may want to review Susan McKenney and Jan Herrington's chapter on Design Research appearing in this Handbook.

The Savvy Instructional Designer

In workplace settings, IDs creating training would be wise to adopt a performance-based approach that mixes elements of ID and HPT (Sims & Koszalka, 2007). This approach lends itself to improved transfer of learned skill and knowledge to workplace. In this setting, training that closes a skill gap removes a barrier to meeting a business goal or enables an organization to meet some aspect of its mission. Training professionals who fail to align their efforts with business goals or consider non-skill sources of performance gaps and non-training solutions proceed at risk, with these factors being the top two reasons contributing to the failure of training and development efforts in the workplace (Phillips & Phillips, 2002). Like their HPT counterparts, savvy IDs align their efforts with meeting the needs of their workplace sponsors in ways that focus on results, take a systems view, add value, and establish partnerships (Addison, Haig, & Kearny, 2009).

A savvy instructional designer:

- Collaborates with others in the organization to
  - Identify performance gaps
  - Align them with missions and business goals to focus on valued performance
  - Determine whether the gaps are worth closing
- Identifies all possible causes of given performance gaps and collaborates with others to address them
  - IDs often address knowledge gaps by creating training and guidance gaps by creating job aids

Table 4.3 Design thinking elements in ID and HPT

Aspect	d.school bootcamp (2010)	Baek et al. (2007)	Villachica and Stone (1998, 2010)
Mindsets	• Show, don't tell • Focus on human values • Craft clarity • Embrace experimentation • Be mindful of process • Bias toward action • Radical collaboration	• User participation • Contextual analysis • Iterative design • Rapid prototyping	• Collaborative analysis and design • Rapid prototyping • Usability testing • Timeboxing • SWAT teams
Phases	• Empathize • Define • Ideate • Prototype • Test	• Not specified	• Alignment • Joint requirements planning • Design reviews • Prototyping • Usability testing

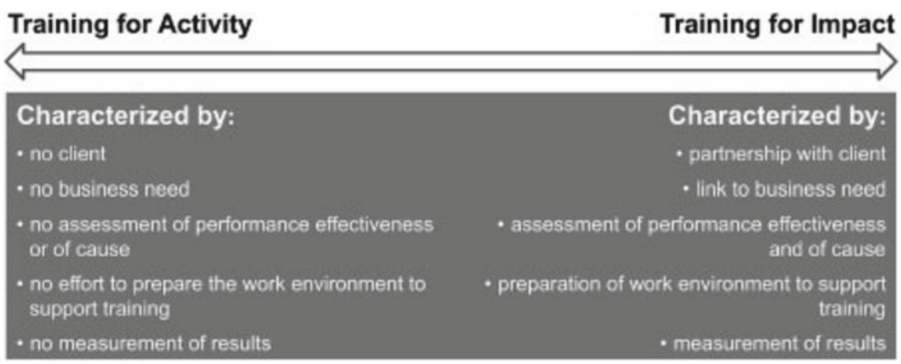

Fig. 4.3 Training for activity and impact. From Robinson and Robinson (1990)

  – IDs partner with other professionals to address other sources of gaps, knowing that the training department is often blamed for any unclosed gap
  – IDs may employ strategies associated with either the performance support or the technology integration literatures. Readers wishing more information about the latter may want to review Mark Lee's chapter on Technology Integration Work Settings appearing in this Handbook.
- Collaborates with others to ensure that training transfers to the workplace. This involves asking for executive and management support for transfer before and after the training (Broad & Newstrom, 1992)
- Partners with others in the organization to ensure that the different components of the solution system integrate in ways that close the gap
- Employs rapid prototyping and participative design to shrink development time while improving quality
- Reports the extent to which the solution system closed the performance gap
- Collaborates with others to conduct needs assessments and evaluations to answer other questions that keep decision-makers up at night

This recommendation for performance-based ID corresponds to Robinson and Robinson's (1990) concept of training for impact. As depicted in Fig. 4.3, a continuum of training approaches lies between training for activity and training for impact. In the former, a requestor typically asks for some sort of training. IDs create the training. Once delivered, the activity is finished. This form of topic-focused instruction often fails to transfer to the workplace. While training for activity is unfortunately commonplace, this approach does not prepare people to perform their jobs. Robinson and Robinson contrast this approach to training that produces a positive impact in the workplace. Performance-based training is designed to produce such a favorable organizational impact.

Robinson and Robinson (2006) later refine this continuum to compare traditional to performance-centered approaches, where the former is characterized by focus on learning produced in a firefighting mode largely independent of collaboration with the client group. In this approach, implemented learning equates with success. In a performance-centered approach, the focus is on what people need to do in the workplace, with learning and other solutions being means to this end. Practitioners of this performance-centered approach are solution-neutral, partnering both proactively and reactively with client groups to identify causes of gaps and potential solutions. In the performance-based approach, success means closing performance gaps. In workplace contexts the practice of ID should be informed by HPT. While the two fields are not twins, they should be cousins in practice.

Conclusion

Clearly, it is conceptually possible to do ID without using an HPT framework, and it is equally possible to do HPT without doing ID. The two fields shared common theoretical roots and methodologies more than a generation ago, but they have different goals and have evolved in very different ways into different professions. That said, it is increasingly common (except perhaps in academic settings) for ID to be done within an HPT framework which coordinates a broad range of training and non-training interventions, using cross-functional teams, and to evaluate the overall success of the project in terms of improved organizational performance, as HPT requires. We believe that (at least in nonacademic organizations), the trend will continue of training departments redefining their mission in organizational performance (HPT) terms. Thus, we believe the fields will continue to cross-fertilize and evolve their theoretical structures and methodologies. For example, the emerging interdisciplinary field of design is an influence on both ID and HPT. However, we believe ID and HPT will remain distinctly different fields of professional practice. The savvy ID practitioner, therefore, should develop the conceptual flexibility to work effectively within an HPT framework, on a multidisciplinary team.

Implications of Neuroimaging for Educational Research

Nicht das Gehirn denkt, sondern wir denken das Gehirn
(The brain does not think, we think the brain.)

Friedrich Nietzsche

Abstract

Neural functions are fundamental to learning, instruction, and performance. Although tremendous progress has been made in neuroscience in the past two decades, its applications in educational research are just beginning to be realized. This review focuses on selected technologies, methods, and findings from neuroscience that have important implications for educational sciences. Specifically, this chapter discusses conceptual and empirical research on the use, implications, and limitations of neuroimaging techniques such as continuous electroencephalography, event-related potentials, and functional magnetic resonance imaging in the domains of language and reading, mathematics learning, problem solving, cognitive load, and affective processes in learning. Neuroimaging has enabled scientists to open "the black box" of neural activity that underlies learning. It seems timely, therefore, to consider how educational researchers may employ the increased understanding of brain function to explore educational questions.

Keywords

Neuroscience • Neuroimaging • EEG • ERP • fMRI • fNIRS

Introduction

Developing learners' cognitive capacities to confront and resolve real-life, cross-disciplinary situations is a key goal of educational research (National Research Council, 2005). Cognitive function has also been a central issue in neuroscience, which examines the complexity of human perception, cognition, emotion, and action based on the neural activity of brain cells. Human brain consists of about 100 billion neurons. Information is transmitted from neuron to neuron via electrical signals passing through the axons and generating the release of chemical neurotransmitters from the neural connectors called synapses (Bear, Connors, & Paradiso, 2006). Analysis of the patterns of neural activity allows scientists to map brain functions associated with performing a variety of

tasks. The resulting knowledge of the neural structures that underlie macro-level processes, such as perception, attention, cognition, and learning, can be of interest to psychologists and educators.

Since "The Decade of the Brain 1990–2000" (Jones & Mendell, 1999), the study of the brain has been driven by substantial government investments, which resulted in the development of new methods and technologies (e.g., brain–computer interfaces) and research "collaboratories" like the Japan–US Brain Research Cooperative Program and the European Union's Promemoria Consortium (Tosetti, Nagy, & Bernard, 2008). The membership of the Society of Neuroscience has doubled in the past 20 years (Minnery & Fine, 2009), with many of the new members representing fields outside of neuroscience, such as psychology, education, and human factors.

A survey of the recent literature in neuroscience reveals that one of the focus areas of the current research is improving our understanding of cognitive, affective, and social functions of the brain during learning. The implications for education and behavioral sciences generated through this line of inquiry are outlined in the recently created journal "Mind, Brain, & Education" (*Fischer et al., 2007) and publications like "Brain lessons" (Jolles et al., 2006), "Understanding the brain: The birth of a learning science" (*Office of Economic Cooperation and Development, OECD, 2007), "Explorations in learning and the brain" (De Jong et al., 2009), and "Handbook of neuroscience for the behavioral sciences" (*Berntson & Cacioppo, 2009). However, how much of this knowledge is "usable" to educators remains the subject of debate (Fischer, 2009; Goswami, 2009; Varma, McCandliss, & Schwartz, 2008). Even what is considered by many to be the most salient finding in neuroscience—the "critical periods" for synapse formation or synaptogenesis (e.g., Carnegie Task Force, 1996)—has been subjected to well-deserved skepticism and critique in terms of its relevance to informing educational practice (Bruer, 1997, 2006). In this chapter we try to refrain from making irresponsible extrapolations and propagating educational "neuromyths" (OECD, 2007); instead, we focus on describing neuroscience techniques and the findings that the application of those techniques has already generated for the education research community (e.g., De Jong et al., 2009; Goswami, 2006; OECD, 2007) in the domains of language and reading, mathematics learning, problem solving, cognitive load, and affective processes in learning.

A Primer on Neurotechnologies

Much of our brain activity is not available for conscious introspection and neuroscientific evidence has made it clear that nonconscious neural activity is essential for controlling our behavior (Kringelbach, 2009). Empirical research in neuroscience has been driven by methods and technologies that enable researchers to collect data on nonconscious processing and compare these data with observable behavior. The basic assumption in neuroscience research is that tasks make specific demands on the brain and these demands cause changes in the chemical and electrical neural activity. These changes result in a host of physiological responses affecting cerebral blood flow, heart rate, muscle activity, electrodermal responses, eye movements, pupil size, blood pressure, respiration, oxygen consumption, salivation, skin temperature, immune function, endocrine function, and others (*Andreassi, 2007). There are multiple technologies and methods to measure such physiological responses but the techniques that have been most successful in advancing cognitive neuroscience, a branch that is arguably the most relevant to the educational research community, including noninvasive tools of two varieties. They either provide high-resolution spatial information and track changes in cerebral blood flow such as functional magnetic resonance imaging (fMRI) and functional near-infrared spectroscopy (fNIRS) or tools that provide high-resolution temporal information and assess changes in the electrical activity of the brain—electroencephalography (EEG) and event-related potentials (ERPs).

Functional Magnetic Resonance Imaging

The advent of fMRI in the 1990s enabled neuroscientists to "see" changes in brain activity associated with performing an experimental task. This neurotechnology requires inserting the participant into a scanner with a large, tube-shaped magnet (Fig. 5.1), which creates images of the magnetic resonance signal generated by the protons of water molecules in brain cells. Task performance activates certain brain areas which leads to enhanced oxygen consumption by cells in those areas and therefore enhanced blood flow to those cells. With fMRI changes in the oxygenation state of hemoglobin can be registered. This is called the blood oxygenation level-dependent (BOLD) response, which is the outcome measure used in most fMRI studies. The fine spatial resolution of fMRI (1–3 mm) has allowed neuroscientists to analyze brain activation patterns and link them to cognitive functions ranging from discourse comprehension (Martín-Loeches, Casado, Hernández-Tamames, & Álvarez-Linera, 2008) to mathematical problem solving (Anderson, Betts, Ferris, & Fincham, 2011). Yet, despite the obvious advantages over more direct but also more invasive imaging techniques like positron emission tomography, which relies on the injection of radioactive tracers into the bloodstream which are then tracked, fMRI is not without its drawbacks. While most fMRI scanners allow participants to be presented with different visual, auditory, and kinesthetic stimuli, and to make different actions such as pressing a button or moving a joystick,

Fig. 5.1 Varian 4T fMRI, part of the Brain Imaging Center, Helen Wills Neuroscience Institute at the University of California, Berkeley (public domain, Wikimedia Commons)

participants must remain relatively motionless, which limits the range of behaviors that can be studied (an overt verbal response, for example, results in a small movement of the lower part of the head, which could potentially distort the measurement). Participants also have to wear headphones to shield their ears from noise, and this noise also makes the analysis of overt verbal responses difficult, although methods have been developed to filter out the scanner noise (e.g., Jung, Prasad, Qin, & Anderson, 2005). These issues limit the application of fMRI educational research and render fMRI methods impractical in authentic, in situ settings. Furthermore, the cost ($500,000 and up) and expertise required to maintain the equipment as well as collect and analyze data act as barriers to educational researchers looking to incorporate fMRI into their work.

Functional Near-Infrared Spectroscopy

A lower cost noninvasive alternative to fMRI that is gaining popularity among neuroscientists is fNIRS. Like fMRI, the fNIRS signal reflects the dynamics of cerebral blood flow. Unlike fMRI, this neurotechnology penetrates only a few millimeters below the skull and thus, does not reveal the activity of deeper brain structures. Nevertheless, the higher cognitive functions relevant to the study of learning and instruction such as visual-spatial processing, or executive control, are localized within the superficial layer of brain tissue called the cerebral cortex, which is readily accessible to fNIRS. As most neuroimaging methods, fNIRS has its functional and practical limitations. Unlike PET or fMRI, fNIRS cannot measure deep brain structures and it is limited to measuring cerebral blood flow dynamics in the forehead, as hair can introduce noise into the optical signal. Another weakness of fNIRS is its low temporal resolution, as it takes several seconds for an fNIRS sensor to detect changes in blood in the brain. Finally, since most current research in fNIRS concerns validating the tool itself, extensive applications in cognitive neuroscience conducted with brain imaging techniques such as EEG have yet to be implemented with fNIRS.

Electroencephalography and Event-Related Potentials

Tracking changes in cerebral blood flow is only one of several possible ways to measure brain function. While this group of methods has the advantage of high spatial resolution that allows localizing neural events, methods that track the electrical activity of the brain like EEG and ERPs have the advantage of being sensitive to millisecond differences in electrical activity and therefore of being able to provide evidence on the time course of neural processing. EEG and ERP setups consist of electrodes that are fitted over an individual's scalp to record low-amplitude electrical brain activity at the surface of the skull. Recording of the spontaneous natural rhythms of the brain is called EEG. At present, it is believed that electrical activity in the brain generates at least four distinct rhythms (*Basar, 1999). Figure 5.2 shows that brain waves are a continuum from the large, slow delta waves to smaller and faster (i.e., higher frequency) beta waves. Analysis of the amplitude, frequency, and power of neural oscillations within these brainwave rhythms has furthered our

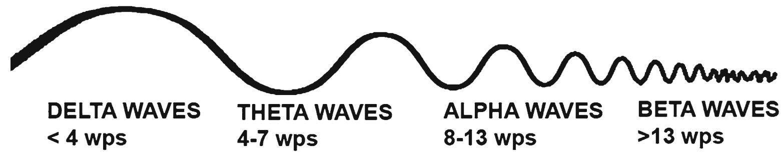

Fig. 5.2 Human brainwave rhythms (waves per second)

understanding of human cognitive architecture and interaction between its components during cognitive tasks. For example, one recent study shows that theta and alpha oscillations during working-memory maintenance predict successful long-term memory encoding (Khader, Jost, Ranganath, & Rosler, 2010). Although the drawbacks of EEG (poor spatial resolution, high susceptibility to electrical noise, and the necessity to conduct multiple trials to isolate the brain activity of interest) limit its utility, recent advances in signal processing and electrode headset design, including wireless EEG, have expanded its range of applications to include research in natural settings like the classroom.

ERPs are measured using EEG and refer to systematic deviations from the natural brainwave rhythms that precede, accompany, or follow events determined by the experimenter. Unlike spontaneous EEG, ERP rhythms are time-locked to particular events designed to study brain function. The different potentials are referred to by a preceding letter indicating polarity followed by the typical latency in milliseconds. For example, P300, N100, P200, etc. mean positive peak at 300 ms, negative peak at 100 ms, and so on. The sequence of observed potentials as well as their latency, amplitude, duration, and distribution are used to understand the cognitive processes underlying the experimental task. For instance, language-related ERP components such as the N400, left anterior negativity (LAN), and P600 have proven useful in understanding the processing of language in children and adults, in native and nonnative language, in normal processing, and in language disorders (Goswami, 2004).

Summary

In summary, measures of cerebral blood flow like fMRI typically have high spatial resolution but relatively poor temporal resolution (5 or more seconds). EEG and ERPs directly measure the brain's electrical activity, yielding high temporal resolution (in the order of milliseconds) but low spatial resolution. As a result, neuroscientists have begun to explore integrated uses of these techniques in order to provide information on both the spatial location and temporal changes in brain activity associated with task performance (e.g., Ullsperger & Debener, 2010).

In order to make effective use of neurotechnologies and link neural activity with educational research, it is important to have a profound understanding of both theories and tools of neuroscience and the cognitive, affective, and social processes that underlie learning. Cognitive neuroscience is a branch of both psychology and neuroscience that uses cognitive theories and evidence from neuroscience to explain and predict cognition and learning based on neural activity. The sections below provide a small yet representative sample of state-of-the-art research in cognitive neuroscience with translatable implications for educational research.

Language and the "Reading Brain"

Learning to read requires the mastery of a collection of complex skills (Mayer, 2008)—morphology (formation of words), orthography (spelling), phonetics (mapping words to sounds), syntax (word order), and semantics (extraction of meaning from words and sentences). In fluent readers, the entire process from visual processing (seeing) to semantic retrieval (understanding) occurs very rapidly, all within about 600 ms (OECD, 2007). Brain imaging research in cognitive neuroscience has made significant strides to advance our understanding of the "reading brain" (Dehaene, 2009). Though certain brain structures are biologically primed for language (e.g., Broca's area and Wernicke's area, 44–45 and 22, respectively, in Fig. 5.3), language acquisition requires the catalyst of experience. There are developmental sensitivities as language circuits are most receptive to particular experience-dependent changes at certain stages of the individual's development. For example, sound discrimination is best developed in the first 10 months of age (Gopnik, Meltzoff, & Kuhl, 1999) and accents are acquired most effectively before 12 years of age (Neville & Bruer, 2001). If the initial exposure to a foreign language occurs between 1 and 3 years of age, grammar is processed by the left hemisphere—as in a native speaker, but when it is delayed, brain imaging reveals an aberrant activation pattern consistent with the behavioral finding that later exposure to a second language leads to significant difficulties with learning grammar (e.g., Fledge & Fletcher, 1992; Neville & Bruer, 2001).

Recent ERP and fMRI studies show that the major systems for reading alphabetic scripts for both children and adults are lateralized to the left hemisphere (Turkeltaub, Gareau, Flowers, Zeffiro, & Eden, 2003). The occipital-temporal areas of the brain are most active when processing visual features, letter shapes, and orthography. Activation in these areas also increases with reading skills (Shaywitz

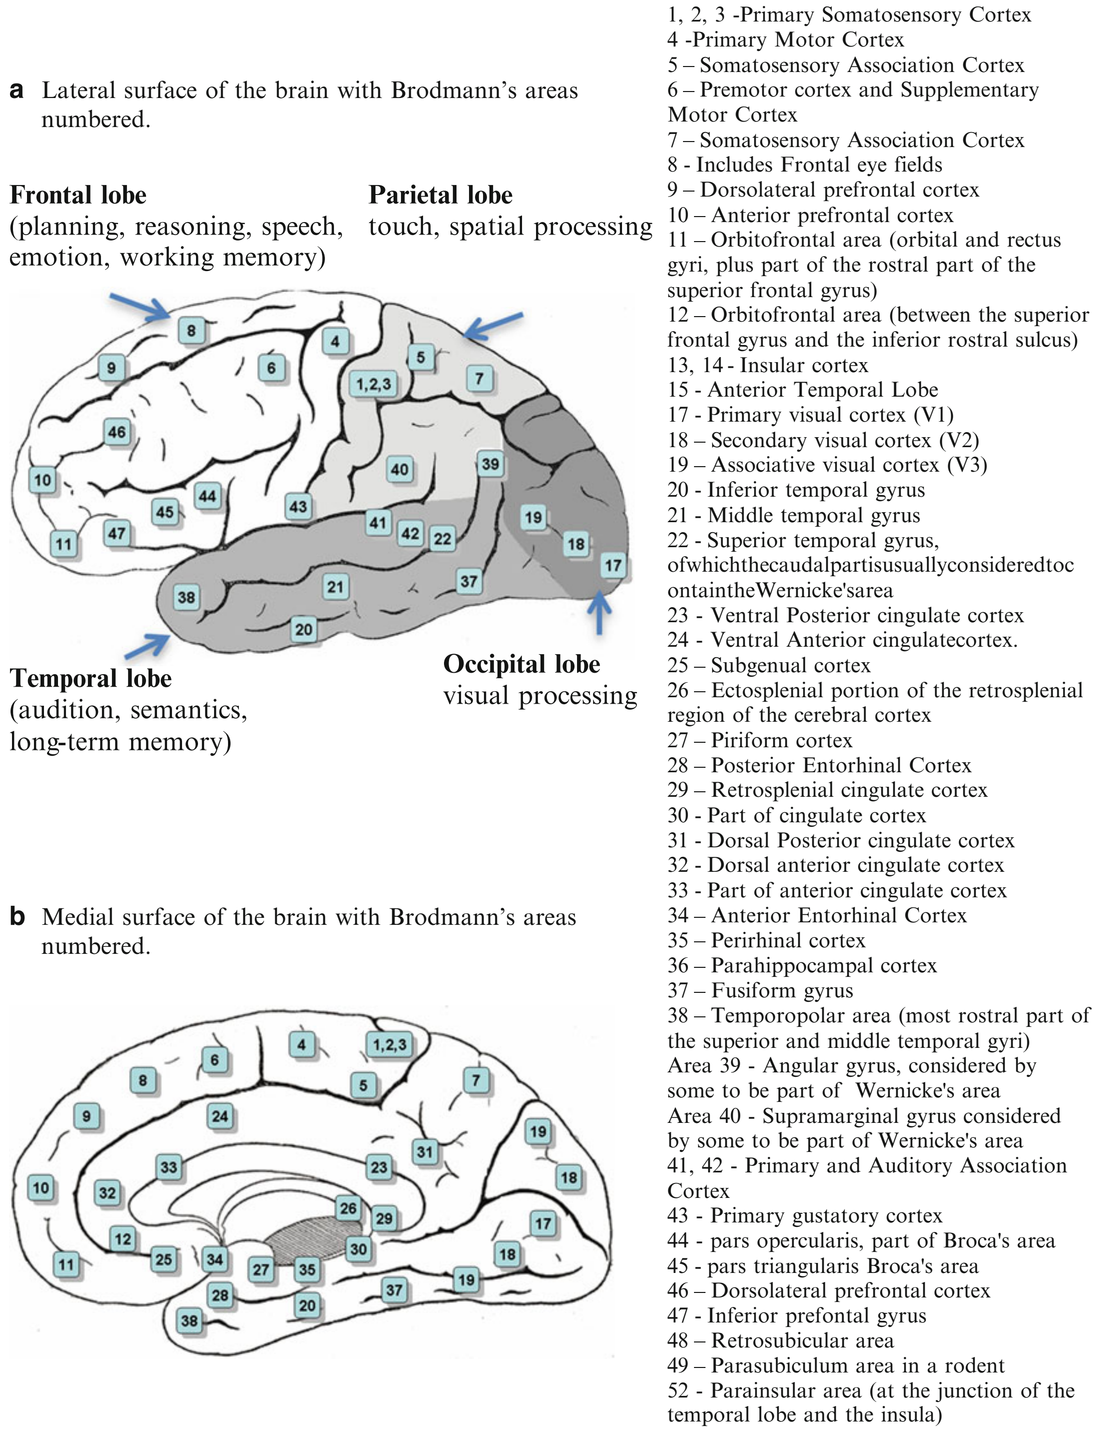

Fig. 5.3 Cytoarchitectural organization of the cortex according to Brodmann (1909). While more verifiable maps have been produced since then, Brodmann's atlas of the human brain is still considered to be the standard reference in the functional neuroimaging community (Thompson & Toga, 2000). (**a**) Lateral surface of the brain with Brodmann's areas numbered. (**b**) Medial surface of the brain with Brodmann's areas numbered

et al., 2002) and is diminished in children with developmental dyslexia (Goswami, 2004). One example of the contributions that cognitive neuroscience has made in understanding orthography is a PET study of the cultural effects on brain function that compared adult readers of Italian and English (Paulesu et al., 2000). The Italian language has a transparent orthography that allows readers to easily convert graphemes into phonemes. On the other hand, English is known for its inconsistent, non-transparent orthography that creates problems for both native and second-language readers. This study demonstrated that Italian readers were faster in reading words and nonwords than English readers (a behavioral finding), and that Italian readers showed greater activation in left superior temporal regions associated with phoneme processing, whereas English readers showed increased activation in the posterior inferior temporal gyrus (area 20 in Fig. 5.3) and anterior inferior frontal gyrus (area 11 in Fig. 5.3), which are associated with word retrieval during reading (a neuro-cognitive finding). These results can serve to corroborate the orthographic depth hypothesis (Katz & Frost, 1992)—a cross-language theory of reading suggesting that readers adapt their reliance on the orthographic (i.e., whole word recognition) or phonological (recoding) strategy, depending on the orthographic depth of the language. The phonological strategy is predominant in readers of languages with a consistent orthography because mapping between letters and sounds is unambiguous, while in an inconsistent orthography readers rely more on whole word recognition (Ziegler & Goswami, 2006).

One of the classic debates in literacy research and education focuses on the role of "whole language" text immersion versus the development of phonetic skills (National Reading Panel, 2000). Neuroscience research aimed at delineating the brain areas that support reading provides useful insights regarding this issue. For example, the so-called dual-route theory provides a framework for describing reading in the brain at the level of the word (Jobard, Crivello, & Tzourio-Mazoyer, 2003). Supported by dozens of neuroimaging studies, this theory proposes that words are first processed by the primary visual cortex (area 17 in Fig. 5.3) and then pre-lexical processing occurs at the left occipito-temporal junction (area 37 in Fig. 5.3). After that, processing follows one of the two complementary pathways (Jobard et al., 2003). The assembled pathway involves an intermediate step of converting letters and words into sounds (grapho-phonological conversion), which occurs in certain left temporal and frontal areas, including Broca's area (areas 44 and 45 in Fig. 5.3). The discovery of this pathway suggests the importance of the phonic approach to reading instruction. In case of the second route, the addressed pathway, information is transferred directly from pre-lexical processing to semantic processing (meaning extraction), which implies the significance of using the whole language approach to teach reading. Both pathways terminate in the left basal temporal area, the left interior frontal gyrus, and the left posterior middle gyrus, or Wernicke's area (area 22 in Fig. 5.3), which is known to be involved in the understanding of written and spoken language. These results confirm the assumptions of the dual-route framework, which helps explain different patterns of activation observed in participants during a reading task. This neuroscience evidence is also consistent with the conclusions of the US National Reading Panel (2000) and National Research Council (Snow, Burns, & Griffin, 1998) that highlight the educational benefits of a balanced approach to reading instruction, which combines whole language and phonics approaches.

Numeracy and the "Mathematical Brain"

Although the neuroscientific research on numeracy is still in its infancy, the field has already made significant progress in the last decade. The mere representation of numbers involves a complex circuit that brings together the sense of magnitude, and visual and verbal representations. As in the case with literacy, development of quantitative skills requires a synergy of physiology and experience. There are brain structures that are believed to be genetically assigned to the numerical sense, as well as supplemental neural circuits that are shaped to fit this function by experience through "neural recycling" (Dehaene, 1997). The number sense system is known to be supported bilaterally by the intraparietal areas, because these regions of the brain are activated during tasks involving number comparison, regardless of the representation format used (e.g., Arabic numerals, dots, number words). Because symbolic notations have no effect on the location of parietal ERP components, the parietal cortex is thought to organize knowledge about number quantities (Goswami, 2004).

Research on the role of the parietal lobe in the processing of quantitative information provides interesting insights as to why some children have good mathematical skills but have trouble reading and processing symbolic notations. For example, evidence from lesion and neuroimaging studies demonstrates that patients with parietal damage know that there are 2 h between nine and eleven but fail to subtract nine from eleven in symbolic notation (Dehaene, Spelke, Stanescu, Pinel, & Tsivkin, 1999). Relatedly, they are not able to answer which number falls between three and five but at the same time they have no difficulty solving a similar task in another domain—like identifying which month falls between June and August (Dehaene, 1997). These findings indicate that mathematics is dissociable from other domains like reading, and even within the domain of mathematics different abilities can be dissociable from one another (OECD, 2007). This conclusion highlights the importance of providing multiple forms of representation and assessment of mathematical knowledge—to include children that may not learn optimally from print text or do not perform well on paper-and-pencil tests.

An interesting series of behavioral and brain-imaging experiments (fMRI and ERPs) was conducted to explore the cognitive and neural activity underlying the linguistic competence and visuospatial representation in mathematics learning (Dehaene et al., 1999; Zago et al., 2001). Language-specific exact arithmetic was shown to transfer poorly to a different language or to novel facts, and use networks involved in word-association processes. Many mathematical problems are rehearsed to such an extent in elementary school that they are stored as declarative knowledge (Goswami, 2004). This result also explains the processing behind drill-and-practice counting exercises and rote learning like the multiplication tables. In contrast, approximate arithmetic was found to be language independent, rely on a sense of numerical magnitudes, and recruit bilateral areas of the parietal lobes (including a distinct parietal-premotor area) involved in visuospatial processing. Zago et al. (2001) found that a region associated with the representation of fingers (left parieto-premotor circuit) was activated during adults' arithmetic performance. Observers note that this result may explain the importance of using finger-counting as a strategy for the acquisition of calculation skills and have important consequences for the developing brain because they partially underpin numerical manipulation skills in adults (Goswami, 2004). The complex interplay of the brain systems responsible for processing and storing the different types of numerical knowledge is believed to result in the development of advanced quantitative skills and mathematical intuition characteristic of experts in mathematics, statistics, and other related disciplines (Dehaene et al., 1999).

Cognitive Load

Cognitive load theory (CLT) proposes a model of human cognitive architecture (Sweller, 2010; Sweller, Van Merriënboer, & Paas, 1998) that helps explain and predict the allocation of working memory resources and the interaction between working memory and long-term memory to deal with (a) intrinsic cognitive load (caused by the intrinsic complexity of information), (b) extraneous cognitive load (caused by ineffective presentation of information), and (c) germane cognitive load (effective processing resulting in deeper learning). In addition to these three types, cognitive load can be characterized in terms of its temporal dimensions such as instantaneous load, peak load, average load, accumulated load, and overall load (Xie & Salvendy, 2000). Researchers working in the context of CLT have been concerned with analyzing the effects of cognitive load types on learning and devising strategies and tools to help learners maintain an optimal level of load in various learning contexts. As a consequence, measurement of cognitive load plays a key role in research (Paas, Tuovinen, Tabbers, & Van Gerven, 2003).

Cognitive neuroscience provides tools that may prove useful in advancing the measurement of cognitive load and CLT (Clark, 2010, provides a detailed review). Neurotechnologies like EEG, ERPs, fMRI, and fNIRS have been employed to measure mental workload in human factors and ergonomics (Gevins & Smith, 2008; Wilson & Russell, 2003) and assess cognitive load in educational research (Antonenko, Paas, Grabner, & van Gog, 2010; Stevens, Galloway, & Berka, 2007). For example, the high temporal resolution of EEG can provide useful insights regarding the changes in cognitive load over time. Schultheis and Jameson (2004) employed the novelty P3 methodology (Friedman, Cycowicz, & Gaeta, 2001) and showed that the amplitude of P300 reflected cognitive load required to process difficult text. A recent review by Antonenko et al. (2010) suggests that event-related desynchronization percentage (ERD%) of alpha and theta band power over frontal and parietal regions of the brain can serve as an online, continuous measure of instantaneous cognitive load, which can help explain the effects of instructional interventions when measures of overall cognitive load fail to reflect such differences in cognitive processing. In the case of ERD%, each participant serves as his/her own control because this measure compares the brainwave power of individuals during the baseline period when the participant is relaxed to the test period when the participant is engaged in the learning task (Pfurtscheller & Lopes da Silva, 2005). Empirically, ERD% of alpha and theta coupled with the results of learning tests has been shown to be sensitive to changes in extraneous load associated with split attention in learning from hypertext (e.g., Antonenko & Niederhauser, 2010) and explains the differences in processing video, textual, and pictorial information by gifted students in multimedia learning (Gerlic & Jausovec, 1999).

Another study used EEG to compare learners' mental workload (cf. cognitive load) while solving science problems in a multimedia learning environment (Stevens et al., 2007). This study employed a wireless EEG headset and software that quantifies alertness, engagement, and mental workload in real time using linear and quadratic discriminant function analyses with model-selected power spectral density variables, event-related power, and wavelet transform calculations. As expected, workload increased when students were presented with problem sets of greater difficulty. Less expected, however, was the finding that as skills increased, the levels of workload did not decrease accordingly, suggesting that significant mental effort may be involved during strategic refinement (Stevens et al., 2007).

Neuroscientists are also beginning to explore the possibility of measuring cognitive load using a combination of neurotechnologies with high temporal and spatial resolution such as EEG–fNIRS (Hirshfield et al., 2009) and EEG–fMRI (Ullsperger & Debener, 2010). A growing body of literature discusses assessment of cognitive load using online psychophysiological measurement tools like pupil dilation (e.g., Marshall, 2007), galvanic skin response (Shi, Ruiz, Taib, Choi, & Chen, 2007), and electrocardiogram's median absolute deviation (Haapalainen, Kim, Forlizzi, & Dey, 2010).

In order to successfully interpret the findings from neuroscience and translate them into instructional design, however, it is important to analyze the evidence in the context of the concepts and learning tasks used in the original study. For example, neuroscience research on "working memory load" may not always have translatable implications for "cognitive load" research because studies on working memory load are purposefully designed to use tasks that do not rely as much on prior knowledge and interactions with long-term memory (e.g., indicate when a certain letter is repeated in a sequence of letters, as in the n-back task) as the more complex and less structured learning tasks used by educators in cognitive load research (e.g., read a passage and recall information from that passage).

Problem Solving

Much of the recent research in cognitive neuroscience has focused on the development of insightful problem solving (De Jong et al., 2009). Unlike the traditional, plug-and-chug textbook problems, insightful problems are authentic, real-life challenges that among other things require the learner to overcome a mental impasse, restructure the problem, reconfigure the understanding of the problem, and experience the suddenness of the solution (Sandkuhler & Bhattacharya, 2008). Jung-Beeman et al. (2004) used fMRI (Experiment 1) and EEG (Experiment 2) to explore brain activity during insightful and non-insightful solving of verbal problems. These problems required the participants to compare three different words (e.g., pine, crab, sauce) and find a single word that could be used in combination with them (e.g., apple). Participants reported whether they experienced insight or not, and the differences in responses were compared to the differences in their neural activity. The first experiment showed that insight solutions (59 %) were associated with increased activation in the right-hemisphere anterior superior temporal gyrus or RH aSTG (area 22 in Fig. 5.3), part of Wernicke's area, which is known to reflect the semantic processing of distant relations (e.g., Bowden & Beeman, 1998). Experiment 2 used the fine temporal resolution of EEG to determine whether insight really occurs suddenly (e.g., Metcalfe, 1986). A burst of high-frequency gamma band activity was observed over the RH aSTG about 0.3 s before the button was pressed to indicate the solution that was insightful—confirming the researchers' hypothesis. As in Experiment 1, no differences were observed between insightful and non-insightful solutions in the left hemisphere. As De Jong et al. (2009) note, these findings indicate that increased cognitive processing in the RH aSTG reflects the importance of semantic integration processes involved in the analysis and synthesis of the various problem features in verbal problems.

A related study cited in the De Jong et al. (2009) meta-analysis explored neural activity associated with the processes of overcoming the mental impasse, restructuring the problem, improved understanding of the problem, and abruptness of the solution in a compound association task (Sandkuhler & Bhattacharya, 2008). This EEG study found that mental impasse was correlated with increased gamma activity in the parieto-occipital cortex (selective attention) and enhancements in the theta band in the same region (working memory). This result suggests that both top-down attentional control and increased memory search lead to mental impasses. Gamma band frequencies in the parieto-occipital cortex (Fig. 5.3) were also found to be stronger for correct solutions than for false-positive solutions that were incorrect. Problem restructuring involved improvements in the alpha band frequency in the right prefrontal cortex, which is known to reflect the brain's executive function (Stuss & Knight, 2002). Activity in the right hemisphere (parieto-occipital regions) was also related to the suddenness of the solution, as demonstrated by changes in the power of the theta band. Thus, alpha, theta, and gamma activity in the prefrontal and parieto-occipital regions of the cortex appears to be a useful indicator of insightful problem solving.

Neural activity in the prefrontal and parietal areas of the brain was also explored in a recent study on mathematical problem solving (Ravizza, Anderson, & Carter, 2008). This fMRI study examined whether activity in these regions tracked with subsequent errors in solving algebraic equations. Unlike previous studies that used recognition paradigms (e.g., decide whether $2+2=5$ is correct) to assess the relationship of neural functioning with performance, participants in this study were asked to generate an answer themselves. The prefrontal region, which in previous studies exhibited activity modulated by retrieval demands, exhibited activation that was greater when equations were solved correctly, with no errors. More intense activity in this region was observed for successful problem solvers. However, the parietal cortex that has been associated with representing the number of transformations to the equation (e.g., Qin et al., 2004) showed no significant differences in activation between poor and effective problem solvers. This finding suggests that successful mathematical problem solving is related to retrieval abilities rather than to difficulty in representing or updating changes in the equation, as it is being solved.

Ravizza, Anderson, & Carter (2008) results are consistent with a previous study of error detection in mathematical processing. Using a verification task, Menon, Mackenzie, Rivera, and Reiss (2002) reported effects of accuracy in the prefrontal cortex whereas parietal regions were not affected by the accuracy of the equation. Instead, parietal cortex was modulated by the number of operands in the equation, consistent with previous work showing activation increases with increases in the number of mathematical steps that are required to solve the equation (Qin et al., 2004). Taken together, these results imply that students may be better served practicing equations with varying levels of retrieval demands rather than working with large quantities of equation operands, in order to master algebra.

The common limitation of most studies in cognitive neuropsychology, including the ones reviewed in this chapter, is their low ecological validity. Tasks used in neuroscience research are short, decontextualized, and isolated, while in educational research tasks are lengthy, content-rich, diverse, and embedded in complex social environments. Obviously, real-life problem solving can't be reduced to the association tasks described above. Educational neuroscience research involving "real" learning contexts is in its infancy; however, the recent technological advances enable educational researchers to collect neural activity data in actual classrooms. For example, a wireless EEG system allowed Stevens, Galloway, Berka, Johnson, and Sprang (2008) to begin the development of a rapid, neuroscience-based assessment of students' understanding of complex problem spaces. In this study, teams of novices and experts encoded chemistry problem spaces by completing online problem-solving simulations. Memory encoding was verified by comparing their strategies with established probabilistic models of strategic performance from a database of over 700,000 problem-solving performances (Soller & Stevens, 2007). For memory retrieval, researchers used the Rapid Sequence Visual Presentation method (Gerson, Parra, & Sajda, 2005) to show students stacks of images that represented sequences of chemical reactions. Then, the researchers probed the neural correlates of the encoded problem space by measuring differential EEG signatures that were recorded in response to rapidly presented sequences of chemical reactions that represented different valid or invalid approaches for solving the chemistry problems. Results showed that experts completed performances in stacks more rapidly than did novices and they also correctly identified a higher percentage of reactions. Furthermore, ERPs revealed increased positivities in the 100–400 ms range following presentation of the image preceding the decision when compared with the other stack images. This neural activity was used to explore reasons why students missed performances in the stack. One situation occurred when students appeared to have a lapse of attention characterized by increased power in the 12–15 Hz range, a decrease in the ERP positivities at 100–400 ms after the final image presentation, and a slower reaction time. A second situation occurred when the students' decisions were almost entirely the reverse of what was expected. These responses were characterized by ERP morphologies similar to those of correct decisions suggesting that the student had mistaken one set of chemical reactions for another. This study demonstrates that lapses of attention and correct use of incorrect content knowledge are common problems among novices in chemistry.

Emotion and Affect in Learning

According to Plato, "all learning has an emotional base" (Goleman, 1995). Yet, the emotional aspect has long been neglected in formal education (Boekaerts, 2003; De Jong et al., 2009). Recent contributions of neuroscientists are helping to rediscover affective learning by revealing the emotional dimension of human behavior. The term "affect" refers to a conscious and subjective interpretation of the complex psychophysiological reactions known as emotions. In situations of intense anxiety, stress, anger, or fear, social judgment and cognitive performance suffer through compromise to emotional regulation. For example, the human body's response to stress includes secretion of catecholamines and cortisol, and, as neuroscience research demonstrates, highly elevated levels of these hormones modulate cognition by influencing learning and memory (Sapolsky, Romero, & Munck, 2000). In extreme cases, exposure to negatively charged emotional experiences may result in permanent neuronal loss in the hippocampus (Kerr, Campbell, Applegate, Brodish, & Landfield, 1991). Thus, if learners are continuously exposed to stressors like school bullies, aggressive teachers, or incomprehensible learning materials, their cognitive functions may be impaired.

Catecholamines are also known to modulate memory consolidation, the process through which encoded information is transformed from its initially labile, transient to a more stable form (Dash, Herbert, & Runyan, 2004). Neuroscience research demonstrates that emotionally charged experiences result in stronger memories. For example, one such study had the participants rate a series of pictures as pleasant, unpleasant, or neutral (Dolcos & Cabeza, 2002). Participants were then asked to recall what was shown in the pictures and the results showed that the recall performance was better for the images that were rated either as pleasant or unpleasant. The results of ERP measurements demonstrated differences in the processing of emotional and neutral visual stimuli, which, coupled with the results of the recall test, suggest the importance of emotional anchors during the encoding and retrieval of memories. Simpson et al. (2000) conducted an fMRI study to compare participants' cognitive task performance, while they viewed either neutral or negative images. Results showed that different neural circuits were activated during task performance accompanied with neutral versus negative images, and use of negative imagery resulted in decreased task performance. These findings underline the importance of providing students with positive emotional experiences and emotionally safe learning environments that support rather than hinder knowledge acquisition.

Neuromyths

The term "neuromyths" was coined to refer to the growing number of misconceptions about the brain, its functions, and implications of neuroscience for research and practice in other domains such as parenting, early childhood education, marketing, and others (OECD, 2002). Many of these myths were developed in an attempt to explain and predict human learning. Neuromyths are difficult to debunk because they are typically rooted in valid neuroscience and psychology literature, but reflect extreme extrapolations beyond evidence and are presented through a lens that focuses only on evidence that fits the theory.

An exhaustive discussion of neuromyths is beyond the scope of this chapter; however, below is an examination of what is probably the most persistent neuromyth in education—"the myth of the first three years" (Bruer, 1999). The basic assumption behind the myth of the first 3 years is that most synapses (and hence most of the critical brain functions) are developed from birth to the age of 3 years, and if this critical period is missed, these brain functions may never develop. The neuroscientific origins of this myth are numerous. From the neuroscience perspective, learning can be defined as the creation of new connections between neurons (synapses), or the strengthening of existing synapses. It is known that after 2 months of growth, the synaptic density of the brain increases exponentially and exceeds that of an adult, peaking at 10 months of age. There is then a steady decline until age ten, when the "adult number" of synapses is reached (OECD, 2007). There have also been studies demonstrating that rats living in "enriched" environments (i.e., cage with other rodents and objects) had increased synaptic density and were thus better able to perform the maze learning test than rats living in "poor" or "isolated" environments (Diamond, 2001). The seemingly important implications for educational practice stemming from these findings have led teachers and parents to generalize, exaggerate, and extrapolate far beyond the actual scientific evidence resulting in new approaches to parenting and early childhood education that involve brain-stimulating music, videos, and gymnastics for newborns.

On the other hand, empirical research in education suggests that learning can't be reduced to the creation of new brain synapses in highly artificial contexts, characteristic of laboratory experiments. For example, a number of studies in education show that even children growing up in what could be defined as an "impoverished" environment (e.g., a ghetto) may over time come to excel in school and go on to higher education (e.g., Bruer, 1999). There are simply too many social, environmental, affective, and experience-dependent factors to take into account when defining what an "enriched" environment should be for the majority of students. While grammar is indeed learned faster and easier at a young age, the capacity to enrich vocabulary actually improves throughout the life span because it depends heavily on experience (Neville & Bruer, 2001). Also, contrary to the common belief that the brain loses neurons with age, the number of neurons in the cerebral cortex was found to be not age dependent (Terry, DeTeresa, & Hansen, 1987), and certain parts of the brain—like the hippocampus—can actually generate new neurons with age (OECD, 2007). "Understanding of the brain: The birth of a learning science" (OECD, 2007) provides a systematic discussion of the origins, common exaggerations, oversimplifications, and extrapolations, as well as evidence that helps refute this and the other popular neuromyths.

Conclusions

This chapter merely scratched the surface of neuroscience and its methods, challenges, and implications that are relevant to the education community. Each of the areas reviewed here—language and reading, mathematics learning, problem solving, cognitive load, and affective learning—lies at the intersection of neuroscience and education; however, caution must be exercised in drawing conclusions for learning, instruction, and performance. Neuroscientists examine cognitive functions at such a fine level of detail that their findings are frequently deemed unusable by educational researchers (e.g., Bruer, 2006). Most current neuroscience methods limit access to such important educational considerations as context; localizing cognitive functions to different brain areas does little to inform actual educational practice; and it is very easy for educational researchers to resort to reductionism and propagate neuromyths (Varma et al., 2008).

While educators are often disappointed that neuroscience findings do not lead to direct and straightforward applications, no such direct application exists in other fields (Ansari & Coch, 2006). For example, in medicine, basic research in fields like epidemiology and actual practice of health care interact to produce tangible and mutual benefits. Doctors' observations stimulate new research, the results of which can, in turn, improve medical practice. In the case of education, a growing number of scholars representing various domains of educational research discuss educational applications of neuroscience with optimism. De Jong et al. (2009) report new and exciting developments in cognitive, affective, and social neuroscience relative to the neural activity underlying metacognition and self-regulation, multimodal processing, and social cognition. Use of fMRI to develop cognitive models to explain and predict complex problem solving is explored by Anderson et al. (2008). Goswami (2009) argues for the integration of educational, cognitive, and neuroscience research paradigms and illustrates the application of this integrative framework using the concept of biomarkers, or cognitive signatures, that can potentially help identify children with learning difficulties very early in their development.

Interaction of neuroscience and education can be facilitated in many ways. Most current reviews discussing the implications of neuroscience for education conduct post hoc interpretations of neuroscience findings, trying to identify results of most relevance to the education community. This process consumes time and resources but, as practice shows, it does not always result in usable knowledge for educators. Instead, real interdisciplinary research should be fostered, for example by developing laboratories including neuroscientists, psychologists, and educators, who can collaborate and conduct experimental work on educational neuroscience from the early stages of experiment conceptualization to the final interpretations. Innovative designs produced as part of such interdisciplinary efforts can allow researchers to study the effects of context and other variables of interest, and update and develop new instructional theories and principles. Finally, establishment of collaborative professional organizations and journals like the recently created Mind, Brain, and Education can improve communication and sharing of the relevant ideas and findings.

Direct translation of research in neuroscience to inform instruction can still be problematic (Bruer, 2006; Varma et al., 2008). However, advances in neurotechnologies like wearable, wireless EEG (e.g., http://www.b-alert.com and http://www.neurosky.com) and signal analysis techniques that remove irrelevant artifacts and automatize most of the data processing make neuroscience tools and methods more and more usable, useful, and accessible to educational researchers. Even policy-makers are enthusiastic about the possibilities of using neurocognitive findings to inform learning and instruction. The USA's National Council for Accreditation of Teacher Education (NCATE) has recently issued a report that urges teacher education programs to integrate neuroscience findings about human development into their curricula (NCATE, 2010). Observers note that incorporation of educational neuroscience discoveries into educational policy and practice will shape the twenty-first-century teaching and learning in ways that are analogous to the contributions of educational psychologists like John Dewey, B.F. Skinner, and Jean Piaget in the twentieth-century education (Sylwester, 2010). The collective work of neuroscientists and educational researchers must, therefore, continue. The stakes are high for all parties involved, but, most importantly—for students.

6 Emotions and Motivation in Learning and Performance

ChanMin Kim and Reinhard Pekrun

Abstract

This chapter reviews theories and research on academic emotions and motivation that can be integrated into the processes of instructional design and development. First, we discuss the impact of emotions in learning and performance contexts. Second, we review theories describing how emotions occur. Third, we discuss how to optimize emotional experiences in learning and performance contexts and review several models and approaches that can be used in instructional design. Fourth, we review instruments and technologies measuring emotions and emotion regulation. We conclude the chapter by suggesting future research directions including reframing motivation research that considers emotions in the realm of educational communications and technology.

Keywords

Academic emotions • Motivation to learn • Cognitive appraisal • Causal expectancies • Causal attribution • Emotion regulation

Introduction

Motivation and emotions play a critical role in learning and performance (Astleitner, 2000; Carver & Scheier, 1990; Goetz, Pekrun, Hall, & Haag, 2006; Op't Eynde, Corte, & Verschaffel, 2006; Pekrun, 1992; Pekrun, Goetz, Titz, & Perry, 2002). When students do not exhibit high motivation, they either do not initiate or discontinue learning tasks. Furthermore, when students have high anxiety, their performance is not ideal. However, instructional designers and researchers often pay little heed to motivation and emotions due to their indirect effects on learning and performance (Schiefele & Csikszentmihalyi, 1995). Additionally, little research examines interventions designed to improve learners' emotional experiences in learning and performance (Astleitner, 2001; Gläser-Zikuda, Fuß, Laukenmann, Metz, & Randler, 2005; Kim & Hodges, 2012). While some studies have examined interventions to reduce learners' motivational problems (e.g., Hodges & Kim, 2010; Kim & Keller, 2008, 2010, 2011), there is little research in which both emotions and motivation are considered in efforts to improve learning and performance. In this chapter, we explore the intersection of motivation and emotions in the learning process, and how to support students in this critical area.

The Inseparable: Emotions and Motivation

Emotions result from "the dynamic interplay of cognitive, physiological, and motivational processes in a specific context" (Op't Eynde et al., 2006, p. 193). In order to understand educational experiences, emotions and motivation need to be considered alongside cognition (Ainley, 2006; Hannula, 2006; Meyer & Turner, 2006; Op't Eynde et al., 2006; Op't Eynde

& Turner, 2006; Pekrun, 2006; Turner & Patrick, 2008). The interplay among emotions, motivation, and cognition can be understood from the perspective of goals (Ainley, 2006; Dweck, 1992; Linnenbrink, 2006; Linnenbrink & Pintrich, 2002; Op't Eynde & Turner, 2006; Pekrun, 2006; Schutz, Hong, Cross, & Osbon, 2006). For example, a mastery goal orientation can promote positive emotions and sustain motivation whereas a performance-avoidance goal orientation can promote negative emotions and poor motivation (Dweck, 1992; Pekrun, Elliot, & Maier, 2006). Emotions and motivation are enacted while striving to pursue or avoid goals (Carver & Scheier, 1990; Op't Eynde & Turner, 2006).

In addition to their organization around goals, there are bidirectional (reciprocal) influences between emotions and motivation (Kim & Hodges, 2012; Kim, Park, & Cozart, 2013; Pekrun, 2006). Emotions and motivation interact with each other and make each other activated (or deactivated), which directs behaviors (Hannula, 2006; McLeod, 1988; Op't Eynde et al., 2006; Op't Eynde & Turner, 2006; Pekrun, 2006). Some researchers regard motivation as part of emotion processes (e.g., Op't Eynde et al., 2006), whereas others regard emotions as part of motivation processes (e.g., Ford, 1992; Hannula, 2006). Buck (1985) explained the relation between emotions and motivation using the analogy of energy and matter in physics: "Just as energy is a potential that manifests itself in matter, motivation is a potential that manifests itself in emotion. Thus motivation and emotion are seen to be two sides of the same coin, two aspects of the same process" (p. 396). Although emotions and motivation are not inseparable conceptually and empirically, it is difficult to separate them in the contexts of learning and performance (Ainley, 2006; Op't Eynde et al., 2006). An integrative view of emotions and motivation is needed to understand and facilitate learning and performance (Kim & Hodges, 2012; Pekrun, 2006).

The purpose of this chapter is to discuss theories and research on emotions and motivation that can be integrated into instructional design and development. A detailed review of motivation research is not included in this chapter because previous editions of the *Handbook of Research for Educational Communications and Technology* addressed motivation research in multiple chapters (e.g., Park & Lee, 1996; Seel, 2007). Much of this chapter focuses on academic emotions while acknowledging that emotions and motivation are difficult to separate. First, we discuss the impact of emotions in learning and performance contexts. Second, we review several theories describing how emotions occur. Third, we discuss how to optimize emotions in learning and performance contexts and present design strategies that employ emotion regulation. Fourth, we review instruments and technologies that measure emotions and emotion regulation. We conclude the chapter by suggesting directions for future research.

How Emotions Influence Learning and Performance

Emotions impact the quality of learning and performance (Gläser-Zikuda et al., 2005; Goetz et al., 2006; Pekrun, Elliot, & Maier, 2009; Pekrun, Goetz, Daniels, Stupnisky, & Perry, 2010). The impact of emotions on learning and performance should be studied in the context where the emotions are occurring. This in turn would improve explanations of how emotions impact learning and performance. The following list overviews what mediates the impact of emotions on learning and performance:

- Emotions influence cognitive processes and strategies
- Emotions influence decision making
- Emotions influence motivation
- The aforementioned influences are reciprocal

Impact of Emotions on Cognitive Processes and Strategies

Emotions influence cognitive processes (Forgas, 2000; Gläser-Zikuda et al., 2005; Linnenbrink, 2006; Pekrun, 2006; Pekrun et al., 2002; Schwarz, 1990, 2000). Information processing can be initiated, accelerated, altered, or interrupted by emotions (Astleitner, 2000; Pekrun, 1992; Pekrun et al., 2002). Emotions can alter how information is stored and retrieved (Levine & Pizarro, 2004; Linnenbrink, 2006; Schwarz, 2000). Memory can be organized differently depending on emotions experienced when the information was stored and/or the information is being retrieved.

Mood-congruent retrieval implies that a person's current emotional state influences the way his/her memories are recalled (Blaney, 1986; Bower, 1981; Levine & Pizarro, 2004; Parrott & Spackman, 2000). For example, in one study, people recalled their experiences about blood donation differently depending on their current feelings about blood donation (Breckler, 1994). In another study, people retrieved memories about their early marriage life differently depending on how happy or unhappy they feel about their marriage at present (Holmberg & Holmes, 1994). This is consistent with the notion that "emotions enhance the availability of emotion-congruent information" (Levine & Pizarro, 2004, p. 537). In other words, people tend to retrieve information that is congruent with their current emotions (Schwarz, 2000). For example, a student may recall enjoyable memories about mathematics while having fun playing Sudoku rather than while taking a mathematics exam in a classroom.

The type of emotion (e.g., positive vs. negative; activating vs. deactivating) can influence the use of cognitive strategies (Pekrun, 2006; Pekrun et al., 2002). People experiencing positive emotions tend to use more general knowledge in heuristic ways whereas people experiencing negative emotions tend to use systematic analyses with more focus on details (Hertel, Neuhof, Theuer, & Kerr, 2000; Levine & Pizarro, 2004; Schwarz, 2000). Research has shown that activating positive emotions (e.g., happiness) facilitates flexibility and creativity (Isen, 2000; Levine & Pizarro, 2004). Activating negative emotions (e.g., anxiety) can lead to the use of narrowly focused, rigid strategies and deactivating negative emotions (e.g., boredom) can lead to superficial information processing due to unfocused attention (Pekrun, 2006). For example, students with high test anxiety could dwell on one exam question with which they are struggling because their use of narrowly focused strategies keeps them from allocating time for all exam questions. The impact of emotions on cognitive processes and strategies influences learning strategies, problem-solving behavior, and performance (Kim et al., 2013; (Op't Eynde et al., 2006; Pekrun, 2006).

Impact of Emotions on Decision Making

Emotions influence decision making (Schwarz, 2000). When making decisions, people intend to minimize the likelihood of negative emotions and maximize the likelihood of positive emotions; therefore, anticipated emotions can influence decision-making processes (Schwarz, 2000). As a negative consequence of such influence, Schwarz (2000) provided the following example:

> Parents may hesitate to vaccinate their child when the vaccine has potentially fatal side effects, even under conditions where the likelihood of a fatal side effect is only a fraction of the death rate from the disease, presumably because anticipated regret looms larger for the act of vaccination. (p. 436)

When parents choose not to vaccinate their children, they make such a decision because they are motivated to avoid the possibility of the anticipated emotion (regret) and also because regret for action (vaccination) is usually more intense than that for inaction (Schwarz, 2000).

Anticipated emotions may also impact decision-making processes in learning and performance contexts (Stephens & Pekrun, 2011). For instance, if Jake decided not to study for the final exam because he thinks he would fail anyway, he may have made such a decision to minimize the likelihood of the negative emotions such as hopelessness and shame that would come from ineffective action.

Past experiences of emotions (i.e., emotional memories) influence decision making as well (Levine & Pizarro, 2004; Schwarz, 2000). In the aforementioned example, Jake may have felt hopeless in the past when he did not perform well on an exam for which he studied. This past, negative emotion (a) made Jake underestimate the probability that studying for the exam would result in success in the exam, and (b) influenced his decision not to study. In Jake's decision-making process, expectancy assessment was involved, which is heavily dependent on memories of prior experiences (Carver & Scheier, 1990). One would then wonder if Jake would never make a decision to study for an exam due to his past experience of negative emotions. "Emotional memories are not indelible" (Levine & Pizarro, 2004, p. 535). Instructional designers can promote positive changes in learners' expectancy assessment processes. For example, goals in tasks should be specified. Without knowing what is expected, it is not likely that learners' expectancy assessment will be constructive. Nonetheless, "goal specificity in itself does not necessarily lead to high performance because specific goals vary in difficulty" (Locke & Latham, 2000, p. 706). Task difficulty needs to be modified per learners' ability; the provision of incremental success experiences can increase learners' assessment of the probability of success in completing tasks.

Impact of Emotions on Motivation

Different emotions correspond to different actions. For example, fear can induce withdrawal or avoidance and anger can induce a physical attack (Frijda, Kuipers, & Schure, 1989; Plutchik, 1980). Action tendencies result from discrete emotions that create specific action impulses. For example, the physical attack (an action) induced by anger (an emotion) is meant to hurt someone (a motivational intention) (Roseman, Wiest, & Swartz, 1994). How emotions influence one's motivation to act in a certain way can be explained in terms of memory and goals. Some researchers view emotion as a kind of information in working memory that could contribute to motivation regulation (Carver & Scheier, 1990; Levine & Pizarro, 2004). In the previous example, Jake's memory of past, negative emotions deactivated his motivation to study, as did anticipatory, negative emotions. As "emotions can cause interruption and reprioritization of one's goals" (Carver & Scheier, 1990, p. 31), the influence of emotions on motivation may also be mediated by goals. As illustrated earlier, students' expectancy assessment can be involved in this process of emotions influencing motivation. Emotions also influence goal pursuit (Seifert, 1995). Emotions along with expectancy assessment are used in monitoring, which leads to either goal-pursuit or goal-disengagement (Carver & Scheier, 1990). The monitoring process can be either conscious or nonconscious (Carver & Scheier, 1990). Through the monitoring process involving emotions, emotions facilitate or impede self-regulatory behaviors toward goals.

Optimizing academic emotions can in turn optimize motivation and ultimately learning and performance. For example, compared with students in the control group, students who received an emotion regulation intervention showed more positive motivation and positive emotions than those in the control group (Kim & Hodges, 2012). To promote optimal learning and performance, instructional designers need to consider not only the content to be learned but also student needs related to academic emotions and motivation during the design of instruction (Pintrich & Schunk, 2002). Also, instructional designers need to consider ways of highlighting intrinsic task value. Autonomy-supportive learning environments can promote learners' curiosity and desire to take on a challenge (Ryan & Deci, 2000). An emphasis on mastery goal orientations helps learners perceive task value beyond instrumental usefulness (Ames, 1992; Covington, 2000).

Reciprocal Effects

Up to now, how emotions influence learning and performance has been explained through the discussions of the impact of emotions on cognitive processes and strategies, decision making, goal-pursuit, and motivation. Cognition, emotions, and motivation are reciprocal (Pekrun, 2006). For example, emotions influence memory but memory also influences emotional reactions (Carver & Scheier, 1990). Emotions can influence goal orientations, but also different emotions are possible when a student displays a particular goal orientation (Dweck, 1992; Linnenbrink & Pintrich, 2002; Schwarz, 2000). In short, emotions influence ongoing behaviors (Carver & Scheier, 1990) and vice versa because emotional processes interact with motivational and cognitive processes (Astleitner, 2000). Second, situational aspects influence this interactive process (Pekrun, 2006). For example, the quality of communications and understanding between students and teachers is influenced by emotions (e.g., empathy) and impacts the interactive process (Goetz et al., 2006; Meyer & Turner, 2002). In the next section, the manifestation of academic emotions is discussed in light of instructional design.

How Emotions Occur

Emotions arise when a person *appraises* a given situation. *The meaning and causal structures* of the situation and *controllability* are cognitively evaluated and expectancy is formed accordingly (Gross, 2008; Pekrun, 2006; Scherer, 1999; Schutz & Davis 2000; Weiner, 1985). This appraisal process, which can be either conscious or nonconscious and either deliberate or automatic, brings about an emotional response (Gross, 2008; Johnson-Laird & Mancini, 2006; Op't Eynde et al., 2006; Pekrun, 2006; Schutz & Davis, 2000, 2010).

A person's expectancy and perceived values of a certain action (or inaction) and its outcomes determine the person's responses to the situation where the person takes (or does not take) the action (Carver & Scheier, 1990; Pekrun, 2006). Motivational and emotional responses occur based on these expectancy and value appraisals. In this section, what forms the expectancy and values is discussed to explain how emotions occur.

The *meaning structure* of a given situation initiates expectancy and value assessment; that is, the subjective controllability and value of the situation (i.e., achievement activities and/or outcomes) are analyzed (Carver & Scheier, 1990; Pekrun, 2006; Schutz & Davis, 2000). For example, Bill just entered a 2-year college and is required to take a remedial math course. Without taking the remedial math course, he is not allowed to take any other course. If he drops the remedial math course, he must drop other courses that are being taken together as well. Bill values the remedial math course in that it can determine whether he can continue to pursue his goal—completing the 2-year college, eventually transferring to a 4-year college, getting a college degree in social work, and becoming a social worker. On one hand, the value of an anticipated outcome—the completion of the remedial math course that leads Bill one semester closer to his dream job—strengthens his motivation to study hard. On the other hand, anxiety could grow due to the extremely important and relevant meaning of the remedial math course to Bill's goal. As discussed in Pekrun's (2006) control-value theory of achievement emotions, this meaning structure analysis involves the appraisal of extrinsic value and intrinsic value. In terms of extrinsic value, Bill values the instrumental usefulness of the remedial course for his goal attainment. In terms of intrinsic value, Bill may value the course itself (if Bill just likes to learn math). However, the meaning structure of the situation alone does not bring about emotional responses; rather, it should be accompanied with the analysis of what controls the situation, one's actions, and their outcomes.

The *causal structure* of a given situation forms the expectancy in part; that is, learners' perceived control (i.e., subjective control over achievement outcomes; perceptions of what the outcome of their action depends on) is critical in their expectancy assessment (Pekrun, 2006; Weiner, 1985). The causal structure of the situation is analyzed and leads to one's perception of the locus of control (internal vs. external) and the stability of control (stable vs. unstable) (Weiner, 1985). In Bill's case, if he perceives that his ability will help him succeed in the remedial math course, his perceived control is internal and stable. If he perceives that he needs luck to be successful in the course, his perceived control is external and unstable. As described in expectancy-value theories, this perceived control influences a person's motivation (e.g., Eccles, 1983). Bill would not be motivated to study for the course when he perceives that his effort would not matter but luck does. At the same time, Bill's emotional experience can also be different according to his perception of the causal structure. For example, Bill would be proud of himself if he thinks that he passed the midterm exam because his effort paid off rather than he was lucky. In contrast, if Bill failed the exam and he thinks that his failure was not from lack of effort but from lack of support by others, he would experience the emotion of anger. As discussed by Pekrun (2006), the process of this causal structure analysis involves causal expectancies and causal attributions: the former is prospective appraisal of the relation of causes to anticipated effects (examples about Bill's course success above), and the latter is retrospective appraisal of the relation of observed effects to causes (examples about Bill's exam results above).

People can perceive the causal structure of the same situation differently for various reasons. Past emotions, memory of prior experiences, task difficulty, goal specificity, and vicarious experience are examples of sources of individuals' different analyses of the causal structure and corresponding different emotional responses (Carver & Scheier, 1990; Locke & Latham, 2000; Pekrun, 2006; Weiner, 1985). Bill may feel hopeless because unpleasant memories of 8th-grade algebra returned (past emotions). He may still be ashamed of his low scores on the college placement test that resulted in a required remedial math course (past emotions). He may be frustrated because taking an online course is new to him (task difficulty; lack of goal specificity). He may be nervous because a friend who had taken the course told him that the exam questions were unpredictable (vicarious experience).

Even when people perceive that they are equipped with internal and stable dispositions that are important to attain success, their expectancies are not necessarily positive. For example, Bill may perceive that his ability is the enabler for success in the remedial math course, but if he thinks that he is not able to exert the required effort due to habitual procrastination, his expectancy of course completion could be low and he might experience negative emotions. Bill's controllability over his own effort would also be critical in the appraisal process. Thus, how people evaluate the *controllability of actions*—i.e., subjective control over achievement activities in Pekrun (2006)—also forms expectancies and drives emotional responses (Weiner, 1985). The concept of controllability is worth mentioning especially because some causes can be viewed as either stable or unstable (Weiner, 1985), and as either controllable or uncontrollable. Ability is perceived as stable and uncontrollable if math ability is regarded as a fixed entity, but it can be perceived as unstable and controllable if Bill thinks that math ability can be acquired over time because math is learnable.

In summary, the appraisal process that forms perceived control, expectancies, and subjective values plays a central role in an emotion process (Levine & Pizarro, 2004; Op't Eynde et al., 2006; Pekrun, 2006; Weiner, 1985). The perceived meaning and causal structure of the situation can be considered by instructional designers to optimize emotional experiences and motivation in learning and performance contexts. It is also important to address learners' needs not only individually but also in groups. As mentioned earlier, vicarious experience from peers can lead to learners' different perceptions of meaning and causal structures of the situation, as shown in research on goal contagion (e.g., Aarts, Dijksterhuis, & Dik, 2008).

How Emotional Experience Can Be Optimized

Understanding learners' emotions implies understanding not only their values and beliefs but also their learning and problem-solving behaviors (Astleitner, 2000; Op't Eynde et al., 2006). However, simply understanding learners' emotions is not sufficient; rather, positive activating emotions should be cultivated since they can lead to positive outcomes such as open-mindedness, effective cognitive strategy use, motivation, self-regulatory behaviors toward goals, academic achievement, psychological growth, and positive career aspirations (Astleitner, 2000; Fredrickson, 1998; Goetz et al., 2006; Pekrun, 2006). Theory-driven interventions can be designed to cultivate learners' positive activating emotions (Astleitner, 2000; Goetz et al., 2006; Kim & Hodges, 2012; Pekrun, 2006). In fact, several theoretically guided models and approaches can be used in instructional design to improve learners' emotional experiences as discussed below.

Models and Approaches for Optimizing Emotional Experience

The FEASP (fear, envy, anger, sympathy, and pleasure) approach was proposed to help design "emotionally sound instruction" (Astleitner, 2000, p. 173):

- *Fear* arising from subjectively judging a situation as threatening or dangerous
- *Envy* resulting from the desire to get something that is possessed by others
- *Anger* coming from being hindered to reach a goal and being forced to an additional action
- *Sympathy* referring to an experience of feelings and orientations of other people who are in the need of help
- *Pleasure* based on mastering a situation with a deep devotion (Astleitner, 2000, p. 175)

A set of instructional strategies can systematically decrease fear, envy, and anger and increase sympathy and pleasure (Astleitner, 2000). For example, strategies for reducing learners' fear include helping learners accept their mistakes as opportunities to learn. Astleitner (2000) argued that the strategies should be implemented by instructional designers and teachers to promote the desired emotional experience of learners. He also emphasizes that strategies should be designed and implemented based on learners' problems and the outcomes should be evaluated. As part of an empirical validation of the FEASP approach, Astleitner (2001) asked both teachers and students how important they thought emotions were in learning and instruction and if and how often the strategies in the FEASP approach were used in classroom. Based on the survey results, Astleitner (2001) concluded that the FEASP approach was “relevant, usable, consistent, and affecting emotions in daily instruction” (p. 209). However, his approach has not been tested in the process of design, development, implementation, and evaluation of interventions aiming to improve learners’ emotional experience. Also, his validation process seems to be limited. A finding that students state that emotions are important in school may be limited by students’ (often) inaccurate understanding of academic emotions. In addition, the functions of emotions for motivation and learning were not elaborated; for example, he defined envy as a maladaptive emotion, which does not address benign envy, as opposed to malicious envy, that can serve as a motivation to study more (for further discussion of benign vs. malicious envy, see Van de Ven, Zeelenberg, & Pieters, 2009, 2011).

Keller’s attention, relevance, confidence, and satisfaction (ARCS) motivational design model (1987, 2010) considers learners’ emotional experiences, although Keller did not explicitly mention design for emotions. The model provides instructional strategies to increase the four components in learners. For example, one motivational strategy for attention is creating curiosity in learners by asking them questions that are not congruent with their current knowledge (e.g., paradoxical questions) (see Keller, 2010). Keller (2010) discussed learners’ emotional states such as anxiety, boredom, pleasantness, and so on, and he provided specific strategies to deal with these emotional states in instructional design. There has not been much research implementing the ARCS model to promote learners’ emotional experience, although there have been numerous studies that applied the model to the design of interventions to promote motivation (e.g., Martindale, Pearson, Curda, & Pilcher, 2005). Keller’s more recent model, called an integrative theory of motivation, volition, and performance (MVP), includes design to facilitate learners’ volition (Keller, 2008). The MVP model has been used in a few empirical studies (Kim & Keller, 2008, 2010, 2011). The model recommends using emotion control as a volitional strategy but lacks specific strategies to promote emotion control.

Park and Kim (2012) introduced an approach to enhance students’ enjoyment and reduce boredom in online learning contexts by promoting interest in course readings. Specifically, the virtual tutee system (VTS) was proposed as a computer-based peer-tutoring environment where learners teach virtual tutees. The VTS was designed based on the concept of *learning by teaching* to increase interest and enjoyment and decrease boredom. Role theory and self-determination theory were used as theoretical foundations. However, empirical validations of the VTS design framework have not yet been published; one study illustrating the positive outcome of applying the VTS framework to a college course is under review.

Emotional scaffolding has been studied in face-to-face classrooms (e.g., Meyer & Turner, 2007; Rosiek & Beghetto, 2009) as well as in online environments (e.g., Aist, Kort, Reilly, Picard, & Mostow, 2002). Emotional scaffolding refers to activities that are tailored to specific aspects of the content of teaching as well as to emotional experience of students in the classroom (Rosiek, 2003). Emotional scaffolding requires teachers’ knowledge of interactions among “curricular content, cultural discourses, community histories, students’ personal histories, and general attitudes about schooling that precipitated students’ emotional response to their lessons” (Rosiek, 2003, p. 406). Also, emotion regulation has been used to promote positive emotions and desired motivational states. Gross (2008) proposed four antecedent-focused strategies (used before the activation of certain emotions) and one response-focused strategy (used during the activation of certain emotions):

- Situation selection—choosing to be in environments that are likely to diminish negative emotions
- Situation modification—changing a certain environment to reduce negative emotions
- Attentional deployment—shifting attention to something else
- Cognitive change—reappraisal; cognitively reevaluating the situation
- Response modulation—suppressing certain emotions activated (pp. 500–505)

Kim and Hodges (2012) designed and implemented an emotion regulation intervention that focused on the renewal of cognitive appraisal processes using three of these strategies (attentional deployment, cognitive change, and response modulation). They intended to help with learners’ conscious and deliberate awareness and reappraisal of the situation.

Schutz and Davis (2010) proposed four emotion regulation processes in test-taking contexts as follows:

- Cognitive-appraising processes related to the goal-directed person–environment transaction involving goal importance, goal congruence, agency, and problem efficacy
- Task-focusing processes
- Emotion-focusing processes involving wishful thinking and self-blame
- Regaining task-focusing processes involving tension reduction and reappraisal (Schutz & Davis, 2010, p. 2)

Schutz and Davis (2010) did not produce an instructional intervention; they examined naturally occurring processes. However, their proposed dimensions for emotion regulation processes, especially the *regaining task-focusing processes*, can be applied to the design of interventions promoting emotion regulation. The effects of emotion regulation may persist beyond the intervention because acquired regulatory reappraisal skills can be transferable to other contexts. This approach of emotion regulation may be worth pursuing since one of the important goals as to educational contexts should be to raise self-regulatory learners who can help themselves outside of class.

A Comprehensive Framework: The Control-Value Theory of Achievement Emotions

Pekrun's (2006) control-value theory of achievement emotions provides a comprehensive framework illustrating four paths that can be used to promote emotion regulation: (a) emotions, (b) appraisals, (c) competences for learning and achievement, and (d) design of tasks and learning environments.

First, the emotion path is *emotion-oriented regulation* that directly deals with emotions. For example, when students feel anxious before an exam, they can try to focus on "tasks to do" before the exam without thinking of "the exam." *Response modulation* and *attentional deployment* can be categorized as emotion-oriented regulation (Gross, 2008). Second, the appraisal path is *appraisal-oriented regulation* that deals with the subjective control and subjective value of a given context. For subjective control, causal expectancies and/or causal attributions need to improve; for subjective value, the perceived intrinsic and/or extrinsic value need to improve. That is, the meaning and causal structure of the situation and controllability, as described in the *How Emotions Occur* section, need to be reappraised. Schutz and Davis' (2010) *regaining task-focusing processes* can be explained by this appraisal-oriented regulation. Gross' (2008) emotion regulation strategy, *cognitive change*, can be categorized as appraisal-oriented regulation. Third, the learning and achievement path is *competence-oriented regulation* that deals with the improvement of learning and achievement. For example, abilities can be enhanced and study skills can be acquired. Keller's (1987, 2010) ARCS model can be used for competence-oriented regulation. Park and Kim's (2012) intervention to increase reading interest through the learning by teaching technique can be regarded as an example of competence-oriented regulation. Last, the environment path is *design of tasks and learning environments* that deals with improvement of learning and performance contexts. Examples include a clarification of course requirements (i.e., a change relevant to the specificity of goal structure and expectations; e.g., Locke & Latham, 2000), adding choices for an assignment completion (i.e., change relevant to autonomy support; e.g., Ryan & Deci, 2000), and so on. Astleitner's (2000) FEASP approach as well as Keller's ARCS model can be used for the design of learning and social environments.

Pekrun (2006) discussed how education should cultivate learners' positive emotions and emotion regulation through these four paths. For example, he argued that positively perceived value of learning should be induced through learners' communications with and observations of people around them, which can be possible in learning environments corresponding to students' needs (Frenzel, Goetz, Lüdtke, Pekrun, & Sutton, 2009; Pekrun, 2006).

How Emotions Can Be Measured

Instructional design starts with needs assessment and instruction is evaluated through formative and summative assessments (Dick, Carey, & Carey, 2008). This means, in order to create interventions cultivating positive emotions and/or emotion regulation, first, there should be an investigation of learners' current emotional states. Also, there should be assessment instruments to evaluate the effect of interventions. In this section, we introduce several instruments and technologies that can be used to measure the types and levels of emotions as well as emotion regulation skills and processes. We also discuss issues with measuring emotions in relation to *situatedness* of emotions in learning and performance contexts.

Measurement Instruments

The Achievement Emotion Questionnaire (AEQ; Pekrun, Goetz, Frenzel, Barchfeld, & Perry, 2011) has been widely used in educational emotion research. The AEQ is a self-report instrument designed to assess students' emotions experienced in academic contexts. The AEQ measures nine discrete emotions relating to attending class, studying and doing homework, and taking tests and exams: enjoyment, hope, pride, relief, anger, anxiety, shame, hopelessness, and boredom. The AEQ scales for assessing emotions in the specific context of test-taking have been called the Test Emotions Questionnaire (TEQ; Pekrun et al., 2004). Other self-report instruments used in educational emotion research but measuring emotion regulation are the Emotion Regulation During Test Taking scale (ERT; Schutz, DiStefano, Benson, & Davis, 2004), the Emotion Regulation Questionnaire (ERQ; Gross & John, 2003), the Cognitive Emotion Regulation Questionnaire (CERQ; Garnefski & Kraaij, 2007; Garnefski, Kraaij, & Spinhoven, 2001), and the COPE scale (Carver, Scheier, & Weintraub, 1989).

Measurement Technologies

The affective computing group at the MIT Media Laboratory, the Emotive Computing Lab at the University of Memphis, and the Affective Learning Companion research group at Arizona State University have developed and tested sensing systems and tools that detect people's psychophysiological responses in order to infer their emotional experience in a variety of contexts (e.g., D'Mello & Graesser, 2010; El Kaliouby, Picard, & Baron-Cohen, 2006; Gonzalez-Sanchez et al., 2011; Picard, 2003; Scheirer, Fernandez, Klein, & Picard, 2002). Such technologies include *Expression Glasses* to collect data of interest, surprise, confusion, satisfaction from facial expressions, *Galvactivator* to collect data of arousal and excitement from skin responses, *Pressure-sensitive mouse* to collect data of frustration and anxiety from mouse-click behaviors, and *AutoTutor* including an automatic affect coding system based on Ekman's Facial Action Coding System (Ekman & Rosenberg, 1997) to detect affective states (for details, see D'Mello & Graesser, 2010; El Kaliouby et al., 2006; Gonzalez-Sanchez et al., 2011).

Another interesting development of a technology detecting learners' emotions is the *Subtle Stone*. It is a wireless, handheld squeezable ball and permits private communications between students and their teacher about emotional experience in real time (Alsmeyer, Luckin, Judith, & Harris, 2009; Balaam, Fitzpatrick, Good, & Luckin, 2010; Kim & Balaam, 2011). The *Subtle Stone* displays different colors and individual students can choose colors to express different emotions; the unique association between colors and emotions is not revealed to peers. The *Subtle Stone* has potential to be used for formative assessments during learning processes that allow not only the redesign of lessons but also teachers' emotional scaffolding for students (Kim & Balaam, 2011).

Problems in Measuring Emotions

Academic emotion research has often been criticized because of its reliance on self-report data and the lack of real-time data collection (Ainley, 2006; Kim & Hodges, 2012; Pekrun, 2006; Picard, 2010; Schutz & Davis, 2010). The development of advanced technologies such as psychophysiological sensing systems reviewed above is expected to resolve some of the issues. However, emotions are only partially observable; individuals' facial expressions or skin reactions, for example, can have different meanings even in the same situation (Buck, 1999; Hannula, 2006). Also, even if such technologies are capable of detecting accurate data related to learners' emotions, still there is the possibility of their interference with emotion processes. For instance, suppose wearable sensors are used to detect emotional states during test-taking. Even if those are lightweight and interruptions are minimal, they could detract on-task behaviors, which brings up ethical concerns as well (Schutz & Davis, 2010). In addition, emotions tend to constantly occur and change rapidly (Buck, 1985; Folkman & Lazarus, 1985; Op't Eynde et al., 2006; Pekrun, 2006; Schutz & Davis, 2010). The points in which changes are occurring or occurred can be difficult to investigate. Moreover, even if technologies, such as embodied conversational agents, relational agents, and affect-aware tutors (Bickmore & Cassell, 2004; Campbell, Grimshaw, & Green, 2009; Woolf et al., 2009, are implemented to promote positive emotions, it would be difficult to provide just-in-time support corresponding to the detected changes in emotions.

These issues are related to the *situatedness* of emotions, meaning that emotions are reciprocally and dynamically linked to cognitive and motivational processes in a specific, social-cultural context (Op't Eynde et al., 2006; Pekrun, 2006). Emotions should be studied within learning and performance contexts (Pekrun, 2006; Schutz et al., 2006). Therefore, the multilevel approach including several dimensions of analysis for personal, interpersonal, community-level, interactive, socially situated appraisal processes should be employed to fully understand and support learners' emotional experience in learning and performance contexts (Op't Eynde & Turner, 2006; Pekrun, 2006).

Conclusion

This chapter discussed the impact and process of emotions, design possibilities for optimizing emotional experience in learning and performance, and measurement instruments, technologies, and issues. Foundations for creating theory-based interventions and evaluation programs have been presented for instructional design and research on emotion and emotion regulation. Further research should continue to develop a design framework for cultivating learners' positive emotions and thereby motivation to learn and perform better. Also, a multi-method approach (Meyer & Turner, 2002; Pekrun, 2006) using not only self-report instruments and emotion-detecting technologies but also other data collection methods, such as discourse analysis, interviews, observations, interaction analysis, etc., should be considered to minimize limitations in emotion measurement. In addition, in order to test the effects of interventions developed for promoting or reducing certain discrete emotions, interventions should be implemented in the contexts where targeted emotions are present. There have been numerous studies where emotion-evoking stimuli were used, such as movie clips, images, and so on (e.g., Coan & Allen, 2007; DeSteno, Petty, Rucker, Wegener, & Braverman, 2004; Lepper, 1970). However, emotional responses can be different person to person and it is likely unethical to induce intense frustration, anxiety, hopelessness, anger, etc. (e.g., Lepper, 1970; Scheirer et al., 2002). Last, reframing motivation research that considers emotions in the realm of educational communications and technology is necessary (Meyer & Turner, 2002, 2006; Turner & Patrick, 2008).

7 Instructional Design Models

Robert Maribe Branch and Theodore J. Kopcha

Abstract

This chapter presents information about the role of models used for instructional design. While heuristics provide broad references for approaching instructional design, specific applications of procedures necessary to actually develop teaching and learning materials require more defined models. The purpose here is to promote a better understanding about the appropriate utilization of instructional design models. Instruction is posited here as including both teaching and learning, and that teaching and learning are inextricably connected with regard to the construction of knowledge and skills. Since the first appearance of instructional design models in the 1960s there has been an ever-increasing number of models published in both the instructional technology and other education literature based on the assumptions that instruction includes both teaching and learning. While there are hundreds of instructional design models, there have been only a few major distinctions among them, until recently. Still, instructional design models provide conceptual tools to visualize, direct, and manage processes for creating high-quality teaching and learning materials. The proper selection of instructional design models assists us in appropriately matching the right process with the right situation. Thus, instructional design models serve as a valuable source for matching the right creative process to the right design situation as well as an effective framework for conducting instructional design research.

Keywords

Educational technology • Teaching • Learning • Instruction • Instructional design • Design models

Introduction

This chapter presents information about the role of models used for instructional design. Instructional design is a system of procedures for developing education and training curricula in a consistent and reliable fashion (Branch & Merrill, 2011). Instructional design is intended to be an iterative process of planning outcomes, selecting effective strategies for teaching and learning, choosing relevant technologies, identifying educational media, and measuring performance. Instructional design focuses on human learning by deliberately arranging sets of external events based on educational and training contexts (Gagné, Wager, Golas, & Keller, 2005). An instructional design process works best when it is matched to a corresponding context. However, educational contexts are often complex and feature complex issues related to teaching and learning. Therefore, effective instructional design models need to be sensitive to different

educational contexts and be responsive to complex teaching and learning situations.

Instructional design is also known as instructional development. The specific term *instructional development* appears to have its origins in a project conducted at Michigan State University from 1961 to 1965 and defined as a systematic process for improving instruction Gustafson and Branch (2002). The final report entitled "Instructional Systems Development: A Demonstration and Evaluation Project" (Barson, 1967) is available as ERIC document ED 020673. The Barson (1967) model is one of the few models ever subjected to evaluation in different situations at a variety of institutions. According to Gustafson and Branch, the Barson project also produced a set of heuristics for instructional developers. These heuristics provided the basis for much of the early research on the instructional design process and also served as a general guide for developers in higher education.

While heuristics provide broad references for approaching instructional design, specific applications of procedures necessary to actually develop teaching and learning materials require more defined models. Markle (1964, 1978) produced models that applied the systematic approach to delivering programmed instruction, which successfully featured the tryout and revision process, although Markle did not use the specific term *instructional design*. Several attempts have been made to define instructional design and derive a standard set of meanings for various terms (Association for Educational Communications and Technology, 1977; Ely, 1973, 1983; Januszewski & Molenda, 2008; Seels & Richey, 1994), but the results have only been recently adopted or consistently used in the literature and in practice. Seels and Richey use the term instructional systems design (ISD) and defined it as "an organized procedure that includes the steps of analyzing, designing, developing, implementing, and evaluating instruction" (p. 31). The Seels and Richey definition is similar to that of the Association for Educational Communications and Technology (1977) committee's definition of instructional development:

> A systematic approach to the design, production, evaluation, and utilization of complete systems of instruction, including all appropriate components and a management pattern for using them; (p. 172).

Consistent to both definitions is that the overall instructional design and development process includes activities associated with preparing lesson plans and determining moment-to-moment instructional strategies, sequencing, motivational elements, and learner actions. Thus, the terms instructional design and instructional development have been used interchangeably and often considered synonymous. A complete discussion about the possible differences and other nuances of each term is beyond the scope of this chapter. However, the position taken here is that instructional design is different from instructional development. Design refers to the comprehensive process from beginning to end, while development specifically refers to creation activities within the overall design process. Hence, the term instructional design will be used herein for the sake of clarity.

Some Assumptions

The purpose of this chapter is to promote a better understanding about the appropriate utilization of instructional design models. Both long-time practitioners and those new to the field as well should benefit from a greater awareness about the variety of models used to portray the instructional design process. The role of instructional design models is based on three assumptions: (1) instruction includes both teaching and learning, (2) education encompasses macro-learning activities, and (3) instruction focuses on micro-learning activities.

Instruction includes both teaching and learning because teaching and learning are inextricably connected with regard to the construction of knowledge and skills. Teaching is the action performed by the person or the technology that facilitates the presentation of content and the exchange of knowledge and skills. Teaching is an attempt to organize external events for the purpose of constructing knowledge and skills. The assumption is that instruction deals with learning that is intentional (Tennyson, 1997) rather than unintentional. Unintentional learning results from everyday natural occurrences. While unintentional learning can happen in a variety of ways, such as through conversations, observations, impressions, and any unintended stimuli that occur within a context, intentional learning fosters immediate information flow, authentic experiences, and a sense of community. Intentional learning is characterized by goal-oriented strategies rather than incident-oriented strategies. The goal-oriented nature of intentional learning promotes self-regulatedness in students. Figure 7.1 summarizes some of the main differences between unintentional learning and intentional learning. Thus, focusing on intentional learning provides an opportunity for a student to be reflective, yet purposeful during periods where they are constructing knowledge, during instruction.

Unintentional	Intentional
1. Unplanned	1. Planned
2. Existential	2. Directed
3. Incidental	3. Guided
4. Accidental	4. Purposeful
5. Opportunistic	5. Defined Teacher-Student Roles
6. Informal	6. Formal

Fig. 7.1 Unintentional learning compared to intentional learning

Learning is a personal and covert cognitive activity, which is idiosyncratic to an individual. Individuals who construct knowledge and skills accomplish learning. Education encompasses macro-learning activities and refers to the activities occurring outside the classroom that directly influence the context in which intentional learning occurs. Factors that influence an educational context consider such things as human resources, technology resources, financial resources, infrastructure, and curriculum that support formal and informal learning opportunities. Instruction focuses on micro-learning activities concerned with the specific actions between the teacher and the students on a daily basis, where the intention is on achieving a defined and agreed-upon outcome. Instructional strategies are the overt means by which knowledge, skills, and procedures are constructed during intentional learning. Instructional design models vary in the amount of attention each devotes to considering macro factors (educational) related to teaching and learning, and micro factors (instructional) related to teaching and learning. Thereby, a need arose for a comparison framework by which instructional design models could be reviewed.

Since the first appearance of instructional design models in the 1960s there has been an ever-increasing number of models published in both the instructional technology and other education literature based on the assumptions that instruction includes both teaching and learning, education encompasses micro-learning activities, and instruction focuses on micro-learning activities. However, a clear need has emerged during the same time period for a way to properly utilize contextualized models to support intentional learning. This chapter presents the role of instructional design models and a taxonomy for classifying instructional design models, and describes a framework for conducting instructional design research.

The Role of Models in Instructional Design

Models conceptualize representations of reality. A model typically is a simple representation of more complex forms, processes, and functions of physical phenomena or ideas. Models by necessity simplify reality because the reality often is too complex to portray and because much of that complexity is unique to specific situations. Thus, models generally seek to identify what is generic and applicable across multiple contexts. Seel (1997) identifies three different types of instructional design models (theoretical/conceptual, organization, and planning-and-prognosis) and would label instructional design models as organization models that can be used as general prescriptions for instructional planning.

One of the most influential instructional design model builders was Silvern (1965) in the 1950s and 1960s. Silvern's work with the military and aerospace industry resulted in an extremely complex and detailed instructional design model with multiple variations that drew heavily on general systems theory. Silvern's instructional design model is rarely used today, but it remains an excellent original resource for those willing to wade through Silvern's sometime obscure writing. Students of the instructional design process easily observe Silvern's influence on the content of contemporary instructional design models.

A model developed by Hamreus (1968), while at the Teaching Research Division of the Oregon State System of Higher Education, is another classic instructional design model. One of Hamreus' significant contributions to the instructional design process was to present *maxi* and *mini* versions of his model. Hamreus' *two-size* approach to instructional design was based on the belief that there is a need for a simple model to communicate with clients and a more detailed operational version for those working on the project. Hamreus' process provided the basic structure for the Instructional Development Institute (IDI) model (National Special Media Institutes, 1971). Hamreus' model was extensively reviewed by Twelker (1972). The IDI model received extremely wide distribution and was among the best known in the United States in the 1970s and 1980s.

During the same period, instructional design scholars began reviewing the growing plethora of instructional design models to ascertain any fundamental tenets of the instructional design process. Stamas (1972) reviewed 23 models to determine whether or not each included a list of components he felt were part of the ID process. Andrews and Goodson (1980) reviewed 40 instructional design models and similar to Stamas, Andrews and Goodson developed a matrix of instructional design elements and analyzed the models for their inclusion of those elements. Salisbury (1990) reviewed a number of instructional design models from major textbooks in the field to determine the degree to which they contained specific references to a range of general systems theory concepts. Salisbury concluded that most models contained few specific references to those general systems concepts contained in his matrix. Edmonds, Branch, and Mukherjee (1994) presented the results of a review of instructional design models as a way to address their proliferation over the previous decade. Edmonds et al. concluded that an instructional design model is understood better when it is classified by its context and by the level of application for a specific context.

Such reviews of instructional design models provide a sampling of the array of processes dedicated to the systematic design of instruction. Generally, the overall instructional design process as originally conceived has changed very little, even though additional learning theories and delivery tools have emerged. The last few years have seen a shift in thinking about how instructional design can be practiced. Thus, the role of instructional design models in generating effective teaching and learning materials is ever more important.

Instructional design models now convey the guiding principles for analyzing, producing, and revising learning environments. Instructional design models either old or new should accommodate contemporary and emerging theories about planned learning and the broad array of contexts in which instructional design is being applied. Philosophical orientation and theoretical perspective frame the concepts upon which instructional design models are constructed. The more compatible the theory and philosophy are to the context in which a model is to be applied, the greater the potential that the original intent of the model will be achieved. Reiser (2001) noted "although the specific combination of procedures often varies from one instructional design model to the next, most of the models include design, development, implementation and evaluation of instructional procedures and materials intended to solve those problems" (p. 58). There are many different and inconsistent uses of terminology to describe the comprehensive process we call instructional design, but the position here is that all instructional design processes consist of at least five major activities:

1. Analysis of the setting and learner needs
2. Design of a set of specifications for an effective, efficient, and relevant learner environment
3. Development of all learner and management materials
4. Implementation of instructional strategies
5. Evaluation of the results of the development both formatively and summatively

The addition of detail related to specific applications has led to the creation of many different instructional design models. Conceptual tools and operational tools assist in identifying those contexts within which an instructional design model might be utilized.

Instructional Design Models as Conceptual Tools

Models help us describe relationships between entities, and prescribed actions among and between entities. The instructional design process is both descriptive and prescriptive. It is descriptive because it shows relationships, illustrates what happens during a process, is interactive, explains, and provides if–then relationships, and models can be conceived from displays of the processes. The instructional design process is prescriptive because it guides, assigns methods, generates strategies, is goal oriented, is active, and applies to a variety of procedures.

Instructional design models visually communicate their associated processes to stakeholders by illustrating the procedures that make it possible to produce teaching and learning materials. Instructional design models provide communication

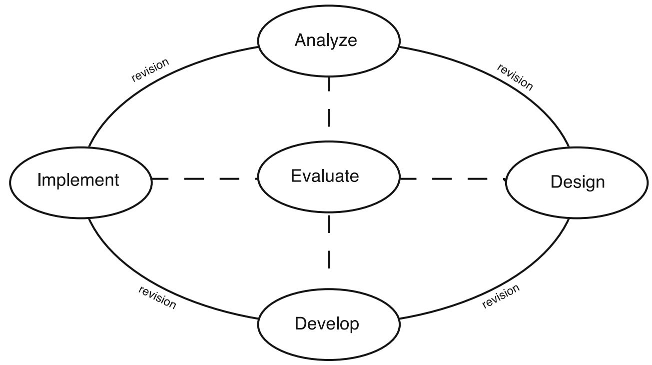

Fig. 7.2 Conceptual core elements of instructional design

tools for determining appropriate outcomes, collecting data, analyzing data, generating learning strategies, selecting or constructing media, conducting assessment, and implementing and revising the results. Figure 7.2 shows a conceptual relationship among the core elements of the instructional design process. The five core elements, Analyze, Design, Develop, Implement, and Evaluate (ADDIE), inform each other as development takes place and revision continues through the completion of the instructional design process.

The five core elements, typically referred to as ADDIE, should be regarded as a generic instructional design concept and not a model. ADDIE provides a useful tool for measuring whether a model is inclusive of the entire instructional design process or only one or more of its essential elements. Conceptual tools assist in identifying the contexts within which an instructional design model might be utilized. In fact, the quantity and quality of tools accompanying a model become significant criteria for selecting one for a specific context.

The instructional design process can be conceived as a single linear process or as a set of concurrent and recursive procedures. Rectilinear portrayals typically build from the ADDIE concept by bringing greater depth to key aspects of the design process. They are often used to teach novice designers the design process because they are simple, generic, and applicable across many different contexts. Critics of instructional design models sometimes interpret them as stifling, passive, lockstep, and simple because of the visual elements used to compose the corresponding model (Branch, 1997). This is partially due to the portrayal of the design process as rectilinear rows of boxes connected by straight lines with one-way arrows and one or more feedback (revision) lines that are parallel to other straight lines (Fig. 7.3). The visuals associated with rectilinear portrayals of instructional design models often do not acknowledge the actual complexities associated with authentic instructional design practice. Bichelmeyer, Boling, and Gibbons (2006) have criticized the use of rectilinear models for failing to provide novice designers with a portrayal of the design process that reflects

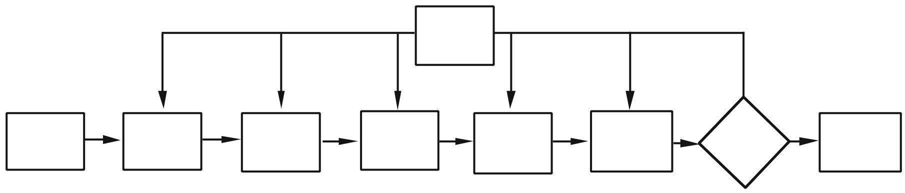

Fig. 7.3 Rectilinear portrayal of the instructional design process

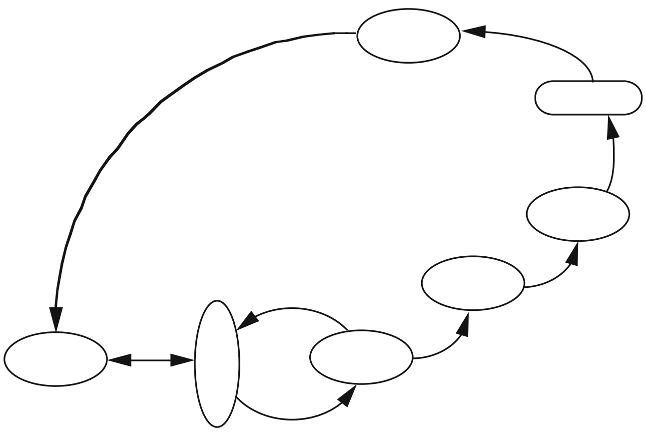

Fig. 7.4 Curvilinear portrayal of the instructional design process

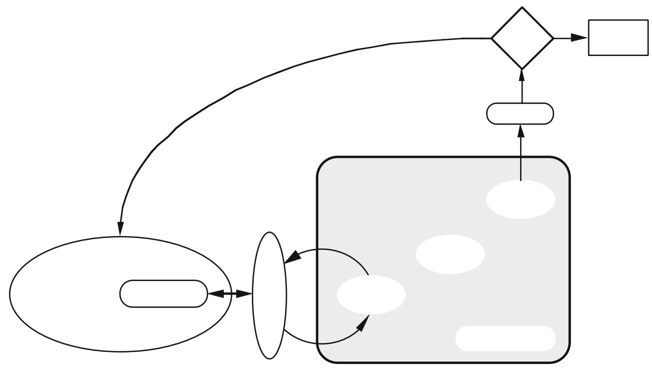

Fig. 7.5 Nested portrayal of the instructional design process

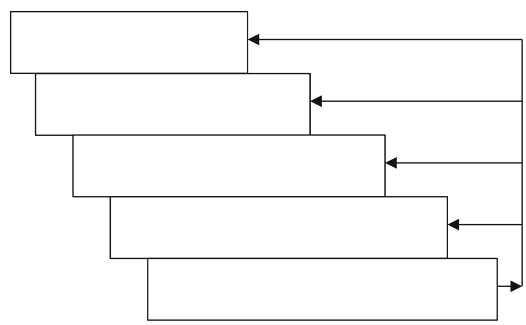

Fig. 7.6 Concurrent portrayal of the instructional design process

the manner in which designers in the field engage in instructional design.

Curvilinear portrayals of instructional design models attempt to acknowledge the complex reality upon which the instructional design is often practiced (Fig. 7.4). These are different than rectilinear models in that they are composed of various shapes (e.g., ovals, rounded rectangles, etc.) that are connected by curved lines or two-way arrows. The curved lines, arrows, and sequence of shapes attempt to represent the cyclic nature of design, where information gained at later steps in the design process can lead to revisions in earlier steps. Such models are helpful in portraying design situations where analysis cannot be completed before development and, as a result, early field trials will be treated as an opportunity to gain critical design information. However, even here, there remains an implied sequence, at least among the core elements.

Nested and concurrent portrayals of the design process tend to acknowledge the nonlinearity that is inherent within the design process. Unlike rectilinear and curvilinear portrayals, nested and concurrent portrayals present specific design elements as smaller shapes within larger shapes or as overlapping shapes. In this way, these models convey the idea that certain aspects of the design process may occur at the same time rather than in a neat, orderly sequence. The nesting and overlapping of shapes in these models is an attempt to better portray the simultaneous iterations that characterize the way instructional design is commonly practiced (Rowland, 1992; Visscher-Voerman, 1999).

Figure 7.5 portrays a nested portrayal, which contains a combination of rectilinear and curvilinear modeling as an attempt to accurately conceive the true practice of instructional design. In a real design situation, this might represent a designer who begins developing instructional goals and objectives as part of conducting the initial analysis in an effort to improve the efficiency and efficacy of the design process. Embedding the design of instructional goals and objectives within the analysis phase allows the designer to prototype and assess the clarity and accuracy of those goals and objectives at an early, critical stage.

As greater utilization of various forms of prototyping has become common in instructional design, two main forms of rapid prototyping have emerged. Some recent models have adopted a concurrent portrayal of the design process (Fig. 7.6) and a spiral design (Fig. 7.7) to indicate the recursive and highly iterative nature of the instructional design process.

The concurrent portrayal presents the design phases as a series of overlapping rectangles. This portrayal is particularly useful in situations where design must occur rapidly and key design phases must occur simultaneously or in near succession.

Much of the work using a recursive approach draws on an original model from computer software development that was created by Boehm (1988). One example of a highly iterative instructional design model is Dorsey, Goodrum, and Schwen (1997). A second form of rapid prototyping model emphasizes early development of a simple and incomplete prototype that then *evolves* into a complete design as the client and developers become clearer on what the problem is and the type of solution desired (Stokes & Richey, 2000; Tripp & Bichelmeyer, 1990). Both forms of prototyping are particularly useful in situations of high uncertainty as to client expectations or when a highly creative solution is desired. Another important instructional design concept is the Layers of Necessity (Wedman & Tessmer, 1991) that has since been refined and extended as the Contextual Instructional Design model (Tessmer & Wedman, 1995). Tessmer and Wedman conveyed the importance of context when selecting the processes and procedures for an instructional design project. Therefore, instructional design is most effective when practiced within context.

While the conceptual display of the core elements and procedures of the instructional design process are helpful, there remains a need to indicate *how to practice* particular elements of the instructional design process within specific contexts. The selection of an appropriate model for an instructional design context may in part depend on the need to reflect the degree of linearity or concurrency planned for the duration of the project. An instructional design model should contain enough detail about the process to establish operational guidelines for managing the people, places, and things that will interact with each other, and to estimate the resources required to complete a project. Given the variety of concepts upon which an instructional design process can be modeled, future instructional design research should consider the role of context during the selection or modification of an instructional design model.

Fig. 7.7 Recursive portrayal of the instructional design process

Instructional Design Models as Operational Tools

While models provide the conceptual reference, they also provide the framework for selecting or constructing the operational tools needed to apply the model. Tools such as PERT charts, nominal group techniques, task analysis diagrams, lesson plan templates, worksheets for generating objectives, and production schedule templates operationalize the instructional design process. Some instructional design models include highly prescriptive information about how to develop the companion tools or provide most of the tools necessary to apply the process. Other instructional design models only provide a conceptual diagram without any operational tools or directions for constructing companion tools necessary for their application. The Interservices Procedures for Instructional Systems Development model (Branson, 1975) is an example of a highly prescriptive instructional design model with a comprehensive set of companion operational tools. The Dick, Carey, and Carey (2005) model is moderately prescriptive and contains an array of companion operational tools. Describe tools that can be used with different instructional design models for those models having few or no accompanying tools. Effective instructional design models directly or indirectly specify products, such as timelines, samples of work, and periodic endorsements by appropriate supervisory personnel with other pertinent deliverables.

ADDIE describes a generic instructional design paradigm. Figure 7.8 presents a version of the ADDIE paradigm.

	Analyze	Design	Develop	Implement	Evaluate
Concept	Identify the probable causes for a performance gap.	Verify the desired performances, and appropriate testing methods.	Generate and validate the learning resources.	Prepare the learning environment, and engage the students.	Assess the quality of the instructional products and processes, both before and after implementation.

Fig. 7.8 A version of the ADDIE paradigm

	Analyze	Design	Develop	Implement	Evaluate
Common Procedures	1. Validate the performance gap 2. Determine instructional goals 3. Confirm the intended audience 4. Identify required resources 5. Determine potential delivery systems (including cost estimate) 6. Compose a project management plan	7. Conduct a task inventory 8. Compose performance objectives 9. Generate testing strategies 10. Calculate return on investment	11. Generate content 12. Select or develop supporting media 13. Develop guidance for the student 14. Develop guidance for the teacher 15. Conduct formative revisions 16. Conduct a Pilot Test	17. Prepare the teacher 18. Prepare the student	19. Determine evaluation criteria 20. Select evaluation tools 21. Conduct evaluations
	Analysis Summary	*Design Brief*	*Learning Resources*	*Implementation Strategy*	*Evaluation Plan*

Fig. 7.9 Common ADDIE procedures

Branch (2009) highlights some of the common procedures and main deliverables associated with the ADDIE paradigm (see Fig. 7.9).

Instructional designers are creating many tools for use by themselves and other designers as well as tools to support teachers or subject matter experts in doing their own development. Goodyear (1997) and van den Akker, Branch, Gustafson, Nieveen, and Plomp (1999) provide several descriptions of some such tools and how they are being used. Conceptual and operational tools assist in identifying the contexts within which an instructional design model might be utilized. In fact, the quantity and quality of tools accompanying a model become significant criteria for selecting one for a specific setting. However, specific procedures for planning, conducting, and managing the instructional design process can be implemented with operational tools that may or may not be identified as part of the instructional design model.

The Proper Selection of Instructional Design Models

Instructional design is practiced in a variety of settings, leading to the creation of many different models. A taxonomy of instructional design models can help clarify each model's underlying assumptions and identify the conditions under which each model might be most appropriately applied. Although the number of models published far exceeds the number of unique environments in which they are applied, there are several substantive differences among instructional design models. Thus, there is some value in creating a classification taxonomy dedicated to instructional design models. A taxonomy also helps to organize the extensive literature on this topic and perhaps to assist instructional designers in selecting a model that is best matched to a given set of circumstances. Gustafson (1981) created such a taxonomy. Gustafson's schema contains three categories into which instructional design models could be placed: classroom, product, and system. Gustafson's classification factors focused on:

1. Typical output in terms of amount of instruction prepared
2. Resources committed to the development effort
3. Whether it is a team or an individual effort
4. Expected ID skill and experience of the individual or the team
5. Whether most instructional materials will be selected from existing sources or represent original design and production
6. Amount of preliminary (front-end) analysis conducted
7. Anticipated technological complexity of the development and delivery environments
8. Amount of tryout and revision conducted
9. Amount of dissemination and follow-up occurring after development

Visscher-Voerman (1999) created different classification schemas for instructional design models and processes based on extensive data collections related to how instructional designers actually performed during instructional design projects, and created a four-category classification framework. Visscher-Voerman's four categories were instrumental, communicative, pragmatic, and artistic. Visscher-Voerman's intent was to characterize the underlying philosophy and values of each approach to instructional design, rather than the context. Visscher-Voerman and Gustafson (2004) used a

Taxonomy		
Delivery Format	Online	Synchronous = any place, but same time
		Asynchronous = any place and any time
	Face-to-Face	Same place and same time
	Blended	Any combination of Online & Face -to-Face
Selected Characteristics	1. Opportunity for Analysis	None, Limited, Unlimited
	2. Opportunity for Formative Evaluation / Assess Objectives	None, Limited, Unlimited
	3. Level of ID Expertise required	Novice, Intermediate, Expert
	4. Planned Course Length	Hours, Days, Weeks, Months, Years
	5. Level of Human Resources Needed	Individual, Small Group, Large Team
	6. Amount of Technology Resources Needed	Less Than Average, Average, More Than Average
	7. Degree of Distribution	Local, throughout the system, beyond the system
	8. Need for Usability Testing throughout Development	Low, Moderate, High
	9. Nature of Objectives and Content	Stable, Changes Infrequently, Changes Frequently

Fig. 7.10 A taxonomy for instructional design models

development research approach to reconstruct the actual practices of professional designers in an attempt to determine the reasons that designers did or did not use a particular instructional design paradigm. The results of the Visscher-Voerman and Gustafson study indicated that most designers in the study's sample followed the instrumental paradigm, and none followed the artistic paradigm; nevertheless, a conceptual framework emerged consisting of the following four design paradigms:

1. Instrumental paradigm: planning-by-objectives
2. Communicative paradigm: communication to reach consensus
3. Pragmatic paradigm: interactive and repeated tryout and revision
4. Artistic paradigm: creation of products based on connoisseurship (p. 76)

Cennamo and Kalk (2005) suggest, "full-scale, systematic instructional design and development efforts are in order in at least four situations:

1. When the content is stable enough to warrant the time and costs
2. When the potential audience is large enough to warrant the time and costs
3. When communication among a team of designers and developers is required
4. When it is important to make sure that the instruction works before it's used." (p. 12)

Dills and Romiszowski (1997) published a comprehensive collection of alternative instructional design paradigms that continue to influence the field today. However, after many years of little change in the underlying structure of the instructional design process and its accompanying models, there are new trends in learning, design, and technology that require an evolution of instructional design models.

Gustafson and Branch (2002) examined the following nine characteristics of each: (1) typical output in terms of amount of instruction prepared; (2) resources committed to the development effort; (3) whether it is a team or an individual effort; (4) expected ID skill and experience of the individual or the team; (5) whether most instructional materials will be selected from existing sources or represent original design and production; (6) amount of preliminary (front-end) analysis conducted; (7) anticipated technological complexity of the development and delivery environments; (8) amount of tryout and revision conducted; and (9) amount of dissemination and follow-up occurring after development. Figure 7.10 presents a revision to the selected characteristics section of Gustafson's (1981) taxonomy, and intends to represent contemporary instructional delivery formats. The revised taxonomy will retain the original three categories: (1) individual classroom instruction, (2) products for implementation by users other than the developers, or (3) larger and more complex instructional systems directed at an organization's problems or goals. Consider the following additions to the taxonomy above:

- Nature of the situation
- Prevailing type of knowledge
- Intended audience

- Nature of the course in terms of the curriculum, such as experiential
- Degree of flexibility inherent in the ID model

The taxonomy is intended to help designers consider the characteristics of a design situation and decide which model or aspects of specific models may be more or less appropriate based on those characteristics. For example, situations where opportunity for formative evaluation is low or where user feedback is needed on a frequent basis may benefit from employing elements of concurrent or recursive models to acquire critical user feedback throughout development rather than after it. Similarly, designers may benefit from incorporating the evaluative elements of rectilinear models in situations where the content is somewhat stable or the intended audience is large in size. By considering the characteristics noted in the taxonomy, designers might make more informed decisions about the models they employ and the reasons for doing so.

Instructional Design Research

While there are hundreds of instructional design models, until recently, there have been only a few major distinctions among them. Many of the models are simply restatements of earlier models by other authors, often using somewhat different terminology. The typical journal article simply describes the major steps in the instructional design model and perhaps how they are to be performed. Books on the topic provide extensive guidance on how to apply the models and some computer-based tools are beginning to appear. However, in almost all instances, the authors assume that their models are worthwhile, but evidence to substantiate their positions was unavailable. Ertmer and Quinn (2006) provide a useful compilation of general case studies intended to support instructional design knowledge, which has proven a valuable asset to the field of instructional design. Still, there is a disturbingly small volume of literature describing any testing of instructional design models. While instructional design models have been applied to many situations over the decades, a rigorous evaluation during the implementation of those instructional design models rarely included collecting empirical evidence about the model's effectiveness. A case study of a development project is presented along with the instructional design model in some instances, but even such low level of validation is less than desired for a healthy scholarly community or a community of practice, such as that related to instructional design theory and practice.

Instructional design models need to be subjected to rigorous validation. Such validation would require precise description of the elements of the model followed by systematic data collection concerning their application and the impact of the resulting instruction. The investigator would also need to be alert to possible discrepant or negative data. Repeated trials under such conditions would, if the model had validity, result in a set of specifications regarding the conditions under which the model was valid. Very few of the instructional design models currently available in the literature have been subjected to such rigorous scrutiny.

Rarely are instructional design models tested in the sense of rigorous assessment of their application and the resulting instruction against either predetermined criteria or competitive means of developing instruction using some other defined process. Rather, instructional design models with wide distribution and acceptance gained their credibility by being found useful by practitioners, who frequently adapt and modify them to match specific conditions. Richey (2005); Van den Akker, Gravemeijer, McKenney, and Nieveen (2006); and Richey and Klein (2007) offer relevant ideas and appropriate insights into instructional design model validation research.

Conclusion

There will continue to be an interest in instructional design models; however, the level of specificity at which they are applied will change over time. People who intend to utilize instructional design models may be well served to investigate the instructional design competencies required to successfully implement an instructional development model, such as those promoted by the International Board of Standards for Training, Performance and Instruction (Richey, Fields, and Foxon, 2000).

New trends in learning are clearly being influenced by contemporary theories in educational psychology as they concentrate on moving from teacher-centered approaches to student-centered approaches. The concept of instruction design promoted here is intended to facilitate active, multi-functional, inspirational, situated approaches to intentional learning. The presumption is that intentional learning involves multiple, concurrent interactions among people, places, and things, situated within a context, during a period of time. New trends in technology reflect improved digital delivery tools. Advances in technology increase our ability to create more interactive and engaging learning environments, such as beginning to think about the instructional design process that includes performance support systems, information management systems, and concurrent engineering.

Instructional design models provide conceptual tools to visualize, direct, and manage processes for creating high-quality teaching and learning materials. The proper selection of instructional design models assists us in appropriately matching the right process with the right situation. Finally, instructional design models serve as a valuable source for conducting instructional design research.

The Impact of Technology and Theory on Instructional Design Since 2000

8

Scott Joseph Warren, Jennifer Lee, and Anjum Najmi

Abstract

The impact of shifting epistemologies in the field of instructional design during the last century has had a major impact on how we design instruction. The goal of this chapter is to provide an overview of important shifts in ideas about what knowledge is, how it can be produced or constructed, and what it has meant for instructional design in the last decade. We discuss how technology has influenced instructor, learner, and designer beliefs about knowledge, instruction, and learning. Furthermore, we look at the changing landscape of theory and research that supports and questions these perspectives, and the implications it has on instructional practices.

Keywords

Conceptual age learning • Multiuser virtual environment • Epistemology

Introduction

Systematized models and theories of instruction can be traced as far back to pre-Socratic times of the Elder Sophists. Early educators such as Comenius, Pestalozzi, Herbart, and Montessori developed their own instructional models (Saettler, 1990; Jonassen, 1996). Since the early twentieth century, instructional design has moved through four stages, each being built on the previous one and each of them being characterized by a specific focus, theoretical assumptions, and practical implications (Winn, 2002). According to Winn (2002), the Four Ages of Educational Technology are the Age of Instructional Design, the Age of Message Design, the Age of Simulation, and the Age of Learning Environments. We will discuss how the four ages were guided by different philosophical assumptions that shaped how we design instruction, implement learning, and determine assessment.

For the purposes of this chapter, we define instructional technology according to Seels and Richey (1994) as "the theory and practice of design, development, utilization, management and evaluation of processes and resources for learning" (p. 1). While almost two decades old, this characterization manages to provide a succinct description of the field, without excluding the innovations that have come since that time. Winn proposed that current instructional design research should focus on learning environments that integrate technological innovations. Some of these include (1) artificial learning environments, (2) communication tools used to foster social interaction, (3) distributed cognition in the form of communities of practice, and (4) integrated or "complete systems" (Winn, 2002, p. 343). These technologies include high-level graphic representations of users in three-dimensional learning environments, synchronous and asynchronous communication tools, and Web-based instructional materials for guiding students to research and other learning materials.

This focus on learning environments fits well in the US public schools today. In these environments, there is call for

shifting toward a new paradigm for learning. This is one that takes advantage of advances in technology that have been made for more than a decade. We argue that instructional design has entered a fifth age, the Age of Conceptual Learning, which was predicted nearly two decades prior:

> Technology will play central roles in teaching, assessment, and keeping track of learner progress…computer-based simulations will be excellent tools for modeling the real-world, authentic tasks and for maximizing active involvement and construction of learning. Multimedia systems will integrate computers and interactive video. (Reigeluth & Garfinkle, 1994, p. 67)

Such advances that were once viewed as a part of the future, are now at the forefront of many technology integration efforts in both K-12 and higher education settings. However, much past and current research focuses on whether learning improves, as measured by standardized tests, from the use of particular technologies. This is as opposed to studies that examine how the use of technology can transform learning environments to address higher order thinking skills and teach advanced concepts (Christensen, 2002; Guzman & Nussbaum, 2009; Zhao, Pugh, Sheldon, & Byers, 2002). Topics such as how a technology-supported learning environment increases student critical thinking ability, creativity, organizational ability, or research skills are now being explored. However, much research remains focused on teacher perceptions of technology integration rather than teaching high-level skills with technology as tool rather than as central facet of instruction (Gorder, 2008; Makki & Makki, 2012; Yanchar & Gabbitas, 2011). Throughout the chapter, we discuss how new research findings affect the state of instructional design today. In the next sections, we examine how the four ages of educational technology have led to the Age of Conceptual Learning.

Age of Instructional Design

In this section, we present the four ages of instructional design as distinct from one another in terms of theoretical frameworks, foci, and methods. While this is a necessary oversimplification to delineate the unique characteristics associated with each age, the four ages chronologically overlap as one paradigm begins to take hold as another recedes. This is not to say that vestiges of older paradigms do not continue to exist in daily practice. Many instructional designers today first learn rudimentary instructional design methods from older paradigms to gain prerequisite knowledge regarding how to design from different perspectives, as clients may desire one or another. Further, one must understand the rules of a prior paradigm before one is qualified to break them. Knowing where we have been as a field is important as we seek the future of design.

The Age of Instructional Design, which focused mainly on content creation, was based on behaviorist and cognitivist theories of learning. Learning was perceived as simply a change in behavior or cognitive structure or both with instruction designed to effectively transfer knowledge to the learner. This age was heavily influenced by the curriculum reform movement of the 1950s and specifically Tyler's (1949) linear model of instruction (Jonassen, 1996; Saettler, 1990). This included the mechanisms of scientific management emphasis and focused on both standardization and increasing learning efficiency through content and task analysis. The instructional model follows the sequence of input–process–output and its goal is to construct a comprehensive plan of instruction. Such designs presume that optimal conditions for learning primarily depend on defined learning process goals. As such, analyzing the goals of education is expected to allow instructional designers to devise methods for the achievement of these goals (Mager, 1997; Smith & Ragan, 2005). Through content and task analysis, the designer and teacher identify specific prerequisites and skills needed and select the tasks the learner should complete to achieve the specific learning outcomes (Saettler, 1990; Jonassen, 1996; Vrasidas, 2000). The approach leads to emphasis on content structure and analysis techniques and to the presentation of information (Dijkstra, 2005).

Several instructional models and learning taxonomies have followed this approach and each has made significant contributions. These have included theoretical frameworks provided by Gagné and Merrill (1990), Piaget (1972), Bruner (1990), Bloom (1984), and Ausubel (1978) among others (Cennamo & Kalk, 2005). The combination of behavioral and cognitive theories of learning gave rise to the systems approach of instructional design, which was an effort to design a complete program to meet specific needs and objectives (Reigeluth, 1999). Technology was perceived as a means to boost performance and support programmed instruction representing mastery learning, drill and practice, and convergent tutorial programs (Jonassen, 1996). Task analysis was the main method for determining content organization and instruction was to be planned, designed, evaluated, and revised (Winn, 2002).

Age of Message Design

The Age of Message Design emphasized instructional format rather than instructional content. In this era, the instructional designer and the learner had greater control over learning material than in the instructor-directed paradigm that preceded it and students with different skills and abilities were recognized to learn differently from different instructional treatments (Cronbach & Snow, 1977). During this time, pedagogical foundations emphasized how an environment was designed and its particular learning affordances were made available in conjunction with an underlying psychological model. The challenge for instructional designers working in the design of instruction has been to regulate philosophically informed principles, take advantage of technological capabilities, and to look beyond "the assumption that the format of the message alone determines the level of encoding in memory" (Jonassen, 1996, p. 317).

The basis for learning in this model is what John Dewey (1943) identified nearly a century ago as the greatest educational resource—the natural impulses to inquire or to find out things; to use language and thereby to enter into the social world; to build or make things; and to express one's feelings and ideas. Dewey saw these impulses rather than traditional discipline as the foundation for curriculum, to be nurtured for lifelong learning. The focus shifts from the features of hardware or software and instead to the user or the learner, which serves as the starting point for instructional design. Instruction centers on understanding and meaning making, with a focus on the analysis of learning processes, in particular on the way technology alters environments for thinking, communication, and action. The interactive, multimedia capabilities of the computer (i.e., sound and graphics) account for individual learning differences, individual aptitude, and learner preferences. Hence, the term "message design" evolves with both the media and the learner. Flexibility of technology provides designer and learner greater control over the learning process.

The social constructivist paradigm. Social constructivists assert, "knowledge is individually and socially constructed by learners based on their interpretations of their experiences in the world" (Jonassen, 1999, p. 217). Drawing upon foundations of situated cognition (Brown, Collins, & Duguid, 1989), context is critical in influencing how information is processed, negotiated, and used, as well as how understanding evolves. Lesson content and heuristics for performance are seen as best embedded or situated within an authentic task. As such, learning activities are interpreted by each learner rather than only an external agent such as an instructor (Brown & Palincsar, 1989). Technology and other instructional aids scaffold performance, making complex tasks more manageable without simplifying the task itself (Glaser, 1990; Vygotsky, 1978).

The goal is to cultivate the learners' thinking and knowledge construction skills. Learning becomes an act of critical and creative thinking. Accompanying instructional design principles include:

- Embedding learning in complex real-world problems
- Providing rich and flexible learning environments with goals and objectives set by the learner
- Including continuous assessment embedded in the instruction
- Detailing an evaluation which gives feedback to both learner and teacher

Multiple perspectives and social negotiation are integral parts of learning (Jonassen, 1992) in this paradigm. The overarching goal is to encourage manipulation rather than simple acquisition, and to root the learning process in concrete experiences.

Age of Simulation

As the Age of Message Design faded, the Age of Simulation emerged in response to the wide availability of technologies that allowed for the development of digital models that students could directly experience, which encouraged interaction that is learner centered. We adopt Saunders' (1987) definition of simulation in that they are "a working representation of reality … [that] may be an abstracted, simplified, or accelerated model of process" (p. 9). These tools nurture individual learning and understanding, rather than teach explicitly (Olson, 1988). Dewey (1933, 1938) perceived schools as settings in which students received life apprenticeships. Thus, interest in environments that immerse individuals in authentic, reality reflecting learning experiences, where the meaning of knowledge and skills are realistically embedded, has been long standing.

Advances in technology (e.g., Internet, increased computing power) and software innovations (i.e., *synchronous/asynchronous*, *multimedia development*, *production tools*, *simulation software*) have changed the nature and breadth of learning experiences and the instructional professional's capacity to support the learners. These technologies have greatly advanced our ability to deliver instruction in different formats and in different ways. Learning systems of enormous power and sophistication have been developed to represent evolving notions of partnerships among learners, their experience, discourse, and knowledge (Hannafin & Land, 1997).

Age of Learning Environments

Winn (2002) stated that the next paradigm shift in the field would be the Age of Learning Environments. This was an expected product of the shift from the design of instruction to the design of learning environments with learning being more dependent on the learner. Such environments cognitively and/or physically situate content and skills within complex, adaptive educational scaffolding spaces both face to face and online. From an instructional design perspective, we argue that the advances made during the Age of Learning Environments were crucial in paving the way for the current Age of Conceptual Learning. Winn's argument has been borne out with a transformation of learning environments in the last from face-to-face classrooms to online, distance-delivered courses now ubiquitous across the United States and the world.

Keefe and Jenkins (2000) categorized learning environments into three distinct periods: traditional, transitional, and interactive. Traditional learning environments were "based on nineteenth-century factory models, scientific management, the behavioral research of Thorndike and Skinner, and the learning hierarchies of Gagné and Bloom" (p. 6). According to Keefe and Jenkins, transitional learning environments came about as attempts to improve the behaviorist classrooms by emphasizing individualized instructions and group-based mastery. They go on to note that, during this period, several benchmarks were used to measure school effectiveness including test scores, attendance, completion rate, and school ratings. However, the authors contended "the movement failed to move schools toward authentic and reflective environments that the new century seems to demand (p. 10)." As a result of this failure, Keefe and Jenkins further argued that a third period called the interactive learning environments emerged to meet the needs of the next generation of learners.

Keefe and Jenkins (2000) also stated that the purpose of interactive learning environments is "to involve students and teachers in a total learning experience. Who and what define(s) a total learning environment? We argue that the definitions are different for different learners" (p. 12). To wit, Winn (2002) stated "learning environments can either be entirely natural, or they can be artificial, existing only through the agency of technology" (p. 335).

There are two reasons why artificial learning environments were proposed as beneficial by Winn. First, he asserted that artificial learning environments help people avoid the dangers associated with learning in the natural environment. Flight stimulation and army combat training come to mind as examples where the artificial learning environment provides an alternative to the real ones and have been used to train both pilots and soldiers (Nieborg, 2005; Schneider, Carley, & Moon, 2005). Secondly, Winn proposed using artificial learning environments such as digital simulations to show a child the concept of friction through a rolling virtual ball or may provide interactive demonstrations of Newton's Laws of Motion.

Interactive learning environments have been at the forefront of many research agendas including projects such as *River City* led by Chris Dede, *Quest Atlantis* under the direction of Sasha Barab, and other emerging projects funded by the National Science Foundation. Additionally, the National Institutes of Health have long funded research into the use of virtual environments to help treat psychological and addiction disorders (Anderson, Zimand, Schmertz, & Ferrer, 2007; Bordnick, Copp, Brooks, Ferrer, & Logue, 2004; Bordnick, Copp, Traylor, Walton, & Ferrer, 2009; Bordnick et al., 2008). Researchers have also explored the use of Second Life, a 3D virtual world in education, finding some benefits to learning from providing learners with advanced models with which they can interact (Brown, Gordon, & Hobbs, 2008; Derrington & Homewood, 2008). Bares, Zettlemoyer, and Lester (1998) proposed that 3D learning environments enable "learners to participate in immersive experiences" that help them "develop a deep, *experiential* understanding of highly complex biological, electronic, or mechanical systems" (p. 76–77).

Dawn of a New Age: The Age of Conceptual Learning

Winn (2002) reminds us that:

> as our technologies become more able to bring information, learning materials, even learning environments to whenever people to be, the argument can be made that we no longer need to remember what we need to know; we can simply call it up and display it when it is needed. Whether this trend spills over into the world of education to any great extent is unclear. If it does, then the impact on traditional curricula will be tremendous. (p. 348)

In a similar vein, Pink (2006) argued that we are moving from the Information Age to the Conceptual Age. He goes on to add that the future belongs to a new breed of empathizers, pattern recognizers, and meaning makers. Today, one of the biggest criticisms of instructional design is that instruction created from older paradigms does not prepare students for the real world. Many of us are still held fast in the era of traditional or transitional learning environments.

As we shift to a new Age of Conceptual Learning, a determination must be made of what a learning environment that includes these characteristics should look like. Spector (2010) suggested the shift as a reconceptualization of learning rather than the reinvention of learning itself. Current research often focuses on systemic change of school learning environments themselves, as well as the use of instructional technology to develop or expand alternative learning environments. This is instead of exploring how technology and curriculum can be aligned to merge the needs of the Industrial Age or the Information Age paradigms with what is currently available. However, a number of questions remain regarding the emerging concepts of what constitutes a comprehensive learning environment and how contemporary technologies and/or technology-supported learning environments and their complementary instructional methodologies may be used to support them.

In the context of this chapter, technology-supported learning environments are those that employ tools such as computers, distance learning equipment, Internet resources, or other comparable hardware or software in order to improve student understanding.

This notion is comparable to Winn's (2002) concept of an artificial learning environment or Grabinger's (1996) notion of a rich environment for active learning (REAL). The use of such environments is increasingly prevalent as the availability of technology in K-12 schools increases through access to online forums, educational games and simulations, and integrated digital learning environments (Squire, 2008). In the next section, we examine several trends that emerged last decade and how they have redefined instructional practices today.

Major Development: The Learning Sciences

An important development in the aughts was the establishment of the learning sciences. As with other paradigms, the learning sciences drew some inspiration from both the previous decade and fields outside of education such as cognitive science, psychology, neuroscience, computer science, engineering, and linguistics. Soon after, the Cognition and Technology Group at Vanderbilt (1990, 1993, 1994) experimented with situated cognition and anchored instruction at Vanderbilt with Jasper Woodbury and laser disc-delivered instruction. Ideas such as situating learning in context (Barab et al., 2007) and anchoring learning within narrative and ill-structured problems (Jonassen & Hernandez-Serrano, 2002) have supported later developments such as learning games (Kafai, Quintero, & Feldon, 2010; Squire, 2006), advanced forms of problem-based instruction to support science learning (Kolodner, 2002; Walker & Shelton, 2008), and multiple forms of literacy (Steinkuehler, 2007, 2008; Warren, Barab, & Dondlinger, 2008). In 1999 and 2000, the National Research Council released *How People Learn* and its companion text *How People Learn*: *Bridging Research and Practice*, which combined to outline not only the theoretical model of the learning sciences but also how the model would be implemented in classrooms and its efficacy researched.

Instructional Design from 2000 to 2010

During this period, several learning environments have been of special interest. These include computer-assisted language learning (CALL) environments, mobile learning, multiuser virtual environments, and games and simulations designed to support learning concepts and or practicing science, mathematics, and language arts skills. Each of these foci responds to the changing needs of our schools such as the large increase of non-English-speaking students at every grade level, the recent shift in the needs of businesses from Industrial Age skills to Information Age skills, and the increase in student computer knowledge and experience with new technologies.

Table 8.1 Affordances of technology-supported learning environments

General	PBL	IBL
Frees teacher to act as facilitator (Grabinger, 1996; Hewitt, 2004)	Allows for authentic, embedded assessments and rapid feedback (Grabinger, 1996)	Allows for customized teacher and environmental feedback to address learner needs (Grabinger, 1996)
Allows for learner-control of instruction (Winn, 2002)	Has propensity for strengthening fledgling communities resolved around common practice (Wenger, McDermott, & Snyder, 2002)	Allows for embedding of simulations to practice dangerous techniques with feedback (Winn, 2002)
Allows rapid customization to learner needs (Hannafin & Hannafin, 1995)	Allows for peer feedback (M. Hannafin, Hannafin, Hooper, Rieber, & Kini, 1996)	Allows for self-directed learning using situational role-play and team-building games (Winn, 2002)
Motivational for students (Hannafin et al., 1996; Prensky, 2001)	Allows for active learning through interaction with peers to solve authentic problems (Grabinger, 1996)	Allows access to large databases to support individual and group knowledge building (Hewitt, 2004)

The use of virtual/digital environments is increasingly prevalent as the availability of technology in K-12 schools increases through online forums, educational games, simulations, and integrated digital learning environments. This is especially true in theoretical frames stemming from social constructivism such as inquiry-based learning (IBL) and problem-based learning (PBL). IBL has commonly been employed to challenge students to experiment with the world and find answers to perplexing questions rooted in science. The latter, PBL, involves learners in interacting with ill-structured problems with no single answer to construct their own knowledge and solutions. These solutions are constructed in small groups through communication and inquiry with the instructor serving as facilitator of learning rather than provider of fixed knowledge. Research-supported benefits of technology-enhanced learning environments are presented in Table 8.1.

At present, there is an emerging focus on using K-12 students in studies using digital learning environments. This primarily stems from research showing students in grade school are strongly motivated by the visual and self-regulated learning elements of digital learning environments (Foster, 2008; Tuzun, 2004), impacts on student empathy for social and other complex systems (Brush & Saye, 2003; Gee, 2004), and that they can provide strong visual models through graphical representation (Englert, Manalo, & Zhao, 2004), simulation (Aldrich, 2003; Baylor & Kim, 2005), and animated pedagogical agents (Baylor, 1999, 2002, 2005; Baylor & Kim, 2005) within designed digital learning environments that are complemented by rich face-to-face learning interactions facilitated by knowledgeable teachers (Barab et al., 2007; Warren, Dondlinger, Stein, & Barab, 2009; Warren et al., 2008).

Also during the last decade, we have witnessed the transformation of clunky cell phones into elegant smart phones. These small but powerful devices are minicomputers that are fundamentally redefining teaching and learning. Mobile learning allows us to embrace the anytime–anywhere learning model worthy alternatives to help educators, administrators, and researchers achieve the nation's vision for the twenty-first-century model of wired schools.

As developers flood the educational market with technology products, researchers must separate those that have little or no educational value from those with research-supported uses in K-12 classrooms. Spector (2010) reminded us "technology is not what learning is all about" (p. 30). This makes our research role larger than simple academic inquiry and places the researcher in a position as a shield against potentially harmful or ineffective technologies. As such, we need research-driven data to help us sieve through technologies that help advance the field and technologies that are simply available.

Game-Based Learning

Over the last few years, one major area that has emerged in education for design, development, and research is in the realm of digital games and simulations. In 2009, the Entertainment Software Association (ESA) estimated that the US computer and video game software sales generated $10.5 billion (Entertainment Software Association, 2011). Between 2005 and 2009, the industry grew at an annual rate of more than 10 %.

According to De Freitas (2006), there are four types of game-based learning: (1) educational games, (2) online games, (3) serious games, and (4) simulations. For the purpose of this chapter, games for learning are "applications using characteristics of video and computer games to create engaging and immersive learning experiences for delivering specified learning goals, outcomes, and experiences" (De Freitas, 2006, p. 3).

Beginning with such seminal games as *Math Blaster*, *Lemonade Stand*, and *Oregon Trail* in the early 1980s, the educational gaming or *edutainment* market has become massive (Slagle, 2004). Since then, digital products by companies such as *Leap Frog* have become best sellers, despite a lack of research to support their use (Dondlinger, 2007; Hays, 2005). Without such research, companies that sell products and digital learning environments may make unsupported claims regarding the educational benefits of their edutainment products.

Recently, researchers have begun exploring foundational questions about learning through interaction with digital gaming environments themselves, as well as through interactions with other participants in massively multiplayer online games (Squire, 2006, 2008; Squire & Steinkuehler, 2005; Steinkuehler, 2004). Gee (2004) believes that for games to be educational, three principles in design must be included empowered learners, problem solving, and understanding. Educational games must encourage learners to be active participants in their learning, be flexible in meeting the needs of the learners, and create a sense of identity for them.

The complexity of the digital environment, as well as the intensity of communication use to solve problems and meet objectives in video games such as Blizzard's *World of WarCraft* and NCSoft's *Lineage* series, provides a rich environment for qualitative inquiry, using such methods as computer-mediated discourse analysis (CMDA) (Herring, 2004), interviews with players, and observer participation. In a Kaiser Foundation study (2008), 97 % of the teens said that they have played games on the computer, the Internet, gaming devices, or TV; further, over half of these teenagers stated that they play games on a daily basis. This study also noted that for teens, games offer a social experience for them whether it is face to face or online.

Researchers are now examining whether gaming is educational for students (De Freitas & Oliver, 2006; Mikropoulos & Natsis, 2011; Squire, 2006). Questions such as why, when, and how learning is taking place in a digital gaming environment, the depth of cognition engaged in by learners, the social nature of learning, and player motivation for learning have implications for the design of future technology-supported learning environments.

Emerging research methods and questions. While important because of the promise of student interactivity, autonomy, motivation, and modeling potentials (Prensky, 2001; Salen & Zimmerman, 2004; Winn, 2002), the limitations of games and simulations as platforms for K-12 learning must be explored. Additionally, research regarding the educational value of console and computer games and simulations is still uncertain. The field has yet to face extensive, systematic research, so serious questions remain (Bowers, 2000; Warren & Lin, 2012). Current research has started to explore a number of important research questions such as:

1. What organizational structures in a K-12 setting represent the greatest challenge to introducing new kinds of learning environments such as those based on games and simulations?
2. Once a limitation is identified, how have successful systems been chosen and how have they implemented a systemic change process that overcame this obstacle?

3. At what point does their use begin to interfere with the larger educational, affective, and disciplinary goals of K-12 schools? Are there harmful side effects to their use in the classroom to attention span, level of independent thought, or motivation to learn without the extrinsic reinforcement of the game or simulation? Are the instructional goals and affordances of a game at cross-purposes with those in a state curriculum?
4. Are learning environments that take advantage of several computer technology affordances concurrently, such as communication tools or the ability to embed audio and video, more successful at engaging students in learning than traditional, non-digital learning environments as Gee (2003), Squire (2006, 2008), and others suggest?

This last question focuses primarily on the use of integrated, digital learning environments. Such online spaces have been built based on research on the use of games and simulations, forums, web logs, and online scaffolding as instructional tools (Barab, Warren, & Ingram-Goble, 2008; Barab et al., 2009; Warren & Jones, 2008). The combination of several different technology tools to take advantage of the learning affordances of each in an attempt to build an immersive learning environment is a next step in the use of technology to support education. It would move beyond the use of isolated technology tools and create a thematically unified experience for learners.

One attempt to create such a situation at the K-12 school level was *Quest Atlantis* (Barab, Thomas, Dodge, Carteaux, & Tuzun, 2005; Barab et al., 2009). This digital learning environment was designed to improve elementary school students' understanding of science through IBL methods in which students develop solutions to difficult, persistent environmental problems. Research studies with *Quest Atlantis* indicated improvement of student motivation and a reduction in gender differences communicated in the game environment (Barab et al., 2005; Group, 2004). New designs, coupled with stringent research, will help determine whether such complex learning environments have other benefits to learning and allow the development of guidelines for future designs.

In addition to quantitative methods, the researchers at Quest Atlantis also employed qualitative methods to describe the experiences of the learners in the learning environment. This included data collection and analysis tools such as interview, CMDA (Herring, 2004), critical ethnographic analyses (Carspecken, 1996), and case studies (Robson, 2002) in order to identify those learning experiences in the environment that make the most impact. In addition, multiple observations, teacher interviews, and document analysis were also used in order to gain additional data regarding (1) student attitudes toward using the digital learning environment, (2) student motivations for completing schoolwork in the space, and (3) teachers' multiple means of scaffolding or otherwise aiding student learning either in the classroom or in the digital environment.

Further research may result in findings that support the development of engaging educational games and simulations. Research completed at the end of the decade has already provided some guidelines for the appropriate design and use of games and simulations in or as learning environments (Dondlinger & Warren, 2009; Warren & Dondlinger, 2008; Warren, Dondlinger et al., 2009; Warren & Lin, 2012; Warren, Stein, Dondlinger, & Barab, 2009). Without such research, a number of products with problematic content or instructional methods may make their way into classrooms, resulting in reduced student learning, disciplinary problems, or other unforeseen consequences. Further, it is important that researchers make known their successful, and even unsuccessful (Baker, 2008), attempts at making games and simulations for learning so that others may replicate or improve upon those instructional designs.

Computer-Assisted Language Learning Environments

CALL is a theory of language learning that focuses on using the audio-visual, tactile, and interaction affordances of computers to improve student acquisition of second and foreign languages (Egbert & Hanson-Smith, 1999; O'Bryan & Hegelheimer, 2007). While many of these products been standalone CD-ROM-based computer programs, teachers increasingly use online learning environments to improve language learning (Bacherman, 2007; Edasaw & Kabata, 2007; Vilmi, 1999; Wimberly, 2007). One of the most common online learning environments used to support language learners in the early to mid-2000s was *Tapped In* (http://www.tappedin.org). This technology was used in English-as-a-second-language (ESL) and English-as-a-foreign-language (EFL) classrooms to allow primary language speakers and secondary language speakers to meet synchronously. During their interactions, second language speakers could clarify questions about idiom, grammar, and spelling rules, as well as discuss cultural issues relevant to learning a foreign language from a peer. Inquiry in this area is under way, but is mainly conducted by researchers in fields lacking knowledge of message design, media design, or production that would generate studies that are more valid. Of notable exception is the work of Boling and Soo (1999) in the area of CALL software design. Their chapter provides an excellent example of what our field can contribute to the study of CALL environments.

Emerging research methods and questions. Because of the use of online forums, research in the area of CALL has focused on the use of these spaces to increase student understandings of foreign culture, foreign language idiomatic use, and as a means to practice textual exchanges with native language speakers (Bacherman, 2007; Edasaw & Kabata, 2007; Kirkley, 2004; O'Bryan & Hegelheimer, 2007; Wimberly, 2007). Possible research questions include the following:

1. How does a technology-supported CALL learning environment impact the learning experience of nonnative learners as they work to improve their fluency in a foreign language, as mediated by a digital learning environment?
2. How is learning impacted when native language speakers act as peer tutors, modelers of appropriate idiom and general language use, or instructors regarding their local culture for nonnative speakers?

Research methods such as CMDA (Herring, 2004) may be useful for examining learning in such a setting. CMDA methods are used to analyze online textual interactions among learners to help identify critical periods of learning. This is especially helpful when using instant messaging, e-mail, and electronic forums as part of CALL. Quasi-experimental studies using pre- and posttests to measure changes in language fluency stemming from intervention using a CALL environment should also generate important findings regarding their effectiveness. These research methods should be valuable for measuring gains regardless of whether the learning environment consists of daily classroom use of software programs or online learning environments such as *Tapped In*.

Online environments used to support ESL and EFL learning such as electronic forums and video games such as *Where in the World is Carmen San Diego*? have been used since the 1980s to explore other conceptions of a learning environment in order to understand a foreign culture (Egbert & Hanson-Smith, 1999). This view of learning conceives of learners as central participants in the generation and sharing of knowledge in a supportive learning environment.

Conclusions

While the Age of Learning Environments has opened up new possibilities, there remain challenges and limitations faced during the era that still must be overcome. Among them: (a) K-16 are systems prone to technological fads (Cuban, 2001; Lee, 2009); (b) there remains a lack of research supporting instructor choice of appropriate emerging technologies; and (c) some instructors and administrators still resist new technologies as classroom tools (Cuban, 1988; Cuban, Kirkpatrick, & Peck, 2001).

Where is instructional design going next? What major developments of the last decade in the fields of technology, education, epistemology, and cognitive science will come together to create the next stage in our development? We believe that mobile computing is the next frontier in the field of instructional design. For far too long, we have relied on instructional design models of the past to prepare learners for the Age of Conceptual Learning. Today, learning is personal, portable, and unpredictable. As we leap from an industrial society to a knowledge society in a single generation, learning means greater flexibility, accessibility, immediacy, interaction, and collaboration. These changes have significant ripple effects on education and instructional design. Pink (2006) reminds us that early adopters may do extremely well but the rest may miss out and fall behind.

For instructional designers, this means asking what we can do *through* technology instead of what can we do *with* the technology? The answer may be deceptively simple. The Age of Conceptual Learning is about harnessing the power of the mind rather than the machines. This would require generating new ideas rather than acquiring inert knowledge and, importantly, designing instruction to teach conceptual thinking rather than only concrete facts to be repeated on a standardized assessment. It is an age when students will learn to see computers as tools that help them see and create their own bright future.

The Technological Pedagogical Content Knowledge Framework

9

Matthew J. Koehler, Punya Mishra, Kristen Kereluik, Tae Seob Shin, and Charles R. Graham

Abstract

In this chapter, we introduce a framework, called technological pedagogical content knowledge (or TPACK for short), that describes the kinds of knowledge needed by a teacher for effective technology integration. The TPACK framework emphasizes how the connections among teachers' understanding of content, pedagogy, and technology interact with one another to produce effective teaching. Even as a relatively new framework, the TPACK framework has significantly influenced theory, research, and practice in teacher education and teacher professional development. In this chapter, we describe the theoretical underpinnings of the framework, and explain the relationship between TPACK and related constructs in the educational technology literature. We outline the various approaches teacher educators have used to develop TPACK in pre- and in-service teachers, and the theoretical and practical issues that these professional development efforts have illuminated. We then review the widely varying approaches to measuring TPACK, with an emphasis on the interaction between form and function of the assessment, and resulting reliability and validity outcomes for the various approaches. We conclude with a summary of the key theoretical, pedagogical, and methodological issues related to TPACK, and suggest future directions for researchers, practitioners, and teacher educators.

Keywords

TPACK • Professional development • Teacher knowledge • Technology integration

Introduction

The increasingly ubiquitous availability of digital and networked tools has the potential to fundamentally transform the teaching and learning process. Research on the instructional uses of technology, however, has revealed that teachers often lack the knowledge to successfully integrate technology in their teaching and their attempts tend to be limited in scope, variety, and depth. Thus, technology is used more as "efficiency aids and extension devices" (McCormick & Scrimshaw, 2001, p. 31) rather than as tools that can "transform the nature of a subject at the most fundamental level" (p. 47).

One way in which researchers have tried to better understand how teachers may better use technology in their classrooms has focused on the kinds of knowledge that teachers require

Matthew J. Koehler and Punya Mishra have contributed equally to this chapter. We rotate authorship in our writing.

in order to use technology more effectively. Shulman (1986) proposed that effective teaching requires a special type of knowledge, pedagogical content knowledge (or PCK), that represents "the blending of content and pedagogy into an understanding of how particular topics, problems, or issues are organized, represented, and adapted to the diverse interests and abilities of learners, and presented for instruction" (p. 8). The central idea of PCK is that learning to teach a particular subject matter requires not only understanding the content itself but also developing appropriate instructional strategies and skills that are appropriate for learners.

Mishra and Koehler's (2006) formulation of the technological, pedagogical, and content knowledge (TPACK) framework extended Shulman's (1986) characterization of teacher knowledge to explicitly consider the role that knowledge about technology can play in effective teaching. Specifically, three major knowledge components form the foundation of the TPACK framework as follows:

- *Content knowledge* (*CK*) refers to any subject-matter knowledge that a teacher is responsible for teaching.
- *Pedagogical knowledge* (*PK*) refers to teacher knowledge about a variety of instructional practices, strategies, and methods to promote students' learning.
- *Technology knowledge* (*TK*) refers to teacher knowledge about traditional and new technologies that can be integrated into curriculum.

Four components in the TPACK framework, address how these three bodies of knowledge interact, constrain, and afford each other as follows:

- *Technological Content Knowledge* (*TCK*) refers to knowledge of the reciprocal relationship between technology and content. Disciplinary knowledge is often defined and constrained by technologies and their representational and functional capabilities.
- *Pedagogical Content Knowledge* (*PCK*) is to Shulman's (1986) notion of "an understanding of how particular topics, problems, or issues are organized, represented, and adapted to the diverse interests and abilities of learners, and presented for instruction" (p. 8).
- *Technological Pedagogical Knowledge* (*TCK*) refers to an understanding of technology can constrain and afford specific pedagogical practices.
- *Technological Pedagogical Content Knowledge* (*TPACK*) refers to knowledge about the complex relations among technology, pedagogy, and content that enable teachers to develop appropriate and context-specific teaching strategies.

The TPACK framework suggests that teachers need to have deep understandings of each of the above components of knowledge in order to orchestrate and coordinate technology, pedagogy, and content into teaching. Most importantly, TPACK is an emergent form of knowledge that goes beyond knowledge of content, pedagogy, and technology taken individually but rather exists in a dynamic transactional relationship (Bruce, 1997; Dewey & Bentley, 1949; Rosenblatt, 1978) between the three components (Koehler & Mishra, 2008; Mishra & Koehler, 2006). An important part of the TPACK framework is that TPACK does not exist in a vacuum but rather is grounded and situated in specific contexts as represented by the outer dotted circle in the TPACK diagram.

Relationship Between TPACK and Similar Constructs

The TPACK framework is not the only framework developed to understand and explain teachers' use of technology. Though these alternative approaches may employ slightly different labels they are in broad agreement that the advent of new technologies requires teachers to possess knowledge that connects the affordances (and constraints) of these new technologies to the transformation of content and pedagogy. Our focus on the TPACK framework (as opposed to the others) in this review is that amongst the similar and related approaches, the TPACK framework has received the most traction in research and in professional development approaches, as evidenced by over 600 journal articles about TPACK.

Similar frameworks have been developed both independently and directly out of the TPACK framework, most based upon Shulman's (1986) model of Pedagogical Content Knowledge Similar frameworks include (but are not limited to): *ICT-Related Pedagogical Content Knowledge* (ICT-Related PCK); *Knowledge of Educational Technology*; *Technological Content Knowledge*; *Electronic Pedagogical Content Knowledge* (ePCK); and *Technological Pedagogical Content Knowledge-Web* (TPCK-W) (Angeli & Valanides, 2005; Franklin, 2004; Lee & Tsai, 2010; Margerum-Lays & Marx, 2003; Rhonton & Shane, 2006; Slough & Connell, 2006). Each of these alternative approaches are briefly defined below, highlighting significant departures from the TPACK framework.

ICT-Related PCK

ICT-Related PCK is an instructional systems design model based on Shulman's (1986), and Cochran, Deruiter, and King's (1993) conceptualization of PCK defined as an integrated understanding of four components: pedagogy, subject matter content, student characteristics, and the environmental context for learning. Specifically According to Angeli and Valanides (2005), ICT-Related PCK comprises the body of knowledge educators must possess to teach with ICT, and consists of a combination of five components of teachers' knowledge: pedagogical, subject area, students, environmental context, and ICT. ICT-Related PCK is defined as knowing how to: (a) Identify topics to be taught with ICT; (b) Identify

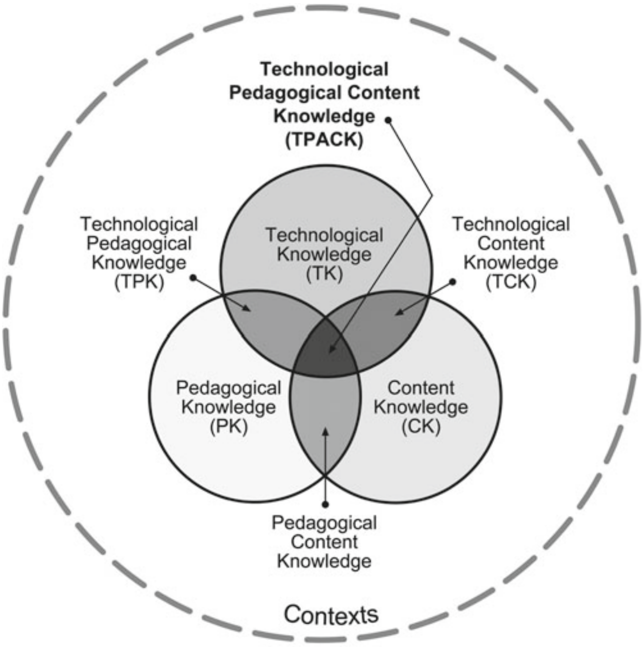

Fig. 9.1 The technological pedagogical content knowledge framework

representations for transforming content; (c) Identify teaching strategies that were difficult with traditional technology; (d) Select ICT tools to support content and teaching strategies; and (e) Infuse ICT activities in classrooms.

ICT-Related PCK differs from TPACK in that it conceptualizes the integration of technology into teaching as happening within the realm of PCK, and requiring additional types of knowledge within PCK. Whereas the TPACK framework considers technology knowledge as its own body of knowledge (Fig. 9.1), it should interact with other bodies of knowledge (CK, PK, and PCK) to form new types of knowledge (TCK, TPK, and TPCK).

Knowledge of Educational Technology

Knowledge of Educational Technology (Margerum-Lays & Marx, 2003) views teachers' understanding of educational technology through the lens of Shulman's (1986) conceptualization of teacher knowledge—content knowledge, pedagogical knowledge, and pedagogical content knowledge. Knowledge of Educational Technology is different from the TPACK framework, in that the TPACK framework emphasizes the interactions between content, pedagogy, and technology—treating technology knowledge as separate but interacting with all other forms of teacher knowledge. In contrast, Knowledge of Educational Technology treats the integrated understanding of teaching with technology as understandable, for the most part, using the Shulman's existing framework of teacher knowledge. Specifically, teachers' knowledge of educational technology can be understood as three components: Content Knowledge of Educational Technology, Pedagogical Knowledge of Educational Technology, and Pedagogical Content Knowledge of Educational Technology.

Technological Content Knowledge

Technological Content Knowledge is a theoretical framework defined by an emphasis on the "total intersection" between technology and content (Slough & Connell, 2006). Slough and Connell use the analogy of lenses, one each for technology and content through which teaching and learning can be viewed, as such the two components, technology and content become one. Additionally, according to Slough and Connell the lenses serve to "magnify" teaching and learning providing a more focused approach and collaborative professional development process. Slough and Connell offer the example of computer-generated visualizations, as the total overlap of technology and content, offering a new way building scientific understanding. The Technological Content Knowledge framework differs from the TPACK framework in that the TPACK framework conceptualizes technology as a realm of knowledge separate from content or pedagogy and focuses on the areas of overlap between the three realms of necessary knowledge.

Electronic Pedagogical Content Knowledge

Electronic Pedagogical Content Knowledge (ePCK) consists of knowledge that teachers must possess in order to successfully integrate technology into their classrooms (Franklin, 2004; Irving, 2006). ePCK is not a framework necessarily but a specific type of teacher knowledge that exists alongside knowledge of content, pedagogy, and curriculum. This type of knowledge is distinctly different from basic technical knowledge and linked to teacher efficacy, a necessary component of technology integration (Becker, 2000; Dawson, 1998). Teachers who possess ePCK are able to develop and implement a curriculum that includes methods and strategies for integrating technology in content areas in an effort to maximize student learning. Electronic Pedagogical Content Knowledge differs from the TPACK framework as ePCK emphasizes pedagogical practices specific to educational technology rather than conceptualizing technology as a distinct realm of knowledge.

Technological Pedagogical Content Knowledge-Web

Technological Pedagogical Content Knowledge-Web (TPCK-W) consists of knowledge of TPACK components content and pedagogy, and in place of general technology, the World Wide Web (Lee & Tsai, 2010). TPCK-W is identified as an extension of both Shulman's (1986) original framework and Mishra and Koehler's (2006) TPACK framework. This framework was specifically developed in response to the generality of technology in the TPACK framework and attempts to elaborate and clarify the more advanced knowledge necessary to teaching specifically on the Web. The new Web component includes knowledge regarding general uses of the Web, specific Web tools, and advanced use of the Web. An example of TPCK-W is being able to select proper (to desired content and pedagogy) existing Web-based courses to assist teaching.

To summarize, although these alternative approaches employ different labels, they are in broad agreement that the advent of new technologies requires teachers to develop new forms of knowledge that connect the affordances (and constraints) of these new technologies to the transformation of content and pedagogy. Early research on TPACK focused on establishing and developing the underlying conceptual framework (Koehler & Mishra, 2005a, 2005b; Mishra & Koehler, 2006). As the TPACK framework has been increasingly adopted, research has turned to measuring TPACK as well as to test the effectiveness of various TPACK-based interventions (Graham, Tripp, & Wentworth, 2009; Guzey & Roehrig, 2009).

Research on Measuring TPACK

A wide range of instruments have been developed to assess pre- and in-service teachers' use and understanding of TPACK (Koehler, Shin, & Mishra, 2012). Using a specific set of inclusion criteria, Koehler, Shin, & Mishra (2012) identified a total of 66 research publications that implemented TPACK measures after reviewing a total of 303 TPACK-related articles that were published in journals, conference proceedings, dissertations, and conference presentations. They found that 141 instruments, which included 31 self-report measures, 20 open-ended questionnaires, 31 performance assessments, 30 interviews, and 29 observations, were used across those studies to assess participants' understanding of TPACK. The following section briefly reviews each of the five types of instruments and provide some concrete examples (see Koehler et al., 2011 for a more detailed analysis of these different instruments).

Self-Report Measures

A total of 31 self-report measures have been developed and utilized, most commonly for pre- or in-service teachers (29 of 31). Typical self-report measures take the form of asking participants to numerically rate their agreement with statements regarding technology and teaching. For instance, the Survey of Preservice Teachers' Knowledge of Teaching and Technology consists of 47 self-report items that assess pre-service teachers' knowledge of 7 subscales of TPACK (Schmidt et al., 2009).

Open-Ended Questionnaires

A total of 20 TPACK instruments utilized open-ended questionnaires, all with pre- or in-service teachers. Typical TPACK open-ended questionnaires contain items that ask teachers to write about their overall experience in an educational technology course or professional development program that are designed to promote pre- or in-service teachers' TPACK. For instance, So and Kim (2009) used a prompt such as "what do you see as the main strength and weakness of integrating ICT tools into your PBL lesson?" in their research. The authors then coded pre-service teachers' responses focusing on their representations of content knowledge with relation to pedagogical and technological aspects of the course.

Performance Assessments

Performance assessments are intended to directly evaluate participants' TPACK by examining their performance on tasks that are designed to represent authentic teaching tasks or scenarios. There are 31 known TPACK instruments that utilize performance assessments, most of which are designed for use with pre- or in-service teachers. Performance assessments take many forms; for instance, some ask participants to create artifacts such as lesson plans, portfolios, or reflective journals (Graham et al., 2009; Harris, Grandgenett, & Hofer, 2010; Kereluik, Casperson, & Akcaoglu, 2010; Suharwoto, 2006). Other types of performance assessments ask participants to respond to a teaching scenario that involves complex problem solving (Curaoglu, Bu, Dickey, Kim, & Cakir, 2010; Graham, Borup, & Smith, 2012).

Interviews

As of June 2010 there were 30 known TPACK interview assessments. Interviews typically include a pre-determined set of questions and are typically recorded for later transcription, analysis, and coding. A vast majority of interviews were conducted with pre or in-service teachers. For examples, to examine changes in pre-service teachers' TPACK, Ozgun-Koca (2009) interviewed those teachers and asked them about the advantages/disadvantages of calculator usage and the effects on the teaching and learning process and environment.

Observations

Observations are intended to directly observe participants' TPACK at a given time point and to track the development of their TPACK over time. Observations were typically conducted either in classrooms or during a professional development session. There are 29 known studies that utilized observation, and a vast majority of the observations were conducted on pre- or in-service teachers. Observations, like interviews, were typically recorded for later analysis. For example, in Suharwoto's study (2006) researchers videotaped all the courses taught by internship teachers to see how they implemented technology in their own teaching. Once the observations were completed, researchers analyzed the transcript of the observation by following the coding scheme that was grounded in the TPACK framework.

Issues of Reliability and Validity in Measuring TPACK

Koehler et al. (2011) found that of the 141 TPACK instruments used as assessment tools, most were done so without any evidence of reliability or validity. Approximately 69 % of the studies included in their analysis did not present any evidence of reliability. Over 90 % of them failed to establish the validity of the measures that were used in their research. As research in TPACK becomes more empirical, it becomes more important that researchers scrutinize the measurement properties of TPACK instruments. The critical issue of "does my instrument accurately capture my participants' levels of understanding in TPACK?" needs to be addressed first as it is essential for good research (Kelly, 2010; Koehler et al., 2011).

Researchers who develop TPACK survey instruments, however, have devoted attention to the reliability and validity properties of TPACK measurement. Specifically, TPACK survey research has allowed researchers to further address the following issues about the measurement of TPACK: Internal consistency, test–retest reliability, and discriminant and convergent validity.

Internal consistency of TPACK surveys. Across several different TPACK survey instruments, researchers have found high levels of internal consistency (a form of reliability), indicating that the items of the TPACK survey correctly focus on the individual factors comprising TPACK. For example, Schmidt et al. (2009) created a 47 Likert item survey designed to measure each of the seven components of TPACK. One hundred and twenty-four preservice teachers completed the survey and showed significant growth in all seven TPACK areas, with the largest growth in their TK, TCK, and TPACK. Schmidt et al. (2009) report good to excellent internal consistency (using Cronbach's alpha between 0.75 and 0.92) for each of the seven constructs.

Similarly, Archambault and Crippen (2009) developed a survey of 24 statements to measure teachers' knowledge with a national sample of 596K-12 online teachers. These teachers assessed their own knowledge (PK/CK/TK/TCK = 12 items, PCK/TPK/TPACK = 12 items) using a 5-point Likert scale. They established the instrument's internal consistency (using Cronbach's alpha) to be 0.70 to 0.91 for each of the seven constructs. Sahin's (2011) TPACK survey also finds internal consistency ranging between 0.88 and 0.93 for the seven constructs of TPACK.

Test–retest reliability. To date, the only TPACK survey to study test–retest reliability is Sahin (2011), reporting test–retest reliability ranging from 0.79 to 0.86 on each of the seven constructs of TPACK. The time between the two measurement periods was not reported.

Discriminant and convergent validity. Discriminant validity tests the extent to which a concept is not highly correlated with other measures of theoretically different concepts. In the Schmidt et al. (2009), Archambault and Crippen (2009), and the Sahin (2011) studies, discriminant validity was addressed through exploratory factor analysis, finding support for each of the seven factors in each study. Additionally, the Sahin (2011) study measured the correlation between the seven TPACK subscales and external variables including the grades achieved in various types of teacher education courses (content courses, pedagogical courses, technology, courses, etc.).

The flip side of the coin to discriminant validity is convergent validity—the extent to which two measures agree (correlate) when they are both theoretically related. Sahin found high degrees of convergent validity, finding that scores on Pedagogical Knowledge (PK), for example, correlated significantly with grades achieved in pedagogical courses. Sahin also concluded that there was evidence of discriminant validity because PK did not correlate with grades in content courses or technology courses. Sahin (2011) found similar results for each tpack subscale and course grade pairing, consistent with a high degree of discriminant validity (when the measure and the grade in a course shouldn't correlate) and convergent validity (when the measure and the grade in a course should correlate).

Survey studies have also shown, however, significant correlations between the seven constructs of TPACK. For example, Schmidt et al. (2009) wrote:

> With respect to correlations between subscales, coefficients varied from 0.02 (social studies and math content knowledge) to 0.71 (TPK and TPACK). TPACK was significantly correlated with eight subscales at the 0.001 level and with social studies content knowledge (SSCK) at the 0.05 level. The highest correlations were between TPACK and TPK ($r = 0.71$), TPACK and TCK ($r = 0.49$), and TPACK and PCK ($r = 0.49$). (p. 135)

Similarly, Archambault and Crippen (2009) noted "correlations between pedagogy and content knowledge responses were high (0.690) as were those between pedagogical content and content (0.713) and pedagogical content and pedagogy (0.782)" (p. 318). Similar high degrees of correlation exists across studies, although which of the seven subscales of TPACK are most strongly correlated differs from study to study.

The high degree of correlation between the subscales of TPACK raise questions about the extent to which the components of TPACK are, in fact, separate components. Archambault and Crippen conclude, for example, that "We are concerned, however, that this distinction between content knowledge and pedagogic content knowledge introduces an unnecessary and untenable complication into the conceptual framework on which the research is based…" (p. 318).

Correlation between the subcales, per se, is not problematic in the TPACK framework. For example, theoretically TPK and TPACK should relate (and therefore correlate) to one another (see Fig. 9.1). TPACK, in part, derives from an understanding of TPK. To what extent the components of TPACK should correlate, however, is a question for further research. Answers to such questions have important implications for how TPACK should be measured, as well as what researchers are actually measuring when they administer TPACK instruments.

Models for Developing TPACK

The development of TPACK is clearly an important area of research due to its significant implications for teacher education and teacher professional development. Research to date, however, has not identified an ideal developmental sequence for developing TPACK in teachers, though many have raised the issue (Brush & Saye, 2009; Graham, 2011; Holmes, 2009; Niess, 2008).

There are some unique challenges in developing TPACK within the pre-service teacher population. Pre-service teacher candidates, for example, typically begin with minimal levels of all the TPACK constructs, meaning there is not a natural knowledge base upon which to build. In-service professional development programs, on the other hand, can usually depend on participants having a certain level of pedagogical content knowledge, and increasingly, as technologies become more ubiquitous and easy to use, technology knowledge, that they can use as a starting place for developing TPACK.

Several professional development approaches can be found in the literature for helping pre-service and in-service teachers develop TPACK. It should be noted that there is some overlap in the different approaches. In the sections below, we broadly characterize these approaches into three broad categories (Fig. 9.2). We also try to provide a key example of what these efforts look like in practice.

From PCK to TPACK

In this approach, technology is introduced as a way to support and enhance the strategies already being used in the classroom. For in-service teacher training this is a natural approach because it builds on teachers' years of teaching experience. Researchers have found, however, that this approach also has its limitations because in-service teachers bring prior beliefs that actually limit their vision and willingness to try new technology-supported strategies (Niess, van Zee, & Gillow-Wiles, 2010). In this approach, a teacher who first develops PCK through methods courses and experiences that don't involve the use of technology. Then later, the teacher learns how technology might be used to enhance and build upon the strategies they are already familiar with.

An example of the PCK to TPACK approach in practice is the use of activity types (Harris & Hofer, 2009; Harris, Mishra, & Koehler, 2009). In this approach, learning is driven content focused pedagogies called *activity types*, a shorthand for that which is "most essential about the structure of a

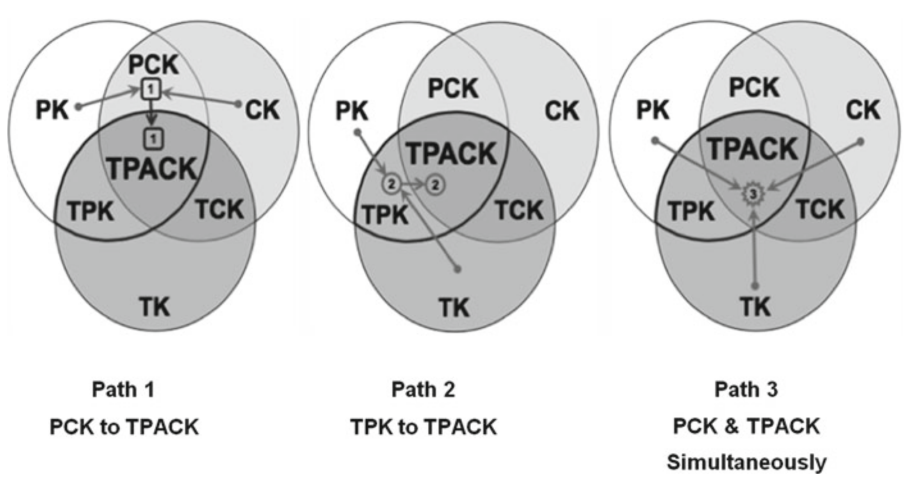

Fig. 9.2 Three paths to developing TPACK

particular kind of learning action as it relates to what students do when engaged in that particular learning-related activity." Examples of activity types include "group discussion," "role play," and "field trip" (Harris & Hofer, 2009; p. 101).

In this approach, activity types are seen as content-specific. The activity types for social studies teaching, for example, might be different than those used for mathematics teaching. Using activity types, teachers first focus on learning goals, and based upon pedagogical decisions, teachers then select appropriate activity types for a given learning experience, formulate assessment plans, and select tools (including technology) that will best help students benefit from the learning experience.

A recent study looking at the use of an instructional intervention using an activity types approach for in-service teacher professional development found that teachers' decisions around educational technology use became more deliberate and judicious and their use of learning activities and technologies became more "conscious, strategic, and varied" (Harris & Hofer, 2011, p. 211).

Other notable examples of the PCK to TPACK pathway include the use of dynamic spreadsheets for teaching mathematical reasoning and problem solving (Niess et al., 2010), the use of geospatial technologies to facilitate science inquiry (Trautmann & MaKinster, 2010) or teaching geography (Doering, Veletsianos, Scharber, & Miller, 2009), and the use of moviemaking to create digital documentaries to promote historical thinking among students (Hofer & Swan, 2006).

From TPK to TPACK

An approach prevalent in my teacher preparation programs is going from TPK to TPACK. The typical example of this approach involves a pre-service candidate who has had not yet taken content-specific methods courses when he/she is required to take a prerequisite technology integration course. These courses are typically taught by an instructional technologist with either limited expertise in all subject areas, or an explicit goal to broadly cover technology that spans all content areas. Because the candidate does not already know pedagogical strategies specific to teaching science, mathematics, language arts, social studies, or other subject areas, the technology integration courses tend to focus on how technology can support teacher productivity and general pedagogical strategies. For example, candidates may learn how to use Web 2.0 technologies to increase active learning or technologies for communicating with parents and students, but that learning isn't directly connected content-specific methods such as guided inquiry in science or balanced literacy in language arts. It is only later when the candidate takes methods courses and has field experiences that she can start to integrate her TPK with PCK to develop TPACK. Thus, the first step in this path is to develop TK and TPK in these early course experiences. As candidates take methods courses specific to their content specialty, their knowledge of TPK should expand into TPACK, and they should incorporate their knowledge into their disciplinary understandings.

This approach is the "default approach" in most institutions of higher learning. Technology is relegated to a few courses and teachers are left to take those lessons and apply them to their own content areas.

A more sophisticated example of the TPK to TPACK pathway is an approach called *Technology Mapping* (Angeli and Valanides, 2009). As "an empirically-based approach for understanding and promoting a situative orientation toward the development of ICT–TPCK" (p. 160), the technology mapping approach emphasizes mapping or connecting the properties of technological tools with the ability to transform content representations and/or support student-centered pedagogies. Examples of ways that tools can transform content include making representations visual, multimodal, or interactive. So, a tool like Google Earth transforms a static visual geographic representation into one that the learner can interact with. Similarly, the affordances of a tool may facilitate or make difficult certain pedagogies. For example, Google Earth could facilitate a virtual field trip in a way that a whiteboard cannot. Angeli and Valanides (2009) conducted a study to investigate the effectiveness of the technology mapping approach for developing TPACK with over two hundred pre-service teachers. They found statistically significant improvements in students' performance on design tasks towards the end of the semester as compared to the beginning of the semester.

Developing PCK and TPACK Simultaneously

A third pathway to TPACK is to try and develop PCK and TPACK simultaneously. In a pre-service context this means replacing the educational technology course, as we know it, with a systematic integration of technology-supported strategies into the methods courses and field experiences. For example, a program following this approach might not have a technology integration course at all but rather require that each of the content-specific methods courses teach candidates how to use technology for teaching within the discipline. Thus, candidates would be developing their PCK and their TPACK simultaneously.

One challenge of this approach is the cognitive load that students experience when they are simultaneously trying to develop their pedagogical, content, and technological knowledge. Brush and Saye (2009) comment on this, "Many times, pre-service teachers are simultaneously learning content, technology, and pedagogy—as well as learning the craft of teaching—which can prove overwhelming to individuals just entering the teaching profession" (p. 47).

An example of this approach in practice is the *Learning Technology by Design* approach (Koehler & Mishra, 2005a, 2005b). In this approach, teachers develop TPACK by them working in teams to design solutions to ill-structured, real-world problems of teaching and learning over an extended period of time. Instead of directly teaching technologies to teachers, teachers' learning is driven by the design-problem and a consideration of different technologies that may contribute to the final design solution. Because real problems of practice require designers to integrate content, pedagogy, and technology, learners necessarily engage with actively integrating these types of knowledge as they work on a solution.

Others have also explicitly used design as a vehicle for helping teachers to develop TPACK (Angeli & Valanides, 2005; Lambert & Sanchez, 2007; So & Kim, 2009; Valanides & Angeli, 2008). The *Learning Technology by Design* approach, however, is the only approach of these that uses the simultaneous development TPACK and PCK pathway.

Research that looked at the effectiveness of the learning by design approach found that participants on design teams significantly developed knowledge in each of the seven components of TPACK (Koehler & Mishra, 2005b), and that design team conversations increasingly demonstrated higher forms of integrated understanding, in the form of PCK, TPK, TCK, and TPACK (Koehler, Mishra, & Yahya, 2007).

Developing TPACK in the Content Areas

A central theme of TPACK development is that this kind of knowledge is situated in a content-specific context rather than a more general context. This section outlines three aspects of TPACK development that are woven throughout the TPACK research.

Teaching Strategies/Methods

One distinction between TPACK and traditional technology integration efforts is a focus on content-specific pedagogies as opposed to general pedagogies. The TPACK literature is full of examples, predominantly in social studies, math, and science. Many of the activity types identified by Judi Harris (see http://activitytypes.wmwikis.net/) are content-specific activities that are found in one content domain but not others (Harris & Hofer, 2009). Bull, Hammond, and Ferster (2008) focus on the strategy of historical investigations for social studies teachers and show how Web 2.0 tools can support that strategy. Other examples in social studies include using technology to support empathetic role-paying or historical think-alouds (Brush & Saye, 2009), using geospatial technologies to develop a "sense of place" (Doering & Veletsianos, 2007), and the use of primary sources to develop historical thinking (Swan & Locascio, 2008). In math and science, examples include using technology like spreadsheets to analyze real data in the science inquiry process (Niess et al., 2010) and the use of technology to support different phases of scientific problem-solving inquiry in biology classrooms (Toth, 2009).

Knowledge of Learners

Content-specific understandings of learners is a focus of the PCK literature, but it has not been a strong focus in the TPACK literature, even though several TPACK measurement instruments have questions related to content-specific learner understandings (Cox & Graham, 2009; Graham, Borup, & Smith, 2012; Mouza & Wong, 2009; Schmidt et al., 2009). Knowledge of learners' content-specific understandings is an implicit part of both the technology mapping (Angeli & Valanides, 2009) and activity structures (Harris & Hofer, 2009) approaches to teaching TPACK. However, more research could be done on specifically how technology supports teachers in identifying learner content-specific understandings and not just how it is used to address misconceptions or difficult concepts.

Content Representations

Many researchers have noted that the properties of a particular technology support teaching specific content, and that technological tools can transform representations in ways that afford some conceptual understandings better than others to students (Angeli & Valanides, 2009; Bull et al., 2008; Valanides & Angeli, 2008). McCrory's research on representations in science teaching (McCrory, 2008; McCrory, Putnam, & Jansen, 2008), for example, demonstrates how technological affordance can be useful to (1) speed up the time of natural events, (2) organize large bodies of data, and (3) record data that would normally be hard to gather.

The need to attend to context is by no means restricted to TPACK research—These three themes have also been identified as central in the existing PCK literature base (Lee & Luft, 2008; van Driel, Verloop, & de Vos, 1998). The further development of an understanding of the contexts in which TPACK is developed is an important dimension of future TPACK related research.

Conclusions

Clearly the TPACK framework since its introduction in 2006 has had significant impact on both theory and practice in educational technology. In conclusion we point to both what the framework has achieved as well as point to some key limitations and directions for future work.

The single biggest contribution of the TPACK framework has been in the area of teacher education and teacher professional development (Koehler, 2012; Mishra, & Wolf, et al., 2012). Research has indicated that most pre-service and in-service professional development of teachers often fail to "support and develop educators identities as fluent users of advanced technology" (US Department of Education, 2010, p. 45). The TPACK framework argues that programs that emphasize the development of knowledge and skills in these three areas in an isolated manner are doomed to fail. Thus, effective teacher educational and professional development needs to craft systematic, long-term educational experiences where the participants can engage fruitfully in all three of these knowledge bases in an integrated manner.

One of the significant limitations of the TPACK framework is that it is neutral with respect to the broader goals of education. For instance, the TPACK framework does not speak to what kinds of content need to be covered and how it is to be taught. As many scholars have pointed out the new millennium requires a great level of focus on higher order thinking skills, collaboration and creativity (see Mishra & Kereluik, 2011 for a review). A beginning in this direction has been made through an argument for the role of TPACK in developing twenty-first Century trans-disciplinary skills (Mishra, Koehler, & Henriksen, 2011).

Finally, though there has been a flowering of research on TPACK and its measurement, the review indicates that there is still much to be done—particularly in the area of measuring how TPACK works in different disciplinary contexts. The quality of research has also been patchy, and there is a clear need for better-designed studies and instruments.

Concerns, however, go beyond merely research designs and instrumentation. A key aspect of the TPACK framework has to do with teacher autonomy and seeing teachers as designers, particularly with technologies that change at a very rapid pace (Koehler & Mishra, 2008; Mishra, Koehler, & Kereluik, 2009). This open-endedness and rapid rate of change have implications for the kinds of research we do since it is challenging to develop instruments when the final goals are creative products that often cannot be specified in advance, or when the tools inherent to the pedagogy and content keep changing. This means that we need to newer methodologies and ways of capturing and analyzing phenomena that respect this open-endedness and creativity even while being sensitive to statistical variability and experimental biases. Norman (2010) recently made a similar argument new research paradigms for the design sciences as well. Thus, though we applaud the effort that has gone into extant instruments and measures for TPACK we also argue that we need to be looking beyond existing methodologies to develop newer techniques and approaches that recognize the pragmatic, applied and creative goals of teaching with technology.

Ethics of Educational Technology

10

Stephanie L. Moore and James B. Ellsworth

Abstract

While ethics has been an under-researched area in educational technology, it is receiving current recognition as a critical focus for inquiry and development. In this chapter, we review the contribution of ethics as part of the history of professionalization of the field, the development of a code of ethics for the profession, and contemporary ethics issues like cultural competence, intellectual property, accessibility and universal design, critical theory in educational technology, system ethics, and social responsibility of professionals. In addition, this chapter presents major theoretical and philosophical models for ethics that pertain specifically to technology in educational systems along with implications of research from other fields exploring the integration of ethics into policy, standards, and higher education curricula. Existing research on ethics in educational technology programs suggests a very low level of integration in such domains at present; findings from a survey of the curricular landscape and implications for future research and development are discussed along with consideration of ethics as a foundational component not only to professional standards, practices, and leadership, but also to education policy, as we highlight the role of faculty and graduate programs, practicing professionals, and scholarly associations in shaping future directions and research in this emerging domain.

Keywords

Professional ethics • Ethics as design • Ethics across the curriculum • Social responsibility • Conative domain

Introduction

> "*Neither stability nor change have any intrinsic value. The worth of stability is in the goodness it preserves, while the worth of change is in the goodness it brings about.*"
>

We must start any conversation on ethics within the discipline of educational technology by underscoring how dramatically understudied this topic has been—and by suggesting that much of this owes to our legacy of viewing ethics as the domain of philosophy rather than action. Yet ethics, properly conceived, are about more than abstract pondering; they are the foundation of the exemplary standards of performance we expect of professionals (Dean, 1993) and thus the necessary precursor to any valid and effective planning and design (Moore, 2010, in press).

Unfortunately, while calls for a more systematic treatment of ethics in our field are increasing, educational technologists today have little to turn to as a robust, well-defined discourse within our own literature. This chapter examines priorities for addressing this gap through development of

J.M. Spector et al. (eds.), *Handbook of Research on Educational Communications and Technology*,

models (including instructional design, instructional systems design, and evaluation frameworks), proposing a synergistic relationship between ethics and research: one that suggests how we can look to the history of the field and the research represented in this very volume as informing professional ethics for the field. Based on this, we advance a framework and research agenda for deepening our discourse and understanding in the ethical domain.

This is only a beginning. If we succeed in our call to action, then this chapter looks dramatically different in future editions, as rigorous investigations of the relationship between our models and theories and the societal impact of our practice become habitual and intertwined through the discourse of our profession.

A Brief History of Ethics in Educational Technology

Attention to the ethics of technology, in general, is a relatively recent phenomenon. Although "techne" has been a part of the human condition since antiquity, it was long considered too worldly for philosophical consideration, and since ethics were the domain of the philosophical, technology and ethics rarely met in discourse over the centuries, even though their narratives are tightly entwined (Scharff & Dusek, 2003). Until the last 100 years or so, when thought was given to technology at all, it was generally assumed to be an inherent good. Under this Positivist paradigm, because technology was viewed as the derivative of science—and science claimed the objective high ground—its products and outputs inherited those same claims to objective virtue. Today, though, we live in a world where a century of unintended consequences—and of their greater transparency to public scrutiny—has recast this faith as naïve. Scanning the popular literature, it might almost appear that the default narrative of technology today is one in which it is inherently bad. These two storylines do daily battle in the headlines: one side is boldly proclaiming "the Internet promises to democratize the world," and the other is whispering "the Internet promises to expose our children to pedophiles."

In between these rival claims is a chasm—one created and widened by our legacy of neglecting any meaningful deliberation on the ethics of technology; it is this chasm that our discipline and many others are seeking to bridge today. Davis (1999) details what he calls the "ethics boom" across disciplines. Thanks to national scandals, technological advances, or poor professional performance, a host of disciplines began to build ethics into college curricula and map ethics-related standards for professional practice.

During this time, the military profession returned to wrestling with the ethical obligations of leadership in war, after civil-military tensions came to a head when President Truman fired General Douglas MacArthur in Korea, and when soldiers under an inexperienced lieutenant massacred Vietnamese civilians at My Lai. Medicine was also among the first to integrate ethics into the curriculm by attempting to define what constituted "practical ethics" or "applied ethics," according to Davis (1999), as physicians confronted increasingly difficult decisions due to technological advances that pitted expensive devices that treated the most ill patients against (for example) building a clinic to serve more people with less serious ailments. Medical faculty worked with faculty in philosophy to develop a new approach to integration of ethics into the curriculum that emphasized ethics as practice or part of a decision making process. The legal profession has faced national scandals like Watergate, which led states to start mandating ethics courses in law programs, and they similarly started developing "practical ethics" as part of the curriculum. Soon after, engineering and science disciplines began to follow suit, following their own scandals ranging from bribery (kickbacks paid by civil engineers to receive preferential treatment in contracts, which ultimately forced the resignation of Vice President Spiro Agnew), to discovery of falsified testing records for airbrakes supplied by B.F. Goodrich for the Air Forice's A7D plane, to the Ford Pinto's exploding gas tank and poorly designed cargo doors on DC-10 aircraft. Similarly, social science disciplines faced an extensive history of cases of mistreatment, deception, abuse, debilitation, or even death of human subjects during research spanning several centuries and occuring in numerous countries. In 1948, the Nuremberg Code was the first international document to establish ethical boundaries for research in social and medical sciences, establishing core principles and practices such as informed consent. Then the boom really took off, as business, accounting, nursing, journalism, financial analysis, public administration, and even dentistry followed suit.

Yet one glaring and curious void in Davis' history of ethics in higher education curricula is the profession of education itself (in general, and educational technology specifically). Although he discusses research ethics extensively, his primary focus is on their application in medical or social science fields like sociology and psychology. Based on Davis' logic, however, that disciplines integrate ethics based on responses to public scrutiny, the time appears at hand for education disciplines to explore ethics beyond just research ethics. *A Nation At Risk* and *No Child Left Behind* reflect increasing national scrutiny of educational systems and teacher preparation, calling into question the value that we add to—or subtract from—our learning systems and society in general. Critics of educational technology such as Cuban (1986, 2003) and Healy (1990, 1999) offer pointed indictments underscoring a perceived failure of technology to contribute anything worthwhile to teaching and learning, challenging our relevance and therefore our *raison d'etre*. A policy brief from WestEd (2002) poses the question directly:

> Investments in education technology can pose major dilemmas for policymakers. Most agree that in today's world, technology is not a frill but an important part of any modern curriculum. Equally clear, however, is its expense.... Over the last decade, K-12 spending on technology in the United States tripled, now totaling more than $6 billion. Given these realities, policymakers at state and local levels are asking the predictable question: Does this level of spending on technology make a difference in student learning? (p. 1)

This question of "worthwhileness" was raised in several early foundational pieces of the field. Texts republished as "classics" by founding figures in Ely and Plomp (1996)—such as Finn (1996a, original published 1962, 1996b, original published 1953), Davies (1996, original published 1978), and Kaufman (1996, original published 1977; see also Kaufman, Corrigan, & Johnson, 1969)—explicitly focused awareness on ethics for the profession, calling for a professional code of ethics, reflection on the ethical nature of educational technology, and development of assessment models that evaluated societal level impact of educational technology as a profession. According to Davies (1996), while technology and creativity expanded the range of choices available to educators, they also "made it more difficult to foresee the full consequences of the choices made and the actions taken" (p. 15). He states:

> Technology, contrary to popular belief, is not necessarily confined to the *means* by which educators realize their ends. Technology also raises anew questions about the nature of the ends themselves. It forces us to reflect on the morality of what we are about, by its very insistence on defensible choices. … Unfortunately, the deep satisfaction, sense of creativity, and feelings of accomplishment that can be expressed in the *doing* of educational technology are too often preferred to the related, but very different, pleasures of *contemplating* educational technology. Yet contemplation and responsibility go hand in hand, one without the other is meaningless (sic, pp. 15–16).

Emphasizing the importance of a results orientation, Kaufman (1996, reprinted from 1977, 2000) provides a practical way of discussing results (or ends) and societal benefit by framing this discussion in terms of assessment. Kaufman outlines the explicit relationship between what educational technologists do and the ultimate impact of such work on society:

> The simple truth is that what the schools do and what the schools accomplish is of concern to those who depend upon the schools, those who pay the bills and those who pass the legislation. We are not in a vacuum, and our results are seen and judged by those outside of the school—those who are external to it.… This external referent should be the starting place for functional and useful educational planning, design, implementation, and evaluation—if education does not allow learners to live better and contribute better, it probably is not worth doing, and will probably ending up being attacked and decimated by taxpayers and legislators (1996, p. 112).

From Kaufman's perspective, school is not an end but rather a means to an end, for education is ultimately judged by graduates' ability to survive and positively contribute to society. If that is the real end of our efforts, our practices should begin by assessing the "gaps between current outcomes and required or desired outcomes based on external survival and contribution" (p. 112). Thus, according to Kaufman, the practice of educational technology should first begin by determining and justifying what the ultimate *desirable* impacts of our actions are on society and using that as a guide for the design process. Kaufman has developed this over the years into a full framework for assessment that he calls "Mega" (2000), which may very well prove to be a guiding framework for applied ethics in the field given its focus on societal impact. This framework is explored later in the review; here we note that as the field was developing, Kaufman made explicit this question of social responsibility—of the profession's ultimate impact on society—as something that its practitioners must answer to if educational technology was to be a viable, respected profession.

Reinforcing this focus on results, Finn (1996a, original published 1962) asserted that technology is not a collection of gadgets, hardware and instrumentation, but is instead "a way of thinking about certain classes of problems and their solutions" (p. 48). Finn argued that the questions of "what is desirable and why" should be subjects of continual contemplation by the profession. In fact, it was Finn who, in seeking to define the educational technology profession, laid out six traits that characterize any profession, and included ethics among these (1996b, reprinted from 1953):

1. An intellectual technique
2. An application of that technique to the practical affairs of man
3. A period of long training necessary before entering into the profession
4. An association of members of the profession into a closely knit group with a high quality of communication between members
5. A series of standards and a statement of ethics which is enforced
6. An organized body of intellectual theory constantly expanding research

Since Finn's initial advocacy for a professional code of ethics (1953), educational technology's associations have reliably addressed ethics within our profession in this manner. The Division of Audio Visual Instruction (DAVI) of the National Education Association did formalize a code of ethics (Hitchens, 1970; National Education Association, 1975), and this was carried over by the Association for Educational

Communications and Technology (AECT) through the Committee on Professional Ethics. That committee was formally charged with conducting an annual review of the code and adjusting it over the years, and continues to do so today (see Welliver, 2001). Ethics have also been preserved in formal definitions of the field among its essential characteristics. In the 1977 definition reprinted in the opening chapter of Ely and Plomp's *Classic Writings on Instructional Technology* (1996), the authors outline 16 parts, including two reflecting ethics:

> 9. Educational technology has an association and professional communications. There is at least one professional association directly concerned with educational technology—the Association for Educational Communications and Technology. *In addition to facilitating communication among members through its annual convention and three periodic publications*, ***it serves to develop and implement the standards and ethics***, ***leadership***, ***and training and certification characteristics of the profession***. (p. 13, emphasis ours)
>
> 11. Educational technology operates within the larger context of society. It advocates being a concerned profession—concerned about the uses to which its techniques and applications are being put. Further, as a profession, it has taken stands in favor of intellectual freedom, in favor of affirmative action, against stereotyping in materials, and in favor of enlisting technology in support of humane and life-fulfilling ends. (p. 13)

The 1994 Seels and Richey definition still included Finn's fifth criterion, but only a page and a half was devoted to how ethics have been addressed since Finn's original publication. The authors recognized that issues like copyright, fair use, and equity were becoming increasingly important. Still, the lack of depth they accorded this topic, and the contemporaneous dearth of citable research or applied work on ethics reveals that this particular "defining characteristic" has gone relatively unexamined for decades.

Despite this prolonged period where educational technology's code of ethics may have risked falling victim to Finn's warning that codes can become mere window dressing, later in the very year that definition was published (1994), a discussion began on the ethic of "social responsibility" that would revitalize one of the codes and suggest a means of making ethics actionable. Based on discussions at the 1994 AECT convention, an entire issue of *Educational Technology* was devoted to the topic of the ethics of the profession. Authors in that edition tackled the topic from a variety of critical theory perspectives including postmodernism and feminism.

Whereas the focus of ethics in educational technology had previously been the individual's behavior and correction where necessary, it was now expanding to include a sense of a professional "social" responsibility. The eleventh part of the 1977 definition that stated "Educational technology operates within the larger context of society" (fully quoted above) had become a formal topic in the literature. Yeaman, Koetting, and Nichols (1994) brought the notion of social responsibility to the fore as they introduced the special issue of *Educational Technology*. Their emphasis was "not on the ethical behavior of individuals, which seems to be the domain of the existing professional codes of ethics, but on the ethical position of educational technology in society" (p. 5). For the authors, social responsibility is an awareness of culture with its intrinsic values and interests and a commitment to basic human rights (p. 10). Social responsibility within educational technology seeks to understand how the profession relates to society, culture, politics, gender, and science and technology in general (Yeaman et al., 1994, p. 10). The authors close with a remark on what is lacking in our field's emphasis on "how to" research and presentations: "there is definitely nothing wrong with liking and advocating educational technology. It is good to find better ways of doing things. Nevertheless, it is important that better should include the qualities of being ethical and more humanizing" (p. 12). This led to changes to AECT's code of ethics to reflect an emphasis on the profession's social responsibility (Yeaman, 2004). Contemporaneously, other associations like the International Society for Performance Improvement (ISPI) began a similar shift in the emphasis of their codes and competencies (Watkins, Leigh, & Kaufman, 2000).

Most of this seminal discussion, however, remained philosophical, approaching the topic through a critical theory lens. With little of it linking results to professional practices, an evidentiary basis for prescribing how one would actually go about addressing ethical outcomes in one's work remained elusive. In one key exception, practitioners in the Human Performance Technology domain of the field have developed a professional certification, the Certified Performance Technologist (C.P.T.), which seeks to address this gap. In moving from a focus on code to one on competencies, the ISPI certification process has started to shift the emphasis of professional ethics to an empirical basis defined by desirable, demonstrable results that can be used to evaluate performance. Furthermore, in addition to competencies related to analysis, design, development, implementation, and evaluation (ADDIE), key authors in this domain have repeatedly called for the inclusion of assessment—which Kaufman (2000) argues is essential to ensuring socially responsible decisions—and ethics in the competencies for certification (Dean, 1999; Guerra, 2001; Stolovitch, Keeps, & Rodrigue, 1999).

The Current State of Affairs: Ethics Across the Curriculum and the Literature

Unfortunately, for a profession that prides itself on its grounding in research and evidence-based theory, educational technologists have very little to guide us, either in

Table 10.1 Count for articles on ethics across educational technology journals

Journal	Number of articles on ethics as of 2011[a]
Educational Technology Research & Development (ETR&D)	39 (since 1950) 4 with ethics as the primary topic; remaining have ethics as a subtopic[b] (1.5 % of articles based on 2,501 total articles since 1950 have some mention of ethics) Of what we deem to be the substantive research and theory in the field, 98.5 % doesn't even mention ethics
TechTrends	111 (since 1980)[c] (4.8 % of articles—based on 2,307 total articles—since 1980 have some mention of ethics)
Instructional Science	12 (since 1970)[d] (1.2 % of articles based on 958 total articles since 1970 have some mention of ethics)
Contemporary Issues in Technology & Teacher Education	52 (since 1997)
International Journal of Educational Telecommunications	9 (since 1997)
Journal of Interactive Learning Research	19 (since 1997)
International Journal on E-Learning	37 (since 1997)

[a]"Ethics" was defined broadly in this search, including articles on ethics, social responsibility, accessibility, copyright, and cultural considerations. No articles specific to research ethics turned up in this search, probably owing to the fact this is a much more general topic affecting many disciplines and therefore appearing in research methodology journals

[b]A majority of these articles focused on application of educational technology in non-US settings. In articles where "ethics" or "social responsibility" were explicitly in the title, the article's focus was still on cultural considerations, suggesting that this is the current predominant conception of ethics in the field. In every instance except one (Lin, 2007), ethics was mentioned as a "need" or a gap but not the actual topic of investigation

[c]An initial search yields 176 articles in *TechTrends*; however, the 111 reported exclude convention reports, calls for proposals, "Datebook" entries, and "Editor's Notes." Of those 111, 11 (10 %) are Paul Welliver's "Ethics Today" series from 1990 to 1995. Twelve are Andrew Yeaman's contributions to that series, and another seven from his 2004 "Professional Ethics" series (17 % of the total articles)

[d]Technically, all articles with any mention of ethics in *Instructional Science* appeared from 1999 onward; no such articles appeared in this journal prior to that year. Further, none of these articles focused on ethics as a primary topic; rather, all gave passing mention to ethics in their discussion of other matters. These trends in treatment are also representative of the remaining journals

considering the ethics of our own practice or in the preparation of our students for contemplating their own. A recent study by Moore (2005, 2009) surveyed faculty and graduate curricula in educational technology programs in the USA and Canada using Kaufman's "Mega" framework mentioned earlier. The survey asked faculty to indicate which dimensions of social responsibility the field currently adds value to and which dimensions it *should be* adding value to that it presently does not. Moore's study also reviewed vision and mission statements for degree and certificate programs in the USA and Canada, as well as curricula (represented by course offerings), to assess the presence of ethics as a subject of study and the degree to which ethics are formally integrated into professional preparation.

Faculty responses to the survey painted a telling story of the current collective disposition towards social responsibility, both as a topic within a course or curriculum and as a guiding ethical framework for the profession. While Kaufman's framework did validate as a comprehensive social responsibility construct (Moore, 2005), of its 13 elements, faculty believed 12 applied rarely or never to their current professional practices. Survey responses did suggest faculty believed that the field should do better in a few of the areas, but even there, ratings of relevance and commitment were relatively low. In short, the findings suggested—and open comments on the survey supported—that faculty in the educational technology field do not perceive a connection between societal level outcomes and what they do or should focus on as scholars in the profession.

Moore concluded, based on these findings as well as implications from her curriculum analysis, that educational technology professionals simply do not have a well-developed schema for considering social responsibility, differentiating between its various elements, or identifying those for which our profession shares responsibility. Her curriculum review of 67 educational technology programs found only 1 in 5 offering any courses reflecting an explicit consideration of ethics, fewer than 1 in 10 declaring ethics among the program's stated objectives, and fewer than 1 in 15 including ethical practice in its vision—even when "ethics" was as broadly defined as possible.

Finally, a current analysis of the educational technology literature reinforces the sense that professional ethics are rarely on our collective mind. In conducting this search, we defined "ethics" as the topic of an article broadly, to include articles on ethics, social responsibility, accessibility, copyright, and cultural considerations—and, based on this definition, counted related articles in the primary research and applied journals in the domain. Table 10.1 summarizes these counts along with notes on each to better assist in interpreting nuances within the articles and data.

Together, such findings begin to paint a troubling picture. It seems clear that, despite the contributions of prominent authors on the topic, such as Yeaman, Nichols, and others noted above, systematic consideration of the ethics of our professional practice has not diffused throughout educational technology's research, design models, or curricula. What's more, this scant literature's focus on cultural sensitivities and on legal themes like intellectual property, accessibility, and content filtering—issues similar to (or possibly orthogonal to) but not properly part of ethics itself—is typical of constructs around which a collective and individual schema has yet to form (Anderson, 1977; Ormrod, 1999), reflecting the work still to be done in this area.

From Current Themes to Promising Frameworks

This chapter aims to chart some promising pathways toward such a schema, while illustrating how educational technology professionals can reconceptualize existing ethics themes to incorporate a greater focus on measurable results (in accordance with principles long-embraced in other domains of educational practice, such as change facilitation and technology integration and human performance technology). First, we consider a few of the examples noted above, where the lack of a common ethics schema has often led our consideration of ethical issues to veer off into discussion of legal mandates or regulatory compliance.

Intellectual Property and Open Content

Discussions of intellectual property "ethics" in educational technology have most often centered on issues like copyright (law), work-for-hire (law), and similar considerations, where "what is right"—while it may perhaps be obscure to the participants—is grounded in statute or regulation. While important, and while one hopes that laws enshrine practices that are ethical, the ability to conceive of an unethical law—or an illegal act that is nevertheless an ethical obligation—makes it clear that the two constructs are distinct. Losing sight of this distinction can obscure other aspects of intellectual property in our professional practice, however, which are more properly the domain of ethics. Consider one common scenario: a graduate student "co-authors" a presentation at a major conference with a prominent faculty member. The student does virtually all the work, with the senior scholar contributing little more than his name. Yet without that name, a presentation by the unpublished grad student would probably not have been accepted for such an important venue. Who owns the intellectual property? Can the faculty member ethically claim principal authorship to increase the student's likelihood of acceptance?

Another ethical issue related to intellectual property is found in the burgeoning discussion of open content. Open content advocates such as Wiley (2010) argue that society's interests are maximized when intellectual property is shared freely, with proper attribution, for noncommercial purposes. Ironically, this notion of a public interest in the free and open exchange of ideas was the *genesis* of modern copyright law (Ferguson, 2012). It is of special interest in this chapter's context to note that the subtitle of the United States Copyright Act of 1790 was "an Act for the encouragement of learning." And yet, once we set about trying to resolve an issue of ethics using the blunt instrument of law, "over time, the power of the market transformed this principle beyond recognition" (Ferguson, 2012). In short, open content represents an attempt to reclaim a public good that has actually been *subverted* by the legal framework created to protect it, because we have virtually abdicated our reponsibility to oversee that framework within the domain of ethics.

Other frameworks are possible; that is, in fact, the point. Our ethical obligations do not center on "finding the right answer," but rather on *achieving a desirable outcome*—in this case, creating a rich "primordial soup" in which ideas and innovation can flourish, by balancing incentives for content creators with a vibrant public domain in which their creations are accessible to all to drive the next cycle of innovation. Further research is required to measure the contribution of Open Content to this end and to identify and similarly validate other possible frameworks for wrestling with the ethics of intellectual property. Still, Open Content exemplifies the ethical *approach*, by finding its touchstone in this purpose rather than in law and compliance—which are, by definition, means and not ends.

Accessibility and Universal Design

Accessibility and Universal Design have their early roots in the idea of "barrier free design" that emerged in the 1950s across Europe, Japan, and the USA. Like intellectual property, accessibility is among the more common topics associated with the concept of professional ethics in the current literature that exists on ethics in educational technology journals specifically, as noted above. Yet, once again, much of this discussion tends to gravitate toward legal issues—like Americans with Disabilities Act (ADA) compliance—or conflates the term with other concepts (like "having access" to a computer). The literature defines accessibility as the ability of a person with a disability to use an environment—including digital environments—as effectively as people who do not have disabilities (Slatin & Rush, 2003). Clearly—whether we consider children born with congenital disabilities yet active minds, accomplished adults developing a natural disability later in life, or service members wounded in combat—making learning environments accessible to all is an area where educational technologists must play a crucial role if individuals and the society of which they are a part are to benefit. While accessibility can seem a purely technical issue, with emphasis on hardware or software accommodations, such details are better understood as manifestations of design choices and cognitive principles that enable or inhibit socially desirable objectives.

Here, too, we have largely ceded an ethical issue to the domain of law—and here too, this has produced unintended consequences that have undermined the social good being sought. The first time most designers encounter accessibility is when they are told, on the job, that a module or course must be Section 508 compliant. In 1998, Section 508 was added as an amendment to the Rehabilitation Act of 1973, extending the requirement for accessibility of *physical* environments (e.g., buildings and transportation) to cover electronic and information technologies. Unfortunately, legislation by definition promotes a compliance orientation—emphasizing strict adherence to the requirements of the statute, over actually ensuring equal access. For example, in one learning management system, the live collaboration environment is not accessible during the actual meetings, but the recordings from these meetings are made accessible afterwards with subtitles and transcripts from chat windows. While meeting the technical and legal standards of Section 508, this still clearly excludes learners with disabilities *from the main instructional strategy* of live collaboration, relegating them to observers of—rather than participants in—the learning process. Such unintended consequences are consistent with research that suggests compliance-oriented training fails to produce actual changes in behavior or performance, compared to values-oriented training supported and modeled by leadership (Dean, 1993; Harrington, 1991; Trevino, 1987, 1992; Weaver, 1999).

In contrast, in a discussion article on accessibility from an outcomes perspective, Roberts (2003) showed how technical solutions can be informed by the learning sciences to yield *cognitive* access to information and environments. Roberts states that cognitive accessibility is

> the super layer of strategies and methods that help any learner or user understand or cognitively integrate the interface and content. Every user accessing an environment should have the same understanding of how the interface operates and the meaning of any content regardless of form or media. Cognitive accessibility accounts for message and information design behind everything on a website, for example, from an entire interface design down to a specific graphic to ensure those same messages are conveyed through multiple avenues for users accessing the site in different ways. (p. 2)

She describes techniques developed to improve Web site navigation for blind or visually impaired users based on cognitive load theory that improved efficiency of user navigation and allowed users to spend more time on content integration rather than navigation. This sort of technique requires a mindset that goes beyond compliance: one focused on achieving the desired outcomes, for learners both with and without disabilities, through our design choices. To date, however, we have little to no research examining accessibility in light of learning sciences research, or viewing accessibility of digital environments as a cognition question; future research might productively examine the role of design theories or principles in developing learning environments that are truly accessible to all.

A promising approach in recent literature, called "universal design for learning" (UDL) defines the goal more broadly than accessibility. UDL is a design disposition adapted from the more generic principles of "universal design," a term coined by US architect Ron Mace asserting that the design of products, environments and communication should focus on making them usable by all people *to the greatest extent possible* (Fletcher, 2002; Mace, Hardie, & Plaice, 1991). Universal design was adopted as a guiding principle in other design-oriented fields by the World Design Congress in 1987 and has become policy in corporations like Microsoft and Pacific Bell and international organizations such as the United Nations. In recent years, this concept has been imported into education, principally by Rose and Meyer, who assert that "barriers to learning are not, in fact, inherent in the capacities of learners, but instead arise in learners' interactions with inflexible educational materials and methods" (2002, p. vi).

Moore describes UDL as a way of thinking about the design of learning environments that "takes diversity of the learner population into account from the start and builds features into the learning materials, environment, and system that allow a broad set of learners to access the learning (both the content and the instructional strategies) and accomplish learning goals" (2007). This begins to connect UDL to specific Instructional Systems Design (ISD) processes such as definition of learner characteristics, articulation of learning objectives, and message and materials design. UDL encourages a plural definition of learners, with ripple effects throughout other design decisions like clarification of objectives to emphasize learning results rather than means of assessment, selection of appropriate instructional strategies, and development of flexible learning materials. This hypothesized relationship between a broader precept of design for accessible learning and elements of our ISD models suggests another path of ethics research, shaping what we as a profession consider socially responsible design practices.

Access and the Digital Divide

Access, which is distinct from accessibility, has traditionally been defined as physical availability of computer equipment and software and, later, networks—without which it was assumed that society's "digital have-nots" would be shut out from modern citizenship and prosperity, creating a "digital divide." This simplistic understanding of sociotechnical systems assumed that everything else required for computers' effective educational use was already present in the classroom, as it was for blackboards and textbooks. Warschauer (2003)—in one of the definitive texts on the topic—notes that "digital divide" as a construct appears to be waning, as research calls into question not "access," but "access to what," and whether what learners are accessing is worthwhile. This is a fundamental issue of our profession, as poor design or implementation choices *can* perpetuate social inequalities or even deepen existing ones. The challenge then becomes defining what constitutes a gap in *results* and designing contextually appropriate solutions that close those gaps.

An artifact-based "digital divide" construct proved especially vulnerable to hijacking by the obvious commercial interest of technology providers in selling their products, when it met the traditional legalistic approach. In the 1980s and early 1990s, a legislative and budgetary agenda emerged to get "technology" and connectivity into schools—often with little discernable effect. Yet the relevance of rethinking access is not limited to the "hard technology" aspects of our profession. The mere presence of an educational program of *any* sort does not ensure, and therefore should not assume, positive societal impact. Rather, any societal benefit from educational endeavors is *purposeful*, resulting from intentional objectives that drive their design and align them *toward* that outcome, from the system level down to specific projects and programs.

This is not just the case in developed nations. In its review of the role of education in fragile states (defined as states that are in conflict or crisis), the Inter-Agency Network for Education in Emergencies, as part of a commissioned study for the World Bank, explains how education—depending on how it is implemented—can mitigate *or contribute to* fragility. Employing a scale describing education's impact on fragility—ranging from actively reinforcing or perpetuating it, through inadvertently favoring it, to mitigating against it—INEE's analyses show both the complexity and the criticality of determining impact. For example, in Afghanistan, schools are often attacked by insurgents, owing both to their use as polling places and to education's role in empowering women. Building physical schools can therefore inadvertently *increase* fragility by consuming resources *and* inviting lethal attacks on the community's children and best-educated adults. Radio-based distance education was employed to remove this paradox, enabling safer schooling and measurably reducing fragility (INEE, 2011).

In other settings the learning materials themselves may promote social divides. In Bosnia and Herzegovina, INEE documented biased curricula, textbooks and teacher training that were designed to maintain ethnic and language divisions. These biases reproduced patterns of inequality that ultimately determined outcomes and employment opportunities for students on an ethnically differentiated basis, increasing fragility. Armed with these results, however, the country appears to be reducing these impacts, through more national governance and intentional designs to promote social cohesion (INEE, 2011).

Such examples reveal a layer of design considerations we may not normally confront: how do our designs work with—or *against*—other parts of the educational system to affect learning; how could our choices increase or decrease participants' safety; to exactly what are we providing access—and is that contributing to desirable outcomes, or maintaining *undesirable* ones like social inequalities? These questions challenge us to clarify the actual needs and objectives we pursue—and highlight that *learning* outcomes are not the only results of instructional designs, but rather a subset of the ethical considerations that should inform the design process.

Security and Privacy

Outside conflict-affected nations like those mentioned in the preceding section, safety issues like privacy invasion and identity theft, cyberbullies and sexual predators tend to take center stage—and educational technologists have important roles to play in shaping the design of learning environments that both leverage the capabilities and resources of the Internet for inquiry, problem solving, and growth *and* protect the security of learners of all ages.

Once again, though, our primary response to these challenges has often sought to substitute law for ethics. Legislation has been passed making cyberbullying a crime, in response to widely reported incidents that have even led to fatalities. Inappropriate access to and use of student records has been addressed through the Family Educational Rights and Privacy Act (FERPA). Societal concern over access to age-inappropriate content or exposure of students to exploitation and abuse—sexual or commercial—via the Internet led to passage of the Children's Internet Protection Act (CIPA) and the Children's Online Privacy Protection Act (COPPA) in the opening years of the century. Ethics research and literature in the educational technology field frequently points to the importance of such laws in society's attempt "to balance the safety of children and the rights of adults," and to "balance freedom of speech with freedom from unethical uses of information" (Yeaman, Eastmond, & Napper, 2008, pp. 312–313).

While the serious crimes such laws target ensure them a place in any future strategy, a purely legalistic approach continues to present the shortfalls noted throughout this chapter. Laws against cyberbullying leave unaddressed the ethical responsibilities of educators (including instructional designers) in providing learning environments resistant to the conditions allowing such dynamics to develop in the first place. The requirements of FERPA, while providing important safeguards for student privacy, are also in some instances preventing instructor access to *their own students*' performance data, and obstructing cooperative research studies involving researchers and students from multiple institutions. Statutes like CIPA and COPPA tend to focus on content filters and other (frequently ineffective) technological "solutions," potentially sacrificing attention to the human and social issues and challenges underlying inappropriate content and risky behaviors online—or to the lessons and critical thinking that are more appropriately the domain of ethics, which could *continue* to protect students after they've graduated into adult life.

Cross-Cultural Competence

A large portion of the literature that does mention ethics focuses on cultural considerations. International collaborations and the introduction of technologies and technological systems into different cultures require additional attention to cultural differences that can affect every part of the instructional design cycle.

The relationship between cultural competence and moral reasoning is perhaps more established than other ethics topics. Endicott, Bock, and Narvaez (2003) examined the relationship between moral reasoning and intercultural sensitivity, finding a strong relationship between participant scores on scales of intercultural development (Intercultural Development Inventory, or IDI) and moral judgment (Defining Issues Test, or DIT) corresponding to participants' depth of multicultural experiences. They offer a cognitive framing of the relationship between moral and intercultural development as an increase in sociocognitive flexibility, which they hypothesize is largely facilitated by multicultural experiences. Hammer, Bennett, and Wiseman (2003) developed the IDI to measure "intercultural sensitivity," hypothesizing that sensitivity is associated with exercising competence. They distinguish "intercultural sensitivity"—which they define as the ability to discriminate and experience relevant cultural differences—from "intercultural competence"—a performance-oriented construct they define as the ability to think and act in interculturally appropriate ways. While the IDI measures five categories of an individual's intercultural sensitivity, as of yet it has not been used to determine whether scores on this inventory predict culturally sensitive behaviors—behaviors that, as the authors articulate them, are worth noting as strongly similar to Mega level outcomes as identified by Kaufman (2000) in our own field (e.g., "lower levels of prejudice and discrimination" and "decreased conflict and/or violence toward people from different cultures" from Hammer et al., 2003, p. 441).

Hammer et al. (2003) suggest that the IDI is "useful for purposes of assessing training needs, guiding interventions for individual and group development of intercultural competence, contributing to personnel selection, and evaluation programs" (p. 441)—language that again should sound very familiar and that suggests ways in which we can begin to translate an abstract concept like "cultural sensitivity" into a performance expectation for professionals and therefore a professional competency addressed through programs and further studied through research. Other disciplines are already integrating this approach into the development of professional practitioners. The US military, increasingly finding itself cast in international humanitarian relief, infrastructure development, and security coorperation roles around the world, is devoting substantial resources and emphasis to cultural competence as a training and performance outcome, although much remains to be done (Alrich, 2008). In academic circles, other disciplines are increasingly emphasizing global awareness. For example, one of the major program outcomes for accreditation in engineering is development of students' ability to "understand the impact of solutions in a global and societal context" (ABET, 2009). Using Bloom's taxonomy, researchers in engineering education have defined learning and performance objectives to support the development of more courses on global and societal impact in more programs around the country (Besterfield-Sacre et al., 2000). This is beginning to show up in engineering both in the curriculum as well as in engineering education journals (Downey et al., 2006; Jesiek, Borrego, & Beddoes, 2010; Moore, May, & Wold, 2012).

A shift towards a definition of "cultural competence" as a professional competency affords our own discipline several opportunities through this framework: an expanded definition of applied professional ethics and framework for discussing existing research in international education as a component of our professional ethics complexion, an existing framework for defining and measuring cultural sensitivity, opportunity to extend existing literature by defining and measuring cultural competence in learning and performance terms to examine the predictive ability of cultural sensitivity measures, a framework for developing courses within programs, and a framework for evaluating graduates of programs as well as projects and project outcomes.

Social Responsibility

Social responsibility is also one of the primary themes identified in what literature exists on ethics, but it is most rightly treated as the overarching concept that authors are converging on—and rather emphatically—as the most appropriate construct for moving discussion (and therefore research, design, and development) beyond codes that focus on individual behavior to a description of the profession's position within society with pervasive influence on practice and research. Ethics have traditionally focused on the individual (an emphasis reflected in the normative ethics research tradition based on cognitive constructs of ethics, such as Kohlberg's theory of moral development, 1969), but the emphasis is shifting to systemic (i.e., global and societal) impact of technological designs and systems (Barbour, 1993; Kaufman, 2000; Moore, 2010; Strijbos, 1998; Yeaman et al., 1994). In this section, we extend this emphasis on social responsibility by looking at the convergence point between four models that heretofore have not conversed with each

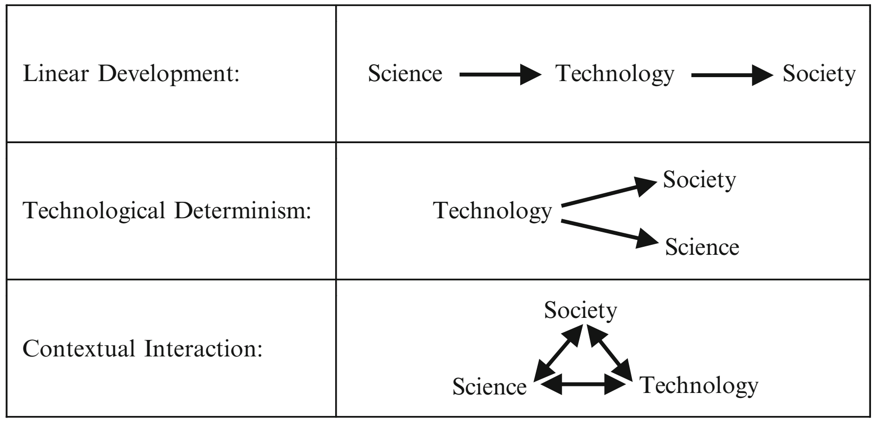

Fig. 10.1 Three views of the Interactions between Science, Technology, and Society (Barbour, 1993, p. 20)

other and the implications of this for future work: Barbour's model of ethics in a technological society, Whitbeck's notion of ethics as design, Kaufman's model for socially responsible planning and design, and Reeves' resurrection of the conative domain. Throughout, we suggest that we are not without a model for how to proceed from here, as we can take a page from the discipline of Science, Technology and Society (STS).

Barbour: Technology as Social Constructions—It Is What We Design It to Be

Barbour's work, *Ethics in an Age of Technology*, provides a strong foundation for a design disposition towards ethics beyond codes and regulations. Barbour examines three differing views of technology: technology is liberating (beneficial), technology is a threat (destructive), or technology is an instrument of power (design and use are defined by context). Based on these three views of technology, Barbour examines assumptions about the relationship between science, technology and society to lay out three different models for thinking about technology and its consequences, advocating for the third "contextualist" model (see Fig. 10.1).

Traditional models are either linear (technology develops out of science) or deterministic (technological requirements drive science and society) and represent what has historically been a dichotomous approach. Linear development models and rhetoric assume that all technological developments have their roots in scientific discoveries and therefore inherit the moral objectivity of the scientific tradition. Determinist models and rhetoric view technology as such a predominantly overarching force that it drives all aspects of society. Common to all variations of deterministic models is the implication that both human freedom and technological choice are limited (Barbour, 1993; Together these two positions also reflect the vast majority of rhetoric on technology: something to be embraced or something to be rejected as a polarized discussion with no real middle ground. The Internet will bring about democracy, or the Internet will expose children to pedophiles.

Barbour argues that instead, there are complex interactions between technology, science and society, where social goals and institutional interests are built into the technical designs we choose. He explains that the third model, with three bidirectional arrows, represents the complex interactions between science, technology, and society:

> Social and political forces affect the design as well as the uses of particular technologies. Technologies are not neutral because social goals and institutional interests are built into the technical designs that are chosen. Because there are choices, public policy decisions about technology play a larger role here than in other views. (p. 21)

Barbour states that many authors/theorists in this third group are still critical of most current technological features but maintain the optimistic belief that technology can be used for humane ends. Those humane ends would be brought about by political measures for more effective guidance within existing institutions or by changes in the economic and political systems themselves. For example, within educational technology, we could develop measures for ensuring decisions and designs are driven by a sense of social responsibility. In order to achieve such an end, Barbour calls for "greater public participation and a more democratic distribution of power in the decisions affecting technology" (1993, p. 16). Other authors such as Andrews (2006) echo this sentiment of engaged "technological citizenship" in which both technical experts and nontechnical experts work together on design and implementation decisions. Pinch and Bijker (1984), developers of the model of social construction of technology (SCOT), would take this a step further to assert that "relevant social groups" *do* influence how new technologies are developed, including input into and modifications of designs, and actively shape policies guiding implementation and diffusion. This is closely akin to the findings of stakeholder involvement in the change literature our field draws from extensively, providing a direct link between that body of research and ethical practices in educational technology. Participation of end users in every stage of technology development is not only a desirable approach for professionals but is a realistic representation of the social dynamics at play that influence how something develops, whether it is adopted, how and whether it is modified, and so forth.

The essence of this third position is that technical design cannot be meaningfully developed separate from human context. The impact on society and the change it brings about must be considered and *can* be considered. Instead of adopting a reactive position to technology, where we simply accept what is already given, society at large and members of technology professions can (and should) adopt a proactive stance to embed socially responsible values in technological designs (Barbour, 1993, pp. 22–23). To tie this to research in our field, what Barbour effectively argues for is a systemic view of technology that demands stakeholder participation in design and decisions. He lays out a design philosophy that focuses on social responsibility as the prime directive: "I believe that we should neither accept uncritically the past directions of technological development nor reject technology *in toto* but redirect it toward the realization of human and environmental values" (italics in original, 1993, p. 24).

Whitbeck: Ethics as Design

In other design-oriented disciplines, such as engineering, there is increasing recognition that the act of design is also one of developing solutions to meet societal challenges. For example, Whitbeck writes that solving moral problems "is not simply a matter of choosing the 'best' of several possible responses. It is also a matter of *devising* possible responses" (1996, p. 9, emphasis added). She explains that moral problems are practical challenges and bear many striking similarities to another class of practical problems—the design problem. Developing a response to an ethical problem requires one to take multiple considerations into account—and often there is some tension or conflict between these demands. Traditionally, a philosophical approach to ethics would conclude that these are irresolvable conflicts, so a person must "opt" for a solution. However, design processes tend to approach these competing demands as varying needs or constraints that can often be at least partially satisfied through a more considered design. Whitbeck notes, for substantive design problems, that "there is rarely, if ever, a uniquely correct solution or responses" but emphasizes that this is an entirely different claim than saying there are no right or wrong answers. Whereas the latter is an extreme expression of relativism in ethics, the former is a practical approach to ethics offered by design. While there may be no one correct solution or response, it *is* possible to devise—or design—a response or solution that effectively balances the competing requirements.

There are even broader examples in these other fields that can inform our evolving ethical discourse in educational technology. In the field of Science, Technology and Society the literature has long since moved past deterministic models of technology to focus on a design disposition to this question of the ethical consideration of technology: the ethics of any technology lie in our design decisions and our implementation processes. Humanity is not a victim of technology (nor are we necessarily the grand benefactor)—but rather the consequences of a given technology are a result of design and implementation choices. There is a complex interaction effect between technology and culture, one which STS authors term "mutual shaping" or "coshaping" (Neeley, 2010), in which technology simultaneously shapes and is shaped by the culture around it.

When we examine historical examples or look at cross-cultural comparisons, the pattern that really emerges is that technology has been shaped across history and cultures to reflect a culture's emphasis on desired ends. Carlson's seven-volume review of technology across world history paints the most compelling portrait of this design orientation (2005). Historical analyses and cross-culture comparisons of varying technologies and the ways they have developed, or did not develop, or were implemented demonstrate repeatedly that a deterministic narrative of technology is a false narrative—culture, context, and what Carlson calls the "prime directives" of different cultures dramatically influence what technologies are developed, how they are shaped, and how they are implemented.

Kaufman and Reeves: Planning, Design, and Conation

Within our own field we have some excellent building blocks already—but we are only likely to see them as such when we reframe ethics through the design lens. For example, in the area of needs assessment, planning, and evaluation, Kaufman's model for organizational performance presents a robust framework for planning and evaluating multiple levels of impact which includes societal impact. In Kaufman's (2000) model, societal impact is both the basis for planning (a process that starts there then plans "downward" into organizational outcomes, performance outcomes, inputs and processes) and the longitudinal measure of an organization's success (as results at each level align back from the inside out). He presents an operational definition of societal outcomes as well as a framework that assesses and employs societal needs as the basis for design, implementation, and evaluation—in short, one that not merely hopes, but *plans* for ethical outcomes.

Kaufman's model for planning starts with societal level outcomes, which he terms "Mega," and in which he details basic measures of societal impact:

- Zero pollution—no permanent destruction of our environment
- No deaths or permanent disabilities from what is delivered

Table 10.2 The organizational elements, the related results, and definitions used with permission from Kaufman (2000, 2006)

Name of the organizational element	Name of the level of planning and focus	Brief description
Outcomes	Mega	Results and their consequences for external clients and society
Outputs	Macro	The results an organization can or does deliver outside of itself
Products	Micro	The building-block results that are produced within the organization
Processes	Process	The ways, means, activities, procedures and methods used internally
Inputs	Input	The human, physical, and financial resources and organization can or does use

- No starvation and/or malnutrition resulting in incapacity
- No partner or spouse abuse resulting in incapacitating physical or psychological damage
- No disease or disabilities resulting in incapacity
- No substance abuse resulting in incapacity
- No murder, rape, crimes of violence, robbery, or destruction of property
- No war, riot, or terrorism, or civil unrest resulting in incapacity of individuals or groups
- No accidents resulting in incapacity
- Citizen positive quality of life

Kaufman argues that all organizations and all professions either add value to or subtract value from each of these dimensions. Responsible planning and design, thus, treats these as top-priority constraints that can be articulated as higher-order objectives to inform design or planning (Moore, Ellsworth, & Kaufman, 2008, 2011). These measures then also inform an evaluative framework for the societal impact of any given product or process (or Outputs, in Kaufman's model). In Table 10.2 summarizing his model, above, planning or design occurs from top to bottom (reflecting an approach that begins by defining external impact first and is next aligned downward); implementation then proceeds from bottom to top—with evaluation conducted at all levels. An example of this applied in educational institutions is provided by Guerra and Rodriguez (2005) as they followed the positive societal impacts across eleven years from a university that used Kaufman's model for their strategic planning process, with impacts including decreased poverty, decreased crime, and increased employment opportunities in the surrounding community.

Further, in recent years, Reeves has been emphasizing the importance of the little-discussed but highly relevant conative domain (2006, 2011). In the early twentieth century, the conative domain was a generally assumed equal, along with the cognitive and affective domains (McDougall, 1923), with roots stretching back to ancient times. However, from mid-twentieth century onward, it has all but disappeared from the psychology lexicon as cognition dominated learning research. From the Latin word "conation," the conative domain pertains to the act of striving and has to do with intention, will, and drive or desire. Kolbe (1990) provides a summary comparison of the three domains of the mind (Table 10.3).

Table 10.3 Comparison of cognitive, affective, and conative domains (adapted from Kolbe, 1990, emphasis ours)

Cognitive	Affective	Conative
To know	To feel	To act
Thinking	Feeling	Willing
Thought	Emotion	Volition
Epistemology	Esthetics	*Ethics*
Knowing	Caring	Doing

Reeves laments the complete absence of this domain today in research or practice in teaching, learning and assessment, noting its vitality to students' ability to perform in authentic and global contexts once they graduate (2006). For this chapter, we draw specific attention to "ethics" as part of the conative domain—in the same category as doing, acting, and volition. These are the very same definitions and descriptors often used to define design. Design is a goal-oriented activity that seeks not just to understand, but to produce and act upon a problem. This would imply that the very act of design itself is a manifestation of ethics, and conversely that the most accurate way to discuss ethics is not as contemplation, or knowing, or even as a code that requires a compliant response, but as a goal-oriented activity that requires us to engage sophisticated design processes—just as Whitbeck suggests and as Kaufman exemplifies.[1]

Conclusions

The implications of a design-oriented ethics framework for educational technology research are exciting. Ethics is transformed from the subject of compliance-oriented codes and abstract philosophy into one of action, of leadership of our profession as it seeks and creates its future. Rather than the relationship between ethics and research getting confined to the institutional review board, research becomes the primary informant for ethical practices of our profession, envisioned in a recent research article in *Educational Technology Research & Development*. Towards the end of a study on multimedia principles from Mayer and the "reversal effect" of redundancy for experts, its authors state,

[1] The Smithsonian exhibit "Why Design Now?" as part of their National Design Triennial features a host of examples across disciplines that further reflect this intersection of design and ethics. (McCarty, Lupton, McQuaid, & Smith, 2010)

> If educational technology is not adapted to the human cognitive system, we run the risk of introducing novel procedures that inhibit rather than facilitating (sic) learning. Providing learners with auditory or visual information, or a combination of both, can be highly beneficial but the circumstances in which a benefit is obtained depends on human cognitive factors. (Leslie, Low, Jin, & Sweller, 2012, p. 11)

The body of evidence reflected here in the *Handbook* is a distillation of the best we have to offer to the design of instructional technology products and systems that measurably benefit their users and the society they comprise. This suggests both that we have a firm foundation and broad discourse for deeper integration of ethics into our models and discourse and that we have new avenues of research available to extend this even further. Much of our research retains its primary focus on learning as our chief or only outcome. Yet our professional practices impact far more than learning outcomes; thus our body of research can, and should, expand to examine this full range. Other fields such as medicine, defense, business, and engineering actively discuss the societal implications of new technological developments, not with an eye towards rejecting innovation but rather as a way to actively and collectively make the complex design choices that shape technology towards worthy results.

Kuzma and Tanji (2010), in an extensive review of synthetic biology using a blend of historical and policy analysis, employed research to identify policy problems and lead public oversight, suggesting a continuum of evidence-based policy approaches: preventative, precautionary, permissive and promotion. Yet such analysis benefits not only external audiences like policymakers, but also informs the research and development of the technology. Similarly, Sparrow and Sparrow (2006) examine the implications of humanoid development and specific applications for such technology to eldercare, concluding from an ethical analysis that certain envisioned uses would be detrimental and other applications beneficial – and that the decision space to be navigated demands shaping from policy makers and technologists alike. It may be easy to dismiss these examples as coming from domains that can't assume the same "educational" benefit of our discipline, but consider the ancient wisdom of Quintillian (2006) in his "Institutes of Oratory" in which he lays out an entire system of schooling for young boys in ancient Greece. With the "techne" of writing long debated on an accept/reject basis (with Plato concluding it should be rejected!), Quintillian instead suggested that writing had both value and drawbacks – and therefore its integration into the educational system should be based on how to maximize the benefits and minimize the harm. The effective citizen required both the skill of oratory and the skills of critical reflection & refinement. Writing and revision developed cognitive flexibility and agility – yet the student could spend too much time trying to perfect a written piece, and had instead to cease writing, eventually, and leave his room to speak publicly. The use of each tool, each pedagogy, should be deliberately harnessed to a specified public good. This impacted not just what the young scholars learned in school, but also the type of leaders they grew into – and ultimately the direction of the society they led. It is this very sort of longitudinal perspective that our study and practice of ethics must encourage.

Acknowledgments We would like to thank Heather Tillberg-Webb, Lesley University, for conversations about access and the history of evolution around this construct that contributed to the section on access.

Section II

Methods

Jan Elen and M.J. Bishop

At the core of scientific research are the methods. This second section of the *Handbook* is devoted to research methods with a focus on approaches that have, in previous editions of the Handbook (Jonassen, 2004; Jonassen, Harris, & Driscoll, 2001; Spector, Merrill, van Merriënboer, & Driscoll, 2008), attracted less attention or that have been evolving over the last several years. In contrast to the very first edition, for instance, attention on philosophical and experimental methods has shifted in this edition to more design research-based methods. This growing diversity of available research approaches in educational technology research is reflected in this section of the *Handbook*, which reviews the current research methodologies and—an interesting addition from our perspective—the tools that are used in order to support those methods as well.

The first chapter in this section is devoted to educational design research. McKenney and Reeves stress the ambition of educational design research to contribute to both practice and theory. The authors highlight the diversity of solutions that is paid attention to in educational design research. Challenges for educational design research such as finding a balance between information richness and efficiency or the need for more clear examples of impact are clearly outlined. The authors stress the need and potential for more close collaboration between researchers and practitioners in order to handle current issues in education.

The chapter on educational design research is followed by the chapter on design and development research. Through means of 11 recent publications, Richey and Klein illustrate the nature of design and development research. The authors stressed that this type of research is unique to the field of instructional design and technology. Two main categories are distinguished: those studies that focus on products and tools, and those that are oriented towards the study of design and development models. The authors nicely describe the research space of design and development research by specifying the problems addressed, the settings and participants involved, the research methodologies used, and the role of evaluation.

Two new chapters address research practices in educational technology research that did not get a lot of attention in previous editions of the *Handbook*. Karakus presents the potential of Activity Theory for educational technology research arguing that Activity Theory provides a productive framework to analyze and understand how tools within particular contexts work. The potential is illustrated by references to examples. As an extension, Activity Network Theory is presented as a framework to analyze interactions among multiple activity systems. While the Karakus chapter shows the impact on research methods of theoretical frameworks, Manfra and Bullock reveal the practical and theoretical consequences of a widely used research method: action research. They argue that action research fundamentally transforms the relationship between practitioners and researchers by putting practice at the core. This transformation may help to close the gap between theory and practice. Concrete examples of approaches in action research are discussed in view of extending action researchers' toolkits.

The educational technology research field used to be a field dominated by quantitative research. Today, an increasing number of researchers use qualitative methods in their efforts to get to an in-depth understanding and to generate relevant and broadly applicable principles. The more widespread use of qualitative research methods in a variety of disciplines has engendered the further development of these methods. As a complement to chapters in previous editions of the Handbook on qualitative research, the chapter by Mardis, Hoffman, and Rich presents a well-documented overview of recent trends. Demonstrating that qualitative research is far from an easy thing to do, the chapter nicely presents the various issues of design, method selection, and

J. Elen (✉)

e-mail: jan.elen@ppw.kuleuven.be

M.J. Bishop
Lehigh University, Bethlehem, PA, USA

knowledge generation with concrete examples of how these were tackled in recent educational technology research.

While different aspects of formative evaluation methods have been discussed in previous *Handbook* editions, a chapter solely dedicated to program evaluation has been missing. The chapter on Program and Project Evaluation by Spector fills this gap by discussing and illustrating methods used in an effort to evaluate the entire process from needs assessment through design, development, deployment, and support. The author stresses that project and program evaluation are directed towards increasing the probability of successful technology integration. Program evaluation calls for a holistic approach in order to consider the multiple and interwoven factors that affect successful integration.

This section concludes with two new chapters on data analysis tools that should be very informative for researchers. While Knezek and Christensen discuss tools for quantitative research, Gilbert, Jackson, and di Gregorio do the same for qualitative data. By discussing the tools and research in which these tools are used, Knezek and Christensen show how such tools might contribute to improving data acquisition, making data analysis even more sophisticated. and enriching data exploration often through visualization. The ongoing evolutions and developments in these tools are stressed by these authors and for qualitative research confirmed by Gilbert, Jackson, and di Gregorio. In response to frequent questions from researchers on what tools to use, these latter authors distinguish between Qualitative Data Analysis Software to support qualitative research and tools that are especially interesting when gathering data and/or presenting results are at stake. Issues related to the use of these tools as well as the potential of Web 2.0 tools are discussed.

The variety of chapters in this section reveals the diversity of research methods used in educational technology research today. New research questions have given rise to the use of new methods that, in turn, have resulted in the more frequent use of a diversity of tools. The diversity in research methods reflects the diversity in research questions and theoretical orientations. Considering that disciplines are characterized by some methodological agreement, it must be noted that the field of educational technology is a discipline characterized not by methodological unity but by methodological diversity. Such diversity is a benefit as long as there is a shared agreement on methodological decision making, on how to decide what methods are most appropriate for what questions. Putting that agreement on paper might be the biggest challenge for a methods section in a possible fifth edition of the *Handbook*.

Educational Design Research

11

Susan McKenney and Thomas C. Reeves

Abstract

Educational design research is a genre of research in which the iterative development of solutions to practical and complex educational problems provides the setting for scientific inquiry. The solutions can be educational products, processes, programs, or policies. Educational design research not only targets solving significant problems facing educational practitioners but at the same time seeks to discover new knowledge that can inform the work of others facing similar problems. Working systematically and simultaneously toward these dual goals is perhaps the most defining feature of educational design research. This chapter seeks to clarify the nature of educational design research by distinguishing it from other types of inquiry conducted in the field of educational communications and technology. Examples of design research conducted by different researchers working in the field of educational communications and technology are described. The chapter concludes with a discussion of several important issues facing educational design researchers as they pursue future work using this innovative research approach.

Keywords

Design research • Design-based research • Formative research • Design experiments

Introduction

Educational design research is a genre of research in which the iterative development of solutions to complex educational problems provides the setting for scientific inquiry. The solutions that result from educational design research can be educational products (e.g., a multiuser virtual world learning game), processes (e.g., a strategy for scaffolding student learning in online courses), programs (e.g., a series of workshops intended to help teachers develop more effective questioning strategies), or policies (e.g., year-round schooling). Educational design researchers attempt to solve significant real world problems while at the same time they seek to discover new knowledge that can inform the work of others facing similar problems. This chapter summarizes arguments and evidence presented by Barab and Squire (2004), Burkhardt (2009), Reeves (2011), Schoenfeld (2009), van den Akker, Gravemeijer, McKenney, and Nieveen (2006a), and others that educational design research is an innovative and exceptionally promising approach to improving the quality and impact of educational research in general, and educational communications and technology research in particular.

Educational Design Research Origins

> *Design research is not defined by its methods but by the goals of those who pursue it. Design research is constituted within communities of practice that have certain characteristics of innovativeness, responsiveness to evidence, connectivity to basic science, and dedication to continual improvement.* Bereiter (2002) p. 321.

What has prompted scholars around the globe sharing the above-mentioned characteristics of "innovativeness, responsiveness to evidence, connectivity to basic science, and dedication to continual improvement" to come together in the pursuit of educational design research? At least two main motives can be identified. Interestingly, both perspectives have strong historical ties to educational psychology, and both perspectives are concerned with making a contribution to educational practice. The first motive is driven more by what society needs while the second has more to do with finding adequate methods to meet those needs.

First, stemming from the notion that scientific understanding should be used to solve or at least gain a better understanding of practical problems, the call for scientific inquiry to yield what Lagemann (2002) refers to as "usable knowledge" has been present for over a century. Although this focus on demonstrable impact may be ignored by some who recommend that educational researchers should emulate the methods of the so-called hard sciences (e.g., physics) that seek knowledge without expectation of practical application, the expectation for social science research to connect fundamental understanding with applied use dates back to Münsterberg (1899) and Dewey (1900), if not earlier. Both of these former American Psychological Association presidents expressed the need for a linking science, which would use empirical insights and theoretical advancements to inform problem-solving and improvement initiatives in practice. This call has been taken up gradually within the fields of education and psychology, for example in the work of Robert Glaser (1976) who laid out the elements of a psychology of instruction and called for a science of design in education. Donald Stokes (1997), an American political scientist, provided a fresh look at the goals of science and their relation to application to real world problems, in his highly acclaimed book titled, *Pasteur's Quadrant: Basic Science and Technological Innovation*. Stokes promoted more "use-inspired basic research" akin to the work of the French chemist and microbiologist, Louis Pasteur. He contrasted Pasteur's pragmatic research approach with that of the basic science goals of Danish physicist, Niels Bohr, and the applied research aims of the American inventor, Thomas A. Edison.

Second, educational researchers have been searching for adequate methods to yield the kinds of empirical insights and theoretical advancements that could be used to address real concerns in educational practice. Acknowledging the limitations of laboratory settings, the value of relinquishing control of variables in return for increased ecological validity of the findings has been gaining support over the last 30 years. In 1992, two landmark papers were published which are often credited with launching educational design research as a specific genre of scientific inquiry. Brown's (1992) article in the *Journal of the Learning Sciences* discussed tensions between laboratory studies of educational innovations and challenges inherent in integrating these innovations into real world classrooms as background to describing her own design experiments. That same year, Collins (1992) published a book chapter arguing that education should be viewed as a design science akin to aeronautics, as opposed on an analytical science similar to physics, emphasizing the fact that laboratory conditions could rarely approximate conditions in real classrooms.

By the turn of the millennium, support was increasing for innovative research approaches that might yield the kind of knowledge that can be put to use for the improvement of education. Advocates for these new approaches accepted that the kinds of knowledge needed would have to be constructed in the complex "laboratories" of everyday learning environments such as classrooms or online courses. The establishment of educational design research is growing steadily. This momentum became apparent through several special issues of highly respected journals, including *Educational Researcher* (2003, 31(1)), *Journal of the Learning Sciences* (2004, 13(1)), and *Educational Psychologist* (2004, 39(4)). Since then, several books have been written about educational design research. Books have focused on conceptualization (van den Akker et al., 2006a) methodological considerations (Kelly, Lesh, & Baek, 2008), and the details of conducting design studies (McKenney & Reeves, 2012) across educational fields. Related volumes have appeared specifically in the domains of literacy (Reinking & Bradley, 2008) and instructional design (Richey & Klein, 2007). In addition to special issues and books about educational design research, numerous reports of educational design research initiatives have been published in research journals such as *Instructional Science* (cf. Xie & Sharma, 2011), the *Journal of the Learning Sciences* (e.g., Schwarz & Asterhan, 2011), the *Journal of Research on Technology in Education* (e.g., Basham, Meyer, & Perry, 2010), and *Educational Technology Research and Development* (e.g., Reynolds & Caperton, 2011). In addition, doctoral dissertations using educational design research have been completed at multiple institutions such as the University of California, Berkeley (e.g., Brar, 2010), Unversity of Florida (e.g., Drexler, 2010), the University of Georgia (e.g., Oh, 2011), the Pennsylvania State University (e.g., Lee, 2009), and the University of Twente (e.g., Raval, 2010).

Today we see many sectors within education that seem to embrace educational design research, including: learning sciences, instructional design, curriculum development and teacher professional development. While educational design research is not inherently tied to any specific subject area, much of the work published so far has been related to science or mathematics, perhaps because more funding has been available for research related to STEM (science, technology, engineering, and mathematics) disciplines than for other areas (Kelly et al., 2008). However, educational design research is also being increasingly used in language and literacy research (Reinking & Bradley, 2008), as well as other disciplines. A wide variety is present across educational design study literature, a development that is partly accounted for by the methodological traditions within the various educational sectors, individual researcher preferences and the resources available for specific projects. In addition, variance across the twofold motives driving educational design research plays a large role in explaining the diversity of these kinds of studies. While pursuing both goals simultaneously remains a defining feature of educational design research, one goal may feature more prominently than the other. For example, relating more to the motive of improving practice, educational design research may be conducted primarily to:

- Solve a problem (e.g., increase the participation of women and other minorities in engineering and science careers),
- Put knowledge to innovative use (e.g., use the affordances of smart phones to enable mobile learning), and/or
- Increase robustness and systematic nature of design practices (e.g., establish a set of design principles for implementing inquiry-based learning in middle school science).

Or, relating more to the motive of enhancing the quality of research findings, educational design research may be conducted primarily to:

- Generate new knowledge (e.g., develop a theory of game-based learning),
- Generate different types of knowledge (e.g., enhance and extend knowledge related to professional development for scaffolding strategies for math teachers), and/or
- Increase the ecological validity of research-based knowledge (e.g., increase the likelihood that educational innovations will be used to transform educational practice).

Clarifying the Nature of Educational Design Research

What Is Educational Design Research?

While studies do differ in terms of which motives are more powerful determinants in shaping the inquiry, educational design research in general distinguishes itself from other forms of inquiry by attending to both solving problems by putting knowledge to use, and through that process, generating new knowledge. As stated elsewhere (McKenney & Reeves, 2012), educational design research is a genre of research in which the iterative development of solutions (e.g., educational products, processes, programs or policies) to practical and complex educational problems, provides the setting for scientific inquiry, and yields new knowledge that can inform the work of others. Working systematically and simultaneously toward these dual goals may be considered the most defining feature of educational design research.

Educational design research is not a methodology. It uses quantitative, qualitative and—probably most often—mixed methods to answer research questions. In so doing, educational design research is held to the same standards as other scientific work when it comes to providing transparency of the process and adequate warrants for the knowledge claims it yields (cf. Shavelson, Phillips, Towne, & Feuer, 2003). In addition to the knowledge generated, the value of educational design research is measured in terms of its ability to improve educational practice (Design-Based Research Collective, 2003).

How Does Educational Design Research Compare to Other Approaches?

While both are concerned with developing new knowledge and are connected to design processes, *educational design research* has commonalities but also differences from the instructional design focused *design and development research* described by Richey and Klein (2007, and in this volume). If considered as a Venn diagram, educational design research and design and development research would overlap in projects that are concerned with actively solving problems in educational practice (e.g., design and testing of software to help plan lessons). The area that would be unique to design and development research would be those projects that are concerned with developing tools or models to support education in the long run, but that do not function as educational interventions (e.g., retrospective analysis of how instructional designers carry out their tasks). Design research projects that would not overlap with design and development research would be those not specifically concerned with advancing the field of instructional design (e.g., design and testing of a learning sequence for early literacy).

Educational design research is also different from evaluation research (Clarke, 1999), although formative and summative evaluation methods are among the main vehicles used to study and fine-tune interventions in both cases. First, problem definition and solution design are rarely featured in evaluation research. Second, a key difference is that evaluation research is primarily concerned with evaluating and possibly improving the qualities of a particular intervention. The broader scientific orientation of generating usable knowledge (e.g., in the form of models to underpin design, theories about how teachers learn, descriptions of what engages learners, etc.)

is not as overtly present in evaluation research as in educational design research.

Educational design research also entails more than research-based educational design. They are both forms of scientific inquiry, and often, each values a rational approach. They both embrace systems thinking and are both shaped by iterative, data-driven processes to reach successive approximations of a desired intervention. However, research-based educational design focuses solely on intervention development, whereas design research strives explicitly to make a scientific contribution—of value to others outside the research/design setting—in addition to the intervention development. This has important implications for the entire process. Additional information on these differences is available in (McKenney & Reeves, 2012; Oh & Reeves, 2010). Similarly, action research (cf. Mills, 2002) also lacks the emphasis on finding the kind of robust public knowledge that is a hallmark of educational design research.

Distinguishing educational design research from other forms of inquiry in education is made more difficult because it has been referenced in the literature by a number of different terms such as "design-based research" (cf. Barab & Squire, 2004), "design experiments" (cf. Brown, 1992), "development research" (cf. van den Akker, 1999), "formative experiments" (cf. Reinking & Bradley, 2008), "formative research" (cf. Newman, 1990), and simply "design research" (cf. Kelly et al., 2008). There are subtle differences in how these terms are used by various researchers as delineated in McKenney and Reeves (2012). The term "educational design research" is used in this chapter and elsewhere (cf. Plomp & Nieveen, 2009; van den Akker, Gravemeijer, McKenney, & Nieveen, 2006b) because including the word "educational" in the term helps to avoid confusion with design research as used in other fields. For example, Laurel's (2003) book simply titled *Design Research* concerns the field of human computer interface design and industrial engineering rather than education.

Conducting Educational Design Research

Characteristics

Characteristics of educational design research have been offered in the literature (Kelly, 2003; Reinking & Bradley, 2008; van den Akker et al., 2006a; Wang & Hannafin, 2005). Common descriptors include: pragmatic, grounded, interventionist, iterative, collaborative, adaptive and theory-oriented. Educational design research is pragmatic because it is concerned with generating usable knowledge, and usable solutions to problems in practice. It is grounded because it uses theory, empirical findings and craft wisdom to guide the work. It is interventionist because it is undertaken to make a change in a particular educational context. Educational design research is iterative because it generally evolves through multiple cycles of design, development, testing, and revision. It is collaborative because it requires the expertise of multidisciplinary partnerships, including researchers and practitioners, but also often others (e.g., subject matter specialists, software programmers or facilitators). Educational design research is adaptive because the intervention design and sometimes also the research design are often modified in accordance with emerging insights. Finally, it is theory-oriented not only because it uses theory to ground design, but also because the design and development work is undertaken to contribute to a broader scientific understanding.

Process

There is no set process for conducting the "manifold enterprise" (Bell, 2004, p. 245) of educational design research. This approach to inquiry is rich with variation in terms of models and frameworks that describe, and in a few cases, guide the process. Across that variation, some similarities can be identified:

- Educational design research uses scientific knowledge (and to varying degrees, also other kinds of knowledge such as craft wisdom) to ground design work
- Educational design research produces scientific knowledge (and in some cases, also craft wisdom among the participants)
- Though the terminology and contents differ, three phases can be distinguished in educational design research: an analysis/orientation phase; a design/development phase; and an evaluation/retrospective phase; these are often revisited in the lifespan of a project
- Educational design research strives to develop both interventions in practice and reusable knowledge

Rich Variation

Thought-provoking differences in design research are also present. Some of the differences stem from the units of analysis, scope of implementation, nature of the subject areas addressed, or from the research domains and methodological traditions in which studies originate. As mentioned earlier, the relative emphasis on each motive (solution development, new knowledge or equally on both) can also wield strong influence on the design research process. But other differences stem from the concerns of those interpreting the concept and conducting the studies.

McKenney and Reeves (2012) surveyed models for educational design research and, in addition to highlighting similarities like those mentioned above, noted unique con-

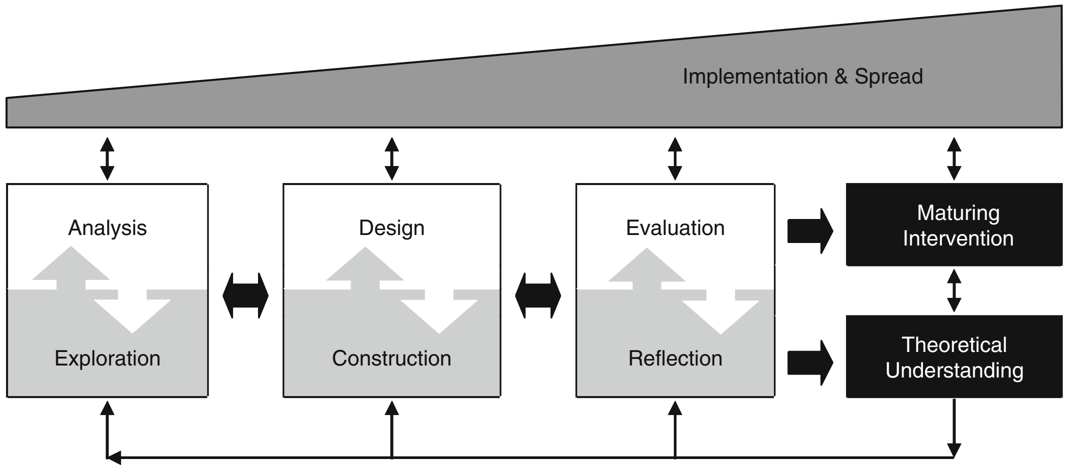

Fig. 11.1 Generic model for conducting educational design research (McKenney & Reeves, 2012)

tributions each one has to offer. The Osmotic Model, offered by Ejersbo et al. (2008), depicts the parallels of the design cycle and the research cycle. The authors point out that both cycles originate from the problem and would ideally run simultaneously, but state that this ideal is often not the case. Bannan-Ritland and Baek (2008) developed the Integrated Learning Design Framework, which depicts four main stages and across those, 14 steps, in a combined approach to research and development. Along with the process model, guiding questions for research and examples of applicable methods for each main phase are given. Reeves (2006) presented a minimalist model that highlights four main phases of design research: problem analysis; solution development; iterative refinement; and reflection to produce design principles. He compared these phases to the four phases of predictive research. In contrast to the aforementioned three models, McKenney, van den Akker, and Nieveen (2006) offered a model which is more conceptually oriented than process-oriented. This model depicts tenets guiding a research and development cycle, situated in a particular context, yielding three main outcomes: professional development of the participants; the designed intervention; and design principles.

In addition to these visual models, Gravemeijer and Cobb (2006) described important steps in the three main phases of their work: preparing for a design experiment; conducting a design experiment; and retrospective analysis. Based on a review of literature, Wang and Hannafin (2005) delineated and argued for nine principles of design-based research. Finally, Reinking and Bradley (2008) posed six questions as a guide for conducting formative experiments, relating to: pedagogical goals; classroom intervention; factors affecting the intervention; modifications to the intervention; unpredicted effects of the intervention; and changes in the instructional environment due to the intervention.

Based on their survey and analysis of existing models and frameworks for design research, McKenney and Reeves (2012) created a generic model for design research (see Fig. 11.1). Through this basic visualization, this model shows only the core elements of a flexible process that features the three main stages described earlier, taking place in interaction with practice and yielding the dual outputs of knowledge and intervention.

Scientific Outputs

Different terms have been used to describe the kinds of theoretical knowledge that are produced by educational design research (cf. Edelson, 2002; McKenney & Reeves, 2012; van Aken, 2004; van den Akker, 1999). Descriptive, substantive or declarative knowledge is generated to describe certain phenomena (e.g., what learner behaviors are triggered by certain prompts). Prescriptive or procedural knowledge is generated to help inform interventions in practice (e.g., how to facilitate learning through the strategic use of certain prompt types under certain circumstances). Some projects may develop a research agenda more attuned to one type of knowledge over another, though eventually attending to both types seems to be the case more often than not.

Different terms have been used in literature to describe the kind of integrated procedural and declarative knowledge that comes out of design research, but design principles is probably the most prevalent (cf. Kali, 2008; Kim & Hannafin, 2008; Mishra & Koehler, 2006; Quintana, Reiser, Davis, Krajcik, Fretz, Duncan et al., 2004; van den Akker, 1999). Bell, Hoadley, and Linn (2004) describe design-principles as:

> …an intermediate step between scientific findings, which must be generalized and replicable, and local experiences or examples that come up in practice. Because of the need to interpret design-principles, they are not as readily falsifiable as scientific laws. The principles are generated inductively from prior examples of success and are subject to refinement over time as others try to adapt them to their own experiences. (p. 83).

Table 11.1 Three examples demonstrating educational design research variation

	Thomas et al. (2009)	Klopfer and Squire (2008)	Oh (2011)
Problem	Middle school students were relatively unengaged in meaningful scientific inquiry	High school and college students were frequent users of handheld devices such as smart phones, but were not using them to learn	Graduate student collaboration in online learning course was superficial and unproductive
Main focus	Investigating the implementation of a technology-rich educational innovation in a public elementary school in the USA	Developing innovative applications for mobile computing for environmental science education	To optimize collaborative group work and student learning in an online higher education learning environment
Intervention developed	Quest Atlantis: a 3D multiplayer virtual environment	A series of games that can be played on handheld devices such as PDA and smart phones	"E-learning Evaluation" course based on authentic tasks for online delivery
Knowledge created	Theory of transformational play	Theoretical framework called "augmented reality educational gaming"	Multiple design principles and associated strategies to enhance group work in online courses
Research methods used	Observations Interviews Surveys Document analyses Three qualitative case studies	Observations Interviews Focus groups Discourse analysis Case studies Design narratives	Participant observations Questionnaires Interviews Three sequential case studies
Research scope	This design research initiative has been underway for more than a decade with substantial funding from NSF and other sources	The design research study has been underway since 2001 with initial funding from Microsoft and other sources	This study lasted 2 years with no direct funding
Primary practical contribution	As of 2010, Quest Atlantis had been used by 50,000 students in more than a dozen countries. atlantis.crlt.indiana.edu	The work started with this project is now part of the Games, Learning, and Society group at the University of Wisconsin where numerous learning games can be found. www.gameslearningsociety.org	An online course design for a graduate level course based around authentic tasks was developed with substantial support for group work. http://authenticlearning.info/AuthenticLearning/Home.html

On the other hand, van den Akker (1999) suggests that the knowledge encompassed in design principles can be conveyed through heuristic statements, such as, "If you want to design intervention X [for purpose/function Y in context Z]; then you are best advised to give that intervention the characteristics C1, C2, …, Cm [substantive emphasis]; and do that via procedures P1, P2, …, Pn [procedural emphasis]; because of theoretical arguments T1, T2, …, Tp; and empirical arguments E1, E2, … Eq." (p. 9). Complementing these perspectives on design principles, Linn and Eylon (2006) also describe design patterns, which illustrate promising instructional sequences, and may be guided or fine-tuned by design principles.

Practical Outputs

In educational design research, research and development are integrated to create educational interventions that address practical problems. In early stages, this involves analysis of the problem to be addressed. Using the findings from a needs and context analysis, together with a clarified problem statement, design work commences. Depending on the scope of the project, (re-)design work can last from several weeks to several years. Especially the revisions are fed by field investigations using a range of strategies and methods to study either the intervention itself (e.g., as a type of intervention for which guidelines or design frameworks are needed); or phenomena that are engendered by the interventions (e.g., learner reactions).

Examples

Different research reports are used here (Klopfer & Squire, 2008; Oh, 2011; Thomas, Barab, & Tuzun, 2009) to illustrate the variety of educational design research conducted within the field of educational communications and technology. One study (Thomas et al., 2009) was conducted by a research team led by Sasha Barab, one of the most highly respected senior professors in the field, with substantial funding from the National Science Foundation and other sources; one study was co-led by an at-the-time early career assistant professor, Kurt Squire, with start-up funding from Microsoft and other sources; and the last was carried out by a doctoral student, Eunjung Oh, working with one other doctoral student and a practitioner with no funding beyond a graduate teaching assistantship. For each one, the problem addressed, the primary focus of the research, the intervention that was developed, the theoretical contributions, the methods used, the scope of the intervention involved as well as its practical contribution are summarized in Table 11.1.

The three examples described here illustrate how different types of research reports are published as sub-components of larger educational design research projects. Published in the *Journal of Educational Computing Research*, Thomas et al. (2009) is one of a series of journal papers in which Barab and his colleagues have described their efforts to refine a theory of transformational play while at the same time seeking to develop advanced forms of interactive learning games. This paper summarizes the results of three qualitative studies focused on the challenges and successes involved in implementing Quest Atlantis, a 3D multiplayer virtual environment (MUVE), which serves as the primary vehicle for instantiating Barab's transformational play learning theory and for allowing it to be refined through iterative design-based research.

Published in the *Educational Technology Research and Development* Journal, Klopfer and Squire (2008) describe a multi-year project to enhance student learning related to environmental science through the development and refinement of learning games that are accessed with handheld devices such as PDAs and smart phones. In addition to developing an array of learning games, the project has sought to develop and refine a theoretical framework called "augmented reality educational gaming" that can be applied by other games designers. The paper provides considerable detail about the development of the learning games using a unique "design narrative" approach. This particular paper focuses on iterative design cycles based on five case studies conducted in real high school classrooms.

Oh (2011) reports the findings of a doctoral dissertation that pursued two primary goals: (1) optimizing collaborative group work in an online graduate level course focused on "E-Learning Evaluation," and (2) developing a refined model of group work in online courses and identifying design principles for supporting online collaborative group work among adult learners The dissertation provides a comprehensive portrayal of a 2-year design research project using what Boote and Beile (2005) called the "compilation of research articles" (p. 10) format for dissertations. The dissertation includes one published article, three submitted papers, one detailed methodology chapter, and one detailed results chapter. Oh (2011) documents how mixed methods were applied across several semester-length iterations of an online course to yield multiple distinct design principles for supporting group work by adults.

Addressing Inherent Challenges

Inspired by van den Akker's (1999) design research challenges, this section briefly touches on several important issues that often crop up in educational design research, how they may be attended to, and areas that require further consideration.

Information Richness and Efficiency: Seeking a Productive Balance

When conducting educational design research, it is necessary to address questions about appropriate tactics for increasing the information richness and efficiency of data collection procedures and instruments without being over-whelmed with data. Design researchers should not be driven by the misconception that "more is better." This notion is aptly conveyed by Dede (2004, p. 107) who noted in reference to a design study that "everything that moved within a 15-foot radius of the phenomenon was repeatedly interviewed, videotaped, surveyed and so-forth—this elephantine effort resulted in the birth of mouse-like insights in their contribution to educational knowledge."

Optimizing Processes: Stacking Smaller Studies Together

Other questions arise around the linkages among design, prototyping, implementation, data collection, processing, analysis, and re-design. Managing the process of communicating evaluation findings and subsequently utilizing them for improvement of interventions is difficult. Realistic timelines must be established with allowances for flexibility. Educational design research projects must inevitably be divided into smaller, more manageable chunks. These chunks and the smaller studies involved in them can function as "bricks" in a larger structure that forms both the evolving intervention and the refined knowledge. Emerging insights can be shared through shorter (e.g., article-sized) reports of smaller chunks, whereas books or other media might be more appropriate for sharing new knowledge derived from the whole of long-term efforts. Often, the interim (i.e., smaller chunk) reporting stands on its own and does not (need to) mention the larger study; also, interim reporting for an external audience can be a timely vehicle for fostering reflection among design research team members.

Measuring Impact: Powerful Examples Needed

Ultimately, educational design researchers must address questions regarding the most relevant indicators of quality, success and impact of the interventions and knowledge advances that result from their efforts. Burkhardt (2006) writes about what is needed to bring about greater acceptance of educational design research. He describes several Nobel Prize winners for design and development in other fields and concludes that educational design research candidates should be assessed on the basis of their: impact on practice; contribution to theory and/or knowledge; and improvement in either research and/or design methodology. While it is surely too early to be expecting Nobel Prizes for educational design researchers, this approach will only gain wide acceptance when it can be shown to make the much-needed gains in demonstrating the impact educational research (cf. Kaestle, 1993).

Generalizability: Toward Uptake and Use of New Knowledge

The main conceptual vehicle through which new knowledge is transferred outside of the research context, generalizability means different things to different researchers. All researchers must seek to identify promising approaches to enable uptake and use of research findings. Because educational design research takes place in natural settings where more variables are present than can be controlled for, the findings from these studies cannot yield immutable rules, easily transferred without consideration. But they can yield useful insights to inform the work of others (design work or otherwise). For example, when designs are tested in multiple settings and under varying conditions, or when design features are systematically varied under similar conditions, theory development can occur through analytic generalization. According to Yin (1989, p. 44), analytic generalization is a process through which "the investigator is striving to generalize a particular set of results to a broader theory" which can be of use to others. Alternatively, knowledge produced through design research can be shared and used through case-to-case generalization. Firestone (1993) refers to case-to-case generalization as the transfer of ideas that takes place when a person in one setting considers adopting an intervention, or its underlying propositions and frameworks in another setting. To do this, the knowledge producer is obligated to explicate how the specific instance studied compares to other instantiations of the phenomenon. In so doing, description of salient characteristics of both the intervention and the context in which it is enacted are essential. Clearly, when it comes to putting the knowledge of design research to use, the knowledge producer must portray the work well enough. This could mean, for example, adhering to Lincoln and Guba's (1985) criteria for naturalistic inquiry: credibility, transferability, dependability and confirmability (parallel to internal validity, external validity, reliability and objectivity, respectively). At the same time, knowledge consumers are obliged to critically assess the applicability of certain ideas for their own specific contexts.

On the Horizon

Educational design researchers and arguably all educational researchers must seek to balance rigor and relevance (Reeves, 2011). To find this balance, educational design researchers might do well to learn from sister fields. For example, engineering and product design tend to embrace creativity more than most educational researchers (e.g., Laurel, 2003). Another perspective can be found in appreciative inquiry in health care (e.g., Carter et al., 2007) that emphasizes design based on opportunity, as opposed to patching gaps uncovered by reductionist problem diagnostics.

Since the landmark design research articles in 1992, a growing appreciation for educational design research in a wide variety of contexts has been evident (Anderson & Shattuck, 2012). Gradually, the design research literature is beginning to show more consideration of factors that affect implementation. Instead of tossing innovations over the metaphorical walls of classrooms and online learning environments, educational design researchers are working hand in hand with practitioners to conduct design and research in ways that make substantive change possible. The importance of collaborative approaches and on-the-ground understanding of implementation issues, which were privileged topics of research in the 1970s (cf. Fullan & Pomfret, 1977; Hall, Wallace, & Dossett, 1973; Havelock, 1971) seem relatively new—but also quite dear—to many of those currently practicing design research. Some researchers emphasize this perspective by referring to their work as design-based implementation research (e.g., Penuel, Fishman, Cheng, & Sabelli, 2011). We embrace the surge of interest in these concerns, and express our hope for a renaissance of scholarship that brings researcher and practitioner expertise together to bear on substantial educational issues (McKenney & Reeves, 2013). Educational design research is one of several genres of inquiry that can lead the way in contributing to scientific understanding in the long term through its study of meaningful implementation in the here and now.

Design and Development Research

12

Rita C. Richey and James D. Klein

Abstract

This chapter focuses on design and development research, a type of inquiry unique to the instructional design and technology field dedicated to the creation of new knowledge and the validation of existing practice. We first define this kind of research and provide an overview of its two main categories—research on products and tools and research on design and development models. Then, we concentrate on recent design and development research (DDR) by describing 11 studies published in the literature. The five product and tool studies reviewed include research on comprehensive development projects, studies of particular design and development phases, and research on tool development and use. The six model studies reviewed include research leading to new or enhanced ID models, model validation and model use research. Finally, we summarize this new work in terms of the problems it addresses, the settings and participants examined, the research methodologies employed used, and the role evaluation plays in these studies.

Keywords

Design and development research • Instructional and non-instructional products • Design and development tools • Instructional design models

The Empirical Nature of Design and Development

Design models often parallel the scientific problem solving processes. Thus, the practice of design and development is to a great extent empirical by nature. Therefore, it would reasonable to assume that design and development processes have robust empirical support. Yet historically there has been a scarcity of research on our models, products and tools. While there has been increased empirical work on design and development recently, we have been writing about and advocating this type of research for the past 15 years (Klein, 1997; Richey, 1997; Richey & Klein, 2005, 2007, 2008; Richey, Klein, & Nelson, 2004; Richey & Nelson, 1996).

This chapter is a continuation of our work. It examines design and development research (DDR) by providing an overview of its definition and scope. The major part of the chapter focuses on representatives of recent design and development research. Finally, we summarize this new work with special emphasis on the problems it addresses, the settings and participants examined, the research methodology used, and the role evaluation plays in these studies.

Design and Development Research: Rationale, Definition, and Scope

Opinions on the role of research on design and development often depend on one's own view of what it actually is. We take the position that design and development is a science,

even though it is highly influenced by the creativity of the designer. We approach design and development (and in turn research on it) with the assumption that science and empiricism provide a more effective and reliable route to disciplinary integrity than depending on artistic tactics and craft-based solutions. As a science, design and development should be bound by understandings built upon replicated empirical research. Our models and procedures should be validated. The solutions to our problems should be supported by data. We believe that our field has not sufficiently employed empirical methods to facilitate our understanding of design and development processes. The need for research is especially critical with respect to the models and processes employed by designers and developers. Few models, design strategies, and tools employed in practice have been empirically tested and validated. This is the gap that design and development research seeks to address.

Design and development research is a type of inquiry unique to the Instructional Design and Technology (IDT) field that is dedicated to the creation of new knowledge and the validation of existing practice. We define DDR as "the systematic study of design, development and evaluation processes with the aim of establishing an empirical basis for the creation of instructional and non-instructional products and tools and new or enhanced models that govern their development" (Richey & Klein, 2008, p. 748). This definition aligns with recent suggestions that professionals in the IDT field facilitate learning and improve performance by creating, using and managing appropriate instructional and non-instructional interventions (Definition and Terminology Committee of the Association for Educational Communications & Technology, 2007; Reiser, 2012; Richey, Klein, & Tracey, 2011).

Design and development research covers a wide spectrum of activities and interests. It includes the study of the design and development process as a whole, of particular components of the process, or the impact of specific design and development efforts. Such research can involve a situation in which someone is studying the design and development work of others. It can also involve a situation in which someone is performing design and development activities and studying the process at the same time. In either case, there is a distinction between *doing* design and development and *studying* the processes.

Design and development research is an umbrella term for a wide range of studies that employ an assortment of traditional quantitative and qualitative research methods and strategies. Most design and development research, however, tends to rely more on qualitative strategies and deals with real-life projects, rather than with simulated or contrived projects. Many studies can be viewed as multi-method research.

Understanding the nature of this research is a matter of understanding the range of problems to which it can be applied. It is also a process of recognizing those research interests and endeavors that are *not* a part of this orientation. DDR does not encompass the following: instructional psychology or learning science studies; media delivery system comparisons or impact studies; message design studies; and research on the profession. While results from research in these areas impact design and development, the study of variables embedded in such topics does not constitute DDR.

Design and development research, as with all research endeavors, leads to knowledge production, a more complete understanding of the field, and the ability to make predictions. DDR reaches these goals through two main categories of research projects: (1) research on products and tools and (2) research on design and development models. We previously referred to these two categories of design and development research as Type 1 and Type 2 developmental studies (Richey, Klein, & Nelson, 2004). Others have referred to instructional product development studies as design-based research (Wang & Hannafin, 2005), systems-based evaluation (Driscoll, 1984), and formative research (Reigeluth & Frick, 1999; van den Akker, 1999).

Below we describe design and development research in detail and briefly examine 11 studies conducted since 2007 in this line of inquiry. In addition to being quite recent, these studies were selected to exemplify the major categories of DDR, the types of methodologies commonly employed, and the range of research settings examined. They also highlight studies conducted in a variety of locales around the world. We begin by discussing research on product and tools, followed by an examination of research on models.

Research on Products and Tools

The most straightforward type of DDR falls into the first category—research conducted during the design and development of a product or tool. Often, the entire design and development process (analysis–design–development–implementation–evaluation) is documented. In some cases, researchers concentrate only on one facet of design and development (e.g., needs assessment). Many recent studies focus on the design and development of technology-based products and tools.

Below, we discuss three classes of product and tool research. These include studies of (1) comprehensive design and development projects, (2) specific ID project phases, and (3) tool development and use. We review recent representative product and tool research in each of these categories.

Recent Comprehensive Design and Development Research

Studies of comprehensive design and development projects usually demonstrate the range of design principles available to practitioners. Frequently, the entire design and development process is studied and documented. The design processes used in a particular situation is described, analyzed, and a final product is evaluated. Consistent with predominant practice in the field, the procedures employed usually follow the tenets of instructional systems design (ISD), encompassing analysis through evaluation. This is the case in a research study by Visser, Plomp, Armiault, and Kuiper (2002) who describe the design and development of a product which addresses learner motivation in distance education programs. This work includes an initial pilot study, as well as a year-long try-out and evaluation of the product. A study by Sullivan, Ice, and Niedermeyer (2000) is also an example of comprehensive DDR that focuses on the impact of an instructional program. These researchers use field evaluation to test a comprehensive K-12 energy education curriculum that was the product of a design, development and implementation project on-going for 20 years. While few researchers have the opportunity to study an instructional program for such a long period of time, recent research continues to examine comprehensive design and development projects. Below we discuss two such projects.

Developing a Web 2.0 System for Community and Teacher Use

Research by Cifuentes, Sharp, Bulu, Benz, and Stough (2010) provides an example of a comprehensive product design study. The purpose of this 2-year study was to investigate "the design, development, implementation, and evaluation of an informational and instructional Web site in order to generate guidelines for instructional designers of read/write Web environments" (p. 378). The researchers implemented and documented the entire ISD process. Needs analysis was conducted on a practical problem—individuals with disabilities and their families have difficulty gaining access to information about support services. Findings pointed to the development of an online directory of resources using the capabilities of Web 2.0 technologies. Design decisions were based on theory including social constructivism, distributed cognition, and rapid prototyping. Formative evaluation occurred throughout product development. Participants included the design team, a variety of intended users in multiple locations, college students contributed resources to the Web site, as well as internal and external evaluators. The researchers provide context-specific findings related to problems and issues encountered, resources required, and product impact and use. They also give generalized recommendations for others designers of Web 2.0 solutions.

The Cifuentes et al. (2010) study is a good example of comprehensive product design research. The researchers identified and analyzed a real-world problem, used theory and formative evaluation to inform design and development decisions, meticulously documented these decisions, employed multiple research methods, considered issues such as researcher bias and instrument reliability, and collected data from several sources.

A Task-Centered, Peer-Interactive Course Redesign

A descriptive case study by Francom, Bybee, Wolfersberger, and Merrill (2009) provides another example of comprehensive design and development research focusing on a product. This study addresses the real-world problem of converting a passive, face-to-face college biology course to an online course that includes peer-interaction and task-centered instruction. The authors describe how the instructor selected content topics and "complex, authentic tasks that would require students to gain a sufficient knowledge of the subject area in order to complete the task" (p. 37). They also explain how the First Principles of Instruction (see Merrill, 2002) were used to redesign instructional activities and assessments. A formative evaluation was conducted during the first semester the course was offered; data included observations of the instructor, classroom activities, and online discussions, as well as a student survey measuring perceptions of the course and their learning. The authors offer a discussion of how these data were used to revise and improve the course.

While the work by Francom et al. (2009) does not provide the same level of detail as the Cifuentes et al. (2010) study, both are examples of comprehensive design and development research. They report on projects in which a researcher studies design and development while comprehensive ISD processes are used to produce a specific product.

Recent ID Phase Research

Not all DDR pertains to a comprehensive project. Instead, some researchers examine specific phases of an ID effort. These studies typically relate to data gathering phases of the ISD process (e.g., needs assessment, formative evaluation). For example, Klein, Martin, Tutty, and Su (2005) identify the optimal research competencies of graduate students by conducting a content review of course syllabi from several leading instructional design and technology programs and by administering a survey to faculty and students. In addition, Fischer, Savenye, and Sullivan (2002) conduct a formative evaluation of computer-based training on an online financial and purchasing system to verify the program's effectiveness and identify necessary revisions. Below, we discuss another design and development study that is representative of very recent research on a component of ID.

Formative Evaluation of a Learning Game

A recent study by Sahrir (2012) is an example of DDR on a specific phase of ID, namely, formative evaluation. This research investigates the development of an online vocabulary game for beginning Arabic language learners at a Malaysian university. The researcher employed a mixed-method approach to collect data on prototypes of the online learning game. Data sources included instructors, subject-matter experts, evaluators, and learners who participated in one-to-one, small group and field test phases of formative evaluation. Characteristic of most product design studies, the researcher provides context specific findings (i.e., the online game improved student enjoyment, immersion and knowledge of Arabic). In addition, issues, problems and lessons learned are discussed to inform other designers of similar products. For example, the researcher suggests "there should be sessions of cooperative work and research activities between language teachers … instructional designers and computer experts to design and develop … effective games" (p. 366). This study is particularly notable because it provides an empirical test of how the phases of formative evaluation suggested by ISD scholars (e.g., Dick, Carey, & Carey, 2009; Tessmer, 1993) can be used in actual practice.

Recent Tool Development and Use Research

Some researchers concentrate on studying the development and use of tools, rather than on the design of products. These tools may support design and development or teaching and learning processes. Many of these studies focus on computer-based tools and some of this research is directed toward automating design and development. For example, Nieveen and van den Akker (1999) focus on a computer system that serves as a performance support tool for designers during the formative evaluation phase of an ID project. In addition, Mooij (2002) conducted a tool study examining the development and use of an instructional management system for early education. Below we describe a two other studies that are representative of recent research on tool development and use.

Development of Performance Support Tool for Teachers

A recent comprehensive study by Hung, Smith, Harris, and Lockard (2010) illustrates research on a tool to support the teaching/learning process, specifically the design and development of a performance support system (PSS) for classroom behavior management. These researchers "adopted design and development research methodology … to systematically investigate the process of applying instructional design principles, human–computer interaction, and software engineering to a performance support system" (p. 61). The study was conducted in six phases that mirrors an ISD approach. Qualitative and quantitative techniques were used to collect data from several sources. For example, a Delphi technique was used with subject matter experts to enhance the design of the PSS. In addition, elementary and junior-high school teachers completed a survey about system requirements, tested the usability of two prototypes of the PSS, kept activity logs during implementation, and participated in post-implementation interviews. The researchers report contextually based findings about their tool (e.g., navigation, functionality, efficiency, and ease of learning). They also discuss how design and development research served as a "conceptual guide to not only maintain a systematic approach to the development process but also to broaden the perspective of the system's instructional implications to a holistic approach that addressed system, user, and development process as a whole" (Hung et al., 2010, p. 78).

Design of a Computer Support System for Multimedia Curriculum Development

A study by Wang, Nieveen, and van den Akker (2007) focuses on the design of an electronic performance support system (EPSS) to help teacher-designers in China develop scenarios for multimedia instruction. The main purpose of the study was "to produce a practical computer support system for multimedia curriculum development by following an evolutionary prototyping approach" (p. 277). The researchers wanted to create an EPSS that was valid, practical and effective. They created four prototypes of the tool and collected data from experts and end users who completed questionnaires and participated in focus groups. Summative evaluation of the tool was also conducted. During this phase of the study, teacher-designers were observed using the tool to create scenarios for multimedia instruction; they also provided suggestions for improving it. Results indicate that participants found the tool to be usable and practical. An unintended outcome was that the tool helped "teacher-designers become acquainted with a systematic approach to multimedia instructional design" (p. 289).

The Wang et al. study is particularly noteworthy because it includes summative evaluation. This type of evaluation is often not included in DDR and is infrequently used in practice.

Research on Models

The second type of design and development research pertains to studies of the development, validation and use of models. These studies focus on the design and development models and processes themselves, rather than their demonstration. While it is possible to conduct model research in conjunction with the development of a product or program, many model studies concentrate on previously developed instruction, and consequently are not project-specific. Model research may address the validity or effectiveness of an existing or newly constructed development model, process or technique. In addition, these studies often seek to identify and describe the conditions that facilitate successful design and development. Since model research studies are oriented toward a broad analysis of design and development processes, they tend to be more generalizable than product and tool studies.

Model research tends to address three major related phases—model development, model validation, and model use. Here we review very recent representative model research in each category.

Recent Model Development Research

Model development research may result in new, enhanced, or updated models that guide the ID process or a part of the process. Such research has produced a rapid prototyping ID model (Jones & Richey, 2000), components of a model of ID competencies (Vallachia, Marker, & Taylor, 2010), and a Web-based knowledge management system model that provides for its continuing development (Plass & Salisbusry, 2002). Model research encompasses a wide range of settings and participants and it employs a variety of research methodologies (see Richey & Klein, 2007).

We examine two recent model development studies that address very different design problems using research methods that are totally different from each other. However, both contribute to the advancement of design and development models.

A Model for the Design of Visual Information

Message design is a specialized task of those who select and develop instructional materials, and it is an area informed by a broad knowledge base. Consequently, Voss (2008) conducted an extensive literature review resulting in the development of a model to guide designers as they work with one particular type of message—two-dimensional visual images that will transfer information to the learner/viewer. This study explores the research literature of message design, cognitive psychology, neurology, and information theory to identify those principles that govern visual communication, mental imagery, and visual memory. The literature and the resulting model suggest that visuals have their own set of rules that are based upon the nature of perception rather than the view of communication as being controlled by language.

While reviewing the literature is an important early step in conducting any research, a literature review is not typically used as a research methodology in the IDT field. However, large-scale reviews such as Voss's provide an opportunity to build an empirically based model that covers many variables. For instance, the Voss model addresses pre-attentive and attentive brain functions, the mental processes of selecting visual images, the varying functions of pictures, symbols and signs, as well as a range of distortions that can occur during message transmission.

Reviews of large bodies of research and theory are likely to cover many settings, be they instructional, transfer, or design and development. Therefore, this technique facilitates the identification of factors that are not context-specific or learner-specific. This is the case with the Voss model.

Identifying the Components of a Transfer Model

Like many researchers and practitioners interested in improving workplace performance, Hillsman and Kuptritz (2010) seek to identify empirically based predictors of transfer. Specifically, they focus on elements in the physical work environment. Their work is an example of a study that can be viewed as content-specific research, but then ID researchers can also interpret their findings in terms of design and development. More specifically, the research can be viewed as model development since it provides justification for including an entire class of variables into a design model directed towards transfer of training.

The Hillsman and Kuptritz study was a multi-methods project (both qualitative and quantitative) that collected data from 50 supervisors who had participated in 4 hours of interpersonal communication training and then applied their new skills working with their employees on the job for 6 months. The research involved conducting 6 hours of field observations, surveys, and structured personal interviews. In addition, there was an archival review of work records.

The results show that workplace design did "contribute to transfer outcomes. Supportive as well as unsupportive workplace design features were elicited as most often facilitating or impeding transfer" (Hillsman & Kuptritz, 2010, p. 23). While this research clearly has implications for workplace design, it also adds to the body of literature that seeks to model those factors that impact transfer of training. Thus, it also informs training designers of those aspects of context that are critical to the success of their interventions. These researchers do not fully develop a design-related model, but instead they identify the building blocks required to construct a comprehensive model.

Recent Model Validation Research

While the ID literature is rife with models of the design process, far less attention is paid to the validation of these models. Such validation is an empirical process that demonstrates the effectiveness of a model's use in a real-world setting (i.e., external validation) or provides support for the various components of a model (i.e., internal validation) (Richey, 2005). In some validation research, experienced design practitioners are used as subject matter experts to authenticate a design model or specific design phases. For example, Cowell (2001) interviews current designers to substantiate the regular use of needs assessment techniques (even though other terms are often used for the process). In other research, learner data confirms the model. (See Roszkowski & Soven, 2010, for their research which validates an updated Kirkpatrick evaluation model.) We summarize two other recent DDR studies which highlight the characteristics of model validation research.

Updating and Validating Gilbert's Behavioral Engineering Model

Thomas Gilbert's Behavioral Engineering Model (BEM) has profoundly influenced designers who work in employee training environments, and it has been credited with the origination of cause analysis. (See Gilbert, 1978, for a full discussion of this model.) Crossman's (2010) research examines BEM's relevance in the contemporary workplace.

The participants in Crossman's study are 600 fire fighters and the specific area of interest is safety culture, the motivation to follow safety rules. The fire fighters completed a survey whose items reflected the environmental elements of the BEM—information (i.e., communication), resources, and incentives. Data were analyzed using correlations and path analyses. Crossman found that the combined effects of the three variable categories did influence safety motivation. Furthermore, she found that incentives directly impacted safety motivation while absorbing the indirect effects of communication of information and resources. The environmental facet of Gilbert's long standing model was validated in this setting.

Crossman's study exemplifies an internal model validation asking whether the parts of the model are justified. It is an empirical study that relates to an actual work environment. It is statistically sound and based in both theory and practice. However, there are other ways to approach model validation.

Testing the Impact of the Multiple Intelligence Design Model

Tracey (2009) uses very different tactics to validate her ID model which blends multiple intelligence (MI) theory with traditional instructional systems design. The study has two parts—a designer usability test and an examination of product impact. As such, it provides both internal and external validation of the MI Design Model.

Designer usability was tested by randomly assigning two Masters-trained designers to a 2 hours team building workshop project using the MI Design Model; two similar designers were assigned to the same project using the Dick and Carey ISD Model. (See Dick et al., 2009 for a full discussion of this model.) Work conditions were the same for each design team. Following completion of the workshop materials, the MI Model designers filled out a model usability survey detailing their reactions to the model. Product impact, on the other hand, was tested by using the two design team's products. Five sessions with eight to ten learners each were conducted using the MI-oriented workshop, and another five similar sessions were conducted using the ISD product. Posttest and attitude-toward-training data were collected. While both groups felt confident in their new skills, participants who were trained with the MI materials scored slightly (but significantly) higher on the posttest and learning seemed to be stimulated by the use of the MI instructional strategies.

Tracey's research supports the use of the MI Design model. Like other design and development studies, it exemplifies comprehensive model validation techniques performed under real-world design conditions.

Recent Model Use Research

While it is not unusual for model validation research, such as Tracey's (2009) study, to address usability issues, there is another genre of design and development research that emphasizes how models are used. Many of these studies focus on the conditions that impact model use; these show the interplay between varying design and development contexts and model effectiveness. For example, Roytek (2000) conducted a comprehensive case study which focuses on two design projects using rapid prototyping procedures; this study is designed to determine which contextual factors, strategies, and events facilitate or impede project success. Other research focuses on the designers themselves to understand exactly how the design and development process is actually used. Visscher-Voerman and Gustafson (2004) conducted interviews with designers working in diverse settings and reviewed related project materials to determine the procedures designers used and their rationales for these approaches. Recent model usability research continues in a similar vein with much of the current work concentrating on the role of technology.

The Rapid Implementation of e-Learning

Many academic programs are faced with the prospect of changing quickly from face-to-face delivery of their courses to on-line learning. Coetzee and Smart (2012) present a case study describing the process of developing a module and placing it on learning management system (LMS). In doing so, they demonstrate the merger of two models—the traditional ADDIE (analysis, design, development, implementation, evaluation) design model and The Technology Process model used in technology development projects. The situation in this study was realistic in that the university instructor was working essentially alone with only one other person giving advice. Resources were limited. There was little lead time and thus the modules were used as developed. The course thus moved from a face-to-face delivery to a blended delivery. Subsequent units were modified based upon student feedback. This case study demonstrates how two recognized models can be modified to meet the demands of a given instructional situation. The models can be scaled up or scaled down to meet the varying needs of a particular intervention.

The Coetzee and Smart study is particularly useful because model use is not examined in a technology-rich environment. This demonstration takes place in university located in an underdeveloped country. Nonetheless, the two models are successfully adapted to the conditions present in their specific context.

Teacher Technology Integration

There are many models directed towards classroom teachers as they integrate technology into their lessons. The existing research, however, provides little data supporting teacher use of either classic ID principles or the consistent use of technology in their classes. Hart (2008) uses a "think aloud" protocol to study how middle school language arts and social studies teachers actually integrate technology into their lesson plans While these teachers were not applying specifically designated design or technology integration models, Hart explores which model components are used by identifying the design decisions made and the rationale for these decisions. Eight teachers (four of whom had graduate education in instructional design) completed a background survey, then a technology design task using the think-aloud techniques, and a post-design interview. Hart found that in general these teachers demonstrated a reliance on mental planning rather than use of design principles. Technology was not incorporated into all teachers' lessons in a meaningful way (even though that was the assigned task). Moreover, when it was used, the technology did not tend to support student higher level thinking. Contextual factors (e.g., accessibility) had the most impact on technology use.

Model researchers typically look forward to positive results that confirm their model's utility. Hart's (2008) research, on the other hand, produces less satisfying results. The data, however, provide an empirical basis for changing models to accommodate the real-world conditions.

Summary of Key Characteristics

We have described 11 studies published since 2007 which are representative of the most recent design and development research. These studies encompass the various types of both product and tool research and model research. They were conducted in a variety of work and geographical settings and address diverse problems currently being faced by the field. The researchers also use a wide assortment of approaches and methodologies to study design and development problems. Table 12.1 below summarizes this recent research.

Source of Design and Development Problems

Design and development research typically stems from problems encountered in the workplace (Richey & Klein, 2007). Of the 11 studies reviewed in this chapter, seven of them are directly rooted in real-life problems. For example, this research was used to answer questions such as: What facilitates transfer of training to the job? How can we help teachers to take on the role of designers? How can we get vital information to individuals and families?

In keeping with the increased use of technology in education and training, it is not unusual for design and development studies to have a technology focus. Over half of the

studies we highlighted had a technology emphasis, and five of the seven studies with a workplace focus also examined problems related to technology. These studies concentrated on online learning, Web site design, technology integration, electronic performance support systems, and gaming. All of these topics reflect emerging technologies as well as current trends in the IDT field.

Over half of this body of recent research also reflects theoretical problems and issues. While some of these studies (such as Voss's, 2008 exploration of factors affecting the perception of visual messages) emanate only from an interest in theory, others (such as Francom et al.'s, 2009 study of online course design using Merrill's First Principles) combine a theoretical orientation with practical concerns.

Most DDR addresses problems which have multiple sources. In our sample of 11 recent studies only the model research with a theoretical focus seemed to have a more singular focus. This conclusion, however, may only be a peculiarity of the particular sample of studies we reviewed.

Research Settings and Participants

Design and development research problems (like ID itself) are typically contained in a specific context which includes distinct participants. ID is now used extensively in business and industrial settings, healthcare organizations, community and government agencies, as well as schools and universities. The 11 studies described in this chapter reflect this diversity for the most part. Four of the five product and tool studies are situated in educational settings—two at the P-12 level and two in higher education. On the other hand, half of the model research reviewed pertains to employee training.

All but one of the recent design and development studies reviewed in this chapter were conducted in a setting that included adults as participants, although in some cases the participants were adult learners rather than instructional designers alone. For example, product and tool research was done in the context of a learning community that included the parents of children with disabilities and county extension agents (Cifuentes et al., 2010). Model research was conducted with managers in a training setting (Hillsman & Kuptritz, 2010) and with fire fighters employed by a local government (Crossman, 2010).

Even recent design and development research conducted in P-12 school and higher education settings focuses primarily on adults. Our review identified three studies that concentrated on school teachers. The product and tool studies by Hung et al. (2010) and Wang et al. (2007) examined the design and use performance support tools for teachers while the model use study by Hart (2008) focused on how teachers integrate technology into their lesson plans. Furthermore, 3 of the 11 studies we reviewed in this chapter were conducted in a higher education setting (Coetzee & Smart, 2012; Francom et al., 2009; Sahrir, 2012). In all three cases, participants included faculty who were responsible for designing instruction for their students.

Research Methodology

The majority of design and development studies use multimethod approaches typically blending both qualitative and quantitative methods (Richey & Klein, 2007). This may be a reflection of the complexities of most projects and the multiple sources of the problems address in such research. However, qualitative methods were dominant. Nine of the 11 studies reviewed in this chapter employed qualitative techniques. We believe that this is a typical phenomenon. The qualitative methods, however, vary widely. They include the use of case studies, participant interviews, focus groups, field observations, activity logs, archival reviews, and think-aloud techniques.

Many studies also employ quantitative methods and may at times use experimental designs. Not surprisingly, evaluation phases of design and development research often rely upon assessment measures. Probably the most common quantitative method involved the use of surveys and questionnaires. For example, Crossman (2010) used survey data collected from fire fighters to validate the Gilbert model and Hung et al. (2010) surveyed classroom teachers to identify the requirements of their performance support system. Standard statistical techniques such as correlations and path analyses were then employed.

Finally, there is a critical methodological issue somewhat unique to design and development research. In many of these studies, the researcher also serves as the designer/developer. This situation is a common and often unavoidable by-product of the practical constraints of studying real-life design projects. These conditions occur in all of the recent product and tool studies summarized in this chapter and in one of the model studies (i.e., Coetzee & Smart, 2012). In these cases, data validity can be an issue, but when special attention is given to instrument design, data collection and triangulating multiple sources of data, the concerns have been addressed. The position of the designer/researcher is comparable to the role of participant observer in qualitative research, and similar data collection tactics are employed.

The Role of Evaluation

Evaluation is a major part of the design and development process and correspondingly plays a role in DDR although it is far more prominent in product and tool research than in model research. Since designers who follow a systems approach typically evaluate the intervention during development, researchers who study the design and development of a product or tool often collect similar evaluation data to determine its impact on learning. As expected, the comprehensive research projects such as those conducted by Cifuentes et al. (2010), Hung et al. (2010) and Francom et al. (2009) include formative evaluation tasks in their studies. However, all of the product and tool studies and one of the model studies we summarized in this chapter included some form of formative evaluation. Sahrir (2012) placed a major emphasis on this process when he empirically tested how the various phases of formative evaluation can be used by university instructors. Typically these data include learner assessments, but it often includes designer reactions as well.

Of special consideration is the study by Wang et al. (2007) which also includes a summative evaluation to investigate the impact of a performance support tool on teachers who develop curriculum. The inclusion of both formative and summative evaluation data is an encouraging trend in the IDT literature and we hope it continues.

Researchers who study design models are less likely to concentrate on evaluation data unless they are studying evaluation models. However, some researchers such as Coetzee and Smart (2012) may include formative evaluation in their studies of model use. Additionally, others develop and implement an intervention to test the efficacy of the model. In this process learner assessment data is often used.

Conclusions

In the past, instructional design strategies were supported primarily by research on the learning process. While that is still a valuable source of information, ID is now substantiated by a much broader array of research. One trend in the field is the use of design and development research. It establishes practical and theoretically sound solutions to the many problems faced in the IDT field. While this type of research is not yet commonplace, it is growing. The studies reviewed in this chapter reflect this phenomenon. Design and development research is being conducted in many parts of the world. It is being applied to many new topics and areas of concern. These researchers are providing the field not only with innovative examples of how such studies are conducted, but with new knowledge about how to design and develop interventions which address critical problems in education, training, and organizational improvement.

Practices and Potential of Activity Theory for Educational Technology Research

13

Turkan Karakus

Abstract

This chapter aims to examine the practices and potential of Activity Theory (AT) for educational technology research (ETR). AT provides a framework within which to understand object-oriented, collective, and social environments (Engeström, *Perspectives in activity theory* (pp. 19–38). Cambridge: Cambridge University Press, 1999). Activity systems provide flexible frameworks that can be modified according to the nature of the context. In ETR, AT has been used as a tool to analyze and design complex learning situations as well as to analyze the contradictions and barriers in technology integration and to describe the dynamics of organizational knowledge creation. In this chapter, the basics of AT are presented and the available research using AT as a methodological tool in ETR is examined. The use of AT as a metaphorical tool in learning design and artifact development, as an analytic tool in an innovation study, and as a descriptive and prescriptive tool in a knowledge management study is explained. I also refer to the potential use of Actor Network Theory (ANT) as a possible third generation AT (Engeström, Journal of Education and Work 14(1):134–156, 2001) that can be used to understand the symmetrical relationship between multiple activity systems.

Keywords

Activity theory • Educational technology research • Actor network theory

Introduction

Modern technologies and new expectations of learners have enabled modern teaching strategies based on rich, multidisciplinary, collaborative, authentic, and real-life tasks (Van Merrienboer & Martens, 2002). As these new approaches also affect the educational design process, it is necessary to seek new ways of understanding all aspects of the educational context and to suggest new design solutions suitable for different learning situations. Distance learning, social networking, technology integration, and the use of technology by teachers and students are current issues in educational technology research (ETR), according to Ross, Morrison, and Lowther (2010). They also suggested that educational technology researchers have reduced efforts to prove the "effectiveness" of technology, while focusing on conducting rigorous and relevant mixed-methods studies to explain which technology applications work to facilitate learning, in what ways, in which contexts, for whom and why (p. 31).

From this perspective, contextual thinking in the implementation of new technologies becomes more attainable than proving the effectiveness of the technology for each context. Currently, learning is not perceived as an individual action, but as a social activity in which people and artifacts play important roles (Winn, 2002). Therefore, ETR's new focus is the learning environment as a whole rather than the design of the instruction (Mihalca & Miclea, 2007; Winn, 2002).

J.M. Spector et al. (eds.), *Handbook of Research on Educational Communications and Technology*,
DOI 10.1007/978-1-4614-3185-5_13,

Mihalca and Miclea (2007) also point out that ETR has embraced the belief that learning is highly dependent upon the activity of the learner, rather than upon the information and processes provided by the learning environment.

The transfer of focus from individual learning to societal learning (Engeström, 1987, 1999) brought a new complexity to teaching and learning situations that requires comprehensive frameworks for the investigation of these situations. AT, the roots of which were planted by Vygotsky (1978) and expanded upon by Leontev (1978) and Engeström (1987), provides a contextual framework that can be used to understand complex human interactions (Yamagata-Lynch & Smaldino, 2007) and describe the important components needed to design complex learning environments (Jonassen & Rohrer-Murphy, 1999). AT can help us to understand how the actors of any object oriented collective system transform the actions, operations, and other sub-activities into an object and how the contextual dynamics mediate this process (Barab, Barnett, Yamagata-Lynch, Squire, & Keating, 2002). Using a deductive perspective also helps to "break down problems into smaller, more manageable subproblems, set priorities and establish the relative importance of research issues" (Kaptelinin & Nardi, 2006, p. 27). Thus, in any context where purposeful human social activities take place to reach an object, AT enables us to understand that the activities of the community and the outcomes of the activities are shaped by the context of the activities (Engeström, 1987; Kaptelinin & Nardi, 2006; Leontev, 1978).

Basics of Activity Theory

AT is based on mediated action (Vygotsky, 1978) which uses individual action as a unit of analysis. In Vygostky's model, mediated action occurs when there is an individual subject, an object (motivation of the action), and a mediated artifact (Engeström, 2001). Vygotsky proposed that mediated artifacts might be societal artifacts that influence individuals' responses to a learning context; thus, Vygotsky's unit of analysis was still based on the individual (Engeström, 2001). Individual action differs from collective activity, according to Leontev (1978), who believes that individual goal-based actions and operations are part of a larger collective activity system (Engeström, 2001). Therefore, according to Leontev, the unit of analysis should be the activity system, not the individual. Certainly, there are smaller goal directed actions and condition-directed operations performed by subjects to realize the whole activity (Leontev, 1978, 1981) and analysis of the whole activity requires analyzing these actions and operations. While Leontev did not draw a conceptual framework for AT, Engeström (1987) did represent the components of a collective activity system. Thus, after Vygostky's first generation of the activity system, which included a subject, an object and a mediating artifact, the second generation of AT framework was proposed (Engeström, 1987).

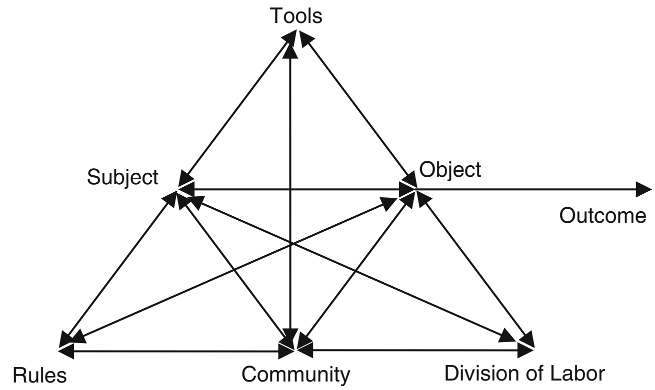

Fig. 13.1 Second-generation activity system triangle (Engeström, 1987)

According to Engeström (1987), each activity is a system in which there is an object (motive) that leads stakeholders (participants, actors, or performers) of the activity to act and perform many smaller activities. At the core of the activity, a subject performs to transform the object into the outcomes. Additionally, there are contextual dynamics that mediate between subject and object. An activity system consists of seven main components that can be located on an activity system triangle (Engeström, 1987; see Fig. 13.1). As seen in the activity triangle model, a subject interacts with other system components to transform the object. When the object is achieved, outcomes of the activity are revealed. The outcome, which is a concrete or abstract artifact of the activity, is also called a transformed object (Mwanza & Engeström, 2005). The tools of an activity system are any tangible or intangible artifacts that mediate between the subject and object. A subject is connected to a community (the context and people with whom the subject interacted) by means of rules (norms or regulations that influence performance in activities). Rules might be considered the actual contextual factors that enable or limit the actions and operations of the subject or community. Finally, division of labor defines the responsibilities of community members. Alterations in the dynamics of these components of activity influence the quality of object transformation and, consequently, the outcome. As seen in the activity system triangle, each component has a dual relationship (tool—rules, rules—division of labor, rules—community, etc.) and all of the mediating components have a direct connection to the subject and object.

The activity system triangle constitutes a descriptive framework that can be used to analyze and evaluate any object oriented context. In general, when using an activity framework, the contextual issues are first represented within the framework and then the contradictions, tensions and transformation of a system to another system are revealed with detailed descriptions. However, it is not possible to understand the context with just a representational model of a learning situation or any other learning context. The following five principles of AT might illuminate the analysis of the context: the activity system as a unit of analysis, multi-voicedness of the activity, historicity of the activity, contradictions as the driving force of change in an activity, and expansive cycles as a possible form of transformation in an activity (Engeström, 2001).

The first principle of AT is that the collaborative, artifact mediated, and object oriented activity system is the unit of analysis (Engeström, 2001). As Engeström and Kuutti (1996) pointed out, actions, operations and smaller activities can be independent, but the entire activity system should be considered when these smaller pieces are interpreted. Multi-voicedness means that a diversity exists within the components of the activity system. The diversity in the background, history, interests and traditions of a community as well as rules and division of labor cause the activity systems to have a dynamic structure with problems and contradictions. Thus, the multi-voiced structure of activity systems enables us to see how the negotiation between or within the components is achieved over time. Two studies that investigate the contradictions in university–school partnerships (Tsui & Law, 2007; Yamagata-Lynch & Smaldino, 2007) might be given as examples of this AT principle. In both studies, the researchers followed a design-based approach to resolve the contradictions caused by institutional differences.

Using the historicity principle, the transformation of the activities and objects, which change over time, can be observed. This principle enables understanding of how the developments occur in the system over time. Yamagata-Lynch's (2003) study constitutes an historical analysis of the transformation of technology usage in a specific school district. In her analysis, Yamagata-Lynch explores the teachers' professional development by comparing the school context before, during, and 1 year after the implementation of technology integration. In that study the contradictions between and within the components of the activity were the main sources of change in the activity systems, as in the fourth principle. Contradictions occur when a component's dynamics change. The conflicts between old and new dynamics are also taken as the bases of acceptance of innovations (Blin & Munro, 2008; Demiraslan & Koçak Usluel, 2008; Nocon, 2008; Russell & Schneiderheinze, 2005).

Finally, as the dynamics and conflicts change and increase, new cycles of activity systems are generated. The change in dynamics and conflicts move the activity system from its current state to a new state. These expansive cycles are crucial for collective activities within which the object is to change the current state to a new one Examples are Engeström's (2001) study that aimed to change the treatment procedures of a health center or Kaptelinin's (2003) study of the development of a user centered virtual environment. As Kaptelinin and Nardi (2006) pointed out, this principle, called "development," is especially useful when combined with the first principle in designing a system.

Actor Network Theory and Activity Theory

The need to compare different activity systems requires new conceptual frameworks beyond AT (Barab, Schatz, & Scheckler, 2004). Actor Network Theory (ANT), as a potential for third generation AT, proposes finding an approach to understand the dialog between multiple activity systems (Engeström, 2001). ANT can be considered to be related to AT (Engeström, 2001; Kaptelinin & Nardi, 2006) as ANT also seeks relationships between the components of the context, but it differs in terms of considering whether human and nonhuman actors have equal roles in the context (Callon, 1999; Kaptelinin & Nardi, 2006; Latour, 1993). ANT provides an approach to understanding the "creation of networks of aligned interests" (Mähring, Holmström, Keil, & Montealegre, 2004) and to examining the symmetrical relationship between nature and society (Miettinen, 1999).

ANT's potential was investigated in Information Systems research where the technology became an active role player in (social) network creation (Engeström & Escalante, 1996; Gao, 2005; Mähring et al., 2004; Miettinen, 1999). In technology integration, change management and the diffusion of innovation studies, ANT can potentially provide a framework for understanding the heterogeneous links between the different activity systems in innovation settings (Fenwick, 2009). However, ANT does not have a clear framework that can be used in a research context (Hitchings, 2003; Mähring et al., 2004) and does not have any fixed components prior to network construction (Broer, Nieboer, & Bal, 2010); instead, ANT allows researchers to understand the historical phases of a network building process. ANT examines how the networks of actors are connected to discover how human and nonhuman entities join a network after the selection, persuasion, and change processes have happened (Fenwick, 2009). Consequently, the unit of analysis for the ANT is the gradually growing network, which includes nodes and links (Engeström & Escalante, 1996).

Although no structured framework exists for ANT, network expansion is defined as a four-step process, also called the sociology of translation steps. These are (1) problematization (subscribing and clarifying the actors), (2) interessement (setting up and strengthening the links between the actors), (3) enrollment (developing agreements between the actors), and (4) mobilization of the allies (optimizing the functionality of the network) (Callon, 1986). These steps explain the success or failure of the dissemination of an innovation (Tatnall & Gilding, 1999).

The fluid structure of ANT makes it difficult to use it in a structured learning setting where the stakeholders are fixed but it might help to explore the collective network building process in free learning and knowledge sharing settings. For example, Broer et al. (2010) illustrated this issue by examining the efforts of the collaborators in two improvement projects related to mental health care and care for the intellectually disabled. In that study, the clients, anchors, friends, acquaintances and professionals were the actors of the network and the purpose of all of the collaborators (professionals) was to improve the recovery process of the clients. In their analysis, Broer et al. began by examining how the collaborators identified a clear understanding of the roles of the network members, such as reducing the roles of the professionals in the lives of the clients instead of continuously stimulating them. This process might be assumed to be an effort to build an optimized network helpful to the clients. In the second phase of the analysis, Broer et al. observed how the collaborators generated ideas on how to guide their clients. In other words, this phase strengthened the network by means of optimized solutions. Each of these steps was nested within the other but still the authors succeeded in explaining the process of building an optimum-functioning network after clarifying, defining, changing and improving the roles of the actors in the network.

AT differs from ANT in that AT examines the inner contradictions and interactions in the different nodes of the networks (Miettinen, 1999). In AT, a subject exists who is in a dialog with the community, rules and tools to transform the object. ANT's framework, on the other hand, reveals the symmetrical relationships between the nodes of the network, when each node has an equal role and strength in the network expansion process (Callon, 1986). In addition, in ANT many nodes exist that might have similar structures and different connections to the network, while in AT a stable framework exists.

Practices and Potential of AT in ETR

Kaptelinin and Nardi (2006) pointed out that AT is descriptive (identifies key concepts and variables), explanatory (reveals relationships and processes), and generative (facilitates creativity, invention, and discovery). In the design, development, and implementation of learning artifacts and situations, AT has enabled researchers to characterize the learning tools for different contexts (Barab et al., 2004; Collis & Margaryan, 2004; Mwanza & Engeström, 2005). By design, AT has also created a metaphor to represent interactions in a learning environment (Barab et al., 2002; Yamagata-Lynch & Smaldino, 2007) and to represent pedagogical structures of learning artifacts (Mwanza & Engeström, 2005). For these studies, AT provided more manageable data for understanding the context and proposing systemic implications (Yamagata-Lynch, 2007). The main issues for analysis in AT are the tensions (Barab et al., 2002; Yamagata-Lynch, 2003, 2007) and contradictions (Lim & Hang, 2003; Lim, Tay, & Hedberg, 2011) within the activities. Exploration of the tensions and contradictions in diverse innovation settings provides the big picture which shows not only the dynamics that have created barriers in the innovation setting (Blin & Munro, 2008; Issroff & Scanlon, 2002; Lim & Chai, 2004; Lim & Hang, 2003) but also the ways in which the contradictions were balanced or negotiated over time (Yamagata-Lynch, 2003).

In knowledge management studies of communities of practice and computer supported communication environments, AT has been used as a methodological tool to describe and prescribe social interactions in context (Engeström, 2000, 2001; Mwanza, 2002). In some studies, learning tools have constituted the tool artifacts of the activity system and the practitioners have sought to learn how these tools interacted with the other components and influenced the outcome (Bellamy, 1996; Cole & Engeström, 1991; Tan & Melles, 2010; Zurita & Nussbaum, 2007). In the next section of this chapter I present five examples of how to use AT. These are as a methodological tool in an historical analysis of contextual changes, a framework for course design, a tool in characterizing contextual learning artifacts, an analytical tool in innovation studies, and a tool by which to explain a developmental study.

As a Tool for an Historical Analysis of an Activity System

As a descriptive theory, AT has been used to describe many learning contexts (Barab et al., 2002). Barab et al. (2002) used it to understand the historical transformation of course dynamics. The authors began by clarifying two tensions (building virtual models vs. learning astronomy and teacher-centered instruction vs. student-centered learning) that arose during an astronomy course. Then, they conducted an in-depth analysis of the actions and operations associated with those tensions. Thus, they could see how a tension was transformed into a solution and how that solution became a component of a next level activity. Every goal-based action was shown on the triangles and then the relationships between the triangles were represented. For example, a student who had trouble in creating a model [subject] understood the model development process [object] by means of a model created by his friend [tool]. Then he used that model [tool] to create his own model [object]. Those representations were helpful in that it allowed readers to understand how the students learned astronomy concepts by means of the social interaction in class. This kind of analysis might allow a characterization of balanced course environments, which is useful in instructional design (Barab et al., 2002).

Cultural historical AT that requires longitudinal observations in a context is a commonly used method (Roth & Lee, 2007; Russell, 1997). Yamagata-Lynch's (2003) study, which benefited from a cultural historical analysis using AT, examined a school district to understand the effect of a teacher professional development technology integration program on the district and the effect of the school district on the program. The results revealed tensions after analyzing the different phases of technology integration (before, during and after). The author then showed, by means of the AT framework, how these tensions affected the integration process and illustrated the historical development of human activities and how these activities became an artifact for a future phase (Yamagata-Lynch, 2003). Both Barab et al. (2002) and Yamagata-Lynch (2003) showed that tensions are crucial elements in the transformation of activity systems, whether or not those tensions are overcome.

A Course Design Framework for Constructivist Learning Environments

In complex learning environments, AT could provide a broad lens to investigate and simulate the dynamics of the context (Jonassen, 2000) and to draw a bigger picture to see how learners learn when they are involved in a particular learning activity (Stevenson, 2008). Jonassen and Rohrer-Murphy's (1999) proposed a framework for constructivist learning environments, showing how the AT activity triangle can be used as a course design framework. This framework can be used in a flexible manner as it consists of many context-based questions. Its extensive examination of the context includes six main processes: (1) clarification of the purpose of the activity system, (2) analysis of the activity system by identifying and describing its components, (3) analysis of the activity structure (activities, actions and operations), (4) analysis of mediators, (5) analysis of the context, and (6) analysis of the activity system's dynamics (pp. 71–78). Therefore, it can be argued that the activity system approach is based on the elaboration of contextual issues and the development of solutions by moderating the effective dynamics of the system. This framework was used to design a blended course (Collis & Margaryan, 2004) and to characterize a mobile learning environment (Uden, 2007). For example, Collis and Margaryan (2004) used four of the steps suggested by Jonassen and Rohrer-Murphy (1999): (1) clarification of the purpose of the activity system, (2) analysis of the activity system, (3) analysis of instruments and resources (to be used in the learning environment), and (4) analysis of the activity system dynamics in the learning environment. Collis and Margaryan (2004) combined the design of work-based activities and computer supported collaborative learning situations to teach health risk assessment in workplaces. Students who had jobs at different workplaces, as well as supervisors and instructors, became the subjects of the activity. Students contributed to the content of the course by investigating the activity system of their workplace. Thus the authors improved both their course design and the learning outcomes in a student-centered manner using this framework.

As a Tool for Characterizing and Designing Contextualized Learning Artifacts and Systems

Reeves (2006) believes that, as design is a contextual, social, and active process, educational technologists should seek strategies that incorporate contextual issues into design as much as possible. AT facilitates the research by modeling pedagogical and contextual issues of learning artifacts and technologies (Barab et al., 2004; Mwanza & Engeström, 2005). As an example, Mwanza and Engeström (2005) used the activity system to create new learning object metadata (LOM) standards for a newly developed project called Lab@Future. This project proposed creating virtual laboratories combining virtual reality, 3D and mobile technologies to engage high school students in learning. In the development of the learning objects, the activity system approach was used to include the pedagogical and contextual aspects of the learning environment in the metadata descriptions (Mwanza & Engeström, 2005). Under the educational category of LOM standards, the project team used the activity system analysis "to enhance the meaningfulness in the interactions and the usefulness in the nature of objects accessed" (p. 463). The researchers showed possible contextual issues that might interact with these tools in the activity system. The learning outcomes were defined as the objects of the activity system. For example, for history, they described the object as "to acquire and internalize historical knowledge as proposed in the curriculum" (p.461).

Mwanza & Engeström, (2005) study might be counted as a suitable example for ETR trends as mentioned by Ross et al. (2010), when one takes into account the context as a basis for designing the learning objective. However, this contextual thinking does not mean that they examined all of the pedagogical dynamics of each learning object to fit in different contexts.

Barab et al. (2004) also used AT to characterize their social network platform. But they also had to build up the network community to make the platform functional and analyzed the process of socialization by means of another framework. In this sense, Barab et al.'s (2004) study might be a good example of using AT with a framework derived from ANT, called the sociotechnical interaction network (STIN). As Barab et al. argued, STIN was different from ANT because while the network structure might be drawn simultaneously in STIN, there was no need for an historical understanding of network building as in ANT. In the study, they created a community of practice platform for teachers by using AT to characterize the context in which the platform would be used. While using the platform, they used STIN to define the community building process and its tensions. After their analysis, Barab et al. suggested that AT might be used as an explanatory tool to understand the network characterized by STIN where STIN constituted a whole activity or any component of a new activity system. Thus, AT and ANT might be used interchangeably to understand any community creation process. In the innovation process, for example, they might be used to explore how people become users of innovation by using ANT and then characterizing the components, tensions or contradictions of the whole innovation setting using AT.

Lim et al.'s (2011) study embraced a similar method to investigate the efforts of teachers to integrate a multiuser environment into the curriculum. Neither study contained information about how the contradictions were resolved over time; however, both of the studies exemplified a third generation activity framework that took multiple activity systems as a minimal model (Engeström, 2001). Representation of the relationships between the different systems might be associated with ANT since its approach is to compare different activity systems; however, Lim et al.'s study only shows the contradictions between existing activity systems and ICT was not considered a separate activity system on its own. ANT is an approach often used when exploring technological innovations (Tatnall & Gilding, 1999) when the technology itself becomes an active part of the network.

As a Tool for Discovering and Describing Reactions to Innovation

Technology integration is a dynamic process used to improve the performance of schools (Tondeur, Cooper, & Newhouse, 2010). Typically, technology integration is not an easy process, considering the social tensions, contradictions and resistance of the users. Each contradiction constitutes an issue that needs to be resolved to advance to the next step of technology integration. The educational technology field plays an important role in understanding these resistances, developing effective implementation strategies, resolving contradictions, and training stakeholders. In this respect, AT has been used to discover how contradictions enable or frustrate changes in the innovation setting (Lim & Chai, 2004; Lim & Hang, 2003; Lim et al., 2011; Russell & Schneiderheinze, 2005; Yamagata-Lynch, 2003).

Lim and Hang's (2003) study of ICT (information and communication technologies) integration into curriculum in schools in Singapore contained three analyses of the activity systems. First, they investigated the primary inner contradictions of each component. For example, they observed how the teachers struggled with classroom management, while trying to use technology to improve the students' higher order thinking skills (contradictions in objective). In the secondary inner contradictions, the researchers focused on the contradictions among the components of the activity system. For example, technology changed the role of the teacher from a traditional teaching role to facilitating learning, which meant that a contradiction existed between the tool and division of labor. Finally, they compared different activity systems and they discovered that the objectives and activities of the classrooms', schools', and educational technology divisions' activity systems differed. Each school was competing to get a higher rank in the educational system league to which it belonged. The students' success rates needed to be high in order for the school to get a higher rank.

As a Tool for Describing and Prescribing the Improvement Developmental Cycles

Knowledge creation, like other types of production, is not an abstract process; contextual and social dimensions influence it. Engeström (2001) expanded the definition of AT to include the expansive learning approach, which accepts that activity systems have their own zones of proximal development where the subjects continuously question the established norms of the system. Thus; expansive learning might be associated with the developmental cycles of resolving a problem. Using this approach, Engeström answered "Who is learning?" [subject], "Why do they learn?" [object], "What do they learn?" [outcome], and "How do they learn?" [actions, operations] for each dimension of AT. Using this matrix, Engeström (2001) showed how an AT framework can be used for historical inquiry and the redesign of knowledge management situations step-by-step in a healthcare setting.

In answering each question, Engeström (2001) used a step-by-step approach. He observed the processes through which a child patient passed until a diagnosis was completed. He started by observing a particular physician. He observed the physician's actions and operations in determining the preliminary diagnostic test results for the patient. After this physician examined the patient, a series of additional diagnostic tests were conducted and different specialists examined the patient in accordance with the policies of the hospital. A patient with a number of problems had to make several visits to different care providers and follow different paths (procedures) to be diagnosed and treated by a care provider. This situation created some disturbances because of uncoordinated communication between the physicians and specialists. The critical pathway (procedures of the treatment), as a tool of the health center system, also caused the patient to make many visits to the health center and care providers. After examining the problems of the system in the health center via a question matrix, Engeström revealed the outcomes as “excessive numbers of visits, unclear loci of responsibility and failure to inform other involved care providers” (2001, p. 143). Then, Engeström presented a new model aimed at improving the healthcare system of the health center. The model required a new kind of knowledge management system to be used by the stakeholders (physicians, specialists, nurses, administrative staff, patients and their parents) in the patients’ treatment activities.

In Engeström’s (2001) study, AT played a crucial role in understanding the history of the case and its contradictions, proposing a solution model and examining the new system. A third generation AT was also used to understand the interconnections between the different activity systems (the health center, children’s hospital, patient’s family). This study is an important example of using the different dimensions of AT to explore, describe and develop a solution for design problems which might also be a base for developmental studies.

Conclusion and Discussion

In this chapter, I have provided several examples of how to use AT as an analysis framework and analytical tool. The expandable nature of AT makes it useful in many disciplines and research areas. I have shown that AT uses a contextual framework to explore contexts that have contradictions, conflicts, and dual relationships. The results constituted examples of designing optimized learning environments and artifacts, understanding technology and innovation integration efforts and creating courses where learners become active players in course design and performance improvement. In addition, I examined ANT and AT to understand whether they could be used as complementary approaches in socialized networked environments. I anticipated that the ANT approach would be a tool that could be used to reveal the interactions and connections between the activity systems.

The contextual approach of AT looks promising for ETR methodologies. In addition, as AT is so flexible, it can be expanded and modified in response to the nature of the research context. For example, Halloran, Rogers and Scaife (2002) extended the use of an activity system by revealing several contradictions within the components of the system instead of contradictions between the components. Similarly, AT has the potential to be expanded and modified for use in any social, object-oriented, collaborative, and tool-mediated context. Many studies have benefited from different applications of AT by dealing with manageable units of analysis, reaching systemic implications, understanding systemic contradictions and tensions, and comparing the findings meaningfully (Yamagata-Lynch, 2010). The types of use of AT are summarized in Table 13.1

As seen in Table 13.1, no unique way exists by which to run AT for a particular research purpose. This diversity might be an issue that researchers need to overcome when deciding the starting point of their analysis. Initially, deciding a meaningful activity system to examine might be challenging (Uden, 2007; Yamagata-Lynch, 2007). This decision is especially important when exploring a series of activity systems or different activity systems at one time (Yamagata-Lynch, 2007). In the rich data, an activity framework needs to remain static to show the unsteady dynamics, tensions, and relationships

Table 13.1 Different ways of using AT as a methodological tool

AT analysis steps	Contribution to ETR research	Specific studies using AT
Analysis of the activity systems of a school district and the teachers before, during, and after a technology integration and the availability of a technology coordinator to reveal tensions. Discovering the relationships between a series of activity systems	A potential framework for deriving practical implications in design-based research	Analysis of transformation of learning (Barab et al., 2002). Diffusion of innovation (Blin & Munro, 2008; Russell & Schneiderheinze, 2005). Redesign of teacher education program (Roth & Tobin, 2002). Technology integration process (Yamagata-Lynch, 2003, 2007)
Step-by-step analysis of an activity system to characterize the learning environment	Exemplary constructivist course design framework	Design of mobile computer supported environment (Zurita & Nussbaum, 2007; Uden, 2007). Design of learning artifacts (Mwanza & Engeström, 2005). Computer supported course design (Collis & Margaryan, 2004)
Characterizing the optimum context of the platform from designer and teacher perspectives. Using another theory for the community building process	Use of different theory(ies) interchangeably with AT to understand different phases of system development	Barab et al. (2004)
An analysis of the activity systems of a hierarchical structure, the internal contradictions in each system and the external contradictions between the different activity systems that are influencing each other	A method of analysis for diffusion of innovations	Diffusion of innovation (Lim & Hang, 2003; Lim et al., 2011). Comparison of different e-learning platforms (Benson, Lawler, & Whitworth, 2008; Benson & Whitworth, 2007)
The analysis of contradictions via four predetermined questions for each principle of AT, proposing new models for problem situations and examining and developing solutions	A potential framework for developmental research	Workplace knowledge management (Engeström, 2001). Educational innovations (Yamazumi, 2008). School–university partnership (Fenwick, 2009; Tsui & Law, 2007)

Table 13.2 Comparison of AT and ANT

Property	AT	ANT
Type of the theory	Descriptive, prescriptive, generative	Descriptive
Framework	All components of the AT are defined	No clear network structure at the beginning
Objective of the activity	A definite objective of the activity system	Creating a durable network of actors having similar objectives
Unit of analysis	Sociocultural activity as a unit of analysis	Process of the creation of human and nonhuman networks as a unit of analysis
Purpose	Sociocultural historical analysis of an available activity system	An historical analysis of a durable network building process
Participants	Human actors that cannot be separated from the activity context	Human or nonhuman actors, which can be separate from or joined to the network
Orientation	Object oriented activity	Process oriented activity
Focus of analysis	Focus on sociocultural activity	Focus on sociotechnical action
Initializing the analysis	Starts with an analysis of the available activity context	Starts with defining the actors in the network
Analysis steps	Varied, but mainly depend on the analysis of dynamics, contradictions, tensions, and development of negotiation in the system	Problematization, interest, enrollment, and mobilization of allies

between the different activity systems. Therefore, researchers should find creative ways to show those relationships.

Another activity-based approach, ANT, needs developing to become a usable framework for ETR. From an ANT perspective in innovation or technology integration studies, the technology itself is defined as an actor of the system with as much importance as the human actor. But ANT still needs to clarify how nonhuman units contribute to the network. Innovations or different nonhuman actors cannot function without humans; they cannot be a power by themselves in the educational environment. In addition, systematic and hierarchical processes of technology integration might constitute a barrier when using ANT because ANT advocates a natural formation of the networks in which no hierarchy exists between the nodes. It does not explain how we can create a network within an innovative setting, but we might use it to explain the natural creation of a network. In other words, it is a descriptive approach rather than a prescriptive or predictive approach. Therefore, ANT might be more suitable for free learning environments, such as community of practice platforms or organizational learning, when no specific actors exist at the beginning of the network creation (Fox, 2000). In this case, AT and ANT might be considered complementary approaches; that is, AT reveals the inner contradictions and problems in a node and ANT creates a vocabulary to reveal whether and to what extent a certain node of the network (i.e., actor) is a part of the network system. A detailed comparison appears in Table 13.2.

Although AT and ANT might be used to complement each other, a need still exists for a method between AT and ANT analysis, as ANT allows the user to see how a negotiated network is built overtime, while AT examines networks in several dimensions, such as history, interaction, and contradictions. Another strategy is needed to see the interrelationships of different available activity systems. For example, in Lim and Hang's (2003) study, the stakeholders of the educational system were stable and the roles and hierarchy were defined. In Benson and Whitworth (2007), the cases, which were examined using the activity approach, were also defined at the beginning. Although the researchers found a method to show the relationship between the activity systems, more systematic questions would analyze the relationships between the activity systems.

Implications

It is clear that more flexible approaches to conceptualizing methodological frameworks are needed. Static representations of frameworks are insufficient when attempting to understand complex learning situations, which is why a third generation of AT needs to be developed. Today, within the investigation of a unique context, it is not enough to understand its complexity; we also need to examine the relationships between the contexts in addition to the dynamics in each of the contexts. In addition to ANT, as Engeström (2001) suggested, more approaches and methodologies are needed to understand the dialog between different activity systems. It is suggested that for each research context other representations of the activity exist instead of just a rigid activity triangle. In this respect, ANT might be a more flexible way of representing the available context. As each actor or component (there might be an infinite number) of the network has different distances from and relationships with each other, they might not always have a dual relationship nor have a direct effect on each other. However, these features of ANT do not provide a well-suited approach to understand current educational contexts as long as these contexts continue to have definite objectives, systematic designs, and developmental learning situations. Therefore, ANT might need to be combined with different frameworks to be used in ETR.

Clearly, an AT framework requires extensive, in-depth, qualitative analysis of the context. Both the AT and ANT practitioners should be a part of the activity to understand the contextual structure. In the examples given, discourse analysis constitutes an important instrument for activity theory-based research. Researchers should be a part of the context to characterize the activity systems and investigate contradictions as well.

Conceptualizing a learning environment with an activity system is not sufficient when attempting to explain the whole context or understand the whole activity (Wells, 2002) and the triangle model does not constitute the heart of the findings (Yamagata-Lynch, 2003). The triangle model visualizes the context to describe it. In order not to represent an activity system, like a "black box" (Barab et al., 2002), the framework should be extended so that it explains the relationship between the dynamics of the context. Wells (2002) especially emphasizes that the dialog within the system should be represented in an expanded triangle model; he drew another framework in which he added "means, experience, realization" to represent a cooperative production system (p. 49). Similarly, the black box issue is present for ANT, even more so than for AT, because ANT does not focus on the inside of the nodes of the networks. Therefore, a combination of different frameworks could be explored to investigate the structure of the relationships in the context.

Action Research for Educational Communications and Technology

14

Meghan McGlinn Manfra and Daniel Kelvin Bullock

Abstract

Action research refers to the formalized, self-reflective research of practitioners. According to Cochran-Smith and Lytle (Inside and outside: Teacher research and knowledge. NY: Teachers College Press, 1993) action research is "systematic and intentional inquiry" (p. 7). It is often conducted collaboratively in research groups that meet in person or at a distance via communication technologies. Action research transforms the traditional "outside-in" relationship between practitioners and the educational community. It can provide a powerful means for bridging the divide between theory and practice and encouraging practitioners to engage in innovative practices. Action research includes a cyclical process of posing questions, collecting data, reflecting on findings, and reporting results. This chapter provides a comprehensive overview of action research and its history in the USA, Great Britain, and Australia. It also describes the epistemological and ontological differences between practical and critical action research. To inspire future action research in our field, we detail the action research method, including data collection and analysis techniques and provide example studies from the field of educational communications and technology. More specifically, we demonstrate the manner in which action research has already been used to better understand the impact of the integration of technology in classrooms and social settings. At the same time, we describe how action researchers have used educational communications and technology to conduct action research and to teach this research method through online or hybrid classes. Technology can be both the focus and part of the method of the action research.

Keywords

Action research • Participatory action research • Technological pedagogical content knowledge

Introduction and Overview

According to Savenye and Robinson (2004), "Assumptions, questions, methods, and paradigms that formerly dominated research in the [educational technology research] field are changing" (p. 1045). Concerns about the scope and impact of technology integration dominate the field of educational communications and technology and relevant research questions require new strategies and methods. Action research represents a dynamic methodology, enabling our field to address persistent questions within the context of practice.

In this chapter we introduce action research and its history in three contexts—the USA, Great Britain, and Australia. We also describe the characteristics distinguishing practical and critical action research and the various forms of data collection and analysis that contribute to an action research study. More specifically we review current action research studies focused on the integration of technology. Action research has the potential to transform our field by engaging stakeholders in meaning-making through the process of systematically collecting and analyzing data to improve practice. Elliot (1991) wrote, "It [action research] aims to feed practical judgment in concrete situations, and the validity of the 'theories' or hypotheses it generates depends not so much on 'scientific' tests of truth, as on their usefulness in helping people to act more intelligently and skillfully" (p. 69).

Action Research Defined

According to Cochran-Smith and Lytle (1993) action research is "systematic and intentional inquiry" (p. 7). It has often been linked to Dewey's (1933, 1938) notion of the teacher as a reflective practitioner (e.g., Cochran-Smith and Lytle, 1990), but it can be conducted by anyone seeking to enhance practice, regardless of their context or status. Action research is often conducted collaboratively in research groups that meet in person or at a distance via communication technologies. Due to the intimate nature of action research, the findings can reveal new understandings and knowledge not always readily apparent to outside researchers. As a result, action research transforms the traditional "outside-in" relationship between practitioners and educational researchers (McNiff and Whitehead 2010).

"Action research" is often used interchangeably with "teacher research" or "practitioner research." Borko, Whitcomb, and Byrnes (2008) group action research with "participatory research", "self study", and "teacher research" as a distinct genre of "practitioner research" (p. 1029). We use the term "action research" (unless an alternative appears in direct quotations taken from authors) to refer to the systematic and intentional research undertaken by practitioners about their own practice.

Action research is a cyclical or spiraling process "that integrates theory with practice, through reflection and action planning" (Altrichter, Feldman, Posch, & Somekh, 2008, p. 9). The process includes a series of steps including posing a question, collecting and analyzing data, and reporting findings. Kurt Lewin was the first to describe action research as "a spiral process of data collection to determine goals, action to implement goals and assessment of the result of the intervention" (Bargal, 2006, p. 369). The process spirals as the action researcher reflects on and continues the inquiry, basing decisions about new directions in the research on previous findings. Stringer (2007) described the spiral as repeating the routine of "look", "think," and "act" and Altrichter et al. (2008) pointed to several "'mini' action research cycles" within one project (p. 11).

History of Action Research

A variety of histories of action research have been published (e.g., Carr & Kemmis, 1986; McKernan, 1991; Noffke, 1997). Almost all of the accounts agree that industrial psychologist Kurt Lewin's work in the 1940s did the most to encourage the growth of action research inquiry (see also Bargal, 2006). Lewin's original model for action research developed from the field of group dynamics and included a focus on systematic study in a cyclical process to create new knowledge. Lewin's effort to "find ways to involve social actors with research through group decision making and elaborate problem solving procedures" (Hollingsworth & Sockett, 1994, p. 3) helped to define the process.

Action research eventually evolved from its origins to focus on educational issues. Stephen Corey (1953) first applied action research to educational settings in his work at the Horace Mann-Lincoln Institute at Teacher's College (Ferrance, 2000). By the late 1950s excitement over action research in the USA ebbed. However in the UK and Australia "a strong tradition of 'action research' by teachers began in the 1960s and continues today" (Lampert, 2000, p. 65).

Action Research Movement in the UK

Current scholarship on action research draws heavily upon the work of Lawrence Stenhouse (1985) and his colleagues at the Centre for Applied Research in Education (CARE) in the UK. According to Goodson (1999), under Stenhouse's leadership CARE began to push for acknowledgment of the "educational researcher's social and political purpose" (p. 279). Stenhouse nurtured an emphasis on critical inquiry during his tenure at CARE and encouraged educators to push for social change beginning in schools. "He [Stenhouse] saw teaching and research as closely related, and called for teachers to reflect critically and systematically about their practice as a form of curriculum theorizing" (McNiff & Whitehead, 2002, p. 43). Stemming from the Humanities Curriculum Project (HCP) which began in 1967, CARE "drew deeply on the egalitarian commitments of sections of post-war British society" (p. 279). From the beginning, CARE emphasized emancipatory strategies and critical outcomes for practitioner research. Especially when the conservative financial and economic events of 1976 ushered in the federal "New Right Programme," Stenhouse encouraged educators to push for change beginning in schools. According to Goodson (1999), "During the 1970s, besides conducting a wide range of curriculum development and evaluation projects, CARE became a centre for defining educational research modalities in the public sphere" and its major task became finding "intellectual answers to the problems of empowering education for all" (pp. 283–284).

Stenhouse's ideas were extended by John Elliot and Clem Adelman with the Ford Teaching Project, 1973–1976 (Altrichter et al., 2008; Carr & Kemmis, 1986). Later, Elliot, the coordinator of CARE in 1991, continued the tradition established by Stenhouse of moving beyond objective curriculum research to focus on the process of teacher inquiry. His revised version of Lewin's model argued that, rather than consistently pursue a single aim in practitioner research, the "general idea should be allowed to shift" as the study progressed (cited in McNiff & Whitehead, 2002, p. 46). Elliot (1991) also emphasized a continual cycle of research and action, of planning and implementation. He cautioned against too quickly judging a teaching strategy's value without first clarifying the extent to which it was implemented.

Critical-Emancipatory Action Research in Australia

Stenhouse influenced the work of action researchers in Australia (e.g., Carr & Kemmis, 1986; Kemmis & Grundy, 1997; McTaggart, 1991a, 1991b, 1997). Carr and Kemmis (1986), for instance, wanted to help teachers understand the social and political construction of educational practices and described classroom-based inquiry as "educational action research." Their model of action research involved a spiral process including devising a question, planning, implementing, observing, reflecting, and replanning. They wrote:

> Action research is a form of self-reflective enquiry undertaken by participants (teachers, students or principals, for example) in social (including educational) situations in order to improve the rationality and justice of (a) their own social or educational practices, (b) their understanding of these practices, and (c) the situations (and institutions) in which their practices are carried out. p. 162

Carr and Kemmis also applied Habermas' (1972) early work to conceptualize critical action research within the framework of the "emancipatory interest." They encouraged teachers to critically interrogate their practice and its social impacts.

Robin McTaggart of Deakin University was a colleague of Kemmis and collaborated on *The Action Research Planner* (Kemmis and McTaggart, 1988) which became a well-known text for practitioners and university-based educators around the world. McTaggart (1991a, 1991b) also wrote extensively about his cross-cultural work with Aboriginal people. He repeatedly emphasized the emancipatory possibilities of action research and was severely critical of what he considered to be more benign forms of action research. McTaggart (1997) feared that the action research cycle would lose its radical potential and develop "iconic simplicity" (p. 17).

Collectively the work of Australian and British action researchers created a more critical philosophical tradition for the genre. According to Cochran-Smith and Lytle (1999) this tradition "shared a grounding in critical and democratic social theory and in explicit rejection of the authority of professional experts who produced and accumulated knowledge in 'scientific' research settings for use by others in practical settings" (p. 16). Action research that was grounded in critical social theory emphasized the emancipatory function of action research as a path to greater democracy in schooling and society.

Contemporary Action Research Movement in the USA

Influenced in part by the work of action researchers in Britain and Australia, American educators grew increasingly interested in practitioner-based inquiry towards the end of the twentieth century. Also contributing to this trend, according to Cochran-Smith & Lytle (1993) was a "paradigm shift in researching, teaching, and assessing writing that evolved during the 1970s and 1980s" (p. 6). For example, the Writing Projects were designed to improve the teaching of writing through teacher reflection on practice and examination of student work (e.g., Bay Area Writing Project, 1979). At the same time, influential texts such as Schön's (1983) *Reflective Practitioner* and Berthoff's (1987) phrase "The teacher as RE-searcher" provided the necessary language to articulate an interest in teacher inquiry. By 1999 Cochran-Smith and Lytle identified five major trends in action research in the USA: (1) growth in the prominence of action research in teacher education; (2) development of conceptual frameworks and theories of action research; (3) dissemination of action research findings in journals and conference proceedings; (4) critiques of action research; and (5) belief in the transformative potential of action research in education.

According to educational historian Ellen Lagemann (2000) contemporary action research holds a more prominent position within the American educational research community than in previous times. Increasingly, action researchers present their work at national conferences, including the American Educational Research Association (AERA) annual conference. They share their findings in national and international educational journals (e.g., *Educational Action Research*, *Action Research*, *Systemic Practice and Action Research*, *Action Learning,* and *Learning*) and other outlets.

Theoretical Frameworks

Perhaps as a result of the history of action research, there are differing ideas about its aims and purposes as well as its epistemological and ontological assumptions (Altrichter et al., 2008). For instance, Noffke (1997) offers three "dimensions" of action research as "political," "personal," and "professional." Our review of the literature (including manuals and texts for conducting action research, journal articles, and anthologies chronicling action research studies) revealed more of a bifurcation between those who advocate for practical or critical action research (see also, Cochran-Smith & Lytle, 1999; McCutcheon & Jung, 1990). We found practical action research focuses on the day-to-day issues teachers face, whereas critical action research seeks to better the classroom while also confronting larger political and social issues (see also Manfra, 2009a). Below we describe the diverging conceptions of action research as practical or critical.

Practical Action Research

Practical action research focuses on improving "teachers' professional knowledge landscapes" (Clandinin & Connelly, 1995) and "craft knowledge" (Grimmett & MacKinnon, 1992). In an overview of the different forms of action research, Cochran-Smith & Lytle (1999) explain that "theorizers in this [practical] group assume that some of the most essential knowledge for teaching is practical knowledge" (p. 19). Here the day-to-day work of teachers or other practitioners is of primary importance. The emphasis repeatedly is on "real classrooms and real schools" (Allan & Miller, 1990, p. 196). Proponents of practical action research argue that through reflection on practice, teachers can generate knowledge about teaching and learning. Implicit is the emphasis on the *practicality* of action research for teachers and schools. According to Cochran-Smith & Lytle (1999), "practical inquiry is more likely to respond to the immediacy of the knowledge needs teachers confront in everyday practice and to be foundational for formal research by providing new questions and concerns" (p. 19).

Critical Action Research

Critical action research aims to bring about social change and a more just and democratic society by influencing educational structures (e.g., Gitlin & Haddon 1997; Kemmis & Grundy, 1997; Kincheloe, 1991, 1995; Noffke, 1997). "The emphasis is on transforming educational theory and practice toward emancipatory ends and thus raising fundamental questions about curriculum, teachers' roles, and the ends as well as the means of schooling" (Cochran-Smith & Lytle, 1999, p. 18). Proponents of critical action research refer to the work of a variety of critical theorists, including Freire (1972) and Habermas (1972). For example, Kincheloe (1995) wrote that, "The critical teacher researcher asks questions of deep structure of his or her school or classroom settings—in other words, he or she takes Habermas's notion of emancipatory interest of knowledge seriously" (p. 81). Critical action research seeks fundamental change in social and institutional structures.

Table 14.1 A summary: practical action research compared to critical action research

Practical action research:	*Critical action research*:
• "Practical-Deliberative" (McKernan, 1996)	• "Critical-Emancipatory" (McKernan, 1996)
• Concerned with practical knowledge or "craft knowledge"	• Concerned with social and cultural factors that impact school
• Interest in day-to-day issues of practice	• Interest in democratic participation and emancipation
• May result in improved practice and student performance but not social or cultural change	• Seeks deep change [enlightenment] within the classroom
	• Implicit goal towards improving society

Manfra 2009a)

In some cases, proponents of critical action research criticize "benign" versions of action research because they ignore political and social issues (Kincheloe, 1995). For example, Noffke (1997) argues that practical versions of action research are separated from the "political sphere" and, according to Zeichner (1994), they serve to "further solidify and justify practice that is harmful to students" (p. 66). Kincheloe argues that uncritical action research is "dangerous" in that it "upholds status quo" practices and "reproduces extant ideology" (p. 82). According to this perspective, practical action research only serves to entrench a view of teachers as uncritical actors manipulated by the educational status quo.

The epistemological disagreements in the field of action research have created a division between practical and critical action research. Table 14.1 outlines some of the major differences of these two forms of action research. Currently there is little dialogue in the literature between the two (Manfra, 2009a).

In our discussion of methodology below we choose not to privilege practical or critical action research, emphasizing instead that the diversity of approaches can be liberating for researchers. Similar to MacLean & Mohr (1999) we believe "that teachers are thinkers and inquirers with knowledge about teaching and learning" and, accordingly "we don't 'prepare' or 'train' teachers to ask the 'right' questions in the 'right' way" (p. vii). According to Altrichter et al. (2008), Elliott similarly rejected much of the criticism of supposedly benign forms of action research. "He [Elliot] argues that teachers do not need to be liberated from oppression, but are able to generate knowledge and understanding of their practice through engaging in systematic research and reflection" (p. 12). In this chapter we describe the variety of methodologies and potential outcomes as strengths of action research.

Action Research Methodology

Of course the differing philosophical rationales for action research means there are also "methodological variations" (McCutcheon & Jung, 1990, p. 144). Data collection methods range from conventional quantitative and qualitative approaches to ethnographic storytelling and autobiography. There is general agreement across these methodological differences, that action research involves a cyclical process of action and reflection and a systematic approach to data collection and analysis. Action research is distinct from the everyday work of teachers and practitioners since it goes beyond reflection to interrogate the action through data collection. According to Glanz (1998) there are six steps in an action research project: (1) "Select a focus", (2) "Collect data", (3) "Analyze and interpret data," (4) "Take action," (5) "Reflect," and (6) "Continue and modify" (p. 27). There can be many variations to the steps, yet the basis of the cycle is always the same—reflection in action. Below we provide more details about each of the steps in the action research cycle.

Selecting a Focus

Altrichter et al. (2008) recommend identifying "experiences of discrepancies" as "starting points" for action research (p. 41). That is, practitioners should use action research to confront pressing concerns and issues. Similar to educational research in general, a variety of types of research questions can set the focus and scope of an action research project. The theoretical framework that the researcher brings to the process will impact the research questions asked and the data collected. According to McNiff and Whitehead (2010), action research involves "a commitment to educational improvement; a special kind of research question, asked with educational intent; putting the 'I' at the center of research; educational action that is informed, committed, and intentional" (p. 34).

Ethical Considerations

Before embarking on a project there are important ethical considerations for the action researcher. First, action researchers should be aware of the relevant requirements of their Institutional Review Boards (IRBs). Depending on university regulations, action research may be exempt from full IRB review or prohibited (Brydon-Miller & Greenwood, 2006; Stoecker, 2008). Since most action research focuses on human and social issues, researchers must follow the ethical rules and regulations required in human subjects research. Action researchers must remain "cognizant of the power and privilege we carry with us into our interactions with research participants" (Brydon-Miller & Greenwood, 2006, p. 125). Given its democratic nature, issues of coercion, power, and risk must be addressed by action researchers (Judah & Richardson, 2006) and important ethical principles for researchers should include "negotiation," "confidentiality," and "participants' control" (see Altrichter et al., 2008, pp. 154–155).

Data Collection

As in other forms of educational research, the research question determines the data collection methods used in action research. Action researchers conduct inquiry by collecting quantitative data and/or qualitative data. According to Glanz (1999), "In action research, we apply traditional research approaches (e.g. ethnographic, descriptive, quasi-experimental, and so forth) to real problems or issues faced by the practitioner" (p. 301). Ross and Morrison (2004) provide a useful description of experimental methods and Savenye & Robinson (2004) outline qualitative methods in educational technology research. Throughout the process of data collection, the action researcher analyzes the information gained, draws conclusions, and makes plans for change. Action researchers often triangulate, or collect multiple forms of data, to ensure their findings are meaningful, accurate, and credible (Hendricks, 2009).

According to Hendricks (2009), the methods of data collection in action research fall into three overarching categories: "artifacts, observational data, and inquiry data" (p. 81). Artifacts are items created by participants and usually fall within one of three subcategories: "student-generated," "teacher-generated," and "archived" (see Hendricks, 2009, p. 82). Observational data is generally collected in the form of field notes. Inquiry data is collected specifically to address the overarching research questions, often via interviews or questionnaires. In some instances these categories of data overlap, but, nonetheless, they provide a framework for delineating the various forms of data in the action research process.

Engaging students in action research

Engaging students in data collection provides both rich sources of information and insights about student experiences. Reflecting back on his study about high school drop-outs, Shager (2007) wrote, "They [students] brought a lot of knowledge to the project in the form of anecdotal information and personal experience; as they gathered more evidence, they built upon that knowledge" (p. 42). Rarely do teachers have explicit opportunities to learn from their students. However, the action research cycle provides a framework for engaging students in meaning making within the classroom. According to Lytle and Cochran-Smith (1994), "Researching teachers create classroom environments in which there are researching students" (p. 37). As a result of engaging students actively in the research process, teachers develop empathy and a new "mindfulness" (van Manen, 1990) towards their students. The combination of increased empathy and mindfulness leads teachers to be more responsive to their students. Often this results in changing teaching practices by incorporating more student-centered learning activities. According to Brause and Mayher (1991), "We [action researchers] increase our effectiveness as teachers because we are able to design and institute practices which are sensitive to the needs of our individual students (p. 208). The opportunity to learn from students leads teachers to consider new approaches to teaching that often allow for greater student engagement (Manfra, 2009b).

Keeping an action research journal

Action researchers may also include samples of their own work in their data archives, including lessons plans and other ancillary materials. The action researcher's journal or log is often an important source of more nuanced data, including perceptions about student outcomes and behaviors and written reflections about the data (Altrichter et al., 2008; McNiff & Whitehead, 2010). MacLean and Mohr (1999) advise teachers to keep a "research log"—a "systematic and organized" journal that "will include dates and times, careful quoting, observations and reflections" (p. 12) and "thinking writing" about data (p. 13). According to Strieb (1993) keeping a teaching journal provided her with an effective means for collecting and analyzing data. She wrote, "Keeping a journal has been a realistic way for me to learn about, inquire into, collect data about, and enhance my practice as well as to learn about and plan for the children" (in Cochran-Smith & Lytle, 1993, p. 121).

Triangulating data

In order to make their findings more accurate, action researchers collect a variety of data, from a variety of sources. For instance quantitative, archived data, including statistics, may be paired with qualitative data such as portfolios of student work. In her action research study on African American male student experiences, Nguyen (2007) relied heavily on archived data. She analyzed quantitative data including student enrollment figures, free and reduced lunch statistics, special education status, and achievement data from the district. She paired this data with student interview data to uncover those factors that supported or hindered student success in school. According to Mills (2011), "Observational data… can suggest questions that can be asked in subsequent interviews" and "pairing observation and interviewing provides a valuable way to gather complementary data" (p. 78). For example, Richards (2007) studied strategies to help English language learners (ELL) in her classroom by observing classroom interactions between students and recording revelations about her own teaching in her research journal. She used this data to develop follow-up interview questions for her ELL students. Again, the form and scope of the data collection methods will relate to the aims of the researcher and the overarching research questions. Throughout the process, action researchers engage in data analysis.

Data Analysis

Since action research is an iterative process, data collection and analysis occur continuously. According to Hendricks (2009) "This may mean altering an intervention plan, changing data collection strategies as the study progresses, or modifying the project timeline" (p. 121). Analytical strategies help the researcher make sense of the data and answer the overarching research questions. "Analyzing therefore involves looking at the data, taking account of your categories of analysis, and noting any emergent patterns within them" (McNiff & Whitehead, 2010, p. 175).

When action research studies include multiple types of data, the researcher needs to develop clear analytical strategies to compare and contrast across data and interpret findings (MacLean & Mohr, 1999) Analyzing quantitative data will often involve running statistical operations using software programs or creating charts or tables to illustrate data graphically (see also Ross & Morrison, 2004, p. 1029 for a detailed list of "common statistical analysis procedures used in educational technology research").

Qualitative data analysis can provide a rich description of the subject under study (see also Savenye & Robinson, 2004). To manage the amount of data, field notes and audio or video recordings should be transcribed into a workable format for data analysis. Then qualitative coding schemes should be developed to begin analyzing data and looking for patterns across the data (Glesne, 1999). A "constant-comparative" method (Glaser & Strauss, 1967) or other analytical methods may be used to refine the coding scheme and to make initial interpretations about the data. Data analysis is a complex process, involving multiple iterations. Once all of the data have been organized and analyzed, the action researcher is left with the final stage of implementation and reflection.

Implementation and Reflection

After data collection and analysis the action research cycle continues as the researcher reflects on the implications of the research findings. Glesne (1999) writes, "During the reflection phase, the data are interpreted and the multiple viewpoints are communicated and discussed among those with a stake (the stakeholders) in the process" (p. 13, parenthetical note in original). Throughout the process, the action researcher continuously reflects on and shares the findings (Kindon, Pain, & Kesby, 2007). According to McNiff and Whitehead (2010) action researchers should communicate their findings both within and outside of the workplace via conferences and publications. They write, "The purpose of sharing your work is so that people can learn from it and adopt or adapt your ideas to their own situations, in terms of subject matter as well as the enquiry processes involved" (p. 242). Sharing findings and making research reports available for peer review and critique is an important way action researchers "ensure quality and rigor" (Borko et al., 2008, p. 1031).

Action Research Groups

Action research groups provide support and guidance throughout the action research process and can be an important venue for sharing findings (MacLean & Mohr, 1999). Research groups help members refine research topics and data collection methods through meaningful conversations. "The group challenges each other's assumptions, proposes alternative interpretations, offers suggestions about research methodology, responds to drafts, and often lends personal as well as professional support" (p. 21).

There are numerous examples of large action research groups or networks working together to answer pressing, critical research questions (Cochran-Smith & Lytle, 1993; Mohr et al., 2004). The Madison Metropolitan School District (MMSD) has supported a school district-wide action research initiative focused on creating more equitable classrooms since 1990 (see Caro-Bruce, Flessner, Klehr, & Zeichner, 2007). All teachers and support staff in the district are invited to join action research groups focused on social justice and equity. The district has supported this initiative over the years by providing access to district data systems, leadership development, and professional development. As a result of the collective work of numerous teachers and staff in MMSD, action research has supported the "empowerment of students from diverse backgrounds" (p. 290) and "engagement through culturally relevant practice" (p. 291). The pervading notion in the district is that action research could contribute to research-based understandings regarding equity. Other examples of large teacher research groups include the Physics Teachers Action Research Group in San Francisco (see Feldman, 1993, 1996) and the Classroom Action Research Network (see Cochran-Smith & Lytle, 1993; Hollingsworth, 1994). These collaborative groups support the collective professional development of member researchers and the development of professional learning communities.

Large scale action research collaboratives often include university researchers. Cornelissen, vanSwet, Deijaard, and Bergen (2010) describe school-university research networks in which the "relationships in the research partnership can be collaborative with a high degree of mutual engagement; the research agendas, methods and outcomes are negotiated and collective research activities are undertaken" (p. 148). For example, a collaborative effort in Philadelphia, PhilWP, has been focusing on studying issues affecting urban youth for many years (Lytle, Portnoy, Waff, & Buckley, 2009). The project began as a Writing Project partnership between faculty at the University of Philadelphia and teachers in the Philadelphia school district. PhilWP has had numerous iterations including "'inquiry communities'—single school, across-school, and across-district groups" (p. 26). Action research collaboratives that include university researchers also often engage in participatory action research or community based research.

Participatory Action Research

Participatory action research (PAR) differs from the previously described classroom-based action research because it is "a social, collaborative process" (Hendricks, 2009) that aims to "change practices, social structures, and social media which maintain irrationality, injustice and unsatisfying forms of existence" (McTaggart, 1997, cited in Reason & Bradbury, 2006, p. 1). In PAR the researcher is both a researcher and activist—"collaborating with marginalised or 'vulnerable' others" (Kindon et al., 2007, p. 11). PAR alludes to the work of Brazilian educator, Freire (1972), who used a problem posing method to teach adult literacy and bring about "praxis". There are more direct links in parts of the world where participatory action research is used to improve adult education and empower the working poor. For instance, McTaggart (1991a) investigated Aboriginal education by transferring control of the research process to the "researched." According to Kindon et al. (2007) "The most common methods used in PAR focus on dialogue, storytelling, and collective action" (p. 16). Participatory action research projects involve the subjects of study actively throughout the research process (Kemmis & McTaggart, 2005).

Results of Action

Regardless of the aims, methods, or processes undertaken, action research is intended to bring about change—mainly changing and improving some aspect of practice. Johnston (2005) writes, "The distinguishing characteristic of action research, however, is its focus on *action*…. The action is intended to create change for the better and the study is intended to find out if it does" (emphasis in original, p. 60). Emancipatory action research may result in larger social change, such as bringing about more democratic classrooms and institutions. The potential benefits cited by proponents of action research include: alleviating the gap between theory and practice (Brause & Mayher, 1991; Lytle & Cochran-Smith, 1994; Richardson, 1994; Zeichner, 1994); enhancing teacher education (Cochran-Smith & Lytle, 1993; Levin and Rock, 2003; Price, 2001; Price & Valli, 2005); improving teacher professional development (Alan & Miller, 1990; MacLean & Mohr, 1999; Mohr et al., 2004); improving student learning (Falk and Blumenreich, 2005); affirming and empowering teachers (Falk & Blumenreich, 2005; Mohr et al., 2004); reforming education (Brause & Mayher, 1991); and changing society (Carr & Kemmis, 1986; Grundy, 1997; Johnston, 2005; McTaggart, 1991a).

Educational Technology and Action Research

There are numerous ways that action research can support the goals of the field of educational communications and technology, including improving pre-service and in-service teacher professional development and university-based teaching that integrates technology. At the same time technology can enhance and improve the work of action researchers by supporting new forms of data collection, facilitating the work of action research groups, and providing tools for training pre and in-service teachers on action research methodology (McNiff & Whitehead, 2010). Technology can be both the focus and part of the method of the action research.

Improving Technology Integration

Action research has been used to study the integration of technology in classrooms and schools. A typical model involves university researchers engaging and supporting pre-service and in-service practitioners as they systematically study technology integration (e.g., Cavanaugh & Dawson, 2008; Dawson, 2007; Dawson, Cavanaugh, & Ritzhaupt, 2008). For example, Dawson (2007) reported the professional development outcomes when pre-service teachers collected and analyzed qualitative data during their field experiences. She concluded, "The results of this exploratory study suggest that when prospective teachers are supported through the inquiry process during technology integration, student learning comes to the forefront" (p. 10). In a similar study Cavanaugh et al. (2007) integrated action research into the professional development of Florida teachers using laptops in instruction. Their findings reported on the value of the action research process for improving teacher understandings about technology and instruction.

Action Research and TPACK

Action research appears to be a particularly promising method for studying and improving technological pedagogical content knowledge (TPACK, Mishra & Koehler, 2006). TPACK expands on Shulman's (1987) notion of "pedagogical content knowledge" (PCK) by adding technological knowledge. According to Harris and Hofer (2009), "TPACK can be developed when educational technologies become one of the foci of teachers' reflective action research" (p. 100). Arizona State University has integrated action research into the work of a cohort of doctoral students including administrators, teachers, and other educational personnel. "Using action research as a model for change, TPACK is integrated throughout the action research process and grounded in the unique needs of each candidate's site (Cunningham et al., 2011, n.p.). Similarly Hechter and Phyfe (2011) engaged science teachers in action research studies exploring the facility of lessons that reside in the "space between" each of the TPACK elements—"technological pedagogical knowledge," "technological science content knowledge," and "pedagogical science content knowledge" (p. 4115). Across these studies action research appeared to be an effective means for improving TPACK (Pierson, 2008).

Investigating Technology Education Courses

University based researchers have also used action research to study the effectiveness of their own teaching about the use of digital technologies. For example, over several years a group of teacher educators collected data on the Innovations Mini-Teach project (see Foulger & Williams, 2007; Foulger, Williams, & Wetzel, 2008; Wetzel, Foulger, & Williams, 2008–2009; Williams, Foulger, & Wetzel, 2009). The Mini-Teach project was designed to help pre-service teachers investigate numerous technologies for possible integration in classroom instruction. "Instructor researchers sought to investigate the process, perceptions, and outcomes of students after their experience with the *Innovations Mini-Teach* project" (Foulger et al., p. 31). In order to investigate whether the Mini-Teach project was effective the "instructor researchers" collected data including the culminating wiki projects, focus group interviews, and questionnaires. The authors reported: "Based on their analysis of student voices, the instructors concluded that students gained high levels of expertise with their assigned innovation and became familiar with the range of innovations covered by their classmates and archived in the class wiki" (p. 36). In this case, action research proved to be a particularly robust method for investigating the affordances and limitations of a particular method of instruction on technology integration.

Participatory Action Research and Technology Integration

New computer-based technologies can facilitate participatory action research (PAR) and group action. According to Kindon et al. (2007) technology tools have been integrated into the PAR process as the focus of study as well as to help collect data and convey findings. For instance, Elwood et al. (2007) led a participatory geographic information system (PGIS) project that involved university based researchers and community organizations in using GIS to impact community planning and development. They focused on critical issues such as affordable housing and crime prevention. Other PAR projects have investigated the integration of technology to bring about change in marginalized communities. For example, PAR was conducted collaboratively by university-based IT specialists and social service providers in Taipei, Taiwain to determine the most effective approaches to integrating technology (Chang, Liao, Wang, & Chang, 2010). Another PAR study, "The Pocket School," investigated the use of "a mobile learning model of literacy development for underserved migrant indigenous children in Latin America" (Kim, 2009, p. 415) and involved multiple researchers and stakeholders. These selected examples provide a snapshot of the myriad ways technology has increasingly entered into PAR as an important tool for both facilitating the action research method and as the focus of the research.

Technology-Rich Instruction About Action Research

Emerging technologies and social media have also positively impacted the instruction of action research (see Carroll, Jenkins, Woodward, Kop, & Jenkins, 2012). Perhaps the usefulness of technology to facilitate action research is most obvious in online and hybrid action research courses (Ostorga, 2010). Increasingly university instructors and academic programs are supporting the methodological instruction of future action researchers in technology rich environments. Due in part to increasingly affordable access to technology and the individualized nature of action research projects, action research methods courses seem to be effectively taught and supported at a distance.

Technology and Action Research Networks

Computer based technology also facilitates the work of action research networks, including disseminating research results. Action researchers increasingly use multimedia to share their findings (McNiff & Whitehead, 2010). At the same time, technology supports the collaboration of action researchers by engaging researchers at a distance. According to Cochran-Smith and Lytle (2009) technology has "enabled new inquiry communities to form and communicate on-line" (p. 22). Notable examples include the Bread Loaf Network (see Lewis, Guerrero, Makikana, & Armstrong, 2002), the Carnegie Foundation's CASTL Program for K-12 teachers/teacher educators (see also Hatch 2006, Hatch & Shulman, 2005), and the Collaborative Action Research Network (CARN). According to Cochran-Smith & Lytle (2009) emerging technologies have "spawned innovative uses of technology for sharing inquiries and classroom practices with audiences" (p. 22).

Conclusion

Action research is a complex, cyclical process that systematizes reflection in action. The history of action research and current variations of the methodology reflect divergent views about practical or critical action research. Hopefully proponents of both forms of action research will begin to look across their differences to recognize the suitability of action research to answer a variety of questions in educational research.

The variability in method may actually better serve the field of educational communications and technology where paradigm debates continue to arise (Savenye & Robinson, 2004). Action research can be used to answer myriad educational research questions. It can serve as the methodology of doctoral dissertations, guide the framework of professional development initiatives that focus on technology integration, and address larger social issues. Action research provides exciting opportunities to engage stakeholders in constructing new understandings about education and technology integration and to transform our field. Technology can both facilitate the action research process and serve as the subject of study.

Trends and Issues in Qualitative Research Methods

15

Marcia A. Mardis, Ellen S. Hoffman, and Peter J. Rich

Abstract

In the almost two decades since the first AECT *Handbook* article on qualitative research debates about research philosophy, design, and purposes have led to clashes of opinion in the field of educational communications and technology as well as in the larger sphere of educational research. At the same time, the number of publications on qualitative methods specific to the field has increased, expanding the understanding of the potential of such approaches to explore, describe, and explicate key issues in instructional design and the application of technology to learning. While other chapters have included examples of qualitative studies related to specific disciplinary topics, this chapter focuses on trends in the use of qualitative research design and emerging approaches more generally. Within this framework, issues of design, methods, and knowledge generation are reviewed and examined through a sample of recent directions in qualitative studies and designs. For each method reviewed, examples are provided along with common issues and potential directions for future use of these.

Keywords

Qualitative research • Interpretive tradition • Case study • Ethnography • Discourse analysis • Cooperative inquiry • Grounded theory • Research quality

Introduction

In the almost two decades since publication of the first article in the AECT *Handbook* on qualitative research (Savenye & Robinson, 1996), debates about research philosophy, design, and purposes have led to clashes of opinion in the field of educational communications and technology (ECT) as well as in the larger sphere of educational research. At the same time, the number of published ECT studies using qualitative methods increased, expanding the potential of such approaches to explore, describe, and explicate key issues in instructional design and the application of technology to learning.

While other chapters have included examples of qualitative studies related to specific disciplinary topics, this chapter focuses on qualitative approaches more generally.

Within the qualitative framework, issues of design, methods, and knowledge generation are examined. In this chapter, we will

- Explore definitions of qualitative research.
- Provide a framework for discussing various qualitative traditions and methods that have been applied in ECT research.
- Describe some key methods briefly, providing a sample of recent studies that are representative of the approach.
- Review current issues in application and implications for the future of qualitative research approaches.

We should preface the chapter with what is not covered. The chapter is not intended to be a general introduction to qualitative research which is covered in multiple textbooks, but rather is a brief review of current application and issues in qualitative methods within the field of educational communications and technology. Because the scope of qualitative research is beyond a single chapter, our intent is to lead the reader to other authoritative sources for more detailed reviews and explanations.

In this review, the authors focus on methodological strategies and their related data collection and analysis methods that are typically classified as qualitative in scope rather than on the epistemological or political debates that have emerged over several decades. Following Denzin and Lincoln (2008), we recognize that all research is political and implies value judgments about purpose and the warrant of knowledge. We propose that our descriptive approach allows us to present an overview of trends in ECT empirical studies that does not privilege a particular stance in the continuing debate over educational research methods. We also point to the separate chapter in the *Handbook* on the use of technology in qualitative research (Chap. 20), noting that we understand the importance of this topic but have limited our discussion in this review.

The Issue of Terminology: What Is Qualitative Research?

In developing this chapter, a central issue that arises concerns the definition of *qualitative research*. A number of authors have attempted to delineate the scope covered by this concept. To date, no commonly accepted terminology for defining or describing "qualitative" has come into common usage in educational research or more widely in social research.

At one level, qualitative research has been defined in the negative; it is understood to mean systematic social and behavioral research studies that are *not* quantitative (numerical and statistical) in character. Qualitative research more typically is portrayed as focusing on language and meaning, individual perspectives and beliefs, discourse and social interaction, and emergent group processes and culture. Studies tend to be in naturalistic settings involving direct researcher interaction with participants or derived from primary sources and artifacts. It is usually described as an approach to best answer what and how questions, providing rich descriptions to explore and understand complex, multilayered, and multicausal social perspectives and dynamics.

Table 15.1 Levels of qualitative research

Level	Some examples
Methods: Data level	Collection methods: interview, observation, focus group Analysis methods: discourse analysis, thematic coding, categorical analysis
Methodology: Design level	Phenomenology, narrative, ethnography, case study
Theoretical or conceptual level	Feminist theory, ecological theory, activity theory, grounded theory[a]
Epistemological level	Post-positivist, post-modern, constructivist, interpretivist, connectivist, critical

[a]Grounded theory has elements of both methods and theory which are discussed in more detail below

Terminology and Levels of Qualitative Analysis

The term "qualitative research" is used in a variety of ways that are not equivalent, a fact that is particularly confusing to novice researchers. In fact, the terms method, methodology, tradition, framework, and paradigm are not applied consistently from one author to another.

At one level, the discussion of qualitative research focuses on the philosophy and worldview of the researcher and research community, often under the topic of epistemology and ontology. Such discussions applied to qualitative research relate to beliefs about the nature of knowledge and truth statements; the approaches that are brought to interpretation of empirical data; and the relative importance of social equity and change in research purposes. Intense debates arising in the 1980s, commonly referred to as the "paradigm wars," and continuing into the present, focus on epistemological issues, describing qualitative research by such terms as post-positivist, post-modern, constructivist, interpretivist, or critical.

At another level, the qualitative label applies to what may be called methodological strategies or traditions typically associated with research design, such as phenomenology, grounded theory, qualitative case study, narrative research, or ethnography. At a more pragmatic level, the qualitative descriptor is applied to particular methods of collecting and analyzing data, such as interviews, observation, thematic coding, or narrative analysis.

This difference in levels in qualitative research is summarized in Table 15.1. The table generally provides the terminology as we are using it in this chapter, with the recognition that other authors use different classification schemes. As we will show, the boundaries between some of these levels and the overlapping use of specific terms is actually more complex than a simplified table can show.

Qualitative Versus Quantitative Research: A Slippery Divide

In practice, qualitative research is not neatly bounded, nor is there a clear dichotomy between qualitative and quantitative (Ercikan & Roth, 2006). While the paradigm wars between those strongly advocating differing research traditions suggested the incompatibility of quantitative and qualitative approaches, literature in the past decade appears to increasingly acknowledge the artificiality of the divide. Twining (2010) suggests that the degree to which quantitative and qualitative approaches are considered complementary is dependent on the level at which one is looking. Some vocal proponents of the qualitative tradition such as Denzin and Lincoln (2008) continue to champion the need for a highly distinct qualitative discipline essential to the advancement of a critical focus and in recognition of the subjectivity of language and meaning. Yet they acknowledge that at the level of practice, qualitative researchers may use statistical methods or alternatively, approaches that are more literary than systematic.

Symonds and Gorard (2010) show that there is no one-to-one correspondence between types of data collection and analysis to the qualitative or quantitative paradigms, while all methods have inherent strengths and weaknesses in terms of validity. In any given research study, qualitative methods and strategies may be mixed and matched to meet the demands of the research setting, the research questions of interest, the personal characteristics and history of the individual researchers, and the accepted norms of a scholarly community (Bryman, 2008; Greene, 2008; Haggis, 2008; Maxwell, 2010; Willis, 2008). The real-world complexity of social research practice eludes simple classification schemes or tightly bounded definitions for qualitative research. As Gorard and Smith (2006) note, "qualitative or quantitative represents only one, perhaps not very useful, way of classifying methods" (p. 61), yet it remains a currently accepted way to examine as well as teach differing research approaches.

The Tradition of Qualitative Research in Educational Studies and ECT

The expansion of qualitative approaches has long historical roots that precede the formalization of ECT as a scholarly discipline (Denzin & Lincoln, 2008; Fielding, 2005). Initial practices from the early 1900s of field studies in anthropology and sociology were increasingly incorporated into a larger research tradition labeled "qualitative," promoting the expansion of more naturalistic, interpretive, and critical research methods. Linking social sciences and the humanities and following a post-positivist critique of the rational, technical and scientific paradigm of progress, new views of research were explored that promoted pluralism, emergence, deconstruction, contextualism, and criticism as themes of inquiry beginning in the 1960s (Solomon, 2000).

The outcome of these expanded views of research within education was a more nuanced examination of teaching, learning, organizational structures, and change along with expanded tools and methods for research (Willis, 2008). In reviewing the history of qualitative approaches, Denzin and Lincoln (2008) note that each stage in the development of qualitative research has been additive in terms of designs and methods. This has led to an "embarrassment of choices" (p. 27) for qualitative researchers and continuing debate about the purposes and processes of social research. Further, they indicate that qualitative traditions continue to vary nationally and culturally, pointing to diverse strands such as:

> the British tradition and its presence in other national contexts; the American pragmatic, naturalistic, and interpretive traditions in sociology, anthropology, communications, and education; the German and French phenomenological, hermeneutic, semiotic, Marxist, structural and post-structural perspectives; feminist studies, African American studies, Latino studies, queer studies, studies of indigenous and aboriginal cultures. The politics of qualitative research creates a tension that informs each of these traditions. (p. 13)

Usage Studies of Qualitative Methods in ECT Scholarship

The diversity of approaches and tensions among qualitative traditions is equally applicable to ECT and, as this review will suggest, not all qualitative methods and methodologies are equally represented. Despite active exploration of new qualitative approaches in the past decade, quantitative studies appear to continue to predominate in major ECT journals, particularly in the USA (Axtell, Chaffing, Aberasturi, Paone, & Maddux, 2007; Hrastinski & Keller, 2007). In a survey of articles from a single journal covering 2006–2008, the researchers found 58 % of the articles using descriptive research designs, including qualitative studies as well as case studies, developmental research, formative evaluation, observation, and surveys; an earlier study of articles prior to 2001 showed a predominance of experimental designs (Ross, Morrison, & Lowther, 2010). Using a different classification scheme including a focus on methods, Hew, Kale, and Kim (2007) found that qualitative data collection methods were common in published empirical research articles, with 94 including interviews, 82 observation, and 121 content analyses out of 340 articles in three ECT journals from 2000 to 2004.

Randolph, Julnes, and Sutinen (2009) in a content review of computer education journal articles, noted that North American authors were less likely to publish qualitative research studies than those in Europe and the Middle East in both computer education and other educational fields. In a similar finding resulting from a study of ECT journals and

Table 15.2 Types of qualitative research

Research focus	Types of qualitative research[a]	Role of researcher
Individual and perceptions	Phenomenology Narrative Biography	Typically external, privileges the individual(s) being studied but may be empathetic
	Hermeneutic phenomenology Autoethnography Autobiography	Insider or shared perspective
Social interaction and group behavior	Discourse analysis Conversation analysis Computer-mediated discourse analysis	Strongly objective examination of language process and structure
	Cooperative inquiry Participative action research Practitioner action research	Insider view of participants, shared inquiry
	Ethnography Virtual ethnography Case study[a]	Objective approach common although researcher may be an insider to the group studied
Behavioral representations (Human "artifacts")	Qualitative content analysis Visual ethnography	Objective observer, often retrospective

[a]Case studies are commonly seen as intensive study of a group or groups, but the broader definition sometimes used includes intensive study of a single person who typifies a group or phenomenon

conference papers in New Zealand beginning in 1994 (Williamson, Nodder, & Baker, 2001), half were qualitative. Qualitative research can be seen as an important although nondominant element in ECT studies with distinct regional variations.

No formal analytical studies have been published to date reviewing the prevalence of qualitative methodological traditions such as case study, ethnography, phenomenology, etc., in studies published within ECT journals. In the absence of any quantitative basis for selection of studies, this article provides a snapshot approach in terms of sampling to show a range of high quality and emerging qualitative research in ECT.

A Classification of Qualitative Methodologies

In the following sections of this chapter, we explore some of the methodologies in greater depth. We offer a framework for grouping qualitative methodologies that is unique to this chapter, but we think offers one way of looking at qualitative studies that helps researchers see relationships of methods and methodology, as well as the centrality of purpose in research design. Table 15.2 lays out the framework we have used in organizing our discussion. Some of these methodologies are reviewed in more depth, reflecting their more common use in ECT or what appears to be an emerging trend of inquiry.

Interpreting Individual Experience

The study of experience has led researchers to seek out ways to describe an individual's interpretation of a certain event or phenomenon, often from the participant's point of view. In the *interpretive tradition* in ECT research, understanding individual experience is as paramount as learning. While learning is socially and contextually mediated, it is ultimately an individual endeavor (Barg, Gollwitzer, & Oettingen, 2010; Brown, Collins, & Duguid, 1989).

Interpretivistic approaches offer personal, often imperfect descriptions of human cognition (Bengston & Marshik, 2007), behavior (Sutin & Gillath, 2009), emotion (Frie, 2010), or interrelations (Schönpflug, 2008). Perception therefore becomes as important as, if not more important than, an agreed-upon reality. As demonstrated by the Pygmalion effect (Rosenthal & Jacobson, 1992), the way people interpret the world often affects the way they interact with and ultimately act on it and other individuals. Thus, interpretivistic methods seek to understand the individual's interpretation of experience without imposing the researcher's own interpretations of such events. Researchers acknowledge potential influence on interpreting others' interpretation of their own experience by bracketing their own subjectivities (Tufford & Newman, 2010), or by embracing them through a hermeneutical (Van Manen, 1995) or autoethnographical rendering of accounts.

Interpretivistic research tends to describe experience from three different perspectives: (1) the individual, (2) the researcher, or (3) the experience itself. These are each discussed in more detail.

Research Focus on the Individual

The individual may best be understood through *narrative analysis* (Clandinin, 2007) or *phenomenographic* methods (Marton & Booth, 1997).

Narrative analysis methods recreate the participant's view of experience by piecing together snippets of oral or written accounts of experience into stories of lived experience (Clandinin, Pushor, & Orr, 2007), portraying events in the words of the participant wherever possible. The product of narrative analysis is a story that may be expressed as a case, a life history, or a biography constructed from the data collected. These narratives are dependent on the audience to which one is telling the event (Langellier, 2003) and the speaker's relationships to this audience (Cortazzi, 1993).

Narratives may even change with the proximity to or distance from the occurrence of the event (Gergen, 2004). Clandinin et al. (2007) proposed that narrative inquiry has been employed in educational contexts to better understand temporal conditions, social interactions, and spatial influences. Recently, researchers have used narrative analysis to understand the second-grade experience of English-language learners (Brown, 2009), the differing accounts of online learners (Coryell & Clark, 2009), educational policy (Craig, 2009), and international influences on learning (Liang & Lin, 2008).

While also attempting to demonstrate individual interpretation of events, *phenomenographical approaches* seek to understand the breadth of variety of human experiences surrounding an event, process, entity, or effect (Marton & Booth, 1997). That is, these studies' findings explore the many different ways one might experience and interpret the event. Phenomenographical researchers emphasize that they do not describe the primary experience itself, but instead seek to illuminate a second order account (Bowden, 2005). Because the focus of phenomenography is on variation of experience, most phenomenographic studies involve a larger number of participants than many qualitative studies. Studies often include at least 15 participants to get sufficient variation (Trigwell, 2006), although it is possible for a single participant to experience a range of the possible variations (Åkerlind, 2008). Recent educational studies have used phenomenography to understand issues surrounding higher education, such as academics' conception of teaching and learning (Åkerlind, 2007); graduate students' understanding of research (Bruce, Stoodley, & Pham, 2009); general graduate student attributes (Barrie, 2006); professors' perception of the use of e-learning in the classroom (Gonzalez, 2010); and how individuals interact with technological artifacts (Collier-Reed, Case, & Linder, 2009).

Sharing Voices: Researcher, Participants, and Readers

Some interpretivist methods recognize that it is impossible to separate the researcher's own biases from the retelling of another's accounts. Researchers who adhere to this philosophy seek to include their own voices as part of the interpretation of events, often through a *hermeneutic phenomenology* (Van Manen, 1995) or even by describing themselves as learners (Fox, 2008).

Autoethnographic accounts offer a unique window into experience because the researcher is not constrained to be either a researcher or a participant, but rather can embrace that duality, offering greater reflexivity than is possible in other methods that only stimulate reflexivity through secondary means such as interviews and surveys (Anderson, 2006). The work by Magdalene Lampert (2001) to study student thinking in her own fifth-grade mathematics classroom provides a valuable example of the detail and insight that might be gained through autoethnographies. Autoethnographic methods have been employed to understand the role of language in a child's education (Souto-Manning, 2006); to examine the quality of software (McBride, 2008); and to reflect on how to teach qualitative research methods (Humphreys, 2006).

The Personal Experience

Rather than a focus on the individual or the researcher, *phenomenology* and an *analysis of narratives* provide ways for researchers to attempt to describe the essence of an experience itself.

By focusing on the lived experience of an individual (Van Manen, 1995), *phenomenology* seeks to enable readers to better understand and feel what the participant may have felt in the way s/he may have felt it. Whereas phenomenographic methods seek variation (Marton & Booth, 1997), phenomenology looks for commonalities among participants that help describe the shared or lived experience. "Phenomenological analysis becomes a tool for investigating what occurs outside awareness" (Schwartzman, 2007, p. 210). In order to draw out this awareness, researchers conduct in-depth, searching interviews in hopes of making participants aware of that which occurred but they may not have explicitly noticed previously (Seidman, 1998). Recent phenomenological research in education has investigated student attitudes in learning to design software (Schwartzman, 2007); the way a teacher engaged students' authentic learning contexts (Miller, Veletsianos, & Doering, 2008); student perceptions of academic success and failure (Forsyth, Story, Kelley, & McMillan, 2009); perceptions of students with disabilities in higher education (Denhart, 2008); and participants in social networks (Corwin & Cintrón, 2011).

The goal of *analysis of narrative* research is to interpret story elements or structure as opposed to that of narrative analysis, which is to produce rich narratives in the participants' own voices (Crawford, Brown, & Majomi, 2008). An analysis of narratives might present a series of themes, categories, and subcategories, possibly resulting in quantitative counts or statistical comparisons (Møller, Theuns, Erstad, & Bernheim, 2008). Langellier (2003) suggested that an analysis of narratives allows the researcher to focus not only on the content of a participant's story, but on the way it is told. This *performativity* reveals important characteristics of the participant as well as his/her assumptions about the story's audience and what is important for them to hear. Thus, researchers using an analysis of narratives may seek differing accounts of the same event (Pacheco, 2010). Through an analysis of narratives, researchers have been able to demonstrate the importance of education as an exit strategy (Crawford et al., 2008); the effect of policy on English-language learners' academic achievement (Pacheco, 2010); and social change over a lifetime (Sliwa, 2009).

Issues and Trends in Interpretivist Approaches

Despite benefits including close attention to participant perspective and usefulness in approaching a range of research questions, many issues exist in interpretivist work in general and within ECT more specifically. First, despite well-established guidelines by experts in narrative analysis (Clandinin, 2007), phenomenology (Moustakas, 1994; Van Manen, 1995), autoethnography (Ellis & Bochner, 2000), and analysis of narratives (Rymes, 2001), there does not appear to be any continuity amongst the specific procedures researchers follow to employ such methods. Phenomenographic research stands in stark contrast, as most such research relies on methods detailed by Marton and Booth (1997) or other key phenomenographers.

This lack of continuity in many of the described approaches makes it challenging to understand exactly how to apply interpretivist methods to analyze and present research. This problem may further complicate the utility of such research because "research on learning…demonstrates that novices and advanced beginners in any craft…rely heavily on rule-based structures to learn" (Tracy, 2010, p. 838). Thus, it is less likely that qualitative researchers in ECT will engage in interpretivist research, instead applying more well-outlined methods or generic *open-coding* schemes (e.g., Corbin & Strauss, 2008; Spradley, 1980). Exacerbating the problem is that many of these approaches are often used in tandem with each other in the same study without the researchers' acknowledging their potentially conflicting assumptions and processes. While narrative and autoethnographic traditions are commonly employed together successfully (Pacheco, 2010), open-coding and phenomenology are combined under the guise of *case study* along with multiple other qualitative approaches (see below). It is interesting to note that many of the interpretive approaches addressed in this section share the customary method of collecting data, semi-structured interviews, to make them appear more compatible. Though the interview is one of the qualitative researcher's most important tools, relying on it as the sole tool for data collection has inherent limitations and weakens the researcher's ability to strengthen credibility through triangulation (Denzin & Lincoln, 2003; Kvale & Brinkmann, 2009).

Of lesser methodological importance, but of note nonetheless, is the fact that interpretivistic work seems to be gaining ground in Europe (Hallett, 2010; Ingerman, Linder, & Marshall, 2009; Virtanen & Lindblom-Ylänne, 2010), Asia (Yang, 2008), Oceania (Stein, Shephard, & Harris, 2011), Latin America (Gonzalez, 2010), Africa (Collier-Reed et al., 2009) and Canada (Fox, 2008; Lyle, 2009) but is underrepresented in ECT research in North American contexts (Cilesiz, 2011). By contrast, qualitative research published in North American journals tends to be heavily centered on open coding techniques and case studies.

Communication and the Social Group

The study of naturally occurring conversation, face-to-face or online dialogue not mediated by the researcher, is typically initiated using qualitative methods but final analysis may be qualitative or quantitative. Growing interest in discourse practices within ECT research has been propelled by shifting paradigms such as constructivism, situated learning, and communities of practice that emphasize the social nature of learning. Also impacting expansion in use are communication technology developments such as the expansion of ubiquitous social media and distance learning (Maddux & Johnson, 2009). Recent thinking in *connectivism* premised on the networking of knowledge is promoting a renewed look at the nature of discourse (Ravenscroft, 2011).

Types and Processes of Qualitative Analyses of Language Interactions

The primary approaches that underlie discourse-related research were developed in other disciplines including communications, linguistics, and psychology. Language-focused forms of content analysis are most commonly identified by the process of analysis rather than by a single overarching methodological name (Hammersley, 2003; Leech & Onwuegbuzie, 2008). ECT journal articles often refer to empirical research studies of discussion as *discourse analysis*, whether at the level of meaning or centered on group communication interactions. However, discourse analysis as initially developed in linguistics is a narrower, highly formalized approach applied to the study of meaning and context of words (Hammersley, 2008). The related study of formal conversation procedures known as *conversation analysis* is another way of understanding talk-in-action growing out of the larger research framework of *ethnomethodology* (Hammersley, 2003, 2008). Research purposes may emphasize understanding of content, structure, interaction patterns, participation, or social presence (Herring, 2004b), with authority and power being of particular interest in critical theory approaches such as *critical discourse analysis* (Wodak & Meyer, 2009).

Analysis of online discourse occurs in the areas of *computer-mediated communication* (CMC), *computer-supported* *collaborative learning* (CSCL), and *computer-mediated discourse analysis* (CMD/CMDA) as well as in gamer interactions (De Wever, Schellens, Valcke, & Van Keer, 2006; Jeong & Hmelo-Silver, 2010). While existing studies have focused on human-to-human dialogue, an emerging area is analysis of conversation with non-animate agent technologies in support of learning (see this volume, Chap. 20).

From Live Conversations to Online Discourse

Historically, naturally occurring talk was one form of collecting data in field observational studies such as anthropology and sociology (Moerman, 1988), continuing into the present with some recent suggestions for using field notes to record the talk of students in teacher action research (Dana & Yendol-Hoppey, 2009). Focus on conversation was spurred by audiovisual and later digital methods of capturing talk in detail, with intensified focus on theory and methods of analysis since the late 1990s (Evers, 2011; Hammersley, 2008; Rostvall & West, 2005).

With the growth of digital communications for human messaging, discourse analysis began to be applied to electronic discussions. Although there is a recognition that face-to-face and online conversations differ in many ways, the analysis of either follows similar steps once spoken conversations have been converted to text (Davidson, 2009; Hammersley, 2010; Rostvall & West, 2005); computer and online discussions have the advantage of not requiring transcription.

Methods in Analyzing Discourse

In *conversation analysis*, transcripts are examined for evidence of the procedures by which speakers produce utterances and make mutual meaning of ordinary talk, with particular attention to turn taking and sequences of action (Wooffitt, 2005). In all forms of conversational *discourse analysis*, content is "chunked" into meaningful units which may be counted and analyzed statistically or classified thematically in relation to a study's purpose and research questions (Gee, 2011). As Herring (2004a) notes, using discourse analysis methods requires precision and understanding of its techniques, with attention to conventions and limitations.

> As with other forms of content analysis, the CMDA researcher must meet certain basic requirements in order to conduct a successful (i.e., valid, coherent, convincing) analysis. She must pose a research question that is in principle answerable. She must select methods that address the research question, and apply them to a sufficient and appropriate corpus of data. If a "coding and counting" approach is taken, she must operationalize the phenomena to be coded, create coding categories, and establish their reliability, for example, by getting multiple raters to agree on how they should be applied to a sample of the data. If statistical methods of analysis are to be used, appropriate statistical tests must be identified and applied. Finally, the findings must be interpreted responsibly and in relation to the original research question. (p. 343)

Applications in ECT

Early studies using conversation and discourse analysis in ECT focused on face-to-face classroom student interaction while using computers (Dalton, Hannafin, & Hooper, 1989; Wegerif, Mercer, & Dawes, 1998). Classroom studies of interaction continue, particularly in science and mathematics education (Warwick, Mercer, Kershner, & Staarman, 2010). The importance of teacher–student and student–student interactions are key in several major recommended frameworks in the study of teaching and learning (Ball & Forzani, 2007; Hirumi, 2009; Rovai, 2007), providing a major impetus to discourse studies in natural classroom settings. Qualitative studies of communication have also been used in understanding team interaction and processes in design (Duncan, 2010; Games, 2010; Pan & Thompson, 2009).

Increasingly, many of the current ECT research studies come from examination of interaction in e-learning and online professional development (Clarke, 2009; Donnelly, 2010; Kim & Bateman, 2010; Ng'ambi, 2008; Soter et al., 2008; Zhang, Scardamalia, Lamon, Messina, & Reeve, 2007). While most studies of online discussion rely on methods of discourse analysis or procedures developed in CMC studies, Gibson (2009) applied classic concepts from conversation analysis in his study of an asynchronous postgraduate reading group.

Trends and Issues in Discourse Studies

A number of issues arise around qualitative discourse studies in ECT (Valcke & Martens, 2006). Discourse analysis, conversation analysis, and methods of CMC/CSCL/CMDA are covered by few introductory education or general social qualitative research methods textbooks, in which emphasis is on naturalistic field research and participant–researcher interaction such as interviews. As with interpretivist methodologies covered in the earlier part of this chapter, limited guidelines to help novice researchers may result in decreased or weak applications of discourse analysis in ECT studies. However, as conversation-based approaches grow in popularity, new textbooks are beginning to appear that may help beginners with differentiating the methods (e.g., Wertz et al., 2011).

While the focus within ECT has been primarily discourse analysis relating to discussion and language interaction for learning, finding appropriate theoretical and methodological frameworks can be challenging without a clear recognition of the variation among studies with the common label of discourse studies but very different purposes. The issues of methodology are confounded because *discourse analysis* is not congruent among scholarly disciplines. The term *discourse* is applicable to all aspects of human use of language to communicate. Thus, the study of human language production ranges from a very specialized interpretation with statistical analysis of word usage, sequence, and context in linguistics to the study of policy "discourse" in public documents or candidate speeches in political science. Discourse study also emerges in the humanities in studying literature, often from a critical perspective. In more literary approaches to discourse studies, interpretivist approaches such as those in the previous section may predominate.

The diversity in approaches and lack of a common vocabulary for these studies presents a challenge to those in ECT attempting to apply conversation or discourse analysis without a strong background in the disciplines from which the methods emerged. Reflecting general concerns raised in the broader arena of discourse analysis, ECT studies may lack grounding in earlier research; fail to acknowledge emerging critiques and limitations; and be confounded by imprecise and overlapping terminology (Antaki, Billig, Edwards, & Potter, 2003; Hammersley, 2008). Each variant of discourse analysis has unique processes for transcription, coding, classification, interpretation, and validity (Herring, 2008). Silverman (2006) argued that lack of theory and over-reliance on general thematic analysis of talk in many studies results in weak common sense or normative reinterpretations in the results of poorly designed studies. Others have raised concerns relating to the relationship of communication patterns to effective learning and teaching, with critics urging increased attention to studies that go beyond description of interaction among social groups to more development of theory and use of frameworks related to learning (Dennen, 2008; Naidu & Järvelä, 2006; Spatariu, Quinn, & Hartley, 2007).

Beyond terminology and critiques of application, a number of challenges in such studies relate to discourse interactional process and shifting technologies (see this volume, Chap. 20). Many methodologists have urged greater attention to the differences in content and context between face-to-face and online interactions which might impact appropriate methods, but this remains an area for continued research and theoretical development (Greenhow, Robelia, & Hughes, 2009). The proliferation of studies of digital discourse practices and communities-in-action has been accompanied by exploration of new and more specific research techniques (Hmelo-Silver & Bromme, 2007; Park, 2007; Zemel, Xhafa, & Cakir, 2007). More than in face-to-face studies, concerns arise over ethics and privacy in studying online discussions (Bos et al., 2009; Eynon, Schroeder, & Fry, 2009; Kanuka & Anderson, 2007; Zimmer, 2010).

The Researcher as Practitioner

The ongoing concerns in qualitative research about the unequal relationship between researcher and researched, particularly in critical approaches (Denzin & Lincoln, 2008), promote methods that are more inclusive of participant voices, such as action research, participatory approaches, and collaborative research. While some methodologies such as design research (see this volume, Chap. 20) may be jointly initiated, the role of the researcher remains that of the expert. However, a number of proposals have urged greater teacher voice and empowerment in research, along with recognition of the methods of evaluation and practice, as providing needed context for theory and policy (Loughran, 2002). In particular, Tabachnick and Zeichner, 1999 has pointed to the role of self study as "sensitive to the social and personal complexities of the work," and its contribution to a "deep and critical look at practice and structure" (p. 11). In contrast to the traditions covered above focused on data collection and analysis, participatory researchers typically adopt procedures from the broad palette of social science methods but the emphasis here is on research purposes related to stakeholder involvement and shared understandings, as well as action oriented outcomes.

Cooperative inquiry (CI), a form of participatory research, is designed for institutions responsible for social transformation, a category that includes schools. CI has potential for a field like ECT, with its foundations in improving educational opportunities for learners and exploring new technologies for teaching and learning. The CI tradition has roots in such diverse areas as human–computer interaction, cooperative design, contextual inquiry, and activity theory (Druin, 2010). Although participatory research is a long-established research method, there are limited examples in ECT and therefore little recognition in earlier *Handbook* editions, with a single case study cited in the third edition in the chapter on change agentry (Beabout & Carr-Chellman, 2007). In schools, CI was initially spurred by calls for teacher research (Cochran-Smith & Lytle, 1990), but has gained traction with the push for evidence-based practice and effective professional development (Desimone, 2009; Groundwater-Smith & Mockler, 2009). However, CI is also relevant to workplace and adult learning (Yorks & Kasl, 2002), design studies (Druin, 2010), and instructional design (Morris & Hiebert, 2011).

Because cooperative inquiry is both a methodology and a method, the philosophy behind CI guides the way data are collected. Group members share the values of the endeavor and then, in concert, compile information and develop strategies for implementing solutions, gathering more data, and making adjustments to enactment. CI adds a humanistic quality to scientific inquiry by seeking the opinions of those who are truly experiencing the research questions. Qualitative approaches are often recommended because they fit with the flow of classroom routine and focus on context, process, and relationships in CI, but quantitative methods may also be applied (Dana & Yendol-Hoppey, 2009). Debates exist about the potential for rigor in collaborative inquiry studies (Hodgkinson & Rousseau, 2009; Kieser & Leiner, 2009; Newton & Burgess, 2008), but others have noted that stakeholders are more likely to be aware of potential data sources as well as practitioner or stakeholder wisdom, and are thus able to exploit these in ways not possible by outsiders (Dana & Yendol-Hoppey, 2009).

Cooperative inquiry is an emergent process that contributes to the acquisition and creation of knowledge through strengthening trust and collaborative relationships among group members (Oates, 2002). It is designed to bridge the perspectives and approaches of diverse stakeholders through the phases of mutual inquiry across multiple iterations, cycling between action and reflection in an effort to "heal" their divergent points of view into a common solution (Ospina, El Hadidy, & Hofmann-Pinilla, 2008). The experience of CI requires coinvestigators to share how they react to particular situations and sensitive topics. As such, coinvestigators must build a trustworthy rapport. Participants often find their research creates empathetic connections through previously unrecognized perspectives (Kovari et al., 2004). Some have suggested the process is more applicable to formative evaluation in applied educational settings because of its openness to nontraditional data sources and iterative nature, but purposes may vary.

While some researchers may regard these experiences as insignificant and not objective, Reason and Heron (2004) indicate researchers can "develop their attention so they can look at themselves—their way of being, their intuitions and imaginings, their beliefs and actions—critically and in this way improve the quality of their claims to four-fold knowing" (p. 43). Reason and Heron stressed that such "critical subjectivity" adds strength to cooperative inquiry, allowing coinvestigators to be objective without having to disregard their personal experiences. Instead, coinvestigators use their personal knowledge and the experiences they have shared with others who are involved in the same task to gain an authentic perspective on a particular issue (Paulus, Woodside, & Ziegler, 2010).

For educators and education researchers, collaborative inquiry can be a powerful means to develop cultural competencies and the awareness necessary to function effectively in a variety of educational and political contexts (Kasl & Yorks, 2010; Seidl, 2007). The CI process is particularly useful for ECT because it allows for the merging of perspectives of diverse stakeholders at every stage of using technology in addressing a mutually agreed-upon problem.

Application in ECT

The ever-changing relationship between education and technology in schools is well suited to exploration through CI. Indeed, researchers have noted that a complex or "hypertextual" learning environment as found with increasing technological innovation in education demands user-centered approaches since structures of information are relatively unfixed and are intended to be suited to a particular user's needs (McKnight, Dillon, & Richardson, 1996). However, this focus on interactivity and personalization accompanied by the need to account for rapid technological change results in a recurring complication in determining the effects of ECT on a learning environment. In addition to personal differences, the determination of effect involves capturing the access, skill, structural, and political factors as well as the needs and motivational perspectives across roles and generations, potentially including adult and youth learners, parents, school librarians, educators, technology personnel, administrators, and community members (Hill, Wiley, & Nelson, 2004; Mardis, Hoffman, & Marshall, 2008). The CI method can help participants to articulate learning experiences and requirements in difficult-to-study environments in educational contexts, such as informal education and professional development (Lom & Sullenger, 2011).

In response to this tradition's documented benefits, researchers have used CI to ensure that the variations in interpretation, development need, and use are explicitly accounted for in design of ECT learning experiences, two of which are detailed here. The first example reflects how CI has been used in the development of distance learning platforms that meet the needs of a diverse range of learners and faculty (Palaigeorgiou, Triantafyllakos, & Tsinakos, 2011). With the use of participatory design organized as a Cooperative Inquiry, undergraduate students from two Informatics Departments worked together to describe a learning platform which would accommodate their learning differences and needs, build on their new Web 2.0 tool preferences, and could be seamlessly situated in their daily routines. Students came up with 773 different learning needs that developers had not considered. Through the CI process, students were revealed to have refined views of successful elements of online learning applications. Their findings not only paralleled previous instantiations of online learning platforms, in which course content and contextualization of knowledge were top priorities, but included essential complements that designers otherwise neglected such as various aspects of networking, participation, content distribution, and collaboration mediated through Web 2.0 technologies.

CI has also been applied to the design of interactive activities to achieve learner engagement and effective learning outcomes for a variety of educational purposes (Brown et al., 1989; Druin, 2005; Triantafyllakos, Palaigeorgiou, & Tsoukalas, 2008). The research team headed by Allison Druin at the University of Maryland (UMD) Human Computer Interaction Lab (HCIL) recognized that children today have unique experiences and are savvy about technology in ways that are often unrepresented in design. In response, the UMD HCIL team now includes children in cooperative inquiries. They codesign methods to enable adults and children to share their ideas through brainstorming, use a variety of feedback mechanisms, and provide input on creative change in prototype designs for the International Children's Digital Library (ICDL) a digital library of children's literature from all over the world (http://childrenslibrary.org). A group of six children, ages 7–11, work regularly with the adults in the HCIL to develop and evaluate computer interface technologies that support searching, browsing, reading, and sharing books in electronic form. Both the ICDL's CI approach and its interface have been the subject of numerous studies and commendations (Druin, 2010).

Trends and Issues in Practitioner-Focused Research

The increasing pace of change in ECT is driven, in part, by the need to serve greater numbers of learners and, in many instances, stakeholders through an increasingly multifaceted formal and informal learning complex. Trends in student types can be seen in the growing number of adult learners seeking career re-tooling or advanced education (U.S. Department of Education National Center for Education Statistics, 2007); the increased enrollment in virtual schools (Watson, Murin, Vashaw, Gemin, & Rapp, 2010); and an emphasis on twenty-first century skills in all curriculum areas (Trilling & Fadel, 2009). Likewise, the partnerships that result in charter schools, magnet programs, and alternative programs (Epstein, 2007; Epstein & Sanders, 2006) as well as the globalization of learning experiences bring a greater number of stakeholders to the ECT table (Reimers, 2009) at a time when technology's alienating effects are being seen and felt in education (Turkle, 2011). The use of CI has increased in other applied fields, including community development, public health, social work, nursing, and special education (e.g., Guha, Druin, & Fails, 2010; Ospina, El Hadidy, & Hofmann-Pinilla, 2008). This increase suggests that the blending of qualitative methods with participatory methods is not just becoming more accepted, but may be an essential tool for knowledge-building on the role of ECT in learning environments and meaningful contribution to practice to incorporate diverse perspectives.

Qualitative Research on Groups: Case Study and Beyond

Any qualitative study of groups, be they work teams, classrooms, schools, regional populations, or other human communities, may be addressed through case study research. While not all researchers will agree with broad usages of the term, at a practical level almost any study of a human group could be seen as a case study requiring a bounding by population, locale, timeframe, and/or process. As a term, *case study* is widely used and has long traditions, with some referring to this as a methodology or tradition while others suggest it is the nature of what is studied (Stake, 2008; VanWynsberghe & Khan, 2007). Although case study has also been used to describe detailed studies of a single person (a case) as an exemplar of some larger group (i.e., Luehmann, 2008), this review discusses the concept of case study in relation to empirical research on groups, particularly using qualitative methods.

Case study is centered on systematic empirical research employing multiple methods to generate rich descriptions to understand bounded complex social systems or processes, whether inductive or deductive in design (Stake, 2008; Yin, 2008). Qualitative data collection and analysis often predominate in case studies, but may be accompanied by surveys or other quantitative methods. Such mixed methods studies are lauded because of the ability to reveal a level of detail about content, context, and process that is concealed in purely quantitative studies (Buchanan & Bryman, 2007; Horn, 2008; Onwuegbuzie, Johnson, & Collins, 2009; Onwuegbuzie & Leech, 2004; Symonds & Gorard, 2010). In fact, many argue that the qualitative–quantitative divide is artificial and limiting when applied to the complexities of groups, proposing that methods should be adopted from the range of possibilities on a pragmatic basis to fit the research situation and purpose (Yin, 2008).

Methodologists regularly cited as guiding case study research design include Yin (2008, 2011), Creswell (2007), and in education, Merriam (1998, 2009). Stake (2006, 2008, 2010) is influential in his development of qualitative and multiple case study methodologies.

Application of Case Study in ECT

There are many case study types, including descriptive, exploratory, explanatory, instrumental, critical, longitudinal, deviant, extreme, or intrinsic, with competing paradigms or frameworks in which this research is couched such as interpretive, positivist, constructionist, or critical (VanWynsberghe & Khan, 2007). Qualitative case study in ECT may apply to:

- In-depth descriptions of instructional design projects (Bennett, 2010; Khan, 2008; Larson & Lockee, 2009).
- More evaluative or applied approaches including action research focused on what works (Girvan & Savage, 2010; Kim & Hannafin, 2010; Whipp & Lorentz, 2009).
- Descriptive studies providing detail on a particular process or phenomena (Ghislandi, Calidoni, Falcinelli, & Scurati, 2008; Roytek, 2010).
- Studies examining change processes and effects related to technology innovation in education (Juuti, Lavonen,

Aksela, & Meisalo, 2009; Lawson & Comber, 2010; Wong, Li, Choi, & Lee, 2008).

- Knowledge building studies aimed at generating or testing theory (Arnold & Paulus, 2010; Hong & Jung, 2011; Yanchar, South, Williams, Allen, & Wilson, 2010).
- Critical studies aimed at critique and reform (Arshad-Ayaz, 2010; Lee, 2010).

The popularity of case study research in ECT has been attributed to limited resources leading to small-scale (sometimes called small-n) studies and the presence of prescriptive guidelines in methods books and articles that make the approach more understandable to novice researchers. Case study, particularly as presented by Yin (2008) and Stake (2006), tends to promote a positivist or pragmatic philosophy that aligns with prominent views of ECT as a science and the field's grounding in the technical (Twining, 2010; Willis, 2008). In addition, the exploratory use of case study research provides a way to examine situations that are new or relatively unknown which is pertinent to examining the factors and processes of adoption and use of emerging technologies in teaching and learning.

Many Methods for Studying Groups

While case study may be a dominant form in ECT research on groups, many methodologies may be applied that are purely qualitative in method or are mixed methods with a major qualitative component. Some of these are discussed in detail in other chapters within this *Handbook* so are not reviewed here. However, two of the better known qualitative traditions, *ethnography* and *grounded theory*, should be mentioned although neither has been extensively applied in ECT studies. Both have deep histories of application in education and beyond, are described in multiple books and articles on methods and methodology, and have been the source of heated debates among proponents that have served to highlight strengths, weaknesses and variants in use (Hammersley, 2008; Lincoln, 2010).

Ethnography as a Qualitative Approach

Ethnography with its focus on culture has an associated set of methods and field procedures, culture-centered definitions for what constitutes a group, and a theoretical framework within which results are interpreted emerging from a disciplinary paradigm in anthropology (Hammersley, 2006; Hammersley & Atkinson, 2007; Wolcott, 2008). Traditional ethnographic studies were conducted over long periods primarily through participant observation, supplemented by additional methods of data collection including interviews with key informants, questionnaires, and examination of material artifacts and documents. The term "ethnography" is also used as the name of the resulting research report in which the emphasis is on "thick description" as delineated by Geertz (1973) and holistic cultural interpretation.

More recently, ethnography has been used to classify qualitative field studies in many disciplines that result in rich descriptions. Research in which participant observation over time is used in data collection is sometimes referred to as applying ethnographic methods although these may lack the grounding in culture, prolonged study times, and the goal of holistic interpretation. Wolcott (2001) argued against terming such studies as ethnography, proposing these are merely educational research drawing on "ethnographic approaches in doing descriptive studies" (p. 167).

Recent examples of ethnography in ECT studies include research on faculty who teach online (Yoshimura, 2008), children's experiences in educational gaming (Dodge et al., 2008), use of whiteboards in classrooms (Reedy, 2008), and technology in college classrooms (Hemmi, Bayne, & Land, 2009; Lohnes & Kinzer, 2007). Of particular relevance to ECT research are two more recent variants of ethnography: *virtual ethnography* with a focus on populations in digital environments, particularly online games and virtual worlds (Garcia, Standlee, Bechkoff, & Cui, 2009; Kozinets, 2010; Schuck, Aubusson, & Kearney, 2010); and *design ethnography* as a way to understand impacts of instructional design (Barab, Thomas, Dodge, Squire, & Newell, 2004; Blomberg, Burrell, & Guest, 2003; Bossen, 2002).

Grounded Theory: More than Methodology

In contrast to ethnography, *grounded theory* is a qualitative approach that does not presuppose that the study participants are groups or individual; as such it does not easily fit into the classification scheme used in this chapter.

In grounded theory, the researcher is encouraged to approach data with an open mind not limited by prior conceptions, take a reflexive stance in relation to participant interaction, examine data to saturation to ensure full coverage and trustworthiness, and from the analysis, extrapolate commonalities that lead to theory development (Bryant & Charmaz, 2007; Charmaz, 2006; Corbin & Strauss, 2008; Glaser & Strauss, 1967; Mills, Bonner, & Francis, 2006). Grounded theory may be used with multiple forms of data collection. Unlike the holistic approach of ethnography, analytical techniques emphasize deconstruction through formal mechanisms of coding, then reconstruction of concepts and themes that will lead to building theory or frameworks (Shah & Corley, 2006; Urquhart, 2012). While early development of grounded theory was a response to calls for a more empirical process of qualitative research with systematized and formal methods to parallel positivist research approaches (Glaser, 2002), more recently grounded theory has been advocated within an interpretivist, constructionist, or critical approach (Charmaz, 2006; Mills et al., 2006; Mills, Chapman, Bonner, & Francis, 2007).

Examples of grounded theory application in ECT research include studies of the instructional design process (Ertmer et al., 2008), cross-cultural distance learning (Rogers, Graham, & Mayes, 2007), learning in virtual worlds (Oliver & Carr, 2009), educational game environments (Dickey, 2011), and adoption of wireless on a university campus (Vuojärvi, Isomäki, & Hynes, 2010).

As was the case with ethnography, the analytic methods of grounded theory have been applied within multiple research studies in which the overall methodology and epistemological framing is not present. In a number of cases, grounded theory is merged with other frameworks, including cultural–historical activity theory (Seaman, 2008) or case study in research on virtual networks in Peru (Díaz Andrade, 2009).

In particular, the partial adoption of grounded theory as method is found in research that Merriam (2009) classifies as a *general qualitative study*, which uses open coding and thematic analysis, commonly referred to as the constant comparative method, in the absence of grounding in a more encompassing methodological framework. She notes that general qualitative studies are common in applied fields such as education, in which such research may examine bounded groups such as classrooms or schools, or specific populations such as teachers or learners.

Some critics have proposed that the widespread use of the general qualitative study identified by Merriam (2009) is more a result of under-specification of method and approach in case study rather than an ideal type in social research (Backman & Kyngäs, 1999; Caelli, Ray, & Mill, 2003; Urquhart, 2012). This is an issue in ECT research, where an analysis of empirical research articles in journals by Randolph (2008) found that research procedures were "grossly underreported" (p. 68). Further, Leech and Ongwuegbuzie (2007, 2011) note the unfamiliarity of education researchers with methods of qualitative data analysis other than the constant comparative method used in general qualitative studies. They also point to lack of coverage of varied qualitative data analysis techniques in textbooks as contributing to the limited use of other data analysis methods even when it is appropriate or would strengthen conclusions. Their recommendation is that researchers consider using at least two if not more data analysis methods to triangulate results.

Issues and Trends in Studying Groups

Many commonly applied methods and methodologies in qualitative research on groups are not new but arise from long-standing traditions in social and educational research (Travers, 2009), whether case studies, ethnographies, grounded theory studies or the many others described in this *Handbook*. While the volume of the arguments over appropriate research techniques has waxed and waned erratically over time, the critiques have also opened doors to refinement, convergence, and expansion of qualitative research options as well as new insights on the context, processes and dynamics of human groups.

A number of the challenges relevant to studying groups are also those that are foundational to the challenges of qualitative research as a whole, and are parallel to issues reported in earlier sections of this chapter. These include issues of level of analysis, relationship of methods, methodology and purpose in research design, matching analysis to purpose, and the validation and inference from results (Anfara & Mertz, 2006; Leech & Onwuegbuzie, 2011; Onwuegbuzie & Leech, 2005). While each methodology may use overlapping methods of data collection and analysis, such as interview and observations or formal processes of categorizing data, methodologies vary in other ways including appropriate design of questions, the prescribed level of researcher intervention in the interaction with the participant, and the assumptions about the concreteness of responses and observations in relation to some social or physical reality (e.g., whether a conversation is unique, situated, and emergent or is direct evidence of a person's culture, identity, cognitive or emotional self). Further, methods and methodologies may be merged without adequate attention to impacts on validity or potential contradictions arising from disparate data sources (Bryman, 2007; Morse, 2010). The multiple dimensions of variability elude simple categorization and present challenges to researchers using qualitative methods and methodologies.

The requirement for parallel structuring of theory, purpose, methodology and methods in research is commonly referred to as *coherence* (Kline, 2008; Tracy, 2010). Such coherence may be lacking in research design among novice researchers who initially see methods as a technical issue or normative process, thus following prescriptive guidelines in the absence of a more refined understanding of a particular qualitative method's history and limitations (Walford, 2001). Yet even experienced researchers can run into such problems when approaching a new research technique. Such issues may be most pronounced in case study in which creative repurposing of methods and traditions to best answer research questions posed is both a strength and weakness (Taber, 2010). However, methodological "borrowing" can also be a concern when such traditions as ethnography or grounded theory are used in new ways and outside the disciplinary paradigms in which they developed.

Conclusions

This chapter's review of qualitative traditions and methods reveals an increasing range of possibilities for ECT researchers along with a multitude of qualitative studies examining questions of significance to the discipline. The diversity of theoretical perspectives, methods, and methodologies provide support for Denzin and Lincoln's (2008) perception that qualitative approaches continue to proliferate. Some methods are just beginning to gain prominence, while new methods are emerging that have yet to make a major impacts on the field (e.g., Hesse-Biber & Leavy, 2008). Such advancements hold promise for expanding research designs useful in approaching the complexity of context and content in instruction, technology, and education.

In this final section of the paper, we will take a look at some of the broader prospects and concerns impacting qualitative research in ECT.

Opening New Vistas in ECT Qualitative Research

Perhaps most exciting in terms of new vistas from the perspective of ECT are the repurposing of the traditional methods of qualitative studies in the context of new digital technologies. Not only do new technologies provide additional tools for data collection and analysis (see Chap. 20), but online social technologies, knowledge management systems, powerful search engines, and computerized logging of user actions allow insights not previously possible into human behavior and social interaction. Some examples have already been given in this chapter such netnography or the study of dialogic interaction with computerized agents, with more appearing regularly.

An area of heated debate and also one that has substantial potential to lead to innovation in methods and theoretical frameworks revolves around the issue of explanation and causation in social behavior. In particular, an increasing number of proponents argue for the utility of case study research and the rich descriptions resulting from qualitative studies as legitimate means for theory development and testing, including the potential for meaningful contributions to evidence-based practice (Bennett & Elman, 2006; Chenail, 2010; Eisenhardt & Graebner, 2007; Flyvbjerg, 2006; Larsson, 2009; Shaw, Walls, Dacy, Levin, & Robinson, 2010). Support for the role of qualitative research as an accepted approach to theory on causation comes from multiple perspectives, including those who urge recognition of complex systems and evolutionary processes in social analysis from a positivist perspective (Morrison, 2009) and those who focus on informants' words, views, and sense-making following interpretive traditions (Díaz Andrade, 2009).

A third trend of interest is in the increasing sophistication and numbers of articles reviewing research, both those that are syntheses of research results that include qualitative studies, and those that examine the processes of research itself. At one level, many of these reviews are a form of qualitative study in the categorization of article types or internal content, although most reviews also apply some statistical analysis. While studies such as Randolph's (2008) reporting on the methods of research used in computer education journal articles are a beginning for ECT, some of the reviews beginning to appear in medicine and organizational studies comparing the uses of specific methods and methodologies in published research provide models for using the results of qualitative content analysis for a better understanding of research design. Of particular relevance is the application of findings to practice through meta-synthesis qualitative review in such fields as medicine (Cunningham, Felland, Ginsburg, & Pham, 2011; Donaldson, 2009), suggesting future trends in education.

Prospects in an Age of Quantifiable Outcomes

Despite some positive examples of qualitative research trends described above, the prospects for qualitative research in ECT and education more broadly are unclear. Internal debates about the purposes and methods of research continue, but perhaps more critical are the external critiques raising questions about appropriate methods and purposes in educational research (Denzin, 2009; Hammersley, 2008).

The Politics of Educational Research and the Qualitative Tradition

Externally, particularly in the USA and increasingly in other English-speaking countries, policy-makers are taking a more activist role in defining what is appropriate educational and social science research (Atkinson & Delamont, 2006; Denzin & Lincoln, 2008; Eisenhart, 2006; Liston, Whitcomb, & Borko, 2007). Such policies impact potential funding and lead to internal debates about research directions. With a focus on evidence-based practice and assumptions about proving cause through linear science, the trend, if played out, could increasingly negate the qualitative premise of explicating complex causes and emergent social processes. Such political forces could push qualitative research to a minor status of exploring phenomenon primarily to determine directions for quantitative studies (Denzin, 2009, 2010).

Further, as Denzin and others suggest, current policy debates about education not only have implications for research methods but also raise broader issues about what are considered appropriate research topics by equating "quality" with "useful" in the sense of immediately applicable to practice and "proven" to work (Biesta, 2007). Recent calls by ECT journal editors for effectiveness studies echo this direction (Roblyer & Knezek, 2003; Schrum et al., 2007; Thompson, 2005), while others have argued against such narrowed definitions of scholarship (Gardner & Galanouli, 2004; Hammersley, 2000, 2005, 2008). The role of politics and social values on education is well recognized given the scope and public nature of the institution in modern society, with the fallout as it relates to research direction and the future of qualitative research in the field yet to be determined.

The Internal Problems of Quality

The issues raised by Randolph (2008) of under-specifying research design in ECT empirical studies remain true in the samples of numerous articles reviewed by the authors for this chapter. Given many examples of under-delineated methods and design, it is not surprising to see ECT research discussions imply qualitative research has at best a secondary role to more rigorous quantitative results (Ross & Morrison, 2007). Maddux (2003) has vehemently railed against ECT qualitative research as lacking rigor and produced by those who are incapable of understanding scientific design and statistics—what he calls number fear, while other critics have taken a more moderate approach seeking new designs or promoting mixed methods (Amiel & Reeves, 2008; Creswell & Garrett, 2008).

Inspiration Within and Beyond ECT Borders

Despite some negative indicators, qualitative research is thriving, particularly in Europe and other parts of the world with stronger traditions of philosophy and theory supporting studies produced than in the USA. In addition, qualitative research in other applied fields is being critically examined in terms of rigor and quality, and through critical review being used to impact practice (Maggs-Rapport, 2001; Onwuegbuzie & Leech, 2007). This provides an opportunity not only for self-examination but for ECT to look outside the field for strengthening its own qualitative work.

Improvement Through Enhanced Evidentiary Standards

The debates over educational research are not entirely without benefit. The critiques of the earlier "paradigm wars" and the more recent discussion of validity and generalizability resulting from discussion of the "gold standard" in educational research have pushed for increased consideration of rigor and quality, not only in qualitative but in quantitative studies as well (Fielding, 2010; Gorard, 2002). Desimone (2009) and others have suggested that we are in a period of increased evidentiary standards, requiring more careful definition of terms and clearer delineation of methods that may promote knowledge building and theory (Ball & Forzani, 2007).

Recent articles in social work (Barusch, Gringeri, & George, 2011; Lietz & Zayas, 2010), counseling (Kline, 2008), organizational studies (Beverland & Lindgreen, 2010; Easterby-Smith, Golden-Biddle, & Locke, 2008; Gibbert & Ruigrok, 2010), and particularly health care (Collingridge & Gantt, 2008; Macdonald, 2009; Smith, 2009), provide models of enhanced quality and precision in qualitative methodology. These approaches may portend strategies for the evolution of rigor in ECT qualitative research and lead to reexamination of submission criteria by journal editors (Chenail, Duffy, St. George, & Wulff, 2011; Lin, Wang, Klecka, Odell, & Spalding, 2010). It should be noted that some of the recommendations for research standards emerging in other fields are not explicitly aimed at creating a one-size-fits-all scientific standard of evidence but propose that researchers be more transparent about the theory, epistemologies, and ontologies that framed their study (Freeman, deMarrais, Preissle, Roulston, & St. Pierre, 2007; Koro-Ljungberg, Yendol-Hoppey, Smith, & Hayes, 2009; Lewis, 2009; Tracy, 2010).

Building on Our Strengths

Like all disciplines, ECT research has norms of appropriate content and research design established by the disciplinary community and largely enforced by issues of hiring, publication and funding (Randolph et al., 2009). Willis (2008) has suggested that this community is more pragmatic, positivistic and conservative in its adoption of new research methods and methodologies than other areas of education. Relatedly, Maddux (2001), Maddux and Cummings (2004), and others warn about fads and assumptions that create barriers in developing continuity, urging researchers to build on past theory and research findings.

Qualitative research has potential to do more than it does by thoughtfully building on what we already know and then attentively crossing disciplinary boundaries for inspiration (Czerniewicz, 2008; McDougall & Jones, 2010; Wiles, Pain, & Crow, 2010). The outlook for qualitative research in ECT is high and the options exciting, as new technologies and innovative methods are added to freshen perspectives on our world.

Program and Project Evaluation

16

J. Michael Spector

Abstract

Educational technology research and development nearly always involves an intervention of some kind aimed at solving a problem or improving a situation pertaining to learning and instruction. Those involved—the stakeholders—naturally want to know whether the problem was solved and/or the extent to which the situation was improved. Attributing any outcomes to the intervention is not as easy as it may appear, as many factors are typically involved, beyond just the technology involved. This chapter describes a holistic approach to educational technology project and program evaluation. The emphasis is on evaluating the entire process from needs assessment through design, development, deployment, and support with particular attention to evaluating every aspect of the process so as to increase the likelihood of successful technology integration. The use of a logic model to organize evaluation as well as research is described.

Keywords

Confirmatory evaluation • Formative evaluation • Logic model • Needs assessment • Program evaluation • Summative evaluation • Theory of change

Introduction

There are of course many different kinds of research. Typically, research is aimed at determining causes and/or explanations for unusual or unexplained phenomena or at making predictions about what might happen when certain situations occur. Explaining what happened or might happen (and why) as a result of particular educational policies and practices and instructional interventions represents an important kind of research not specifically addressed in previous editions of this *Handbook*. Such applied research is typically called program or project evaluation. Critical questions that inform program and project evaluation include the following:

1. To what extent were the goals and objectives of the program or project met or being met?
2. Did the implementation happen as planned?
3. Was adequate preparation and training provided?
4. Was the design clearly aimed at the problem identified at the outset?

One can of course imagine other questions, some of which will arise in the course of this chapter. First, however, it is necessary to distinguish products, policies, practices, programs, and projects. The latter two are easily distinguished. A project is typically aimed at addressing a particular problem situation by introducing something new or different, which can be called an intervention. As a consequence, a project has a goal and objectives, a beginning (could be the start of the needs assessment but is more typically the start of the development of the intervention), and an ending (typically a short time after the intervention has been deployed

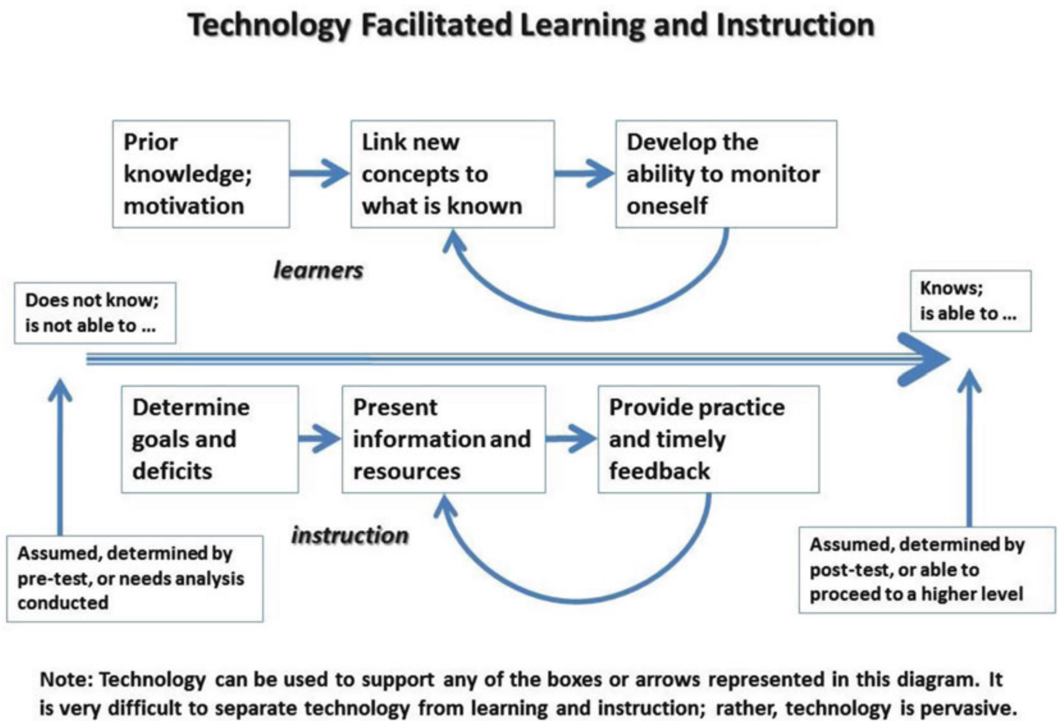

Fig. 16.1 Research on technology in learning and instruction (adapted from Spector, 2010)

and is being used regularly). A program shares many of the same attributes, but unlike a project a program is typically intended to continue in use and evolve over time, so the period of time associated with a program evaluation is longer than that associated with a project evaluation, and changes in the situation surrounding the program need to be actively considered as the program is periodically reviewed. Confirmatory evaluation is a kind of evaluation appropriate for determining if the original assumptions and problem situation are still pertinent to an ongoing program or a long-term project. Projects often mark the initiation of a new program, so there is a close association between projects and programs. Moreover, programs and projects typically alter practice (how those involved conduct their affairs and accomplish specific tasks), and they may involve the introduction of products, policies, and procedures to guide practice and the use of new technologies. This chapter is not focused on the evaluation of policies, procedures, or products, although some of the same principles and techniques are likely to be pertinent in those contexts as well.

Next, there are the notions of learning, instruction, and technology to consider. A technology involves the disciplined or systematic application of knowledge to solve a particular problem or achieve a specific goal (see Spector, 2012). Examples of educational technologies include online discussion forums, animated models, interactive simulations, checklists for procedures, mnemonic memory aids, and much more. Learning involves recognizable and persisting changes in an individual's (or organization's) abilities, attitudes, beliefs, knowledge, or skills (Spector, 2012). Instruction is that which supports or facilitates learning (Gagné, 1985; Spector, 2012). Based on these common definitions, it is obvious that there are close connections between learning, instruction, and technology, as depicted in Fig. 16.1. Just as technology can support any of the boxes in Fig. 16.1, each of those boxes can and should have an associated evaluation activity. Evaluation, properly understood, pervades educational practice and is essential for understanding the impact of projects and programs.

One can conceivably ask many different kinds of questions about a variety of technologies used to support and facilitate learning and instruction. Many of these questions involve the characteristics of scientifically based research, including the notions of baseline studies, comparison and control groups, analyses of significance and effect size, growth curve modelling, and so on (Cronback, 1989; Nagel, 1994; Scriven, 1960, 1994; Spector, 2010; Suchman, 1967; Suppes, 1978).

The history of educational research is rich and diverse, with more than 100 years of empirical investigations (Aldrich, 2002; Knox, 1971; Langemann, 2000; Suppes, 1978). In spite of such a large body of evidence, there is little evidence that the many educational technology innovations that have been introduced in the last 100 years have had a significant impact on learning (Langemann, 2000; Russell, 2001; Suppes, 1978). Several explanations for this unusual

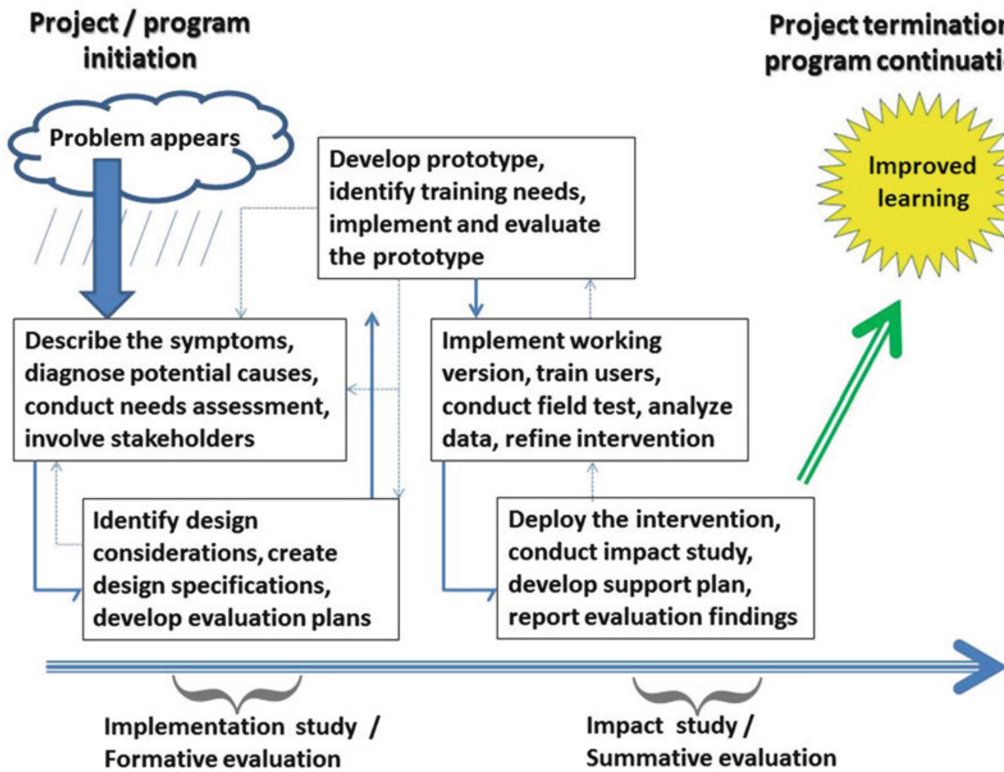

Fig. 16.2 A representation of projects and programs

finding have been provided, many of which focus on the inadequate kind of evaluation research conducted in association with the integration of new technologies into learning and instruction (Langemann, 2000; Russell, 2001; Suppes, 1978). A major inadequacy of prior research on the impact of educational projects and programs involves a tendency to examine superficial indicators of impact without examining the quality of the implementation and training associated with an intervention. Typically, project evaluations have focused on three indicators of success: (a) Did the implementation stay within budget? (b) Did the implementation occur on schedule? and (c) Did the implementation meet the design specifications? Such evaluations are summative in nature—that is to say that they do not provide any information or input that will improve the development of the effort while it is under way. Moreover, associated with such a summative evaluation there might be a research effort that looks at learning outcomes before and after the intervention was developed and deployed. The analysis of the before and after research data often indicates that there is little impact on learning (Russell, 2001; Suppes, 1978), although the three project indicators may reflect success. What is one to think?

The conclusion that will be elaborated in what follows is that a summative evaluation is not adequate and serves little real purpose without the support of a thorough formative evaluation along with a confirmatory evaluation for longer term efforts. Project and program evaluation can and should be aimed at the entire life cycle of the effort and be designed to ensure that the development effort will not only meet the design specifications but also address and solve the indicated problematic situation (see Fig. 16.2). Formative evaluation that is intended to improve an intervention as it is being designed and developed is required; this notion goes to the heart of what project and program evaluation is really about—one does evaluation to help ensure that time and money are not wasted, which means that evaluation must begin early and continue as the effort progresses. One can make the same argument with regard to assessing student learning—the proper emphasis is on helping to improve student learning and not merely on reporting what learning seems to have occurred at the end of a sequence of learning activities.

Confirmatory evaluation is worth emphasizing at this point as it helps distinguish projects from programs and reinforces the formative and summative nature of evaluation. Confirmatory evaluation is aimed at reexamining the problematic situation after an extended period of time, often after a project has been completed and a program has been under way for some time; long-term projects often revisit the needs assessment and requirements analysis phase of a project to make sure that essential aspects of the problem are still the same as originally identified. Confirmatory evaluation is conducted to ensure that the right problem is being addressed and solved. More specifically, confirmatory evaluation involves a systematic program analysis that is aimed at attributing effects to causes as well as reexamining assumptions and the original problem situation; this is important in explaining significant effects as well as the lack of significant effects (Reynolds, 1998).

Logic Models and Program/Project Evaluation

By way of summary, when conducting applied or development research, one may have a new educational technology or system that one believes will be beneficial in some way. This situation is a prime target for research and inquiry. One kind of inquiry often associated with development research is program (or project) evaluation. The basic questions are whether and to what extent an intervention (e.g., an innovative technology or new learning environment or educational system) achieves its intended aims, and why it succeeded or fell short in some way. The emphasis is not on the technology as a product but rather on its use in promoting learning and/or improving performance. One can imagine two kinds of studies emerging from a program evaluation: a fidelity of implementation study (a kind of formative evaluation) and an impact study (a kind of summative evaluation) (see Fig. 16.2). The notion of a logic model can be used to explain the differences in these two kinds of research and evaluation studies (see Fig. 16.3). A logic model portrays a current situation and the associated problem, the implementation of an intervention intended to address the problem situation, and the projected or the predicted outcomes and benefits of that intervention if and as successfully implemented. A theory of change that would explain why and how the intervention would lead from the problem state to the desired outcomes is normally associated with and depicted in a logic model. The fidelity of implementation study could be structured such that the results of the study reflected degrees of successful implementation (as in high, medium, low, or superior, adequate, or marginal involving such variables as professional development and technology support). Having such data is useful in explaining why and to what extent significant differences were or were not found in outcome variables. For additional detail on such studies, see the chapter by Jennifer Hamilton in this *Handbook*.

The problem description is important as that is the outcome of some kind of analysis typically called a needs assessment.

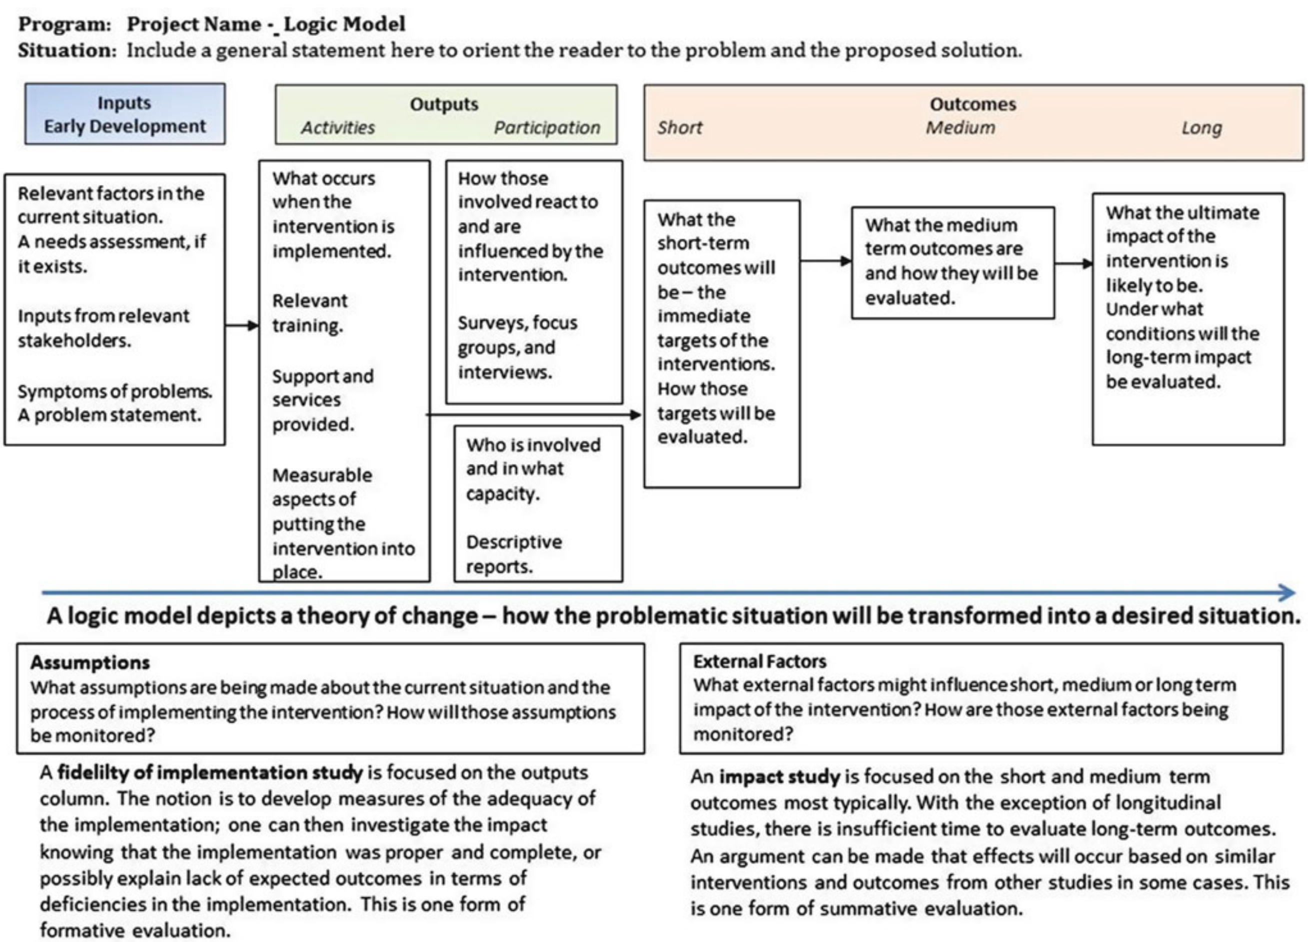

Fig. 16.3 Logic models, fidelity of implementation, and impact studies

The problem indicators become the targets of desired outcomes of the effort, which means that the impact study (summative evaluation) will measure the extent to which the problem situation has improved. However, the responsibility of program evaluation far exceeds simply reporting outcomes, even when resources (time, funds, etc.) are included in the outcomes analysis. The work of program and project evaluators begins with the analysis of the problem situation. Who was involved in the needs assessment? Were all stakeholders involved? Was there a divergence of views? How reliable were the methods and instruments used to collect and analyze needs assessment data? If the problem identification process is flawed, then it is unlikely that the subsequent development effort will produce desired outcomes. Evaluators should observe the early analysis and planning phases and provide formative feedback to help ensure that a comprehensive and high-quality needs assessment drives the effort.

Since nearly all technology implementation efforts involve training users, it is important for evaluators to observe and report outcomes of training plans as well as actual training. Inadequacies in training often result in suboptimal outcomes even when the technology implemented is of high quality. Moreover, planning for change and properly preparing users for a new technology are critical for the successful diffusion of an innovation within an organization (Ellsworth, 2000; Rogers, 2003). Again program evaluators have a responsibility to report any shortcomings or potential problem areas concerning preparing users for an innovation; this responsibility falls into the category of formative evaluation. A formal analysis of how well the project or program is preparing end users for the effective integration of a new technology is known as a fidelity of implementation study. Such a study is primarily aimed at the inputs and outputs in the logic model (see Fig. 16.3) and the degree to which the intervention can realistically be expected to support the underlying theory of change if it is properly or fully implemented.

A primary obligation of evaluators is to alert the implementation team and management of anything that might jeopardize the desired outcomes of the effort at any time during the entire process of planning and implementing an intervention. However, it is quite rare to find a project or a program that involves evaluators throughout the process in this way. Perhaps this lack of ongoing formative evaluation is another reason that few significant differences are reported even for well-supported educational technology efforts.

Evaluation vs. Research

Why include a chapter on program evaluation in a research handbook? Hopefully the answer is obvious enough at this point. In one sense, an evaluation effort represents one kind of applied research in the sense that an explanation for what has happened (or failed to happen) is developed, especially through the quantitative and qualitative data used in the fidelity of implementation study. Evaluators often use the same tools and methods used by other educational researchers. One difference is the focus of evaluation vs. that of other forms of educational research. Evaluation is focused on decisions made during the planning and implementation of an intervention with the aim of helping to improve the effort so as to produce desired outcomes. Other forms of educational research are focused on answering questions that contribute to a body of knowledge or the development of theories to explain a range of phenomenon (see Popper, 1963). Of course it can and does happen that program and project evaluations inform research about the many phenomena associated with learning and instruction, so the distinction between educational project/program evaluation and education research is not sharp and distinct.

An Example

To suggest how the application of this approach to program evaluation might work, a brief discussion of an invented case is provided here. Obviously other approaches, methods, and instruments are possible to use. This case is meant to emphasize the formative nature of program evaluation as this is the most challenging aspect to implement.

A school district has determined that a significant percentage of its students are at risk. In making this determination, the district used an expanded set of indicators that included some things beyond the control of district personnel (e.g., socioeconomic status, physical and learning disabilities, etc.), and some things that district personnel (both administrators and teachers) believed that they could influence (e.g., absenteeism, test scores, pass/fail rates, graduation rates, discipline cases, etc.). The expanded set of indicators showed many more students at risk than teachers, administrators, and parents had previously imagined. District leadership then initiated focus group discussion with administrators, teachers, parents, and students to determine what problems these groups perceived as most relevant to the situation. Two quite different kinds of problems were mentioned most often: (a) instruction that was not well suited to individual student needs, and (b) lack of easy, real-time access to data that would enable teachers and administrators to be more responsive to individual student needs.

This needs assessment took place over the course of an entire year; it led the district to settle on a solution approach that involved an integrated data system that could provide data on individual students and that could also support differentiated instruction and personalized learning. Since the external evaluator was not involved in the needs assessment, there was an initial concern with regard to confirming the problem situation as represented by district personnel. As it happened, the district had documented the process quite thoroughly, so the first thing the evaluator did was to review that documentation and confirm that the needs were real and worth addressing through additional focus group discussions with the relevant stakeholders.

Having settled on an approach to resolve the problematic situation, a grant was submitted and funded, a company was hired, and a project team put in place that included an external evaluator. The goals of the project were focused on reducing absenteeism and discipline rates, increasing graduation rates, and improving test scores. These became the outcome indicators in the project's logic model developed by the external evaluator. The theory of change was based on the notion that personalizing learning and making instruction relevant to individual student performance and interest would result in increased student interest and performance, thereby reducing absenteeism and discipline problems while increasing test scores and graduation rates. That theory of change had some support in the published research literature, and it proved convincing to the funding agency. In this case, the impact study (summative evaluation) was easy to construct and implement since the measures were obvious and the data readily available. As it happened, the outcome measures did not provide sufficient basis to say that the intervention made a significant difference. In part, district personnel and the evaluator believed that this was because there was an influx of new students to the district whose first language was not English and because the economic downturn caused some high school students to take part-time jobs leaving them with less time for studies. These facts partially explained the lack of significant impact in terms of the outcome indicators.

During the project, the evaluator collected information from administrators, faculty, students, and parents with regard to training for and use of the new data system. The focus was on the ability of the system to support teachers' needs for timely information and students' needs to have customized learning activities. Prior to the implementation of the system, the evaluator noticed that the company originally hired to provide the system was not responding to teachers' needs for real-time information nor would the system be able to support personalized learning and differentiated instruction without extensive teacher intervention, which was not possible given existing workloads and enrollments. The evaluator recommended requiring the company to comply with the district's requirements or find a company that would. The district followed the evaluator's recommendations and found a company that was able to deliver a system that was responsive to the needs of both students and teachers. Due to a delay, however, the initial training was not as thorough as it could have been. The evaluator documented the time spent on training and problems that teachers and students had with the new system; the evaluator then recommended additional training and support materials, which were developed, but not soon enough to impact the outcome indicators by the time the funded project ended.

Two things are worth noting. First, the evaluator (who is fictitious of course) was able to add to the explanation of lack of significant difference on outcome indicators due to the implementation study that focused on the development process and the training of teachers. In addition, the district did manage to deploy a new system that is having an impact, although that impact was delayed due to the change in software providers. While the project itself could not report significant differences due to personalized learning and an integrated data management system, the project has evolved into a program that is now reporting significant differences, in part thanks to the formative evaluator's recommendation with regard to the software development provider.

Conclusions

This chapter is intended as an introduction to an important area of educational research called program (or project) evaluation. The treatment of program evaluation here was not intended to be comprehensive or describe specific evaluation methods or tools. Rather, the intent was to stress the significance of fidelity of implementation studies as they serve to explain the findings in an impact study, and to emphasize the responsibility of evaluators to report potential problem areas during a development effort to the implementation and management team. Readers can find a wealth of information on specific program evaluation methods and tools elsewhere (Louw, 1999; Potter, 2006; Rao & Woolcock, 2003; Rossi, Lipsey, & Freeman, 2004).

Tools for Analyzing Quantitative Data

17

Gerald A. Knezek and Rhonda Christensen

Abstract

Data analysis tools for quantitative studies are addressed in the areas of: (a) enhancements for data acquisition, (b) simple to sophisticated analysis techniques, and (c) extended exploration of relationships in data, often with visualization of results. Examples that are interwoven with data and findings from published research studies are used to illustrate the use of the tools in the service of established research goals and objectives. The authors contend that capabilities have greatly expanded in all three areas over the past 30 years, and especially during the past two decades.

Keywords

Quantitative tools • Data acquisition • Data analysis • Data visualization

Introduction and Overview

Advances in personal computers over the past 20–30 years have made it possible for researchers to apply a vast array of quantitative research tools to data analyses at hand. Just three decades ago many sophisticated techniques required mainframe computer access and ran in batch processing modes that required researchers to wait for hours or days to see the output of a single run. Today, however, the processing power of personal computers (PCs) has improved to the point where the modern day data analyst can run a half dozen different techniques on a massive set of data in a typical afternoon.

In this chapter an overview is presented of tools for analyzing quantitative data, and examples of research in which these tools used are presented as well. The progression is generally from simple to computationally complex; however, even the most sophisticated can typically be executed on a high end personal computer (PC). Relationships among data elements are usually best illustrated with the most parsimonious (unembellished but complete) available techniques. Therefore, trying several analysis techniques will allow the researcher to choose the one judged to be best. Examples of this process are interwoven in this chapter.

Tools for Data Acquisition

There are many ways to gather data from subjects, ranging from simple and traditional paper-based surveys to more sophisticated feedback-based online systems. While paper was the most common method even as recently as the beginning of the 21st century, other techniques have rapidly evolved. The reasons are simple: paper-based surveys are often expensive, time-consuming, and cumbersome ways to gather data required for evaluation or assessment of project activities. Over the past decade many projects have moved away from paper surveys to Web-based acquisition of data from teachers and students. These vary in sophistication, cost, and constraints. Some issues related to appropriateness for certain types of research projects also remain to be resolved. These topics are addressed in the following sections.

Paper Survey

Paper-based surveys have been the traditional method of gathering responses for many decades. For many populations, such as young children or those without access to information technology, paper continues to be the most viable alternative because paper surveys require little or no special technology to administer or complete and can be tallied by hand. The method is familiar and fault tolerant. However, it is also labor-intensive and time-consuming for large-volume applications. A decision about whether or not to use paper is often strongly influenced by the accessibility of online submission technology for respondents and whether or not there is a time critical need for mass administration and collection of data in a single sitting. It is typical with an online system to gather data from hundreds or thousands of subjects in a few days, and to have the data ready for analysis within a few hours following acquisition. And yet there is often a need for the use of paper surveys or other alternatives that have evolved in the last decade. Manual data entry from a handwritten survey into a machine-readable file is one of the most time-consuming aspects of using paper surveys. The following section discusses alternatives that have been used in the past, along with their strengths and weaknesses.

Mark Sense/OCR

Preprinted forms that utilize machine-readable bubble-coded responses have been common in education for several decades. Typically these can be completed and scored very quickly, and they can be administered simultaneously to hundreds in an environment such as an auditorium, with little administration overhead. Mark sense forms are also expensive when commercially produced, are quite rigid in response format, and require lead time to print in volume. These characteristics make their use impractical in many research environments. Newer optical character reader (OCR) technology that can actually sense which response was circled by the respondent holds promise for improvements in this area. In these kinds of systems, multiple page surveys simply have the staple removed and each page is fed through a photocopier-type feeder mechanism. If the scanner mechanism has a problem deciphering the mark, it stops and requests that the operator make a judgment based on the scanned image.

HTML/Database Approaches

In Hyper Text Markup Language (HTML) and database survey administration systems, the server presents the form to the respondent and gathers the data when the respondent replies to an item, or at the end of a survey when a respondent clicks the “send” button after completing the survey. The server application writes the data into a text file or database for further processing via a statistical analysis package at the second stage. Several competing database approaches vied for universal adoption. Microsoft Access and FileMaker Pro were two that were successfully used for producing near real-time tabular or graphical feedback (color bars) for survey participants—if the number of items and/or simultaneous users were not too large (Knezek & Christensen, 2001).

Perhaps the current pinnacle of this line of development is a system that feeds into a sophisticated database such as those created with MySQL (Cartwright, 2005). However, many of these are based on expensive hardware/software platforms costing much more than the solutions envisioned as more affordable for an individual researcher or school district.

The database approach to online data acquisition is centralized and elegant. Theoretically it should have worked well with standard database packages. However, many researchers in the early 2000s became frustrated with slow operating systems and database bottlenecks, and constructed their own Unix-based data collection systems that wrote simple tab or comma-delimited text files for use with intermediate (data cleaning) packages such as Excel. These files could also be entered directly into statistics packages such as SPSS.

Modern Web-Based Approaches

As of 2011, Web 2.0 systems that combine advertising-based user interfaces, cloud computing (computing power residing at unspecified locations but available on demand), and small administration fees, are clearly becoming dominant. Some examples include Survey Monkey, Google.docs, Survey Tool, Zoomerang and Free Online Surveys. These are similar in that they all offer users the ability to create, send, and analyze online survey results on-demand. Some of the systems offer this Web-based survey tool for free on a limited level (maximum number of questions, responses, etc.) and also offer an upgraded fee-based version. Strengths include the ability to quickly create and gather the data and present results in a graphical format or provide the data to be easily imported into a statistical analysis package. Weaknesses include constraints on item formats and difficulty in managing data integration from multiple-survey (battery) administrations.

Two systems commonly used by university researchers as of 2011 are Survey Monkey and the Google.docs survey system. A Survey Monkey instrument typically presents HTML-formatted selections with mouse-clickable radio buttons as labeled response choices. User responses are written into a text file. Small project versions of Survey Monkey instruments can be developed and administered free of charge. Leaders of larger research projects will find the need to upgrade to the fee-based version of Survey Monkey.

Google.docs provides a free Web-based, online survey system with a variety of question types including multiple choice, Likert scale, short answer, and open response. The data are gathered by the system and provided to the researcher in a Google spreadsheet that can then be converted into an Excel stand-alone spreadsheet or a text file, as the researcher prefers. The survey can be embedded in an email or a Web page, or the researcher can send a link to the administration system. For a quick look at your data, there is a report feature that produces descriptive graphs immediately. One drawback of the Google.docs survey system as of 2011 is that it is difficult to incorporate the descriptive graphs into other documents. A researcher may be forced to resort to screen capture for this purpose. Another drawback is that the entire descriptor written for a multiple choice item is automatically written to the google.docs spreadsheet, making the output from the Google.docs survey system not concise enough for practical use in a statistical analysis package such as SPSS.

Both Survey Monkey and the Google.docs survey system generally function well for researchers, thanks to massive advances in server processing power and the ubiquity of Internet access in many parts of the world today.

Future Prospects

For the future, we see two strong prospects emerging quickly: Mobile survey administration and instant feedback with descriptive results. Smartphones and other handheld devices are certainly capable of presenting a single item from a survey, with which a person might agree or disagree on a Likert-type scale. These devices are also capable of displaying results showing how a survey participant's response (perhaps on a scale produced by combining answers to 5–10 items) compares with other respondents. One can readily envision the response pad system used in large lecture halls today, replaced by smartphone-based systems, where it matters little if the students are in the lecture hall or not. Systems of this nature generally return a bar graph to each participant who replied. Data acquired though a system such as this would seem to have great potential for later analysis, because every participant's answer to each question would be in a common database. This would allow straightforward analyses such as computation of Pearson's correlation coefficients.

The social networking movement, which appears to be sweeping the world in the second decade of the 21st century, also provides new opportunities for data acquisition. Researchers are now gathering data in sufficient sample sizes to complete reliability estimates very quickly, simply by polling associates in Facebook. Emerging social network systems also enable researchers to track subjects longitudinally, for purposes of follow-up studies. For example, Tyler-Wood, Ellison, Lim, and Periathiruvadi (2011) completed an 8-year follow-up study of fourth grade girls, and their matched comparison peers, to assess the long-term impact of having participated in a summer science program designed to engage their long-term interest in this field. The original subjects were located, agreed to participate, and completed follow-up surveys via social networking media. This follow-up study would not have been affordable, and would probably never have been completed, if carried out through conventional procedures.

Data Acquisition Issues and Concerns

Issues related to sampling and attrition, coding errors and data cleaning are common to new and old systems of data acquisition. There is a vast range of opinions regarding acceptable numbers (percentages of potential respondents) that are required for the data to be meaningful and useful. Many formal mechanisms exist for calculating power in a given situation, and for calculating optimum sampling scenarios to achieve preferred results. However, even the best-funded, most carefully planned research projects seldom complies with textbook design specifications after the data are gathered and cleaned. In pretest to posttest paired data acquisition situations, attrition is often a more serious issue than sampling or power. The major issues appear to boil down to what Campbell and Stanley (1963) called issues of internal validity and issues of external validity. The former have to do with whether one trusts that the research study or experiment was justified in the conclusion reached. This has to do with the ability of the instrument to measure change (power), the type of analysis employed, and many other factors including fidelity of the data subjected to the analysis procedure (was it cleaned with decisions made about nonresponders and doodlers, were outliers removed) and the possible effects of subject attrition. External validity is concerned with whether the conclusions the researchers reached can be generalized outside the group used to produce the results. This is closely tied to sampling issues and dangers due to failing to consider the vast diversity of environments where decision makers might hope that a single, local finding might be said to apply. These kinds of issues are common to all alternatives for data acquisition introduced in the previous section.

Several issues specific to online data acquisition are worthy of mention because they remain unresolved even after a decade of experience with online systems by the research community.

Lack of Universal Access

Online systems require that the person completing the survey have access to the response system. This is typically a computer connected to the World Wide Web (www).

If research data are being collected from a school or university computer lab where every student has access, or from teachers where every participant is known to have his/her own laptop at home, then this is not a problem. But if survey responses are being gathered from parents or the general public in economically disadvantaged areas, or from any nation outside the industrialized world, then sampling bias is certainly being introduced. A related problem is emerging even among sites that appear to offer full online access. Many schools block access to any URL that is not on an "approved" list. Survey sites from universities or some sites considered to be noneducational and/or commercial are blacklisted. Getting the IT managers for 50 or 100 schools to add a URL to the approved list is problematic. Because of this access issue, most researchers conducting a large-scale study develop an alternative paper version of a survey instrument, just for situations where online acquisition is not possible. This alternative solution then leads to the question of whether or not paper administration is comparable to online. This question is addressed in the section that follows.

Age Appropriateness/Lack of Basic IT Skill

Paper and pencil is considered universally accessible for the young and old, throughout the world. Online survey completion requires basic IT skills. Young children—perhaps those younger than third grade (8 or 9 years old)—may not be able to operate online surveys, and even older primary school children may require teacher or parent supervision in understanding written questions or alternative response options. Older citizens are often inexperienced with IT systems because the systems became commonplace after the citizens' workforce careers were completed. Both younger and older citizens (as well as those with disabilities) may lack the manual dexterity needed to move a mouse and click on options desired. These and other issues need to be considered when planning an online data acquisition research project.

Reliability of Data Gathered Online

In the early days of online data acquisition, many scholars and practitioners questioned whether this new form would yield responses as reliable as paper forms. Although little has been published on this matter, the research that has been completed seems to indicate there is not great cause for alarm. Vallejo, Jordan, Diaz, Comeche, and Ortega (2007) studied the reliability and validity of online versus paper versions of general health questionnaires and symptom check lists in the medical field. Based on paper (test) and online (retest) completions by 100 psychology students in Madrid, they concluded that the construct validity and the reliabilities of the responses by the students were acceptable and comparable in either form.

Table 17.1 Internal consistency reliability indices (Cronbach's Alpha) for online versus paper-based administrations of the Young Children's Computer Inventory (YCCI)

Likert Scale	No. items in scale	Alpha online	Alpha paper	Combined
Computer Importance	6	0.60	0.65	0.62
Computer Enjoyment	5	0.48	0.44	0.47
Attitude Toward Computers	11	0.67	0.68	0.68
Motivation/Persistence	5	0.41	0.45	0.45
Study Habits	6	0.52	0.52	0.53
Motivation to Study	11	0.65	0.66	0.66
Empathy	9	0.76	0.73	0.76
Attitude Toward School	4	0.73	0.66	0.73
Creative Tendencies	13	0.74	0.79	0.77

Note: Online sample = 907; paper sample = 343

Knezek and Christensen (2002) compared online versus paper and pencil survey instrument reliabilities for school age children in the USA spanning grades 1–6 and representing 17 school districts. In their study, 907 students completed online versions of the Young Children's Computer Inventory (YCCI) while 343 students from comparable schools completed the same surveys on paper. No large differences between the reliability estimates for paper administration versus online administration were found. As shown in Table 17.1, Cronbach's Alpha indices for the online version of the YCCI deviated from the paper version indices by no more than 0.05; there was no systematic pattern for paper versus online being higher or lower; and these trends were consistent for the Alphas in the range considered "acceptable" or "good" (≥ 0.6), as well as those considered substandard or unacceptable (<0.6) (DeVellis, 2003).

Additional research based on item response theory (IRT) and other approaches focusing on the functioning of the items, rather than the classical scale-level approach presented in this section, is needed before definitive conclusions can be reached regarding the comparability of paper-based versus online survey administrations.

Compatibility with Data Analysis Systems

One problem that arises with administering surveys through content management systems (CMS) such as BlackBoard, WebCT, or Moodle, and also through many standard database systems, is how to get the data out of the database and into a tab-delimited or comma-delimited text file for use in a statistical data analysis package such as SPSS or SAS. Typically a researcher will not be sufficiently familiar with systems such as Access (a relational database package), FileMaker (a flat file manager), or an online course management system, to the point where he or she can merge files and write the proper output in a single record as text. Reliance on database packages and CMS surveys appear to create the need for a manager at the server site who can transform these files on short notice.

In summary, data acquisition systems that provide alternatives to paper-based surveys have become well established in the academic world. The current trend is toward technology-based systems that are more timely in providing data for the researcher and more direct in their measurement. Newer automated systems that can quantify human activities previously requiring a single expert or panel of judges are beginning to blur the lines between quantitative and qualitative data acquisition, and hence the analysis tools applied after the quantification stage. Two examples are the video camera-based face-reader software systems described by Schulz-Zander, Pfeifer, and Voss (2008), that can recognize and log emotions conveyed by human facial expressions while the subject is carrying out an information processing task, and film analysis software (Anderson & O'Connor, 2009) that can process and automatically label frames and transition sequences according to changes in color balance and other attributes. Nonintrusive brain-scanning equipment can now record brain wave data as well as images at the same time as various types of learning and performance activities are taking place. One can envision the day when self-report data, which Cattell (1950) has pointed out is typically observation data where the observer is oneself, is routinely triangulated with brain activity data and eye tracker data, as one example. This process might be called concurrent validation by quantitative researchers, but it would also be consistent with triangulation techniques commonly advocated by qualitative researchers (Tashakkori & Teddlie, 2010). Some analysis techniques and tools that could potentially be employed to analyze traditional paper-based survey data as well as multichannel, time synchronized participant responses, are presented in the following sections.

Tools for Data Analysis

A major criterion for selecting an appropriate tool is consideration of the goal or purpose toward which the tool will be applied. Three common purposes for employing quantitative data analysis tools are described here:

Exploratory Data Analysis encompasses *Descriptive Statistics*, the typical goal of which is to use a small number of indices (mean, standard deviation for example) to represent a larger set of numbers, and *Data Mining*, where the researcher typically examines large data sets with many variables, in order to uncover summarizing trends. Some of the most elementary quantitative tools, and some of the most complex tools described in this chapter are for exploratory data analysis. Detailed coverage of data mining, which often also includes visualization techniques, is reserved for the third major section of this chapter.

Hypothesis Testing is another type of goal toward which tools for quantitative analysis are commonly applied. In these techniques, the data set at hand is assumed to be a *sample* drawn from a larger *population*, and findings from analysis of the sample(s) are used to infer conclusions to be applied to the population as a whole. Quantitative analysis tools applied to hypothesis testing commonly contrast the distributions of scores around two or more means (*t*-test, analysis of variance), compute the strength of association between two or more continuous variables (correlation, regression); or count the frequency of occurrence of instances, or perhaps the rank order of entities, without making assumptions about the underlying distributions. The latter branch of *distribution free statistics*, which is also called *nonparametric statistics*, can also form a basis for drawing inferential conclusions. Two commonly used statistical analysis packages described later in this chapter (SPSS and SAS) offer comprehensive data analysis tools for hypothesis testing.

Spreadsheet and Relational Database Packages

Many application tools not created for quantitative data research have become sufficiently powerful to be used for that today. Applications vary from score reversals, to computing means and standard deviations, to aligning pretest with post-test scores, to adding regression lines to graphs and much more. Two common tools, spreadsheet packages and relational database packages, are described in this section.

Spreadsheet Packages

Spreadsheet packages such as Excel are commonly used by quantitative researchers for manual data entry from paper forms, or for intermediate processing/cleaning between the online data collection system and the statistical analysis package. These can also be used for data processing. One simple example is the computation of means and standard deviations, as well as frequency counts for variables in a data set. Variables are usually represented by columns in a spreadsheet program, and cases are represented by rows, so anchoring one's cursor on a cell below a column of data for a given variable allows a researcher to evoke functions such as =AVERAGE(b2:b32), =STDEV(b2:b32), or =COUNT (b2:b32) to compute basic descriptive statistics. These cell-based functions can then be dragged across a row to produce the same sample statistics for multiple variables. If the sort function has been used to divide the data set on a variable of interest (such as male vs. female) and these computations have been replicated for each sex, then the statistics for each portion can be entered directly into an equation from a text to carry out an independent samples *t*-test, or a researcher can simply search online for a *t*-test calculator such as GraphPad Software (2005). A researcher simply enters the values to produce the *t*-statistic and probability value (significance level) for the differences between the group mean values for the two groups.

Spreadsheet-Based Effect Size Computations

Effect size computations such as Cohen's *d* (Cohen, 1988) are a common use of spreadsheet packages. Reporting effect sizes is now strongly recommended for inclusion in publications by the American Psychological Association (American Psychological Association, 2001; Thompson, 1998), but effect size estimates are not yet produced by default in statistical analysis packages such as SPSS, when an analysis procedure such as an independent samples *t*-test, or a one way ANOVA with two groups (similar to independent samples *t*-test) is run. Cohen's *d* effect sizes (for males vs. females, for example) can be computed directly from the computation example previously provided, if just one additional statistic, the pooled standard deviation, is computed through an =STDEV function. In most existing versions of SPSS, as of 2011, the descriptive statistics option of the procedure *One Way* produces a table containing the mean of group 1, the mean of group 2, and the pooled standard deviation. Simply copying and pasting this output into a spreadsheet allows a researcher to quickly produce an "effect size" additional column in the spreadsheet that specifies a cell location for [(group mean 2) − (group mean 1)]/Pooled standard deviation for groups 1 and 2 combined. This is Cohen's *d*. If the spreadsheet manipulation is too complex, one can also simply take the output from the *Descriptives* option of the procedures *One Way* and enter it directly into an online effect size calculator such as the one provided online free of charge by Becker (1999).

MS Access Pre/Post Pairs Matchup

Relational database packages such as Microsoft Access can be very useful for merging separately gathered data sets (such as pretest and posttest) and producing a data file that contains only those entries common to both. In order to run a paired *t*-test analysis, the separately gathered pretest and posttest files must be merged such that the pretest responses for a given individual are in the same record (on the same line of a text file or spreadsheet) as the posttest responses for the same individual. The ability to conduct a paired *t*-test makes our research more credible.

Special Purpose Resources

Many special purpose resources are currently available online, in book form, and through machine-readable media such as DVDs. These are currently free or available for the price of a typical textbook. Selected examples are described in this section.

t-Test Calculators

An independent samples *t*-test compares the means of two groups. For example, a medical researcher could compare whether systolic blood pressure differs between a treatment and control group, between men and women, or any other two groups (GraphPad Software, 2005). GraphPad is a popular *t*-test calculator that is Web-based and free of charge. A researcher simply enters group 1 and group 2 means, standard deviations, and *n*'s (sample sizes), then the calculator produces a *t* statistic with degrees of freedom and two-tailed probability (level of significance). If a one-tailed (directional) hypothesis is being tested using this calculator, the researcher simply divides the computed significance level by two. An example incorporating a *t*-test calculator is included along with effect size calculators, in the following section.

Effect Size Calculators

As described in the section of this chapter devoted to spreadsheet applications, one common measure of effect size (magnitude or practical significance for an intervention) is Cohen's *d*. Cohen (1988) provided the following guidelines for interpreting the magnitude of *d*: 0.2 = small, 0.5 = moderate, and 0.8 = large. Additional researchers (Bialo & Sivin-Kachala, 1996; Kulik & Kulik, 1991) have observed that an effect size ≥0.3 is commonly considered educationally meaningful. If a researcher is armed with this basic knowledge, plus group means and standard deviations for two samples such as treatment and control, then entering this information into an online effect size calculator will enable the researcher to obtain an estimate of the magnitude (importance or practical significance) of an observed difference. Becker (1999) provides an online calculator. The format is shown in Fig. 17.1.

An example of the use of an effect size calculator in combination with a *t* test calculator is in order. In the previously cited study of the effects of a technology-based reading program on reading achievement for first and second grade students (Knezek & Christensen, 2008a, b), the Classroom Reading Level Index values for matched-sites first grade treatment and control groups were approximately even at pretest time but the treatment group was observed to be "somewhat" higher at the posttest time period (see Fig. 17.1). The precise values for the pretest and posttest means graphically

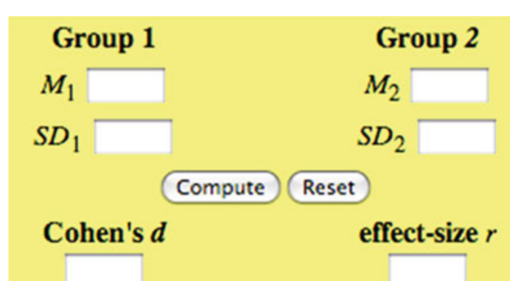

Fig. 17.1 Data entry interface for Becker's online effect size calculator

Table 17.2 Descriptive statistics for first grade pretest–posttest Classroom Reading Level Index

	Pretest			Posttest		
	Mean	St. Dev.	*N*	Mean	St. Dev.	*N*
Treatment	0.768	0.339	123	2.09	0.226	123 (6 schools, 11 classrooms)
Control	0.778	0.386	101	1.76	0.216	101 (7 schools, 13 classrooms)

displayed in Fig. 17.1 are provided in Table 17.2. If one enters the pretest means, standard deviations, and sample sizes into the t test calculator listed in the previous section, the resulting t value is =0.21 with 222 degrees of freedom, $p=0.84$ (NS). This indicates the small difference in means shown in the graph of Fig. 17.1 were very likely due to chance. The effect size resulting from entering mean and standard deviation values into Becker's effect size calculator is ES=0.03, which is extremely small according the guidelines set by Cohen (1988). We judge there is no credible evidence that treatment versus the randomly assigned controls were different at pretest time, and therefore we are justified in analyzing the outcomes of this experiment as a simple posttest only design (Campbell & Stanley, 1963).

For the analysis of posttest data, relevant values for the two groups are: treatment group posttest mean=2.09 (Std.=0.226) for $n=123$ first grade students from 11 classrooms in 6 schools; control group posttest mean=1.76 (Std.=0.216) for $n=101$ first grade students from 13 classrooms in 7 schools. If a researcher enters these values into a t-test calculator, the resulting value is $t=2.69$ with 11 degrees of freedom, two-tailed $p=0.02$, based on the most conservative perspective where each school is considered the proper unit of analysis. From a slightly different perspective, the result based on the assumption that each classroom is the proper unit of analysis yields $t=3.65$ with 22 degrees of freedom, $p=0.001$. As a third perspective, if the researcher believes that the schools and classrooms are just sampling units, and the individual student is the proper unit of analysis, then $t=11.09$ with 222 degrees of freedom, and $p<0.0001$. All three of these views indicate significance at the $p<0.05$ level reported in publications about this study (Knezek & Christensen, 2008a, b), with the more conservative interpretations generally consistent with the visual analysis guidelines based on Cumming (2003) for Fig. 17.1. Entering mean and standard deviation values into an effect size calculator such as Becker's produces an approximate Cohen's $d=1.49$. This would be considered a large effect (Cohen, 1988) and provides assurance that the intervention was educationally meaningful, well beyond the ES>0.3 cutoff published by Bialo and Sivin-Kachala (1996).

Which level of significance is correct? After considering the three alternatives, Knezek and Christensen (2008a, 2008b) elected to report the most conservative ($p<0.05$) interpretation in the refereed journal article about this study. Researchers often face these practical decision points with respect to which outcome(s) to report. Having a visual interpretation such as is presented in Fig. 17.1, can help a scholar decide.[1]

CRC Standard Mathematical Tables and Formulae

CRC Standard Mathematical Tables and Formulae, released in its 31st edition in 2003, continues to be among the most accessed and respected scientific references of its type in the world (Zwilliger, 2003). CRC originally stood for "Chemical Rubber Company." As late as the 1962–1963 the CRC *Handbook* (3,604 pages), which is the original reason for the CRC book of tables, contained a myriad of information for every branch of science and engineering plus useful information for less technical disciplines. Later editions of the *CRC Handbook* focused almost exclusively on chemistry and physics topics and eliminated much of the more "common" information. However, many of the tables in the companion *CRC Standard Mathematical Tables and Formulae*, such as those for the cumulative binomial distribution (for nonparametric sign tests) and Poisson distributions (for large sample, rare occurrence events), are appropriate for calculating the probabilities of numerous psychological outcomes.

An example of the use of the *CRC Standard Mathematical Tables and* Formulae book is provided here. Knezek and Christensen (2008a, 2008b) were concerned that the previously reported analysis of the impact of a technology-based reading program for first and second grade students might suffer from inflated probability levels. They conjectured that this could have been due to the assignment of the weighted mean for the class to every student in the class (Knezek & Christensen, 2002). A nonparametric binomial (sign) test conducted on the 21 first grade treatment classrooms in the data set (Dunn-Rankin, Knezek, Wallace, & Zhang, 2004; Gibbons, 1976), using the average whole class reading level indicator gain of 0.94 for the eight control classrooms in the complete data set as the standard for indicating positive (+) or negative (−) gains in treatment classrooms, resulted in 16 treatment classrooms with reading achievement gains greater than the average gain for the control group classrooms, and 5 treatment classrooms with reading achievement gains smaller than the average gain for the controls. The tabled probability of 16 or more treatment classrooms of 21 total having reading

[1] Note that multilevel analysis could also be used for detailed examination of this type of research question, and for separating out effects at different levels of a multilevel design. However, other issues such as having sufficient degrees of freedom to develop robust solutions also enter with multilevel designs. One practical consideration is the lack of broad-scale researcher access to multilevel analysis software, as of 2011. Multilevel approaches such as Hierarchical Linear Modeling (HLM) (Roberts & Herrington, 2005) are destined to gain in popularity in the coming years.

achievement gains greater than the average for the control group classrooms is $p < 0.014$ (Zwilliger, 2003). This reaffirmed that the gains were not likely due to chance.

Online Binomial (Sign) Test

GraphPad Software (2005) provides free access to a convenient, Web-based binomial test calculator that can produce approximately the $p < 0.014$ result of the previous paragraph, in short order. A researcher enters the "number of successes" (16), followed by the "number of trials" (21) and the "probability of success on each trial" (0.5). In this case the precise resulting one-tail p value = 0.0133.

A binomial test can often be completed from the table-reported data included in a publication. GraphPad reports that a researcher should use the binomial test when there are only two possible outcomes. The researcher should know how many of each kind of outcome (traditionally called "success" and "failure") occurred in an experiment. Also one should have a hypothesis regarding the true overall probability of "success." The binomial test answers this question: If the true probability of "success" is what your theory predicts, then how likely is it to find results that deviate as far, or further, from the prediction. The sign test is a special case of the binomial case where the theory is that the two outcomes have equal probabilities (GraphPad Software, 2005).

Standard Statistical Packages

SPSS (Statistical Package for the Social Sciences)

SPSS was created in 1968 by Norman H. Nie, C. Hadlai Hull, and Dale H. Bent in order to computerize the process of turning data into useful information. SPSS is one of the most widely used programs for statistical analysis and was acquired by IBM in 2010. Newer versions contain a spreadsheet-like interface for data entry and manipulation, plus a point-and-click approach to most analysis procedures. SPSS also has a provision to execute programming language-like commands, the latter of which were the only interface in the earlier versions of SPSS (SPSS, 2010).

Statistics included in the base software package include:

- Descriptive statistics: Cross tabulation, Frequencies, Descriptives, Exploratory Procedures.
- Bivariate statistics: Means, *t*-tests, ANOVA, Correlations, Nonparametric tests.
- Predicting outcomes: Linear regression, Discriminant analysis.
- Dimension reduction: Factor analysis, cluster analysis, multidimensional scaling.
- Scale consistencies: Cronbach's alpha and others.

The graphical user interface has two views that allow the user to toggle between the "data view" and "variable view." It can read data from American Standard Code for Information Interchange (ASCII) test files, spreadsheets and other formats. Output by default is in a proprietary .spv format, but it can be exported to Microsoft Word or captured as a graphic image. It is the experience of the authors that SPSS is often the favorite of applied quantitative researchers (for example, social scientists) and those who infrequently carry out analyses. It is known for extensive documentation containing comprehensible descriptions of analysis routines. Versions of SPSS produced near the end of the first decade of the 21st century were called PASW.

SAS

SAS (originally Statistical Analysis System) began at North Carolina State University as a project to analyze agricultural research but has evolved into an integrated package of analyses tools (SAS, 2011). SAS was originally conceived by Anthony J. Barr in 1966. It provides the following features for the data analyst:

- Data entry, retrieval, management, and mining
- Report writing and graphics
- Statistical analysis
- Business planning, forecasting, and decision support
- Operations research and project management
- Quality improvement
- Applications development
- Data warehousing (extraction, transformation, loading)
- Platform independence and remote computing

SAS normally operates in a command file structure, with sequences of operations performed on data stored as tables. SAS programs have three major parts:

1. The Data definition step
2. Procedure step(s)
3. Macro language manipulations

Graphical user interfaces to aid nonprogrammers exist for SAS, but these are often just a front-end that facilitates the generation of command file-type programs. SAS components are intended to be accessed via application programming interfaces, in the form of statements and procedures. SAS is known for its statistical precision and matrix manipulation. In the opinion of the authors, SAS is often the favorite of those who teach multivariate data analysis.

Other Statistical Packages

There are dozens of other statistical packages available for general and specific analyses. We include just one example that is becoming widely used in university environments.

The R Project for Statistical Computing

R is a free software environment for statistical computing and graphics (Ihaka & Gentleman, 1996). It compiles and runs on a wide variety of Unix platforms, Windows and MacOS.

R is a language and environment for statistical computing and graphics that was developed at Bell Laboratories. R provides a wide variety of statistical and display routines, including linear and nonlinear modeling, classical statistical tests, time-series analysis, classification, clustering, and graphical techniques. One of R's strengths is the ease with which well-designed publication-quality plots can be produced, including mathematical symbols and formulae where needed. R is available as Free Software in source code form (The R Project for Statistical Computing, 2011).

R is an integrated suite of software facilities for data manipulation, calculation and graphical display. It includes:

- An effective data handling and storage facility.
- A suite of operators for calculations on arrays, in particular matrices.
- A large, coherent, integrated collection of intermediate tools for data analysis.
- Graphical facilities for data analysis and display either on-screen or on hardcopy.
- A well-developed, simple, and effective programming language which includes conditionals, loops, user-defined recursive functions and input and output facilities.

R allows users to add additional functionality by defining new functions. Advanced users can also write C code to manipulate R objects directly. R has its own documentation format.

LISREL

LISREL is an acronym for linear structural relations. It was developed by Karl Joreskog and Dag Sorbom in the 1970s at the Educational Testing Service in Princeton, New Jersey (Joreskog & Van Thillo, 1972). LISREL is mainly syntax-based, although recent versions have featured a graphical user interface (GUI).

A common use for LISREL is confirmatory factor analysis, an accepted means of verifying construct validity for a psychometric instrument. LISREL is also used for structural equation modeling, combining the measurement model with the structural model. With this approach, the impact of one or more construct(s) on another can be tested while also testing the extent to which the measurement scales completed by the participants represent the constructs for which they were intended. In brief, researchers can empirically assess their theories formulated as theoretical models for observed and latent (unobservable) variables. If data are collected for the observed variables of the theoretical model, the LISREL program can be used to fit the model to the data (Scientific Software International, Inc., 2011).

Morales (2007) used LISREL to confirm that more than 90% of the variance in classroom technology integration could be explained by a linear combination of a teacher's attitude or *Will*, technology proficiency or *Skill*, and access to technology *Tools*. This was found to be true for a cross-cultural sampling of teachers from Mexico ($n=978$) and Texas in the USA ($n=932$). The structural equation modeling (SEM) approach he employed involved two models (see Fig. 17.2). The first is the structural model, which consists of the latent variables Will, Skill, Tool, and Integration, and the arrows indicating the direction of the influence, i.e., Will, Skill, and Tool are the independent latent variables, influencing the latent dependent variable Integration. The second model is the measurement model, which consists of the indicators, or the measures of the latent variables, and the regression paths that connect each latent variable with their respective set of measures. Generally data from large numbers of subjects, with each subject completing multiple measures, are required to achieve satisfactory fit with this powerful quantitative data analysis technique. Shumacker and Lomax (2004) provide an overview of SEM for a quantitative researcher.

Amos

Amos is a package that works with SPSS and has functionality similar to LISREL. Amos is well respected for its ability to graphically represent the measurement and structural components of a structural equation model. R and S-Plus are also emerging as widely used packages for SEM.

Tools for Exploring Relationships in Data and Visualizing Results

Data mining, scaling methods, and visualization/display techniques have made great advances in recent decades as quantitative analysis tools. Applications of these tools are commonly intermixed in 21st century research studies, and often bridge the gap in the spirit of mixed methods research (Onwuegbuzie & Teddlie, 2003) toward quantifying and analyzing judgments or observations collected for qualitative studies. Data mining enables a researcher to examine large data sets with many variables for the purpose of uncovering summarizing trends. Scaling methods seek to discover or confirm the dimensionality of a set of data or examine the relationships among subjects producing a set of psychometric data. Visualization/display techniques present findings in intuitively recognizable forms that go far beyond the tables of numbers that have been the historical mainstay for quantitative data analysis tools. While tabular output is still available and required for publication precision, most findings determined through tools described in this chapter can be represented visually in the form of a figure. Common quantitative tools such as Excel, and widely used statistical packages such as SPSS, have features which enable straightforward graphical representations of findings. Other tools such as Wolfram Alpha, Mathematica, and MATlab have special capabilities for producing camera-ready graphs. One data visualization tool, Google Fusion Tables, allows users to upload tables and display the data in many alternative forms, including maps,

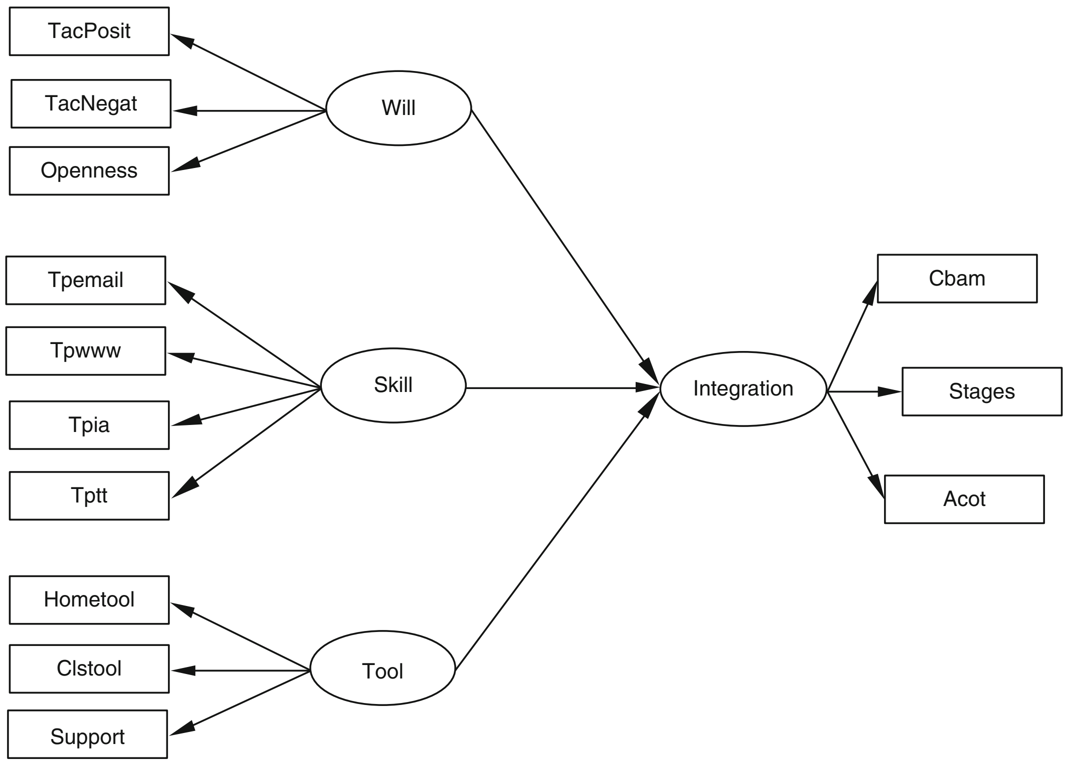

Fig. 17.2 The structural Will, Skill, Tool Model of Technology Integration (WiSTTI Model), with standard measures for each latent variable (Morales, 2007)

intensity maps, motion charts, timelines, and storylines. Some advanced data analysis routines can produce graphical representations of hierarchical associations and underlying dimensional structures, while others can display causal (path) relations or combined measurement and construct relationships (such as structural equation modeling packages). Quantitative tools for scaling methods can often produce displays in the form of associational dendrograms or hyperspace projections of the distances in psychological space between objects. Several examples presented in this section feature data visualization.

The most common purpose for each tool introduced in this section is described within the context of the explanation of its use. Explanations proceed from simple applications, typically useful for alternative presentations of previously produced findings, to more complex analyses that involve data exploration or computations of relationships combined with graphical display.

Spreadsheet Charting

Spreadsheet packages are often useful for producing customized displays of characteristics of data, and the learning curve is often much less ominous than for many graphics display packages. For example, visual representations of mean values and 95% confidence intervals around group means, comparing pre to post, can be produced using the Hi-Lo-Close chart option in Excel. Simply enter upper 95% confidence limit value, lower 95% confidence limit value, and mean value in the slots specified for Hi-Lo-Close. The display is precisely what statisticians such as Cumming (2003) might use to augment or replace arbitrary *p*-level cutoffs to accept/reject null hypotheses, as the field considers moving to what many theoretical statisticians see as the next logical stage beyond routinely reporting effect sizes, on towards using confidence intervals for effect sizes as the primary indicator of the importance (magnitude) of an intervention or a priori effect. As an example, as shown in Fig. 17.3, a cursory glance at the pretest classroom reading level index scores for the control group of first graders reveals that it appears to not be extensively different from the treatment group at pretest time. However, at the posttest time, the treatment group (bottom left display) appears to be a bit higher than the control group (top right display). Cumming has pointed out that since the square box in the middle of each figure element represents the group mean value, while the upper and lower bars surrounding it represent the upper and lower 95% confidence intervals, then greater separation of treatment and control figure elements typically equates to more highly significant *p* levels. A more detailed explanation of the phenomenon is explained in the Effect Size portion of the Hypothesis Testing section of this chapter.

Statistical Package Visualization

Packages such as SPSS contain modules to produce output allowing the researcher to visually explore the variation of the data for particular variables (QI Macros, n.d.). Box plots like those shown in Fig. 17.4 graphically illustrate the median or middle score (Quartile 2) value rather than the geometric mean (average score) illustrated in Fig. 17.3. Whiskers on a box plot typically represent the upper and lower boundaries of the range of the data. Box plots and confidence interval graphs complement each other.

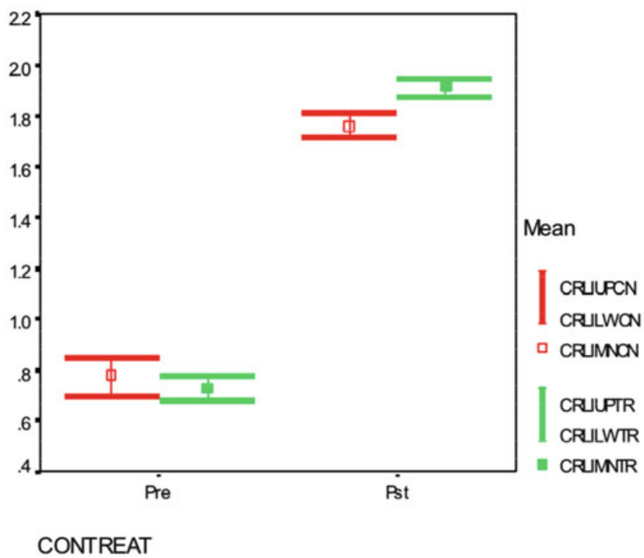

Fig. 17.3 Comparisons between control (*red*) and treatment groups (*green*) on first grade classroom reading level index using Cummings' Confidence Interval Analysis (Knezek & Christensen, 2002, 2008a, 2008b). Note: *CRLI* Classroom Reading Level Index, *CRLICN* control group, *CRLITR* treatment group

Online Aids for Visualization

Wolfram Alpha

Wolfram Alpha is a computational knowledge engine built on Mathematica (Wolfram Alpha, 2011). It is an online service that answers factual queries directly by computing the answer from structured data and often provides a visual display of data. Wolfram Alpha will compute whatever it can from any information put into the search box. For example, "How old was George Washington in 1776?" Or if you just input "George," it displays a graph of the age distribution of the name George as well as many other computations of the name George. Figure 17.5 illustrates the output produced from the query, "How old was George Washington in 1776?"

MATLAB®

MATLAB® (The MathWorks, Inc., 2011) is a high-level technical computing language and interactive environment for algorithm development, data visualization, data analysis, and numeric computation. Using the MATLAB product, you can solve technical computing problems faster than with traditional programming languages, such as C, C++, and Fortran.

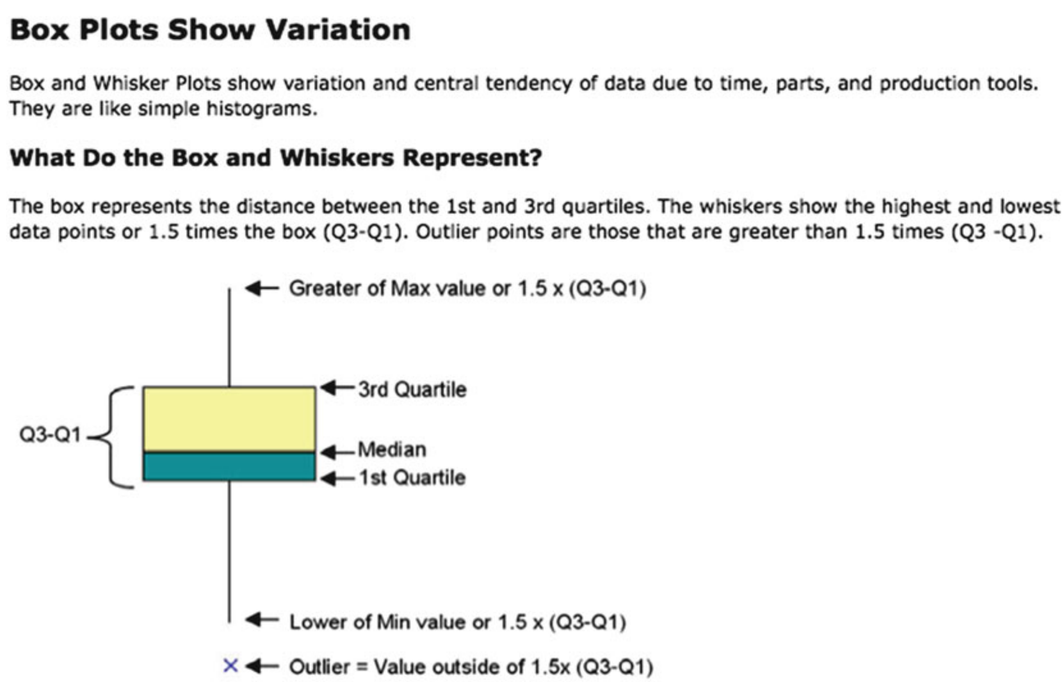

Fig. 17.4 Box plot illustration of variation around median value of a variable

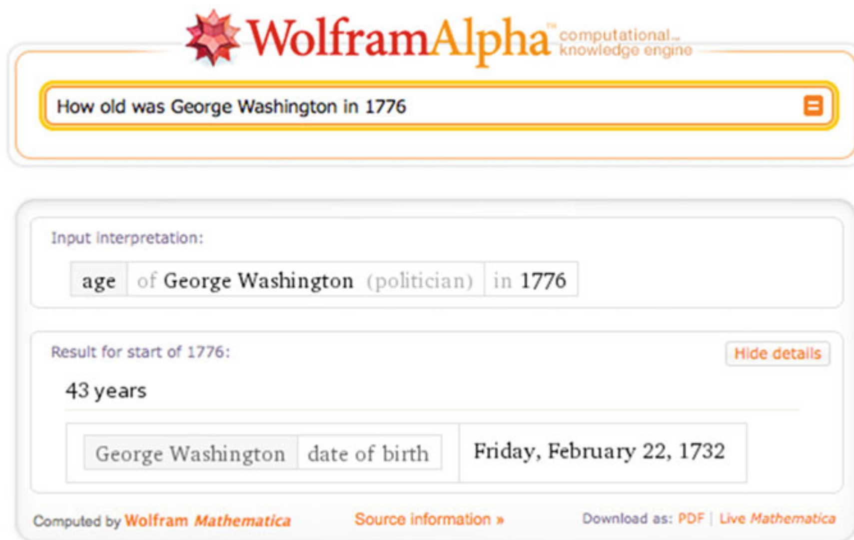

Fig. 17.5 Output resulting from entry of "How old was George Washington in 1776"

Mathematica

Mathematica is an algebra and symbolic math package whereas MATLAB is predominately a numerical computation package. Generally a researcher would use Matlab if wanting to be able to manipulate great quantities of numerical data easily, while a scholar would use mathematica if wanting an aid for symbolic mathematical manipulations. Engineers might find Matlab more useful than Mathematica, while mathematicians might prefer the opposite (Physics Forums, 2007).

Eureqa

Eureqa (pronounced "eureka") is a software tool for detecting equations and hidden mathematical relationships in a data set. Its goal is to identify the simplest mathematical formulas that could describe the underlying mechanisms producing the data. Eureqa is free to download and use (Schmidt & Lipson, 2009).

Eureqa has been used with some success for a form of data mining—to examine data sets with large numbers of measurement points, in an attempt to uncover relationships among variables. This fits well within the overarching definition of data mining as "the nontrivial extraction of implicit, previously unknown, and potentially useful knowledge from data" (Frawley, Piatetsky-Shapiro, & Matheus, 1992 as cited in Wang & Wang, 2009). The following example is provided by Gibson (Gonzalez-Sanchez et al., 2011).

Figure 17.6 is the result of a Eureqa analysis of data from a 7.5 seconds moment in time when a girl who was playing Guitar Hero gets highly frustrated. Eureqa was used to model the activity. All available variables were included in the analysis. The primary dependent variable of interest for the first equation was "Engagement/Boredom." For the second equation the dependent variable was "AF3" which is an EEG lead on the head on the frontal cortex. The assumption setting used was "modulo" math due to the conjectured cyclical nature of the activity. As shown in Fig. 17.6, the model of Engagement in the first equation goes down rapidly to Boredom over just 7.5 seconds, and during the same time frustration becomes high. The resulting equation explains 98% of the variance.

The second equation uses the same approach to attempt to uncover an explanation for AF3. This was initiated due to researcher curiosity about how AF3 might affect decision-making and motor output. Once the equation models get complex enough (they are simple at the bottom to the left and more complex to the right) then Engagement/Boredom shows up! This explains about 96% of AF3. These sorts of models could be used to fine tune classroom teaching/learning simulators such as simSchool (Gibson, 2009; Gonzalez-Sanchez et al., 2011).

Scaling Methods

Scaling methods are concerned with assigning numbers and visualizing relations among things we do not know how to measure. Scaling is a branch of measurement that associates qualitative constructs with quantitative metric units (Trochim, 2006). Scaling methods are generally divided into two broad categories: unidimensional and multidimensional. The unidimensional scaling methods were developed in the first half of the twentieth century and are generally named after their inventor. Three types of unidimensional scaling methods are:

- Thurstone or Equal-Appearing Interval Scaling
- Likert or "Summative" Scaling
- Guttman or "Cumulative" Scaling

In the late 1950s and early 1960s, measurement theorists developed more advanced techniques for creating

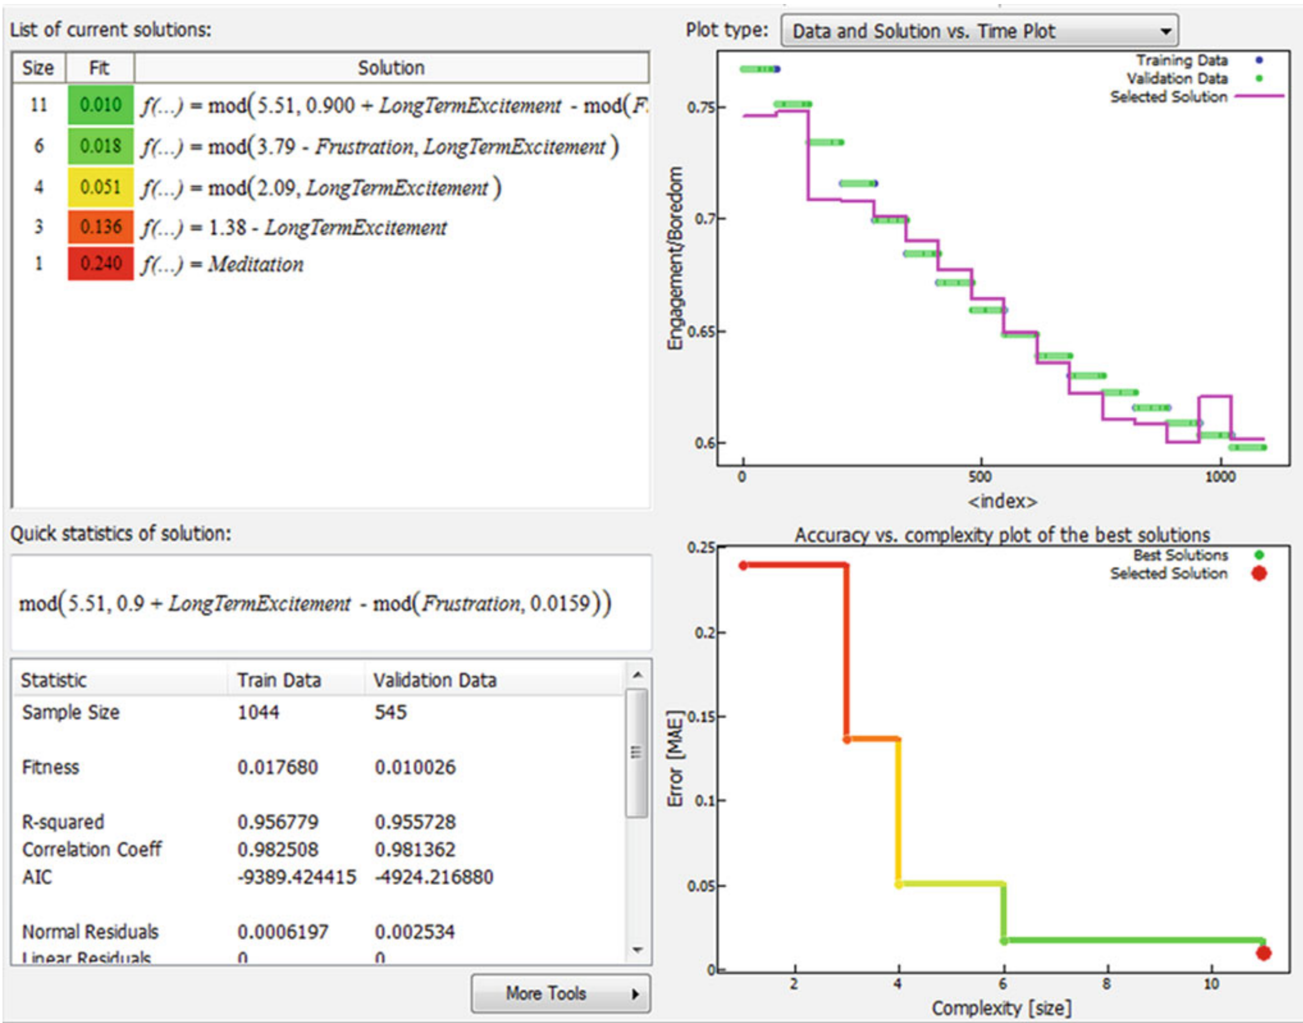

Fig. 17.6 Eureqa output for analysis of engagement/boredom relationship to electroencephalic (EEG) brain activity while playing Guitar Hero

multidimensional scales (Trochim, 2006). Common examples of these include the following:

- Hierarchical Cluster analysis
- Multidimensional scaling
- Multidimensional preference mapping (Dunn-Rankin, 1983)

Dunn-Rankin (1978) was able to apply multidimensional scaling techniques to identify the most salient visual characteristics of letters of the alphabet, and to put forth evidence that most readers use the features to process letter recognition in an integrative rather than sequential processing manner. As shown in the letter wheel displayed in Fig. 17.7, the two underlying dimensions through which most adult readers classify letters are whether letters are curved versus angular, and whether the letter has ascenders or descenders. These two dimensions allow letters to be placed in a circle similar to a color wheel, illustrating the continuous transitions from one letter to the next as the letters are arranged based on human perception, in a clearly defined wheel.

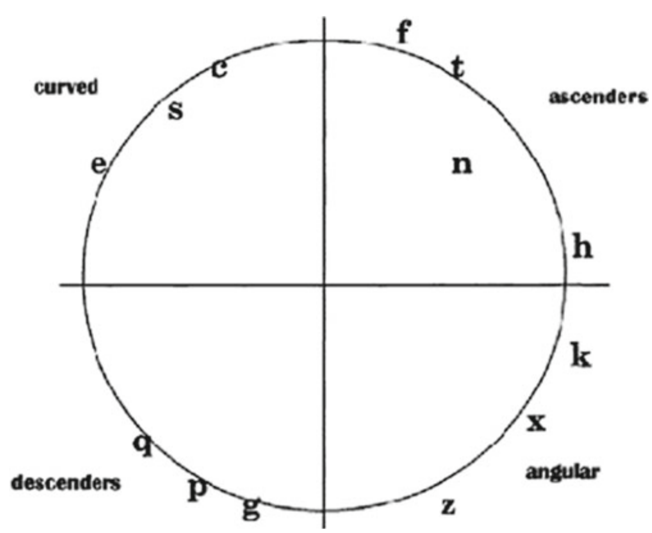

Fig. 17.7 Letter wheel based on multidimensional scaling (ALSCAL) of time latency to respond "same or different" regarding all possible pairs of 13 letters of the English language alphabet (Dunn-Rankin, 1978)

Item	Rank Total	Scale Score
Min	25	0
1	68	86
2	49	48
3	34	18
Max	75	100

```
0    10    20   30   40    50   60   70   80    90  100

        SB-5          SB-4F                 LM
```

Fig. 17.8 Rank-sum scaling analysis of three versions of the Stanford Binet using unidimensional scaling program Ranko (Dunn-Rankin et al., 2004)

Tyler-Wood, Knezek, Christensen, Morales, and Dunn-Rankin (2005) used rank-sum scaling (similar to Guttman Scaling), hierarchical cluster analysis, and multidimensional scaling techniques to examine the measurement characteristics of three versions of the Stanford Binet IQ test. Based on the administration of three versions of the Stanford Binet (SB_LM, SB4, and SB5) in randomized order, to 25 subjects aged 8–14 who had been referred by parents, teachers, and school personnel as gifted, and who were further screened by scoring at the level of 118 or higher on at least one version of the test administered by the research personnel, findings were that the test versions performed differently for students in three categories of giftedness. As shown in Fig. 17.8, a rank-sum (Dunn-Rankin, 1983), unidimensional analysis of the versions of the exam based on scores by the 25 individuals, produced results very similar to a multidimensional scaling analysis (Proxscal) (Dunn-Rankin et al., 2004; SPSS, 2010) of the exam versions, using interval data assumptions and specifying one dimension (see Fig. 17.9). Ninety-nine percent (99%) of the dispersion in among the subjects in their Stanford Binet test scores was accounted for by a unidimensional solution (Tyler-Wood et al., 2005).

As shown in Fig. 17.10, a Hierarchical Cluster Analysis of the subjects, based on their exam scores for the three versions of the Stanford Binet, yielded three apparent clusters.

Further examination of the centroid (median) scores for each test version within each cluster of subjects, revealed the characteristics of each of the clustered subject groups. As shown in Fig. 17.11, Cluster III is a group of subjects that generally have high abilities, well above the norm of IQ 100, but it matters little on which of three versions of the Stanford Binet they are tested. The scores are consistent across the three versions of the exam for this group. Cluster II contains a group of subjects with exceptional IQ, as indicated by the cluster centroids in the range of 130. However, the pattern of the responses across the three Stanford Binet versions is similar to Cluster III. Cluster II subjects perform on the tests like Cluster III subjects, except that the IQ of the subjects in Cluster II is higher. Cluster I subjects might be considered truly gifted, as indicated by a group centroid in the range of

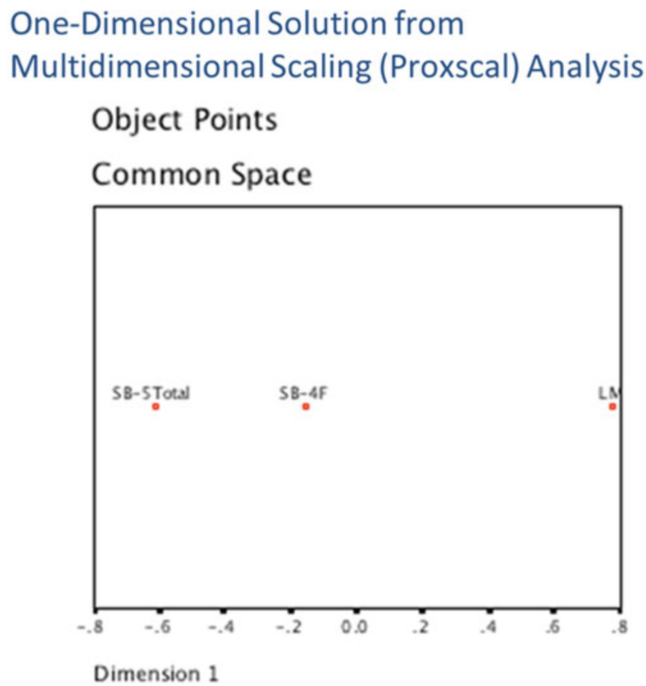

Fig. 17.9 Multidimensional scaling analysis of three versions of the Stanford Binet, using interval data assumptions and specifying one dimension in SPSS Proxscal procedure

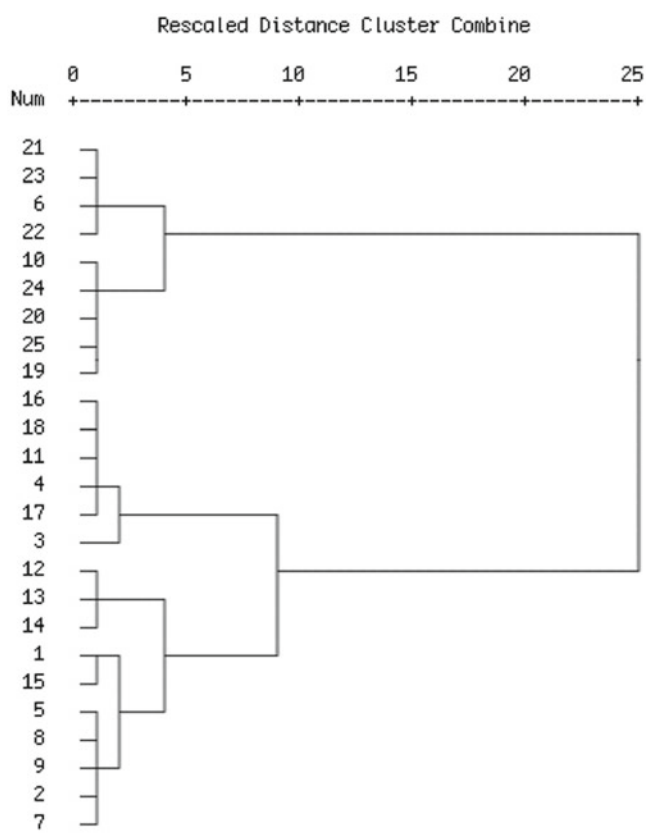

Fig. 17.10 Hierarchical cluster analysis of 25 subjects based scores for three versions of the Stanford Binet IQ test

140 or higher. Their pattern of scoring across the three versions of the Stanford Binet is quite different from the patterns found in Cluster II and Cluster III. For truly gifted subjects, it appears that SB4 (released 1986) and SB5 (released 1998) do not allow them to demonstrate their giftedness as well as the older and more lengthy Stanford Binet Version LM released in 1972.

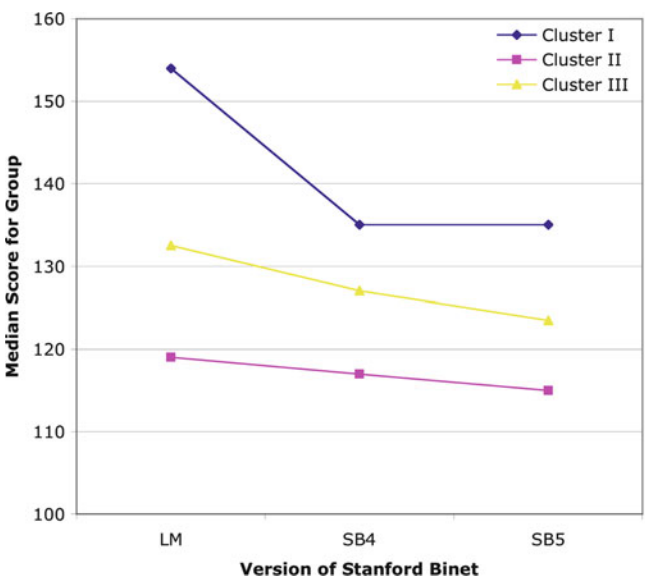

Fig. 17.11 Median score for groups on different versions of the Stanford Binet

Other relationships can be discerned by placing the subjects in the same space as the objects, based on subject preference or affinity for an object. Multidimensional preference mapping (MDPREF) (Dunn-Rankin et al., 2004) can perform this type of analysis. As shown in Fig. 17.12, subjects 5, 11, 19 and 20 have an affinity for the LM version of the Stanford Binet IQ test, while subjects 2, 14, and 16 have a preference for the Stanford Binet version 4. No subjects appear to have a strong affinity with the Stanford Binet Version 5, but many (such as 3, 12 and 13) appear to have an aversion to version 5.

In summary, based on this multiple-perspective scaling analysis of the 1972, 1986, and 1998 versions of the Stanford Binet IQ test, Tyler-Wood et al. (2005) concluded: (a) for above-average IQ subjects in the age bracket of 8–14 years, it matters little which version of the Stanford–Binet IQ test is used to test a subject; but (b) the SB5 (1998) appears to be the least sensitive to true giftedness, followed by the SB4 (1986); and (c) the LM version (1972) is strongly recommended for its ability to register exceptional ability,

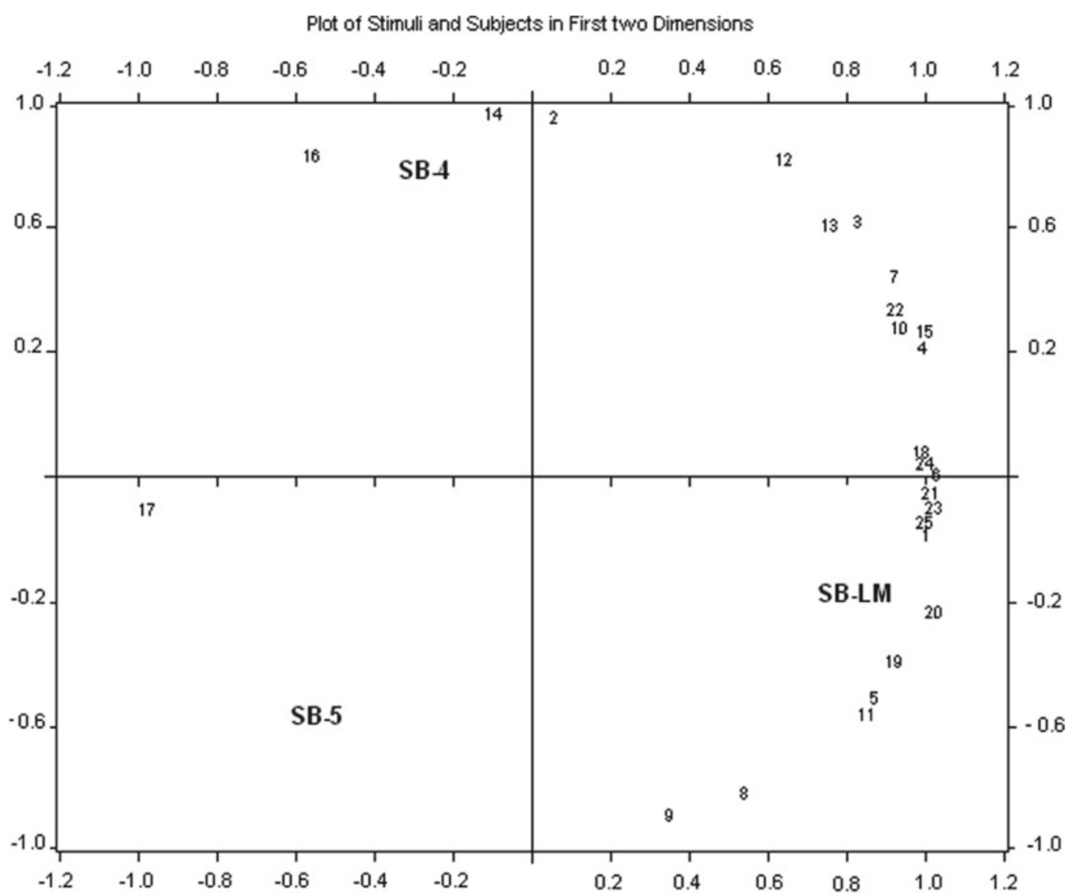

Fig. 17.12 Stanford Binet version affinity by subjects based on MDPREF (Dunn-Rankin et al., 2004)

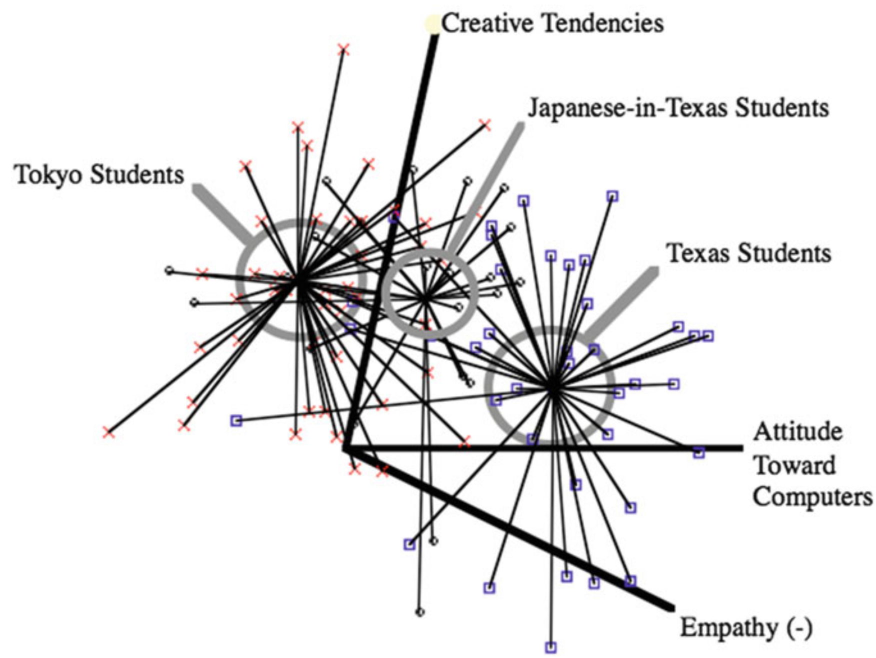

Fig. 17.13 Centroids in three-dimensional space of Attitude Toward Computers, Creative Tendencies and Empathy for first- and second-grade Japanese students living in Japan, Japanese students living in Texas, USA, and Texas students living in Texas

whenever true giftedness is indicated by another credible source (Tyler-Wood et al., 2005).

Many other scaling techniques are available to the researcher to explain and describe as well as explore relationships among psychological objects whose measurement characteristics have not been well defined. Note that these often employ visualization techniques—producing a graph or a picture—for the relationships the researcher wishes to explore. Many of these trace their origins to researchers at the Bell Telephone Laboratories in the 1960s and beyond, the same time and place when Unix was being developed.

Other Visualization Techniques

Many tools exist to enable researchers to place a table of data into a visualization package such that the data become coordinates for display in three-dimensional space. MacSpin was an early package that allowed Knezek and Miyashita (1991) to show that attitudes of first and second grade children of Japanese families living in Texas, USA, actually did lie in three-dimensional psychological space (Attitudes Toward Computers, Creative Tendencies, Empathy) "between" the attitudes of Japanese children living in Japan, and non-Japanese children living in Texas, USA (see Fig. 17.13). Kamakura and colleagues (Naik et al., 2008) have more recently developed a macro-based extension to Microsoft Excel that allows the rotation of three-dimensional scatterplots in much the same fashion as MacSpin.

Currently emerging tools such as the WorldWide Telescope Project of the Microsoft Research Laboratories and the Silverlight Data Visualization Tools of the same lab are believed to have great potential for exploring relationships in biological or social science data (Microsoft Research, 2010). As of 2011, the Microsoft Space Telescope project contains approximately 13,000 images of the landscape of Mars, and a night sky view of objects in our solar system, online, and assessable via the Web, to anyone who wants to explore their relationships. These kinds of systems might one day be capable of displaying all of the neural connections in the brain, for example, or be capable of displaying a complete map of the affective, cognitive, and psychomotor components of an individual's psychological space. There are possibilities for giant leaps forward in the foreseeable future.

Summary/Conclusions

Information technology tools for data acquisition, data processing, and the display or representation of results have advanced rapidly over the past 30 years since interactive data processing first became widely available to the university research community. During just the time passed since the beginning of the 21st century:

- Online data acquisition has become the norm, far dominant over paper surveys.
- Sophisticated data analysis packages are expected to run on normal laptop computers like researchers carry for every day manuscript production and library research needs.
- Multicolored, high-resolution 2D and 3D presentations of major findings have become the norm.

- One can envision the day when fully rotational dimensional perspectives and telescopic macro/micro views are also routinely employed to present or discover relationships in the data.

Statistical data analysis systems have simultaneously become user friendly and very comprehensive. Elegant, special purpose routines have become available (often for free) via the Web. The distinction between analysis, modeling, and display tools is beginning to blur as "math packages" are being routinely employed to produce elegant summaries and visual displays of findings from traditional research. There is no end to this renaissance in sight. In this chapter we have presented just a few examples of the alternatives available to a quantitative researcher. We recognize that before this chapter is printed, there will certainly be at the researcher's disposal many more. Thus, it is our hope that the reader will view the tools and examples presented here as exemplars, rather than an exhaustive list. It is our hope that this chapter is used as a springboard for ideas, from which a quantitative researcher can begin to explore.

Tools for Analyzing Qualitative Data: The History and Relevance of Qualitative Data Analysis Software

18

Linda S. Gilbert, Kristi Jackson, and Silvana di Gregorio

Abstract

The most common question from novices regarding the use of software in qualitative research is "which program should I use?" when they would be better served by asking "what analytical tasks will I be engaged in, and what are the different ways I can leverage technology to do them well?" In this chapter, we first provide an overview of tasks involved in analyzing qualitative data, with a focus on increasingly complex projects, before we turn to the software meant to support these tasks. One genre of software, known as Qualitative Data Analysis Software (QDAS or QDA software), is specifically designed to support qualitative research, as opposed to tools primarily used for the collection of data (such as audio or video recorders), or presentation of findings (such as presentation or modeling software). We briefly review the historical development of QDA software—including associated methodological questions and issues—before identifying the increasingly diverse array of expected features and functions in most of the current software programs. We then summarize the "user experience" literature and subsequently discuss the boundaries between cadres of qualitative researchers who do use software, and those who do not. Finally, we address potential directions as these programs are being influenced by Web 2.0 developments.

Keywords

QDA • QDAS • CAQDAS • Qualitative research methods • Qualitative data analysis software • Web 2.0

Introduction

This chapter focuses on *tools* for supporting the analysis of qualitative data, particularly on software designed for that purpose. The choice of the word "tools" rather than simply "software" in the title of this chapter reflects the role of technology in the context of complex intellectual work. "Tools" is a broad term, which could encompass the broad array of theoretical constructs that fall under the mantle of qualitative research, analytical practices used in conjunction with various theoretical approaches, as well as the wide range of supportive technologies that are increasingly used for this specific kind of knowledge work; these dimensions of the term are interrelated, but not unified. In addition, a variety of technological tools can be used to achieve the same analytic goal, while very different theoretical approaches often involve the same analytical tasks. This complexity leads us to an important point: the most common question from novices regarding the use of software in qualitative research is "which program should I use?" when they would be better served by asking "what analytical tasks will

I be engaged in, and what are the different ways I can leverage technology to do them well?" As recent research on qualitative data analysis software indicates, the researcher's expertise and methodological choices are more critical than specific software selections in determining the quality of the analysis (di Gregorio, 2011; Friese, 2011; Kuckartz & Sharp, 2011; Wiltshier, 2011). At the same time, all tools carry "affordances" for new capabilities and opportunities (Gibson, 1977; Greeno, 1994; Norman, 1988). Thus, as a group, these tools hold implications for the practice of qualitative research that merit examination.

We first provide an overview of tasks involved in analyzing qualitative data, with a focus on increasingly complex projects, before we turn to the software meant to support those tasks. This genre of software, known as Qualitative Data Analysis Software (QDAS or QDA software), is specifically designed to support qualitative research, as opposed to tools primarily used for the collection of data (such as audio or video recorders), or presentation of findings (such as presentation or modeling software). We briefly review the historical development of QDA software—including associated methodological questions and issues—before identifying the increasingly diverse array of expected features and functions in most of the current programs. We include reviews of thoughtful analyses about how these programs affect the field of qualitative research, particularly those that explore the intersections of tools, methods, and theories. We then summarize "user experience" literature regarding novices and experts in qualitative research as they begin using software, after which we discuss the boundaries between cadres of qualitative research experts who do use software and those who do not. Finally, we address potential directions as these programs are being influenced by Web 2.0/3.0 developments.

Analyzing Qualitative Data

What Is Qualitative Data, and What Is Analysis?

In order to use software for qualitative research, it is important to have an understanding of qualitative research as a starting point. Just as word processing programs support writing but do not magically transform the user into a *good* writer, QDA software programs support qualitative research, but still require knowledge and skill on the part of the user to produce *good* qualitative research.

Qualitative data is often used as an umbrella term for any nonquantitative data. However, the "umbrella" is extensive, covering a broad spectrum of data with diverse attributes. Not all qualitative data are alike. Examples of data *formats* include textual data (such as transcripts from in-depth interviews or excerpts from newspapers), images (photographs and drawings), or other artifacts. Since the 1980s there has been an increase in the use of audio, video and photographic data as well (Dicks, Mason, Coffey, & Atkinson, 2005; Mason & Dicks, 2001; Pink, 2007, 2008; Rich & Patashnick, 2002; Silver & Patashnick, 2011; Woods & Dempster, 2011). New innovations offer new data sources such as Web pages, tweets or geo-location data captured through GPS devices (Fielding & Cisneros-Puebla, 2009; Jung & Elwood, 2010; Ross, Renold, Holland, & Hillman, 2009). These data come in various *types* such as interviews, focus groups, observations, historical documents, and artifacts. What qualitative data have in common is that they have a lot of information within them (hence, the term "rich" is often applied), often with complex relationships within the data. This "richness" and complexity make the management of qualitative data a nuanced and sometimes challenging endeavor.

The terms "small scale" and "large scale" are sometimes used as a shorthand way to signify the overall complexity of a study. However, given the multitude of factors that affect complexity, these commonly used terms can serve as only as an imprecise estimate of overall scope, especially when applied to qualitative data. A study may be deemed "large scale" simply because it has a high number of participants. However, a "small scale" study with a few respondents may actually be more difficult to manage if it examines a topic in great depth. Figure 18.1 organizes selected characteristics of qualitative research studies into multiple continuums that tend to affect the complexity of the qualitative data, data-handling, and analysis. While by no means a complete set of descriptors, these characteristics serve to better identify those aspects pertinent to our discussion about software.

Each line in Fig. 18.1 represents a stand-alone descriptor on a continuum, with the left-hand side generally being less complex and the right-hand side more so. Of course, the data for any study would have multiple facets, some of which will contribute more than others to data-handling challenges. This figure does not provide a full range of considerations; qualitative studies that would fall toward the "simpler" side of the continuums may still be quite complex due to specific analytic procedures or other characteristics beyond the scope of this chapter. However, the characteristics we have identified include some challenges common to many qualitative studies as they become more complex. Note that the model does not place value on the level of complexity in a project, as the important factor in the design is an appropriate match between the research question and the methods used.

Starting from the top and working down, we begin by considering the range of data formats and types. As we have already described, qualitative data comes in a wide variety of formats and from a wide variety of types. Obviously, the similarity or dissimilarity of the data formats and types within a study will affect the ease or difficulty of data management.

Fig. 18.1 A partial list of study characteristics that tend to affect data analysis complexity

LESS COMPLEX	MORE COMPLEX
Homogeneous data formats/types	Heterogeneous data formats/types
Structured data, possibly controlled during collection	Unstructured or open-ended ("messy") data
One person/homogenous group	Multiple people/diverse groups
Single site	Multiple sites
Data collection at one point in time (snapshots)	Data collection over time (Long-term/longitudinal)
Predetermined and linear data collection procedures	Iterative data collection procedures
Collected/analyzed by individual researcher	Collected/analyzed by a team of researchers

Another dimension that affects data-handling is the degree of consistent structure in the data collection protocol. Data collection strategies might be highly structured, such as open-ended questions on a written survey, or quite unstructured, including data that may not be relevant and/or data that is relevant though not immediately apparent.

The scope of the study, whether in terms of range of participants (one group, multiple groups), number of sites, or time span (collected at one or multiple points) also contributes to complexity. Iterative or flexible data-collection procedures, which allow for adjustments as the study progresses, not only result in "messy" data but usually require additional tracking to clarify the conditions under which the data were collected and the rationale behind changes.

Finally, the presence of multiple researchers adds yet another layer of complexity, generally requiring coordination and communication during data collection and analysis. Team members may be working in a highly collaborative fashion, where ongoing communication and ability to modify the team activities are paramount. Or, the members may be "trained" by a principal investigator who needs to monitor the consistency of activities among team members. In either case, in addition to his or her own analytic work, one or more team members have an added responsibility of understanding and reflecting on the role of other members; potentially engaging in additional communication, feedback, benchmarking, and negotiation of roles.

We stress that none of these descriptors should be considered in isolation. For example, open-ended questions on a survey seem as if they would generate a straightforward set of data, highly structured by the questions asked. And that might in fact be the case. However, if these questions were asked of multiple groups at different points in time, the data could still achieve a high level of complexity due to its broad scope. On the other hand, a study limited to a small group at a single point in time could also be quite challenging to manage if it included a broad array of data sources. While these two hypothetical data sets are quite different, they both exhibit a high level of complexity that needs to be considered in the course of data management and analysis, especially when considering the use of QDA software (Barry, 1998; Kaczynski, 2004).

With increased data analysis complexity comes a greater complexity of data management. Being "close to the data" denotes both familiarity with the content and access to the specific bits that are pertinent to the analysis at a given point (Richards, 1998), and each increase in complexity brings additional challenges of being able to remain close to the data. As a dataset becomes more complex, the basic processes of data management quickly exceed the capacity of the human brain to remember specifics and connections. In their detailed discussion of the origin of NUD*IST (now NVivo), Richards and Richards (1994a) provide specific examples of the dilemmas associated with the handling of paper records in an increasingly complex project. They point to these dilemmas as the primary motivation behind their construction of a software program that can handle a complex dataset while retaining the crucial characteristics present when handling data manually (such as the examination of extracted quotations in the original context).

The question "what is analysis?" is just as complex as "what is qualitative data?" Different approaches to qualitative analysis are shaped by the theoretical approaches of the researcher and his or her community of practice, as well as the characteristics of the research context and setting. A full introduction to the rich and varied history of qualitative research methods and methodology is far beyond the scope of this chapter. We refer you to the overview chapter on qualitative research in this handbook as a starting point, as well as standard introductory texts by well-known authors such as Bogdan and Biklen (1982), Denzin and Lincoln (1998a), Lincoln and Guba (1985), and Patton (2002). Texts on specific approaches to qualitative research include grounded theory (Charmaz, 2006; Corbin & Strauss, 2008; Glaser & Strauss, 1967; Strauss & Corbin, 1990), ethnography (Hammersley & Atkinson, 1983; Spradley, 1979), discourse analysis (Potter & Wetherell, 1987; Wodak & Krzyzanowski, 2008), narrative analysis (Reissman, 1993, 2008), phenomenology (Moran, 2000; Moustakas, 1994), and thematic analysis (Lofland & Lofland, 1995).

In the introduction to the first three editions of the *Landscape of Qualitative Research* (1998b, 2003, 2008) Denzin and Lincoln help situate the evolving practices of qualitative research in historical context. The current position of qualitative research in the larger research landscape is also addressed by Salomon (1991), who discusses the "quantitative-qualitative divide," as well as Maxwell (2004) and St. Pierre (2006), both of whom address "scientifically based research." Creswell (2008), Creswell and Plano Clark (2010), and Tashakkori and Teddlie (2010) elaborate on the combination of qualitative and quantitative research in the form of mixed methods.

However, as Fielding and Lee point out, "Different schools of thought have different analytic postures but there are generic analytic techniques that can be taught and that will support work in most analytic traditions" (Fielding, 2005, para. 22). We now turn to some of the common tasks of qualitative analysis, and how they can be supported with QDA software.

Common Analysis Tasks in Qualitative Research

Each particular approach to qualitative analysis has its own procedural stages and recommended practices. However, as a broad generalization, the various approaches to qualitative analysis share some common activities with respect to qualitative data. Davidson and di Gregorio (2011a) report that when Tesch (1990) identifies 46 "brands" of qualitative research, she makes the point that there are not 46 approaches to analysis. Instead, she identifies ten principles[1] that are common across most types of qualitative research. Lofland (1971) wrote one of the few books in the pre-software era that articulates those common tasks involved in managing and analyzing qualitative data. For other early overviews of analysis tasks, see Goetz and LeCompte (1984), Lincoln and Guba (1985), and Pfaffenberger (1988).

More recently, Friese (2012) described a Noticing, Collecting, Thinking (NTC) approach, which serves as an umbrella for a diverse array of qualitative methodologies. Jackson (2013) also cites parallels between the language in mainstream qualitative texts (American Educational Research Association, 2006; Patton, 2002) and the literature produced by QDAS experts (di Gregorio & Davidson, 2008; Richards, 2005; Richards & Morse, 2012). They identify similar elements of the qualitative research process and emphasize the importance of articulating logical connections between different components of the research.

To organize our discussion, we use the four broad activities of the qualitative analysis process as identified by Lewins and Silver (2007) and revised by Davidson and di Gregorio: organizing data, exploring data, interpreting/reflecting on data, and integrating data (Davidson & di Gregorio, 2011a; di Gregorio, 2010b). Note that we agree with the assertion made by Lewins and Silver that these activities are not conducted in a linear sequence; the overall process is iterative, with many rounds and intersections, amid much reflection during the "interrogation" of the data. We also acknowledge an overlap of activities in actual practice, and thus a blurring of the heuristic boundaries between the four general activities and the specific tasks associated with them.

Organizing the data is both a mechanical activity and an analytical one. Data, codes, variables and ideas all need to be organized. Organizing includes grouping the data in meaningful ways, possibly by data type, source, chronology, or other data characteristics. It also includes connecting bits of data that are related to one another in some way, often by means of folders, sets, links or codes. These connections or groupings may be thematic, theory-driven or data-driven. In addition, they may be created "top-down" from an existing

[1] The principles are as follows: (1) Analysis is cyclic—concurrent with data collection. (2) Analysis is systematic and comprehensive but not rigid. (3) Analysis is reflective and results in analytical notes (memos) that guide the process. (4) Data are segmented as we are unable to process large amounts of data all at once but the connection to the whole is maintained. (5) Data segments are categorized according to an organizing system that is mostly derived from the data themselves. (6) The main intellectual tool is comparison. (7) Categories for sorting segments are tentative at the beginning; they remain flexible. (8) There is no one "right" way to manipulate qualitative data during analysis. (9) The procedures are neither "scientific" nor "mechanistic"; qualitative analysis is "intellectual craftsmanship" (Mills, 1959). (10) The result of the analysis is some type of higher-level synthesis. (Tesch, 1990, pp. 95–97).

framework (deductively), "bottom-up" by using the data as a foundation (inductively), through a process of creatively experimenting with the "best fit" (abductively or retroductively), or some combination of these depending on the particular methodology. Organizing the data is an important activity that manages the large amounts of unstructured information and data that a qualitative study generates. It enables the researcher "to see" the data more clearly by assigning it to a flexible framework. It is an activity that is revisited many times during a study—as more data is collected and as more ideas about the data are developed.

Exploring the data includes becoming familiar with the data by initially reading/viewing/listening to data and commenting on it. Later on in the study, exploring can involve searching for content and connections, possibly via retrieving previously coded segments or following links through the data and reviewing comments and memos. Tools in the software can support the examination of relationships between themes, looking at word frequencies and relationships between words, annotating and clarifying the data, or making preliminary comparisons between groups. Exploring is an activity that gives the researcher a solid familiarity with the data. This may lead to reorganizing the material in the light of new discoveries.

Interpreting and reflecting requires thinking and rethinking. Memo writing and drawing diagrams or maps to identify connections support this activity, which may lead to the recognition of patterns and relationships. Software tools now include visualizations that can give the analyst a gestalt of key issues. Reconsidering first impressions, pushing back to look at a more topographical view of the data, and diving back in to a particular quote are examples of tasks that support interpretation and reflection and can lead to more exploration of the data as well as reorganization.

Integrating data involves connecting it to other knowledge, such as other studies, references, or comparisons across groups. It may even involve integrating data *within* the study, such as data or perspectives from different team members. The primary intent of this activity involves seeing the data holistically and in context with other studies. Note that this is not an endpoint; reviewing related literature can lead to revisiting the data to reorganize, reexamine, and revise prior relationships.

Lewins and Silver (2007) offer a diagram of these activities; through a cyclical representation, the diagram expresses their nonlinear and iterative nature. Data needs to be organized, so interesting bits can be retrieved easily and compared and contrasted with other parts of the data, presenting possible patterns for exploration and reflection. Such reflections can lead to a reconceptualization of the data, and perhaps a reorganization to bring to the fore other issues and other patterns in the data, and so on.

QDA software can assist with many of these tasks. Obviously, it provides a means to *organize* and *explore* the data: tracking information about the data (data types and formats, timing of collection, a list of the codes that have been applied to a source, and so forth) and retrieving data according to specifications is what computers do best. Software can also link across data bits, for example, to establish chronology or locate related pieces. These aspects support *interpretation and reflection*. While the software cannot think for a researcher, it can provide access to the data in ways that stimulate new ideas. The computer can track reflections in memos and link them with the data that inspired them. Comparing findings with other researchers (or with literature examined as data) assists with *integration* (Wickham & Woods, 2005).

The specifics of using software to do these sorts of tasks have been addressed by multiple authors, some focusing on only one QDA software program and some comparing and contrasting different programs. di Gregorio (2010b) and Lewins and Silver (2007) offer examples of how various software programs support the four generic analytic activities as outlined above. Maietta (2008) and Evers, Silver, Mruck, and Peeters (2011) also describe software features through the lens of analytical tasks. Regarding the NVivo software, several scholars (Bazeley, 2007; Leech & Onwuegbuzie, 2011; Richards & Morse, 2012) align software tools and functions with particular methodologies and analytic approaches (e.g., ethnography, grounded theory, content analysis, discourse analysis, thematic analysis, domain analysis, and taxonomic analysis).

Of course, all the common tasks of qualitative analysis can be accomplished without the use of software to support them, and historically have been. However, as computers became more common, some qualitative researchers began to recognize their potential for assisting with these analytical tasks. We turn now to the history of development before returning to contemporary descriptions of QDA software and the debates about the influence of software on methods.

A Brief History of Qualitative Data Analysis Software

What Is QDAS?

As early as the 1980s, qualitative researchers began to recognize the potential for computers to assist qualitative researchers. General-purpose use of the "microcomputers" and programs available at the time (Pfaffenberger, 1988) gave way to special-purpose programs specifically designed to support qualitative research. The features and functions available within QDA software have expanded as computer capacity has increased. Early programs have been updated or replaced by later products that offer a wider range of support for the common tasks of qualitative analysis which include organization, exploration, interpretation, and integration.

While some functions (such as coding text and attaching notes or memos) have been present since the earliest days of QDA software, others (such as directly coding audio and video data) are recent innovations that only became practical with advances in computer technology. Thus, defining QDA software purely in terms of its features is problematic, since those features constantly evolve. As a more culturally situated approach, we define QDA software as programs intended to support the tasks of qualitative researchers. That is, programs developed within the culture of qualitative research and specifically designed for the purpose of supporting that research, as opposed to more general tools created to help organize "messy" information such as spreadsheets and word processors.

Initial Explosion of Development

QDA programs began appearing in the early 1980s and were developed independently by university faculty from several countries including Australia, Germany, and the USA. Examples include Thomas Seidel (the Ethnograph), Lyn and Tom Richards (NUD*IST, later NVivo), Udo Kuckartz (MAX, later WinMax, then MAXqda), and Thomas Muhr (ATLAS.ti). For the most part, these developers were themselves qualitative researchers who created the programs primarily to facilitate the analysis of their own qualitative data, some of whom then moved into providing software to other researchers. Initially, these early software developers were working in isolation, not aware of how others were creating similar software (Davidson & di Gregorio, 2011a; Fielding, 2008). In 1989, the first international conference on qualitative computing was organized by the University of Surrey in the UK, and a dialogue was established between developers and early users (Fielding & Lee, 2007). However, because of the developers' independence, they employed a range of programming languages and software architectures.

By 1990, there were so many different programs that Renata Tesch organized her discussion of "qualitative analysis software" (at that time, mostly MS-DOS based) according to their functions and uses. In 1994, The Computer Assisted Qualitative Data AnalysiS (CAQDAS) networking project was founded in the UK, so that interested researchers could learn about software options from a resource without formal financial ties to any developer. The project has been funded by the UK Economic and Social Research Council (ESRC). In 1995, Weitzman and Miles catalogued and compared 24 of these software programs. By the mid 1990s, the term Qualitative Data Analysis software (QDA software) was being used to identify this specific genre of software (Yuen & Richards, 1994). Readers will also find the synonymous acronyms "QDAS" and "CAQDAS"[2] in the literature.

Initial programs were limited by the computer capabilities of the time, which created both functional constraints and usability issues. In terms of features, they primarily focused on organizing data—often addressed through some variant of coding—in part simply because those tasks could be well-supported by computers. Memoing or annotating data with the researcher's thoughts and insights are additional functions, and these are still core tools in most programs (Lewins & Silver, 2007). The limitations of the functionality in the early stages became a concern in the larger field of qualitative research where diversity of method is highly valued (Seidel, 1998). Tools for visualizing data were slow to evolve, although ATLAS.ti offered visualization of the database early on with its network tool. Later on NVivo and MaxQDA offered specific mapping tools. More recently, charting and other visualization tools have been developed. Hyperlinking was another tool that was slow to develop in practice although it is one of the strengths of working with computers. For more details on the evolution of specific tools, see Fielding (2008), Hesse-Biber and Croft (2008), Kelle (1995), Richards and Richards (1994b), Tesch (1990), and Weitzman and Miles (1995).

Davidson and di Gregorio (2011a) map the time period in which this development was taking place alongside the qualitative methods stages of "Blurred Genres" and "Crisis of Representation" described by Denzin and Lincoln (2003, 2008). According to di Gregorio and Davidson, the "Crisis of Representation" in general qualitative research corresponded to a "Typology Era" in QDAS, in which users become concerned with methodological alignment of software and research projects:

> As a consequence, much thought was given to the paradigmatic or methodological perspectives of the developer, as it was believed that these were embedded in the software design and would shape the work of users in specific directions congruent with the developer's methodological bias, regardless of the user's intent. (Davidson & di Gregorio, 2011a, p. 630)

The "Crisis of Representation" ended in mid-1990s, but this early perception about and critique of QDAS persists to this day.

As a group, QDAS followed a software development arc similar to other software such as word-processors. The arc (Norman, 1998), begins with a multitude of early products

[2] The CAQDAS networking project Web site identifies "Computer Assisted Qualitative Data AnalysiS" as the original source of the acronym, although subsequent print sources often use "Computer Assisted Qualitative Data Analysis Software" (See the "About Us" page: http://www.surrey.ac.uk/sociology/research/researchcentres/caqdas/about/) Both are in use today.

that collectively expand and define the feature set. After the initial explosion of development, the feature set becomes more well-defined and functionality becomes more consistent across programs. Competition increases, and the number of different products in the market declines. Often, a few major products take the lead, and continue to "leap-frog" one another in terms of new features and functions. After the core features are in place, software development paths vary. Products may eventually become "feature-heavy," leaving a market opening for more streamlined versions; new technical advances may change the market entirely; or the user experience (aspects of interaction, such as ease of use) may simply become the differentiating factor between products (Norman, 1998). However, as we noted, the world of qualitative research was evolving as the QDAS development arc unfolded (Davidson & di Gregorio, 2011a; Denzin & Lincoln, 2008). Thus, the intersections between the two development paths of qualitative research and QDAS helped to shape the *perceptions* about these programs as they approached the convergence stage (Davidson & di Gregorio, 2011a).

Convergence

As the originally specialized QDAS programs converged into a more recognizable set of features, the number of programs decreased. As of this writing, the CAQDAS networking Web site focuses on reviews of only nine software programs. According to Norman, once a technology has reached a mature stage, technical distinctions between products fade into the background as the technology becomes more comprehensive and inclusive (Norman, 1998). In terms of basic functionality, QDAS has reached that point.

Davidson and di Gregorio (2011a) identify ATLAS.ti, NVivo, and MAXQDA as the dominant programs at the end of the "Post-Experimental Inquiry" stage of qualitative research. During this period, experienced QDAS users began to look across programs, compare their features and develop broader perspectives on the common qualities that should be expected (di Gregorio & Davidson, 2008; Lewins & Silver, 2007). Unfortunately, these conversations did not reach the wider audience of qualitative researchers, many of whom had turned away from QDAS either because of lack of access, frustration with earlier limitations, or because they believed "the rumors they had heard about epistemological problems" (Davidson & di Gregorio, 2011a, p. 632). At the same time, researchers began writing about using generic programs to manage their data, such as Word or Excel (Hahn, 2008; Ritchie & Lewis, 2003). Ironically, these epistemological concerns seemed less prevalent when researchers managed their data using software that was *not* intended to support qualitative research, as if these products were somehow more methodologically innocent.

QDA Software Today

In this section we first describe the most common (and generally expected) software features and functions. Next, we address the "user experience" through the research on the individual user's interactions with the software. Finally, we examine the cultural factors surrounding the use and avoidance of QDA software, through a "community of practice" lens.

Common Tools

The metaphor of a "tool" is often applied to these software programs; however, given the complexity of both qualitative research and the software used to support it, a more appropriate metaphor might be a "tool*box*"; that is, a collection of tools that can be used in different ways (Gilbert, 2002). A single functionality can be used to address different activities of qualitative research (organizing, exploring, interpreting, reflecting), and a single task can be supported through various tools. For example, creating memos can be used to organize data (using a narrative with embedded links to group related items), to reflect on data and the research process through writing, or to interpret data through an explanatory note that might even become integrated into a report. Similarly, the task of organizing data can be accomplished with sets, folders, coding, creating memos, linking, and so forth. (As stated previously, the specifics of matching functionality and task have been discussed in detail by multiple authors.)

Two of the original CAQDAS staff developed documents highlighting the common functions in QDAS (Lewins & Silver, 2007), thus contributing to the understanding of the software packages as a coherent class. Their list of fundamental capabilities includes the following:

- Assign multiple codes to a single portion of text/audio/video/photograph.
- Cross-reference the relationships among codes for constellations or patterns.
- Import nominal, ordinal and/or interval data as a means of comparing subgroups in the data.
- Track researcher ideas through the use of links and memos.
- Provide output in the form of reports that can be used for analysis and presentation of findings outside of the software.

Additional features are also available many in the products, such as:

- The ability to code an increasing range of data formats, such as audio, video, or pdf files.
- The ability to track multiple users within the system, or even to limit some users' access as "read only" in order to manage teamwork.

- The ability to create visual representations (models and charts) of data.
- The ability to access program functions in multiple ways (menus, keyboard shortcuts, contextual menus) and to customize the interface.

These four additional features possibly cross into the stage that Norman terms "excess quality uninteresting to consumers" (Norman, 1998). The dilemma for developers is that given the diversity of qualitative data and research methods, one researcher's *featuritis* may be another's *essential function*. Since adding capabilities also adds complexity, the developers face the challenge of balancing a wide feature set with usability.

User Experience

"User experience" refers to the subjective aspects of working with a system—the user's perceptions and responses. It is influenced by usability, by interface design, by the characteristics of the user, and perhaps by practical considerations such as cost, the availability of support and training, and less easily defined attributes such as appearance or prestige.

However, just as Word and WordPerfect had comparable word-processing functionality in the 1980s but nonetheless attracted loyalists who insisted on the supremacy of one over the other, so different qualitative researchers staunchly defend their particular QDA software. Some of this can be explained with a more careful look at the research on user experience. As Norman (1998) reminds us, user experience often becomes the differentiating factor between mature products. In one of the first published investigations about the adoption of QDAS, users reported preferring a particular program because it "fits with their thinking" more than another (Gilbert, 2002).

Although it was common a decade ago to run across comparisons of software in expository literature and the way these different software influenced the research process (for example, Barry, 1998) a more recent investigation yielded new and different results. Organizers of KWALON, the Netherlands Association for Qualitative Research, developed a process whereby experts in several of these software packages (ATLAS.ti, Cassandre, MAXqda, NVivo, and Transana) independently analyzed a common data set (Evers et al.).[3] In addition to posing some specific research questions to the participants that guided the independent analyses, the organizers also asked for responses to questions about the software: How the tools related to the analysis strategies, what

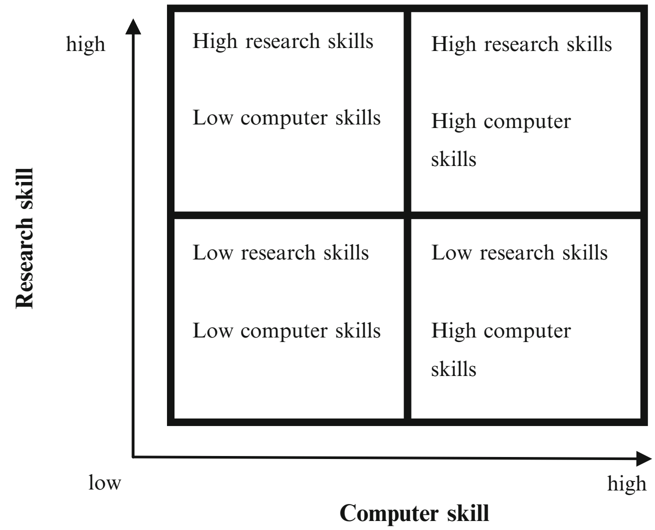

Fig. 18.2 Skill dimensions of individual users (adapted from Gilbert, 2006)

tools helped, which ones got in the way, and if the software influenced the analysis (for examples of responses, see Dempster & Woods, 2011; Friese, 2011).

Two qualitative researchers, one a QDAS novice and the other a QDAS expert, were asked to present their observations of the KWALON study in overview articles. The expert observer (di Gregorio, 2011) said that despite the different emphases in the researchers' descriptions of the process, they came up with very similar conclusions about the primary research questions. This suggested that the overall impact of a particular QDA program in analyzing the data was negligible. di Gregorio attributed this to the fact that the researchers were experts in the software they used as well as experienced qualitative analysts. Therefore, the researchers were not swayed by an unreflective application of a software tool, but were able to expand and reflect on their interpretations with the assistance of software. The novice observer (Schuhmann, 2011) reported that although the software influenced the types of data that became the focus within the larger data set, she also stated that without exception, the experienced researchers articulated their confidence that software expanded their perspectives and opened up new ideas in working with the data, rather than narrowing or confining such perspectives.

The KWALON findings support our previous observation that the distinctions between programs have become less critical now that the technologies have matured. It also reinforces the importance of researcher expertise in terms of understanding both qualitative research and the software tools that have emerged to support it.

With respect to users of QDA software, Gilbert (2006) classifies users according to their skill levels as both researchers and computer users (Fig. 18.2). The different quadrants

[3] Unfortunately, the KWALON experiment did not include investigations in the data set that were not facilitated by software, so no comparison point is available between managing the data with and without QDAS.

have different needs and expectations, and therefore different user experiences.

Using QDA software well requires both general computer skills and—even more importantly—an understanding of qualitative research methods. Users with low computer skills will naturally struggle with the software, regardless of the level of their research skills. Indeed, experienced qualitative researchers who are not proficient computer users sometimes view QDAS with outright suspicion, mired in concerns that these programs will somehow mislead the researcher. At the same time, users with low research skills and high computer skills run the risk of "following the software" too much—using features "because they're there" instead of intentionally selecting the functions that support their research goals.

Difficulties Adopting and Transitioning to Software

Inappropriate use by some novices adds to the unfortunate misconception that the software determines the method, or even worse, that software *is* a method. The conflation of software and method is exacerbated by the lack of training some novices receive in their academic course work on qualitative methods. Use by senior qualitative researchers in academic circles is limited, though the software has achieved broader acceptance in applied (nonacademic) qualitative work (Fielding & Lee, 2007).

In addition to some of the potential misunderstandings that can emerge when novices are left without guidance, expert qualitative researchers also face the challenge of jumping to conclusions about software use too quickly during their transition to using QDAS. The literature reveals five difficulties researchers experience in the transition to QDAS.

- "Missing paper" and initial concerns about "Closeness to data." Beginning software users miss the experience of working with paper, and often conflate the tactile experience with familiarity with the content (Fielding & Lee, 1998; Gilbert, 2002; Richards, 1998; Welsh, 2002). In contrast, experienced software users report feeling *more* knowledgeable about their data after they also gain expertise in the software (Gilbert, 2002; Lee & Fielding, 1996). Despite these reports to the contrary, the reputation persists that software creates "distance" from data. This belief may become less of an issue with generations more accustomed to working with computers.
- "The coding trap." Ironically, this is a problem of being too close to data, and focusing on detail at the expense of synthesis. With increased fluidity and efficiency of coding in software, users engage in nonproductive coding because they do not know when enough is enough, or are uncertain about what to do next and postpone decision-making (Coffey, Holbrook, & Atkinson, 1996; Gilbert, 2002; Richards, 2005).
- Managing analytical distance. Closeness has traditionally been prized in qualitative research but at the same time there is a need to gain a perspective on the whole. While some researchers have criticized software as not allowing them to get close to the data (Weitzman & Miles, 1995), others have commented on the new closeness made possible by QDA software (leading to the "coding trap" described above). Users have had to develop conscious strategies to manage both closeness and analytical distance (Gilbert, 2002; Johnston, 2006).
- Lack of meta-awareness about software use. It is easy to make a mistake when using "computer power tools," such as creating a query that doesn't ask what you think it does. Experienced users of QDA software (and other complex programs as well) usually develop ways of checking that the program did what you actually *meant* it to do, as opposed to what you *asked* it to do (Gilbert, 2002; Sin, 2007).
- Concerns about software inappropriately driving the researcher's methodology (Schwandt, 2007). This includes standardizing the qualitative research process (Coffey et al., 1996) or following the temptation to turn qualitative data into quantitative results without a methodologically clear reason for doing so (Schönfelder, 2011).

While these issues can occur with the use of software, they can also, with practice, be managed. However, some of these initial concerns in the transition to QDAS may prevent a researcher from developing sufficient expertise with the software to use it well, or even to fully understand its implications for use. Equally erroneous negative ("it will drive the research") and positive ("using it makes research more valid") claims are made by those who fail to achieve expert status in both QDAS and qualitative methods. These misconceptions are discussed in more depth as we look at the context of QDA use.

Experienced Researchers Who Make the Transition to QDAS

Experienced qualitative researchers who use qualitative data analysis software tend to report multiple advantages, particularly when handling increasingly complex projects (Fig. 18.1). These researchers often identify an overall perception of increased access to their data (Bringer, Johnston, & Brackenridge, 2004; Garcia-Horta & Guerra-Ramos, 2009; Ku Saillard, 2011; Richards, 2002). More specific benefits include:

- Ability to maintain an increased volume and diversity of information in any given project (Basit, 2003; Darmody & Byrne, 2006; Ozkan, 2004; Sin, 2007).
- Increased opportunities for teamwork (Sin, 2007), particularly in geographically dispersed teams (Dempster & Woods, 2011; Wiltshier, 2011).

- Efficiency of data management (Carvajal, 2002; Mangabeira, Lee, & Fielding, 2004; Wickham & Woods, 2005).
- Increased portability and durability of data, since digital data is more compact than physical data (Corti & Gregory, 2011; di Gregorio & Davidson, 2008).

The general literature on the adoption of technology describes and defines groups of users based on their willingness to explore a new technology, from "innovators" and "early adopters" to "laggards" (Moore, 1991; Rogers, 1995). Early adopters are enthusiasts willing to deal with the idiosyncrasies and usability issues of an immature product. In later stages of development, with a mature technology, the market changes; targeted users are more conservative and pragmatic, desiring ease of use, convenience, and results. The "chasm" between early adopters and "majority users" has been the source of a broad literature on technology adoption, and "crossing the chasm" has entered technology marketing terminology as a short-hand for reaching a broad proportion of a target audience. Though QDA software is now a mature product technologically, in many ways it has not "crossed the chasm" in terms of reaching the mainstream market of qualitative researchers, though there are various "communities of practice" in which its use is common.

Communities of Practice: Negotiated Meaning Around QDA Software

Modern researchers expect to use software of some nature—even if just using a word processor to cut-and-paste—in the course of their research. However, they often approach the use of such generic software quite uncritically. Unfortunately, although QDA software experts have been engaged in rich discussions and debates about issues related to software use for quite some time, the mainstream qualitative methods literature has failed to incorporate some of the most interesting and relevant strands of this discourse. Thus, general researcher beliefs about the use of QDA often either exaggerate or minimize the role of software in research.

We approach these researcher beliefs from the perspective of Communities of Practice (Lave & Wenger, 1991; Riel & Polin, 2004) and "negotiated meaning" (Wenger, 2008). As we previously discussed, use of QDA software is affected by the practices of the larger qualitative research community—or, more accurately, multiple research communities, since qualitative research encompasses multiple disciplines and both academic and applied work. Among these varied and sometimes overlapping communities, the presence of QDA software in the field helps to define three specific groups that are relevant to the current discussion: (1) novice researchers who are trying to understand the role of software through their limited peripheral participation (Lave & Wenger, 1991); (2) experienced qualitative researchers who do *not* use QDA software, and (3) experienced qualitative researchers who use QDA software.

While we have discussed the evolution of this genre of software and some of the perceptions of qualitative researchers as they move to the computer to handle their data, we have not yet addressed the ways QDAS experts have integrated their discussions of software and methods or the extent to which mainstream methods literature has largely ignored these discussions. These are important issues to address, given the different discourses available to novices about software in mainstream qualitative methods literature and the literature produced by QDAS experts.

New tools do offer new affordances—new capabilities and opportunities—and often carry implications for ethics, privacy, and representation that should be addressed directly and thoughtfully. As Wasser and Bressler (1996) observe, there is a complex and interesting "interpretive zone" where the embedded assumptions of researchers and technologies meet. However, the alarmist writings about software in mainstream methods literature usually fail to acknowledge that manual methods are not "tool-free." Much of this literature also fails to unpack the implicit assumption that avoiding certain tools will somehow ensure the trustworthiness of research. The reality is that *every* tool influences practice—from audio and video recorders to word processors or even note-taking—and researcher reflections on methods must also include reflections on the thoughtful use of appropriate tools.

QDA experts have engaged in reflections on this "interpretive zone," and they have focused on a diverse array of important qualitative research practices in the context of software use. Examples include exploring multiple meanings in the data (Richards, 2002), challenging researcher assumptions and first impressions of the data (Garcia-Horta & Guerra-Ramos, 2009), becoming aware of gaps in the collected data (Wickham & Woods, 2005), revisiting data with a new conceptual lens (Sin, 2007), fending off an uncritical reification of method (Ozkan, 2004), examining the ethical implications of working with digital data (Spickard Prettyman & Jackson, 2006), reflecting on the social construction of evidence (Kaczynski & Kelly, 2004), and unpacking some of the tacit views of research transparency among qualitative researchers (Jackson, 2009). Unfortunately, there is evidence that their discussions regarding the dynamic interplay between software and research rigor are not extending beyond their own community of practice. Jackson (2003) and Johnston (2006) demonstrate that the scholars who contribute to methods discussions in QDAS publications rarely contribute to mainstream qualitative text books. Three notable exceptions include *Handling Qualitative Data* (Richards, 2005), *Readme First for a User's Guide to Qualitative Methods* (Richards & Morse, 2012), and *Qualitative Research Design for Software Users* (di Gregorio & Davidson, 2008).

Just as discussions of software are minimal or lacking in most textbooks, they are equally lacking in discussions of methodological rigor or the most recently published guidelines regarding the implementation and publication of rigorous qualitative research in education. Examples include *Scientific Research in Education* (National Research Council, 2002), *Standards for Reporting on Empirical Social Science Research in AERA Publications* (American Educational Research Association, 2006), and *Standards for Reporting on Humanities-Oriented Research in AERA Publications* (American Educational Research Association, 2009).

When software is addressed in mainstream qualitative research literature, it is most often described by researchers who do not typically engage in the community of practice of QDAS experts. These mainstream qualitative methodologists (e.g., Creswell, 2008; Denzin & Lincoln, 1998a; Silverman, 1993) rarely publish articles dedicated to QDAS, nor do they participate in forums or conferences that focus on the use of QDAS. As Jackson (2003) has illustrated, the widely used texts by such scholars position software as a tool to consider long after making methodological decisions and view it as little more than an expeditor of the most mundane research tasks.

In short, in mainstream qualitative literature the relevant opportunities and challenges of QDAS are overlooked. As di Gregorio and Davidson (2008) observe:

> The current divide between QDAS users and non-QDAS users (often the most experienced analysts) means that our most significant commentators on methodological issues are failing to engage in the discussion of the new affordances and also pitfalls that QDAS offers. QDAS should not be seen as something that can be added on in a chapter on qualitative methodology. It needs to be integrated in the whole discussion on methodological practice. (p. 14)

The lack of reflection on software tools in the discussion on methodological practice is a particular disservice to novice researchers, now coming from a generation expecting to use computers as a matter of course. Johnston (2006) focuses extensively on the problems this false dichotomy between software and method creates during the instruction of graduate students, observing that the methodological learning curve for her students is more difficult because it is not being properly informed by the relevance of software. Carvajal (2002) also notes that both inside and outside of the university, in the context of computer lab trainings where the focus of instruction is often on specific software tools, a problem is created for novices who do not understand methods and may even conflate software and methods. Davidson and Jacobs (2008) elaborate on the individual as well as institutional factors that promote and prevent integration of software and methods within academic settings, with special attention on the professional journeys of faculty and doctoral students.

The problem of separation between software and methods has been observed by those who do not use software, as well as those who do. In *The Dictionary of Qualitative Inquiry*, Schwandt (2007) cautions his readers about the unexamined bias of all tools. Schwandt argues that the creation and use of particular tools influences the ways researchers see (and create) themselves and their research environment and states that, "While developers and frequent users of qualitative data analysis tools may customarily reflect on these embedded predispositions, it is not entirely clear that the casual user does" (2007, p. 35). However, according to the above-mentioned QDAS experts (Carvajal, di Gregorio and Davidson, Jackson, Johnston, etc.) it is precisely the segregation of QDAS literature from mainstream methods publications that contributes to the lack of deeper reflection on the relationship between software and methodology.

The efforts of di Gregorio and Davidson (2008) to engage in discussions around this interpretive zone (detailed in Chap. 2 of their book) serve as a recent move in the direction of integrating software and methods in qualitative research. It is a good beginning and one that we hope to see continue, particularly as the use of QDA software increases in applied qualitative arenas (for examples, see di Gregorio, 2006; di Gregorio & Davidson, 2008). On one hand, the use of QDA software sometimes offers methodological insights or creative new ways of understanding and approaching the data. On the other hand, the use of diverse methods in qualitative research helps push software users to consider the kinds of things we should or should not do with software (and certainly influences the recommendations we have for software developers).

New Directions and Implications

The first decade of the twenty-first century has seen massive technological changes in how we communicate across space and time. The evolution of Web 2.0, as the social and information-sharing aspects of the Web have been dubbed, has affected how we shop, bank, search for information, and communicate with each other. Revisiting the software development arc described earlier and viewing it with respect to Web 2.0 tools, we are in the early stages of innovation, where products proliferate and standards are still in early stages of evolution. The evolution is complicated further by the increasing prominence of mobile applications and multiple points of access to information stored in "the cloud." Web 2.0 presents profound challenges for both "traditional" qualitative research and QDAS; not least is the pressure from researchers who have been raised during this period and who thus expect to communicate online, share research materials in the cloud, or blog and work in wikis. In this brave new era,

Table 18.1 Comparison of QDAS and Web 2.0 tools

	QDAS	Web 2.0
Organizing tools	Coding	Tagging
	Sets, families	Grouping
	Hyperlinking	Hyperlinking
Reflective tools	Memoing	Blogging
	Annotating	Annotating
	Mapping	Mapping
Exploring tools	Model, map, network	Visualizing
	Text search, coding search	Searching
Integrating tools	Memoing with hyperlinks	Blogging with hyperlinks
	Merging projects	Collaborating through wikis

Davidson and di Gregorio (2011a, 2011b); di Gregorio (2010a, 2010b)

qualitative researchers can no longer afford to ignore digital tools (Davidson & di Gregorio, 2011a, 2011b).

The current wave of innovation promises a variety of new tools applicable to qualitative research, but also holds implication for new practices, new research needs, and even new researchers. For example, business and government communities are now involved in making sense of vast amounts of unstructured data that this new technology generates (Berners-Lee, 2009; Wang, 2006).

Davidson and di Gregorio (2011a) have termed the development of new QDA tools with Web-based capability "QDAS 2.0." There are two primary development paths for QDAS 2.0 tools specifically designed to support qualitative work. First, existing QDA software developers are starting to open their stand-alone programs to take advantage of collaborative Web technologies. Second, new developers are creating entirely new QDA 2.0 tools using Web-based programming. However, as mentioned above, qualitative analysts are not the only ones who are interested in managing unstructured data. Businesses, governments, news agencies, and ordinary folk are keen to interpret the unstructured data generated by Web 2.0 activity, and tools are being developed to support such by entities such as IBM and Google (di Gregorio, 2010a; Greif, 2009).

In addition to these intentional development paths, there are now many Web-based tools that offer support to some aspect of the qualitative analysis process, and we expect that some users will create their own "mashups" of these tools to meet their research needs. Table 18.1, from di Gregorio (2010a, 2010b), compares features that support the qualitative analysis process in QDAS with those Web 2.0 tools that can do the same.

In addition to new tools, new forms of participating in research have emerged. Davidson and di Gregorio (2011b) have dubbed what is beyond QDAS 2.0 as "Cloud QDA," in which the tools themselves reside in the cloud. Characteristics include technical changes, such as the use of computer algorithms in addition to human coding to analyze large quantities of text, "trawling" through textual data generated through tweets, emails, news feeds, and the like. Even more important innovations include new collaborative structures, such as the use of social-networking features to create a network of analysis peers, or "crowd-sourcing" and "folksonomies," which invite more participation from lay analysts. Reflecting the new models for software, new payment models, such as monthly fees for use, are also evolving.

As this is an area that is developing very quickly, any attempt to list these new tools would be out of date before this chapter is published. However, we have set up the wiki for Digital Qualitative Analysis Tools (DigiQAT) at http://digiqat.pbworks.com, to track of new tools being developed to support qualitative analysis. A wiki allows developers and users world-wide to add information and update existing information, so that information remains current.

It is important to acknowledge that the development of cloud computing is not without issues and challenges. How can the anonymity and privacy of individuals be protected in an open Web-based world? How can the security of qualitative data and analysis be guaranteed? Who owns data on the Web? What are the rights of researchers, participants and platform hosts? What challenges are posed by the participation of "lay analysts," who may understand software but not methodology? New ethical standards are currently being developed by researchers in the field, but with technology changing so rapidly these standards need to be constantly reviewed (Bassett & O'Riordan, 2002; Buchanan, Delap, & Mason, 2010; di Gregorio & Davidson, 2009; Raento, Oulasvirta, Eagle, & Eagle, 2009).

In this tumultuous new environment, the methodological knowledge of experienced qualitative researchers is of great value, but is in danger of being marginalized or overlooked unless researchers can enter the "interpretive zone" of these technological tools more fully. Using these tools *without* an understanding of their implications carries great dangers. We hope that as these new tools develop, they will be accompanied by the kind of reflection upon process that is currently evident in the literature produced by QDAS experts, and that new researchers will continue to critically examine both their research processes and tools.

Summary

Contrary to some common notions about the standardizing influences of QDAS, the complexity and diversity of qualitative data and analysis was the initial impetus for the development of QDAS. Furthermore, the specific functionalities currently available in this genre of software have converged into a fairly standard toolbox that may be very broadly and diversely applied. Most concerns raised about individual programs are overly alarmist (or alarmist for the wrong reasons) and tend to be raised by individuals with limited qualitative research knowledge and/or limited QDAS expertise, or individuals who have failed to keep current on the capabilities of QDAS. However, at the same time, we find the affordances of this genre of software worthy of examination, discussion, and rich critique. Indeed, that discussion should be extended to *all* tools for qualitative research, including common programs such as word processors or spreadsheets when they are adapted for use in research.

New tools are being developed by researchers, businesses and governments to manage the increasing accumulation of unstructured data in order to address questions that are qualitative in nature. Trends to watch include "Cloud QDA," mobile access, modularization of functions (leading to "software mashups"), new ways of accessing software (both in terms of technical access and payment models), and—perhaps most importantly—new forms of collaboration. In this rapidly changing climate there is ample room for rich discussions about technology as it relates to qualitative research tasks (such as data collection, coding, writing, and distributing findings) as well as more substantive debates/issues (such as ethics, trustworthiness, bias, and social justice).

When we hear casual and unsubstantiated claims that software is either a panacea or a plague, we are concerned that the polarizing discourse is essentializing a quite complex interaction between software and method in practice. While this interaction certainly deserves more rigorous research attention, we can conclude from the existing literature that the relationship between method and software, as practiced by qualitative researchers, can be positive and productive if the researcher is reflective, critical, creative, and open to recognition of error. It can be quite damaging and negative if the researcher is unaware of his or her own lack of skill, blind to bias, lazy, myopic, or overconfident. As we move into the twenty-first century, where the use of software is accepted almost too unquestioningly, reflection on such issues becomes increasingly imperative for qualitative methodologists.

Acknowledgments The authors wish to thank Dr. Judith Davidson (University of Massachusetts at Lowell) and two anonymous reviewers for their comments on an earlier version of this chapter.

Section III

Assessment and Evaluation

J. Michael Spector and M. David Merrill

This third section of the *Handbook* is focused on new methods, technologies, and tools to support educational assessment and evaluation. How methods, technologies, and tools have matured and new ones been developed and validated in practical settings are described in several chapters. The intent is to report what is new and avoid repeating what has been published in previous editions of the *Handbook* (Jonassen, 2004; Jonassen, Harris, & Driscoll, 2001; Spector, Merrill, van Merriënboer, & Driscoll, 2008). This section provides an up-to-dateness of research about and with new and emerging assessment and evaluation technologies.

The section begins with a chapter that addresses a topic not previously covered in the Handbook but one that is of global concern—namely, addressing the costs and benefits of educational technology. Thomas Luschei notes the general lack of research about actual cost–benefit analyses of large-scale technology innovations in education and training. The merits and limitations of cost-effectiveness, cost–benefit, cost–utility, and cost–feasibility analyses are described in general. Luschei then describes the methodological issues and challenges of applying these methods in actual settings. More research in this area is encouraged, especially in developing countries where the economic benefits from a cost-multiplier perspective are likely to be significant.

The chapter by Jennifer Hamilton and Jill Feldman on evaluation is also completely new. The traditional perspective on program evaluation is that what is reported is relatively straightforward and simple—namely, the degree to which the program objectives were met. However, there is an increasing interest in being able to connect aspects of an implementation with specific outcomes in order to explain why specific outcomes were or were not obtained. Moreover, the focus has shifted from a simple analysis of outcomes to an ongoing evaluation of a program as it evolves from planning through development and then to implementation and deployment. Formative evaluations along the way have become increasingly significant as evaluators take a more active role in helping program managers achieve intended objectives. Formal methods to evaluate the fidelity of implementation are now required by many funding agencies so that evaluators are positioned to explain why a program did or did not achieve intended objectives. This chapter presents researchers and developers with a practical guide to plan and conduct meaningful program evaluations.

There follow two chapters focused on assessment in domains previously not covered in the *Handbook*—namely, informal learning environments and problem solving. Savenye identifies two areas of informal learning that have received considerable attention in the research literature—museum learning and informal science education. It is well established that much important learning occurs outside school settings. Some informal learning activities can be planned and also assessed. Both quantitative and qualitative methods for such assessments are described by Savenye. Jonassen addresses how to assess problem-solving skills. While research on problem solving has been covered in previous Handbooks, methods to assess improvements in problem solving as a result of training and education have not been addressed. Jonassen provides an overview of assessment methods and coding schemes pertinent to assessing critical cognitive skills, causal reasoning, and other problem-solving skills.

The chapter by Ifenthaler and Pirnay-Dummer on model-based assessment methods and tools is well aligned with the issues raised by Jonassen as it reports on various tools aimed at supporting the kinds of assessments that Jonassen argues are needed for the domain of problem solving. Of particular note is the development of Web-based tools reported in this chapter and the shift that has occurred from a focus on summative assessment to emphasis on formative assessment and dynamic feedback to learners while working on complex and challenging problems.

M.D. Merrill
Utah State University, Logan, UT, USA

This sequence of chapters on new areas of concern (informal learning and problem solving) and new assessment tools (Web-based tools that provide dynamic formative feedback) is followed by a reflective chapter on the value and significance of performance assessment. While this topic has been addressed many times and in many contexts, Andrews and Wulfeck argue that performance assessments have returned as the primary means of determining the efficacy of training and how well learners have mastered intended objectives. Many methods and tools to support performance assessment are reviewed as the authors argue that technology now makes it cost-effective to conduct meaningful and predictive performance assessments in many different contexts.

The chapter by Valerie Shute and Yoon Jeon Kim on formative and stealth assessments exemplifies how technology has empowered performance assessment to the extent that nonintrusive formative assessments can be built into a technology-based learning environment. How dynamic formative stealth assessments have been and can be effectively accomplished is described in this chapter.

There follow two chapters that complete this section of the Handbook. One pertains to the task of evaluating information and communication technology (ICT) competencies. Evaluating ICT competencies is important for planning learning environments and for properly preparing teachers, trainers, and students for those environments. However, technologies change quite rapidly and knowledge and skills vary widely from one region to another, so evaluating ICT competencies remains a challenge. Tristan and Ylizaliturri-Salcedo argue that ICT competencies represent a subset of digital literacy competencies, and are essential for the twenty-first century workers. Several approaches for assessing these skills are presented and discussed in this chapter. The final chapter in this section by Kaufman and colleagues then describes how one can and should use data to drive decision making in the classroom. It is clear that commercial enterprises are using data gathered from past purchases and those with similar characteristics to drive how they advertise to specific Internet customers. Likewise, similar technologies and methodologies make it possible to use data to personalize learning and instruction. A data-driven decision-making model is presented to guide such efforts in the future.

The practice of educational technology as a professional discipline requires reliable and effective methods, tools, and technologies to support assessment and evaluation. Professional practitioners need to be able to assess individual learners and learning experiences and evaluate the efficacy of innovative programs. In order to maintain progress, the discipline requires ongoing and cumulative research on assessment and research methods and tools as well as research on specific innovations and implementations. For this reason, we have placed this assessment and evaluation section of the *Handbook* in volume one along with foundations and methods as part of the core discipline of educational technology.

Assessing the Costs and Benefits of Educational Technology

19

Thomas F. Luschei

Abstract

Educational technology is often cited as a means to improve educational outcomes and reduce costs, leading to greater quality and efficiency in learning and instruction. Yet research that attempts to assess the costs and benefits of educational technology is limited, making it difficult for educators and policy makers to make efficient decisions. This chapter reviews international research on the effectiveness, costs, and cost-effectiveness of educational technology and provides a set of core conclusions from this literature. The chapter also describes methodological challenges to assessing costs and benefits of educational technology and suggests areas for future research. The chapter concludes with lessons learned for educators and educational decision makers.

Keywords

Benefits of educational technology • Costs of educational technology • Cost-effectiveness analysis • Efficiency

Introduction

Educators, researchers, and policy makers often point to educational technology as a means to enhance educational access and outcomes while decreasing costs (Rumble, 1999, 2001). Equipped with convincing evidence of efficiencies, educational decision makers can implement technology-related policies and practices that promise the largest return for a given investment. Yet several challenges beset the empirical verification of efficiency gains stemming from the use of educational technology. To begin with, researchers have not reached consensus as to whether educational technology yields significant benefits and what those benefits are. Estimation of the costs of educational technology presents further challenges, such as measuring both direct and indirect costs and identifying the appropriate "ingredients" (Levin & McEwan, 2001) of technology-related interventions. Additionally, few researchers have attempted to systematically assess and compare both the benefits and costs of educational technology. This chapter discusses the challenges of assessing the costs and benefits of educational technology, summarizes and synthesizes related research, identifies key methodological challenges, and indicates fruitful areas for future inquiry, including a call for cross-disciplinary research in assessing the efficiency of investments in educational technology. The chapter concludes with a set of concrete lessons learned for educational decision makers and educators.

Efficiency and Cost Analysis

What is the point of comparing the costs and benefits of educational technology? In theory, educators and policy makers should use information on both to help them allocate scarce resources among competing priorities. As Levin and McEwan (2001) note in their textbook on cost-effectiveness

analysis, decisions based on knowledge of both benefits (or effectiveness) and costs of a particular intervention "can reduce the costs of reaching particular objectives, and it can expand what can be accomplished for any particular budget or other resource constraint" (p. 6). In other words, such analysis can lead to *efficient* decision making.[1]

Assessing Efficiency

The systematic analysis of information on costs and benefits of competing alternatives falls under the umbrella of cost analysis, which comprises several approaches to assess efficiency, including cost-effectiveness analysis, cost–benefit analysis, cost–utility analysis, and cost–feasibility analysis (Levin & McEwan, 2001). Below I briefly describe these approaches.

Cost-Effectiveness Analysis

Cost-effectiveness analysis can help educational decision makers to evaluate various alternatives based on both their costs and their effectiveness in achieving a common desired goal, such as improving student achievement, increasing graduation rates, or reducing school dropouts. For example, we can use cost-effectiveness analysis to compare how well various types of instructional technology increase students' test scores and how much monetary investment is required for each unit of test score increase. The technology resulting in the largest increase, for a given unit of cost, is the most cost-effective. Alternatively, we can identify the technology with the lowest cost for a given level of test score increase. In the first case, we hold inputs constant; in the second, we hold the outcome constant. One drawback to cost-effectiveness analysis is that it only allows us to assess alternatives according to one specific measurable goal or outcome. We cannot use cost-effectiveness analysis to compare the impacts of alternative interventions with different objectives or on different outcomes, such as test score increases and dropout reductions. Nor can cost-effectiveness analysis help us to determine whether the benefits of a given project outweigh its costs, because benefits and costs are measured in different units (Levin & McEwan, 2001).

Cost–Benefit Analysis

With cost–benefit analysis, we can assess the monetary value of both the costs and benefits of alternatives, which helps us to compare projects or gauge whether a specific project or alternative is worthwhile. When comparing projects, the most efficient alternative is the one with the highest ratio of benefits to costs, or the lowest ratio of costs to benefits. Because this approach assesses inputs and outputs in terms of monetary values (e.g., dollars), it allows us to compare alternatives with different objectives or outcomes. Cost–benefit analysis also allows the comparison of investments across different sectors, like education, health, and transportation (Belfield & Levin, 2010). The disadvantage of cost–benefit analysis is that it can be very difficult to measure the monetary value of the major outcomes that are valued in education, such as increased learning. Cost–benefit analysis is best suited for evaluating educational interventions that have some market-oriented outcome, such as training programs designed to increase earnings or decrease poverty (Belfield & Levin, 2010). Some studies have estimated the private and/or social returns, in terms of wage increases, that result from investments in technology-related endeavors like distance education (e.g., Carnoy & Levin, 1975). However, in evaluating educational technology, cost–benefit analysis is rare (Rumble, 1999). As a result, below I refer primarily to the *effects* or *effectiveness*, rather than the benefits, of educational technology.

Cost–Utility and Cost–Feasibility Analysis

Cost–utility analysis is similar to cost-effectiveness analysis, but the outcome in question is the overall satisfaction or "utility" of a targeted stakeholder group, such as students, parents, or the general public. The goal of cost–utility analysis is to identify the intervention that (1) results in a given level of utility at the lowest cost or (2) results in the highest level of utility for a given cost. The concept of utility allows researchers to combine multiple measures and outcomes of educational interventions into a single measure. Researchers can also weigh outcomes differently, according to the preferences of relevant stakeholders. However, results may differ considerably depending on the methodology and weights used. Although such studies are rare in educational research, they are more common in health-related research (Levin & McEwan, 2001).

Cost–feasibility analysis estimates only the costs of alternatives to identify those that do not violate a given budget constraint. Although this analysis allows us to determine whether a given alternative is feasible given a specific budget, it does not provide sufficient information to choose among various alternatives (Levin & McEwan, 2001). Related to cost–feasibility is cost-efficiency or least-cost analysis, which assesses costs per enrolled student or graduate. This approach assumes that the quality or the effectiveness of educational alternatives and graduates is the same (Rumble, 1999).

[1] Rumble (1986) offers a helpful distinction between effectiveness and efficiency: "It is possible to be effective without being efficient, but it is not possible to be efficient without also being effective. Effectiveness will depend upon the quality and quantity of the output. Efficiency will depend not only on these factors but also on the consumption of resources as an input to the system" (pp. 69–70).

Cost-Effectiveness of Educational Technology

Cost-effectiveness analysis requires (1) measuring the effect or the effectiveness of competing alternatives in producing some desirable outcome; (2) calculating the costs of each alternative; and (3) comparing costs and effectiveness. Below I discuss each step and identify evidence related to educational technology.

Estimating Effects or Effectiveness

In cost–benefit analysis, the "benefit" refers to an actual monetary value of the outcome of an educational intervention. In many cases a more appropriate approach to assessing efficiency is through the estimation of the effect or the effectiveness of an intervention in reaching a given goal, and then comparing this outcome to the costs of the intervention. A key issue in assessing effectiveness or effects is the establishment of a causal link between the intervention and the outcome of interest (Shadish, Cook, & Campbell, 2002). In other words, does the intervention in question actually cause the desired outcome, or do measured "effects" of the intervention stem from an unobserved variable or relationship? If the intervention does not cause the outcome of interest, its value to educators is questionable. I return to this discussion in the section on methodological issues below.

The Effects and Effectiveness of Educational Technology

Research on the benefits and effects of educational technology is so large and diverse as to defy coherent summaries or reviews (Ross, Morrison, & Lowther, 2010). To narrow this discussion and make it applicable to a discussion of costs and benefits, I limit this section to research that attempts to measure the effects of educational technology on some student outcome. Even so, the task remains large. Decades of educational research have identified a wide range of benefits of educational technology, including unique "affordances" made possible by technology (Kozma, 1994), greater accessibility for students, and support for the work of teachers (Kozma, 1994; Ross et al., 2010). Other researchers have pointed out the limitations or the drawbacks of specific technological interventions or educational technology writ large (Clark, 1983, 1994; Cuban, 2001).

Educational technology may impact a number of student outcomes, including achievement, attendance, engagement, persistence, or attainment in school. Most commonly, educational research attempts to measure technology's effect on some measure of student learning, usually student test scores. The preferred method to measure this effect is the calculation of an "effect size," or the difference in achievement between a treatment group that receives some educational intervention and a control group that does not receive the intervention (Ross et al., 2010).[2] Given the large number of studies that estimate effect sizes of educational technology interventions, the most efficient way to summarize this literature is through the examination of "meta-analytical" studies of the research. Meta-analysis, or the synthesis of large number of related studies, can provide an "average" estimate of the effect size of educational interventions and provide a general answer to large and important questions (Bernard et al., 2004, 2009).

Many meta-analyses have been conducted in the field of educational technology; by and large, these studies support the conclusion that students who receive the "treatment" of technology learn as much as or more than students in control settings without educational technology. Of course, results vary according to the types of technology evaluated and other factors. Below, I review evidence regarding computer-based instruction, distance education, and online instruction.

Computer Technology

Analyses and meta-analyses of the impact of computer technology have become so numerous that they allow for the elaboration of "second-order" meta-analyses, which review a large number of meta-analytical studies. For example, Tamim, Bernard, Borokhovski, Abrami, and Schmid (2011) reviewed 25 meta-analyses estimating the impact of computer technology on student achievement. Types and uses of computer technology in these studies included computer-assisted instruction, computer-based instruction, digital media, information and communication technology, hypermedia, simulations, and word processors. The authors found that students in technology-enhanced face-to-face classrooms have higher achievement levels than students in classrooms without technology. Specifically, the mean effect size attributable to technology use is 0.35, which translates to a 12-percentile point advantage for an average child in a classroom with computer technology, relative to an average child in a classroom without computer technology. Tamim et al. (2011) also found differences in effect sizes according to both grade level and the purpose of technology use. The effect size is larger when computer technology is used in K-12 classes, relative to postsecondary settings. The authors also found a larger effect size associated with the use of computer technology for instructional support, compared to the use for direct instruction, suggesting that "one of technology's main

[2] An effect size represents the difference between the means of the treatment group and the control group, which is standardized by dividing by either the pooled standard deviation or the standard deviation of the control group (Harris, 2009).

strengths may lie in supporting students' efforts to achieve rather than acting as a tool for delivering content" (p. 17). Although the authors do not make this link, these two findings may be related: If K-12 teachers are more likely to use technology to provide instructional support, while postsecondary instructors rely on technology principally to deliver content, this difference may help to explain differential effects of computer technology across K-12 and postsecondary settings.

Given growing expenditures on technology in schools, economists have also become concerned with the impact of this spending on student outcomes (Machin, McNally, & Silva, 2007). Results of related studies are mixed and seem to point to the importance of context. In a randomized study of a program in Israel, Angrist and Lavy (2002) found little impact of a large-scale introduction of computers in schools. Similarly, Rouse and Krueger (2004) used an experimental design to evaluate a language and reading computer program in the United States known as *FastForword*. The authors found that the program was not successful in raising reading skills or language acquisition. In contrast, Machin et al. (2007) used a quasi-experimental method to examine the impact on student outcomes of additional expenditures on information and communication technology in the United Kingdom. The authors found a positive impact of these expenditures on English and science performance, but not in mathematics. In an experimental study in urban India, Banerjee, Cole, Duflo, and Linden (2007) found that a computer-assisted program for math instruction had a strong positive impact on student math score increases. The program increased math scores by 0.35 of a standard deviation in the first year and 0.47 in the second year, and was equally effective for all students along the ability distribution. All of these studies together underscore the importance of context in assessing the effects of technology-related or any other educational interventions.

Distance Education

In their meta-analysis of 232 studies comparing distance education to face-to-face instruction, Bernard et al. (2004) found that distance education and traditional classroom instruction are comparable in terms of their effects on achievement. At the same time, the authors found considerable variability across studies, leading them to conclude that "some applications of DE are far better than classroom instruction, and that some are far worse" (p. 397). Additionally, the impact of distance education on student attitudes and retention is slightly worse in comparison to classroom instruction. The authors also found differences between synchronous and asynchronous approaches to distance education, suggesting an advantage for asynchronous approaches in enhancing achievement and student attitudes, but a disadvantage for asynchronous instruction in terms of its impact on course completion.

Online Instruction

A growing number of studies have found that online instructional approaches are as effective or more effective than face-to-face approaches in raising student learning. For example, a meta-analysis by the United States Department of Education (2009) found that students in online settings had greater learning outcomes than students receiving face-to-face instruction. Effect sizes were larger for programs that blended online approaches with elements of face-to-face instruction. However, the authors caution that the blended approaches often made use of more learning time and instructional elements not included in face-to-face instruction, which could help to explain these differences.

Calculating Costs

The second step of cost-effectiveness analysis is the measurement of costs, or the monetary value of the resources sacrificed in applying one intervention over other alternatives. It is critical to recognize that in directing resources toward a given project, we forgo the benefit that would have accrued to another similarly valuable alternative. As Harris (2009) explains, "economists define the costs of resources as the value of a resource in its next best use—the 'opportunity cost'" (p. 5). The most straightforward method to estimate costs of educational interventions is the "ingredients" model, which is also referred to as the "resource cost model" (Levin & McEwan, 2001). The ingredients model requires the researcher to (1) identify and specify all the ingredients involved in the intervention, (2) determine the cost of each ingredient, and (3) analyze costs using an appropriate decision-making framework (Belfield & Levin, 2010).

Since many educational programs take longer than 1 year to implement, costs must be adjusted for inflation by a consumer price index (Levin & McEwan, 2001). Independently of inflation, costs incurred at different times have different values; money that we receive or spend in the present is more valuable than the same amount received or spent in the future. To adjust for this difference, we must employ an appropriate "discount rate" in calculating costs. Previous studies have used bank interest rates, the average rate of return of investments in the private sector, and a combination of the two (Harris, 2009).

Costs of Educational Technology

The vast majority of studies that assess the impact of educational practices and policies (including technology-based interventions) neglect any consideration of costs (Harris, 2009; Levin & McEwan, 2001; Rice, 1997). Yet educational technology's potential to massively expand access relative to traditional classroom teaching, thereby lowering "unit costs," or costs per student, has provided one of the strongest rationales for its use (Jamison, Klees, & Wells, 1978; Rumble, 1999).

Proponents of educational technology have also argued that technology can help to transform education from a labor-intensive endeavor, relying on an inefficient one-teacher-per-classroom model, to a capital-intensive endeavor that provides a much more efficient "mass production" alternative (Eicher, Hawkridge, McAnnany, Mariet, & Orivel, 1982; Wagner, 1982).

The limited research makes clear that in comparison to many other educational interventions, educational technology projects often require a large initial investment of "fixed costs," or costs that do not vary according to the number of users involved (Levin & McEwan, 2001). In order to justify these large fixed costs, such interventions must reach a large number of users and take place over a long period of time (Jamison et al., 1978; Tsang, 1995). At the same time, there is substantial variability in both fixed and variable costs across different types of media (Jamison et al., 1978). For example, Bates (1995) concluded that among various media studied, only radio and audiocassettes had both low fixed and low variable costs. In contrast, high-quality broadcast television had high fixed costs but no variable costs, while preprogrammed computer-based instruction and multimedia had high fixed and high variable costs.

Jamison et al. (1978) calculated per student costs of nine instructional media projects, five using television and four using radio. Across both types of projects, they found large variability in size, scope, application, and costs. In general, they found that (1) costs of instructional radio were one-fifth the costs of instructional television per student per hour; (2) cost estimates varied considerably depending on the discount rate used; and (3) given large fixed or present costs, the technology projects studied must last 10–20 years in order to lower unit costs to a reasonable level. The authors conclude that despite methodological complexity and shortcomings "approximate cost analyses can be done, and done in the timely and relatively straightforward way that can provide useful input decisions" (p. 243).

Rumble (1999) argues that although educational technology has had its strongest application in the area of distance education, cost analyses of distance education projects are rare. Most of the existing studies have used least-cost or cost-efficiency approaches, which assume similar quality or effectiveness across alternatives (Rumble, 1999). Fewer studies assess cost-effectiveness, and even fewer attempt cost–benefit analysis. In a review of relevant studies, Rumble (1999) concluded that "distance education can be, *under the right conditions*, more cost-efficient than traditional classroom-based education" (p. 126). Relevant considerations include size, number of courses offered relative to student population, longevity of courses, choice of technology and media, administrative costs, and type of staff employed. Rumble (1999) also suggests the possibility that "mixed-mode" institutions that combine on- and off-campus teaching may operate at lower costs than purely distance education institutions.

In assessing costs of network-based or online instruction, Rumble (2001) finds that various studies identify and treat costs very differently. For example, analysts disagree on costs that should be taken into account, use different terminology to describe cost elements, disaggregate and aggregate costs in different ways, and use a variety of frameworks. Rumble's own framework divides costs into three categories: course development, course delivery, and administrative costs. Development of instructional materials includes the preparation of text, audio and video materials, computer-based tutoring, and simulation, among others. Costs of course development can vary tremendously depending on the media used. Rumble (2001) cites a study by Arizona Learning Systems (1998) that found course development costs to range from \$6,000 for a course using simple outlines and assignments to \$1 million for a course using virtual reality. Additionally, synchronous online courses tend to be less costly than asynchronous courses due to the use of fewer media. Costs of online course delivery include delivery and reception of materials, opportunity costs for students, tuition, tutors, equipment, and costs of communication between students and administrative staff. Rumble (2001) concludes that in general, course delivery costs for online instruction are smaller relative to costs of traditional face-to-face instruction. Administrative costs of online instruction include costs associated with administrative staff, quality assurance and evaluation, Web site development and maintenance, buildings and furniture, and other equipment.

An important measure of costs in comparing online instruction with other alternatives is the amount of time invested by students and instructors. According to Rumble (2001), online tutoring costs, in terms of time spent by instructors in communicating with students, can be substantially higher relative to other instructional approaches. In a study of online learning programs at Syracuse University, Spector (2005) found no significant difference in outcomes between traditional face-to-face instruction and online courses; however, to achieve similar outcomes, students invested slightly more time in online courses. Faculty, who were experienced online teachers, invested considerably more time in online courses compared to traditional face-to-face courses.

Although Rumble (2001) finds that on average, online instruction may allow cost savings over face-to-face instruction, there is less evidence regarding the costs of online education relative to other types of distance education. He finds that the limited available evidence suggests that "e-education is pushing the costs of distance education up" (p. 85). This means that those who cannot afford such education are "being written out of the game" (p. 85).

Comparing Costs and Effectiveness

Once the effectiveness (E) and cost (C) of an educational intervention are determined, we can calculate an effectiveness–cost ratio (ECR) by dividing *E* by *C*:

$$\text{ECR} = E/C$$

The ECR represents the units of effectiveness of a given alternative for one unit of cost; the alternative yielding the largest ECR is the most cost-effective. Other researchers use a cost-effectiveness ratio (CER), which is calculated by dividing the cost of an alternative by its effectiveness. In this case, the most cost-effective intervention is the one with the lowest CER (Levin & McEwan, 2001).

Cost-Effectiveness of Educational Technology

Whereas information on benefits or costs in isolation is helpful to educational decision makers, the systematic comparison of both provides a much more powerful decision-making tool. Unfortunately, cost-effectiveness studies of educational technology are rare and evidence is mixed. Although there is a great deal of evidence regarding the effects of educational technology, it is difficult to combine this evidence with cost analysis, especially in the case of meta-analysis. Despite its value in assessing the effects of educational technology, several problems limit the use of meta-analysis for cost-effectiveness analysis. While meta-analysis provides general estimates of the effectiveness of a type of intervention, policy makers generally look to cost-effectiveness analysis to make decisions about specific programs or policies. Furthermore, it may be difficult or impossible to identify costs of relevant ingredients when effectiveness estimates reflect the average of many studies from different contexts and interventions (Levin & McEwan, 2001).

Due to the limitations of meta-analysis, evidence on the cost-effectiveness of educational technology comes primarily from evaluations of specific projects, usually conducted by economists, using various types of media and technology. For example, Levin, Glass, and Meister (1987) evaluated the cost-effectiveness of four primary-level educational interventions: a longer school day, computer-assisted instruction (a drill and practice program developed by the Computer Curriculum Corporation), cross-age tutoring, and reduced class size. Whereas the effect size of peer tutoring was highest among the four interventions (0.97 for math, 0.48 for reading), costs were lowest for reducing class size by five students, followed by lengthening the school day by 1 h. The mathematics CER was lowest for peer tutoring, followed by adult tutoring. Computer-assisted instruction was the fifth most cost-effective of eight interventions. In reading, the CER for computer-assisted instruction was second lowest among the eight interventions, following peer tutoring. Although computer-assisted instruction was more costly than increasing the school day and decreasing class size (except by 15 students) and less effective than adult tutoring, it was more cost-effective in raising reading achievement than all of these interventions. These results illustrate the importance of both costs and effectiveness, as determination of the "best" alternative depends on whether the decision-making criterion is costs, effectiveness, or a ratio of the two. This example also illustrates the common use of student test scores as a measure of effectiveness. While increases in student achievement are certainly an important outcome to consider, the degree to which they can be attributed directly to technology interventions—rather than to other unmeasured factors—raises some concern about whether these interventions would cause similar test score gains in other contexts.

Tsang (1995) identified several lessons regarding the cost-effectiveness of new educational media (p. 391): (1) although evidence suggests that new educational media help students to learn, the use of such media in traditional school settings is not cost-effective; (2) small media are more cost-effective than large media; (3) in sparsely populated areas, distance education may be the only way to educate children; (4) distance education for school equivalency is both effective and cost-effective; (5) to be effective, the use of educational media requires technical staff for operation and maintenance; and (6) because different types of media are often used together, it can be difficult to determine which type of medium is most suitable for a given project.

Angrist and Lavy (2002) found no evidence that the large-scale adoption of computers in Israeli schools helped to raise student test scores. They also concluded that the costs of such adoptions make them extremely inefficient. They estimated the cost of the Israeli program at $120,000 per school not including training costs, or the equivalent of one teacher per year per school. Rouse and Krueger (2004) estimated the cost of the *FastForword* reading and language program at $770 per student, not counting cost of the space or the indirect costs of rearranging schedules to accommodate the program. The authors conclude that the program is not cost-effective, except possibly for school districts with many students with needs addressed by *FastForword*. In contrast, Banerjee, Cole, Duflo, and Linden's (2005) evaluation of a computer-assisted mathematics program in urban India found that the program was both effective in boosting student test scores and very cost-effective. The authors estimated the cost to be only $15.18 per student, including the cost of computers. The authors also make an important distinction in computer use, alluding to the strategy of an Indian nongovernmental organization called Pratham. Banerjee et al. (2005) conclude that although computer-assisted instruction may not be the most cost-effective educational strategy in India, "turning computers already in the schools to productive use, as Pratham did in this program, is clearly a very cost-effective proposition" (p. 33).

Evidence regarding the cost-effectiveness of technology interventions is particularly salient in developing countries, where resources and educational access are much more limited. In such contexts, distance education—supported with available technology and media—can be an important way to increase access while reducing costs. There is some evidence of economies of scale of new educational media projects in these contexts. Moreover, "small" media projects, such as instructional radio, are much less costly than "big" media projects like television (Tsang, 1995).

As a result of rapid expansion of primary education in the 1990s and 2000s, coupled with increasing educational requirements for teachers, many lower income countries have turned to distance and online education to prepare and certify large number of teachers (Gulati, 2008; UNESCO, 2006). For example, in Indonesia, national legislation requires that all primary teachers hold a 4-year postsecondary degree and certification by 2015. This requirement has resulted in a massive national effort to upgrade and certify over one million teachers. Given the magnitude of this endeavor and the vast Indonesian geography, the Open University of Indonesia will play a central role in meeting teachers' demand for required degrees through distance education (Luschei, Dimyati, & Padmo, 2008).

Little systematic evaluation of Indonesia's or other large distance teacher education projects have provided evidence that they are either effective or efficient. In their analysis of distance teacher education programs in Indonesia and Sri Lanka, Nielsen, Tatto, Djalil, and Kularatne (1991) found that cost-effectiveness varied according to country circumstances and course subject. In Sri Lanka, distance education was more cost-effective than both conventional pre- and in-service training programs, whereas in Indonesia distance education was more cost-effective than conventional preservice training programs in language but less cost-effective in mathematics. However, if one only considers the costs invested by the government, distance education programs in both Indonesia and Sri Lanka were much more cost-effective than conventional face-to-face programs. On the other hand, opportunity costs for students are high. The authors also conclude that distance teacher education is particularly cost-effective in subjects that are "verbal and information-oriented, as opposed to math and skills-oriented" (p. 4).

Methodological Issues

Several methodological challenges stand in the way of rigorous evaluation of the cost-effectiveness of educational technology. Russell (2010) argues that the goals of large-scale technology adoptions in education are often ill defined, which makes the identification and measurement of appropriate outcomes difficult. Russell also underscores the importance of assessing *implementation* of technology, not just its presence in schools. Russell cites the experimental study by Angrist and Lavy (2002), which found that the provision of computers in schools does not increase student test scores. Russell argues that this study measures the impact of the *presence* of computers, rather than their use. Moreover, measures of technology use must extend beyond frequency of use and explore types and objectives of technology use in a more nuanced way (Russell, 2010).

A second important issue is the identification of causal links between technology-related interventions and student outcomes. To determine whether an educational intervention does cause the effect it is designed to, researchers use correlational, experimental, quasi-experimental, and meta-analytical techniques. Correlational methods or multiple regression analysis are most popular among educational studies, and these studies have potential for high external validity because they examine differences between treatment and control groups under natural conditions (Ross et al., 2010). But selection bias is often a major concern for such studies. That is, when attempting to assess outcomes of "treatment" and "control" groups, are individuals located in each group as a result of random chance, or through self-selection? If the treatment (or control) group self-selects into a group, then the estimated effect of an intervention on that group may be due to unobserved characteristics of the group or the individual, rather than the actual intervention (Ross et al., 2010).

Experimental and quasi-experimental studies can help to solve problems of selection bias, but they are not always feasible in practice. Experimental studies may also suffer from low external validity because conditions under which groups are assigned to treatments may not match the true conditions of technology adoption (Ross et al., 2010). Quasi-experimental methods, such as regression discontinuity, interrupted time series, and propensity score matching, also hold promise for assessing causality, but they cannot always fully control for observable and unobservable characteristics of individuals. Nonetheless, the use of this class of methods, coupled with increasing emphasis on rigor and relevance in educational research, can help to solve the many riddles of educational technology. At the same time, Ross et al. (2010) indicate that despite a growing emphasis on increased rigor in educational research to identify and promote evidence-based practices, the quantity of experimental studies to assess educational interventions, including technology-based interventions, has declined.

As discussed above, meta-analyses provide helpful summaries of a large quantity of studies, providing general answers to large and important questions. But for the purposes of assessing costs, the application of meta-analysis is limited. Additionally, meta-analyses are only as good as the studies they analyze. In their meta-analysis of research on the effectiveness of various types of distance education, Bernard et al. (2009) raise concerns about the quality of the underlying research:

> We have learned … that the research methodologies typically used to assess this phenomenon are woefully inadequate and poorly reported. Fundamental confounds associated with different media, different pedagogies, different learning environments, and so forth, mean that causal inferences about the conditions of design, pedagogy, and technology use are nearly impossible to make with any certainty (p. 1245).

Another important consideration in estimating effects is the multilevel nature of education and learning. Technology effects may differ across students within a classroom, across students within schools, or across schools within districts, states, or nations. Russell (2010) argues that researchers must take account of these multiple levels through the use of multilevel modeling; failure to do so can result in inaccurate and/or misleading estimates of the impact of educational technology on teaching and learning.

As difficult as it is to estimate the effects of educational technology, estimation of costs may be even more of a challenge, and is much more rare. Several analyses of cost studies in education have noted methodological problems and errors in the estimation of the costs of educational interventions (Belfield & Levin, 2010; Harris, 2009; Levin & McEwan, 2001). In the case of distance education, Rumble (1999) argues that many previous studies use traditional management accounting systems, do not recognize the wide variations in course design and student readiness, and fail to identify the real drivers of the costs of distance education.

Finally, cost analysis generally assumes a common outcome across competing alternatives. In contrast, educational technology interventions can lead to many outcomes, both short- and long-term. While short-term outcomes may include improved attitudes and technological skills, long-term outcomes like improved test scores may take longer to achieve. As Ross et al. (2010) argue, "it is incumbent on researchers to understand the multiple purposes and outcomes of complex technology interventions" (p. 22). Evidence of even longer term effects, such as course completion and labor market success, is also extremely important but limited. For example, little research has examined the impact of online instruction on degree completion, success in the labor market, or wages. One exception is Carnoy, Rabling, Castano-Munoz, Duart Montoliu, and Sancho-Vinuesa's (2011) study of degree completion at the Open University of Catalonia. The authors find that while completion rates are generally low for the university's students, students taking shorter degree courses are much more likely to complete their degrees than students in longer programs. These results have important implications for the design of online degree programs, as well as the ultimate labor market success of graduates of online programs. Yet although it is important to consider multiple outcomes of educational technology and their temporal nature, such consideration makes the estimation of costs even more complex.

Areas for Future Research

This review suggests many fruitful areas for future research. To begin with, the field needs more rigorous research designed to assess the causal effects of technology interventions, coupled with serious assessment of the costs of various alternatives. There is also a need for more research that acknowledges and explores nuances in the purposes, provision, and use of educational technology. Educational technology should not be treated as dichotomous variable, either present or not. The research reviewed here has found differences in the effectiveness of technology interventions based on their purpose and use (Tamim et al., 2011; U.S. Department of Education, 2009), level of instruction (Tamim et al., 2011), type of media used (Jamison et al., 1978), and subject matter (Machin et al., 2007; Nielsen et al., 1991). Several studies also indicate that technology effects vary across different contexts or over time (Banerjee et al., 2007; Jamison et al., 1978; Nielsen et al., 1991).

Finally, rigorous cost-effectiveness research is particularly important (but limited) in developing nations, where the stakes of resource allocation decisions are higher. Although much of the early research on the costs of instructional radio and television was conducted in developing countries (e.g., Jamison et al., 1978), as lower income countries adopt newer technologies like online instruction, a new generation of cost-effectiveness studies is needed. Work by Banerjee et al. (2007) in urban Indian slums raises an intriguing question: Can investments in educational technology have a greater impact in lower income settings, where resources are more scarce and children are much less likely to have computers or Internet in their homes? Although a long line of inquiry in international comparative education has found some evidence that school resources have a greater impact on student learning in lower income countries (Chudgar & Luschei, 2009; Heyneman & Loxley, 1983), much less research has explored the possibility that investments in educational technology can reap greater rewards among the most disadvantaged.

Conclusion

Several core conclusions emerge from this review of the costs and benefits (or effects) of educational technology. First, instruction using educational technology may be as effective as traditional classroom instruction, but it is important to estimate *causal effects* and incorporate key information, such as the purposes and context of technology use. Second, although some economists have argued that investments in educational technology are inefficient (e.g., Angrist & Lavy, 2002), others have found that interventions like distance education of teachers can be more cost-effective than traditional face-to-face methods (Nielsen et al., 1991; Tsang, 1995). Key considerations in assessing cost-effectiveness include the ratio of fixed costs to variable costs, the number of users, and the opportunity costs to students.

Although a great deal of excellent and rigorous research has assessed the effects and effectiveness of educational technology in enhancing student outcomes, when it comes to costs, researchers have barely scratched the surface. For example, the subject index of the program of the 2012 annual meeting of the American Educational Research Association does not include the terms "costs," "cost-effectiveness," or "efficiency." A search of submission titles in the online program of the 2010 annual meeting of the Association for Educational Communications and Technology found two mentions of "efficiency" or "efficient" and none of "costs" or "cost-effectiveness." In their excellent review of educational technology research, Ross et al. (2010) do not mention the words "cost" or "costs." This omission from the research leaves such calculations to educational economists, who care deeply about efficiency, but may have less nuanced understandings of the purposes and uses of educational technology. Future research on the cost-effectiveness of educational technology requires cross-disciplinary collaboration of economists, instructional designers, experts in educational technology, and others with relevant interests and expertise. The ultimate result of such collaboration will be more complete information to help educational decision makers and educators make the most of precious resources as they apply educational technology to enhance student learning and other important outcomes.

Despite the importance of future research, educators and educational decision makers need not wait years for concrete lessons from research on the costs and benefits of educational technology. The information presented in this chapter provides at least four lessons that can be applied to the use of technology in classrooms. First, technology can and should enhance learning and other outcomes for students of all ages. Considerable evidence suggests that students who have access to educational technology outperform students without similar resources. However, the second lesson from this review is that the simple existence of technology is not enough; educational technology must be put to use effectively to have a positive effect on student learning. Third, how educators use technology matters. As an example, some evidence suggests that technology may be more effective when it is used directly to support learning, rather than simply to deliver content. Finally, educators and educational decision makers must consider and demand information on costs of educational technology interventions. Simply knowing that educational technology can help students learn is not enough to ensure that students learn as much as possible given the limited resources that are available to teachers and schools.

Planning a Program Evaluation: Matching Methodology to Program Status

20

Jennifer Hamilton and Jill Feldman

Abstract

As Federal agencies have increasingly specified the methodology expected in the program evaluations that they fund, the long-standing debate about what constitutes scientifically based research has been resurrected. In fact, there are no simple answers to questions about how well programs work, nor is there a single analytic approach to evaluate the wide variety of possible programs and their complexities. Evaluators need to be familiar with a range of analytic methods, and it is often necessary to use several methods simultaneously, including both quantitative and qualitative approaches. Some evaluation approaches are particularly helpful in the early developmental stages of a program, whereas others are more suited to situations in which the program has become more routinized and broadly implemented. One of the key points that we stress in this chapter is that the evaluation design should utilize the most rigorous method possible to address the questions posed and should be appropriately matched to the program's developmental status. The warnings not to evaluate a developing program with an experimental design have been sounded for some time [Patton, M.Q. (2008). *Utilization focused evaluation* (4th ed). Thousand Oaks, CA: Sage; Lipsey, M. (2005). *Improving evaluation of anticrime programs*. Washington, DC: National Academies Press], but this is the first time to our knowledge that the developmental phases of program development have been specified in detail and linked to evaluation designs.

To guide design decisions, we present a framework that builds on the goal structure devised by the Department of Education's (DoE) Institute of Education Sciences (IES). It is important to note however that designing a program evaluation is often a complicated process, and the ultimate design rarely comes straight out of a textbook. Rather, design decisions require responsiveness and judgment particular to each setting, given the practical constraints of time and resources. Our intent is therefore not to be prescriptive, but rather to provide guidance, tools, and resources to help novice evaluators develop evaluation designs that are responsive to the needs of the client and appropriate to the developmental status of the program.

Keywords

Program evaluation • Formative evaluation • Summative evaluation • Fidelity • Experimental design • Quasi-experimental design

Over the last decade, Federal agencies have increasingly specified the methodology expected in the program evaluations that they fund, with a particular emphasis on randomized trials (e.g., US Department of Education, 2002, 2004, 2005, 2007; What Works Clearinghouse, 2011). This focus

J.M. Spector et al. (eds.), *Handbook of Research on Educational Communications and Technology*,
DOI 10.1007/978-1-4614-3185-5_20,

has resurrected the long-standing debate about the appropriateness of experimental designs in education with attendant criticism of the role of the legislature in defining what constitutes scientifically based research (Chatterji, 2004; Eisenhart & Towne, 2003; Erickson & Gutierrez, 2002; Julnes & Rog, 2007; Olson, 2004; Schoenfeld, 2006; Slavin, 2002, 2004; St. Pierre, 2002). Although much of the backlash around this debate has focused on the ascendancy of experimental designs as the gold standard of evaluation, they are not always the most appropriate design, nor does the DoE necessarily require them. Much depends on the audience for the evaluation. Decision makers at the national level tend to favor quantitative methods because they are accustomed to basing funding decisions on statistical indicators. In contrast, stakeholders at the local level can be skeptical about statistics and often prefer the richer data obtained through qualitative methods (National Science Foundation, 2010).

In fact, there are no simple answers to questions about how well programs work, nor is there a single analytic approach to evaluate the wide variety of possible programs and their complexities. As a result, evaluators need to be familiar with a range of analytic methods, and be able to use several methods simultaneously, including both quantitative and qualitative approaches. Some evaluation methods are particularly helpful in the early developmental stages of a program, whereas others are more suited to situations in which the program has become more routinized and broadly implemented. One of the key points that we stress in this chapter is that the evaluation design should utilize the most rigorous method possible to address the questions posed and should be appropriately matched to the programs' developmental status.

To guide these design decisions, we present a framework that builds on the goal structure devised by the DoE's IES Request for Applications. With more than $200 million in funding, the chief function of IES is to raise the capacity of education evaluators to conduct rigorous studies (IES, 2012a). Given this, we view the goal structure of IES solicitations as particularly relevant for aligning evaluation designs with programs at various stages of development. It is important to note, however, that designing a program evaluation is often a complicated process, and the ultimate design rarely comes straight out of a textbook. Rather, design decisions require responsiveness and judgment particular to each setting, given the practical constraints of time and resources. Our intent is therefore not to be prescriptive, but rather to provide guidance, tools, and resources to help novice evaluators develop evaluation designs that are responsive to the needs of the client and appropriate to the developmental status of the program.

For a detailed discussion of principles and standards undergirding best practices in evaluation, readers are referred to the standards issued by the Joint Committee on Standards for Educational Evaluation (2010) and those of the Evaluation Research Society (1982). The American Educational Research Association (AERA, 2008), American Evaluation Association (AEA, 2004, 2009), and What Works Clearinghouse (WWC, 2011) provide additional information about standards of evidence in studies of educational programs. For those more interested in a detailed discussion of various evaluation methodologies, there are many excellent resources available, including Hedrick, Bickman, and Rog (1993); Patton (1990); Shadish, Cook, and Campbell (2002); and Weiss (1972).

Distinguishing Between Evaluation and Research

Before we go much further, we need to take a moment to clarify how we are distinguishing between research and evaluation. Research is grounded firmly in the experimental method, and its goal is the creation of new scientific knowledge. Typically, research questions do not address the quality of a specific program, but instead focus on gaps in theory or in certain areas of knowledge. Evaluation uses similar methods and procedures but has different goals. Rather than identifying gaps in knowledge, program evaluations help stakeholders answer specific questions about a program and its components (Yarbrough, Shulha, Hopson, & Caruthers, 2011). Patton draws the distinction this way, "research seeks to prove, evaluation seeks to improve …" (Patton, 1990). Furthermore, research is typically self-initiated by scholars working in an academic environment. Researchers have more control over both the research topic and the research environment than does the evaluator who has to contend with more external intruding factors, such as those occurring within a school setting (Hedrick et al., 1993; Levin-Rozalis, 2003). Evaluation thus has more numerous and varied purposes, has a less controllable context, and is more complex than research (Bickman & Henchy, 1971).

The remainder of the chapter presents an organizing framework for planning program evaluations. It also describes typical elements of evaluations at each stage.

An Evaluation Planning Framework

In 1964, Kaplan issued a famous warning against "the law of the instrument." He warned that where a methodology is equated with a field of inquiry, it limits the field to only what can be answered by the method. Taking that warning to heart, this chapter stresses that there is a time and a place for experimental designs, but they should not necessarily define the field of program evaluation. Experimental designs provide the important causal mechanism that links program participation to the outcome of interest. Quasi-experimental designs (QEDs) can also make this causal connection, under

Table 20.1 Evaluation framework

IES evaluation category	Stage of program development	Research questions	Audience/evaluator	Evaluation design(s)/approaches	Evaluation products
Exploratory	Idea generation	Is my idea likely to work? What has already been tried? Is there a demand for my idea?	Program developer is the audience/evaluator is often internal	*Descriptive:* Needs assessment	*Informal and iterative:* Literature review, description of need
Development and innovation	Program being developed and implemented in limited number of sites	How is the program working? Have I got the right components? How can it be improved?	Program developer is the audience and possibly also funding agencies/evaluator can be internal or external	*Mostly descriptive:* Developmental evaluation, design-based research, pilot studies, evaluability assessment	*Informal and iterative:* Logic model, program description, implementation feedback, initial evidence of promise, evaluability findings
Efficacy and replication	Program is fully developed, not yet tested	Is the program effective under ideal conditions? Does it need further refinement? Is it ready for wider dissemination and testing?	Audience is broader. Often program developer; funding agencies; Federal, state, and local decision makers/evaluator is external	*Experimental/quasi-experimental:* Including implementation data fed back to program developers to improve performance	*Formal*: *some iterative:* Report on program impacts including identification of key active ingredients. Ongoing (iterative) reporting of implementation data
Scale-up	Program is fully developed with some indication of effectiveness	Is the program effective under real-world conditions?	Audience is broader. Often program developer; funding agencies; Federal state, and local decision makers/evaluator is external	*Experimental/quasi-experimental:* Implementation data used to help understand findings (is not fed back to program developers)	*Formal:* Report on program impacts including identifying for whom the program works, and under what conditions, and implementation information

the appropriate conditions. However, the field of program evaluation is broader than this, and causal inference is not the only thing evaluators are interested in (American Evaluation Association, 2009). As Patton (1987) states "evaluators need to know a variety of methodological approaches in order to be flexible and respond in matching methods to the nuances of a particular evaluation."

Table 20.1 provides a framework for matching evaluation methodologies to stage of program development. Programs typically (but not always) move through a series of stages sequentially, and evidence collected at each stage supports progression to the next. The first column of Table 20.1 uses IES categories (IES, 2012b) that divide program evaluations into four groups (exploratory, development and innovation, efficacy and replication, and scale-up). The second column links these evaluation categories to the programs' stage of development, while the third column provides some examples of the types of evaluation questions asked at that stage. The fourth column identifies the primary audience(s) for the evaluation and whether the evaluator tends to be internal or external. Next are the evaluation designs and approaches that are typically used during each developmental stage, and examples of the evaluation products created at each stage.

The framework presented in Table 20.1 can also be thought of in terms of formative versus summative evaluation. Formative evaluations are designed to answer questions about how a program works. Scriven (1991) describes formative evaluations as being conducted during the development of a program with the intent to improve. Thus, a major benefit of a formative evaluation is that it supports midcourse corrections and improves implementation. Summative evaluations, in contrast, provide information on the program's efficacy (outcomes when implemented under ideal conditions) or effectiveness (outcomes under routine conditions). Robert Stake is quoted as saying "When the cook tastes the soup, that's formative; when the guests taste the soup, that's summative" (Scriven, 1981). In practice, it is common for a program evaluation to have some questions that are formative in nature and others that are summative. Looking at the evaluation stages presented in Table 20.1, it is possible to envision a continuum moving from almost completely formative in the first row (exploratory) to almost completely summative in the last row (scale-up). A more in-depth treatment of formative and summative evaluation goes beyond the scope of this chapter. Interested readers are referred to Stufflebeam and Shinkfield (2007), Flagg (1990), and Reeves and Hedberg (2003) for more information.

Stage 1: Exploratory

IES defines the goal of this initial stage as "exploring relations between educational outcomes and malleable factors (i.e., factors that can be changed, such as teacher practices) as well as mediators or moderators of those relations. This type of study is intended to inform the development of interventions that can improve outcomes" (IES, 2012b). The efforts of the program developer are thus focused on identifying and understanding the problem, generating ideas or methods to overcome it, and investigating the efficacy of other methods that have been attempted in the past. The evaluator is usually internal to the development team, or may be the program developer herself. Although external evaluations are not typical at the exploratory stage, independent evaluators can serve as "critical friends" and are sometimes recruited to serve on advisory boards to provide guidance and advice.

The evaluation design at the exploratory stage is largely descriptive in nature, as the goals tend to be understanding of the nature of the problem—generating ideas and constructing a proof of concept. Therefore, this type of evaluation tends to be the least structured of designs and is frequently first in a series of studies on a topic (Hedrick et al., 1993; Lofland & Lofland, 1995).

A common design approach at this stage is to conduct a needs assessment. A needs assessment is a systematic process for determining "gaps" between current conditions and desired conditions. The discrepancy between the current condition and desired condition must be measured to appropriately identify the need. For more information on this topic see Altschuld and Kumar (2010).

Data collection methods used at the exploratory stage are largely qualitative because the evaluation questions typically solicit initial ideas about the feasibility of using a hypothesized approach. Quantitative (data in the form of numbers) and qualitative (data in the form of words) both have their advantages and disadvantages. Conventional wisdom holds that it is usually best to consider using both in ways that complement each other (Mark & Shotland, 1987). Usually, evaluators collect qualitative data to add depth and a fuller understanding of the complexities of a program or an idea. At this exploratory stage, the focus is usually on collecting qualitative information through reviews of existing literature, interviews, focus groups (Stewart & Shamdasani, 1990), observations, and case studies (US General Accounting Office, 1990). Quantitative approaches can also be useful at the exploration stage if, for instance, the objective is to conduct a meta- or cost–benefit analysis or to collect initial evidence that an approach is promising for improving outcomes.

Synthesizing the data collected into a format that is useful to the client is a critical activity in any evaluation. Evaluation products at the exploratory stage are more informal and iterative than deliverables produced during later stages of program development. One goal of exploratory studies is to initiate a continuous feedback loop between evaluator and developer that quickly translates data into program decisions. Unless required by the funder, open discussions and presentations are often the delivery method for sharing findings from an exploratory study, rather than a formal report. However, written deliverables can include a summary report that outlines the results of a literature review, and a description of need resulting from related analysis. If there is a determination of adequate need, and evidence indicates that the concept holds promise, then the program begins to be developed and we move on to the next stage, Development and Innovation.

Stage 2: Development and Innovation

The focus of the development and innovation phase is on the "development of interventions for use in authentic education delivery settings and the generation of pilot data showing the intervention's promise for generating beneficial student outcomes" (IES, 2012b, p. 44). During this phase, the program is being actively developed and implemented in a small number of pilot sites. The evaluator and developer are again in close contact, where evaluation findings are iteratively fed back to guide the design of program materials, which are field-tested, refined, and retested. As in the exploratory stage, the evaluator is usually internal to the development team, while the audience for the evaluation findings becomes slightly wider, with the possibility of various funding agencies and local decision makers becoming interested in the results.

There are a wide range of designs and approaches that are appropriate at this stage, and their selection largely depends on the needs of the client (in addition to practical constraints of time and funding). A handful of the most common are provided below.

Developmental evaluation is particularly well suited to this stage in the development of a new program. Its explicit purpose is to help develop an intervention and is particularly useful in situations where the outcomes are emergent and changing. Here, the evaluator becomes part of the program design team with the role of facilitating team decisions by "infusing evaluative questions, data, and logic, and supporting data-based decision making" (Patton, 2011, p. 20).

Design-based research (DBR) provides rich descriptions of the study context, implementation challenges, development and administrative processes, and the design principles that emerged (Anderson & Shattuck, 2012). Use of DBR involves using mixed methods to design and test an intervention through an iterative and collaborative partnership involving researchers and practitioners that results in actionable theories that directly relate to practice in a particular context. See Anderson and Shattuck (2012) and McKenney and Reeves (2012) for more information on this method.

Pilot studies are often conducted during a program's development phase to provide initial evidence that key program components can be implemented in an authentic classroom setting. Some additional advantages of conducting pilot studies include assessing whether the program components are feasible to implement; testing program materials, evaluation protocols, and analytic techniques; and using findings to convince funders that continued investment in the program is worthwhile. For a very practical guide on this subject, see Teijlingen and Hundley (2001).

Toward the end of this stage, an Evaluability Assessment (EA) can be conducted. An EA can help determine if a program is ready for a summative evaluation. The EA approach was developed in 1979 by Joseph Wholey, and can help ensure that precious evaluation resources are used at the most appropriate time. Lipsey (2005) provides an exhaustive list of factors considered at each stage of EA. For more information on EA, see the Office of Juvenile Justice and Delinquency Prevention (2003), Smith (1989), and Youtie, Bozeman, and Shapira (1999).

Evaluations conducted at the development and innovation stage produce deliverables aimed at (1) clearly describing the intervention, (2) refining and field-testing instructional resources and associated professional development, (3) operationally defining observable features of implementation, and (4) selecting methods and creating protocols to document the extent to which actual implementation matches the intended program model. A key deliverable produced at this stage is a logic model, which graphically represents the program processes hypothesized to improve the outcomes of interest. For more information on creating logic models see W.K. Kellogg Foundation (2004), National Science Foundation (2010), and Mayeske and Lambur (2001). The process of working with an evaluator at this stage is iterative and produces feedback to support program development and generate evidence about implementation of key program components. Findings from development and innovation studies provide the basis for conducting more rigorous summative evaluations at successive stages.

Stage 3: Efficacy and Replication

In the efficacy and replication stage the goal is to evaluate the effectiveness of a program under ideal conditions. It attempts to discover whether the program can have a positive impact on outcomes when significant implementation support is provided. Programs that are difficult to implement under these supported conditions are unlikely to be well implemented in real-world conditions where there is no (or very limited) implementation support. While efficacy and replication and scale-up studies tend to utilize very similar designs, an important distinction is that the implementation results are continuously fed back to the implementation team during an efficacy and replication study. Although implementation is measured at the scale-up stage, this information is not fed back to program staff.

The use of a comparison (or control) group and a focus on more quantitative study designs are key features distinguishing efficacy and replication studies from investigations conducted during earlier phases, and the goals have shifted from being mostly formative to being mostly summative. However, before embarking on a summative evaluation, there are four general conditions that need to be met (Lipsey, 2005):

1. The program is sufficiently developed and documented.
2. It is possible to collect relevant and reliable data.
3. The research design can distinguish program effects from other influences.
4. There are sufficient resources to adequately conduct the evaluation.

In summative evaluations, the objective is to provide evidence that a program's components resulted in the expected outcomes. The task is to demonstrate that not only those outcomes occurred but also the outcomes can be attributed to the program, and not to something else. Demonstrating causality is achieved by dividing the pool of potential participants into two groups—those who receive the program (the treatment group) and those who do not (the control or comparison group), and comparing outcomes for these two groups. How these groups are formed, either randomly or by some form of matching procedure, determines whether the study is considered experimental or quasi-experimental. In the Stage 4: Scale-Up section, we talk in more detail about the design methodology of experimental and quasi-experimental evaluations, but a key resource in this area is Shadish, Cook, and Campbell (2002).

The degree to which a program is practical to implement is determined through an assessment of implementation in general and through determining the fidelity of implementation in particular. It is useful to distinguish between measuring implementation generally and measuring fidelity of implementation more specifically. Broadly speaking, the measurement of implementation is qualitative and attempts to describe what transpired as the program was put into place. It describes the context of the study, and can help the evaluator to understand the extent to which outcomes may be unique to a given context (Cook, 2002). Fidelity is as a subset of implementation, defined as the extent to which the program as implemented is faithful to the pre-stated model (Cordray, 2007), and is increasingly being recognized as a necessary part of program evaluation (US Department of Education, 2003). Fidelity is a quantitative series of measures, usually made up of a score for each program component, which is then weighted and combined into an overall fidelity score. There are a number of well-defined steps for measuring fidelity, as described in O'Donnell (2008); Dane and Schneider (1998); Century, Rudnick, and Freeman (2010); Scheirer and Rezmovic (1983); and Resnick et al.

(2005). Measurement of implementation fidelity occurs at both the efficacy and replication and scale-up phases, although the findings are used differently. During the efficacy and replication phase, implementation findings continue to be fed back to developers to close gaps in the intended versus the enacted program model.

As the efficacy and replication stage moves out of the formative and into the summative realm, the audience for the evaluation also shifts. Federal and local funding agencies and policy makers are likely to have heightened interest in results from these studies, in addition to interest among program developers, and local decision makers. In addition, to generate independent evidence of a program's effects, the evaluator of programs in the last two phases is more likely to be independent and external to the implementation team.

Evaluation products resulting from efficacy and replication studies usually include a formal report of findings, including identification of any key active ingredients in the program. If the findings are promising, and implementation of the program is practical, then the next stage is to implement the program in more and increasingly diverse settings and evaluate it in the scale-up phase.

Stage 4: Scale-Up

The purpose of a scale-up study is to generate estimates of program impact when implemented under conditions of routine practice. That is, users implement the program without support from the developer or the evaluator (using only what is available to users who would purchase the program "off the shelf").

As in previous stages, the collection of implementation data is critical here too. Even though it is not being used to improve implementation, the information provides important contextual information about, and confidence in, the findings. At this stage, documenting fidelity provides evidence that helps to distinguish whether poor program outcomes are a result of a lack of implementation fidelity, or due to an ineffective program (WWC, 2011). In addition to providing a rich descriptive context for understanding how or why a program produces particular outcomes, implementation data can empirically link variations in fidelity and outcomes.

In addition to documenting implementation, evaluations at this stage must be able to attribute outcomes to the program, and no other cause. As described previously, this can be done using either an experimental or a quasi-experimental design. The main advantage of an experimental design is that it provides "strong methods for establishing relatively unequivocal causal relationships between treatment and student achievement variables" (Madaus, Scriven, & Stufflebeam, 1996). Carried out correctly, and with appropriate sample sizes, random assignment results in groups that are similar in both observable and *unobservable* characteristics. As a result, differences in outcomes between the two groups are attributable to the program alone, within a known degree of statistical precision. Correctly designing and implementing the randomization process is therefore a critical and essential element of an experimentally designed program evaluation. A very accessible resource on experimental designs is Kirk (1995).

While it is the strongest design to support causal inferences, an experimental design is not always appropriate, ethical, or feasible. Much has been written about the ethical concerns of depriving services to the participants who are randomly assigned to a control group. The importance of this issue cannot be overstated, and requires significant thought during the design stage. There are some strategies that may allay these concerns. One is to limit the experiment to programs with a waiting list of participants. In this case, the program cannot serve everyone, so even without the evaluation, not all individuals would be served. Selecting participants from the waiting list randomly (by lottery) is often felt to be fair. Another option is to provide the control group with the treatment after a delay.

A QED can be similar to an experimental design, but lacks the key ingredient of random assignment. The QED intervention group includes participants who were selected through another process (such as a school administrator or teacher determining which students receive the program), along with a matched comparison group of nonparticipants. As a result, a QED must demonstrate that the treatment and comparison groups are equivalent on observable characteristics at baseline. However, even with equivalence on observable characteristics, differences in unobservable characteristics may still exist. For instance, the comparison group might comprise individuals who had the option to receive the program but declined, resulting in two groups that are likely to differ systematically in their level of motivation or interest.

The method used to match the treatment to the comparison group members can improve group equivalence at baseline. Generally, it is best to match on variables that are highly correlated with the outcome, such as pretest scores. A relatively new and popular method of matching is the propensity score matching (PSM) approach (Rosenbaum & Rubin, 1983). Its basic idea is to find a group of nonparticipants who are similar to the treatment group participants in all relevant pretreatment characteristics. To do this, a propensity score (i.e., the probability of participating in a program given observed characteristics) is calculated using as many predictor variables as possible. However, PSM requires a large sample size, which can limit its applicability.

While in-depth treatment of the broad range of specific designs goes beyond the scope of this chapter, readers are encouraged to read Shadish, Cook, and Campbell (2002) who provide an authoritative and thorough review of experimental and several quasi-experimental designs. In addition, the WWC *Procedures and Standards Handbook* provides a detailed discussion of factors to keep in mind when designing a quasi-experimental or an experimental study so that it meets the highest standards for rigor (WWC, 2011).

An important factor to consider in any summative design is the power of the design to detect treatment effects, when they exist. The estimation of power is a critical component in the design of experiments, and is calculated to ensure that the sample size is sufficiently large (Cohen, 1988; Lipsey, 1990). Free software is readily available online that will calculate power for a variety of evaluation designs—the most common one is the Optimal Design Software available at the University of Michigan Web site http://sitemaker.umich.edu/group-based/optimal%20design%20software.

Conclusion

Using guidance provided by the IES as a foundation, readers are offered a framework to help guide the selection of an appropriate evaluation design that is consistent with the developmental status of the program. Evaluations conducted in the early phases of a program's development are geared toward describing the need for the program, providing information to guide the development of the program, and detailing how the program is implemented. In short, the initial stages are largely formative in nature, because their goal is program development and improvement.

Once a program has been fully developed and is stable, more summative evaluation methods are used. In the final two stages, the goal is to estimate the impact of the program under optimal conditions, and then under real-world conditions. The difference between these two conditions is that in the optimal condition, the implementation information is used by program staff throughout the evaluation to maintain high levels of program fidelity. In the real-world condition, the implementation information is used to help describe the context and to attempt to explain why the program works and under such conditions. To estimate program effects, either experimental or quasi-experimental designs are recommended, with random assignment distinguishing experimental from quasi-experimental designs.

Notice that at every stage, the collection of implementation information plays an important role in the evaluation. In all stages they are used to describe the context under which the program operated so that potential adopters of the program can determine the likelihood of finding similar results in their classrooms, schools, and districts. In earlier stages, these data are also used to improve performance and fidelity.

In addition to the framework provided, readers should familiarize themselves with established evaluation standards and the broad array of available literature on the subject. It is important to remember that there is no single approach to evaluation, and evaluators therefore need to be familiar with a range of designs including both quantitative and qualitative approaches. Design decisions also require responsiveness and judgment particular to each setting, given the practical constraints of time and resources. Our goal in writing this chapter is to provide guidance, tools, and resources to help novice evaluators develop evaluation designs that are responsive to the information needs of the client and appropriate to the developmental status of the program.

Acknowledgements We would like to express our gratitude to Debra Rog and Cindy Tananis who provided input and friendly advice on this chapter. We also wish to thank the anonymous reviewers whose comments and questions greatly improved our work.

Perspectives on Assessment of Educational Technologies for Informal Learning

21

Wilhelmina C. Savenye

Abstract

Informal learning is a complex area, yet one that increasingly involves educational technologists in practice and research. Informal learning includes many different settings, contexts and goals, and draws upon many fields. Two fields that have yielded considerable research literature are museum/free-choice learning and informal science education. While some have defined informal learning as nonschool learning, the nature of informal learning includes dimensions such as location, timing, structure, control, pacing, regulation and content, and so informal learning is not necessarily tied to space. This means that informal learning can and does occur frequently in museums, after-school clubs, botanical gardens, zoos, science centers, and community centers, but can also be engaged in at home and also be integrated within formal school or college settings. Informal science education, museum learning and workplace learning are designed for varied outcomes and have different frameworks. Reasons for assessing for informal learning include to provide formative feedback to participants and to provide evaluation data to improve the organization's learning goals. Methods for assessment for informal learning encompass both quantitative and qualitative approaches, including traditional tests and measures, but primarily rely on such methods as surveys, group and individual interviews, observations, artifact and product analysis, and sometimes ethnographic or case studies. Emerging educational technologies, such as social media, Web 2.0 tools, eLearning and online learning, provide fertile ground for continuing developments in informal learning and assessment.

Keywords

Informal learning • Informal science education • Assessment • Evaluation

Introduction

As we begin to review the perspectives, issues, approaches and a few of the methods involved in assessing learning in informal environments we face the reality that this is a complex area of practice and research. There are many factors operating in varied ways, numerous complex issues, a diversity of views and approaches, few easy answers, and even some possibly political and controversial concerns. However, one might contend that there is more freedom in working in informal environments than in more formal learning settings. This freedom does come with considerable professional responsibility.

In this review we draw upon theoretical views, approaches, methodologies, and findings from several seemingly disparate fields. These fields, not unexpectedly, include instructional design and development, technologies for learning, evaluation, and assessment. However, free-choice/museum

learning and informal science education are two critical fields in which, arguably, the majority of the informal learning work to date has taken place. We also draw from work in qualitative research methods, workplace learning, eLearning, anthropology, social media/Web 2.0 tools, and other emerging technologies. These diverse fields contribute to a deep and productive understanding of how to assess educational technologies in informal learning contexts.

Our perspective as we begin, is that educational technology includes both processes and technologies, all forming systems designed to improve learning and performance in a wide variety of settings (Reiser, 2012). Like others in informal learning we hold a somewhat "pragmatic" or practical and mixed-methods perspective. Some would term this simply pragmatism (Smith & Ragan, 1999). We tend to agree with Reeves and Hedberg in their discussion of evaluation for technologies, that what they term "Eclectic-Mixed Methods-Pragmatic" is "…the one approach capable of handling the complexity (some would say chaos) that is the hallmark of contemporary society and technology" (2003, p. 34).

Our purpose in this short review is not to provide a manual or handbook on assessment for informal learning; our space is too limited to do that justice. Our purpose is instead to aid the educational technologist working in diverse informal learning contexts and environments by providing a broad overview of ways to approach and make decisions about assessment.

We begin our review by exploring what informal learning is, including definitions, models, frameworks and some arguments. We then explore the purposes and issues involved in assessing learning in informal environments. We examine a few of the key methodologies for assessing informal learning, especially those that involve new and emerging educational technologies. We conclude with recommendations for investigating the evidence of learning from the broad approach that informal learning provides. We close the chapter with a set of resources educational technologists may use to aid them as they endeavor to assess learning in informal environments.

What Is Informal Learning?

What Is Learning?

Falk and Dierking (2000), in their work on free-choice learning, particularly in museums, provide us with a note of caution with which to begin our examination of informal learning: "… learning is *common* but definitely not *straightforward*…" (p. 149). In school learning we often see the term achievement, while workplace learning frequently includes the terms competence and performance. In both settings learning often includes mastery. Defining learning itself may seem simple. However, learning has been defined many ways in the field of educational technology, education in general and in informal learning. Gagne, one of the early and seminal leaders of the field of educational technology, defines learning as a change in an individual that is persistent and that results, not just from growth, but from that person's interaction with his or her environment (Gagne, 1984).

A leading technology proponent of social media in her book for trainers adds to our views of learning by contending that most workplace learning occurs *between* formal training or educational events (Bozarth, 2010). Bingham and Conner (2010), in their review of social media, add that workplace learning provides an organization with a "competitive advantage," adding that, "Social learning is a fundamental shift in how people work—leveraging how they have always worked, but with new tools to accelerate and broaden individual and organizational reach" (p. 5). Cross (2007), too, focuses on informal workplace learning: "Learning used to focus on what was in an individual's head… The new learning focuses on what it takes to do the job right" (p. 5). And so we begin our discussion of the dimensions of informal learning by having already expanded our view of learning.

Definitions and Dimensions of Informal Learning

" …'informal learning' is a metaphor with a severe problem," according to Straka (2004, p.2). He describes a two-dimensional continuum from "explicit" to "implicit" and then from formal to informal "external conditions" surrounding the learner (p. 12). Straka concludes that formality is socioculturally determined and he prefers the term "non-formal education" (p. 13). Sefton-Green (2004) for the FutureLab in the UK concurs, adding that currently the term informal learning is used "quite loosely" (p. 6). He, too, sets up two dimensions related to informal learning, that is the degree of formality/informality of the "organization" of the learning, compared with the degree of formality/informality of the "setting" in which the learning occurs (p. 6). The Organization for Economic Co-operation and Development (n.d.), notably, does consider informal learning to be learning that is not organized in any way, and uses the term non-formal to mean learning activities that are out of school, but are organized and may have learning objectives.

Another aspect of this discussion is that learning activities may be "intentional" or "incidental". Clark (2010) defines "an intentional learning environment" as one designed to help learners accomplish certain objectives and goals, while incidental learning involves learners picking up skills or information on their own, without that necessarily having been the purpose of an environment. (It should be noted that learners themselves may have intentions to learn and seek out this learning.) Clark further contends that both informal and formal learning can include both incidental and intentional learning. He argues that the distinction between formal and informal learning rests in who is directing the development of the learning materials or programs. Clark, too, holds that formal and informal learning represent "part of a continuum" (p. 1).

For the purposes of this chapter, we include in our definition of informal learning activities that may be somewhat organized and planned, though that typically take place out of school, university, or formal training settings. This definition is in line with that of the National Science Teachers Association (2012) related to informal science education.

Hofstein and Rosenfeld (1996) have tackled "bridging the gap between formal and informal science learning" (p. 87), noting too, that there is little agreement about definitions. Informal learning activities can take place in formal/school settings and vice-versa, and informal settings, such as museums, can support "formal" learning activities, such as classes or courses. Hofstein and Rosenfeld term this a "hybrid" (p. 90) definition of informal learning.

Free-choice learning is the preferred term by several museum and informal educators and researchers (Falk, 2001; Falk & Dierking, 2002). They argue that the definition of learning should not depend upon a specific setting and that this term is more descriptive, more all-encompassing and more neutral. They reiterate the key dimensions of free-choice learning: "free-choice, non-sequential, self-paced and voluntary" (Falk, 2001, p. 7). Cross (2007) advocates for helping learners become much more self-directed, especially in our information and technology-rich world and he uses the term "free-range learners" (p. 175).

Rossett and Hoffman (2012) describe informal learning as defined by six factors, related to the type of outcomes and experiences desired and to be designed: the source of the informal learning and the roles of the learner, instructor and designer. One aspect of our discussion is that it is now clearer why these many terms tend to all be used interchangeably: informal learning settings, informal learning contexts, informal learning environments and informal learning experiences. Being comfortable now that the terms may vary and that there is little general agreement about the definitions, but considerable agreement on dimensions, we rely on the term "informal learning."

A Framework for Informal Learning

The US National Research Council (NRC) report (2009) on learning science in informal environments presents an "ecological framework for understanding learning across places and pursuits" (p. 31). The report also adds place and culture to the mix. We can see that some of the key differences between formal and informal learning make effects of informal learning hard to measure. For example, the NRC report notes that informal learning experiences are often short and spontaneous. What occurs cannot always be completely planned or predicted. Pleasure and fun are often important goals. Such informal learning experiences often result in "unexpected" and "emergent" outcomes (p. 63). In them, learners may choose to follow their own paths and develop their own goals.

Developing Outcomes, Goals and Objectives: Examples from Informal Science Learning

The key is to determine, "What is success?" in our particular informal learning situation. This is seldom easy. In the workplace, Allen's (2007) "success-based design" in eLearning is based on "measurable improved performance" (p. 51). In training and education, learning goals are developed, which lead to measurable and observable learning objectives. Cennamo and Kalk (2005) call the activities related to writing objectives and then assessments to measure learners' performance on them, "defining success" (p. 49).

Informal educators have long called for a broader view of indicators of success and effectiveness. It is common for museums, for example, to strive for deep impact on visitors in other forms. If learning is a change in the individual as a result of his or her experience and interaction with a (learning) environment, then educators in informal learning environments often look for a learner's increased interest and excitement about a topic, desire to learn more, change in conceptions, surprise about new learning, and even change in an individual's perceptions of identity with regard to a topic or field.

Science education is arguably at the leading edge of informal education. The US National Science Foundation includes an Informal Science Education program, currently under NSF's Division of Research on Learning in Formal and Informal Settings (NSF, 2011). The NSF has supported projects such as the National Partnerships for After-School Science (NPASS2), which provides science-learning resources for after-school educators (Education Development Center, 2012a). Many informal science learning projects and programs represent partnerships among after-school programs, and community organizations, science centers, museums, zoos, and botanical gardens. For example, Design It! Engineering in After School Programs represented projects developed by after-school programs in partnership with such organizations (Education Development Center, 2002).

The NRC report (2009), focused on informal science learning, notes that outcome statements are not only useful to stakeholders, but are often required by funding agencies. However, it notes that, "… traditional academic achievement outcomes are limited" (p. 3), in that they often do not include the range of goals and settings of informal learning and may in fact "… violate critical assumptions about these settings, such as their focus on leisure-based or voluntary experiences and non-standardized curriculum" (2009, p. 3).

The NRC report outlines six "Strands of Science Learning" which provide useful models for how those working in other settings might develop their learning goals and/or objectives (2009). The strands begin, notably, not with traditional learner achievement, but with attitudinal learning. They include deep, wide, and complex science learning goals and conclude with goals related to a learner's changed view of science and themselves as scientists.

Strand 1: Experience excitement, interest, and motivation to learn about phenomena in the natural and physical world.

Strand 2: Come to generate, understand, remember, and use concepts, explanations, arguments, models, and facts related to science.

Strand 3: Manipulate, test, explore, predict, question, observe, and make sense of the natural and physical world.

Strand 4: Reflect on science as a way of knowing; on processes, concepts, and institutions of science; and on their own processes of learning about phenomena.

Strand 5: Participate in scientific activities and learning practices with others, using scientific language and tools.

Strand 6: Think about themselves as science learners and develop an identity as someone who knows about, uses, and sometimes contributes to science (p. 4).

Keeping in mind that the NRC report calls informal learning, "lifelong," "life-wide," and "life-deep" (2009, p. 28), we turn now to the range of purposes of assessing for informal learning.

Why Assess for Informal Learning?

Definitions of Assessment (and of Evaluation)

What is assessment? Assessment is typically defined as measuring learning. In their book on distance education, Simonson, Smaldino, Albright, and Zvacek (2012), for instance, define assessment as, "the process of measuring, documenting, and interpreting behaviors related to learning" (p. 262). What is measured is individual learning, both for their benefit and for use in improving instruction. Virtually all instructional design models and frameworks direct that learning must be measured in order for instruction to be evaluated and improved.

How does assessment relate to evaluation? Most educators and researchers make a distinction between evaluation and assessment. One way to look at this would be that there are two aspects to be examined, the learner's performance (assessment) and the instruction or learning environment (evaluation). Evaluation is usually focused on a program, course or organizational level. Evaluation does include assessing learning, but also the activities involved in making judgements and decisions about the quality of the program or initiative as a whole.

Evaluation includes what may be considered "types" or "phases". These begin with *front-end evaluation,* in some projects also called needs analysis, to gather data to aid in the later design and development processes. *Formative evaluation* is conducted to collect data to aid in improving a program, product or approach during development, ideally on an ongoing basis. *Summative evaluation* is done typically at the end of development for reporting purposes, or in order to make final determinations about retaining a program, or choosing another, etc. (Fenichel & Schweingruber, 2010; Reeves & Hedberg, 2003; Russ-Eft & Preskill, 2009.) In informal settings are added several others: "critical appraisal" and "remedial evaluation" (Bitgood, Shettel, & Williams, 1991, p. 27) typically are done after an exhibit or program is in place.

Though we find the clear distinction between *assessment* and *evaluation* to be very useful, as Simonson et al. note (2012), many authors use the terms synonymously. It is useful to bear in mind that many stakeholders also use the terms interchangeably.

Purposes of Assessment for Informal Learning

Many educators call for changes in the role of assessment for learning. We use the term assessment FOR, rather than assessment OF learning. This represents what Shermis and DiVesta (2011) describe as the "changing role of assessment" (p. 22). "Assessment *for* learning happens in the classroom and involves students in every aspect of their own assessment to build their confidence and maximize their achievement" (Stiggins & Chappuis, 2006, p. 11). With regard to digital technologies, Collins and Halverson (2009) and Gee (2007) are among those who advocate assessing learners using methods beyond standardized testing. This view of learners as active agents, using ongoing feedback to help them improve their learning performances, is particularly well suited to informal learning. Gee's work, focussed as it is on what students learn through video games and gaming, illustrates the value of examining learning in settings in which learners are engaging in very self-directed and enjoyable activities.

Falk and Dierking (2000) assert that one of the challenges to providing "compelling evidence for learning from museums…." is, "…not because the evidence does not exist, but because museum learning researchers, museum professionals, and the public alike have historically not asked the right questions. The result has been a search for inappropriate evidence of learning using flawed methodologies" (pp. 149–150). They suggest that we look at assessment purposes in two clear ways. One purpose is that assessment can aid learners, via feedback, in their progress toward their own learning goals. The second major purpose is to aid the institution in furthering its learning goals.

Formative assessment contributes information/data to use to further the learner's development on an ongoing basis. The idea is similar to that of formative evaluation, which contributes information/data for designers to use to further the improvement of a product or program on an ongoing basis, during development (Shepard, 2000). In our view an instructional designer could productively substitute the words "practice and feedback" for what classroom assessment specialists and teachers call "formative assessment and feedback." However, it may be more useful to keep the roles of these components of learning materials, programs and experiences separate.

While formative assessment is focused on improving individual learning, as Falk and Dierking (2000) note, another critical role of assessment is to improve the learning goals of an organization. This might be seen as a more traditional role for assessment in instructional design, development and evaluation, that is, to improve a program or course during development (formative evaluation). However, this is also a common role for assessment as part of reporting back to a funding agency, in a summative manner, about the final effectiveness of a program.

A Few Examples of Methodologies for Assessing Informal Learning and Educational Technologies

A multiple-method approach is most effective in assessment for informal learning. Many (or any) approaches, strategies, methodologies and tools may be adapted for your purposes, as long as the assessment purposes are clear. For instance, if one is developing the skills of after-school program leaders, funded by an agency requiring formative and summative reports, then pre–post learning quizzes might reasonably be used. However, for an after-school field trip one leader is designing, the individual might simply do quick group interviews after the experience. Those interviews could serve to provide those students with feedback about their learning (formative assessment), as well as to provide the educator with data for improving that field trip for the next group of learners. (See the work of the Center for Science Education and NPASS2 (Education Development Center, 2002, 2012b) as well as Yager & Falk, 2008, for many examples of mixed-methods studies of informal learning, particularly in projects representing partnerships such as among after-school programs, community organizations and museums, zoos, and science centers).

In this chapter we are not using the terms "quantitative" or "qualitative" methodologies for research quite purposely, as we advocate the value of mixed-methods approaches to assessment for informal learning. However, we have developed earlier guides to qualitative research that provide more technical specifics about how to use many of the more qualitative techniques we discuss here (cf. Savenye & Robinson, 2005; Savenye, Robinson, Niemczyk, & Atkinson, 2008).

We further suggest that one let go of the somewhat common evaluation idea that "learning" is measured using tests, and that "attitudes" are measured using surveys and interviews. A survey or a structured interview may, indeed, include "learning" questions, even formal or traditional "test" questions. Similarly "behaviors" or "performance" are not the only types of outcomes that can be measured using observations.

Assessment for informal learning may rely on traditional measures, such as tests and quizzes. However, typically more qualitative methods make up a good part of the mix of methodologies used to answer research and evaluation questions. These methods may include concept maps; classroom assessment techniques; self and peer reviews; performance assessment; analysis of learning products, discussions and conversations; surveys (administered in writing, via computer or orally); individual and group interviews, as well as many types of observations. We explore some of these measures below.

Traditional and Informal Learning Measures

Tests and quizzes. Other chapters in this volume discuss methods for measuring learning in more formal contexts, such as school and university, graded and standardized settings, so we will, in this review, only briefly review some of these types of more formal learning measures because they can easily be adapted for informal settings. Incidentally, we have found it less intimidating to call, in informal learning settings, such measures, "checks" or "starting at the beginning" or even including these items in a questionnaire, or structured interview. Also, learning measures may be administered as group measures at times in nonschool settings.

These more formal learning measures may include tests and quizzes, which in turn may include diagnostic tests, entry-level tests, pretests of prior learning, embedded or practice tests, and posttest measures. Most instructional design texts provide very effective introductions to these many types of more formal learning measures (cf. Dick, Carey, & Carey, 2009; Gagne, Briggs, & Wager, 1992; Smith & Ragan, 1999). In addition, many good texts on tests and measurement design are available (cf. Kubiszyn & Borich, 2009; Shermis & DiVesta, 2011) (For a more comprehensive overview of evaluation of training see Bassi & Russ-Eft, 1997; Brinkerhoff, 2006; Cennamo & Kalk, 2005; Reeves & Hedberg, 2003).

Concept mapping. Concept maps are increasingly being used to measure learning. These may be used both formally and informally. In more formal approaches, experts may be called upon to create concept maps of their mental models or of their conceptions of relations among concepts in a domain. Learners then also are tasked with creating concept maps and the maps of these more "novice" learners may be compared to those of the experts. Another approach is to have learners develop concept maps both before and after participating in the learning experience. A very promising area of research in concept mapping for measuring skills and knowledge is that of Spector, Shute and colleagues (cf. Pirnay-Dummer, Ifenthaler, & Spector, 2008; Shute, Jeong, Spector, Seel, & Johnson, 2009; Spector, 2006). These researchers have developed computer-based tools that are allowing researchers to have learners input their concept maps more easily. Then the computer tools themselves aid researchers in analyzing the learners' conceptions, thus somewhat automating the analysis process, which otherwise has been time-consuming and quite daunting to practitioners and researchers alike.

Classroom assessment techniques (CATs). Classroom assessment is a formative assessment approach that is designed to provide instructors with information on an ongoing basis about learner performance. Learner performance data are then rapidly analyzed and used to provide learners with feedback, again on an ongoing formative basis. Educational technologies, such as "clickers" are increasingly being used in classroom assessment, but these techniques may or may not rely on technologies. Angelo and Cross present many CATs for use by college instructors that may readily be adapted for informal learning (1993). Additional reference guides for developing classroom assessments are the works of Shermis and DiVesta (2011) and Shepard (2000).

Self and peer reviews. As part of a broad review of the research on formative assessment, Black and William (1998) note that many aspects of learners' perceptions may be assessed, including goal orientations, self-perceptions related to aspects of the learning content, or skills (Black & William, 1998). Shute (2009), in her argument for a revised perspective on assessment, includes self-assessment as a valued aspect of measuring learning. Peer assessment can also quite easily and productively be incorporated into informal learning.

Embedded assessment. Shute (2009) contends that assessment can be designed seamlessly into learning activities, particularly when using technologies. She has termed this "stealth assessment" (p. 7), adding that there is no need to interrupt learners' work, such as when they are engaged in learning in a technology-based environment or game. The system can collect student performance data continuously, and can respond and adapt to learners' choices, providing them learning assistance and support as they go.

Performance assessment. As noted earlier regarding "functions" or "purposes" it is useful to note that many of the same techniques developed for measuring on-the-job performance or competence in the workplace, and for measuring what visitors do in free-choice settings such as museums have much in common and could effectively be adapted for any setting.

Reflective Writing, Discussion and Media Creation

By using wikis, blogs and other social media tools, learners construct and share their own views of the world and of the content with which they are becoming more experienced. These tools are frequently used in online courses and eLearning (Paloff & Pratt, 2009), but they can easily be adapted for assessment for informal learning.

Blogs, vlogs, micrologs, and other types of journaling and reflective writing. In the spirit of formative assessment for the informal learner, blogs, vlogs (video logs), microblogs, like Twitter, and other types of journal and reflective writing can be used in informal assessment. Learners can use these artifacts to examine their own change over time. However, docents, mentors, coaches, and instructors can examine these learner creations and provide formative feedback to the creators as well. In addition, these blogs and journals can be examined as what would be termed artifactual data in more formal evaluations (Russ-Eft & Preskill, 2009). An increasingly common use of Twitter is for participants to develop backchat or backchannels as they engage in learning activities; a recent eLearning Guild conference provided these on monitors for all to view, and included a backchatter game (eLearning Guild, 2011).

Wikis. Wikis provide for a Web-based writing space that could be individual but is designed for collaboratively written pieces or set of pieces. One instructor (Bowman, 2010) has used wikis to allow students to share their critical analyses about various aspects of the criminal justice system in various cities in the USA. Learners not only conducted research online but, as the instructor says, they also called and wrote individuals and experts in the agencies in the cities to which they were assigned. In this way, students not only learned about aspects of criminal justice, but developed their own personal understandings of the topics, based on their own explorations, and in this way, the content "came to life" for the learners.

Discussions and online discussions. Programs both in and after school have long employed discussions to support learning and assessment. Online discussions are also regularly used in online courses. These discussions are frequently assessed for formative assessment and feedback on an ongoing basis in a course (Savenye, 2004). Online discussions can also be examined as data in evaluation studies and research. For instance, Thompson and Savenye (2007) examined the online discussions of learners enrolled in an online MBA program to determine participation rates and activities. Paloff and Pratt (2009), as well as Ko and Rossen (2010), provide guidance for assessing learners in online courses and discussions.

Learner-created media for formative assessment. While student-created portfolios and webfolios have been used in education (Kim, 2001), participants in informal learning environments are now able to develop their own videos, sets of photographs or photographic stories, their own Web sites, and their own (as compared with institutional) blogs and wikis. All these participant-created media could form the basis of rich formative assessments and evaluations. Gee (2007) in his book on gaming and literacies for learning would call this learner an " 'insider', 'teacher' and 'producer' (not just a 'consumer') able to customize the learning experience" (p. 227).

In our view informal learning now becomes not identified simply with museums or nonschool settings, but more clearly with *any* setting. Learners can now build and share their own photographs through sites such as Flickr or Picasa; videos, such as through YouTube; artwork, animations, writings—anything they wish to produce and share. They can set up their webcams to continuously stream videos, such as of birds, weather, natural phenomenon, city venues, etc, via UStreaming, and others can link to those sites and comment upon the videos. Informal learning is arguably truly ubiquitous in our world today and all of us, lifelong, are informal learners. (For an extensive overview of the many social media technologies and tools available for educators see Kim Peacock's site, Web 2.0 for Teachers (2011.) For more ideas about using social media in education see edsocialmedia.com site (2011)).

Use of rubrics. Rubrics are tools by which learner performances and products can be evaluated. "They set criteria for degrees of effective performance" according to Shermis and Di Vesta (2011, p. 133) who include in their review guidelines and examples for creating rubrics. Another useful introduction to rubrics is presented by the Illinois Online Network (2010) in their Web site on Assessment/Evaluation Topics under Online Education Resources. For younger learners, though these could be adapted for adults, Discovery Education's Kathy Schrock's Guide for Educators provides extensive Web-based resources for educators, including many aids for those who wish to develop and use rubrics (Schrock, 1995–2011). Her guide features, for instance, ready-made rubrics that can be used or adapted for evaluating student Web pages; subject-based rubrics; rubrics for Web 2.0 tools, such as blogs, wikis, Animoto, Skype, Glogster, Twitter, and Voicethread; as well as guides for building rubrics and articles about rubrics, performance assessment, and electronic portfolios.

Surveys

Most informal learning professionals rely quite heavily on questionnaires (the survey method) to measure aspects of learners' attitudes, and other affective variables, such as interest, excitement, intentions, and motivation. If designed with a mix of closed-ended questions, to capture considerable data that are not too difficult to analyze, and a few open-ended questions to capture broader or unanticipated views of the learners, they can be relatively efficient. Surveys are not easy to build effectively, so time will need to be spent to design and test the instruments. Though not the specific focus of this chapter, and likely to be covered in other areas in this volume, good references for survey development are numerous. For instance, Korn (1999) and others in the Borun and Korn (1999) volume on museum evaluation include guidance and many examples. For evaluation in general the Russ-Eft and Preskill (2009) text also provides many guidelines and examples of how to ask questions in organizational learning settings. Another excellent online source for survey development is Scheuren's (2004) "What is a Survey?", available free of charge from the American Statistical Association.

In informal learning, increased motivation may make up a major learning outcome to be assessed. John Keller has formulated his "model of motivational design" based on extensive reviews of the motivation literature and his own research. Keller and colleagues have developed and utilized instruments to measure learner motivation, based on his elements of motivation, that is: Attention, Relevance, Confidence and Satisfaction (ARCS) (cf. Keller, 2006; Kim & Keller, 2008). These approaches and measures could, with permission, be adapted for many informal learning environments.

Interviews

Interviews. It should be noted that surveys can easily be adapted and used as interview protocols in many informal learning situations, in which learners often prefer to answer questions verbally, rather than to fill out questionnaires. As an example, we used a survey in interviewing visitors to a free-admission botanical garden to determine their reasons for coming to enjoy the garden (and even in those early days some of the data were collected using PDAs) (Savenye, 1998). Doering (1999) provides guidance for how to develop and conduct interview techniques in survey research.

Interviews in informal learning are typically, however, not necessarily tied to questions with rating scales. They may be conducted individually or in groups (informally or using the specific "focus group" method), and may be structured or unstructured. A structured interview includes use of a somewhat standardized set of questions, or a protocol, that will be used with each respondent; probing questions that ask the learner for more detail can still be asked, but generally there is an attempt to be quite consistent in the questions that are asked of each learner. In contrast, unstructured interviews typically are conducted in a free-form manner, more like a conversation in which the interviewer begins with a very open-ended question and builds his or her next questions based on what the learner says. Interview data are typically analyzed for predominant themes in the learners' responses, though sometimes frequency counts are developed.

Read, think-aloud protocols. A special type of interview is a read, think-aloud protocol that is done in combination with observing a learner working through a program or experience. When these are computer-based programs, the observer asks the learner to talk aloud about how he or she is making decisions, choosing to navigate certain ways, choosing answers, etc.

Observations

Learners who participate in informal experiences for learning are particularly "free." What we learn about learners in these free-choice settings may in the future be applied in Web-based open learning communities and with free-choice technologies, such as Web 2.0 tools. Participation, for instance, can be tallied, via Web hits or attendance in a program or webinar. However, physically, informal learners often follow their own paths through the environment. When conducting formative evaluations in settings such as these, it is often important to observe learners to determine: how many use what, where they go, and what they do when experiencing learning programs or materials. Diamond, Luke, and Uttal (2009), for instance, show how individuals' paths may be observed and tracked and then analyses done of what aspects of a learning environment are, or are not, being used. They describe participant and nonparticipant observational methods for learning more about how learners access and use informal learning offerings.

Museum evaluators use specific observational techniques to measure attracting and holding power, as well as engagement. For example, in a desert botanical garden (outdoor museum) we used techniques adapted from Screven (1999), Bitgood et al. (1991) and colleagues, to determine the attracting and holding power of mock-ups, or rough prototype versions, of exhibits designed to help visitors understand and appreciate the ecology and plants of the Sonoran desert (Savenye, Socolofsky, Greenhouse, & Copeman, 1997).

After the prototype learning exhibits were working well to attract and hold visitors, the next step in the formative evaluation was a form of learning assessment. We interviewed visitors to ask them first a general, open-ended question like, "What do you think was the main message of this exhibit?" to determine first what message was getting across. In subsequent formative and summative evaluation phases we interviewed visitors before and after their visits with specific learning questions related to the main learning goals of the trail (Savenye et al., 1997).

Conclusions and Recommendations

We have come full circle. We have examined the issues and approaches involved in effectively assessing for informal learning. We have introduced a few methodologies that have proven useful in free-choice and informal learning settings. We have briefly toured a few ways that new educational technologies may impact informal learning and approaches to measuring learning.

We would recommend that educators use an informal-learning, free-choice perspective to develop their own goals and outcomes for the learner's experience. One suggestion would be to develop for their program or environment to be assessed "strands" or goals, such as those described earlier that are becoming widely accepted for informal science education (Fenichel & Schweingruber, 2010; NRC, 2009), and, for each of those identified, to develop assessment strategies, then methods, and then tools or instruments.

Another approach would be to adapt the evaluation framework widely used in training and workplace learning, that is, Kirkpatrick's Four Levels of Evaluation (1994): (1) Reactions, (2) Learning, (3) Behaviors, and (4) Results. It is our contention that most models or frameworks for assessment, thoughtfully adapted to the informal learning experience, program or environment at hand, with input from appropriate stakeholders, will ensure a successful evaluation.

Technologies such as eLearning and online learning, social learning media, other Web 2.0 media creation and writing tools, games and virtual worlds will all continue to impact learning in new ways. They will lend themselves well to informal learning techniques and approaches.

As Falk and Dierking (2002) recommend, consider the needs and desires of the learner for continuous, ongoing formative assessment and feedback. At the same time, consider the needs of the organization for evidence/data that can support the organization's learning goals, be those related to reporting to a funding agency or for the organization's decision-makers and community stakeholders alone. Develop your assessment plan, and the decision-making questions that require the evidence, together with relevant stakeholders. Select and build your assessment approaches, strategies, methods, and tools/instruments creatively. Use them efficiently to gather evidence. Report using strategies that address your and the stakeholders' needs. Finally, choose to engage in a continuous iterative cycle of improvement and excitement about your own, the organization's, and its learners' learning and enjoyment.

Assessing Problem Solving

22

David H. Jonassen†

Abstract

Methods for assessing problem-solving learning outcomes vary with the nature of the problem. For simpler well-structured problems, answer correctness and process may be used along with assessments of comprehension of problem schemas, including problem classification, text editing, and analogical comparisons. For more complex and ill-structured problems that have no convergent answers, solution criteria, or solution methods, problem solving may be assessed by constructing and applying solution rubrics to assess mental simulations (scenarios), arguments in support of solutions, and student-constructed problems. Problem solving processes are normally assessed by coding schemes. In addition to assessing problem solutions, assessments of critical cognitive skills, including causal reasoning and student models, may be used to infer problem-solving skills.

Keywords

Problem solving • Problem types • Assessment methods • Rubrics

What Kinds of Problems Can Be Assessed?

An underlying assumption of instructional design is the congruence among goals/objectives, assessments, and instructional/learning strategies employed to meet those goals/objectives. That congruence applies to all levels and kinds of goals and objectives. However, problem solving too often has been conceived as a unitary process or activity. That is, all problems are alike and the normative processes used to solve all problems are similar. Based on that assumption, numerous models of problem solving have been suggested, most of which involve a sequence of steps, including:

1. Define the problem.
2. Analyze the problem (identify possible causes).
3. Investigate the problem (gather information).
4. Generate possible solutions.
5. Evaluate the alternative solutions.
6. Implement the solution(s).
7. Monitor the solution(s).

Jonassen (1997, 2000, 2011) has argued consistently that problems and the methods and strategies used by individuals and groups to solve them, both in the everyday and classroom worlds, vary dramatically. Smith (1991) categorized factors that influence problem solving as external and internal. External factors are those related to the nature of the problem as encountered in the world. Internal factors are related to the personal characteristics of the problem solver, such as prior experience, prior knowledge, or strategies used. Problem solving varies both externally (the problem as it exists in the world) and internally (how the individual or the group conceptualizes and resolves the problem). This chapter addresses internal factors related to understanding and solving different kinds of problems that differ in external factors. Next, I describe the ways in which problems vary externally and how they affect assessment of learner understanding and ability.

Structuredness of Problems

The most significant difference among problems is structuredness. Problems vary along a continuum between well structured and ill structured (Arlin, 1989; Jonassen, 1997, 2000; Newell & Simon, 1972; Voss & Post, 1988). Most problems encountered in formal education are well-structured problems. Often found at the end of textbook chapters, well-structured problems present all of the information needed to solve the problems in the problem representation; they require the application of a limited number of regular and circumscribed rules and principles that are organized in a predictive and prescriptive way; they possess correct, convergent answers; and they have a preferred, prescribed solution process (Jonassen, 2000; Wood, 1983). These problems have also been referred to as transformation problems (Greeno, 1980) that consist of a well-defined initial state, a known goal state, and constrained set of logical operators.

Everyday problems (outside of formal education) are typically ill structured. Ill-structured problems are typically emergent and not self-contained. Because they are not constrained by the content domains being studied in classrooms, their solutions are not predictable or convergent. Ill-structured problems usually require the integration of several content domains, that is, they are usually interdisciplinary in nature. Workplace engineering problems, for example, are ill structured because they possess conflicting goals, multiple solution methods, nonengineering success standards, nonengineering constraints, unanticipated problems, distributed knowledge, collaborative activity systems, and multiple forms of problem representation (Jonassen, Strobel, & Lee, 2006). Ill-structured problems appear ill defined because one or more of the problem elements are unknown or not known with any degree of confidence (Wood, 1983); they possess multiple solutions, solution paths, or no solutions at all (Kitchner, 1983); they possess multiple criteria for evaluating solutions, so there is uncertainty about which concepts, rules, and principles are necessary for the solution and how they are organized; and they often require learners to make judgments and express personal opinions or beliefs about the problem.

Although information processing theories aver that “in general, the processes used to solve ill-structured problems are the same as those used to solve well structured problems” (Simon, 1978, p. 287), more recent research in situated and everyday problem solving makes clear distinctions between well-structured problems and ill-structured problems. Allaire and Marisiske (1999) found that measures that predict well-structured problem solving could not predict the quality of solutions to ill-structured, everyday problems among elderly people. Hong, Jonassen, and McGee (2003) found that solving ill-structured problems in an astronomy simulation called on different skills than well-structured problems, including metacognition and argumentation. Argumentation is a social and communicative activity that is an essential form of reasoning in solving ill-structured, everyday problems (Chapman & McBride, 1992) that is seldom used in solving well-structured problems. Jonassen and Kwon (2001) showed that communication patterns in teams differed when solving well-structured and ill-structured problems. Students solving ill-structured economics problems produced more extensive arguments than when solving well-structured problems because of the importance of generating and supporting alternative solutions when solving ill-structured problems (Cho & Jonassen, 2002). While the solution of well-structured and ill-structured problems requires some different processes, they are not mutually exclusive. Overlap in processing well-structured and ill-structured problems exists, although it varies by complexity and context.

Context of Problems

In everyday problems that tend to be more ill-structured, context plays a much more significant role in the cognitive activities engaged by the problem (Lave, 1988; Rogoff & Lave, 1984) because those problems are more embedded within a specific context. The context in which problems are embedded becomes a significant part of the problem and necessarily part of its solution (Wood, 1983). Well-structured problems, such as story problems, embed problems in shallow story contexts that have little meaning or relevance to learners. Workplace engineering problems, on the other hand, are more ill structured because the context often creates unanticipated problems (Jonassen et al., 2006). Very ill-structured problems, such as design problems, are so context dependent that the problems often have little meaning outside the context in which they occur.

The role of context defines the situatedness of problems. Is the situation predefined by the educator (preauthentication), or is it emergent in some real-world situation in which a problem occurs (emergent authenticity). Predefined problems (well structured and ill structured) refer to analyzing content or activity systems and attempting to simulate the problem in a learning environment that students work in. Almost all problems solved by students in formal education are predefined.

Emergent problems occur during practice within a disciplinary field (Barab & Duffy, 2000), where problems are embedded in authentic situations, allowing students to learn a skill by engaging in the activities germane to that field (Barab, Squire, & Dueber, 2000; Nicaise, Gibney, & Crane, 2000; Radinsky, Buillion, Lento, & Gomez, 2001). These problems tend to be much more ill structured because they are so ill defined.

What Is Complexity of Problems?

Problems also vary in complexity (Meacham & Emont, 1989). Complexity, like problems in general, is an interaction between internal and external factors. Problem solving complexity is a function of how the problem solver interacts with the problem, which is determined partially by the problem solvers' experience as they interact with the problem, importance (degree to which the problem is significant and meaningful to a problem solver), and urgency (how soon the problem should be solved). Ill-structured problems tend to be more difficult to solve, in part because they tend to be more complex (Jacobs, Dolmans, Wolfhagen, & Scherpbier, 2003).

Problem complexity is also a function of external factors, such as the number of issues, functions, or variables involved in the problem and the number of interactions among those issues, functions, or variables. Although complexity and structuredness invariably overlap, complexity is more concerned with how many components are represented implicitly or explicitly in the problem and how much they interact, and how much the learners understand those components. Complexity has direct implications for working memory requirements as well as comprehension. Complex problems impose more cognitive load on the problem solver. The more complex a problem, the more difficult it will be for the problem solver to actively process the components of the problem. Most well-structured problems, such as textbook math and science problems, are not very complex. They involve a constrained set of factors or variables. While ill-structured problems tend to be more complex, well-structured problems can be extremely complex and ill-structured problems fairly simple. For example, chess is a very complex, well-structured problem, and selecting what to wear to work or a social engagement is a simple ill-structured decision problem. Complexity is clearly related to structuredness, though it is a sufficiently independent factor to warrant consideration because of the working memory requirements. As problems become more complex, they make greater demands on working memory. Because most research with worked examples has been conducted with well-structured problems, the relationships between problem complexity and working memory demands remain questionable.

In a more recent analysis, Jonassen and Hung (2008) described problem complexity in terms of internal and external factors. Internal factors included the breadth of knowledge required to solve the problem, the attainment level of problem solver, and the level of domain knowledge. External factors include the intricacy of problem-solution procedures, the relational complexity among domain concepts, the level of intransparency (unknowns in the problem space), the heterogeneity of problem interpretations, and the interdisciplinarity, dynamicity, and legitimacy of alternative solutions. Ill-structured problems tend to be more complex; however, there exist a number of highly complex well-structured problems.

Assessing Problem Solving

Figure 22.1 illustrates the organization of the remainder of this chapter. In the next section, I describe methods for assessing well-structured problem solving, including answer correctness, problem classification, text editing, and analogical comparison. Then, I describe methods for assessing ill-structured problems, including solution rubrics, mental simulations, argumentation, and student-constructed problems. Then I describe methods for assessing underlying conceptual skills, including causal reasoning and students' models.

Finally, I describe how problem-solving processes are assessed using rubrics for assessing essays and coding schemes for assessing think-alouds or discussions.

Assessing Well-Structured Problems

Assessing Correct Answers

In scientific domains such as mathematics and physics, well-structured problems are most often used to represent and assess domain understanding. With those problems, judging student answers against the correct answer most often assesses problem solving. These problems are most often solved using the following procedure (Rich, 1960): (1) representation of unknowns by letters; (2) translation of relationships about unknowns into equations; (3) solution of equations to find the value of three unknowns; and (4) verification or check of values found to see if they fit the original problem. Student responses are therefore assessed by determining if the students selected the correct equation, inserted the correct values into the equations, and derived or solved the equation correctly to determine the correct answer. Instructors infer that if students obtain the correct answer to the problem, then they understand the problem and are able to transfer that skill to other problems. It should be noted that everyday and professional problems in scientific domains become very ill structured (Jonassen et al., 2006).

Summary

Assessing correct answers is the most reliable methods for assessing problem solving, because a correct answer and procedure are known, and student responses can be objectively compared to them. However, for well-structured problems, correct answers should be only one of the assessment methods used. Although correct answers have significant face validity, content and construct validity cannot be assured by correct answers alone. In order to assess conceptual understanding of the problems being solved (content validity), problem schemas should also be assessed.

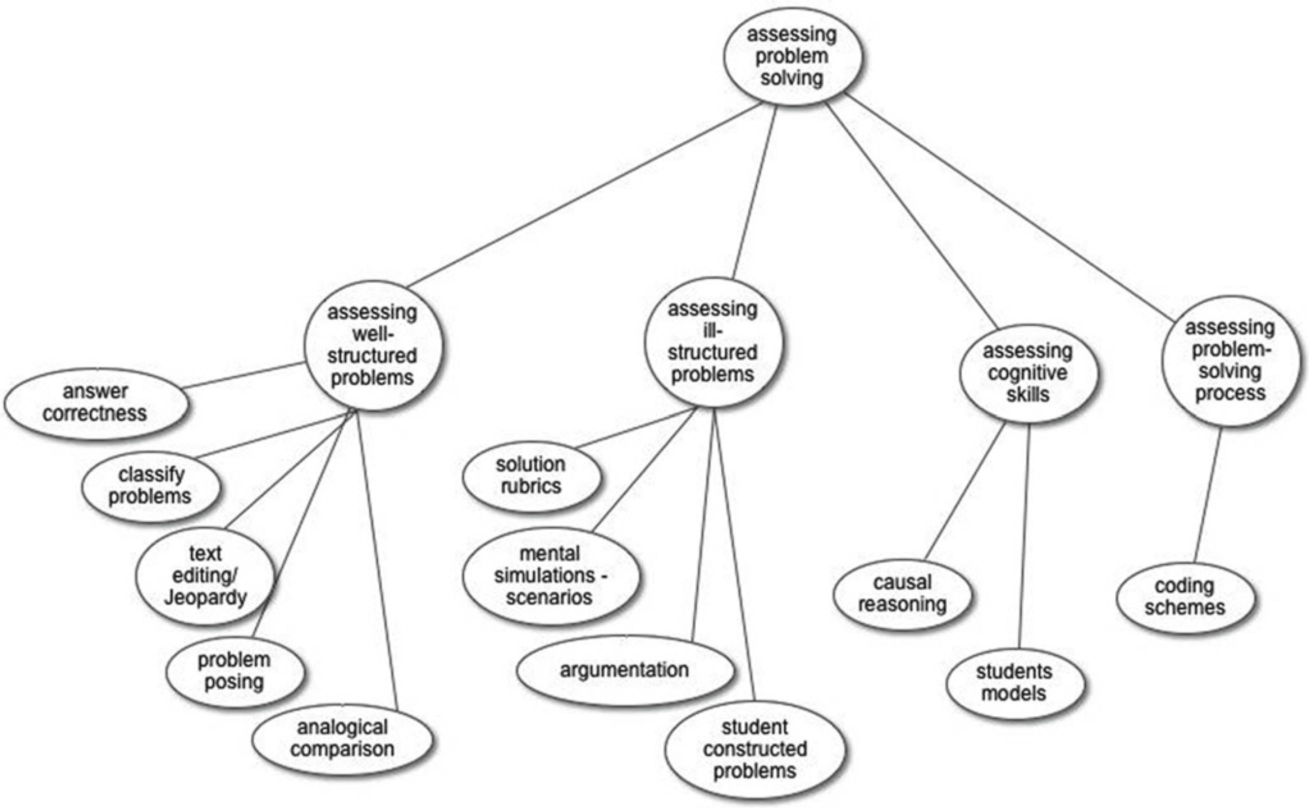

Fig. 22.1 Forms of problem-solving assessment

Assessing Problem Schemas

When problem solvers attempt to directly translate the key propositions in the problem statement into a set of computations (direct translation strategy), they frequently commit errors. Why? Because students have not constructed conceptual understanding of the problem, that is, they have not constructed a robust problem schema for the problem. Rumelhart and Ortony (1977) introduced the concept of problem schema as a form of knowledge structure used to identify the type of problem being solved. Problem schemas include semantic information about the nature of the problem, situational information about its occurrence in a problem situation, and procedural information about how to solve the problem. Typically, problem schemas for only well-structured problems can be adequately defined. Ill-structured problems may exhibit similarities, but the number of variable attributes makes them difficult to classify. Understanding problems requires more than the equations that express them. Conceptual understanding of the problem structure is essential. A robust problem schema enables learners to determine what kind of problem is being solved. Because a robust schema is essential to problem-solving transfer, the quality of a problem schema is predictive of problem-solving ability. In the remainder of this section, I describe alternative methods for assessing problem schemas.

Fig. 22.2 Physics problem used for problem classification

Assessing Problem Schemas with Problem Classification

If students have constructed robust problem schemas for the problems they are learning to solve, then they will be able to accurately classify the problems. For example, present a problem such as that in Fig. 22.2.

Rather than asking students to solve the problem, ask them to classify the type of problem, as, for example, kinematics, Newton's second law, work–energy, etc. (Chi, Feltovich, & Glaser, 1981). Science courses are normally taught as a sequence of problem types, so the first week in a physics course (typically kinematics), you would ask, "is this a kinematics problem or not". For week 2 (work–energy, for example), you would present problems and ask which of the two types (kinematics or work–energy) the problem exemplifies. Each week, you add another problem type to the list of possible classifications.

Fig. 22.3 Text editing question to support problem schema development

Jane, looking for Tarzan, is running at top speed (4.0 m/s) and grabs a vine hanging vertically from a tall tree in the jungle. How high can she swing upward?

For this problem,

a. There is insufficient data presented to solve the problem.

b. There is sufficient data presented to solve the problem.

c. There is more information presented than is needed to solve the problem.

Problem classification exercises are useful for helping students to construct more robust problem schemas, because students tend to generalize problem schemas based on surface-level similarities among problems rather than the physics principles used by experts (Chi et al., 1981; Dufresne, Gerace, Hardiman, & Mestre, 1992; Hardiman, Dufresne, & Mestre, 1989). Any efforts to help students to classify problems based on their structural characteristics will enhance students' problem schema development.

Another related method for assessing problem classification is the card sort or question sort. Rather than asking students to solve a set of problems, simply present a set of problems and ask students to sort them into conceptual piles. You should ask students to explain the reasoning behind their groupings, especially in terms of physics concepts and principles. Again, experts tend to group problems by laws of physics, and novices based on surface features (Chi et al., 1981).

Assessing Problem Schemas with Text Editing and Jeopardy Questions

Text editing is a method for assessing the quality of problem schemas. Text editing questions (Low & Over, 1989; Low, Over, Doolan, & Michell, 1994; Ngu, Lowe, & Sweller, 2002) present standard questions such as those in Fig. 22.2 to which a quantity has been added or deleted or left alone (see example in Fig. 22.3). Students are required to identify whether the problem contains sufficient, irrelevant, or missing information. Students cannot answer such questions unless they understand what kind of problem it is and what elements are appropriate for that kind of problem. While they appear fairly simple, these questions are difficult for students to answer, especially if the students are required to explain their answers. Because students are asked to complete the tasks without solving the problem, students need to understand the interrelationships between various physical quantities, not in terms of equations, but at a conceptual level to be able to successfully complete the task.

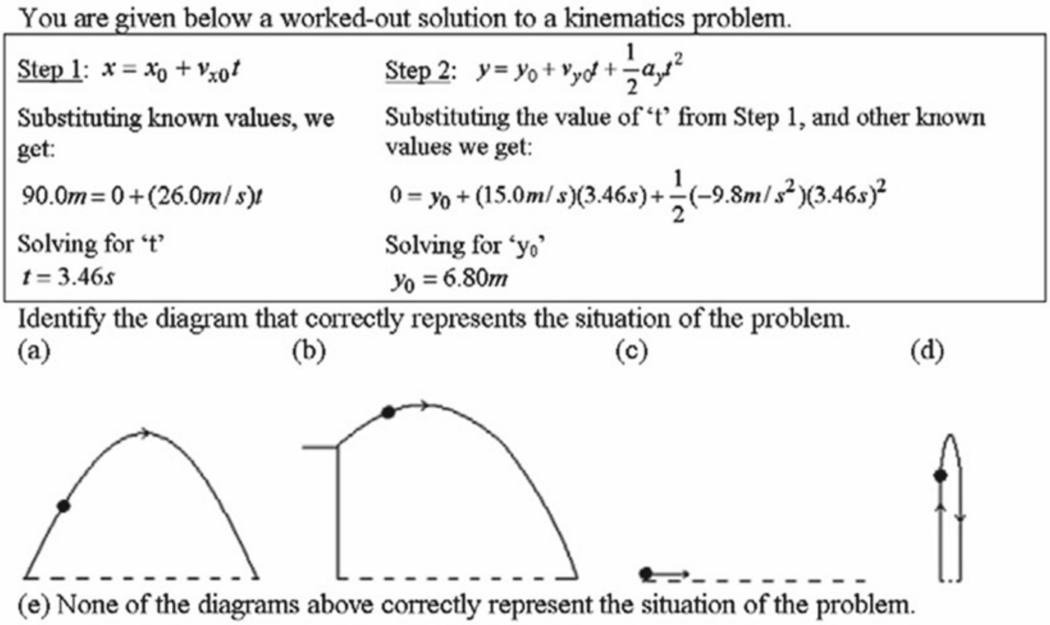
A variation on text editing is a Jeopardy problem, modeled after the popular television quiz show of the same name. Physics Jeopardy tasks were first developed by Van Heuvelen and Maloney (1999). As the game requires, these tasks require the students to work backward. Students are given a fragment of a solution to a problem and asked to identify the physical scenario that corresponds to the solution. The developers point out that these tasks require an effort to represent a physical process in a variety of ways. Because of these features, students are unable to use naïve problem solving strategies while solving Jeopardy problems. Figure 22.4 below shows an example of an adaptation of a Jeopardy problem that provides students with a few steps of a projectile motion. Students are asked to determine what trajectory shown corresponds to the problem. This task requires students to relate information given in the mathematical and symbolic representation to a visual or a pictorial representation.

How Do We Use Problem Posing to Assess Problem Schemas?

Problem-posing tasks were used by Mestre and others (Brown & Walter, 2005; Mestre, 2002; Silver & Cai, 1996) in the context of physics problems. In the tasks presented by Mestre, students were given a scenario, typically in the form of a picture and were asked to construct a problem around the scenario that was based on certain physical principles. Mestre points out that problem-posing tasks are aimed at probing students' understanding of concepts as well as assessing whether they transfer their understanding to a new context. Clearly such a task was rather open-ended with multiple possible answers.

Take a look at the picture below. Create your own physics problem based upon this situation. You may use anything that you have learned from General Physics (Fig. 22.5).

A variation on the problem-posing task is to give students a statement describing a situation and ask them to add a question that would turn it into a problem that uses specified principles or equations. It presents students with the first part of a problem statement that clearly describes a physical scenario (see Fig. 22.6). Students are then asked to select from a list of choices a question, which when added to the statement will create a solvable problem that requires the use of a set of given equations. Clearly, this adaptation differs significantly from the original problem-posing task. First, this task clearly does have a unique correct answer. Second, it requires specific conceptual knowledge, represented in the form of equations.



You are given below a worked-out solution to a kinematics problem.

Step 1: $x = x_0 + v_{x0}t$

Substituting known values, we get:

$90.0m = 0 + (26.0m/s)t$

Solving for 't'

$t = 3.46s$

Step 2: $y = y_0 + v_{y0}t + \frac{1}{2}a_y t^2$

Substituting the value of 't' from Step 1, and other known values we get:

$0 = y_0 + (15.0m/s)(3.46s) + \frac{1}{2}(-9.8m/s^2)(3.46s)^2$

Solving for 'y_0'

$y_0 = 6.80m$

Identify the diagram that correctly represents the situation of the problem.

(a) (b) (c) (d)

(e) None of the diagrams above correctly represent the situation of the problem.

Fig. 22.4 Physics Jeopardy problem

Fig. 22.5 Problem-posing stimulus

You are given the starting statement of a problem below.

A 500 kg cargo shipment, attached to a parachute, drops vertically out of a helicopter hovering 100 m above a large spring (k = 220,000 N/m). The cargo comes to rest when the spring compression is 0.50 m.

Which question, when added to the statement above, will make a solvable problem that *requires ALL of the following* equations to solve?

$W = Fd \quad W = \Delta KE + \Delta PE \quad PE_{spring} = \frac{1}{2}kx^2 \quad PE_{gravity} = mgy \quad KE = \frac{1}{2}mv^2$

(a) What is the speed of the cargo just before striking the spring?
(b) How much time does it takes for the cargo to make contact with the spring?
(c) What is the work done by air resistance acting on the parachute as it drops?
(d) What is the average force of air resistance acting on the parachute as it drops?
(e) None of the above.

Fig. 22.6 Alternative problem-posing question

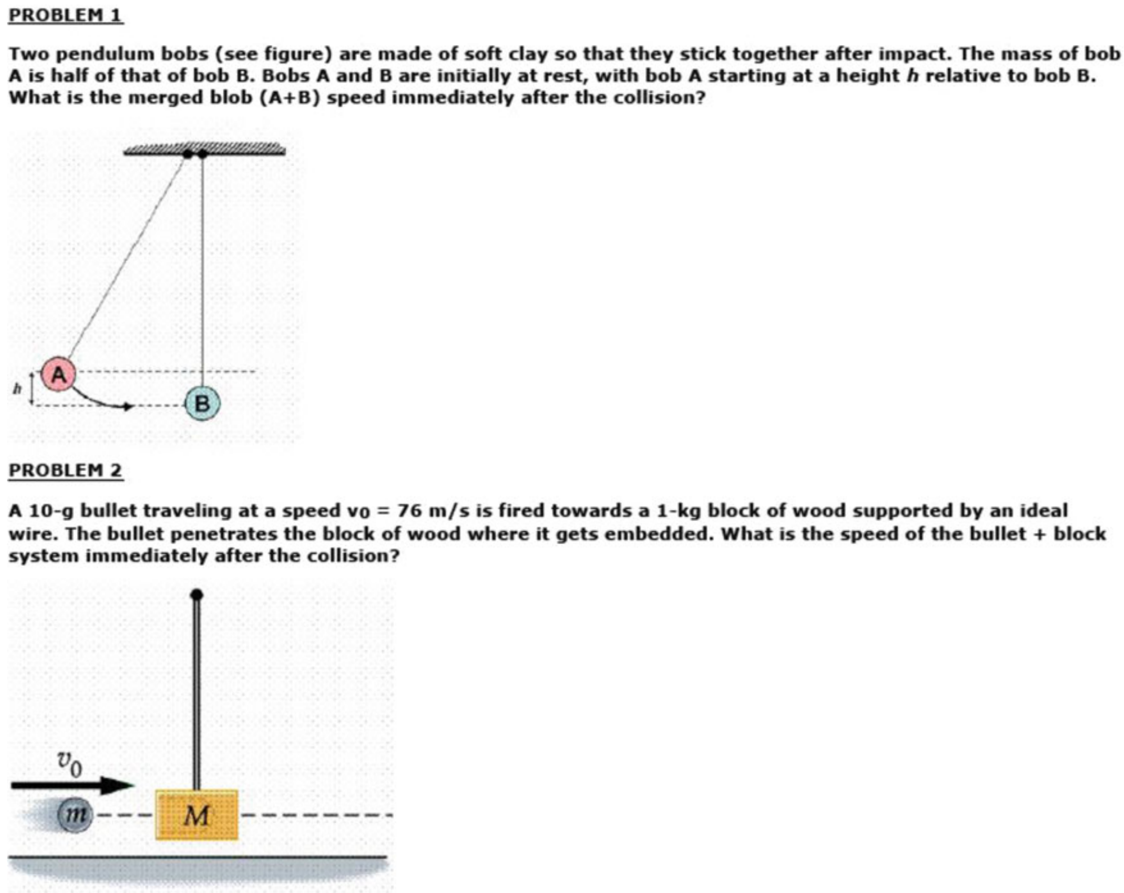


Fig. 22.7 Problem pair for comparison

Assessing Problems by Analogical Comparisons

Analogical comparison of problems requires that learners identify structural similarities and differences between pairs of problems. The simplest method for this comparison is to present pairs of problems and ask learners to identify on a scale how similar the problems are (Littlefield & Rieser, 1993; Low & Over, 1989, 1990, 1992). Hardiman et al. (1989) compared novices and experts on a similarity judgment task and found, like other studies, that experts relied on deep structure, while novices relied on surface similarities (Fig. 22.7).

Another form of analogical comparison question is to present a pair of problems and ask students to identify problem elements and similarities and differences between the problems. Those comparisons may be prompted with multiple-choice questions, such as the following:

In both problems, which of the following physical quantities change?

1. Gravitational potential energy
2. Kinetic energy
3. Mechanical energy
4. Linear momentum
5. None of the above

Summary

Assessing problem schemas generally requires a form of reasoning that most students have not encountered in their studies. Therefore, it will be necessary to provide practice and feedback on whatever kind of problem schema assessment that you select in order to support their performance. While these assessment methods possess content and especially construct validity, reliability will suffer in the absence of practice. Because of the validity of problem schema assessment, some form of this assessment should be required along with assessing correct answers to well-structured problems.

Assessing Ill-Structured Problems

Performance assessment should focus on "can the students perform the task?" not "do they remember how to solve problems?" or "do they remember the domain content required to solve problems?" Can the students solve problems similar to the ones they have been learned how to solve? In order to assess performance, it is necessary to ascertain how well the problem was solved? Performance assessment includes these elements (Elliott, 1995):

- Students must construct a response or a product, rather than simply select from a set of predefined alternatives or answers.
- Assessment consists of direct observation or assessment of student behavior on tasks or on the product that they produced.

To these, I add a third. Assessment also requires the assessment of the quality of the solution using some sort of description of desirable performance, called a rubric. Solving any kind of problem requires multiple operations or actions and different kinds of skills and knowledge.

Assessing Problem Solving with Rubrics

Many problems, well structured and ill structured, require students to generate and derive equations to determine the correct answer. In such problems, successful learners produce the correct answer and demonstrate the derivations of equations in the correct sequence to produce the correct answer. The criteria for assessing this kind of problem solving include the correct answer and the correct sequence of equations. The goal of assessment should be to more clearly articulate the requirements for an acceptable answer. The most common method is to construct performance rubrics that describe the levels of acceptable and unacceptable performance.

Assessing Problem-Solving Performance with Solution Rubrics

Writing and using rubrics is hard work. So why do it? The obvious answer is to communicate the parameters of a good solution to students. That is, rubrics play an important instructional function as well as an assessment function. Rubrics were not originally developed as summative assessment tools. Rather they were designed to provide feedback to students in a formative manner that would enhance the quality of their performance. However, they are often used to communicate final requirements and summatively assess student performance.

Another reason for writing rubrics is a bit more challenging. If you as a teacher, professor, designer, or trainer are unable to articulate the elements of some required performance, then you have no business assessing student performance. If you cannot even describe what proper performance is, how can you make informed, meaningful judgments about the quality of student performances? Most people recognize an excellent performance when they see it but often are unable to say why the performance was excellent. That is not adequate for assessment purposes. It is essential that designers articulate some of the elements of good performance. It is extremely difficult to anticipate every aspect of a complex problem-solving performance, but that should be the goal of any designer assessing problem-solving performance.

Rubrics can be constructed to assess any kind of problem solving. As indicated earlier in this chapter, most story problems require learners to select an appropriate formula to represent the problem, insert the values from the problem into the formula, and to solve the formula for a specific value. Most story problems are assessed based on whether the student produces the correct value for an answer. Rubrics may also be used to articulate the ability of students to understand the kind of problem being solved and also the nature of the structural relationships embedded in the problems. For example, for the problem:

> A policeman chases a master jewel thief across city rooftops. They are both running at 5 m/s when they come to a gap between the buildings that is 4 m wide and has a drop of 3 m. The thief, having studied a little physics, leaps at 5 m/s and at a 45° angle and clears the gap easily. The policeman did not study physics and thinks that he should maximize his horizontal velocity, so he leaps at 5 m/s horizontally. Does he clear the gap? By how much does the thief clear the gap? What type of problem is this? Show all actions, assumptions, and formulae used to answer these questions.

In this example, we may require that the student classify the problem type, identify initial conditions, set up the equation, estimate the answer, and solve the equation. Rubrics can be created for assessing the student's solution method because the students are required to show their work. These operations define the nature of the required rubrics. For story problems, the primary rubric focuses on the correctness of the answer. See Fig. 22.8 for some possible rubrics for assessing physics problem solving.

Needless to say, the nature of the rubrics will differ with the discipline and the structuredness and complexity of the problem. The rubrics must address the specific performances required by the problem. These can only be used when students' responses include some evidence of their thinking.

Accuracy of problem classification

Misclassified problem	Identified correct group, but misclassified specific problem type	Correctly classified the specific problem type

Identification of initial conditions

Unable to identify any initial or final conditions	Identified some initial or final conditions	Correctly identified all initial and final conditions in problem

Accuracy of equation

Used wrong equation or misplaced all values	Used correct equation by misplaced some values	Equation set up correctly with values in correct places

Accuracy of answer estimate

Estimate of answer the wrong order of magnitude	Estimate right order of magnitude but wrong sign or not close to final answer	Estimate of answer very close to final answer

Unit consistency

Units completely mismatched	Units mixed; some correct	Correct units used and cancelled

Accuracy of answer

Answer is quite different from correct	Answer is close to correct answer; arithmetic operation suspected	Answer is exactly correct, to the nearest hundredths

Fig. 22.8 Problem-solving rubrics for physics

For more complex and ill-structured problems that do not have universally accepted answers, the use of rubrics is more important in assessing student performance. We are implementing a problem-based curriculum in an introductory materials science course in the mechanical engineering curriculum. Students will learn by solving decision-making and troubleshooting problems. In the decision problem abstracted below, students must determine the performance problem, determine the material properties needed to meet performance requirements, calculate performance requirement, select and evaluate candidate materials, and construct an argument in support of their decision.

Improved Design of Cassette Plates—You have been asked to redesign X-ray film cassettes so that they are lighter but retain the same stiffness to bending loads. Compare various materials that are compatible with the application to produce an improved cassette.

For this kind of problem, we use the following rubrics (along with others) for assessing student reports. Note that their reports are not constructed during time-pressured examinations. Any kind of performance, including examination performance, can be assessed using rubrics. A corollary is that assessment of student knowledge and ability need not always occur in examinations.

Determination of performance problem:

3 All performance characteristics of problem (e.g., weight, speed, structural strength, thickness, stiffness, higher or lower temperature) identified; all characteristics relevant to problem.

2 Most performance characteristics identified; all relevant to problem.

1 Only a few performance characteristics identified; some not relevant to problem.

0 No performance characteristics identified.

Required performance characteristics:

4 All performance characteristics stated using appropriate descriptors (e.g., lighter, stronger, faster, bending stiffness, X-ray transmission).

3 Most performance characteristics stated, all with appropriate descriptors.

2 Most performance characteristics stated, some with appropriate descriptors.

Few performance descriptors stated.

0 No performance descriptors stated.

Material properties (*for each performance characteristic*):

3 All primary and secondary material properties identified for each performance characteristic.

2 Most primary and secondary material properties identified for each performance characteristic.

1 Some primary and secondary material properties identified for each performance characteristic.

0 No primary and secondary material properties identified for each performance characteristic.

Interactions among material properties on performance stated correctly:

3 All interactions among material properties on performance stated correctly (e.g., 2 increasing the thickness will increase the stiffness but may increase the weight).

Most interactions among material properties on performance stated correctly.

1 Some interactions among material properties on performance stated correctly.

0 No interactions among material properties on performance stated correctly.

3 All interactions among material properties and performance correctly quantified using appropriate equations.

2 All interactions among material properties stated but equations are not all accurate.

1 Some interactions among material properties and *performance* correctly quantified using appropriate equations.

0 No interactions among material properties correctly quantified using appropriate equations.

For specific material selected:

3 Correct calculation of changes from a baseline

2 Partially correct calculation of changes from a baseline

1 Inaccurate calculation of changes from a baseline

0 No calculation of changes from a baseline

For even more complex and ill-structured problems, writing rubrics can become even more difficult. For instance, consider the policy analysis problem:

Waterborne diseases: Most public water supplies are routinely monitored, but private supplies may not be subject to the same quality standards. In the Russian Federation, half the population uses water that fails to meet quality standards. In Latvia, 55 % of water samples from shallow wells fail to meet microbiological standards. Yet half the rural population relies on these wells as a source of drinking water. In Albania, 25 people died of cholera in 1994 after drinking contaminated water. In Latvia, several hundred cases of hepatitis A and bacterial dysentery are attributed to contaminated drinking water each year. In Tajikistan, some 4,000 cases of typhoid fever were reported in 1996 following heavy rainfall. In the past decade there have been some 190 outbreaks of bacterial dysentery, 70 outbreaks of hepatitis A, and 45 outbreaks of typhoid fever associated with drinking water and recreational water in Europe and central Asia. More than five million people, most of them children, die every year from illnesses caused by drinking poor-quality water.

Advise the Secretary General of the United Nations what actions should be taken by the UN.

It is likely that your students would individually or collaboratively write position papers to deliver at the UN council as well as white papers that advise the Secretary General. Because of the complex nature of the problem, the nature of the assessment for such a problem will depend on the nature of the specific problem that you posed to the students. The nature of the rubrics will depend on the nature of the task. If students were to write a policy paper for the United Nations Secretary General, some rubrics for assessing the paper might include the following:

Quality of information sources cited		
Sources of information in report unknown	Sources of information in report were questionable and not well established	Sources of information in report were internationally recognized
Constraint analysis		
Solution considered few, if any, social, political, and economic constraints	Many constraints identified; unequal balance among sources	All known social, political, and economic constraints identified in report
Economic feasibility		
Solution recommendations are economically impossible	Solution recommendations have unclear economic implications	Solution recommendations are feasible within current economic constraints
Relevance of political implications		
Few, if any, political implications identified	Political implications identified but unclear how they affect situation	Political implications are clear and feasible within current political context

Of course, many, many other rubrics could be constructed to describe such a complex performance, including all of the quality issues surrounding the writing of the report. The nature of the rubrics that you construct to assess any activity should emphasize the aspects of the performance that you deem most important. It is difficult to identify all of the rubrics that are relevant to problem-solving performance. While applying rubrics during assessments, I frequently identify other aspects of performance for which rubrics could be written and applied. At some point, however, the number of rubrics can become so numerous and complex that their meaning may get lost.

Assessing Mental Simulations (Solution Scenarios)

Mental simulations, also known as scenarios, are hypothetical sequences of events that may result from alternative decisions (Kahn, 1965). Policy analysts and strategic planners construct scenarios when assessing long-range economic, political, and societal developments. For example, scenarios were used to inform important military and political decisions such as the following:

- Should the United States invade Iraq to depose Hussein?
- Should we increase troop strength in Afghanistan?
- Should we grant marriage benefits to same-sex partners?

According to Kahn (1965), a scenario is:

- Hypothetical, representing a possible future.
- Selective, representing one possible state of complex, interdependent, and dynamic affairs.
- Bounded, consisting of number of states, events, actions, and consequences.
- Connected by causally related elements and events.
- Assessable, providing a judgment based on probability.

Most scenarios are exploratory or anticipatory where the scenario constructor starts with some states and anticipates future consequences (making predictions), although some are normative, where scenarios describe futures as they should be. Scenarios present a chain of causally related events resulting from implementation of some option and leading to some outcome (Tversky & Kahneman, 1980). The network of causally related events in the scenario can take on various states depending on which actions are taken. Scenario generation is a kind of mental simulation of future events.

For purposes of designing problem-solving learning environments (PSLEs), scenario construction can be used to assess the ability to make meaningful decisions and predictions about their outcomes. Although unsupported by empirical research, scenarios that are constructed by learners can be assessed using criteria, such as:

- All beginning factors, states, and conditions identified.
- Assumptions about factors, states, and conditions supported by evidence.
- All predictions plausible (probable).
- Predictions based on interdependent, dynamic relationships among changes in factors, states, and conditions.
- Influences among factors supported by evidence.
- Intermediate events, actions, and consequences plausible.
- Interfering events, probabilities, and impacts plausible.
- Causal map (influence diagram) included.

Assess Problem Solving with Argumentation

Because argumentation is an implied component in every kind of problem solving, students' argumentation about how and why they solved problems as they did provides perhaps the most powerful form of problem-solving assessment. If students can argue effectively about their solutions to problems, how they solved the problem, or why they did what they did, they provide confirmatory evidence about their problem-solving ability.

Student arguments can be collected using a variety of methods, although essays are the most common method. In those essays, educators try to get students to support their own position as well as anticipate and rebut different counterarguments, which is the hallmark of effective argumentation (Jonassen & Kim, 2010). For example, Nussbaum and Kardash (2005) conducted two experiments where they provided directions for different kinds of student essays.

Persuasion Condition: *Please write an essay expressing your opinion on the following question: "Does watching TV cause children to become more violent?" Provide as many reasons as you can to justify your position, and try to provide evidence that supports your reasons.*

Counterargue/Rebut Condition: *Please write an essay expressing your opinion on the following question: "Does watching TV cause children to become more violent?" Provide as many reasons as you can to justify your position, and try to provide evidence that supports your reasons. Then discuss two or three reasons why others might disagree with you, and why those reasons are wrong.*

As expected, Nussbaum and Kardash (2005) found that persuasion instructions reduced the number of counterarguments generated by students, which was consistent with a study by Stein and Bernas (1999) that showed that arguers better support their own position than they do opponent's position because they perceive more benefits accruing from their own position vs. another's. The students in the Nussbaum and Kardash study actually believed that identifying counter-

Quality of conclusions (claims)			
Conclusions unrelated to problem needs or solution	Few conclusions relate to problem needs or solutions; inconsistent relationships	Conclusions relate to problem generally, but some unclear; usually support stated solution	All conclusions relevant to problem; support solutions; related to needs
Premises are sound			
Premises not related to conclusions	Relationship of premises to conclusions is inconsistent; not related well with other premises	Most premises support conclusion	All premises support specific conclusion; add strength to the conclusion; consistent with other premises
Adequacy of premises			
No premises stated; only unsupported conclusions	Few premises stated; most unclear	Most premises stated explicitly; most clear	All premises stated explicitly and clearly
Assumptions related			
Completely unstated and unknown	Few stated but not associated with premises or conclusions; mostly unreasonable or invalid	Most assumptions stated; not all connected to conclusions or premises; some invalid	Clearly stated; consistent with claims and premises; reasonable and valid
Credibility of premises			
Sources of evidence are weak, filled with unsupportable evidence and propaganda	Sources of evidence are questionable or origin is unknown	Sources of evidence mostly valid with limited amounts of unknown data	Sources of evidence (personal, written, etc.) are unimpeachable; accepted as fact
Counterarguments accommodated			
No counterarguments acknowledged	Only one or two counterarguments acknowledged; none argued or rejected	Most counterarguments addressed; refutation not premise based	All counterarguments identified and refuted using valid, supportable premises
Organization of arguments			
Arguments are indistinguishable; unorganized; do not support each other	Arguments identified; relationships to each other not obvious	Arguments articulated but partially integrated; relationships to each other usually positive	Each argument separated; sequenced logically to support solution to problem

arguments would make their own arguments less persuasive. Argumentation is a powerful yet neglected skill that may also provide useful assessment data for problem solving.

Assessing those essays requires the construction and application of argumentation rubrics. This method requires reading and evaluating students' argumentative essays using those rubrics, which are based on the strength of relationships between premises, conclusions, assumptions, and counterarguments (Halpern, 2003). Norris and Ennis (1989) suggested the following criteria for evaluating argumentative essays:

- Do you clearly state the conclusion and define the necessary terms?
- Are the materials that you included relevant to the conclusion?
- Is the argument sound? Do the premises support the conclusion?
- Have you considered the credibility of your experts?
- Is the essay well organized with each argument laid out separately?
- Have you fairly represented opposing points of view and counterarguments?
- Have you used good grammar and a clear style of writing?

Below, I synthesize a series of assessment rubrics for assessing the quality of students' argumentative reports or essays based on Halpern's (2003) conception of arguments. When students construct arguments as part of the problem solution or as an addendum to their solutions, you might use these rubrics, along with discipline-specific rubrics to assess the quality of their arguments.

Student essays or individual verbal or written accounts of problem solving may also be assessed using rubrics based on Toulmin's conception of argumentation, which focuses on claims, supported by warrants, supported by backing or evidence. Cho and Jonassen (2002) scored individual reports of how problems were solved using the scoring rubric below in order to determine the quality of argumentation based on Toulmin's (1958) model of argument. Individual scores were achieved by summing the number of points achieved in each argumentation category (claims, grounds, warrants, backings, and rebuttal).

Claims			
No claim related to the proposition or unclear assertions	The writer makes generalizations that are related to the proposition, but the assertions lack specificity or offer unclear referents. The writer leaves much for the reader to infer in order to determine the impact of the claim	The writer states generalizations that are related to the propositions, but the assertions are not complete. Enough information is available to figure out the writer's intent, but much is left to the reader to determine	The writer states generalizations which are related to the proposition and which are clear and complete
Grounds			
No supporting data are offered or the data are not related to the claim	The data or evidence are weak, inaccurate, or incomplete. For example, (a) an attempt at using a general principle without establishing the truth of the principle; (b) the use of examples from personal experience that are not generalizable; (c) the citation of data when no source is identified; and (d) the use of obviously biased or outdated material	The data offered are relevant but not complete. The writer leaves much for the reader to infer from the data. The writer may have offered the data without the complete citation, which would allow the reader to determine the reliability of the data as evidence. The writer may offer data, which are not complete enough to allow the reader to determine their significance	The supporting data are compete, accurate, and relevant to the claim
Warrants			
No rules and principles are offered	The writer recognizes a need to connect the data to the claim and states some elaboration of data, but the writer fails to make the connection. Or most rules and principles are not valid or relevant	The writer explains the data in some way, but the explanation is not linked specifically to the claim	The writer explains the data in such a way that it is clear how they support the claim
Backings			
No sources of warrants are given	The writer states incorrect, irrelevant sources of warrants	The writer states correct, relevant sources of warrants but the sources are very general, not specific	The writer states correct, relevant, and specific sources of warrants
Rebuttals			
No recognition of constraints of solutions	The writer offers few constraints of solutions but the constraints are not elaborated	The writer identifies constraints of solutions but the constraints are not sufficient	The writer states complete and systematic identification of constraints of solutions

Coding Student Arguments

When students are engaged in an argumentative discussion, either face to face or online, their arguments can also be assessed. If the discussion is face to face, it is necessary to transcribe the discussion in order to later assess it. When assessing online discussions, most bulletin board software allows you to save each student's message as a separate record in a database. The messages that students posted that are stored in the database can be counted and qualitatively analyzed for which components of argumentation used are present in each posting. Cho and Jonassen (2002) also analyzed student online discussion while solving problems by using a coding scheme adapted from Toulmin's (1958) model of argument (described before). Each message was classified by two coders into one of those five categories without knowing the identity of the group. After classifying all of the messages, we counted the number of each category used during the discussion. Analysis showed that students using an argumentation scaffold, Belvedere, produced significantly more argument components during group discussions than subjects in the discussion groups that did not have access to the scaffold. Specifically, groups using the scaffold produced significantly more claims and grounds than groups who did not have access to the scaffold. The analysis also showed that groups solving ill-structured problems produced more arguments during group discussions than students solving well-structured problems, especially in stating rebuttals. Groups solving ill-structured tasks produced more rebuttals than those solving well-structured problems because this kind of reasoning is more important to that kind of problem solving.

Summary

In order to assess problem-solving performance, scenarios, or argumentation as a proxy for problem-solving performance, it is necessary to identify the requisite skills and activities and use those in the form of rubrics to assess performance because rubrics provide the best evidence of content validity. However, using rubrics to assess performance is a difficult work that often lacks reliability. Strategies like blind reviewing and assessing similar elements from student performances at the same time may increase reliability; however, application of rubrics tends not to be very reliable. It is likely that certain rubrics may prove to be more reliable; however, some aspects of subjectivity necessarily enters the process. Coding student interaction suffers the same lack of reliability. In some of our research (Jonassen & Cho, 2011; Jonassen et al., 2009), we used multiple coders to assess different performances. Even after training, inter-rater reliability was often 60 %, requiring reconciliation of code through debate. Despite these difficulties, the generation and application of rubrics is probably the single most important method for assessing problem solving.

Objective Forms of Argumentation

Argumentation skills can also be assessed using objective forms of assessment, such as multiple-choice tests. Questions requiring argumentative reasoning can form the stem of a test item. For example:

Students who work harder in school will make a better living after school. Which is the most appropriate assumption on which this premise and conclusion are based?

1. *Attitude is the most important difference; those who work harder get more.*
2. *What your teachers think of you is the strongest predictor of success.*
3. *Skills acquired in school better prepare you to function in the real world.*
4. *The harder you work, the more you know.*

Which conclusion logically follows from the following premise: the stock market has fallen 200 points in the last week.

1. *Buy more stock; it's a bargain.*
2. *Sell all of my stock; the economy is broken.*
3. *The economy is inflationary.*
4. *Consumer confidence is down.*

These questions focus on the evidence to support the claims stated in the question stem. Similar questions can also be developed to specifically assess the arguments required to solve a particular kind of problem. There is no research on the use of this form of assessment and its relationship to problem solving. With practice, students can develop this skill, at which point assessment may be more reliable. It is most probable that this kind of question would have predictive validity.

Assessing Student-Constructed Problems

Jonassen, Strobel, & Ionas (2008) conducted a 3-year, design-based research study on case-based learning. Beginning with a cognitive flexibility hypertext (see Chap. 13), they found that students slowly adapted to the nonlinear interconnections among the different content-types; however, students experienced difficulties in making comparisons, because the environments did not provide space for student construction of their own ideas. Flexibility hypertexts are static, providing a definitive body of material that is difficult for users to elaborate. Users of the system were unable to contribute their own perspectives, links, or connections, so they were passive consumers of information stored in the environment.

Therefore, in the second and third iterations, the system shifted from a content-navigation environment to a student-authoring environment, because authoring hypertext requires deeper understanding of the domain; identification of core concepts, cases, and themes; and careful selection of new cases to represent the content (Jacobson & Archodidou, 2000; Jonassen, Strobel, & Ionas, 2008). We incorporated authoring functions that gave students more control of the environment so that the focus of designing the hypertext system shifts from content and relationship development to providing support structures and guidance to the end users as the instructional designer of their own learning experience. When students construct and elaborate their own cases, they are more deeply engaged in learning than when interpreting someone else's cases.

A potentially powerful yet empirically unexamined form of problem-solving assessment is the construction of PSLEs by students. Student construction of problems is a transfer task. After engaging in problem-solving activities in instructor-provided PSLEs, we have informally investigated the construction of problems by students. Using simple Web-construction tools, students construct their own problem situations and supports. Their environments may be assessed by asking questions such as the following:

- Are users required to solve a real problem?
- Are the problems authentic? Situated in meaningful context?
- Are supports appropriate for problem type?
- Are meaningful perspectives provided?
- Are analogous cases provided? Prior experiences?
- Do users have to articulate causal model of problem-solution?
- Are questions used to scaffold performance?
- Do users have to construct arguments in support of solution?

Assessing student productions requires the construction and application of relevant rubrics. The use of rubrics to assess student-constructed problems encounters the same validity and reliability issues as described before.

Assessing Cognitive Skills in Problem Solving

There are a number of cognitive skills that are involved in learning to solve problems. Each skill, by itself, is insufficient for learning to solve problems. Whether each skill is necessary for solving each kind of problem depends upon the kind of problem being solved. The most important cognitive skills that are necessary for solving each and every kind of problem are analogical reasoning and causal reasoning. Analogical reasoning is necessary for inducing robust problem schemas (described before). In addition to assessing the quality of problem schemas, problem-solving ability can be predicted by assessing student understanding of the causal relationships between problem elements.

Assess Causal Reasoning

Causal reasoning is central to all problem solving. From a cognitive processing perspective, problem solving is largely a process of understanding the causal relationships among the problem elements and making inferences about what caused a certain state or predicting what state will be the result from a set of conditions (Jonassen & Ionas, 2008). That is, problem solutions are causes that will produce the effect—problem solved. Those solutions are based on the causal conditions used to represent the problem. Asking questions about those causal relationships will focus students' attention on conceptual, qualitative understanding of the problem elements.

In order to ask causal questions, it is necessary to present a scenario and ask students to make an inference or a prediction based on that scenario. That is, it is necessary to ask students to apply the causal relationship in a new situation. It is much easier to ask students about the relationship. In order to elicit causal reasoning, students must apply the relationship. For example the following question (in multiple-choice format) requires an inference (what was the cause of a specific effect).

You have just received a shipment of three boxes, each containing one of the isotope sources for the three nuclear thickness gauges described above. Each box has a radioactive material label affixed. The sources all weigh the same amount. The boxes are the same size but have different weights. What is the likely reason for the different box weights?

(a) *The sources each emit radiation of different energy, so they each weigh differently because of the different shielding needed.*

(b) *The sources each emit radiation of different penetrating ability, so they each weigh differently because of the different shielding needed to attenuate the radiation from each source.*

(c) *The sources each have a different amount of radioactivity, so they each need a different amount/weight of shielding depending on the amount of radioactive material.*

(d) *The sources each have a different half-life, so they each need different shielding depending on the half-life.*

Likewise, in order to assess prediction (what will be the effect of a specific cause) performance provide a scenario and ask students to respond:

Suppose that a sample of 238U is allowed to come to equilibrium with all of its daughters in its decay chain and then the 226Ra is chemically removed from the sample. What will happen to the activities of the isotopes in the decay chain starting with 226Ra and its daughters as time increases? Check the one best answer.

(a) *They will all decrease because the 226Ra has been removed.*

(b) *They will increase because the decay of the parent of 226Ra (e.g., 222Rn) will decay producing more 226Ra and all of its daughters.*

(c) *The activity of 226Ra will increase due to the decay of its parent, 222Rn, but there will be no increase in the activities of the daughters of 226Ra.*

(d) *There will be no increase in the activity of any of the isotopes in the decay chain following 226Ra.*

If students are unable to answer questions such as these, it is unlikely that they will be able to solve problems involving uranium. Note that these examples of causal questions are multiple choice. They could also be presented as open-ended questions that require students to construct and answer, a process that would require more mental effort. With practice in answering this kind of questions, student can develop reliable skills. In addition to constructing validity related to the ideas embedded in any problem, causal-reasoning questions will likely have significant predictive validity. The relationships between causal reasoning and problem-solving performance deserve research.

Assessing Student Models

Although equations are the most common form of problem representation in mathematics and science problems, there are many other ways that students can construct models of problems, such as free body diagrams in physics. Two very powerful methods for modeling problems that require the explication of causal relationships are expert systems and system dynamics models. Modeling is fundamental to human cognition and scientific inquiry. Modeling helps learners to express and externalize their thinking; visualize and test components of their theories; and make materials more interesting. These are all essential skills in problem solving. Models function as epistemic resources (Morrison & Morgan, 1999). When students directly represent problem entities, they are representing the problem space. Constructing a model of a problem requires constructing a different form of problem repre-

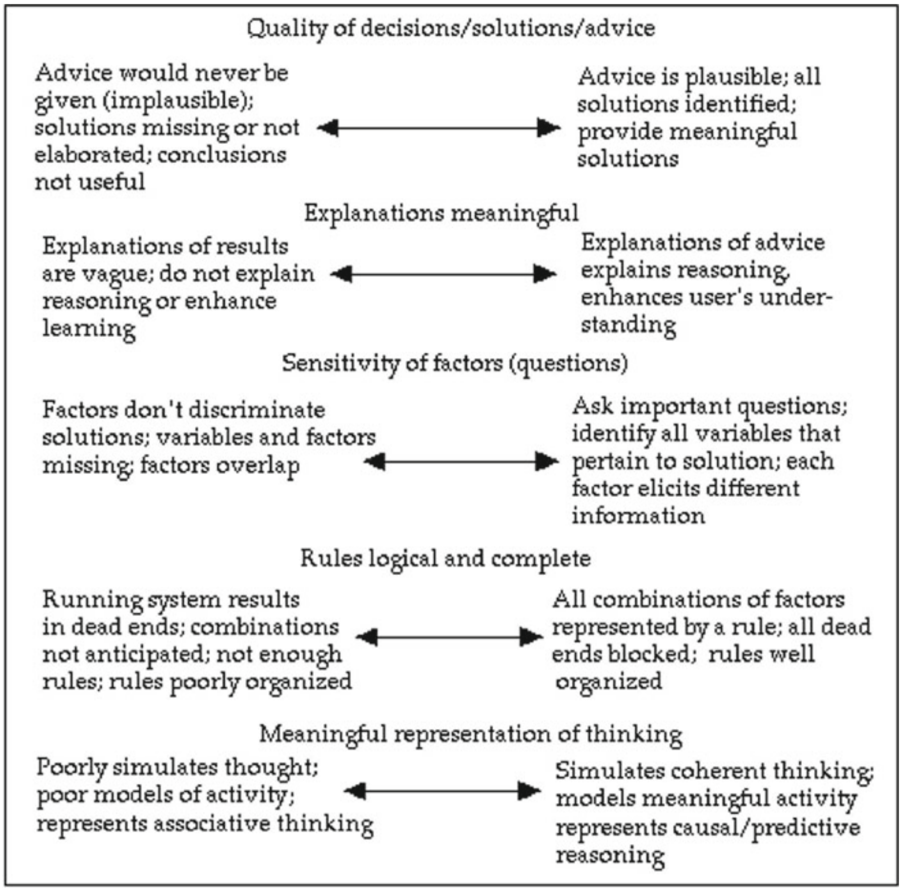

Fig. 22.9 Criteria for assessing student-constructed expert systems

sentation which guides further interpretation of information about the problem, simulates the behavior of the system based on knowledge about the properties of the system, and triggers a particular solution schema (Savelsbergh, de Jong, & Ferguson-Hessler, 1998).

Although models define the structure of most learning systems, "we do not learn much from looking at a model—we learn a lot more from building the model and from manipulating it" (Morrison & Morgan, 1999, pp. 11–12). If students are unable to construct models of systems or problems, then they simply do not understand the problem.

Expert Systems

An expert system is a computer program that attempts to simulate the way human experts solve problems—an artificial decision maker. Expert systems include a knowledge base of facts about objects and IF–THEN rules about the relationships among those objects that can qualitatively represent covariational and mechanistic information about causal relationships. The rule base is searched by the inference engine to provide advice that may be rendered by a human expert in order to reach a decision. Rules state that IF a set of conditions exists, THEN some conclusion is reached. For example, IF temperature increases, THEN pressure increases. Conditions can be combined using conjunctions (condition 1 AND condition 2 must exist), disjunctions (condition 1 OR condition 2 must exist), and negations (condition 1 but NOT condition 2 must exist) in order to reach a conclusion about a set of causal relationships. That conclusion may be an action or it may state another condition, which is then combined with other conditions to reach another decision.

Expert systems are most easily constructed using an expert system editor that provides rule editors and an inference engine for testing the rule base. These editors enable learners to construct and test a qualitative model of a set of causal relationships. Building expert systems better supports understanding the underlying mechanisms of the causal relationships. It is not sufficient to know how much the cause affects something, but also why it does. Necessity and sufficiency of causal effects (very hard concepts for students) are also effectively represented by rules. Criteria for assessing the quality of the rule base constructed by students are presented next (Fig. 22.9).

System Dynamics Models

System dynamics tools, including Stella, VenSim, and PowerSim, help learners to build dynamic simulation models of systems that elaborate causal loops. These tools use

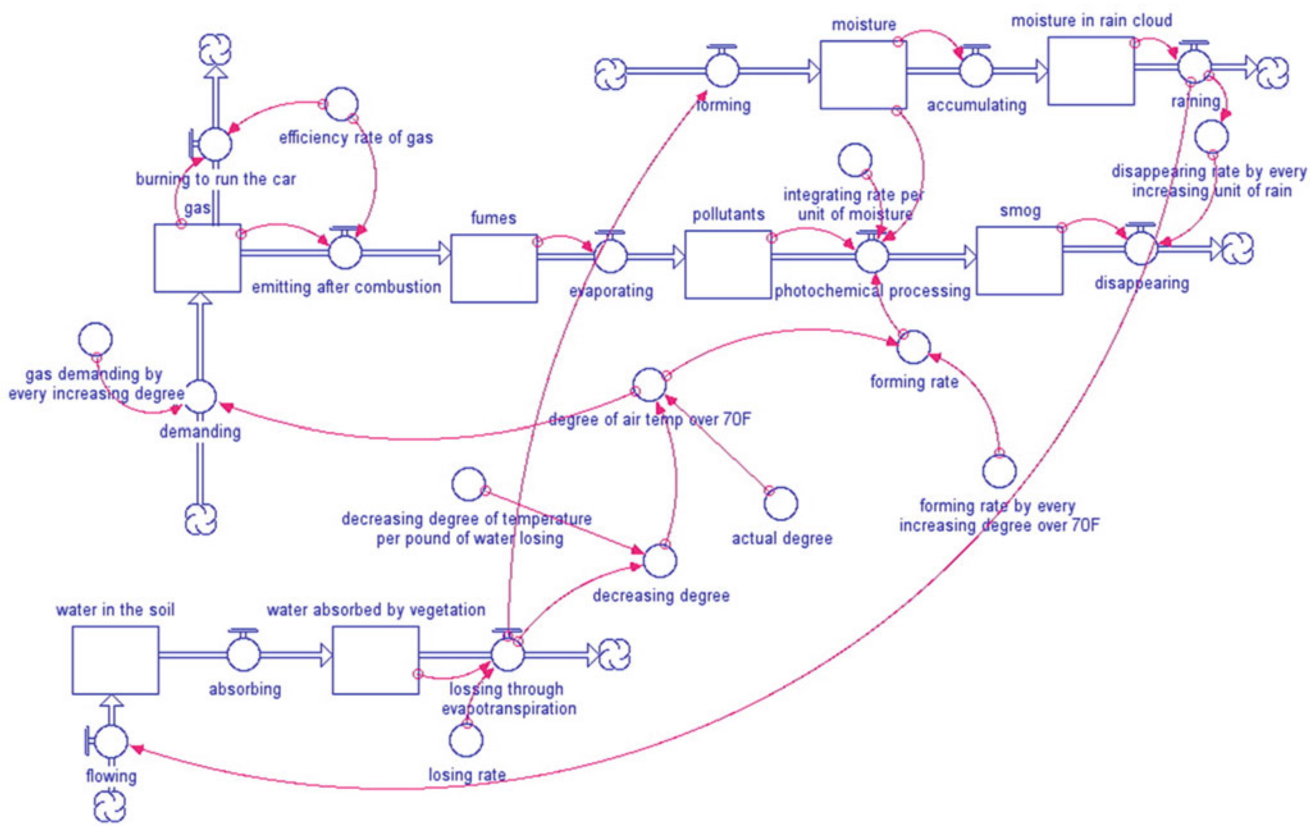

Fig. 22.10 System dynamics models of smog formation

accumulations and flows as the primary modeling tools. For example, the systems model in Fig. 22.10 was built using Stella and represents the factors that contribute the formation of smog. The models use simple algebra to convey the strength of relationships between each other. When the model is run, it becomes a simulation that is driven by an engine based on differential equations, which emphasizes change over time. Running simulations and adjusting the model to contrast alternate solutions are among the most cognitively engaging tasks that students can perform. Figure 22.11 presents possible criteria for assessing the quality of student-constructed systems models. Although empirical research on the relationships of systems modeling and problem solving does not exist, the quality of the model produced by students very likely has the greatest predictive validity of any data source.

Assess Problem-Solving Processes Using Coding Schemes

All of the rubrics described before are used to assess the products of student performance (papers, exams). Rubrics can also be used to assess problem-solving processes as well as products. Another way to assess policy analysis problem solving is to observe and assess the problem-solving process. Audiotaping or videotaping the problem solvers while they are solving problems and transcribing those tapes leave you with a verbal protocol to analyze. Atman and Turns (2001) described a series of verbal protocol studies where they observed engineering students engaged in design tasks. Students would think aloud (Ericsson & Simon, 1993) while solving the problem. They developed a coding scheme including identification of need, problem definition, gathering information, generating ideas, feasibility analysis, evaluation, decision, communication, and implementation. Each thought uttered by students as they solved design problems aloud was classified according to one of these codes. The codes that Atman and Turns used were meant to characterize the cognitive activities engaged by design problem solving. Different kinds of problem solving would require different codes. Atman and Turns (2001) found that older students (seniors) identified more criteria, had significantly more transitions between design steps, and gathered more information than younger students (freshmen). Verbal protocol analysis is a more difficult kind of analysis, but it exposes student reasoning better than most other forms of assessment. After coding protocols, you really understand the students.

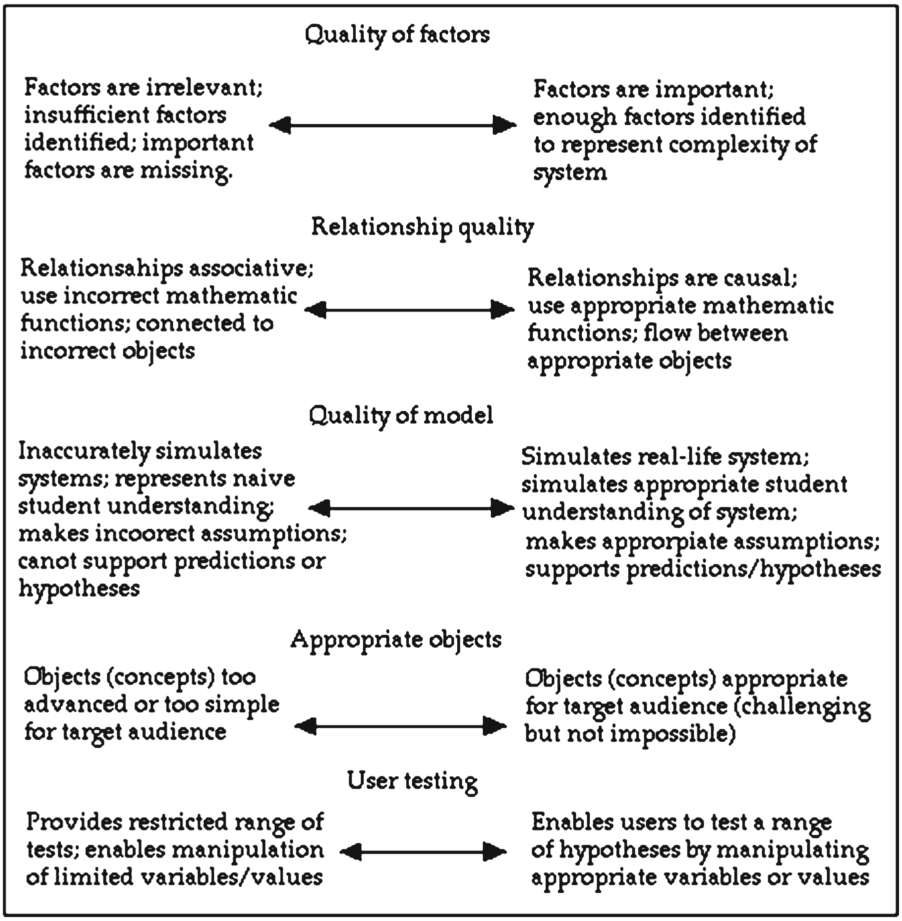

Fig. 22.11 Criteria for assessing the quality of systems models

The verbal protocol analysis process is made easier when the discussions are online, because each message and its producer are already identified, and the contents of the discussion forum can be saved in a database. Cho and Jonassen (2002) analyzed each of the messages posted during problem-solving sessions by classifying each message based on a problem-solving coding scheme, the Decision Function Coding System (DFCS) adapted from Pool and Holmes's (1995). The DFCS consists of seven categories, including problem definition (PD), orientation (OT), criteria development (CD), solution development (SD), solution approval (SA), solution critique (SC), and non-task statement (NS). That is, we classified the purpose of each message according to this scheme. We found that providing a constraint-based argumentation scaffold during group problem-solving activities increased the generation of coherent arguments, and that groups who solved ill-structured problems produced more extensive arguments. The nature of the coding scheme could be changed to focus on the required elements of the problem. For instance, we could have used constraint analysis, political implications, or any other element required in the solution. These codes, in effect, represent rubric, so you as the teacher are coding student responses in terms of desired behavior.

Jonassen and Kwon (2001) used a similar coding scheme to compare problem-solving processes used in computer-mediated communication vs. face-to-face communication. We found greater use of non-task, simple agreement (corresponding to solution approval), and simple disagreement (corresponding to solution critique) categories for both well-structured and ill-structured tasks in the computer-mediated group, relative to the face-to-face group. That is, the nature of the task did not have a significant effect on the problem-solving processes used by students. That is why Cho and Jonassen (2003) scaffolded problem-solving skills. Coding messages or interactions observed while students are problem solving provides valuable information about the nature of problem solving that students performed. Again, the emphasis in all of these methods is to analyze performance.

Coding collaborative communication during the problem-solving process provides perhaps the best evidence of socially co-constructed knowledge. Coding student interaction suffers the same lack of reliability with using rubrics to assess complex performances. As described before, inter-rater reliability among coders is frequently low. Validity of this form of assessment depends on the quality of the coding scheme that is used. As with rubrics, identifying every relevant code is difficult, so important aspects of performance may be missed.

Use Multiple Assessments

In this chapter, I have described multiple methods for assessing students' abilities to solve different kinds of problems, including problem-solving accuracy, comprehension of problem schemas, analogical comparison of problems, solution processes, mental simulations, causal reasoning, student models, and problem-solving processes. The kind of assessment required depends on the kind of problem and whether problem solving is an individual or a collaborative process. Research is needed to compare and contrast assessment methods with problem-solving types.

What has become obvious is the premise that in order to adequately assess problem-solving skills and abilities, it is necessary to use more than one form of assessment. The ability to solve problems and the cognitive residue of that experience cannot be adequately assessed in using any single assessment. Each kind of assessment requires different cognitive skills. In order to understand how learners are solving problems and the cognitive prerequisites and residue from the process, it is imperative to use multiple forms of assessment, especially for research (Jonassen & Grabowski, 1993). If you want your students to learn to solve different kinds of problems, you must learn to teach them to solve different problems and then assess their different abilities to solve the kinds of problems that they practiced. So much research is needed to empirically validate relationships among these different assessment methods and the problem-solving activities they represent.

23 Model-Based Tools for Knowledge Assessment

Dirk Ifenthaler and Pablo Pirnay-Dummer

Abstract

This chapter introduces the functions of knowledge representation and presents a critical review of the model-based tools for assessment: Pathfinder, ALA-Reader, jMAP, HIMATT, AKOVIA. For each model-based tool, foundations and applications are discussed. Next, the tools are compared in order to illustrate their advantages and disadvantages, strengths, and limitations. The latter part postulates that there is no easy and no complete way to integrate any of the model-based tools. However, the strength of good research lies in a best possible integration: Multiple perspectives on the same construct are usually needed. Thus, the further development of existing tools as well as of new ones is necessary to explore human knowledge, its change, decision-making, performance, and problem-solving as our understanding of those complex human potentials evolves.

Keywords

Mental representation • AKOVIA • HIMATT • Pathfinder

Introduction

The rapid advancement of information and communication technologies (ICT) has important implications for learning and instruction. Remarkable repertoires of hypermedia systems, cognitive tools, learning management systems, and computer-based applications have been developed for almost every subject domain during the past decades (Ifenthaler, 2008; Pirnay-Dummer & Ifenthaler, 2010; Spector, 2010). However, these important changes in teaching and learning through emerging technologies require new perspectives for the design and development of learning environments (see Hannafin, 1992; Ifenthaler, 2010b; Kirschner, 2004; Spector, 2009). Closely linked to the demand of new approaches for designing and developing up-to-date learning environments is the necessity of enhancing the design and delivery of assessment systems and automated computer-based diagnostics (Almond, Steinberg, & Mislevy, 2002; Ifenthaler, 2008; Spector, 2010). These systems need to accomplish specific requirements, such as (1) adaptability to different subject domains, (2) flexibility for experimental and instructional settings, (3) management of huge amounts of data, (4) rapid analysis of specific data, (5) immediate feedback for learners and educators, and (6) generation of automated reports of results (Pirnay-Dummer, Ifenthaler, & Seel, 2012a).

Recently, promising methodologies have been developed which provide a strong basis for applications in research and instruction in order to follow up with the demands that come with better theoretical understanding of the phenomena that are a prerequisite or an integral part or go along with the learning process. This chapter introduces the functions of knowledge representation and present a critical review of the following model-based tools for assessment: Pathfinder

Networks (Schvaneveldt, 1990), ALA-Reader (Clariana, 2010), jMAP (Shute et al., 2010), HIMATT (Pirnay-Dummer, Ifenthaler, & Spector, 2010), and AKOVIA (Pirnay-Dummer & Ifenthaler, 2010). On the basis of the reviews, we provide a taxonomy for model-based assessment and analysis where current and future developments can be positioned by developers and researchers as regards to the expected validity, feasibility, range of application, ease of integration (with other instruments), strength of assessment, and scope of analysis.

Knowledge Representation

Knowledge is internal and its representations are internal (Ifenthaler, 2010d; Seel, 1991). Accordingly, it is not possible to measure these internal representations of knowledge directly (Ifenthaler, 2008; Seel, 1999a). Additionally, it is argued that different types of knowledge require different types of representations (Minsky, 1981). Therefore, it is necessary to identify economic, fast, reliable, and valid techniques to elicit and analyze knowledge representations (Ifenthaler, 2008, 2010d). In order to identify such techniques, one must be aware of the complex processes and interrelationships between internal and external representations of knowledge. Seel (1991, p. 17) describes the function of internal representation of knowledge by distinguishing three zones—the object zone **W** as part of the world, the knowledge zone **K**, and the zone of internal knowledge representation **R**. As shown in Fig. 23.1, there are two classes of functions: (1) fi_n as the function for the internal representation of the objects of the world (internalization), and (2) f_{out} as the function for the external re-representation back to the world (externalization). Neither class of functions is directly observable. Hence, a measurement of knowledge representation is always biased as we are not able to more precisely define the above described functions of internalization and externalization (Ifenthaler, 2008, 2010d; Seel, 1991; Strasser, 2010). Additionally, the possibilities of externalization are limited to a few sets of sign and symbol systems (Seel, 1999b)—characterized as *graphical* and *language-based approaches*.

Lee and Nelson (2004) report various graphical forms of external knowledge representations for instructional uses and provide a conceptual framework for external representations of knowledge. Graphical forms of externalization include (1) knowledge maps, (2) diagrams, (3) pictures, (4) graphs, (5) charts, (6) matrices, (7) flowcharts, (8) organizers, and (9) trees. However, not all of these forms of externalization have been utilized for instruction and educational assessment (Ifenthaler, 2008; Scaife & Rogers, 1996; Seel, 1999a). Other forms of graphical approaches are the structure formation technique (Scheele & Groeben, 1984), pathfinder networks (Schvaneveldt, 1990), mind tools (Jonassen, 2009; Jonassen & Cho, 2008), and causal diagrams (Al-Diban & Ifenthaler, 2011; Spector & Koszalka, 2004). Language-based approaches include thinking-aloud protocols (Ericsson & Simon, 1993), teach-back procedures (Mandl, Gruber, & Renkl, 1995), cognitive task analysis (Kirwan & Ainsworth, 1992), and computer linguistic techniques (Pirnay-Dummer & Ifenthaler, 2011a; Pirnay-Dummer, Ifenthaler, & Spector, 2010).

With regard to cognitive psychology and its focus on human knowledge representation the most important result of research consists in the observation that learners are able to use different forms of representation of memorized

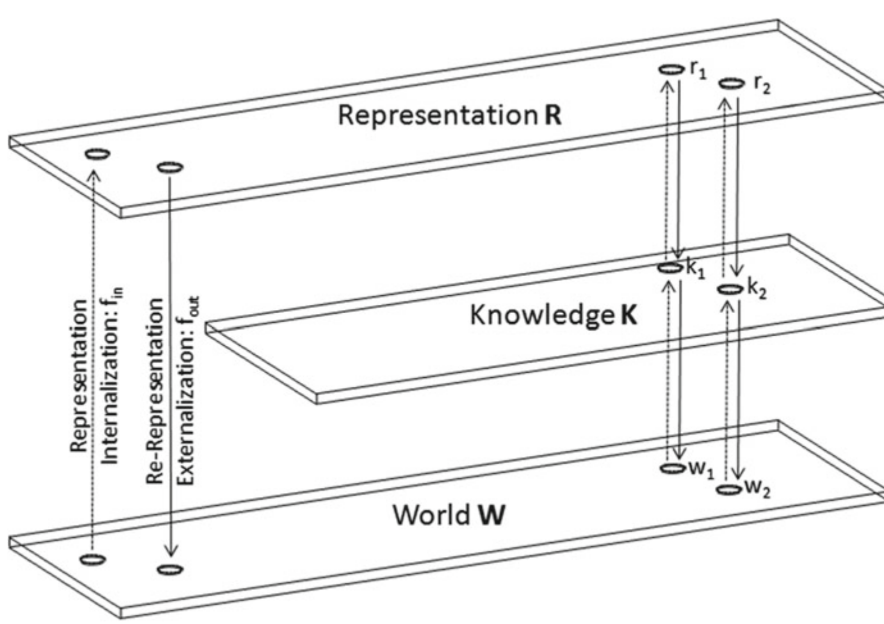

Fig. 23.1 Functions of representation and re-representation (Ifenthaler, 2010d)

information. Learners can either recall an appropriate form of representation from memory or transform memorized information in an appropriate form of representation in dependence on situational demands. However, because it is not possible to assess directly internal representations of knowledge one of the most important issues of research on knowledge representation is concerned with reliable and valid measurements of declarative and procedural knowledge (Galbraith, 1999; Ifenthaler, 2008; Pirnay-Dummer, Ifenthaler, & Seel, 2012b; Seel, 1999a; Stachowiak, 1973; Wygotski, 1969).

To sum up, externalizations are the only available artifacts for empirical investigations of knowledge representation. An externalization is always made by means of interpretation. But the externalization also needs interpretation for its analysis. These are two different kinds of interpretation. All kinds of features may be clustered for a description and aggregation of the artifact. Some of the interpretation is done by the learner and some of it is carried out by humans and technology (Ifenthaler & Pirnay-Dummer, 2010). In most cases a mixture of all three interpreters will be part of the assessment. This mixture and the complexity of the construct both make it specifically difficult to trace the steps and bits of knowledge. Recently, promising tools have been developed which provide a strong basis for applications in research and instruction.

Tools

The latest hardware and software technology provides great potential not only for the design and development of learning environments but also for the enhancement of automated assessment and analysis. Advanced databases and network technologies contribute an especially wide variety of applications for an efficient assessment of individual and group data (Koper & Tattersall, 2004). However, numerous capabilities remain unused because standard assessment tools do not facilitate these technological features (Janetzko, 1999). Foundations and applications of the following model-based tools for knowledge assessment are discussed next: Pathfinder (Schvaneveldt, 1990), ALA-Reader (Clariana, 2010), jMAP (Shute et al., 2010), HIMATT (Pirnay-Dummer et al., 2010), and AKOVIA (Pirnay-Dummer & Ifenthaler, 2010).

Pathfinder

Foundation

Pathfinder is a well-established system for deriving and representing the organization of knowledge structure (Schvaneveldt, 1990; Schvaneveldt, Durso, & Dearholt, 1989). Pathfinder is implemented in the Knowledge Network Organizing Tool (KNOT; http://interlinkinc.net). KNOT includes utilities to facilitate the Pathfinder analysis. KNOT produces graphical representations of the solutions and additional information in the form of text files which can be used for further analysis. Pathfinder transforms estimates of relatedness of propositions (pairs of terms) into a network representation—the Pathfinder Network (PFnet).

The Pathfinder analysis includes three steps: (1) Learners rate the relatedness between a set of concepts (terms) on a scale from low (e.g., one) to high (e.g., nine). The total of pairwise comparisons is calculated as $(n^2-n)/2$ (where n is equal to the total number of concepts). The first step results in a proximity data set. (2) KNOT is used to transform the proximity data into a PFnet. Such a network representation consists of a least-weighted path which links all included concepts. (3) Comparison between different PFnets is calculated in the KNOT software (Goldsmith & Davenport, 1990). As a result, the Configural Similarity of two PFnets indicates how many links between concept pairs they have in common (Goldsmith & Davenport, 1990). KNOT also includes a group average feature which calculates an average of multiple proximity files and represents a group average PFnet representation (Goldsmith & Davenport, 1990).

Application

Pathfinder has a well-established research base. For the past 20 years, numerous empirical studies in several domains have been conducted and proven the utility of PFnets. PFnets have been applied to study multidimensional spaces (Branaghan, 1990; Gillan, Breedin, & Cooke, 1992), conceptual structures of experts (Gammack, 1990), similarity between expert representations (Acton, Johnson, & Goldsmith, 1994), knowledge structures in training programs (Davis & Yi, 2004) as well as knowledge and problem elicitation (Gomez, Hadfield, & Housner, 1996; Gomez, Schvaneveldt, & Staudenmayer, 1996; Gonzalvo, Canas, & Bajo, 1994; Johnson, Goldsmith, & Teague, 1994; Rowe, Cooke, Hall, & Halgren, 1996; Trumpower, Sharara, & Goldsmith, 2010). Finally, new tools have been developed on the basis of the Pathfinder algorithm, e.g., the KU-Mapper (Clariana & Wallace, 2009) and ALA-Reader text analysis software (Clariana, 2010).

ALA-Reader

Foundation

ALA-Reader text analysis software (Clariana, 2010) was modeled on ALA-Mapper software for analyzing network representations (Taricani & Clariana, 2006). ALA-Mapper converts the links between terms (propositions) and the distance between terms (associations) in network representations into proximity array files that can then be analyzed by Pathfinder analysis (Schvaneveldt, 1990). The advantage of this approach is that proximity array files can be compared, combined, and analyzed in many different ways and especially, Pathfinder analysis is proving to be a powerful data reduction approach that can reveal important or salient aspects of the original data set.

ALA-Reader is based on a connectionist knowledge representation approach view that is strongly influenced by Kintsch (1988). Thus, to covert text into proximity arrays, ALA-Reader finds and associates preselected key terms (primarily nouns). The analysis of text is realized sentence by sentence, or linearly within and across sentences. First, the text is preprocessed, i.e., synonyms and metonyms of key terms are replaced with the appropriate key term. In order to validate this process, key terms and their corresponding synonyms and metonyms are determined by content experts.

In the sentence level approach, the key terms that co-occur in the same sentence are entered into a proximity array. A "1" entered in the array indicates that two key terms co-occurred in the same sentence and a "0" means those two key terms did not occur in the same sentence. Each sentence is processed in turn until done. Note that key term co-occurrences are aggregated not summed, so the final proximity array contains only ones and zeroes. In the linear approach, the software searches through the text from the beginning to the end sequentially, adding a "1" in the proximity array to indicate a link between consecutive key terms. Each succeeding key term is "linked" to the next key term found. The software continues to aggregate linearly into the proximity array until all of the text is processed (Clariana, 2010).

Application

ALA-Reader has been applied as a tool for scoring essays and for measuring participant's knowledge structure (Clariana, 2010; Clariana & Wallace, 2007). Reliability of ALA-Reader is regarded as $r = 1.00$, as the software produces exactly the same proximity array for a text every time. Additionally, the researcher may use different key words and different referents, obtaining different proximity arrays for the same text. Validity has been tested for texts with a high frequency of technical vocabulary. Correlations between ALA-Reader and multiple raters' validity scores have been reported as $r = 0.70$ (Clariana & Koul, 2004). For essays with less technical vocabulary, validity scores range from $r = 0.20$ to $r = 0.60$ (Clariana & Wallace, 2007). Probably any instruction or assessment task that involves text or network representations could utilize ALA-Reader. The results for ALA-Reader so far are sufficient to justify further extending the research in this approach.

jMAP

Foundation

jMAP is implemented as an MS Excel application which enables learners to elicit causal understanding of a phenomenon in question, visualize changes of learners' representations, and determine the degree of match between learners and experts (Jeong, 2010). Learners construct their causal representation using MS Excel's autoshape tools. The strength of the causal relations (links) between two concepts is designated by varying the densities of the relations as well as evidentiary support (Shute et al., 2010). jMAP codes the causal representation into a transitional frequency matrix based on the causal strength (1 = weak, 2 = moderate, 3 = strong) and the evidentiary support (0 = none, 1 = weak, 2 = moderate, 3 = strong). If multiple causal representations (e.g., from several students and/or experts; different time points; collective group representation) are available, they can be aggregated. Each individual causal representation can be superimposed over other causal representations. As a result, jMAP produces visual comparisons between the available causal representations, highlighting similarities and difference between time points and/or different causal representations (Shute et al., 2010). In addition, raw scores can be generated from the transitional frequency matrix for further analysis.

Application

The only recently developed jMAP tool provides a good basis for potential instructional applications. For example, using jMAP for solving complex ill-structured problems and assessing students' concept maps, goals, as well as skills in instructional settings. Open research questions, which may be addressed with jMAP, include the change of causal representations over time, variables affecting the way specific relations change, and to what extent do novices converge towards experts based on varying instructional interventions.

HIMATT

Foundation

HIMATT (Highly Integrated Model Assessment Technology and Tools) is a combined toolset which was developed to convey the benefits of various methodological approaches to one environment (Pirnay-Dummer et al., 2010). It integrates the features of DEEP (Dynamic Enhanced Evaluation of Problem Solving; Spector & Koszalka, 2004), MITOCAR (Model Inspection Trace of Concepts and Relations; Pirnay-Dummer & Ifenthaler, 2010), T-MITOCAR (Text-MITOCAR; Pirnay-Dummer & Ifenthaler, 2011a), and SMD Technology (Structure, Matching, Deep Structure; Ifenthaler, 2010c).

The architecture consists of two major platforms: (a) HIMATT Research Engine and (b) HIMATT Subject Environment. Functions for conducting and analyzing experiments are implemented within the HIMATT Research Engine. These functions include: (1) experiment management, (2) researcher management, (3) subject management, (4) view function, and (5) analysis and compare function. The HIMATT Subject Environment provides assigned experiments to individual subjects dynamically.

HIMATT was implemented and run on a Web server using Apache, MySQL (MY Structured Query Language), and PERL (Practical Extraction and Report Language), plus additional packages such as GraphViz (Ellson, Gansner, Koutsofios, North, & Woodhull, 2003).

The core unit in HIMATT is the experiment, which can be laid out flexibly by the researcher. Experiments in HIMATT consist of two assessment modules: (1) DEEP and (2) T-MITOCAR, as well as an INSTRUCTION module which is used to give the subject instructions and explanations. The instructions are texts which may contain HTML code (e.g., to link pictures, videos, or other objects). The subject management function includes multiple options. First, a researcher can add subjects to the HIMATT database. Subject information includes at least a username and a password. If a researcher wants to add a large number of subjects, HIMATT can automatically generate a specified number of subjects with individual usernames and passwords. Additionally, the user can add a prefix to all usernames or passwords in order to more easily identify them later on during experimentation and analysis procedures. Once an experiment has been laid out completely and subjects have been added to the database, researchers can assign subjects to experiments.

The view function presents the knowledge graph as a picture to the researcher. This function allows the researcher to choose from specific experiments and knowledge graphs, which are then available as Portable Network Graphics (PNG) images for download. Depending on the underlying module (DEEP, T-MITOCAR), the graphs will have different features: annotations for DEEP concept maps and associative strengths at the links for T-MITOCAR. Essentially, the standardized re-representation is done in the same way for all modules using the pairwise stored information from the database and GraphViz (Ellson et al., 2003).

The analysis function consists of descriptive measures to account for specific features of the knowledge structure, like interconnectedness and ruggedness. Using the compare function, researchers may compare any kind of knowledge model with standardized similarity measures (Pirnay-Dummer et al., 2010). These measures range from surface oriented structural comparisons to integrated semantic similarity measures (see Table 23.1). The similarity indices range from 0 to 1 for better in-between comparability. Matrices of multiple models can be compared simultaneously. All of the data, regardless of how it is assessed, can be analyzed quantitatively with the same comparison functions for all built-in tools without further manual effort or recoding.

Table 23.1 Description of the seven HIMATT/AKOVIA measures (Ifenthaler, 2011a)

Measure (abbreviation) and type	Short description
Surface matching (SFM) Structural indicator	The surface matching (Ifenthaler, 2010c) compares the number of vertices within two graphs. It is a simple and easy way to calculate values for surface complexity
Graphical matching (GRM) Structural indicator	The graphical matching (Ifenthaler, 2010c) compares the diameters of the spanning trees of the graphs, which is an indicator for the range of conceptual knowledge. It corresponds to structural matching as it is also a measure for structural complexity only
Structural matching (STM) Structural indicator	The structural matching (Pirnay-Dummer & Ifenthaler, 2010) compares the complete structures of two graphs without regard to their content. This measure is necessary for all hypotheses which make assumptions about general features of structure (e.g., assumptions which state that expert knowledge is structured differently from novice knowledge)
Gamma matching (GAM) Structural indicator	The gamma or density of vertices (Pirnay-Dummer & Ifenthaler, 2010) describes the quotient of terms per vertex within a graph. Since both graphs which connect every term with each other term (everything with everything) and graphs which only connect pairs of terms can be considered weak models, a medium density is expected for most good working models
Concept matching (CCM) Semantic indicator	Concept matching (Pirnay-Dummer & Ifenthaler, 2010) compares the sets of concepts (vertices) within a graph to determine the use of terms. This measure is especially important for different groups which operate in the same domain (e.g., use the same textbook). It determines differences in language use between the models
Propositional matching (PPM) Semantic indicator	The propositional matching (Ifenthaler, 2010c) value compares only fully identical propositions between two graphs. It is a good measure for quantifying semantic similarity between two graphs
Balanced propositional matching (BPM) Semantic indicator	The balanced propositional matching (Pirnay-Dummer & Ifenthaler, 2010) is the quotient of propositional matching and concept matching. Especially when both indices are being interpreted, balanced propositional matching should be preferred over propositional matching

Application

Every single measure integrated into HIMATT is tested for reliability and validity. The reliability scores range from $r=0.79$ to $r=0.94$ and are tested for the structural and semantic measures separately and across different knowledge domains (Pirnay-Dummer et al., 2010). Convergent and divergent validity has been tested using several criteria. Ifenthaler (2010c) reports a validity study using a declarative knowledge test as an outside criterion. The study demonstrates convergent (declarative knowledge correlates significantly with the semantic measure, $r=0.355$) and divergent validity

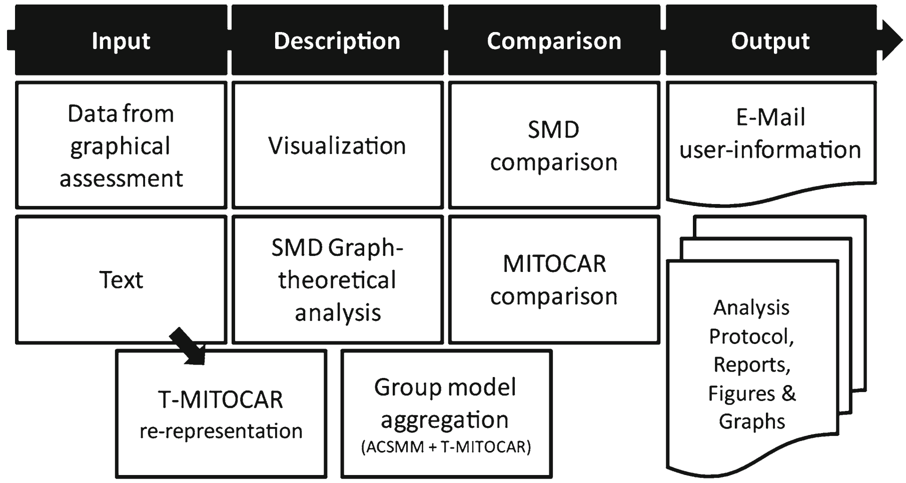

Fig. 23.2 AKOVIA framework (Pirnay-Dummer & Ifenthaler, 2010)

(no significant correlation between declarative knowledge and structural measures). Another validation study showed convergent validity among structural (e.g., SFM and GRM, $r=.79$; SFM and STM, $r=.63$; all correlations are significant) and among semantic (e.g., CCM and PPM, $r=.68$, PPM and BPM, $r=.91$; all correlations are significant) measures (Pirnay-Dummer et al., 2010).

HIMATT and its tools have been successfully applied within classical experimental settings (Ifenthaler, 2010a, 2011a, 2012; Ifenthaler & Pirnay-Dummer, 2009; Spector, 2010) and fields of applications within the domains of instructional planning, medical diagnosis, and geology (see Kim, 2008; Lachner & Pirnay-Dummer, 2010; Lee, 2009; McKeown, 2009; Smith, 2009; Spector & Koszalka, 2004). Further, empirical studies showed that HIMATT measures (e.g., GAM, CCM) helped to distinguish inexperienced from highly experienced problem solvers in all domains examined so far (J. Lee, 2009; McKeown, 2009). Finally, a usability test showed that HIMATT is widely accepted among the users and the usage is easy to learn (Pirnay-Dummer et al., 2010).

AKOVIA

Foundation

AKOVIA (Automated Knowledge Visualization and Assessment) is based on the HIMATT framework, however, concentrates on the model-based analysis methods (Pirnay-Dummer & Ifenthaler, 2010). Instead of limiting the framework to a narrow set of data collection procedures, AKOVIA was development to integrate a large number of interfaces to different methods. The core analysis in AKOVIA is a comprehensive blend of MITOCAR, T-MITOCAR, and the SMD Technology. Thus, it is also based strictly on mental model theory (Johnson-Laird, 1983; Seel, 1991, 2003). In contrast to HIMATT, the input formats and outputs have been changed to better accommodate the needs of researchers, thus allowing more applications as in the original technologies and HIMATT.

Figure 23.2 provides an overview on the modules of AKOVIA. There are two general input formats (text and graph). Thus, the software can be used to analyze many currently available assessment methods. A standard interface may be used for graphical methods. This interface is derived from SMD and HIMATT and uses the list form. Specific interfaces are under construction. The software can visualize, aggregate, describe in detail, and compare the models. The measures from SMD and MITOCAR are embedded and available for use (see Table 23.1), as are the text to graph algorithms from T-MITOCAR. In the following paragraphs we introduce the process from input to output in more detail. There are also examples for the AKOVIA scripting technology, which helps handle large data.

Application

AKOVIA places no explicit limits on the size of data which can be investigated and analyzed. Large concurrent analyses used to slow HIMATT servers down to the point where the browser experienced time outs. Therefore, the topology of the small analysis grid has been separated into the *upload server*, which takes in the files, and the *analysis servers*. The latter access the upload server and process the tickets offline. Afterwards, the results are uploaded to the upload server and the user is notified via email. Depending on the number and size of concurrent jobs, a response may take hours or sometimes even days (Pirnay-Dummer & Ifenthaler, 2010). When users upload data, they only receive an initial confirmation email with either a list of errors (if the data is not formatted correctly) or a short note confirming that their data is being processed. If the data is correct, an available analysis server downloads the files as soon as it has finished previous analyses. After completing a script, the analysis server packs and uploads the results and a protocol to the upload server, which sends an email to the user. The email contains abbreviated information on the progress of the analysis and a protected download link with which the user can access the package for a limited time. Afterwards, the package is deleted from the server as is the download link (Pirnay-Dummer & Ifenthaler, 2010).

The main applications of AKOVIA are clearly in analysis and comparison, whereas the assessment step itself is left to the tools and experimental setups of the researchers. AKOVIA is designed to complement various kinds of technologies as it uses interfaces which allow many forms of data to be analyzed. The visualizations of the models have shown to have an especially positive effect on learning within tasks which involve writing (Pirnay-Dummer & Ifenthaler, 2011a, 2011b). Thus, the possible applications reach beyond the structural and semantic analysis and comparison of knowledge (Ifenthaler & Pirnay-Dummer, 2011). In addition, AKOVIA allows the development of self-assessment technologies, such as automated model-based feedback. In this case, specifically formatted and interpreted outputs of the analysis and comparison are embedded into feedback (Ifenthaler, 2009, 2010a, 2011b).

Comparison of Model-Based Assessment Tools

Several possible solutions to the assessment and analysis problems of knowledge representations have been discussed (e.g., Al-Diban & Ifenthaler, 2011; Clariana & Wallace, 2007; Ifenthaler, 2008, 2010d; Shute, Jeong, Spector, Seel, & Johnson, 2009). Therefore, it is worthwhile to compare the above described model-based assessment and analysis approaches in order to illustrate their advantages and disadvantages, strengths and limitations (see Table 23.2). Yet, there is no ideal solution for the automated assessment of knowledge. However, within the last 5 years strong progress has been made in the development of model-based tools for knowledge assessment. Still, Table 23.2 highlights necessary further development of the available tools, especially for everyday classroom application.

Conclusions

Not all types of knowledge representations have the same types of properties and strengths, e.g., *written language* is always sequenced and has multiple dimensions at the same time, *concept maps* are not semantic webs most of the time due to underspecification problems and a lack of homogeneity, *association networks* do not have directions and propositions, *causality networks* cannot deal with dynamics, and representations of dynamic systems are almost impossible to aggregate—nor are they supposed to be aggregable in the first place. The list is not even complete. There is no easy and no complete way to integrate any of them, and the strength of good research therefore lies, maybe more than in other research domains, in a fitting integration: Multiple perspectives on the same construct are usually needed (Ifenthaler, 2010d; Ifenthaler & Pirnay-Dummer, 2010). The only way to make better decisions about the kind of knowledge representation as well as the type of tool to be used on it is to know the strengths and weaknesses of the tools. It is worth the effort to acquaint oneself with at least a representative selection of the available tools (Ifenthaler & Pirnay-Dummer, 2010; Mislevy et al., 2010). As long as mental constructs are not observable directly, there will be a need for different perspectives on the states and changes of knowledge. Every methodology at our current disposal is only a heuristic to narrow down the gap of the unknown functions between what is considered to be mental (internal) and behavior. In research about knowledge models we rely on the analysis of the artifacts being constructed by this behavior—be it text, graphs, tracks of problem solving or any other observable aspect of the object world.

Aside from automating the processes of elicitation and analysis, another important aspect of the recent developments is that the methodology becomes more and more fine-grained, thus allowing a whole new set of research questions to be ready for investigation. Research on knowledge has become less about how much there is and how complex it looks if it is derived from expertise. With new tools and developments at hand, we can say by far more about how things are structured and build from the inside (Pirnay-Dummer, 2010). This has allowed research to ask more specific questions on what really changes during learning. And it will allow even more specific questions if the researchers who are currently working on the methodologies and tools advance both in integrating and converging the analysis of knowledge structures and in finding more specifics to the artifacts of elicitation.

Scientific Quality Criteria

As discussed above, there are numerous approaches for eliciting knowledge for various diagnostic purposes. However, most approaches have not been tested for reliability and validity (Ifenthaler, 2008; Seel, 1999a). Additionally, they are almost only applicable to single or small sets of data (Al-Diban & Ifenthaler, 2011; Ifenthaler, 2010c). Hence, new approaches are required which have not only been

Table 23.2 Comparison of model-based assessment tools

	Pathfinder	ALA-Reader	jMAP	HIMATT	AKOVIA
Description	Converting estimates of relatedness of pairs of concepts into a network representation	Scoring open-ended concept maps and essays	Workbench to map concepts onto a predefined structure	Experimental toolset to elicit and analyze graphical or text-based artifacts	Automated researcher tool to analyze existing graphical or text-based artifacts
Measures	Graph theory-based measures Network representation	Graph theory-based measures Scoring algorithm	Adjacency matrix of links	Quantitative structural measures Semantic measures Graphical representation as qualitative measure	Quantitative structural Semantic measures Graphical representation as qualitative measure
Objectivity	Model building process depends on the interpretation by the subjects	Model building process depends on observers	Model building process depends on observers	Automated analysis	Automated analysis
Reliability	Tested (Schvaneveldt, 1990)	Tested (Clariana, 2010)	Not tested	Tested (Ifenthaler & Pirnay-Dummer, 2010)	Tested (Ifenthaler & Pirnay-Dummer, 2010)
Validity	Tested (Schvaneveldt, 1990)	Tested (Clariana, 2010)	Not tested	Tested (Ifenthaler & Pirnay-Dummer, 2010)	Tested (Ifenthaler & Pirnay-Dummer, 2010)
Automatization	Partly	Partly	Analysis only	Elicitation and analysis	Model-elicitation (text) and analysis
Strength	Well established research approach	Instant analysis	Off-line availability Instant analysis	Complete experimental setup Server-based for both the elicitation and the analysis	Large datasets Fast analysis Scripting server and online access Data can be assessed by any means outside of the system
Limitations	Connectivity to other learning environments is rather weak	Connectivity to other learning environments is rather weak	Model construction objectivity	Connectivity to other learning environments is rather weak	No elicitation module available

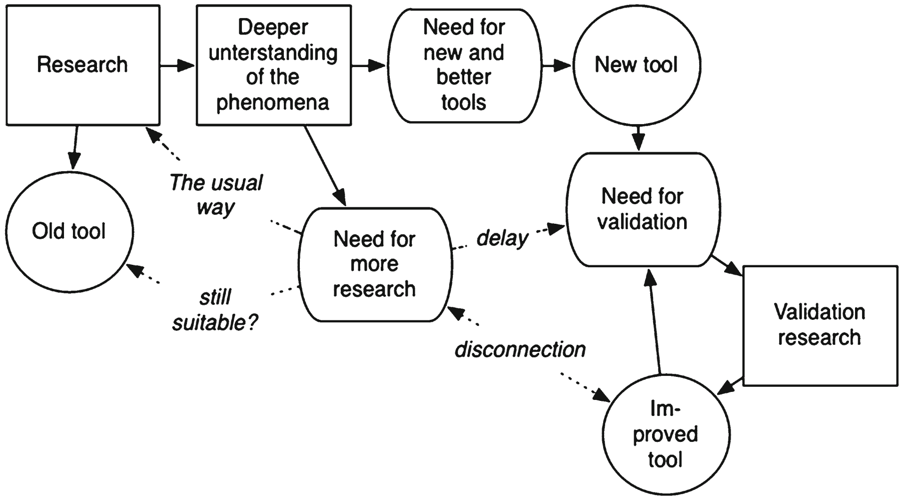

Fig. 23.3 Current disconnection and delay of research and methodology (tools) development

tested for reliability and validity but also provide a fast and economic way of analyzing larger sets of data. Additionally, approaches for educational diagnostics also need to move beyond the perspective of correct and incorrect solutions. As we move into the twenty-first century, we argue that the application of alternative assessment and analysis strategies is inevitable for current educational diagnostics. To do so, there must be a wider discussion that is more innovation-friendly at the same time.

Figure 23.3 shows the disconnection and avoidable delays in common methodology and tools development. To circumvent the disconnection, two competing assumptions need to be addressed in order to properly match the tools to the implicit or explicit demands in research:

First, we cannot afford to use outdated tools just because new ones are not properly tested. No matter how standardized they may be. As theories evolve so will new technologies to keep up with the newly discovered phenomena. Thus, tools which are based on an outdated theory will expire for their use to a deeper understanding of newer developments. If yet the outdated tools are used, research may run into a high risk of producing everlasting circles of the same results and insights, probably renaming the theories to cover for the lack of innovation. Thus, the use of innovative tools for assessment should be considered a scientific standard on its own.

Second, we cannot afford not to test new tools. Tools must be tested in- and outside the community of its developers (Al-Diban & Ifenthaler, 2011). To even make that possible, decisions on funds need to take into consideration the researchers' willingness and ability to triangulate knowledge data and to apply new methodologies in their research even if that research is not directly about new methodologies. Thus, the test of new methodologies alongside already existing ones should become a scientific standard, too. Cross-validation and first large-sample tests should of course still remain a key focus of the developers. But after a series of such studies, a wider analysis and evaluation of feasibility is needed: There will never be resources to widely apply every new tool to a proper set of studies. And we believe, we often saw good developments in the loop and their developers going on a life-quest to run sufficient studies on just everything only to make a point towards the methodology. But this would be a waste of resources and time—since the innovations are already there.

Figure 23.4 shows a way to integrate common research and the innovation of research tools in general by just using innovations along with the standards. This simple application can inform both the innovation process (validation research) and improve the research at the same time without widening the risk for the research results: As a "plan B" the standard tools are still used at that point. The triangulation will give interesting additional insight into the research problem, i.e., by means of post hoc analyses. An integration of methodological innovation alongside with research standards and common research will shorten the time for implementation by years if not decades without harming the research process itself.

Automation of Tools

In many settings manual and therefore labor-intensive methods have limits, e.g., when the groups under investigation are large or practical applications do not have the resources which prototypes may have. Also, from a methodological viewpoint the automation helps in raising the objectivity of studies. Another important focus of our work is to make the applicability of the tools as broad as possible while retaining a very specific set of well-tested algorithms and methods which have shown to be reliable both in technical and empirical

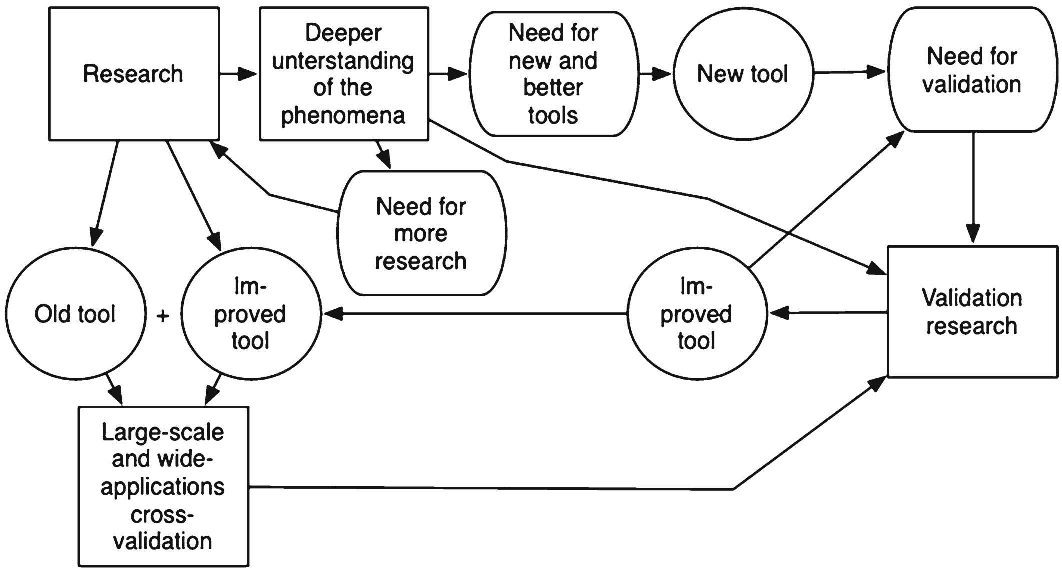

Fig. 23.4 Possible workaround to circumvent the disconnection between research and tools development

respects. Thus, automation does not only make things easier and less expensive. It also allows for a whole set of small and medium research projects to gain access to a reliable means of measurement and analysis. In a way, without automation, many research projects would not be possible from the start. This does not contradict the fact that labor-intense qualitative work will have its own rewards in allowing much deeper insight to questions and aspects of knowledge where automated tools cannot yet look at. But especially in cases, where the resources are not available to go through and analyze a larger set of artifacts by hand, the automated tools will help to explore new boundaries of learning.

Full automation as opposed to part-manual approaches also open up another class of technologies. If the assessment and analysis can be carried out automatically and in real time, then its results can be used to inform both the decision-makers (e.g., teachers) and the learners during an ongoing learning process. Outcomes and results of these assessments can then be aggregated, transformed, and thus utilized to create feedback-panels or even written feedback based on the current learner model. Feedback into the ongoing learning can be explicit by using the results of the analysis, e.g., graphs, change indicators, as well as convergence towards an expert solution (Ifenthaler, 2010a, 2011b). The feedback can also be transformed for a more implicit use of the aggregations by using algorithms to create written feedback based on numerical indicators (Ifenthaler, 2011b; Pirnay-Dummer & Ifenthaler, 2011a, 2011b). Only with the complete automation of the assessment and analysis process an assessment-based feedback to inform the ongoing learning process is possible (Ifenthaler, 2009).

Future Research

Since many new tools focus on how knowledge is structured and it is less and less about how much there is, the gap between qualitative and quantitative approaches will be narrowed down substantially. But narrowing that gap is not only about developing new tools. The process will need an open cross-validation from both perspectives with an emphasis of what can be done (and in what way) that was not possible yesterday.

Future research will change the theories of knowledge and thought substantially. With the finer grain of exploration at hand, those theories will inevitably become more complex because we are now more able to see differences and nuances as well as their effects within learners and problem solvers. Because we find new phenomena, they will be a need for thorough explanation, preferably not quick-shots but deeply reflected theories that explain the new variety of phenomena.

None of the existing tools are finished and complete at the moment. Based on their potential they may be improved in several ways, e.g., a better integration, extended automation, or even finer grain of measurements. Hence, the tools need to be challenged on both empirical and technological ground. This process needs to be conducted in front of and for the research audience that uses the tools. It is imperative that there will not be a parallel universe of methodologists raising the quality of tools to a high orbit if either nobody will understand and use them or they become less feasible.

The latter requirement also comes with an important goal for further development and a very important distinction as regards simplicity: Essentially, implementing the tools and subsets of them in practice needs to be simple and as less invasive to the common processes as possible. The tools need to be simple so that every practitioner has the time to implement them if necessary. This means, that the tools need to be highly usable and easy to apply, which is the easier goal. The second goal is not that simple. There is almost no way around the proper interpretation of the outcome, i.e., of measures or aggregations made by the tools. In order to work properly in practice, this also means, that practitioners as well as researchers will need training on how to interpret the outcomes of the tools, especially when they might look very much alike at the surface. Any decision maker who uses the tools needs to know what the output of the tools is about and what are the heuristic limitations of the output are, e.g., distinguishing an association net from a knowledge map although they look very much alike.

To triangulate the use, usability, and feasibility of the tools, we would suggest to apply them to a large dataset of national and international magnitude. The process can be repeated for validation and comparability should new tools be built or every some years if the existing tools changed significantly. The following aspects should be considered in such a triangulation:

1. The convergent and divergent validities between the tools as compared to available standard measures (e.g., grades, performance indicators)
2. Objectivity measures—if parts of the observation depend on human interpretation
3. The limitations of the tools for any of the investigated target groups
4. The total cost of the implementation per sample
5. The variety of outputs and outcomes per single application of each tool
6. The quality and use of the output as perceived by
   - Researchers
   - Target group
   - Group of the decision-makers (e.g., teachers, policy makers)
7. The possibility of tool- or part-tool reduction if the outputs measure or assess the same (by convergent validity)—in this case the tool that is easier to implement (without any loss of information) prevails. This aspect will also encourage researchers to converge their technologies where possible.

A large scale triangulation study will continuously help to improve and converge the innovations in the methodology of knowledge- and model-assessment. It can also control for the benefits of the existing tool while researchers who built the tools will have a predictable motivation to put their tools to the test. However, the effect of the convergence should not reach out to reduce the diversity in tool initial development. Even already dismissed approaches must be available for reinvestigation. The results of a triangulation study cannot be a shortcut to decide on funding and resources. The development of the existing tools as well as of new ones is necessary to explore human knowledge, its change, decision-making, performance, and problem-solving as our understanding of those complex human potentials evolves.

Performance Assessment: Something Old, Something New

24

Dee H. Andrews and Wallace H. Wulfeck II

Abstract

Education, industry, and the military rely on relevant and effective performance assessment to make key decisions. Qualification, promotion, advancement, hiring, firing, and training decisions are just some of the functions that rely on good performance assessment. This chapter explores issues, tools, and techniques for ensuring that performance assessment meets the goals of decision makers. Important considerations include the following: the task environment in which assessment takes place, the validity of the measures selected, the diversity and scope of the measures, and often the local political environment in which assessments are made. Unfortunately, primarily in education, assessment policy is a matter of intense political debate, and the debate is sustained by misinformation. For example, traditional paper and pencil assessment techniques have come under fire from those who do not feel they have the relevance they once did. Simulation-based training technologies in industry and the military have put more emphasis on performance assessment systems that show real-world work relevance. The chapter examines these topics.

Keywords

Authentic assessment • Alternative assessment • Portfolio assessment • Performance appraisal • Performance evaluation • Performance task

Introduction

In education, performance assessment refers to testing methods that require students to create an answer or product, or execute a process, that demonstrates their knowledge or skills. Performance assessment, in education and work settings, can take many different forms including writing short answers, doing mathematical computations, writing an extended essay, conducting an experiment, presenting an oral argument, executing a series of tasks, or assembling a portfolio of representative work (US Congress, Office of Technology Assessment, 1992). More broadly, performance assessment refers to the measurement of a system or process with respect to goals or benchmarks set for it.

Assessment in one form or another has a history going back at least 2000 years. In early China, prospective civil servants were examined not only on recitation, but on productive originality (Madaus & O'Dwyer, 1999). Later, the focus turned away from production toward reproductive thinking "because government officials became worried that the scoring of these questions would be too subjective; thus, they reverted back to questions that required more rote answers" (Madaus & O'Dwyer, 1999). Twelve hundred years later, universities in France and Italy began the practice of

oral examinations, and written examinations in Latin composition appeared by the sixteenth century (Madaus & O'Dwyer, 1999). Guild membership led to professional certification based on proven skills and knowledge. The industrial revolution brought a focus on quantification in measurement, and by the twentieth century industrial task analysis and "scientific management" had given rise to the invention of multiple-choice testing by Frederick Kelly in 1914 and its large-scale use in the Army Alpha test in World War I. The College Board's Scholastic Aptitude Test used multiple-choice items beginning in 1926. By the 1950s, the invention of data processing systems and optical scanners, as well as taxonomies of educational outcomes (Bloom, 1956) and the behavioral objectives movement, led to the predominance of machine-scorable tests, particularly in the USA.

Since at least the 1950s, there has been a continuing societal debate about the use, fairness, and appropriateness of various forms of assessment. Robert Glaser (1963) focused on the *purpose* of testing and distinguished between norm-referenced and criterion-referenced testing. Performance assessments are usually criterion-referenced because they refer to defined performances, but can be norm-referenced, for example in sales or sports. More recently there has been ongoing controversy concerning the proper role of testing in schooling, and this has tracked larger societal debates concerning the "constructivist" and "situated learning" movements (Anderson, Reder, & Simon, 2000), and most recently, standards-based education policy with so-called "high-stakes" testing.

Definitions

Authentic Assessment: Engaging and worthy problems or questions of importance, in which students must use knowledge to fashion performances effectively and creatively. The tasks are either replicas of or analogous to the kinds of problems faced by adult citizens and consumers or professionals in the field. (Wiggins, 1993, p. 229).

Alternative Assessment: The term alternative assessment is broadly defined as any assessment method that is an alternative to traditional paper-and-pencil tests. Alternative assessment requires students to demonstrate the skills and knowledge that are difficult to assess using a timed multiple-choice or true-false test. It seeks to reveal students' critical-thinking and evaluation skills by asking students to complete open-ended tasks that often take more than one class period to complete. While fact-based knowledge is still a component of the learning that is assessed, its measurement is not the sole purpose of the assessment.

Alternative assessment is almost always teacher-created (rather than created by other test developers) and is inextricably tied to the curriculum studied in class. The form of assessment is usually customized to the students and to the subject matter itself. (Teaching Today. McGraw-Hill Retrieved from http://teachingtoday.glencoe.com/howtoarticles/alternative-assessment-primer.)

Portfolio Assessment: A portfolio is a collection of student work that can exhibit a student's efforts, progress, and achievements in various areas of the curriculum. A portfolio assessment can be an examination of student-selected samples of work experiences and documents related to outcomes being assessed, and it can address and support progress toward achieving academic goals, including student efficacy. Portfolio assessments have been used for large-scale assessment and accountability purposes (e.g., the Vermont and Kentucky statewide assessment systems), for purposes of school-to-work transitions, and for purposes of certification. For example, portfolio assessments are used as part of the National Board for Professional Teaching Standards assessment of expert teachers. (Retrieved from answers.com http://www.answers.com/topic/portfolio-assessment.)

Performance Appraisal: Performance appraisal is the procuring, analyzing and documenting of facts and information about an employee's net worth to the organization. It aims at measuring and constantly improving the employee's present performance and tapping the future potential.

Performance Evaluation: Performance evaluations are prepared by company management on a periodic basis to determine if employees are working up to, or beyond, the minimum standards of their job description. Critical areas are graded by supervisors or department managers in either a written or checklist format, or a combination of both. Decisions ranging from salary increases to possible termination can result from performance evaluations.

Performance Task: A performance task is a goal-directed assessment exercise. It consists of an activity or assignment that is completed by the student and then judged by the teacher or other evaluator on the basis of specific performance criteria.

Current Status

Extensive work on performance testing has been going on since at least the 1960s (e.g., Glaser, 1963; Glaser & Klaus, 1962). Perhaps the best overview of the state of research and practice in educational assessment was given in a recent report on educational assessment by the National Research Council (Pellegrino, Chudowsky, & Glaser, 2001).

In addition there are modern standards for the practice of assessment. The Joint Committee on Standards for Educational Evaluation was formed in 1975 by major professional associations in social, psychological, and education science and practice. Three sets of standards have been published: Personnel Evaluation (Joint Committee, 1988, revised 2009), Program Evaluation (Yarbrough, Shulha, Hopson, & Caruthers, 2011), and Student Evaluation (Joint Committee on Standards for Educational Evaluation, 2003). In addition, the American Educational Research Association, American Psychological Association, and the National Council on Measurement in Education (1999) have produced standards for educational and psychological testing that cover validity, reliability and error, test development, scoring, score comparability, fairness, and testing applications.

Today there is continuing interest in the role and purpose of testing, and performance-based assessments are in vogue. The US Department of Education's *Race to the Top* assessment program provides "funding for the development of new assessment systems that measure student knowledge and skills against a common set of college and career-ready standards … in mathematics and English language arts in a way that covers the full range of those standards, elicits complex student demonstrations or applications of knowledge and skills as appropriate, and provides an accurate measure of student achievement across the full performance continuum and an accurate measure of student growth over a full academic year or course." (Department of Education, 2010).

Performance assessments often appeal to those who are uncomfortable with large-scale, high-stakes, standardized, normative testing. However, performance assessments have obvious shortcomings. These include: difficulty and expense of administration, unreliability of scoring because of human rater error or bias, and poorer validity or generalizability due to limited time and opportunity to sample extensively from a broad universe of knowledge and skill.

Many performance assessments used in classrooms are teacher designed. This has both advantages and disadvantages. Teachers can adapt their assessments more rapidly to individuals, and can therefore diagnose and remediate more effectively. But this flexibility comes at the price of standardization and reliability, because teachers are often not trained or expert in the design of reliable and valid assessments, and because adaptation necessarily involves alteration of the assessment situation from individual to individual. In addition, teachers may have more difficulty interpreting results that are not expected.

There are more subtle problems in the design of reliable and valid performance assessments. Most performance assessments have associated "rubrics" or scoring keys, which are necessary to provide some standardization and reliability in scoring. Many examples are online at, for example http://www.rcampus.com/indexrubric.cfm or http://www.rubrics4teachers.com/. But in reality, most of these are nothing more than checklists for critical events, and "behaviorally anchored rating scales" from 50 years ago (Smith & Kendall, 1963). At the time these rating techniques were originally developed, such checklists and behavioral anchors depended on reasonably extensive critical-incident and behavioral task analyses. Such analyses have their own difficulties: they are expensive and time consuming to conduct; they depend on deep subject-matter or content knowledge on the part of the analyst; they may be incomplete or inaccurate; they often lead to oversimplification of content (and therefore, for performance measurement, to assessment at too rudimentary a level); and to an overemphasis on procedural skill (rather than underlying cognition) (Bell, Andrews, & Wulfeck, 2010). Ironically, without deep task analysis, performance assessment may be just as behaviorally trivial as poorly designed machine-scored objective tests.

In the end, performance assessments, by definition, rely on some observation of behavior, with inferences about underlying knowledge and cognition. The same is true of any objective assessment which relies on the same sort of behavioral and cognitive task analyses. Therefore, claims concerning the supposed superiority of performance assessment (compared to objective tests) in contemporary education advocacy must be taken with a large dose of skepticism. Indeed, we often find recommendations and practices that, at best, show little awareness of decades of development, and at worst, are simply wrong. This is true not only in the popular press, where policies and practices of education and assessment are often the subject of inflammatory but ill-informed political debate, but also in professional guidance for educators. For example, a publication from a state office of education giving recommendations for science teachers about development of performance assessments says: "…objectively scored tests are not valid measures of what is important to learn in school. Objectively scored tests—multiple choice, completion, short answer—emphasize the acquisition of and the memorization of information. They cannot be appropriately used to measure many higher level thinking abilities nor can they be used to measure some other important goals of schooling." (Baird, 1997).

Leaving aside the bizarre implication that acquisition and memorization of information are not important outcomes of schooling, we concentrate on the claim that objectively scored tests cannot appropriately measure higher-level thinking: While it is true that poorly designed tests might not assess very well, it is certainly not true that assessments cannot be designed to provide objective scoring of many kinds of complex performances, including those that depend on reasoning and problem solving. We have known for decades how to do it, when the tasks for which performance is to be assessed are deeply and explicitly analyzed (e.g., Ellis & Wulfeck, 1982; Glaser & Klaus, 1962; Merrill, 1994; Stevens & Collins, 1977).

We are indebted to a reviewer of this chapter for noting that various forms of assessment cover a broad range of alternatives, such as the nature of the contextual setting for response or performance, process vs. product measurement, response modes, types of "items" (or instances of response observation), and methods of scoring. Different combinations of alternatives on these dimensions may be more or less appropriate depending on the specific task(s) to be assessed but there should be no *a priori* claim of superior reliability or validity for any particular combination, assuming, of course, that the assessment is competently designed. Further, however, the choice of different combinations may have substantial implications for the cost and practicality of development, administration, scoring, reporting, and utilization of assessment results. For example, "paper" simulations with "multiple-choice" responses can be designed for many types of mechanical or electronic troubleshooting tasks: they can test logical reasoning and problem solving and can provide diagnostic information concerning misconceptions (cf. Ellis & Wulfeck, 1982). They are much cheaper to administer and score than an actual hands-on troubleshooting event that requires live test equipment and individual administration and scoring by a human observer.

Simulation-Based Performance Assessment

Even before the large-scale development of computer-based simulations, case-based and role-based simulations were used in education, such as "moot courts" in legal training, or wargaming in the military. Non-computer-based simulators are heavily used in many fields, for example, in medical education (cf. www.simulation.com for examples of commercially available human patient simulators), or in firefighting training (cf. www.mobilefireunits.com for examples of commercially available simulators).

In simulation-based training, the simulation is used to provide the context in which human performance may occur and be observed, recorded and measured. The most important ingredients for successful simulation-based training and assessment are the design of the scenarios, since these prescribe the conditions under which performance will be elicited, the physical fidelity of the simulation (for example in medical devices), and (as in any performance assessment) the scoring criteria against which performance will be evaluated. In simulations which are not computer based, observation and measurement generally use the same techniques as in other performance assessments, namely checklists, rating scales, and occasionally time-to-solution measures. These, of course, suffer from the same limitations as most other performance assessments. For example, a review of assessments used in anesthesia simulation in medical training found few which addressed questions of validity or reliability (Byrne & Greaves, 2001).

So, What's New in Assessment?

In recent years, with the development of computing technologies, it has become possible to build detailed, highly veridical simulations of complex phenomena (cf. Baker, Dickieson, Wulfeck, & O'Neil, 2008). Computer-based simulations are now used in many fields of endeavor, such as medicine and surgery, engineering, economics, geology, vehicle piloting, and many others. Simulations are used for system design, system performance analysis, prediction of outcomes, analysis of alternative courses of action, and of course for training and performance assessment.

Computer-based simulations have some properties which may contribute to effective performance measurement. First, the process of constructing the simulation essentially involves a very fine-grained task analysis, since almost every aspect of the user's interaction with the simulation must be taken into account in its design (Wulfeck, Wetzel-Smith, & Dickieson, 2004). Thus, unlike performance assessments where variations in performance can be handled (or missed) by a human rater's observational skill, such variation must be explicitly accounted for in the simulation. Second, the simulation can be designed to collect performance data automatically, and use it for scoring and evaluation, as well as for control and adaptation in the simulation itself. Third, the simulation is, by definition, situated in a task environment, so criticisms concerning the unreality of common standardized multiple-choice testing are avoided.

Simulation-Based Performance Assessment for Aviation

Before we discuss simulation-based performance assessment for aviation it is important to discuss simulation fidelity in its various forms. There are a number of different types of simulation fidelity (Hays & Singer, 1989; Swezey & Andrews, 2001). Physical fidelity refers to the physical characteristics of the simulation or simulator ("does it look right?"). Functional fidelity refers to the way the simulation or simulator behaves ("does it act right?"). Psychological fidelity, which is much more difficult to assess, refers to how an experienced real-world operator of a system believes the simulation or simulator subjectively meets their expectations in terms of its "feel" to them ("does it feel right?"). For example, an aircraft simulator may look and act like the real thing, but an operator may still not get an authentic feeling when they fly the simulator. "Cognitive fidelity" is a construct similar to psychological fidelity.

A simulation or simulator might have different levels (low to high) of each type of fidelity. The training developer and/or assessment developer must decide about the optimal mix of fidelity levels for the simulation's intended purpose. The cost to achieve higher levels of fidelity and the technical challenges in reaching higher levels both enter into the decision. The authors have seen many instances where large amounts of money have been invested to achieve high levels of physical and functional fidelity and yet the operational experts still did not feel that the simulation felt like the real thing. It did not reach a high level of cognitive fidelity. Yet, we have also seen example where physical/cognitive fidelity was achieved with relatively modest investments in physical/functional fidelity. The key is determining as precisely as possible what salient characteristics of the real-world system must be represented in the simulation in order for learning to occur, or in order for the trainee to be able demonstrate competence to an assessor.

A key example of the use of simulation to enable assessment comes to us from years of research and practice in the pilot assessment arena. From the beginning of pilot training, concern has been given to how best to measure pilot performance (Meister, 1999). Assessment of this type is used both in training and in assessing readiness for job performance. Pilots must make rapid decisions in highly dynamic and complex environments. Since the time of the Wright Brothers, the main method for assessing pilot trainee and pilot performance has been via rating sheets, typically with five or seven point rating scales. The instructor pilot, flying with the trainee, determines the pilot's performance for each of the scale dimensions (e.g., mission planning, preflight check, taxi, takeoff, aerial maneuvers, stall recovery, instrument flight, situational awareness, etc.). Once a military pilot progresses beyond their initial undergraduate training and is ready for combat training, the instructor pilot assesses their performance on various phases of tactical flying. This happens not only in their initial aircraft specific training but also periodically throughout their flying career.

This approach for assessing trainee and pilot performance is a tried and true method. Although ultimately subjective in nature, it has proven to be generally valid and reliable. Instructor pilots have come up through this type of assessment system as they gained expertise and are quite used to making judgments on the rating scales after observing trainee/pilot performance.

Andrews, Nullmeyer, Good, and Fitzgerald (2008) provide an overview of the progress made in performance measurement in the aviation field. They note two advancements that deserve highlighting. The first is the advent and use of digital performance recording as described above. This has led to new approaches to automated performance assessment, as well as giving instructors new tools to make subjective assessment decisions. The second advancement is the use of behaviorally anchored rating scales coupled with automated performance assessment tools to develop a more robust total measurement system.

Aircraft simulators have opened up a broad new horizon for performance assessment in pilot training. Digital simulators can record every aspect of the simulated aircraft on a micro-second basis. Every button push, toggle switch movement, image display, radar mode, etc. can be recorded for eventual analysis by instructors and raters. This data can be aggregated both for individual trainee evaluation and across trainees to spot gross trends that can lead to training program improvements. In addition, all audio communication can be recorded and replayed.

In many cases, measurement done in a simulator can be more valid and reliable than measurement done by an instructor pilot. That is especially true in the early phases of training. If the simulator possesses both high physical and functional fidelity it is a relatively straight forward task to measure each button push and control movement. The validity and reliability become more difficult to maintain as the pilot moves into phases of flight that demand more cognitive skill (e.g., understanding how to synthesize the information from various displays, decision making, etc.). In those cases the automated performance measurement system can aid the instructor, but normally can't provide all of the measurement capability required.

One potential advantage of simulator-based assessment systems is that they may give the trainee the feeling that they are not constantly being watched by their human instructor. A number of researchers (Diaper, 1990; Shivers, 1998; Staal, 2004) have shown that performance is altered when it is done in the presence of others. Performers who were unaware that they were under observation typically performed better than a control group on complex tasks. One might then conclude that having an automated performance system do the assessing improves performance if the instructor is not directly involved with observing the trainee's performance.

Lane (1986), in a report examining the performance measurement issue in aviation, cites "seven" criteria that can be used in evaluating aviation performance measurement. They are as follows:

Reliability—"Reliability ... is in the metric sense the most basic issue. If the measures are not dependably replicable over the required time period, other criteria are of little or no importance." p. 36

Validity—Lane provides a cogent quotation from Wallace (1965) that explains the importance of true validity, "... it is possible to develop extremely plausible measure sets, with high apparent relevance, which are in reality mostly irrelevant and provide no evidence of any sort germane to the purpose of the evaluation."

Sensitivity—"The sensitivity of a measure reflects the extent to which the measure behaves 'appropriately' in response to changes in conditions under which the task is performed or to differences in individual capability to do the task." p. 80

Completeness (*Dimensionality*, *Comprehensiveness*)—"… basic, advanced and operational flying, evaluators made consistent and reliable distinctions between such aspects of proficiency as basic airwork, instrument flying and ability to use weapons." p. 81

Seperability of Operator from Measurement Context Contributions—"If comprehensiveness is the inclusion of all the relevant components of performance, then the concern for seperability is for the omission or exclusion of irrelevant components." p. 91

Diagnosticity (*Specificity*)—"To be effective in … diagnostic use, variables must satisfy three general requirements: a) they must provide a level of detail which allows differentiation among skill and knowledge components, b) they must be sufficiently distinct in the content they measure, and c) the measures must be capable of being mapped with a reasonable degree of correspondence into those specific components." p. 93

Utility and Cost Benefit (*Value against Alternatives*)—"A measurement system may be reliable and valid and possess all the other properties required of performance measures and still be of limited utility … To be 'useful', a method must produce results that represent 'true' performance more closely than any other available and affordable way of achieving that objective." p. 94.

Lane's (1986) comments concerning performance assessment in aviation apply well to most new applications of performance assessment technology. While some progress has been made in recent years in applying more modern statistical approaches to questions concerning reliability, validity, and generalizability of performance measurements (cf. Webb, Shavelson, & Haertel, 2006), much remains to be done to build an engineering science using modern computer-based simulations for performance assessment.

Non-aviation Example of Simulation-Based Performance Assessment

An example might help the reader to understand how a simulation-based approach might be of use in K-16 schooling and in higher education. In a history course a teacher wants students to develop more complex decision making capacity. They wish to have the students exercise their abilities to define a problem, describe the key elements of a decision and solution requirements in order to frame their solution alternatives, pick a solution strategy and apply it, evaluate the results of the decision and make revisions where necessary or reject that alternative and choose a different solution strategy. They could use an off-the-shelf game that re-creates a financial emergency such as the great depression. It is not likely that an off-the-shelf game would have the kinds of assessment characteristics that a teacher would likely desire, so they would need to conduct the assessment of student skills manually, but the main point is that the students would be developing decision making skills in a real-world simulation with the types of variability that would expect to be found in the actual historical settings. The huge success enjoyed by decision making games using real-world simulation, (e.g., SimCity and Age of Empires) shows that schoolchildren enjoy such games. We highly encourage educational game makers (i.e., serious games) to build in the types of assessment characteristics discussed in this chapter.

Assessment of medical skills is another area that is benefitting from simulation-based education and training. Past medical specialty certifications by national boards for that discipline consisted primarily of written exams and interviews between the applicant and experts in that field. The expert would ask various questions about the specialty and often pose relevant questions about best treatment paths using verbal scenarios. While that approach is still in use in some cases, the certification boards are turning more and more to simulation-based assessment approaches that can supplement the other elements of the assessment process. These computer based assessment systems allow the certifying assessors to test the medical specialist applicants' hands-on skills. This trend will continue to gain momentum.

Future Research Needs

A fruitful area of research involves extending simulation design to the measurement and assessment of high-level cognition. An entire volume on assessing problem solving using simulations explicitly treated issues and examples in the design of simulations for assessment (Baker et al., 2008).

A second area of research and development would extend the progress made in the use of simulation for assessment for broader application, particularly in education at the preschool through college levels. Here the need is primarily for diagnosis of progress and prescription of curricular and instructional alternatives that maximize the progress of individual students (cf. Lesgold, 2008). These areas of research have been seriously neglected in education and psychology in recent years, due to intense pressure from politicians and others who apparently think that a focus on scores on standardized tests will somehow improve competitiveness in a world economy. While a quick search of the Internet will locate hundreds of computer-based simulations or environments for K-12 tasks, few have mechanisms for recording student interaction to permit significant assessment or diagnosis. This is due in part to the relative infancy of computer applications in education, and in part to the difficult problems of practical management of such systems in today's classrooms.

A third related area of research involves performance assessment for high-level tasks which are complex and ill-structured. These are often the highest-value tasks/skills at any level of work, in any kind of organization. Wulfeck and Wetzel-Smith (2008) described these "Incredibly Complex Tasks" as those that are almost unbelievably complicated, in that they required deep expertise obtained through years of highly contextualized study, practice, and experience for successful performance. In later work, Wulfeck and Wetzel-Smith (2010) described training strategies for incredibly complex tasks. These involve using computer modeling, visualization, and careful design of instruction to deal with task characteristics that contribute to difficulty and complexity, such as multiple sources of variation, interaction, dynamism, continuity, nonlinearity, simultaneity, uncertainty, and ambiguity. These design strategies can also inform the design of performance assessments. Unfortunately, however, developing training and performance assessments for incredibly complex tasks requires at least as high a level of expertise as performance of the tasks themselves, and so such tasks are often considered by non-experts (such as policy-makers) to be impossible to teach or to assess. On the contrary, it is entirely possible to design good assessments for incredibly complex tasks: it merely requires decades of work by task experts and millions of dollars. However, efforts on such a scale, even in education and training, are common. Standardized testing programs for *No Child Left Behind* or college entrance examinations have already consumed much larger amounts of resources.

Conclusions

After a combined 80 years as practicing instructional psychologists, we welcomed the opportunity to examine current developments in the area of performance assessment. In the past 20 years there has been tremendous progress in the application of technology to performance assessment, particularly in developing and applying simulation systems for both individual and team training. Much of this progress has come in the military in the development of simulation-based training systems, and in some professions for certification.

Performance assessment has become more important over time. In our litigious society, the capability to accurately determine who can do what not only makes good educational and economic sense but it also can protect organizations from being sued for hiring, promotion and termination decisions. As a scientific community and community of practice, our performance-assessment standards and tools continue to evolve. We are considerably more likely to make the right judgments about personnel and student performances now than we were, say, 50 years ago. Not only have the accuracy and reliability of our assessments improved, but also the standards and tools we possess make us better able to anticipate and react to, and in some cases mitigate, both individual and societal differences. In addition, our assessments better help our community to make sound prescriptions to improve performance for students and employees.

Despite the progress in assessment over the last few decades considerable work remains to be completed. Research into performance assessment techniques that translate from tests to real-world performance is still inadequately funded. At least some of the considerable public debate about the place of testing in schools stems from a general misunderstanding, and in some cases mistrust, of validity of the assessment process at measuring true educational progress. While there is a general sense that the standardized tests used to measure that progress are not complete, in some cases there is the feeling that the tests are biased in one way or another. Researchers in the educational measurement community have work to do in establishing validated methods for identifying key concepts and principles required in the various academic subjects that can be translated into effective tests.

We generally believe it is a more straightforward, although by no means simple, task for measurement specialists in business, industrial and military settings to develop quality measurement approaches than it might be in formal education. Proximity of their assessment development activities to real-world work places gives them an advantage over their formal education counterparts. Having completed a number of task analyses, from which flow metrics for assessment, your authors know the advantage that comes from being able to observe and interview incumbent workers as they perform their jobs. Formal education assessment developers have access to subject matter experts, but seldom get to watch them use their expertise to accomplish real-world tasks, whether that is performing cognitive or manual work tasks.

However, the task of workplace performance assessment is made difficult because of the increasing complexity of many jobs. While automation has simplified many workplace tasks it has also forced decisions about the allocation of job functions that have resulted in humans taking on more executive control functions. These are almost always more difficult to assess than jobs where the human is doing more procedural work. While the mundane parts of jobs are performed by sophisticated software, the human is left to monitor the job activity and decide when to intervene in the process. These control decision tasks were usually left to senior, more experienced, and better trained employees, but they have been often pushed down to newer and less trained employees. Designing performance measurement systems can help in assessing the preparation of employees who will make these decisions. Since in some cases there may not be only one right answer in a workplace setting, performance assessment systems will have to increase in flexibility.

25 Formative and Stealth Assessment

Valerie J. Shute and Yoon Jeon Kim

Abstract

Assessing generally refers to the process of gathering information about a person relative to specific competencies and other attributes, in formal or informal learning contexts. This should lead to valid and reliable inferences about competency levels, which in turn may be used for diagnostic and/or predictive purposes. Too often, classroom and other high-stakes assessments are used for purposes of grading, promotion, and placement, but not to enhance learning. In this chapter, we focus on formative assessment which posits that assessment should (a) encourage and support, not undermine, the learning process for learners and teachers; (b) provide formative information whenever possible (i.e., give useful feedback during the learning process instead of a single judgment at the end); and (c) be responsive to what is known about how people learn, generally and developmentally. This type of assessment has as its primary goal improvement of learning, which is critical to support the kinds of learning outcomes and processes necessary for students to succeed in the twenty-first century. It is referred to as "formative assessment," or assessment *for* learning, in contrast to "summative assessment" (or assessment *of* learning). This chapter overviews the role of formative assessment in education generally, and also touches on stealth assessment specifically—an evidence-based approach to weaving assessments directly into learning environments (Shute, Computer games and instruction. Charlotte, NC: Information Age Publishers, 2011).

Keywords

Competency • Evidence-centered design (ECD) • Formative assessment • Stealth assessment

Introduction

> Assessment should not merely be done to students; rather, it should also be done for students, to guide and enhance their learning. NCTM (2000).

In the United States, assessment currently plays a significant (and often heavy-handed) role in educational systems. A prevalent form of assessment in education today is the standardized test. The primary goal of standardized tests is to ensure accountability of schools and teachers. Our nation's usage of standardized tests has increased considerably since the No Child Left Behind (NCLB) Act was signed into law in 2001 (Chappius & Chappius, 2008). For example, before NCLB, 19 states required annual reading and mathematics tests in grades 3–8, and one test administered in high school. By 2006, every state required standardized testing (Jennings & Rentner, 2006).

J.M. Spector et al. (eds.), *Handbook of Research on Educational Communications and Technology*, DOI 10.1007/978-1-4614-3185-5_25,

Although there is a little evidence supporting positive effects of the NCLB Act, there is extensive criticism about the hidden costs of NCLB. For instance, Stiggins (2002) argued, "*We are a nation obsessed with the belief that the path to school improvement is paved with better, more frequent, and more intense standardized testing. The problem is that such tests, ostensibly developed to 'leave no student behind,' are in fact causing major segments of our student population to be left behind because the tests cause many to give up in hopelessness—just the opposite effect from that which politicians intended.*" (p. 2).

The primary problem with current assessment practices is that the information from the assessment currently is not being used, as it could and should, to support teaching and learning (e.g., Shute, 2007; Symonds, 2004; Wiliam & Thompson, 2007). Typically, classroom assessments are only administered at the end of some major chunk of time with assessment results arriving too late for teachers to effectively act on them. Symonds (2004) highlighted this problem as she explored policies and practices in dozens of schools that were classified into two groups: successful and unsuccessful in closing the achievement gap. The report showed clear, striking differences between the gap-closing versus non-gap-closing groups—particularly with regard to the use of data. Gap-closing schools assessed students often and used the results to make changes in their instructional program. Non-gap-closing schools assessed students infrequently and did not use the data to effect instructional changes. Two recommendations that emerged from the Symonds study (and which have been endorsed by the Council of Chief State School Officers (2004)) are the following: (1) schools need frequent, reliable data, and (2) teachers need support to use data effectively.

Broadly speaking, the type of assessment that uses test information to support learning is called formative assessment. Despite growing evidence that this type of assessment supports student learning, we don't see wide application of formative assessment in classrooms. Two explanations for the limited adoption of formative assessment in the classroom are the following: (a) it's hard to do, and (b) it's often misconstrued as yet another test. But as James Popham notes, formative assessment is a test-supported *process* rather than a test (Popham, 2009).

The goal of this chapter is to describe formative assessment fully and also present a special approach to formative assessment called *stealth assessment*. Therefore, we discuss (a) measurement and assessment, (b) summative and formative assessment, and (c) formative and stealth assessment. Within each of these sections, we provide definitions, examples, and relevant research. We conclude this chapter with recommendations to help bring formative assessment into the classroom and a discussion about how stealth assessments fit well with a systematic approach to instructional design.

Measurement and Assessment

Different models of educational measurement are associated with different instructional practices in the classroom and thus have different effects on student learning. Historically, the main aim of measuring students' educational progress was to identify differences among students in order to rank order them by achievement. This type of measurement model makes heavy use of summative assessment, which is useful for accountability purposes but only marginally useful for guiding day-to-day instruction and supporting student learning. In contrast, student-centered measurement models rely mostly on formative assessment, which is associated with meaningful feedback that can be very useful in guiding instruction and supporting student learning.

Assessment is a general term that typically applies to individuals and may include testing, observation, and so forth. Progress toward educational goals is usually assessed through testing of some type. Assessment can refer to both an instrument and a process by which information is obtained relative to a known objective or goal (Shute, 2009). Since inferences are made about what a person knows on the basis of responses to a limited number of assessment tasks or items, there is always some uncertainty in inferences made on the basis of assessments. The goal in educational measurement is to minimize uncertainty or error; thus key aspects of assessment quality are validity and reliability. Reliability refers to the consistency of assessment results—the degree to which they rank order students in the same way. Validity refers to the extent to which the assessment accurately measures what it is supposed to measure, and the accuracy of the inferences made from task or test results to underlying competencies.

The focus of this chapter concerns not only measuring students' existing and emergent competencies accurately and reliably but also using that information to render diagnoses and instructional support. Consequently, the focus is on formative assessment (FA) rather than summative assessment. Later, we describe stealth assessment which involves embedding formative assessment into the learning environment such that it is invisible and hence does not disrupt learning and engagement.

Summative and Formative Assessment

> When the cook tastes the soup, that's formative; when the guests taste the soup, that's summative. Robert Stake

The choice and use of a particular type of assessment depend on the educational purpose. As mentioned earlier, schools in the United States today generally make heavy use of summative assessment (also known as assessment *of* learning), which is useful for accountability purposes (e.g., unidimensional assessment for grading and promotion purposes) but only marginally, if at all, useful for supporting personal learning. In contrast, learner-centered measurement models rely mostly on formative assessment, also known as assessment *for* learning, which can be very useful in guiding instruction and supporting individual learning, but may not be particularly consistent or valid. That is, one current downside of the assessment-for-learning model is that it is often implemented in a non-standardized and hence less rigorous manner than summative assessment, and thus can hamper the validity and consistency of the assessment tools and data (Shute & Zapata-Rivera, 2010).

Summative Assessment

Summative assessment reflects the so-called traditional approach used to assess educational outcomes. This involves using assessment information for high-stakes, cumulative purposes, such as for grades, promotion, certification, and so on. It is usually administered after some major event, like the end of the school year or marking period, or before a big event, like college entry. Benefits of this approach include the following: (a) it allows for comparing learner performances across diverse populations on clearly defined educational objectives and standards; (b) it provides reliable data (e.g., scores) that can be used for accountability purposes at various levels (e.g., classroom, school, district, state, and national) and for various stakeholders (e.g., learners, teachers, and administrators); and (c) it can inform educational policy (e.g., curriculum or funding decisions).

Formative Assessment

Formative assessment reflects a more progressive approach in education. This involves using assessments to support teaching and learning. Formative assessment is incorporated directly into the classroom curriculum and uses results from students' activities as the basis on which to adjust instruction to promote learning in a timely manner. A simple example would be a teacher giving a "pop quiz" to his or her students on some current event, immediately analyzing their scores, and then refocusing his or her lesson to straighten out a prevalent misconception shared by the majority of students in the class. This type of assessment is intended to be administered more frequently than summative assessment, and has shown great potential for harnessing the power of assessments to support learning in different content areas and for diverse audiences (e.g., Black & Wiliam, 1998; Hindo, Rose, & Gomez, 2004; Schwartz, Bransford, & Sears, 2005). In addition to providing teachers with evidence about how their class is learning so that they can revise instruction appropriately, formative assessment directly involves students in the process, such as by providing feedback that will help them gain insight about how to improve, and by suggesting (or implementing) instructional adjustments based on assessment results.

While the scope of what comprises an assessment for formative purposes is quite broad (e.g., informal data, test responses, homework, observations), what is key in the definition is that the information or the evidence is used as feedback—by teachers (or systems) and students to improve teaching and learning, respectively. It is essential that an FA system includes support tools to help teachers learn to implement the full range of assessment types, gather evidence, make sense of the data, and adjust instruction accordingly. Such support tools may reside within a professional development strand related to the FA system. An FA system should also provide support for learners to help them improve motivation, volition, self-efficacy, problem-solving skills, and so on.

Finally, notice that we use the term "formative assessment" throughout the chapter as if it were a singular entity, but there are actually two different faces of FA which may be construed as residing at opposite ends of a continuum. That is, at one end of the continuum lives formal FA, which relates to the more traditional, teacher-centric view of formative assessment; this involves administering tasks and quizzes to students, gathering students' results, and then either providing feedback or altering instructional activities on the basis of the data. The other end of the continuum—informal FA—involves the student-centric, interactive classroom activities and discussions that occur, often spontaneously, in various learning environments. Both formal and informal FA provide evidence to teachers and students about learning progress.

Table 25.1 characterizes four assessment variables (main role in the classroom, frequency of administration, typical format, and feedback) that are characteristic of summative and formative assessment. The examples, per variable, for summative and formative assessment are illustrative and not exhaustive (e.g., formative assessment formats may include other types besides constructed response, such as oral response and even multiple-choice questions). Also note that neither type of assessment is an educational panacea—both have strengths and limitations. Table 25.1 is intended to convey general aspects of each approach in terms of the variables and should not be viewed as definitive categorizations.

Research on Formative Assessment in the Classroom

Research suggests that well-designed and implemented formative assessment is an effective strategy for enhancing student learning. Evidence to date suggests that students in classes where formative assessment was implemented learned in 6 months what would have taken a year in other

Table 25.1 Assessment variables in relation to summative and formative approaches

Variables	Summative assessment	Formative assessment
Role of assessment	Assessment of learning, to quantify fixed and measurable aspects of learners' knowledge, skills, and abilities. Used for accountability purposes, often with norm-referenced tests. Produces a static/snapshot of the learner	Assessment for learning, to characterize important aspects of the learner. The main focus is on aspects of learner growth, employing criterion-referenced tests, used to help learners learn and teachers teach better
Frequency of assessment	Infrequent, summative assessments using standardized tests. The focus is on product or outcome (achievement) assessment. These are typically conducted at the end of a major event (e.g., unit, marking period, school year)	Intermittent, formative assessment. The focus is process oriented (but needn't exclude outcomes). Assessments of this type are administered as often as desired and feasible: monthly, weekly, or even daily. Administration is normally informal
Format of assessment	Objective assessments, often using selected responses. The focus is on whether the test is valid and reliable more than the degree to which it supports learning	Constructed responses and an authentic context, collected from multiple sources (e.g., quizzes, portfolios, self-appraisals, and presentations)
Feedback	Correct or incorrect responses to test items and quizzes, or just overall score. Support of learning is not the intention	Global and specific diagnoses, with suggestions for ways to improve learning and teaching. Feedback is helpful, rather than judgmental

Note: This table is adapted from Shute (2007)

classes (Wiliam, 2006). Studies indicate that the regular use of classroom formative assessment could raise student achievement by 0.4–0.7 of a standard deviation (Black & Wiliam, 1998)—enough to catapult the United States into the top five countries in the international rankings for math achievement (Wiliam & Thompson, 2007). Finally, there is evidence that formative assessment can promote significant gains in student self-efficacy and motivation (Kim, 2007), which are predictors of high school graduation (Black, Harrison, Lee, Marshall, & Wiliam, 2003). Another important finding from studies on formative assessment relates to the benefits for disadvantaged and low-achieving students (e.g., Fuchs et al., 1997).

When teachers know how students are progressing and where they are having problems, they can use that information to make real-time instructional adjustments such as reteaching, trying alternative instructional approaches, altering the difficulty level of tasks or assignments, or offering more opportunities for practice. Again, FA in this sense has been shown to improve student outcomes and achievement (Black & Wiliam, 1998; Shute, Hansen, & Almond, 2008).

Feedback is an important and direct component of good FA, and should generally guide students toward obtaining their goals. Helpful feedback provides specific comments to students about errors and suggestions for improvement. It also encourages students to focus their attention thoughtfully on a specific task rather than on getting the right answer or a passing grade (Bangert-Drowns, Kulik, Kulik, & Morgan, 1991; Shute, 2008). This may be considered a direct application of FA.

A more indirect way (compared to feedback) of helping students learn via formative assessment includes instructional adjustments that are based on assessment results (Stiggins, 2002). Different types of assessment data can be used by the teacher to support learning, such as diagnostic information relating to levels of student understanding, and readiness information indicating whether or not a student is ready to begin a new lesson or unit. Examples of instructional support include (a) recommendations about how to use assessment information to alter instruction (e.g., speed up, slow down, give concrete examples), and (b) suggestions for what to do next, links to Web-based resources, and so forth. However, there is much room for improvement in teachers' formative use of assessment results, as one of the most important aspects of formative use (responding to results by modifying instruction and identifying alternative pedagogies) is the least used by classroom teachers and the most neglected with respect to professional development (see Lai, 2009).

Research on Formative Assessment in Computer-Based Learning Environments

A growing number of computer-based educational systems are employing formative assessment as well. A good example of such systems is a Web-based formative assessment platform called ASSISTment (Feng, Heffernan, & Koedinger, 2006; Koedinger, McLaughlin, & Heffernan, 2010). ASSISTment is a Web-based platform that allows teachers to develop formative assessments for fourth- to tenth-grade mathematics classes. In a recent study, Koedinger and his colleagues (2010) reported that the schools using ASSISTment significantly outperformed matched schools on the state mathematics test.

Another example of a computer-based formative assessment system is ACED (Adaptive Content with Evidence-based Diagnosis) (Shute, Graf, & Hansen, 2005). This system uses an evidence-centered design approach (Mislevy, Steinberg, & Almond, 2003) to create an adaptive, diagnostic assessment system to assess and support pre-algebra knowledge and skills. Instructional support is in the form of elaborated feedback. A study was conducted examining its efficacy (Shute et al., 2008). The key issue was whether the inclusion of the feedback into the system (a) impairs the quality of the assessment (relative to validity, reliability, and efficiency), and (b) does, in fact, enhance student learning. Results from a controlled evaluation testing 268 ninth-grade

Table 25.2 Summary of key formative assessment features

Feature	Rationale
Improves student learning	A primary purpose of an FA system is to enhance (or support) student conceptual development as well as skill acquisition. Two kinds of data to support learning include (a) *diagnostic information* relating to levels of understanding and particular misconceptions where the information from diagnostic tasks should be instructionally tractable (i.e., neither too general nor too specific) and (b) *readiness information*, where a general FA task is administered at the outset of a class or a unit and results can show who, in the class, is ready (or not) to begin a new lesson or unit
Promotes student self-efficacy	Feedback in FA should generally guide students through toward obtaining their goal(s) (Ramaprasad, 1983; Sadler, 1989). The most helpful type of formative feedback (on tests, homework, and classroom activities) provides specific comments to students about errors, and specific suggestions for improvement, and encourages students to focus their attention thoughtfully on the task rather than on simply getting the right answer (Bangert-Drowns et al., 1991; Elawar & Corno, 1985; Shute, 2008). This type of feedback may be particularly helpful to lower achieving students because it emphasizes that students can improve as a result of effort rather than be doomed to low achievement due to some presumed lack of innate ability (e.g., Hoska, 1993)
Provides timely feedback	Feedback must be timely to be useful (e.g., Corbett & Anderson, 1989). Whenever possible, the FA system should provide immediate feedback (ideally immediately, but within "same day" time frame). Feedback can be directed to students (e.g., regarding performance on computer-based tasks) or teachers (e.g., summary reports on classroom performance)
Provides information at multiple levels of aggregation	FAs should report out *individual* data and may be *aggregated* to subgroup and full-group levels. Teachers and administrators may be able to specify subgroups based on student demographic variables (e.g., gender, race, attendance, mobility, socioeconomic status, etc.) and also use FA results to create groups with similar performance on specified tasks or sets of tasks
Provides low-to-mid stakes assessment	Given the relatively low-stakes and informal nature of FAs, they should mostly be of two levels: low and intermediate (not high-stakes). Higher degrees of standardization in FAs may occur in certain computer applications. Also note that "low-stakes" does not mean they will be low in reliability or validity (see Shute et al. (2008) for an example of a reliable and valid FA system)
Uses developmental models	Competency models should include developmental aspects that provide pre- and post-requisite relationship information. The function of the developmental part of the models relates to (1) *actual* learning (self- or criterion referenced), and (2) *potential* learning (forecasting near and far term potential—via Zone of Proximal Development and "end of school year" growth modeling research ideas)

students showed that the quality of the assessment was unimpaired by the provision of feedback. Moreover, students using the ACED system showed significantly greater learning of the content compared with a control group. These findings suggest that assessments in other settings (e.g., standardized, state-mandated tests) might be augmented to support student learning with instructional feedback without jeopardizing the primary purpose of the assessment.

Table 25.2 summarizes the key features of formative assessment, along with a brief discussion of each feature.

So far, we have focused on FA. But now consider the following. Rather than stopping an instructional episode at various times to collect information from students and provide support as warranted, what if there was a way to embed FA so deeply in the fabric of the learning environment that the distinction between learning and assessing became completely blurred? This idea, called stealth assessment, is presented next.

Formative and Stealth Assessment

New directions in educational and psychological measurement allow more accurate estimations of students' competencies, and new technologies permit us to administer formative assessments during the learning process; extract ongoing, multifaceted information from a learner; and react in immediate and helpful ways. When formative assessments are seamlessly woven into the learning environment and are thus invisible to learners, we call this *stealth assessment* (Shute, 2011; Shute, Ventura, Bauer, & Zapata-Rivera, 2009).

Stealth assessment can be accomplished via automated scoring and machine-based reasoning techniques to infer things that would be too hard or time consuming for humans (e.g., estimating values of evidence-based competencies across a network of skills). One big question is how to make sense of rich data collected in order to provide meaningful feedback and other support for learning. Another major question concerns the best way to communicate a variety of student-performance information in a way that can be used to inform instruction and enhance learning.

Definition of Stealth Assessment

Stealth assessment is an evidence-based approach to assessment where the tasks that students are engaged with are highly interactive and immersive, such as within video games or other computer-based instructional systems. Like FA, stealth assessment is intended to support learning of important content and key competencies. This represents a quiet-yet-powerful process by which learner performance data is

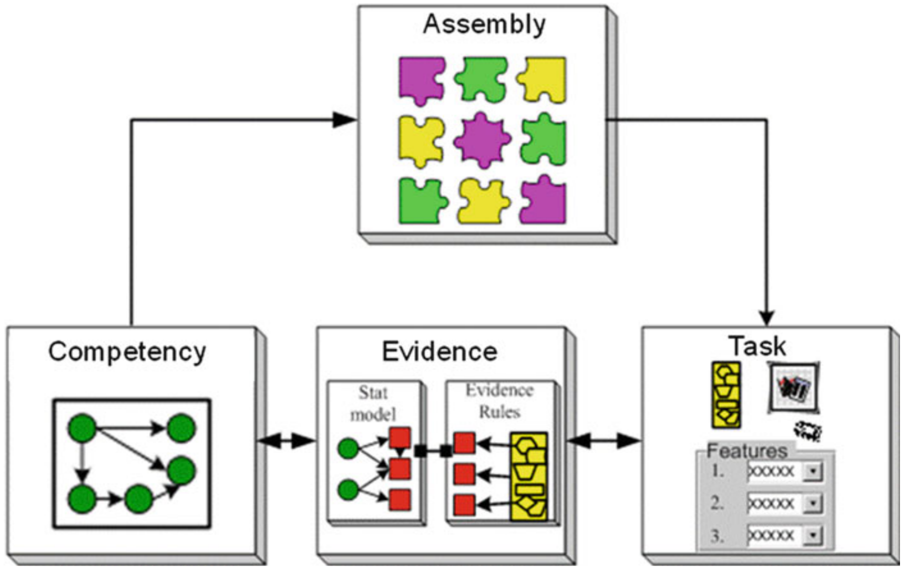

Fig. 25.1 Conceptual assessment framework of ECD (adapted from Mislevy et al., 2003)

continuously gathered during the course of playing/learning and inferences are made about the level of relevant competencies (see Shute et al., 2009). Inferences on competency states are stored in a dynamic model of the learner. Stealth assessment is intended to support learning and maintain flow, defined as a state of optimal experience where a person is so engaged in the activity at hand that self-consciousness disappears, sense of time is lost, and the person engages in complex, goal-directed activity not for external rewards, but simply for the exhilaration of doing (Csikszentmihalyi, 1990). Stealth assessment is also intended to remove (or seriously reduce) test anxiety while not sacrificing validity and reliability (Shute et al., 2008). Again, the goal is to blur the distinction between assessment and learning.

Key elements of the approach include (a) evidence-centered assessment design, which systematically analyzes the assessment argument concerning claims about the learner and the evidence that supports those claims (Mislevy et al., 2003), and (b) formative assessment and feedback to support learning (Black & Wiliam, 1998; Shute, 2008). Additionally, stealth assessment provides the basis for instructional decisions, such as the delivery of tailored content to learners (e.g., Shute & Towle, 2003; Shute & Zapata-Rivera, 2008). Information is maintained within a learner model and may include cognitive as well as noncognitive information comprising an accurate and up-to-date profile of the learner.

Evidence-centered assessment design (ECD), the key element for stealth assessment, is a conceptual design framework to help in the creation of coherent assessments. It supports a broad range of assessment types, from classroom quizzes to simulation-based assessments (Mislevy et al., 2003). The conceptual framework includes several models that work together to answer specific questions, such as "what attributes are to be measured?" and "how do we score them?" (see Fig. 25.1).

The competency model defines variables related to students' knowledge, skills, abilities, and other attributes that we wish to measure. This model accumulates and represents current beliefs about targeted aspects of skill, expressed as probability distributions per variable (Almond & Mislevy, 1999). The evidence model provides detailed instructions about (a) what the student says or does that can count as evidence for those skills (Steinberg & Gitomer, 1996), and (b) how the evidence statistically links to variables in the competency model (Mislevy, 1994). Task/action models express situations that can evoke required evidence. And the assembly model specifies how the competency, evidence, and task/action models work together to form a valid assessment.

Example of a Stealth Assessment

To illustrate the stealth assessment approach, here is an example relating to creative problem solving in a commercial game called Oblivion (*The Elder Scrolls IV: Oblivion,* 2006, by Bethesda Softworks). *Oblivion* is a first-person, 3D role-playing game that is set in an imaginary medieval world. Players enter the game by selecting a character to play (e.g., Argonian, Orc, or Dark Elf). Each character has a particular specialization (e.g., combat, stealth, and magic) and special abilities. The primary goal of the game is to develop the character's skills by completing a series of quests. These quests represent the character's journey to save the empire

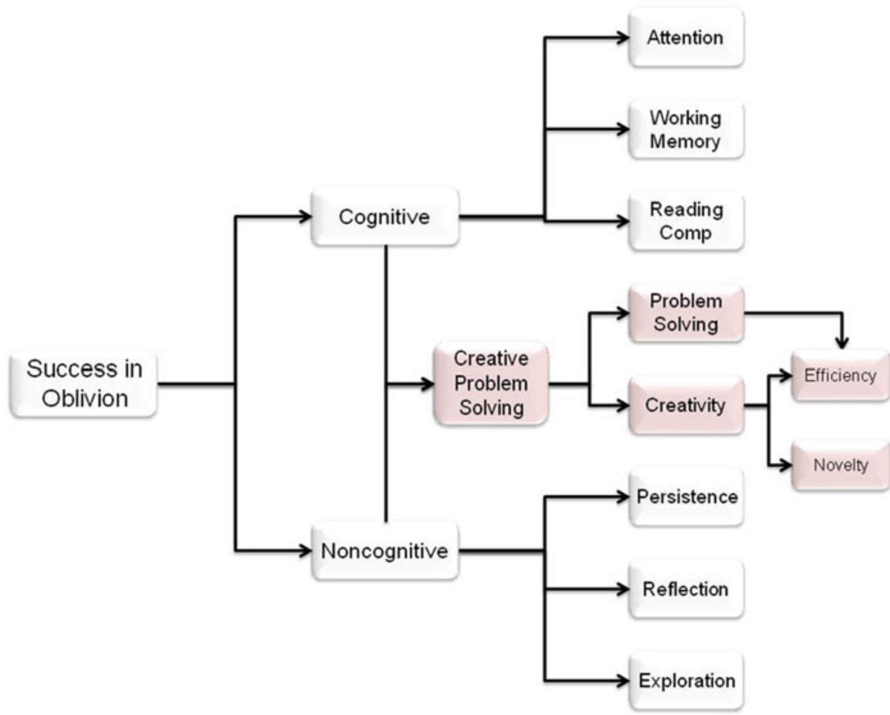

Fig. 25.2 Illustrative competency model for Oblivion (from Shute et al., 2009)

from dark magic, and are typically quite complex problems that players need to solve. During the course of the game, there are about 20 skills that a character needs to develop (e.g., alchemy, illusion, and heavy armor) to level up or to avoid being killed by dark monsters.

Creative problem solving is the main competency in the example, defined as the process of coming up with novel but efficient solutions to a given problem. The shaded competency model variables in Fig. 25.2 represent the nodes of interest in this example.

The evidence model links the specific actions that a player takes in the game with relevant competency variables. This requires the specification of particular observations, and how they differentially inform the level of mastery for different competency variables. The statistical machinery (such as IRT or Bayesian networks) serves to "glue" this information together (i.e., the observable performance data with the unobservable competency variables).

The action model (i.e., task model) in the example relates to the various quests and possible actions that players take in relation to quests. For example, consider a player faced with the problem of having to cross a river full of dangerous fish. Table 25.3 contains a list of actions to solve this problem, as well as the indicators that may be learned from real data, or elicited from experts. For the system to learn indicator values from real data, estimates of *novelty*, for example, may be defined in terms of the frequency of use across all players. For instance, swimming across the river is a high-frequency,

Table 25.3 Example of action model with indicators for novelty and efficiency

Action	Novelty	Efficiency
Swim across the river	$n=0.12$	$e=0.22$
Levitate over the river	$n=0.33$	$e=0.76$
Freeze the river with a spell and slide across	$n=0.76$	$e=0.80$
Find a bridge over the river	$n=0.66$	$e=0.24$
Dig a tunnel under the river	$n=0.78$	$e=0.20$

common solution, thus associated with a low "novelty weight." An estimate of *efficiency* may be defined in terms of the probability of successfully solving a problem given a set of actions—based on time and resources expended.

Swimming across the river would thus have a low efficiency value because of the extra time needed to evade the dangerous fish. On the other hand, digging a tunnel under the river to get to the other side is judged as highly novel, but less efficient than, say, freezing the water and simply sliding across, the latter being highly novel and highly efficient. The indicator values shown in Table 25.3 were elicited from two *Oblivion* experts, and they range from 0 to 1. Higher numbers relate to greater levels of both novelty and efficiency.

Actions can be captured in real time as the player interacts with the game, and associated indicators can be used to provide evidence for the appropriate competencies. This is accomplished via the evidence model using Bayesian network software. Figure 25.3 shows a Bayes net after a player elected to cross the river by levitating over it.

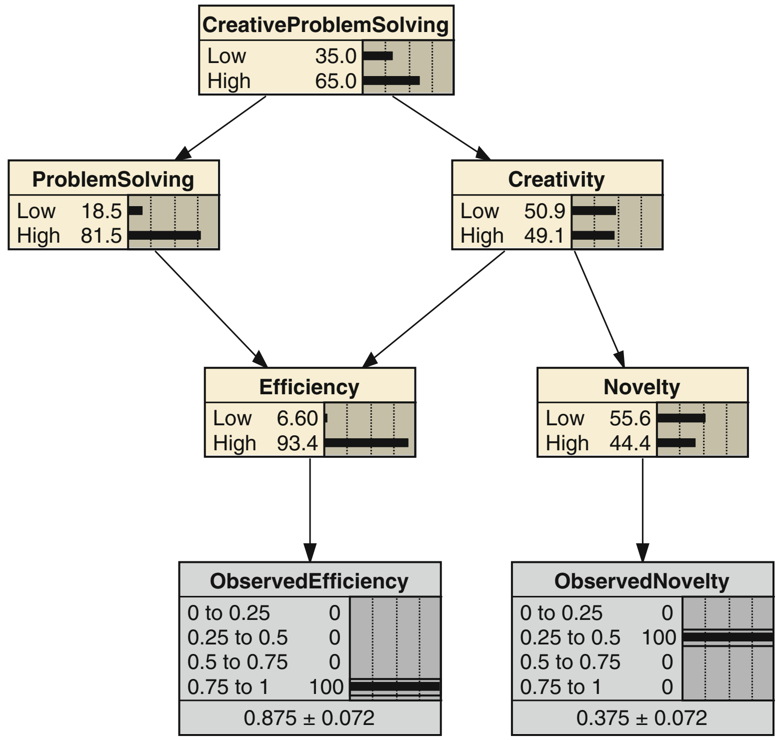

Fig. 25.3 Bayes net estimates from levitating over the river (from Shute et al., 2009)

Even though the player evidenced just average creativity in that solution, the parent node of creative problem solving infers that she is somewhat "high" on this attribute—illustrating that problem solving (based on efficiency) is a more valued competency than creativity, based on the way that the conditional probability distributions were set up in the competency model. Further, the player has more chances to improve this skill during game play. This information can be used in two different ways: (a) as formative feedback, which can be directly communicated to the learner, and (b) adjusting the sequence of quests to focus more emphasis on improving creativity.

Conclusion

In this chapter, we discussed formative assessment in relation to measurement and summative assessment. We also described stealth assessment as a particular instantiation of formative assessment, as employed within a video game or other immersive environment. Despite their intuitive appeal, both formative and stealth assessment have some challenges that need to be addressed for them to be widely adopted in classrooms today.

First, for formative assessment to be embraced more widely there should be more support—such as through professional development—for teachers. This would enable them to be more comfortable and skilled using formative assessment in their classrooms. In particular, teachers should learn to (a) diagnose students' competencies (at various grain sizes) based on different sources of information, (b) figure out what to do next given the obtained data, and (c) build up and employ a pool of rich tasks, probing questions, and other instructionally fruitful activities that can serve to elicit more evidence to inform student models and concurrently support students' learning. In short, teachers should acknowledge that formative assessment is intended to support their decision making for instructional adjustment to help all students grow and learn.

Following are ten recommendations for teachers about how to effectively use formative assessment in the classroom:

1. *Cognitive research*. Employ assessments that have been designed on a cognitive-developmental research foundation.
2. *Complex tasks*. Engage students in cognitively demanding tasks, i.e., ones that actually engage students in thinking about an issue or a problem.
3. *Learning goals*. Inform students clearly of the specific (and more general) learning goals being sought in the lesson or across longer units.
4. *Administration*. Administer assessments (of all types) frequently and usually informally, and require full-class participation in the ongoing, interactive dialog.

5. *Feedback*. Give feedback to students in the form of constructive comments, not grades.
6. *Personal accountability*. Provide students with opportunities to assess themselves and/or their peers to support personal accountability and autonomy.
7. *Evidence-based diagnosis*. Use evidence from formal and informal FAs as the basis for diagnosing students' progress (or lack thereof).
8. *Preplan questions and paths*. Plan questions in advance that probe students' understanding and craft alternative instructional paths based on response patterns.
9. *Leverage prior knowledge*. Build on students' preexisting knowledge and understanding—even if it requires going back through previously instructed material.
10. *Collaboration*. Meet regularly with other teachers to select and share good tasks, discuss student work, plan effective questions, discuss "lessons learned," and so on.

Implementing stealth assessment also poses its own set of challenges. The competency model, for example, must be developed at an appropriate level of granularity to be implemented in the assessment. Too large a grain size means less specific evidence is available to determine student competency, while too fine a grain size means a high level of complexity and increased resources to be devoted to the assessment. In addition, developing the evidence model can be rather difficult in a gaming environment when students collaborate on completing quests. For example, how would you trace the actions of each student and what he/she is thinking when the outcome is a combined effort? Another challenge comes from scoring qualitative products such as essays, student reflections, and online discussions where there remains a high level of subjectivity even when teachers are provided with comprehensive rubrics.

How do teachers fit into this effort? In games designed for educational purposes, the system can allow teachers to view their students' progress relative to the students' competency models. Teachers would then use that information as the basis for altering instruction or providing formative feedback. For example, if the competency models during a quest showed evidence of a widespread misconception, the teacher could turn that into a teachable moment, or may choose to assign struggling students to team up with more advanced students in their quests.

Information about students' competencies may also be used by the game system to select new gaming experiences (e.g., more challenging, ill-structured problems could be presented to students exhibiting high creative problem-solving skills). In addition, up-to-date estimates of students' competencies, based on assessment information handled by the statistical machinery (e.g., Bayes nets), can be integrated into the game and explicitly displayed as progress indicators. Players could then see how their competencies are changing based on their performance in the game. Most games already include status bars, representing the player's current levels of game-related variables. Imagine adding high-level competency bars that represent attributes like creative problem solving, persistence, and leadership skill. More detailed information could be accessed by clicking the bar to see current states of lower level variables. And like health status, if any competency bar gets too low, the student needs to act to somehow increase the value. Once students begin interacting with the bars, metacognitive processes may be enhanced by allowing the player to see game- or learning-related aspects of their state. Viewing their current competency levels and the underlying evidence gives students greater awareness of personal attributes. In the literature, these are called "open student models" and they have been shown to support knowledge awareness, reflection, and learning (Bull & Pain, 1995; Hartley & Mitrovic, 2002; Kay, 1998; Zapata-Rivera & Greer, 2004; Zapata-Rivera, Vanwinkle, Shute, Underwood, & Bauer, 2007).

How is stealth assessment related to the design of instructional systems? Gustafson and Branch (2002) describe five core elements of instructional design: analysis, design, development, implementation, and evaluation. These factors ensure coherence among instructional goals and strategies, as well as the effectiveness of the instruction. Moreover, these five elements should be used iteratively, and evaluation should reside at the center of the iterative revision process. Information obtained from any stealth assessment can also be used by instructional designers to improve learning/instructional systems. For example, information from a stealth assessment may show that many students had difficulty with a particular task. The instructional designer could then examine the task to see if revisions are warranted.

In addition, components of a stealth assessment (e.g., competency, evidence, and task models) are compatible with steps in the instructional design process such as task and content analysis and the development of performance measures. A common goal of both stealth assessment and instructional design is to coherently align learning objectives with how they are measured. Therefore, if instructional designers work closely with assessment developers to design and develop a learning system that has built-in stealth assessment, it can optimize the effectiveness of the instruction.

In conclusion, the ideas in this chapter relate to using formative assessment (in the classroom) and stealth assessment (in immersive learning environments). In both cases, this would help not only to collect valid evidence of students' competency states and support student learning but also to reduce teachers' workload in relation to managing the students' work products. This would allow teachers to focus their energies on the business of fostering student learning. The ideas in this chapter are intended to help teachers facilitate student learning, in a fun and engaging manner, of educationally valuable skills.

Evaluation of ICT Competencies

26

Agustin Tristán-López and
Miguel Angel Ylizaliturri-Salcedo

Abstract

Information and Communication Technology (ICT) competencies comprise a subset of digital literacy, one of the various areas of technological competencies and skills necessary for real-life functioning in all kind of professional activities and levels of education from preschool to graduate levels. Assessment of ICT competencies involves the definition of specific target activities appropriate to the environment in which they are required. These environments range from the home to the workplace and involve such disparate activities as information-retrieval in healthcare settings or libraries; use of clerical, business, or investment applications; and interactions with government or other public services. The range of ICT competencies also includes the specific abilities needed by professionals responsible for the development of software or communication products and services. This chapter discusses several ICT assessment projects, addresses the primary technical specifications required for evaluation, and explores solutions to problems of test administration. These solutions range from electronic quizzes (similar to paper-and-pencil tests) to more "authentic" forms of assessment using e-portfolios or simulations of real software applications. A detailed analysis of the primary approaches for assessment of social, academic, commercial, or economic environments reveals that these approaches primarily focus on a basic core of skills consisting of Web navigation and the use of e-mail and office tools (text processor, spreadsheet, presentation, and database management). In the future, ICT evaluation will involve automatic scoring of natural language responses in documents, solutions of mathematical problems, and graphical or health applications, among many other real-life endeavors.

Keywords

ICT literacy assessment • Digital literacy • ICT competencies • Assessment standards • Automatic scoring

Introduction

Information and Communication Technology (ICT) curricula are aimed at satisfying the academic and professional motivations of individuals on the development of higher order ICT competencies. In addition, ICT also has the potential to empower minorities and produce benefits resulting from the technology itself, regardless of the user's motivations or application field. This potential is important because

it may be a tool for reducing the digital divide between people and among countries.

The importance of ICT assessment comes from the academic and professional interest to identify the level of expertise of persons using ICT, because as indicated in studies conducted by the OECD, the digital gap between countries is related to the well-being of people; therefore, those competencies are directly related to the development of a country (Levy, 2010). A convenient approach to assess ICT competencies should be based on a framework and models that target specific skills and use of new technologies, ranging from basic knowledge of ICT foundations to very sophisticated use and management of tools in simulated environments.

ICT literacy is helping people worldwide to increase communications at different levels, among students within schools, between school and home, or within school-social networks. Today, teachers and students can retrieve information and knowledge from online encyclopedias and special-purpose Web pages. This phenomenon is transforming a resource into a magnificent instrument to improve learning ability, readiness for employment, and attainment of higher academic qualifications, all of which may reduce social gaps (ECDL, 2011).

The goals of this chapter are:

1. To provide a panoramic view of the status of ICT assessment according to the main frameworks and syllabuses developed in several countries
2. To present some of the online platforms from questionnaires and quizzes to e-portfolios and other Internet applications
3. To show the basic concepts of the platforms based on computational simulators

Some of the assessment of ICT competency approaches that are presented in this chapter rely on excellent technological solutions, software platforms, or navigator environments, but the authors wish to emphasize the need that assessment projects must be primarily grounded on valid, objective, and reliable measurement tools to provide the best information and feedback to the user, teachers, authorities, and institutions.

Description of ICT Competencies

The first step in an evaluation project should be to describe the set of competencies to be demonstrated by an ICT user. This definition is not simple, because the various applications of ICT in schools, businesses, government, social networks, health services, and transportation are significant for not only children and families using the computer as an everyday tool but also adults who are just beginning to use modern technologies. For the latter, a good understanding of ICT tools will lead to a better appreciation of their implications for society and a redefinition of their role in connecting individuals and communities (Leye, 2007; Umrani & Ghadially, 2003). Technological literacy is producing a significant impact on everyday activities, ranging from educational practices and curriculum planning to professional work and labor tasks, from projects in industry and engineering to health interventions in medicine and nursing, and from long-distance communication using Web-based translators to participation in democratic processes. Recent political events in several countries have revealed how social networks are using the Internet to send information to the world in an unprecedented way.

Defining competencies is an important issue because each author, researcher, association, or group of professionals should specify ICT competencies in their particular contexts. Table 26.1 contains some examples of ICT competencies in specific contexts for the use in this paper.

The first example in Table 26.1, ICT literacy, comprises everyday situations encountered in an information society. In this context, an ICT user integrates a set of competencies to retrieve and effectively use information with digital technology and communication tools, either online through the Internet or through a local network.

Digital literacy is the use of high technology in everyday life. A digitally literate person may use specific hardware such as a computer, a cell phone, or other digital resource in combination with communication software, such as the Internet, to interact with society at large, thus becoming a digital citizen or e-citizen and improving social and economic opportunities. Information literacy is mainly concerned with information-retrieval and should not be confused with digital literacy.

Computer literacy means that an individual can comfortably use commercial or open-source operating systems and programs and may even achieve higher level knowledge about the computer's operation and controls. Computer literacy combines knowledge, attitudes, and cognitive or psychomotor skills to use computers and technology efficiently.

A technologically literate person can solve real-life problems by manipulating computers or other electronic and technological devices and products and is not necessarily related to information-retrieval competencies. Technological literacy includes, but is not limited to, computer technology or the use of information; rather technological literacy deals with other problems and situations in multiple professional or nonprofessional applications. For example, technological literacy in education may involve new e-learning projects using handhelds or other devices to assess and provide feedback to teachers and students. In healthcare settings, it may focus on the use of technological devices for Para clinical diagnosis and management of patient records. In politics, technological literacy might include the use of optical mark readers or other devices to process election ballots and produce instantaneous statistics and voting trends. Technological literacy positively affects the development of other cognitive, affective, or psychomotor competencies. Through its

Table 26.1 Examples of ICT skills or competencies

Concept	Examples of skills or competencies
ICT literacy	Access, manage, integrate, evaluate, create, transmit, or communicate information. Navigate in digital environments. Search, locate, retrieve, and selectively sieve sets of data. Classify, organize, analyze, synthesize, store, and creatively produce new information, according to specified formats Install, use, and apply digital or electronic devices, manage data and information. Use of telecommunications and other information-retrieval devices or programs with a computer. It may involve the ability to select how to use specific tools or devices
Digital literacy	Search, locate, organize, analyze, evaluate, and synthesize information to communicate, manage, produce, and perform other tasks with the information. Competencies are related to the management of the information itself rather than the use of any particular device
Information literacy	Search, locate, organize, evaluate, and use information, mainly as an information-retrieval activity where the Internet, databases, microfiches, and other digital documents are the resources needed for this particular application. Competencies are related to the information itself rather than its management or the use of a particular device
Computer literacy	Install, apply, and modify commercial or open-source operating systems and programs. Competencies are related to the ability to use and control the computer and peripherals
Technology literacy or technological literacy	Understand, select, apply, use, manage, and evaluate all kinds of technology or technological products and devices. Synthesize information, draw conclusions about consequences, and make creative interpretations, analyzing data and projecting forecasts or trends. Competencies are related to the use of particular devices to manage information or control specific tasks and data
ICT advanced and professional	Install, upgrade, and configure hardware and software. Verify and optimize the operation of peripheral and communication devices, perform maintenance activities, and update programs to protect the system against viruses and other undesirable software. Support server and network operations, manage and maintain permissions, passwords, and accounts on the various ICT users' levels

impact on higher order thinking, technological literacy induces individuals to acquire and develop further abilities (Wonacott, 2001). Technological literacy involves computer skills and the ability to use computers and related technologies to improve learning, productivity, and performance. In schools, it focuses on integrating the use of the information superhighway, multimedia resources, online learning, and e-assessment software and tools into the curriculum. Clearly, this definition of technological literacy requires the availability of equipment, trained personnel, and the most advanced hardware and software technologies and resources for connecting to the information superhighway.

Information technology literacy, originally defined as the set of competencies needed to use digital or electronic devices to manage data and information, has evolved into ICT to explicitly include the use of computers and telecommunications to handle information.

ICT competencies are multiple and contextual to the social, educational, professional, or economic environment (OECD, 2006, 2009). For instance, ICT professionals may be interested in the planning of network applications or in new solutions for technical problems in industry, hospitals, business, marketing, government, or education; alternatively, they may focus on the health of ICT users by developing ergonomically sound workplaces and sustainable environments. From a nonprofessional point of view, ICT competencies involve basic and general-purpose applications in the home or the office, such as using the Internet, producing and sending e-mail texts, or making simple calculations on a spreadsheet. These competencies integrate a wide range of tasks from basic manipulation of elementary software to advanced programming for problem solving.

Importance of ICT Assessment

Global statistics and indicators show that ICT development can have a positive effect on a nation's economy, social welfare, politics, and education (UNESCO, 2009). The use of ICT involves the availability of communication facilities within a country, investment in computers and peripherals at home, and technological resources at institutions using public funds.

ICT assessment can identify and measure several characteristics of the knowledge and skills of ICT users, as well as their attitudes and values concerning the use of this tool to solve daily problems. Evaluating ICT users' competency is essential to produce relevant, useful information. For example, governments may use this information to enact political measures to benefit the population, companies may develop training programs to improve productivity, and educational institutions may create courses to better prepare students for their society's current requirements for daily life.

In addition, ICT assessment allows measurement of the digital divide resulting from differing digital literacy levels among individuals and countries. These differing levels of digital literacy produce a gap between those who have high-quality access to information technology and digital resources and those who have low-quality resources or none at all. This digital divide correlates not only to the availability of hardware and software resources but also to the development of skills and knowledge. This knowledge divide results from sociopolitical and socioeconomic factors and reflects existing gaps attributable to gender, race, income, or disability. Among nations, the global digital divide between developed

Table 26.2 Sources of statistics on ICT

and underdeveloped countries is increasing at a very high rate, creating bigger gaps between economic groups and social strata within countries (especially gaps based on gender, the solutions of which may involve problems of structural change in some countries). Immediate action on a global scale may avoid major differences in the near future (Axelson, 2005; Katz et al., 2008).

Other statistics report the benefits perceived by ICT users, ranging from entertainment and personal or family gain to the greater convenience of educational and professional activities. Table 26.2 includes sources of statistics for various countries that may be useful to readers interested in the global status of ICT competencies.

Frameworks and Syllabus for ICT Evaluation

ICT assessment is grounded on validity, one aspect of which is content validity. Content validity is conveniently defined by the Test Blueprint or Content Validity Table (CVT), a matrix specifying the syllabus of content or objectives (generally on the rows of the table) that should intersect with taxonomical levels (generally on the columns of the matrix). The columns of the CVT require a taxonomy (or framework) to classify ICT competencies at levels of complexity that will translate to levels of proficiency.

A framework should be based on a multidimensional model that includes knowledge, skills (cognitive or psychomotor), as well as values and attitudes toward technology; taxonomies can be theoretical, empirical, or mixed, but they can also be developed by vendors of tests and educational materials. Within a framework, the definition of a competency consists of a sentence that describes what an individual knows or is able to do in a particular domain or content and in a specific context or situation. The active verb of a competency describes the action defined in the competency at one level of the taxonomy. The active verbs are organized in a hierarchical structure from simple memory tasks to complex decisions. For example, active verbs describing ICT cognitive competencies include search, organize, send, insert, add, retrieve, format, analyze, synthesize, design, evaluate, and construct. Verbs and verb phrases such as be sensitive to, be interested in, protect and respond ethically to, and be aware of are used to define affective domain competencies.

Bloom's (cognitive) and Krathwohl's (affective) general-purpose educational taxonomies remain valid frameworks to construct CVTs, but more ICT-oriented frameworks have also been proposed. These have included nomenclature appropriate to ICT content, although their descriptions of cognitive and attitudinal levels remain very similar to those of general taxonomies (Tannenbaum & Katz, 2008; UNESCO, 2008).

For example, the Scottish Electronic Staff Development Library (Campbell, Littlejohn, & Duncan, 2001) organizes technological literacy in six categories: communication, learning, use of the Internet, standards, and educational hardware and software. Competencies include management and creation of files and documents; communication through e-mail, the Internet, and videoconferencing; planning and design of models, procedures, and algorithms; knowledge of standards and computer safety; and the competent use of the computer and its software and peripheral equipment. Tomei (2005) suggests a six-category framework for the technological domain ranging from basic literacy to evaluation of technology's impact and influence on teaching and learning applications. The Standards for Technological Literacy (ITEA, 2007) outline what a technologically literate person should know and be able to do at each academic grade level from age 6 to 18. These Standards provide 20 specifications in five major categories:

1. Fundamentals of technology and connection with other areas
2. Role of technology in society, culture, and the environment
3. Design of applications and solutions to engineering problems
4. Ability to use technological products and systems in everyday life
5. Applications in seven areas where engineering and health represent a primary focus (e.g., transport, construction, health, agriculture, and ICT)

The test blueprint or CVT is translated into a syllabus describing the complete curriculum (or outline of the content) that will be covered by an individual in an educational course or an assessment program. For ease of presentation, a syllabus may show only the content and omit the competency components, but it should be clear that every area of the syllabus must cover all the taxonomical categories, from simple to complex, by defining expected competency levels from beginner to expert.

An ICT syllabus may target digital competencies for the everyday applications used by a digital citizen, excluding some applications that concern informal activities (entertainment and games) and other competencies that may correspond to advanced applications (for example: desktop publishing and professional photo editing, video and sound production). Particular activities or professional skills may require other competencies such as project management or CAD/CAM/CAE/CNC for drafting and engineering; patient registry, clinical information, and management software in medicine and nursing; and accounting and financial software for administration and investment professionals.

Some commercial syllabi are targeted to specific social groups. Such groups may be older adults (basic tools for the e-citizen or the digital citizen); governmental officials (e-government); technicians in hospitals (e-health, e-clinical); and clerical, secretarial, and commercial employees (e-office, e-business, e-commerce) (Kalu, 2007; Omona & Ikoja-Odongo, 2006). New digital literacy projects could be proposed for other groups, including the consular service of a country, armed forces, call center or telephone company employees, industrial plant or laboratory personnel, technical staff in thermal or nuclear plants, journalists in news agencies, and many others.

Since 1996, more than 60 countries have recognized the certification program known as the International Computer Driving Licence (ICDL or ECDL for its European version, www.ecdl.org). This program defines a core of seven modules that include the basics of ICT, use of the computer and operating system, and a subset of standard office tools (word processor or text editor, slide presentation, spreadsheet, database management, information and communication).

From the frameworks and projects discussed above, it is possible to identify the topics and applications that are considered essential for ICT literacy. It is important to notice that the syllabus may differ from a specific program in a certain academic environment, but it represents the set of areas to be covered by a competent ICT literate person. We have combined the proposals found in these previously mentioned frameworks to propose the following general syllabus for assessment of core ICT competencies:

1. ICT environment: Principal components of a computer, use of hardware and peripherals (desktop and laptop models, monitor, keyboard, mouse, ROM and RAM, ports, use of printers, scanners and other digital devices, CD/DVD burners, data transfer to and from USB devices), operating systems (BIOS, MS Windows®, Mac® or Linux®, freeware and open systems, logical units, registry), networking (intranet, extranet, client-server), and graphical user interface. Career opportunities.
2. Human aspects of ICT: Security and privacy measures for protection of computers and ICT users (passwords and authentication, virus protection, spyware, proxy and firewall); health and ergonomics (design of work areas, guidelines for computer use and posture); environmental protection (resources, electricity, minimizing ecological impact, avoiding paper waste). Attitudes and computer ethics (positive attitude toward ICT and confident use of its resources, use of other abilities and skills to improve ICT management, active participation in ICT forums, blogs, and courses to improve ICT skills).
3. Folders, files, and documents: Organizing folders and files (file managers, hierarchical organization, and size of files). Definition of files and the most common file types (document, image, plain text). Searching for documents and retrieving content. Management of files (copying, moving, locating, and retrieving a file; checking, defragmenting, and cleaning a disk unit; sharing and modifying file properties).
4. Text processing: Templates and document creation (letters, essays, memoranda, notices, technical or commercial letters). Page configuration and styles. Use of headers, footers, and pagination (portrait and landscape page formats). Text and word processing. Paragraph formatting. Copy, cut, paste, and insert functions. Tables. Management of objects (graphics, images, formulas). Spell-check and language tools. Document publishing.
5. Spreadsheet: Organization of spreadsheets and applications (workbooks, calculations, databases). Using and formatting cells. Functions, formulas, and cell references. Spreadsheet formatting. Creation of charts and graphs (e.g., bar, pie, trend).
6. Computer-assisted presentations: Templates and creation of slide presentations (e.g., reports, educational or training sessions, promotional and marketing). Design of slides and display options. Publishing presentations.
7. Database management: Organization of a database and applications (tables of objects, commercial data, and contacts). Using data fields and clusters. Functions and formulas. Searching, sorting, and retrieving data units. Publishing a database.
8. Electronic mail: E-mail management (address books and electronic addresses). Sending and receiving messages (opening and reading messages, responding to messages, composing and sending new messages). Electronic messages (parts of a message, the message body, and attachments). Security and protection (precautions when receiving and sending new messages, spam, scams, and phishing).
9. Image handling: Use of photo editing software (crop, resize, rotate, zoom, copy, color, and black and white functions). Use of painting and drawing software

(color, brush and pencil, erase, adding text to an image, graphic manipulation in vector or raster formats). Import–export in multiple formats (e.g., jpg, tiff).

10. Information technologies: Internet and access to information (connectivity and the information superhighway). Virtual sites (World Wide Web, e-commerce, social networks, and other virtual groups; blogs, forums, RSS, and podcasts). Web and related tools (browsers and search engines; HTML and other file formats, pop-ups and cookies, Web authoring software, and publishing of Web pages). Security and the dangers of virtual communities (alteration or theft of code or personal information, hackers and unexpected intrusion, types of computer viruses, virus detection, and protective software).

Requirements for the Assessment Environments

As with any evaluation project, ICT assessment must incorporate standards that provide evidence for the quality of three primary aspects of evaluation: validity, objectivity, and reliability. In addition, ICT evaluation needs to consider access for disabled users and the use of sophisticated software for special applications (AERA-APA-NCME, 1999).

Teachers may consider that existing technology (such as platforms like Google, Yahoo, and other navigation tools) offers a satisfactory assessment platform of "real" or "authentic" tools and environments in which students can produce e-portfolios to demonstrate their ICT competencies. However, this method has at least two problems:

First, it is time consuming because teachers must supervise the student and spend several hours to analyze and score the products included in the e-portfolio and second, it does not eliminate subjectivity despite the use of a rubric. To solve these two problems evaluators may consider virtual or simulated environments or "real tools" that incorporate measurement models in an objective scheme (Smith, 2007), having the advantage that may be used for academic, professional, and certification purposes.

Virtual learning environments (VLE) or learning management systems (LMS) are software platforms consisting of e-learning tools for authoring, data management, planning and structuring educational curricula, homework tracking, forum/blog/chat communication, Web publication, and course management and assessment. Moodle is one well-known, noncommercial VLE product; commercial examples include WebCT, Blackboard, and Virtual Campus. Assessment is a minimal component of these platforms, for two reasons. First, they do not provide relevant psychometric models to score tests; in fact, classical test theory, logistic models, and IRT or Rasch models are rarely included—and in some cases actively avoided—in the development of VLE software. Second, these platforms do not focus on evaluating specific ICT competencies; they provide only a few tools (such as closed-response items) that can be used to assess ICT competencies covering the core syllabus described in the previous section.

Two major issues with computer-based tests must be solved: First, video monitor size and resolution must facilitate test administration for persons with low vision and second, visualization of test items. Computer-based tests should not be merely computerized versions of paper-and-pencil tests. A good visual interface must allow back-and-forth browsing of items and provide information on test status (such as missing items and elapsed and remaining time).

Output feedback is important to provide recommendations for individual test takers; however, it seems preferable not to report details about correct and incorrect answers, especially if the student may submit a test several times, as this may artificially maximize the score without representing a real improvement in competency.

ICT assessment software must work in multiple environments with a variety of hardware (desktop and laptop, handhelds, touchscreens, in-classroom assessments) and software (open-source, Microsoft® or Mac® operating systems). The selection of the most suitable device and platform depends on the application, facilities available (Web, broadband, and Wi-Fi capabilities in a country or a region), and the economic resources of the project. Paper-and-pencil tests will still be used in certain environments where one computer per student is an impossible goal. In these settings, new logistics rules should be implemented to change the practice of assessing all students at one time, along with incorporating improvements in student ethics to prevent cheating. Table 26.3 demonstrates that it is possible to use 20 computers to administer 1-h tests every month to a group of 20 students taking five courses. However, it becomes impossible to use this kind of assessment in a school with 500 students if only 20 desktop computers are available at the school for all educational purposes (teaching, learning, Internet and Web navigation and research, and grading and giving feedback on assignments). Test designers should consider the fact that this unfavorable scenario is very common in underdeveloped countries where ICT is not widely used, where computers and software are out-of-date or where schools have no Internet access or even no electricity at all.

Software for item banking organizes the database, provides multimedia capability for editing items, and generates tests that can be used in either paper-and-pencil or online versions. The most common environments for online testing are local area networks, which are usually supervised by a proctor to authenticate student identity and to ensure the security of the testing system against cheating. Testing at home or in uncontrolled settings is used only for homework, assignments, surveys, and other low-stakes tests because it is impossible to practically standardize and control the conditions of the testing environment or to prevent the availability of external tutors and resource materials.

Table 26.3 Infrastructure requirements for assessment in two educational scenarios

Element	Scenarios	
School	A	B
Number of students	20	500
Computers available	20 (1 laptop per student)	20 (general-use desktops)
Availability of computer time/day	$6 \times 20 = 120$	$6 \times 20 = 120$
Courses to be evaluated every month	5	5
Total hours/month × students	$1 \times 5 \times 20 = 100$	$1 \times 5 \times 500 = 2{,}500$
Days needed for assessment/month	$100/120 = 0.8$	$2{,}500/120 = 20.8$

Online Testing

First-generation online testing platforms merely adapt paper-and-pencil tests, quizzes, and questionnaires to a computer environment (Higgins, Patterson, Bozman, & Katz, 2010). This kind of testing software has two operating modules: management module and testing module.

The management module is controlled by a proctor who monitors the testing area, sends messages to students, solves operating problems, and checks progress during the test (Fig. 26.1).

The testing module is an environment that provides the student with a very simple and user-friendly interface to answer test questions and receive feedback, if appropriate to the test (Fig. 26.2). This module controls the flow of items and, depending on permissions built into the test, can allow the student to go back and modify answers, to ask for hints or access to information capsules giving some help to answer the items, to view a video, or to hear a sound or a piece of music.

An environment for online testing as described here can have several applications for ICT assessment and can address all the topics on the core syllabus described in the previous section. How a question must be answered and how the answer must be submitted can involve one or several competencies within the ICT framework: searching, organizing, analyzing, sending, retrieving, and so forth. The creativity and imagination of the test designer play an important role in achieving the goals of assessment in this environment.

Other capabilities offered by these environments include multimedia resources, simulations, and instructions for specific actions to be performed in a certain sequence. Computerized adaptive tests (CAT) represent another online option. Adaptive tests are based on the psychometric properties of the items and the student's response patterns. CAT requires logistic models to score responses and to determine when to stop administering items, at the point where the student's measurement is convergent to a stable value. With this option, it is possible to assess other kinds of competencies in addition to the core syllabus, for example, those required for professional and health specialties (Ylizaliturri, 2007).

Several studies show no significant differences in scores on a single test administered under different management schemes, from paper-and-pencil to online testing (Cole, MacIsaac, & Cole, 2001). However, security represents a major problem, particularly the need to authenticate student identity; a huge investment in hardware and software is necessary to restrict the use of e-mail and Web pages, opportunities to work with tutors, and other unexpected instances of cheating. Despite the investment, computer-aided testing produces some benefits, for instance: management simplification; reduction of time and effort for teachers and students, elimination of expensive optical forms and optical mark readers; low frequency of errors during input; feasability to use free-response essays.

Other environments provide tools for opinion polls and attitude surveys in a spreadsheet-like environment. In other situations, an assessment may require submitting an essay or other document produced on a text processor or a Web page. New testing techniques may involve the use of a text processor to produce an e-portfolio; however, this capability is not sufficient because more advanced scoring techniques are required to reduce or eliminate the need for teachers to score responses.

Analyzing a sequence of actions performed by a student on a text processor and measuring the quality of the response and the ICT competencies involved may be based on data mining and automated essay-scoring engines that use lexical techniques and knowledge bases, artificial intelligence, and other heuristic methods. The sequence of steps used by the student in a response is stored in a log file during the session that can be reviewed to determine the number of failures and correct actions; it is also possible to obtain a measure from the combination of commands, mouse movements, or keyboard actions that a student performs. These actions are compared to one or several sets of commands that an expert could perform to solve the task or the problem presented in the test. With these techniques, it is possible to automatically score the use of specific tools, such as the production of a document in a text editor or in a presentation environment, the calculations on a spreadsheet, the integration of an e-portfolio, or any other ICT application. Many specific examples of how automated scoring works and how it's being used as well as its growing importance in education have been reported in research and case studies in several coun-

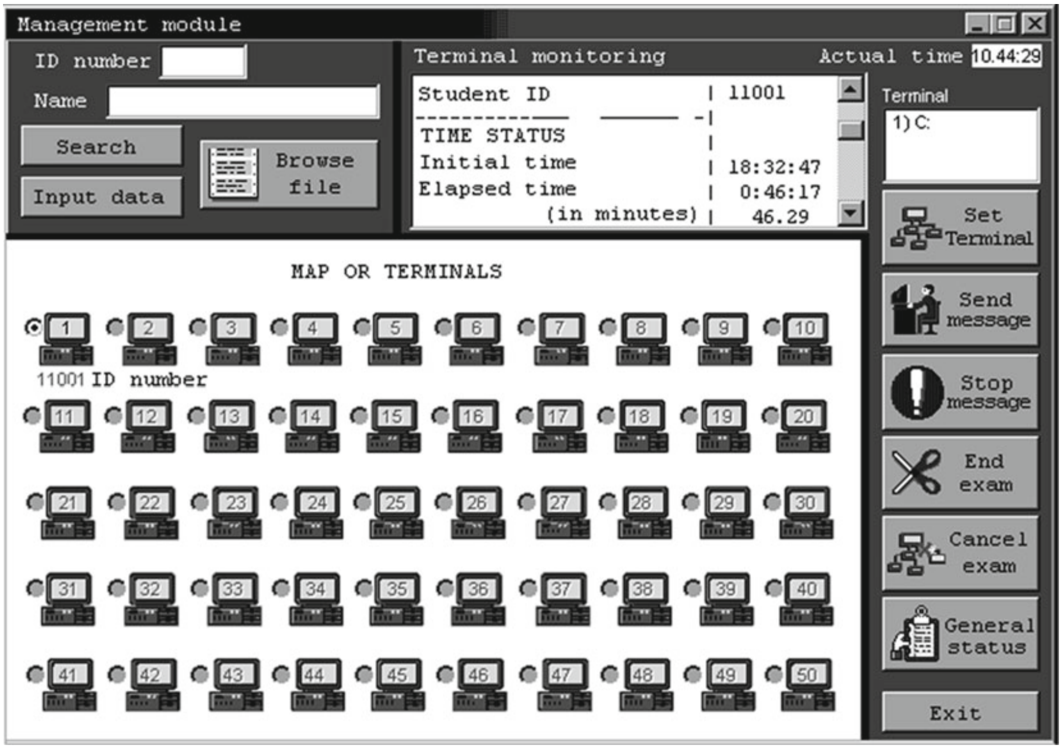

Fig. 26.1 Management module for online testing. Reproduced with authorization by IEIA

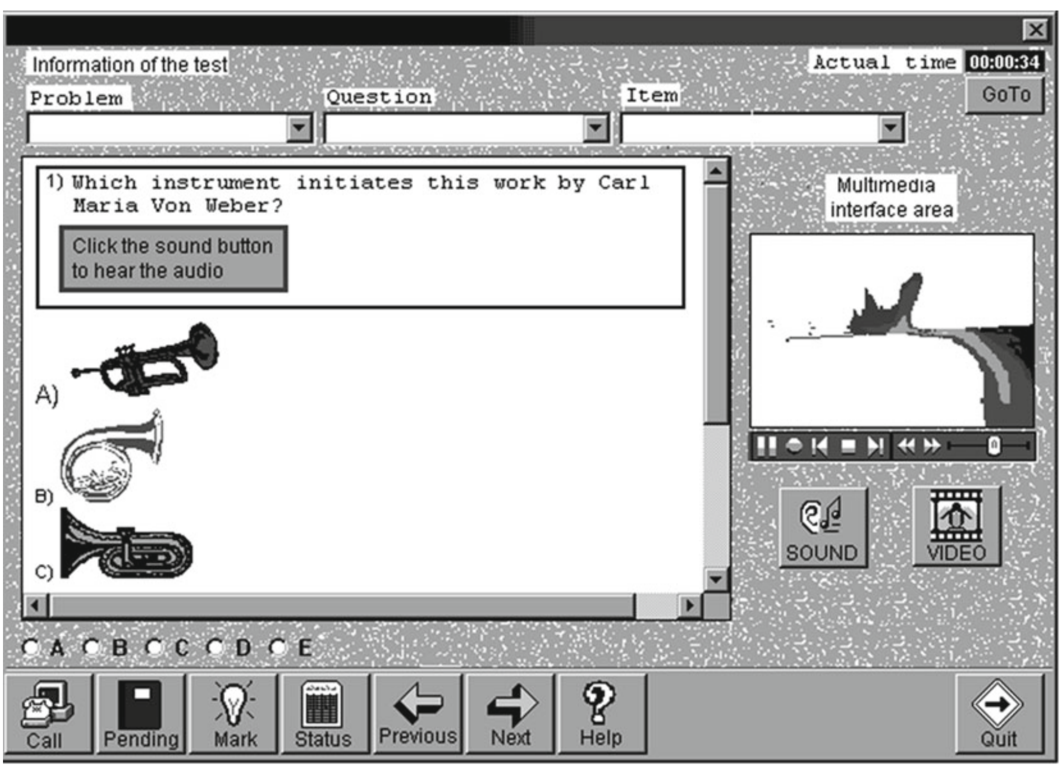

Fig. 26.2 Testing module for online testing. Reproduced with authorization by IEIA

tries (Dikli, 2006) and educational conditions: for the GRE, TOEFL, and other Educational Testing Service (ETS) tests (Attali, Bridgeman, & Trapani, 2010); e-portfolios and Web 2.0 (Kelly, 2007; Mason, Pegler, & Weller, 2004); geometry tests (Masters, 2010); essays in Spanish (Tristán, 2007); and complex tasks (Williamson, Mislevy, & Bejar, 2007).

Several vendors in more than six countries involved in ECDL programs produce courseware and assessment software that include advanced visualization capabilities using Flash® and similar tools to record students' activities. These software products include some tools provided for the management and marketing of the product; however, these vendors are not interested in psychometric models for measuring student competency.

The ETS provides an online scoring service for essays (Criterion®, www.ets.org/criterion) based on an automated scoring engine (e-rater®) proposed by Monaghan and Bridgeman (2005). Other companies also offer solutions in this area: IntelliMetric (www.vantagelearning.com) has an artificial intelligence engine for scoring essays using natural language models of English; IEIA (www.ieia.com.mx) offers an online testing system including multimedia simulation of clinical cases and automatic scoring of essays in Spanish with adaptive options.

ICT-Simulation Assessment Software

Existing assessment techniques for academic or certification purposes have adopted the intensive use of software to assess computer skills in an environment that simulates "real" platforms and real-world situations, according to the specifications of the syllabus presented previously. Simulation software requires design tools both for items and tests; options for customizing the appeareance of the environment to be used by the student or candidate to solve the items and perform the requested activities; network management tools to control a local network or an Internet platform; scoring modules with statistical and measurement models to produce feedback reports.

This kind of assessment platform provides an environment that simulates a suite of windows-based ICT software tools to be used by a student (called candidate) to perform actions defined as a sequence of tasks created by the test designer. All activities and actions are stored by the system in the form of log files that are subsequently processed by a data-mining model and a lexical analyzer to assess the quality of candidate's products, as described previously.

ICT-Simulation Assessment Software (ICT-SAS) is not a local solution in a single country; instead it has been developed for ICT certification or national assessments by institutions such as the Australian Council for Educational Research (ACER, www.acer.edu.au) as mentioned by Ainley and Fraillon (2007), the ETS (www.ets.org) in the United States, Algebra in Croatia (www.algebra.hr), Instituto de Evaluación e Ingeniería Avanzada in Mexico (www.ieia.com.mx), WebScience in Italy (www.webscience.it), Activsolutions in the UK (www.activsolutions.co.uk), and higher education in the United States (Katz & Macklin, 2007), and Mexico and Latin America (Tristán & Ylizaliturri, 2008).

There are several benefits of this technology:

1. Flexibility to use one or several tools according to the set of tasks defined by the designer.
2. Possibility to define a fixed sequence of tasks or to leave the candidates to solve according to their needs.
3. Possibility to get measures of actions or products; then the designer may focus on the procedures or on the results according to particular needs.
4. Independency of specific brands or platforms through a neutral environment.
5. Capability to grow in parallel to future developments for academic, professional, or any other social environment or orientation.
6. Ability to produce psychometric indicators of the quality of the tasks, the activities, and other elements concerning the scale, reliability, and standard error using classical test theory or logistic models. These capabilities may be partially developed using other environments such as Google® or Microsoft Office® but the experience has shown that some of those environments have disappeared or are no longer representative (Eudora, geocities, Lotus, or dBase) while the competencies to be evaluated are practically the same.

Software for ICT-SAS is organized in three modules:

1. Test design, where an expert test designer can describe the tasks to be performed by the candidate, the scoring model, the type of reports, and other test characteristics.
2. Test administration, where the manager of the test can control all testing activities from a server.
3. Test workstations, or terminals, within a local network environment where the candidate will interact with the ICT tools.

A beginner designer can receive training to produce valid and objective assessment tasks in accordance with the purpose of the test; reliability is controlled by the software and the statistical models.

In ICT-SAS candidates do not answer questions. Instead, candidates perform a series of tasks simulating a real-life situation. Each task can comprise two or more activities, which can be categorized as actions or exhibits (Fig. 26.3). The designer should consider the most appropriate items to divide an activity and the possible options to solve them. The software must be able to document procedures that lead to the expected solution in ways not anticipated by the designer. These nonstandard options should be included in the platform's knowledge base and used during the scoring procedure for other candidates. The module for test design provides the tools to specify a test and all its combinations of actions and exhibits obtained during online testing.

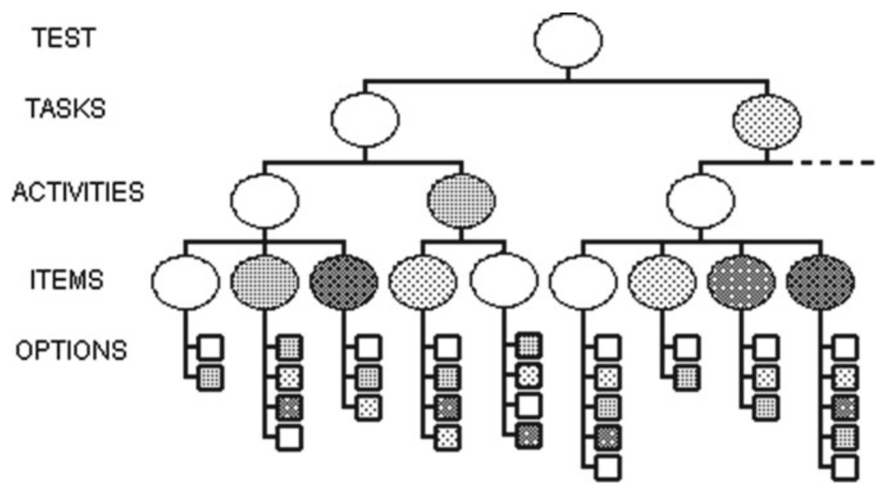

Fig. 26.3 Hierarchical scheme for ICT-simulation assessment software

Fig. 26.4 Desktop environment for ICT-simulation assessment software. Reproduced with authorization by IEIA

Experience with this kind of testing environment can be used in an educational environment, but it is not limited to this focal group. On the contrary, it can involve a wide range of ICT users from children to older adults and from beginners to experts, and has demonstrated its suitability for assessment of ICT competencies in more than 60 countries (ECDL, 2010). Despite the artificial appearance of the platform, the advantages of this environment include time efficiency, little or no anxiety experienced by candidates, and the ability to customize applications in different languages and contexts, not associated with a specific commercial brand. An ICT competent person may work in this platform with a minimal training of less than a minute previous to the administration of the test. The ICT-SAS platforms include a short tutorial that can be studied in 5 or 10 min.

The ICT-SAS platforms provide what is defined as a neutral windows environment, independent of commercial products, based on tools and an online screen display similar to the samples presented in the following figures. ICT-SAS follows the basic syllabus core, including the following:

Desktop: Windows-style main screen where the system controls procedures and runs different applications (Fig. 26.4). At the left of the screen there is a zone to display the tasks or the activities to be performed by the candidate. Other area shows the tools and there is a special area to display messages from the software.

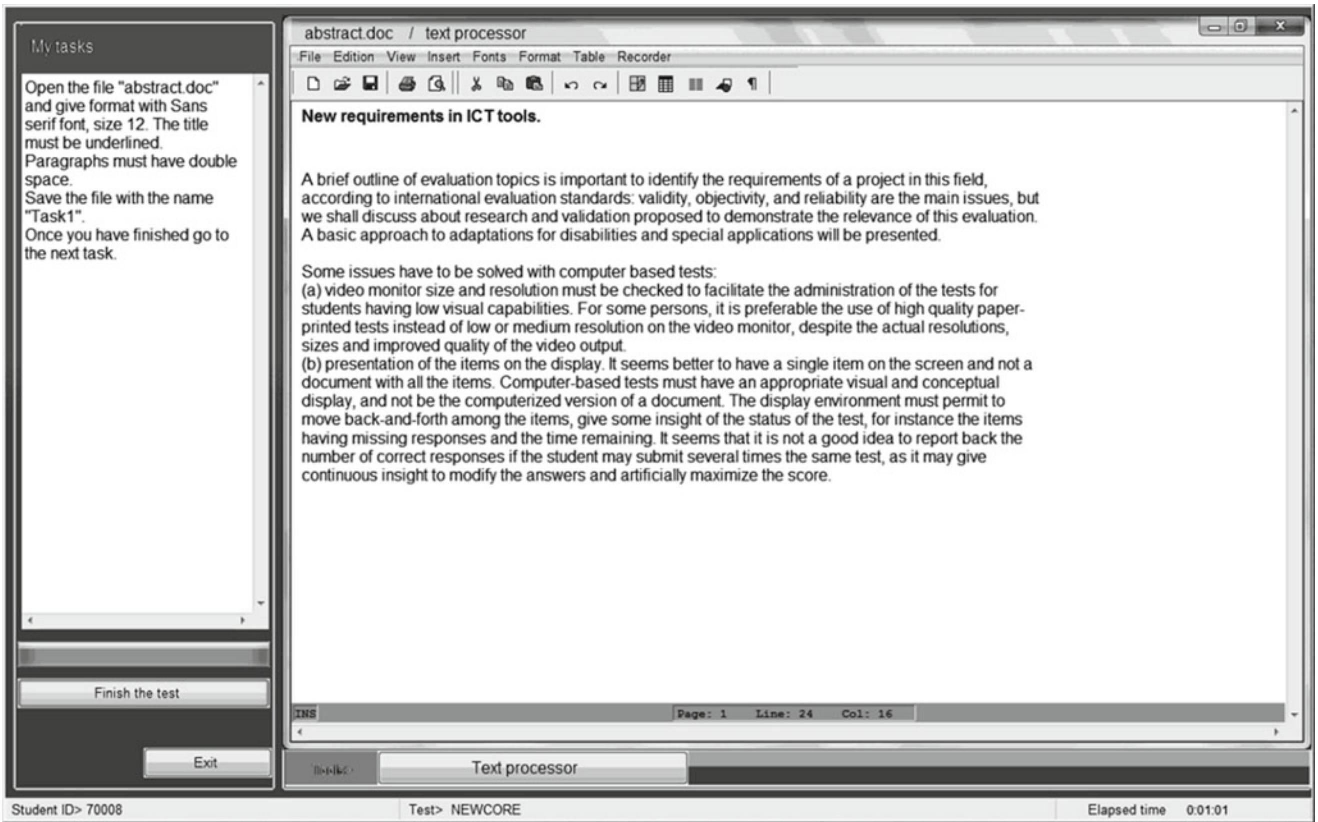

Fig. 26.5 Text processor for ICT-simulation assessment software. Reproduced with authorization by IEIA

Operating system: A file browser is used to browse the directory tree to create, rename, copy, and delete folders or open, save, copy, and delete files.

Notepad: Contains a simplified text editor. Functions include open, save, write, copy, and paste text.

Text processor: Simulates the essential functions of a text editor (Fig. 26.5): open, save, and close files; fonts (type, size, color, bold, italic, underline); and paragraph formatting (such as justification, centering). Vignette management (numbers or symbols), design of tables (defining horizontal and vertical cells, background color, and borders), insert, delete, copy, and paste.

Worksheet: Simulates a grid or a matrix to manage data and functions with spreadsheet features (Fig. 26.6) like open, save, and close files; cell selection and format (numeric, text); menus to perform calculations using basic expressions (sum, average). This module allows the candidate to format data as well as create graphs and sorting options.

Slide presentation: Permits the person to produce, capture, and display a set of "slides" including competencies such as open, save, and close files and the presentation itself; insert, copy, paste, delete, and edit slides; slide design in three basic models (filled area; filling two horizontal zones; title and contents filling two vertical zones); typefaces (fonts, sizes, colors, bold, italic, underline); paragraph formatting (such as justification, centering). Vignette management (numbers or symbols), design of tables (defining horizontal and vertical cells, background color, borders), insert background and display presentation (no special effects).

E-mail: This module simulates an e-mail client. With its main features, the candidate can send and receive fictitious messages, attach documents, and manage the inbox, outbox, address book, and more.

Internet: Lists pages in html for the candidate. This application simulates the Internet search engines and browsers, using fictitious Web pages whose content is limited only by the designer's imagination.

Database: This tool allows the design of data tables and edit, search, and browse functions, using table views and forms.

To use this kind of platform, the test designer has to build a script using pseudo code or, depending on the producer of the platform, a command recorder that simplifies the construction of the sequence of commands. A command is the combination of the ID number of the application tool plus the code of the function to be performed. Every step

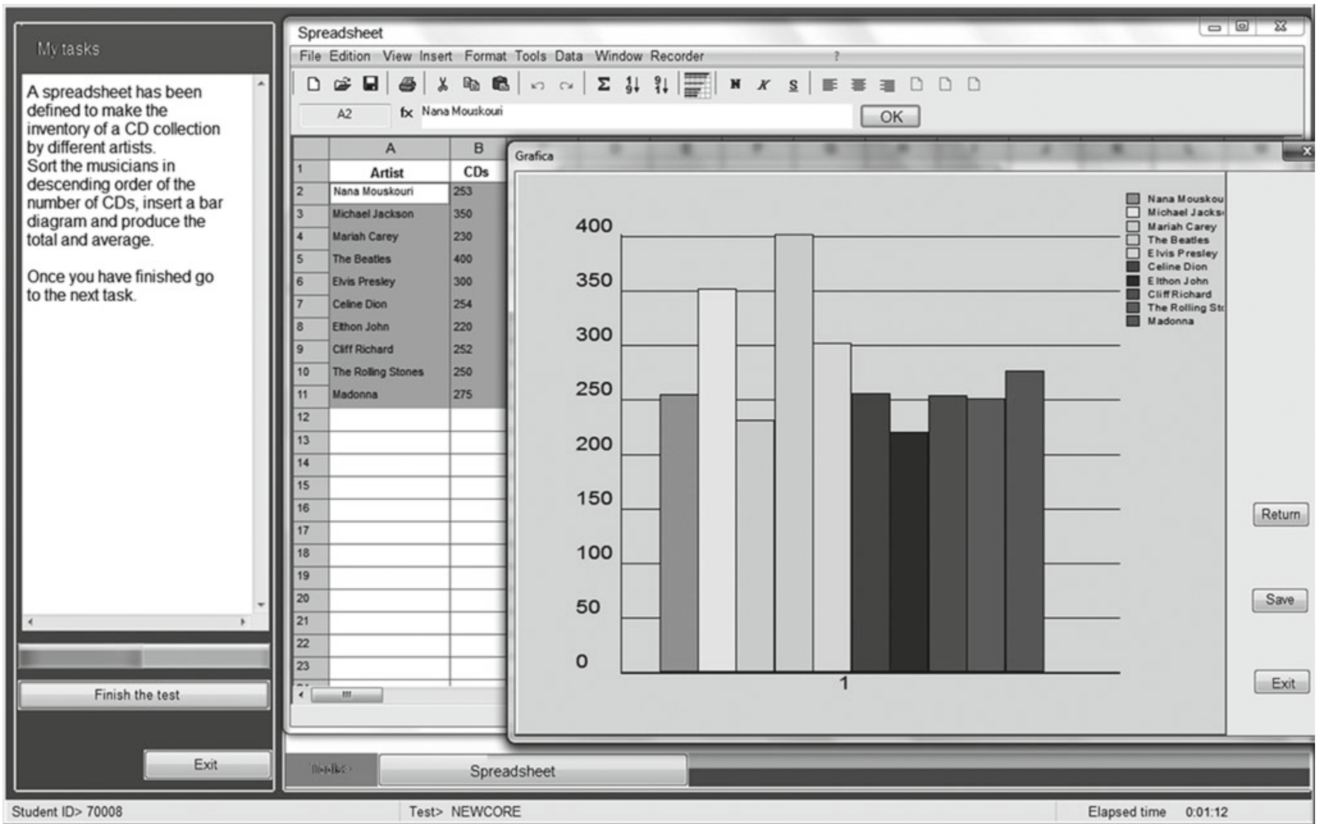

Fig. 26.6 Spreadsheet for ICT-simulation assessment software. Reproduced with authorization by IEIA

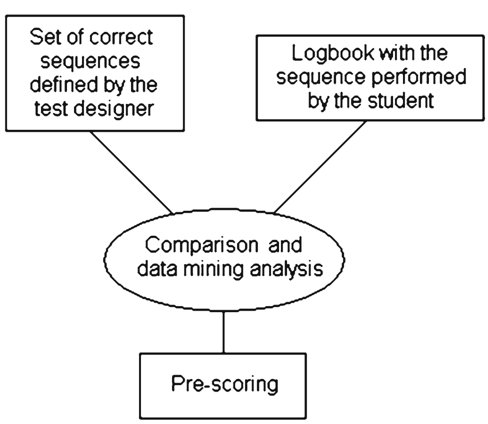

Fig. 26.7 Scoring scheme for ICT-simulation assessment software. Reproduced with authorization by IEIA

produced by the candidate is encoded and can be compared with the sequence of commands that should be produced by the candidate. The recorder can be used to store all the steps performed with the tools; a backup is stored in a log file for later use. All commands stored in the recorder may also be reproduced and can be used as a tutorial or to verify the sequence produced by the candidate.

The scoring process and the production of feedback reports are organized in three subprograms: prescoring, scoring, and reports (Fig. 26.7).

Prescoring compares the script with the sequence of actions performed by the candidate as stored in the log file. The prescoring review uses data mining technologies and may follow multiple criteria to score the whole set of commands or a minimal subset of critical commands.

During scoring, the software uses the prescore registry and counts correct and wrong sequence of commands for each task or activity where the pseudo code is an important tool for scoring (Fig. 26.8). Raw scores can be assigned according to various criteria following classical test theory (including or excluding omissions). Measures using Rasch or IRT models, may be calculated with maximum likelihood or other schemes based on the item's psychometric parameters.

Report capabilities provide two types of reports suitable for this kind of assessment. A test report may be produced on a template including the candidate's name, the school or the location, date, answer sequence, number of correct steps, and actions or sequences that are translated into a raw score. A feedback report contains a set of recommendations for each candidate based on the level of achievement and the competencies demonstrated on the test.

Conclusions

ICT literacy is a means to empower people in situations where minorities suffer from unfavorable conditions, for example, in countries where women's rights are constrained by law or tradition. ICT assessment can be used for academic and professional certification purposes, or even as a way to increase self-esteem at home, regardless of people's age or social condition at any level of education. As a result, some minority groups which hadn't had the chance to attend a school for example can still become ICT literate (to a certain extent). In these situations, people may consider ICT a tool that represents new labor options or a way to have better opportunities for education, learning, and professional and personal growth. For this reason, ICT assessment is of paramount importance in the modern world.

Online testing is a feasible method to assess ICT competencies. Some approaches were presented from the use of environments able to submit questionnaires and quizzes that are mostly a computer version of paper-and-pencil tests, the use of e-portfolios and other Internet tools, and up to simulated environments where the student must produce documents, search information, send messages, and perform other ICT actions.

ICT assessment instruments and software should incorporate psychometric models to obtain valid, objective, and reliable measures of the competency level of students or professionals in specific contexts. That is the reason why simulators are a suitable option for online scoring of the actions performed by the student, for automatic scoring of a text, and to produce feedback reports that improve the way to identify the ICT competency level of the person.

Existing developments focus primarily on simulated environment software, because it allows actions performed in the simulation to closely mirror those performed with real tools. This type of assessment software provides a "neutral" impressive visual platform similar to real digital applications (but not linked to a single product or brand) and may integrate measuring models in a powerful way, including statistical and psychometric models for item and test calibration.

27 Data-Driven Decision Making in the K-12 Classroom

Trent E. Kaufman, Charles R. Graham, Anthony G. Picciano, J. Aaron Popham, and David Wiley

Abstract

During the past decade, data-driven decision making (DDDM) has been at the forefront of many discussions on how to improve public education in the USA. Professions such as medicine, business, politics, engineering, etc. have embraced a data culture and built tools to systematically collect and facilitate analysis of performance data, resulting in dramatic performance improvements. Every day the public depends on companies like Google that collect and aggregate data in ways that help us make decisions about everything from online purchases, to stock investments, to candidate selection. This chapter introduces current research undertaken to bring comparable advantages to education, with the goal of helping classroom- and school-level stakeholders incorporate DDDM as integral to their work. The chapter outlines several different theoretical perspectives currently applied to the DDDM challenge, including the lenses of cultural change, assessment, implementation/adoption, and technology. The bulk of the chapter focuses on research related to models of successful local DDDM implementation, including the design of technological tools and processes to facilitate collection and analysis of actionable data in ways previously not possible. The chapter concludes with implications for research and development that are relevant to those in the fields of instructional technology and learning sciences.

Keywords

Data-based decision making • Data-driven decision making • Evidence-based practice

Introduction

Everyday examples of data-driven decision making (DDDM) include the nearly ubiquitous systems that continually provide unsolicited suggestions. If you buy a book on Amazon, Amazon will use a sophisticated collection of data and algorithms to recommend other books. If you rent or stream movies from Netflix, Netflix will track your data and recommend more movies. The Genius feature in iTunes recommends additional music based on the genius of data. Even your neighborhood grocer probably prints personalized coupons based on data concerning your purchasing behavior.

While a broad array of businesses and organizations now rely heavily on empirical data to drive continuous quality improvement, education seems to lag behind. As Wayman

J.M. Spector et al. (eds.), *Handbook of Research on Educational Communications and Technology*,
DOI 10.1007/978-1-4614-3185-5_27,

(2005) wrote, "Turning data into information has long been a staple in fields such as business and medicine, but the use of student data for educational improvement has not been widespread" (p. 235). Use of empirical data to inform decision making appears under a wide array of names in a broad range of practices: e.g., *business intelligence*, *data-mining*, and *analytics*. The authors who have applied the topic to education use terms including *data-based decision making*, *evidence-based decision making*, and *data-driven decision making*.

With data driving recommendations and affecting decisions in so many fields, educators naturally ask what educational benefits might come from applying these techniques to teaching and learning. Through an examination of current and emerging research and practice, this chapter explores the implications of DDDM for the classroom setting and larger K-12 educational context.

Theoretical Framing of DDDM

No single existing framework is sufficient as a foundation for understanding a complex organizational process such as DDDM. This section integrates concepts from a few existing frameworks setting a basic definition of DDDM, introducing the role of teams and collaboration in DDDM, and the potential for technology to enhance DDDM in education.

DDDM is the use of data analysis to inform choices involving policies and procedures. Data analysis informs but does not replace the expertise, intuition, and judgment of competent educators. Inherent in this definition is the development of reliable information resources to collect and analyze the data on which decision making depends (Picciano, 2006).

Decision making may be defined as choosing among alternatives. In a school organization, decision making is integral to complex management processes like academic planning and policy making. Fundamental to the definition of DDDM is assumption of a rational process directed by values and based on data.

Rationale decision making requires participation by relevant stakeholders and information that will help all who are involved. Much literature is available on the importance of collaboration in decision making, especially as applied to education. Authors such as Senge (1990; learning organizations) and Wenger (1999; communities of practice) see collaboration as crucial for organizations to thrive. In a sense, organizations are considered as organic entities that learn and advance, advance and learn. Sergiovanni and Starratt (1998) reenvisioned educational administration as reliant on "organic management" that makes the promotion of the community the "centerpiece" of supervision.

These patterns of collaborative behavior are not typical in K-12 schools especially in data-based conversations and decision making, prompting Elmore (2004) to express concern that teachers have not been encouraged to engage in organizational decision making dialogue, nor are they given sufficient time to do so. The above authors have promoted concepts to change school management from the bureaucratic top-down style to an increasingly collaborative activity, lined with information sharing, especially regarding the use of data as the fulcrum upon which communities develop. Later sections of this chapter illustrate these suggested changes in practice.

Technology has long promised to improve educators' ability to collaborate in the face of limited time and structure to do so. The evolution of the Internet, for example has allowed timely data to be distributed throughout organizations. Watts (2003) and Birabasi (2002) have studied the effects of networks on various people-intensive processes and found that technological networks can enable individual behavior to aggregate into collective behavior, as individual entities interact to form larger collaborative groups Whether through technology or not, harnessing the collective capacity of a school to improve the teaching/learning experience is an important element of DDDM.

Implementation Contexts for DDDM

DDDM takes place in a wide variety of contexts, from the federal and state levels down to the classroom and individual student levels, each with its unique "reporting and analytical needs" (Thorn, 2001). Currently DDDM is most prevalent at the top levels at which accountability measures such as *No Child Left Behind* (NCLB) have required systematic collection and analysis of high-stakes test data. At the same time there is general consensus that DDDM can have the greatest impact at the local classroom level (Means, Gallagher, & Padilla, 2007; Means, Padilla, & Gallaghar, 2010). This section of the chapter briefly outlines the various contexts in which DDDM takes place, as well as the nature of the data that are useful at the various levels.

State/Federal Level

Federal and state legislation related to school accountability has been a primary driver of the increased emphasis on DDDM in the USA. DDDM at this level is characterized by high-stakes statewide testing that is usually administered once per school year by each state. Many of these high stakes tests have an origin in the 1990s with the standards movement, which culminated in the reauthorization of the Elementary and Secondary Education Act (titled "No Child Left Behind") in 2001.

Data collected as part of No Child Left Behind, while intended to support teaching, is more appropriate as data for state and federal level decision makers. Chen, Heritage, and

Lee (2005) indicate that these "annual tests tell teachers how well students did on the test, but they give limited information about what students did well on, and even less information about why they did well" (p. 310). The indication of which students did well on which topics is a significant improvement upon having no such information. However, teachers need information on why students did well or poorly in order to change instruction to change the outcomes. The summative nature and timing of the assessments used at this level provide very little information that is useful to educators within a school year (Crawford, Schlager, Penuel, & Toyama, 2008).

Instead, end of year state tests that are mandated by the federal government are best used to identify changes in performance across school years. The time required to score and report on these tests is typically 2–5 months, which again makes them more useful to state and federal policymakers who make programmatic and policy decisions than those looking to make immediate decisions (such as classroom teachers).

School/District Level

A significant focus in DDDM has occurred at the district and school levels. Schools and districts are trying to implement both human and technological processes that encourage DDDM. Districts continue to fulfill compliance requirements from state and federal bodies, but those requirements are no longer new. Therefore, more attention has turned to creating processes that inform decision making that is intended to impact student outcomes.

Wayman and Cho (2007) highlight common approaches that districts and schools are adopting to create human processes for DDDM, including common planning time, dedicated collaboration time, and subject- or grade-level teaming. An example of school level teaming for DDDM can be found in the New York City Schools' use of "inquiry teams" tasked with investigating and generating solutions for specific challenges associated with patterns of low student performance (Tucker, 2010). In New York City, like many other school districts, these data-focused teams dig into multiple data sources to identify areas of student weakness. Data is again invoked when plans are made to address these areas of weakness, in order to measure progress as new initiatives are implemented.

While the focus on human processes is increasing, the technological systems that are required for effective district and school DDDM lag in many areas. The simultaneous attempt at fulfilling both policy requirements and decision-making needs of practitioners has left much to be desired in the design and implementation of district data systems (technological tools for DDDM). Systems are often underutilized by end-users (such as teachers or other school-level practitioners) because they find it difficult to access reports that are straightforward to interpret and facilitate quick decisions.

One area of more prominent use of DDDM at the district and school level is in making programmatic decisions. More than ever, education leaders can evaluate the effectiveness of programs and student placement based on longitudinal data systems that are becoming more commonplace in the USA. Examples of programmatic decision making can include decisions about student placement into specific programs or grades, the effectiveness of existing initiatives, and the creation of new ones.

Classroom Level

Classroom level DDDM involves using formative, interim, and summative data to make instructional decisions that impact student performance. Effective classroom level DDDM requires multiple data sources, each of high quality, in order to ensure that well-informed decisions are being made.

While effective teachers always use information about their students to inform their instruction, the quality and timeliness of assessment data available to them for making decisions are rudimentary compared to data given professionals making complex decisions in other high-performance professional fields (Crawford et al., 2008; Tucker, 2010). A 2010 US national survey found that the "greatest perceived area of need among districts is for models of how to connect student data to instructional practice" (Means et al., 2010, p. 47). Research data indicated that a heavy focus of DDDM is on making goals for school improvement and making curriculum decisions rather than on changing classroom teaching strategies (Means et al., 2010).

Classroom level DDM holds much promise for improving teaching and learning in US schools. While randomized controlled experiments, attempting to measure the impact of DDDM on classroom practice, have been rare and inconclusive, much hope remains for DDDM at the classroom level. It is extremely intuitive and logical to even the most experienced classroom teachers that robust information about students can only enhance a teacher's ability to serve her students. Additionally, teachers often find formative assessments, those assessments that provide immediate results, more useful in informing their instruction than larger-scale, more formal interim or summative assessments.

Models of DDDM

The growth of DDDM in districts and schools has highlighted the particular needs specific to the school environment. The previous decade has experienced a marked increase in the development of data systems and decision making tools, but not a corresponding increase in the use of these resources to actually inform classroom-level decision

Table 27.1 Distinguishing features of common DDDM models (Kaufman, Grimm, & Miller, 2012)

DDDM model	Commonalities	Distinguishing features	Number of steps
Data wise improvement process (Harvard Graduate School of Education)	• Have iterative cycles that use data to identify school-based problems • Use instruction as the primary lever to address student learning needs • Emphasize planning for and ongoing progress monitoring of the effects of implemented changes • Use school-level data teams to implement the process, including data examination and the identification of relevant instructional changes • Encourage collaboration, particularly among teachers	• *Includes a "prepare" phase* that emphasizes effective teaming and assessment literacy • *Observes instruction* as part of data collection to understand a root cause of student learning needs • *Develops single, whole-school focus* on an instructional strategy to address a priority need	8
Decision Making for Results (D. Reeves)		• *Focuses on both high- and low-achievers* with a focus on setting SMART goals • *Identifies multiple strategies* to address prioritized needs	6
Plan-Do-Check-Act (P. Davenport)		• *Employs tutorials* to target students at various levels of proficiency (geared around reteaching concepts) • *Facilitates enrichment* pull out to support students who have mastered content • *Encourages instructional grouping* of students based on their performance on standardized assessments	4

making (Mandinach, Honey, & Light, 2012; Means et al., 2010). An increased emphasis on data collection that reveals specific and timely information on individual and collective student learning is necessary for using data to directly inform instruction.

As a result of this need, emerging models of DDDM define *data* broadly, emphasizing the value of classroom data—including student work and instructional practice—to inform decision making. These sources are necessary in developing a deep and collective understanding of student learning, teaching practice, and in their interaction with one another and with content. Likely current efforts at DDDM have been ineffective in part because they depend on large-scale and complex electronic databases, which have proven to be inaccessible and irrelevant to classroom-level instructional decisions (Means et al., 2010).

Despite heightened interest in accountability in public education over the past decade, opportunities for genuine DDDM have been limited. This is in part due to the limited frequency and awkward timing of mandated assessments that form the basis for such decision making. Reeves (2010) likens the current timing of state tests to addressing teen obesity by "weighing students on May 1 each year, lecturing them in September, and giving them meaningful feedback 6 months after we last observed them inhaling a bacon cheeseburger" (p. 15). Current and effective models recognize this shortcoming and emphasize a need for ongoing progress monitoring through DDDM. With an expanded definition of data, teachers and school leaders are better equipped to collect and analyze data—whether in the form of student interviews, student assignments, or more traditional benchmark tests—throughout the school year and make relevant instructional adjustments.

Current models for DDDM address the specific needs and deficiencies that have surfaced over the past decades, many of which we have described in this chapter. In addition to broadening definitions of data, these practices acknowledge the necessary element of collaboration at the center of data analysis and data-informed decision making. Widespread models, including Data Wise (Boudett, City, & Murnane, 2005; Boudett & Steele, 2007), Doug Reeves' Data Teams (Reeves, 2004), and Bernhardt's Portfolio Model (Bernhardt, 2009), emphasize creating and developing collaborative teams that drive data collection, analysis, and decision making within a school. Furthermore, these models all utilize classroom instruction as the primary lever to address student learning needs.

Rather than being linear processes, with a clear beginning and end, current DDDM models are iterative, engaging schools in data analysis, need identification, implementation of identified strategies, and progress monitoring of strategies grounded in data analysis. This cyclical process guides schools in the use of data to regularly to inform decisions, actions, and later adjustments. This deviates from common school improvement efforts that involve creating an action plan that remains unexamined or amended over the course of the school year. Furthermore, an iterative and defined process provides the necessary structure for schools to continue moving forward in the work and ultimately to make data-driven decisions that lead to improvements in teaching and learning. See Table 27.1 for distinguishing features of several common DDDM models.

Establishing Goals and Inquiry Questions

Contrary to the quick identification of problems and solutions characteristic of many school environments, current models of DDDM emphasize a thorough data examination to deeply understand problems, including their root causes. Many contemporary DDDM models utilize quantitative data (student performance data, attendance reports, statistics on discipline referrals, etc.) as a starting point to identify deeper questions and to frame subsequent steps in the inquiry process. For example, a team of teachers may identify a need for students to develop their reading comprehension skills based on standardized test data. After identifying specific areas of need, teachers and school leaders are able to identify additional data that will increase understanding of the problems they hope to address.

Student Work and Teaching as Data

For some time now, DDDM models have encouraged practitioners to use multiple sources of data to provide a comprehensive understanding of specific school needs. Extending beyond student performance data, current models emphasize collection and analysis of student work and teaching practice as data. Through the examination of student work and teaching practice, teachers identify deeper student learning issues, and they are able to also identify a root cause embedded in teaching. This type of analysis enables schools to focus on improving what they can control: instruction.

Rather than looking at student work or examining teaching practice as evaluative processes, in a DDDM model these sources are often considered data. These data sources inform understanding of student thinking and its relationship with instructional practices; this increases the capacity of teachers and school leaders to use data to inform decision making. As data sources, student work and teaching practice more easily translate into informed pedagogical decisions than the numbers of standardized student performance data because student work and teaching happen regularly and are therefore more timely and accessible by nature.

Analyzing and Interpreting Data

Collaboration, which is central to many DDDM models, is a noted absence in current school improvement efforts (Wei, Darling-Hammond, & Adamson, 2010). Research finds that data become more meaningful and more likely to lead to systemic and lasting reforms when examined collaboratively (Means et al., 2010). To support such practice, effective DDDM models utilize both diverse data teams and whole-school involvement and decision making to drive data analysis.

Effective DDDM models provide educators with a structure to analyze and interpret data to identify root causes and to create and implement solutions that effectively address student learning problems. Without a deep understanding of a problem, the solutions created are likely to be ineffective. As noted in the Reeves' (2010) model, the process of analyzing and interpreting data also involves prioritizing needs within the school improvement process: e.g., identifying areas where the needs are most urgent, where the potential for growth is greatest, or where a school community can most readily address a root cause with the resources available.

Similarly, the Data Wise model, used in many school districts in the USA, emphasizes identification of find-grained and specific problems of practice (Boudett et al., 2005). The narrow entry point enables those involved in school improvement efforts to focus their energy and intervention in a specific area, increasing the likelihood that they can develop shared understanding, drive collective action, and directly address the root cause.

Acting Based on Data

Analyzing and interpreting data is meaningful only if those activities result in changes in the practices within schools. While identifying and analyzing data lays the groundwork for impactful improvements to student learning, the resulting actions and progress monitoring will ultimately determine the efficacy of DDDM efforts.

Identifying a root cause and selecting strategies to address it require parallel assessment of available resources—including (but not limited to) teachers' knowledge and existing skills, time, and available funding. This action-oriented focus of DDDM models requires clarity in and support for collective changes in practice.

While models vary in the scope of their focus, several emphasize change at the classroom level. Rather than addressing the larger structures of schools (scheduling, attendance policies, etc.), the three models discussed in this section emphasize implementing change at the classroom level and recognizing instruction as the point of leverage for increasing student learning. This classroom focus places teachers at the center of DDDM.

Along with identifying instructional strategies, DDDM models promote the identification of results indicators. This step requires schools to examine the ways in which progress can be assessed throughout an improvement process and identify specific sources of data that will be collected to support progress monitoring.

Thus the process of creating and implementing an action plan involves implementing specific strategies or changes in practice accompanied by simultaneous ongoing data collection and analysis. This progress monitoring requires increased investments in time and other resources if teachers are to collaboratively examine and analyze data. But the investment provides an ongoing and consistent picture of the effects of changes, both to assess their effectiveness and to inform mid-course adjustments.

The Role of Technology and Data Systems in DDDM

Technological data systems are a critical part of DDDM in the twenty-first century because aggregating, analyzing, and maintaining large complex sets of data would be virtually impossible without them. Brunner et al. (2005) have noted that "the relative ease of use and sophistication of data-gathering, storage, and delivery systems has made data accessible in a meaningful format to whole sets of constituents whose access to data in the past was either nonexistent or presented in dense and unintelligible reports" (p. 47).

Some of the key capabilities that technology enables in a data system include

- Timely access to data (Means et al. 2007)
- Improved mechanisms for data collection (including mobile technologies) (Mandinach et al., 2012)
- Ability to aggregate data across organizational/institutional boundaries in a timely manner (Breiter & Light, 2006; Thorn, 2001)
- Data mining capabilities (Baker & Yacef, 2009)
- Improved data usability and visualization of data (Breiter & Light, 2006)
- Real-time feedback and analysis capabilities (Crawford et al., 2008)

For two decades researchers have been studying how tools such as knowledge management systems and electronic performance support systems (EPSS) can be used to improve human and organizational performance in complex organizational contexts (Alavi & Leidner, 2001; Haney, 2006; Hudzina, Rowley, & Wager, 1991). Both systems incorporate the human/organizational dimension as a critical component of developing a data system. These principles of knowledge management are increasingly applied in data-driven educational decision making (Cho & Wayman, 2009; Thorn, 2001).

Knowledge management systems are intended for capturing and managing organizational knowledge (Alavi & Leidner, 2001). Thorn (2001) articulates four primary goals of educational knowledge management systems: (1) to create knowledge repositories, (2) to improve access to knowledge, (3) to enhance the educational environment through knowledge sharing, and (4) to manage knowledge as an asset to make sure that it contributes to bottom line success (pp. 5–6). Primary concerns of knowledge management include the relationship between tacit and explicit knowledge and ways organizations manage the creation and access to that knowledge (Cho & Wayman, 2009; Nonaka, 1994). Making tacit knowledge about student performance explicit and developing strategies for addressing performance gaps are critical to DDDM in schools.

Electronic performance support is another lens through which one can look at the design and development of data systems for educational decision making (Hudzina et al., 1991; Kirkley & Duffy, 1997). A major focus of the literature on performance support is how to improve performance by providing appropriate integrated support in real time, as opposed to support that is disconnected from the performance task (Cavanagh, 2004). In the educational setting teachers might have access to day-to-day student performance data that will directly affect classroom instructional decisions. Use of the system might go beyond student performance data to include professional development training focused on effective methods and strategies, made available to the instructor when immediately relevant (Hudzina et al., 1991). Or instead of providing real-time access to professional development content, an EPSS could provide "instantaneous and impromptu" access to networks of professionals or communities of practice that could provide support for instructional problem solving (McManus & Rossett, 2006). In addition to providing performance support for instructors and educational administrators, EPSS can also be designed to provide real-time support to the learners themselves and to communicate performance data with parents (Chen et al., 2005; Means et al., 2010; Tucker, 2010).

As noted in practice, the technological systems are only as effective as the capacity of teachers and school leaders to access, understand, and collaboratively analyze the information (Tucker, 2010). As Tucker notes, "Unless systems are designed to be obvious value to these educators—to give them insights into students—then their use will be limited" (2010, p. 14). Despite this progress noted in this section, researchers still acknowledge that "teachers do not have the data-rich, performance-support, and information-feedback work environment that virtually all other high-performance professionals and many service professionals have at their disposal" (Crawford et al., 2008, p. 112). To reach its potential, DDDM within education requires increased development of technological data systems alongside the skills of educators to effectively leverage these resources to inform day-to-day practice.

Implications of DDDM for Educational Research

While technology has contributed to the growth of data available to K-12 practitioners and iterative models of DDDM are increasingly gaining traction within schools, work remains in fully realizing the potential of DDDM to affect classroom instruction and student learning. This section of the chapter focuses on three potentially productive areas of research for those interested in studying DDDM: (1) implementation and adoption, (2) data system development, and (3) evaluation and measurement.

Implementation and Adoption Issues

The most difficult issues related to DDDM are not technological, but rather human issues concerned with changing professional practices and altering the culture of educational organizations. Research has shown that increased attention and access to student achievement data over the past decade has done little to drive wide-scale improvements in student learning. A study commissioned by the US Department of Education, which surveyed hundreds of districts across the USA in 2007 and followed up with site visits to selected districts during the 2006–2007 and 2007–2008 academic years, explored challenges impeding current DDDM efforts (Means et al., 2010). This research found significant adoption challenges, particularly at the level that would impact classroom instruction. "Even in districts that are actively promoting the use of data, however, school staff provided relatively few examples of teachers using data to diagnose areas in which they could improve the way they teach" (Means et al., 2010, p. xiv). Future research could focus on how to improve and even speed up adoption of effective data use practices in school settings.

To address shortcomings in current DDDM efforts, teachers need additional support in using the student data they receive to improve their teaching and in structuring opportunities for collaboration in this endeavor. This capacity-building effort should begin during teacher preparation and continue through on-the-job professional development. Means et al. (2007) documented that "only six percent of teachers surveyed reported having had formal course work on data-driven decision-making" (p. 16)—a finding which may indicate that teacher preparation programs are behind the curve in preparing teacher candidates for DDDM. In contrast, the report showed that 60 % of teachers surveyed had participated in some form of professional development on DDDM within their school or district. Districts identified connecting data to instructional practice as their greatest area of need, including "examining student data to identify which practices work best for which students," "adapting instructional activities to meet students' individual needs," and "collaborating and sharing ideas with colleagues regarding data inquiry and analysis issues" as particularly weak areas (Means et al., 2010). Each of these needs aligns directly with research on effective school improvement efforts, which identify a focus on high-quality instruction, peer collaboration, and regular data collection and analysis as features essential to effective schools (Bryk, Sebring, Allensworth, Luppescu, & Easton, 2009; Chenoweth, 2007, 2009; Ratner & Neill, 2010). Research should also look at how teacher preparation programs and professional development opportunities are preparing candidates with the most critical knowledge and skills identified and how well skills from those programs are transferring to the actual working environment.

Finally, schools that effectively implement a process for DDDM engage in shifts in ideology as well as in practice. Using data to deeply inform an understanding of student learning and thus to make impactful decisions requires a shift in focus from what teachers have taught to what students have learned (Bambrick-Santoyo, 2010). Many schools that have demonstrated measured increases in student learning have worked to create a culture of inquiry and support (in resources including time and training) around the use of data (Bernhardt, 2009; Gallimore, Ermeling, Saunders, & Goldenberg, 2009; Reeves, 2010). As noted by the US Department of Education, "Human and organizational supports for data use are just as important as the technical quality of the data system" (US Department of Education, 2010). In addition to the teaching and adoption of high impact data skills, researchers should consider the perspective of changing school data cultures. Knowing how to use data does not ensure a school environment that supports the application of those skills.

Data System Development Issues

The quality of data systems strongly impacts data use in schools. Marsh, Pane, and Hamilton (2006) outline some of the factors that affect how data are used in schools: (1) accessibility of data, (2) quality and acceptability of data, (3) user motivation to use data, (4) timeliness of receiving data, (5) staff capacity, (6) curriculum pacing pressures, (7) lack of time, (8) history of state accountability, and (9) organizational culture and leadership. Three of these factors have to do with the development of the data system itself, and others have to do with the social and cultural environment in which the data system is used. Research on data system development can focus on the accessibility, quality, and timeliness of data used for decision making.

For DDDM to take place in districts and schools, the faculty, staff, and administrators must first have access to the data and information affecting their decisions. "Although schools have been 'data rich' for years, they are also 'information poor' because the vast amounts of available data they have are often stored in ways that are inaccessible to most practitioners" (Wayman, 2005, p. 296). The problem is one of easy and practical access to data that can be used in real time. Teachers and administrators have had access to large amounts of hard-copy data for decades; however most data have been poorly organized and difficult to work with, often accessible only for short periods of the year. Much of the data that teachers and administrators have had access to have been district, state, and national norm- and criterion-referenced testing data, not formative student performance data. In addition to these district, state, and national datasets, teachers and administrators need a system that is flexible enough to allow them to input and use their own idiosyncratic data and student information in conjunction with the standardized data forms. To design and deploy these data systems, in addition to understanding the types of data, researchers need to understand how, when, why, and under what conditions, teachers and administrators access data for DDDM.

In addition, current research has found issues concerning educators' confidence in data validity.

> Many educators questioned the validity of some data, such as whether test scores accurately reflect students' knowledge, whether students take tests seriously, whether tests are aligned with curriculum, or whether satisfaction data derived from surveys with low response rates accurately measure opinions. These doubts greatly affected some educators' buy-in, or acceptance of and support for the data, which research has identified as an important factor affecting meaningful data use. (Marsh et al., 2006, p. 8).

Evidently, much of the data that teachers and administrators presently have available do not provide the types of insight they need to make critical instructional decisions. Research is needed to understand what types and quality of data teachers and administrators value and how that data can be collected and made available in practical useful ways.

Finally, classrooms and schools continually change and often operate at a rapid pace, and many instructional decisions must be made hourly. If teachers and administrators cannot quickly access decision-relevant data, they will have to rely primarily on their instincts and past experiences. Data systems must make data available to teachers and administrators when they need it. Research concerning knowledge management and electronic performance support has emphasized providing just-in-time data to enhance decision making and performance. How just-in-time access to student performance data will be received by a typical classroom teacher and how the teacher will use the data to change instructional pathways for students are also important areas of investigation.

Evaluation and Measurement Issues

Of the many important evaluation and measurement issues related to DDDM, this chapter focuses on two that are critical: value-added measures and common assessments. The purpose of these sections is not to provide comprehensive coverage of these important issues, but to highlight the issues as important and relevant to current DDDM discussions.

Value-Added Measures

The ultimate goal of value-added measures is to be able to accurately estimate the individual teacher's contribution to student learning (Harris, 2011) and make educational decision making more effective by controlling for factors like prior achievement, access to resources beyond school, and family factors outside the control of the educator (Harris, 2011; Marsh et al., 2006). Once measurement challenges are satisfactorily resolved, value-added considerations can provide accountability focused on educator-influenced growth outputs rather than on inputs or "snapshot" outputs (Harris, 2011).

Value-added measures are concerned with making accountability systems more reflective of what teachers and administrators can and do control in schools and districts, with significant involvement of DDDM and its supporting data systems. Examining how value-added measures work and contribute to the overall data picture in schools and districts will clarify how DDDM is impacted and how it may bring greater equity to these accountability systems.

While value-added measures can contribute to the identification of successful teachers, these measures are limited in their capacity to inform our understanding of the effectiveness of specific practices. Additionally, questions remain regarding the ability of value-added measures to effectively isolate the effects of the current teacher (Amrein-Beardsley, 2008).

Common Assessments

In February of 2009, President Obama signed into law the *American Recovery and Reinvestment Act of 2009,* which included funding for the *Race to the Top Fund* (RTTT), to be administered by the US Department of Education, encouraging "building data systems that measure student growth and success, and inform teachers and principals about how they can improve instruction" (US Department of Education, 2009, p. 2). Additionally, a state-led initiative coordinated by the Council of Chief State School Officers and the National Governors Association came together and drafted *the Common Core State Standards* that have been adopted by 45 of the states (Common Core Standards Initiative, 2011a, 2011b).

In providing a "a clear and consistent framework" and "appropriate benchmarks for all students," the Common Core State Standards (CCSS) have cleared a path for the development and use of common assessments for all students that can cross state lines in ways that have never before been possible. Common assessments, which are the norm for national- and state-benchmark testing, are intended to allow teachers to see how their students' achievement compares with other students across the nation; however before the Common Core it has been a stretch to compare student achievement across states since each state developed its own standards. With these developments educators nationwide will have an unprecedented opportunity to access and analyze data on their students in relation to those across the country.

In addition to the common summative assessments that may be used across states, the CCSS may allow for common interim assessments to be used across states. This addition will enhance educators' abilities to deeply assess specific standards in a formative manner. Furthermore, these interim assessments will give teachers and administrators multiple data points across the school year to monitor student achievement prior to year-end testing. As cross state assessment systems are built on the foundation of the Common Core, research on DDDM will need to go in directions not yet considered.

Conclusions

DDDM is an important area of inquiry for educational researchers in the twenty-first century. In an era of access to powerful technologies for collecting and analyzing data, as well as an increasing demand for accountability in our school systems, the presence of DDDM in K-12 education will continue to increase. Simultaneously, researchers and practitioners are developing and refining DDDM models and tools that meet the unique needs of teachers, school and district leaders, and policymakers. As noted in this chapter, work remains in developing our understandings of the implementation and adoption of DDDM, the development of data systems, and the ways in which DDDM can support effective evaluation and measurement.

Additionally, the development of DDDM models and an increase in access to data from technological advancements must be accompanied by a focus on developing educators' capacities for transforming data into instructional decisions that affect student learning at the classroom level. Without such a development, DDDM will remain a largely unleveraged resource within K-12 education.

Section IV
General Instructional Strategies

Jan Elen and M.J. Bishop

Any handbook related to educational technology and/or instructional design has some key chapters that discuss the heart of the enterprise. This section on "general instructional strategies" presents those core chapters and shows the dynamics of the field by discussing recent research in each area. While some of these chapters reveal perspectives from which (research on) instructional strategies can be discussed, others point to strategies aimed at attaining important instructional goals, and still others focus on particular instructional strategies, approaches, or methods. This section is complementary to earlier sections in previous editions of the *Handbook* (Jonassen, 2004; Jonassen, Harris, & Driscoll, 2001; Spector, Merrill, van Merriënboer, & Driscoll, 2008) as it builds upon and elaborates on those earlier chapters by presenting new perspectives and new research insights. This section is also complementary to the next section of this *Handbook* edition in that it addresses general instructional strategies rather than domain-specific ones. In that sense, the chapters in this section are more abstract and theoretical whereas their applicability range is larger.

One of the major, more recent theoretical insights pertains to the role of context. The field has become well aware that learning and instruction are situated processes. It is no surprise, therefore, that research on the role of culture in learning is growing. The first chapter in this section by Young addresses this issue. This chapter reviews current research across disciplines (i.e., mathematics, science, and e-learning) to provide a critical analysis of applications and conceptualizations of culture in learning. Given this research, implications for culture-based instructional strategies are offered.

The cognitive revolution in research on teaching and learning has brought about a concern for developing learning ability. This has not stopped and research now focuses on the development of self-directed and self-regulated learning skills. The chapter by Brand-Gruwel, Kester, Kicken, and Kirschner argues that the development of these skills requires a flexible learning environment with personalized learning trajectories. The chapter discusses recent research on the design of such learning environments. A rich pallet from well-structured learning materials over portfolios and advisory models is presented.

Instructional strategies and information need to be delivered. With evolutions in technology offering a more diverse set of technological possibilities, research is now delving into these new possibilities and investigating how they can stimulate learning. The chapter by Bishop reveals the need to pay far more attention to instructional messages by considering the highly interactive nature of these messages. The author argues that research on instructional messages has not yet endorsed more constructivist perspectives and reestablishing instructional message design as a valid area of inquiry in instructional design will require that recent reorientations in communication theory be considered. This will help to bring about a research domain that is oriented towards message design for learning. In the chapter on multimedia learning, Mayer provides a concise overview of multimedia research. In multimedia instruction text and images are combined with the intent of enhancing learning. The author argues that this instruction becomes more effective when cognitive architecture is considered in the design of that instruction. The design of effect multimedia instruction implies that research principles with respect to reducing extraneous processing, managing essential processing, and fostering generative processing be considered.

Research in the field of instructional design and educational technology gradually reveals the importance of a number of fundamental aspects of learning environments. Three of them are the need for authentic learning environments, for feedback, and for adaptivity. In the chapter on authentic learning environments by Herrington, Reeves, and Oliver the theoretical background of authentic learning environments is extensively discussed. Furthermore, the authors highlight the

great potential of new technologies and review the recent research on authentic learning environments. The chapter by Molloy and Boud addresses feedback. In addition to a critical analysis of definitions and theories, the authors offer an overview of recent empirical work. The chapter concludes with the insight that feedback is an integral part of any productive learning environment, suggesting a greater focus on formative rather than on summative evaluation as well. Adaptivity and even personalization remain a goal of many learning environments, which aim to optimize learning by considering individual characteristics and providing targeted support. Vandewaetere and Clarebout discuss research on advanced technologies and personalized learning environments. The authors claim that the integration of artificial intelligence and educational data mining provides a firm basis for personalized systems. The chapter concludes with the authors' plea to use the potential of these new developments to foster learning.

Specific instructional strategies are presented in the four (or five) chapters. In each of these chapters an up-to-date overview is presented of the theoretical background and the empirical evidence with respect to one particular strategy. Goodyear, Jones, and Thompson do so for computer-supported collaborative learning; Lazonder for inquiry learning; Seel for model-based learning; and Tobias, Fletcher, and Wind for game-based learning (perhaps still reference to case-based learning chapter). Strikingly, what becomes clear in each of these chapters is that good instructional design decision making first requires that an in-depth analysis is made of the cognitive processes in which learners must engage. An instructional strategy cannot be expected to be effective unless it elicits appropriate cognitive processes.

The provision of instructional support often in the form of scaffolds is addressed in the last two chapters. Belland provides an in-depth overview of research on scaffolds. Given the broad meaning attributed to the term and hence the overwhelming amount of research on scaffolds, some restrictions had to be considered. Great insights emerge from this overview: In order to make learners stronger, fading support is a key characteristic of powerful learning environments and general support are far less effective than scaffolds with a clear domain-specific orientation. This calls for more domain-specific instructional design research as illustrated in another section of this *Handbook*. But even well-designed scaffolds or well-designed instructional support may not be as effective as hoped; the main reason is that learners are self-regulated agents and their interpretation of the support and of the entire learning environment and their motivation will determine whether the support is actually used and/or used as intended by the designer. The issue of support use is the focus of the last chapter by Clarebout and her colleagues.

While this section is long and gives a good overview of recent thinking and current investigations on instructional strategies, it is far from exhaustive. This edition of the *Handbook* is clearly missing chapters on distributed learning. Internet and e-learning have become mainstream and this implies that instruction can now be provided anytime anywhere. The implications of these new possibilities for learning and research on appropriate instructional strategies in distributed learning settings are issues to be discussed in the fifth edition of the *Handbook*.

The Presence of Culture in Learning

28

Patricia A. Young

Abstract

The selection of instructional strategies for learners requires consideration of the role of culture in learning. This chapter reviews current research across disciplines (i.e., mathematics, science, and e-learning) to provide a critical analysis of applications and conceptualizations of culture in learning. Given this research, implications for culture-based instructional strategies are offered.

Keywords

Culture • Learning • Instructional strategies • Culture-specific • Science • Mathematics • e-learning

Introduction

Worldwide there is growing concern about how to educate all people and understand the intricacies of human learning. Given this fact, culture has become a preeminent factor in understanding learners and learning.

The role of culture in learning moves beyond challenging dominate ideologies or world views; it is about defining and identifying instances, methods and processes of learning that are specific to individuals and groups. Thereafter, the selection of instructional strategies begins. That is, instructional strategies cannot be applied to learners; in this sense, instructional strategies must be developed from an ethnographic evaluation of the learner. Instructional strategies are derived from versus applied to the learner.

This chapter reviews international research in the areas of culture, learning, and a specific discipline (i.e., mathematics, science, and e-learning) to determine relevant instructional strategies in this context. Each section begins with a review the qualitative and quantitative studies. This is followed by a review of conceptual and theoretical articles that approach the same topic area. Mathematics, science, and e-learning are each approached differently depending on the literature reviews. In the mathematics and science literature, specific themes arose so those themes were reviewed in context to best compare and contrast the literature.

Other disciplines have been excluded because of the volume of research that is developing in these areas and publishing constraints. In particular, there is a growing body of research related to culture, learning, and disciplines such as computer technology, human computer interaction, instructional design, and game design.

Culture Defined

Culture remains a term institutionally defined and applied. Theoretical and conceptual definitions of culture derive out of the need to make culture discipline specific or to understand processes or practices. Some of these disciplines include: psychology, social psychology, education, anthropology, sociobiology, sociology, and cognitive science to name a few. Matsumoto (2009) situates culture in the field of psychology and associates culture with human behavior and mental processes. For Matsumoto, culture is a "meaning and information system, shared by a group and transmitted

across generations" that allows for human survival, the coordination and transmission of social behaviors, and the pursuit of happiness, health and a meaningful life (p. 5). For another psychologist like Gurung (2009), culture is static as it captures a groups shared attitudes, beliefs, and goals, but culture is also dynamic; it is always changing because of the beliefs held by human beings in the group. Hollins (2008), an educator in sociocultural theory, positions culture as "who we are and how we exist in the world" (p. 18). Hofstede, a social psychologist and anthropologist, states that culture is "the collective programming of the mind that distinguishes the members of one group or category of people from others" (Hofstede, Hofstede, & Minko, 2010, p. 6). Anthropologists propose that culture is a "system of learned behaviors, and explore the ways that humans use it to organize and give meaning to the world around them" (Wanda & Warms, 2011, p. 74). Anthropologists agree that cultures are shared by people and groups who have learned behaviors. Cultures are adaptive to surviving in the world. Cultures change and are never static. Cultures are patterned and relational to one another. Cultures contain symbols (Pieterse, 2009). Sociobiological representations situate culture as an attribute to natural selection. That is, there is a natural selection for behaviors and these behaviors can be transferred from generation to generation. By example, current research in sociobological sciences contends that human behavior is influenced by cultural factors and specific genes (Chiao & Blizinsky, 2010; Fincher, Thornhill, Murray, & Schaller, 2008). Then there are sociologists who delve in cultural studies and argue that culture is about meaning making—that is the exchange and production of meaning, between members in a group or society (Hall, 1997). Rogoff (2003), who studies human development and cognition, proposes that culture is what all humans do; further these cultural practices and cultural processes are enacted by humans in different ways, for different reasons but that they are part of the culture of human development.

This review of disciplines confirms the institutionalization of culture as a theoretical and conceptual term that is transmuted based on human need and desire. This mutation suggests the need to clarify the definition of culture as it pertains to human learning. Therefore, within this chapter, culture is all that we know and have come to know, do, and produce as human beings. Culture is everything! It is everything around us and everything ever created. Culture is all that is man-made, and even those things made by nature.

Notions of Culture in Learning

An interdisciplinary examination of research particular to notions of culture in learning reveals similar conclusions—that learning is actively mediated through learners participation in their culture (Choo, Austin, & Renshaw, 2007; Fischer, 2009; Gutierrez & Rogoff, 2003; Ito et al., 2010; Lee, 2009; Nasir, Rosebery, Warren, & Lee, 2006; Thomas & Brown, 2011). This means that situating learners within culture-based contexts enables learning to happen naturally. Culture-based encompasses culture-neutral (generic) and culture-specific (specialized) contexts (Young, 2008, 2009).

Studies in Culture

Studies that have examined culture and learning reveal culture as the primary focus of the research, and that culture is central to determining the learning preferences, styles, approaches and experiences of learners. Culture is determined to be central to learning. These studies are supported through an interdisciplinary selection of theory that relates to sociocultural, Afrocultural, cooperative learning, cognition, culture, learning styles, and language learning. This suggests the need for an interdisciplinary interpretation of culture and its relationship to learning. The methods of analyses considered both qualitative and quantitative research. All of the studies administered culture or learning related questionnaires or surveys to determine learners' learning styles, strategies, preferences, orientations, or cultural knowledge. The findings indicate that there is a positive correlation between culture and learning preferences; this means that culture influences learners preferred learning pathways (Boykin et al., 2005; Charlesworth, 2008; Ellison, Boykin, Tyler, & Dillihunt, 2005; Sulkowski & Deakin, 2009; Tsou, 2005). These learning pathways can be culture-specific or particular to an ethnic or racial group; however, learning pathways are not always dictated by membership in a racial group as it can be by exposure and lived experiences that an individual acquires these preferences (Boykin et al., 2005).

Theoretical and Conceptual Research in Culture

Theoretical and conceptual notions of culture in learning are articulated as "cultural practices" (Gonzalez, Moll, & Amanti, 2005; Lee, 2009; Nasir et al., 2006), "cultures of participation" (Fischer, 2009), a new "culture of learning" (Thomas & Brown, 2011) and "genres of participation" (Ito et al., 2010).

Researchers propose that cultural practices can be observed through an examination of learners everyday interactions with their environment. For example, Taylor (2009) documented the mathematical competencies of African American youth through their purchasing practices of buying candy and other items at a neighborhood store. These cultural practices were exemplified through school aged children engaged in reading priced items, figuring the costs of purchases, deciding the correct currency for purchase and determining the remaining monies from a transaction as these practices unfolded within a sociocultural context. Observing and analyzing cultural practices supports the modeling of instructional pathways (Lee, 2009); aids in the design of learning environments (Nasir et al., 2006); brings meaning to discipline specific learning; assists in bridging cross-cultural understandings and situates learning in a cultural context (Barta & Brenner, 2009). In this sense, instructional strategies and methodologies are modeled and designed from empirical evidence of learners' interactions with cultural practices; thereby, instruction is derived from versus applied to learners.

Similar research in this area proposes that learning has been altered by twenty-first century networked technologies. In particular, the World Wide Web has shifted the way we learn, why we learn, how we learn, who we learn with, and where we learn. Fischer (2009) argues that there are "cultures of participation" where all individuals can meaningfully interact through networked technologies. Thomas and Brown (2011) conceptualize this digital phenomenon as a new "culture of learning" where individuals learn from and with each other thereby creating collectives. Ito et al. (2010) describes these ongoing learning and technological engagements as "genres of participation," conducted through "networked publics" that engage learners in social and cultural contexts (p. 14). Networked technologies allow individuals to learn by interacting (Fischer, 2009), doing, experiencing and watching (Thomas & Brown, 2011). Learning is mediated by the learner's age, desires, expertise, identity, income, interests, gender, talents, values, etc.—culture.

Ethnography for Culture-Based Analyses

Capturing the culture of learning requires an ethnographic analysis of individuals or groups as they engage in their culture or society. Ethnographic work, in general, aids in describing and understanding "a given process, experience or group" (Orellana & Bowman, 2003, p. 30). An ethnography allows for the construction of in-depth social categorizations that explore the intricacies of culture (Orellana & Bowman, 2003). Kumpulainen and Renshaw (2007) describe it as follows: "To investigate learning as an ethnographer, therefore, is to focus on the practices and understandings of the members of a community, and the interactive processes that establish and maintain such practices and understandings" (p. 110).

It takes an ethnographic analysis of cultures and societies to determine and understand how individuals and groups learn. This point is demonstrated by Ito et al.'s (2010) study where they conducted an ethnographic analysis of youth engagement with new media to better understand literacy and learning.

The use of ethnography for culture-based analyses is becoming common place in cultural studies (Subramony, 2009). Ethnographic work supports the study of learning (Barta & Brenner, 2009), focuses on the localization of knowledge (Crabtree, 2010), assists in the improvement of learning (Lipka et al., 2005), allows for the interpretation of the *purposes* of practices (Carlone, Haun-Frank, & Webb, 2011), enables microanalyses of cultural meanings in learner interactions (Brown, 2004), and encourages the building of learning technologies (Hall & Sanderville, 2009).

This research suggests that notions of culture in learning are real and relevant. If learning happens through learners interactions with their culture; then culture cannot be separated from the learning or learner. Whether it is determined through cultural practices, cultures of participation, cultures of learning or genres of participation, the learner is engaged in a semiotic relationship with their culture and this in turn influences human learning and the acquisition of knowledge. Ethnography can be the method of measurement to better understand the learner and how knowledge is acquired.

Interdisciplinary Applications of Culture and Learning

A growing body of literature in culture and learning proposes that human learning and development are keenly influenced by culture (Lee, 2009; Lee, Spencer, & Harpalani, 2003; Orellana & Bowman, 2003). That is, culture influences and is influenced by human learning and development. Given this, scholars continue to advocate for cultural considerations in the design, teaching, learning, and assessment of content area knowledge (Hood, Hopson, & Frierson, 2005; Swartz, 2009; Warikoo, 2009). This advocacy for the integration of culture seems to have made advances in school aged STEM (science, technology, engineering, and mathematics) related literature and in higher education literature on e-learning.

This section begins first with an overview of theoretical perspectives and paradigms. This is followed by studies and literature reviews in mathematics education, science education and e-learning education. Suggestions about the meanings of the literature are provided throughout.

Perspectives and Paradigms

Theoretical perspectives and learning paradigms that grounded the research in mathematics, science, and e-learning education were diverse. The mathematics education studies situated their research on learners knowledge constructions through social interaction and artifacts (Leont'ev, 1978; Vygotsky, 1978), communities of practice (Lave & Wenger, 1991; Wenger, 1998), cooperative learning and the Confucian

Heritage Culture as advocated in Chinese philosophy (Chang, Hsiao, & Barufaldi, 2006). The science education studies situated their research in sociocultural theory positioning science as a cultural and social process (Aikenhead, 2006) that needs further understanding through human learning, action and development (Cole, 1996; Vygotsky, 1978; Wertsch, 2002). Other science education perspectives and paradigms included the following: cultural historical activity theory that places learners in historical and cultural contexts (Rogoff, 2003), critical and emancipatory theory for the liberation of learners (Freire, 1993), identity as a lens to understand ethnicity, gender and culture (Gee, 2001), cognitive paradigms that allow science learners to explain and predict (Ioannides & Vosniadou, 2002; Wellman & Gelman, 1992), and constructivist paradigms where the learner builds upon prior knowledge (Vygotsky, 1978). The e-learning education studies situated their research in Hofstede et al.'s (2010) five dimensions of culture (i.e., power distance; individualism vs. collectivism; masculinity vs. femininity; uncertainty avoidance; long vs. short term orientation) or general e-learning research. This diversity of theoretical perspectives and paradigms suggests that research about culture and learning can be situated in a multiplicity of ideologies.

Mathematics Education

An analysis of recent studies in the areas of culture, learning, and mathematics reveals a focus on what learners already know as a basis to build mathematical competency. What learners know is articulated as prior understandings (Taylor, 2009); prior knowledge (Hurley, Allen & Boykin, 2009; Leonard, Davis, & Sidler, 2005); or foundational knowledge (Ni, Li, Li, & Zhang, 2011). Collectively, these studies also sought to fill a gap in the mathematics education research.

Several studies administered multiple evaluations to determine learning outcomes. The first evaluation obtained data specific to the learner's cognitive abilities as they engaged in mathematical concepts. Mathematical concepts included calculations and explanation skills (Ni et al., 2011; Wong, 2002); estimation (Hurley et al., 2009); whole numbers (Taylor, 2009) problem solving, word problems and basic geometry (Leonard et al., 2005). The second evaluation obtained learning outcomes data as measured through factors such as behavior, affect, and conceptions. Behavior was measured through learners involvement, communication, participation and affect (Hurley et al., 2009). Leonard et al. (2005) examined behaviors related to tasks, social interactions, dispositions and problem solving. Learning outcomes were also measured through affective factors such as learners' dispositions and interests towards learning mathematics (Ni et al., 2011). Wong (2002) examined learners conceptions to hypothetical mathematical situations to illicit learner feedback on whether performing mathematics was required of the mathematical equation. This suggests that it is important to evaluate mathematical learning outcomes based on cognitive (i.e., knowledge), anthropological (i.e., behavior) and psychological (i.e., affect) states of the learner. Thereby a more holistic portrait of the learner can be fully assessed and accessed.

China and Mathematics Education

Studies from China focused explicitly on the preservation of the Chinese culture. By example, Ni et al. (2011) reported that the goal of the study was to determine whether a new curriculum weakened the foundation of Chinese mathematics particular to mathematical concepts and mathematical skills. In this study and Wong's (2002) the performance of students in mathematical assessments, the culture of schools, and curriculum materials were all intricately tied to the maintenance of the Chinese culture and China's global leadership in mathematics. This suggests that the academic achievement of learners and the maintenance of the nation are intricately tied to the culture of China.

Reviews in Mathematics Education

The role of culture in the learning of mathematics is significant (Eglash, Bennett, O'Donnell, Jennings, & Cintorino, 2006; Ernest, 2009; Leonard, 2008; Martin, 2009; Mukhopadhyay, Powell, & Frankenstein, 2009; Swetz, 2009) enough that it should change the course of teaching, instruction, curriculum and learning theory. Understanding learners can pave the way for understanding human learning across contexts.

Reviews of literature in the learning of mathematics for ethnically diverse populations conclude that culture is integral to the learning of mathematics and learners understanding of mathematics (Kaahwa, 2011; Melis, Goguadze, Libbrecht, & Ullrich, 2011; Ng & Rao, 2010). It is suggested that mathematical language, notations and notions (i.e., story contexts) should be specific to the culture of the learner (Kaahwa, 2011; Melis et al., 2011; Ng & Rao, 2010). In particular, the use of the native language of learners, for the teaching of mathematics content, assists in improving mathematics knowledge. Ng and Rao's (2010) review of literature revealed that the Chinese oral and written language for numbers provided a simpler system to learn counting especially with numbers above ten. These findings disclosed the mathematical advantages and higher achievement of Chinese learners in early grades and beyond based on the Chinese language and other cultural nuances (e.g., days of the week and months are referred to as numbers—Weekday No. 1 or tenth month).

Learners bring their ways of interacting, observing, problem solving, and thinking. These ways of being, seeing, thinking and doing in the world are culture-based and can be utilized to develop instructional methods, avenues for learning, and bridging home and school contexts (Kaahwa, 2011; Leonard, 2008; Moschkovich & Nelson-Barber, 2009). Learners bring their cultural stories and these stories can provide contexts for learning (Gonzalez et al., 2005; Kaahwa, 2011). Kaahwa (2011) used cultural artifacts in teaching mathematics. These cultural artifacts would be evident in the learner's communities (e.g., bean pods in Uganda), thereby bridging home and school learning. The Algebra Project, an urban middle/high school alternative curriculum, drew on the sociocultural and linguistic world of learners to bridge understanding and computing mathematical concepts (Moses, West, & Davis, 2009). According to Moses et al. (2009) the path to learning is enabled through learner's native language articulations and personal experiences that translate into written form and then further articulated into written and verbal mathematical concepts.

Culture-specific learning or framing mathematics learning in a local context signals a valuing of the learners culture, provides a conceptual foundation to build content knowledge (Moses et al., 2009), and validates the local community and its knowledge (Barta & Brenner, 2009). Ethnomathematics exemplifies the use of indigenous or nondominant knowledge to explain and teach mathematics (Eglash et al., 2006). Contrary to this research, Meaney (2002) found that the inclusion of mathematical practices from indigenous cultures presents some areas of concern such as: loss of cultural intent and a focus on more Western dominance.

Nasir, Hand, and Taylor's (2008) comprehensive review of mathematics literature that related to the role of culture in teaching and learning argues that mathematical concepts must be presented to learners in a context that reflects their lived experiences and that these contexts for learning be generated through "conversations and shared experiences (p. 226)." Intersubjectivity or a third space (Gutierrez, Rymes, & Larson, 1995) is offered as a way to bring together cultural knowledge (knowledge acquired outside of school settings) and domain knowledge (knowledge prescribed by math educators) into a hybrid space for discourse about mathematics. Nasir et al. (2008) further argue that these experiential practices should socially and conceptually support deep learning of mathematics and build positive identities for math learners. Math knowing is a "cultural activity, math learning" is a "cultural enterprise, and math education" is a "cultural and political activity (p. 227)."

Similarly, Lipka, Yanez, Andrew-Ihrke, and Adam (2009) argue for a "third way" that is a combination of knowledge and pedagogy – both local and Western. The idea behind the third way is to increase motivation and provide access to the instructional material. Through these curriculum and pedagogical changes both methods as reported by the researchers show improved academic performance as represented by empirical studies (Lipka et al., 2005).

All knowledge (Nasir et al., 2008), curricula, and pedagogy (Lipka et al., 2005) is culture-based. However, whose culture is this knowledge, curricula, and pedagogy based on? Culture-based mathematics education, in the USA in particular, seeks to provide a voice for the marginalized that is as privileged as the dominant cultures (Lipka et al., 2005).

The mathematics education reviews call for a more inclusive examination of how culture influences and is influenced by the learner. It is a rallying call to serve the needs of the few and the many. The lived experiences of learners seem to be the core of this cultural thrust and to use learners lived experiences as a conduit to more culture-specific learning applications.

Science Education

An analysis of studies in the areas of culture, learning, and science reveals a focus on equity, identity, and agency to build scientific competency in marginalized populations living in the USA (Barton, Tan, & Rivet, 2008; Basu, 2008; Brown, 2004; Carlone et al., 2011; Elmesky, 2011; Lee, Maerten-Rivera, Penfield, LeRoy, & Secada, 2008; Lynch, Kuipers, Pyke, & Szesze, 2005; Polman & Miller, 2010; Rivet & Krajcik, 2004; Schademan, 2011; Seiler, 2001; Warren, Ballenger, Ogonowski, Rosebery, & Hudicourt-Barnes, 2001). The focus on equity, identity, and agency is learner centered with the intention to improve academic achievement.

Equity: Equity is not about offering the same educational experiences, content, instruction, etc. to youth based on their age, gender, race, ethnicity, or socioeconomic status. Equity is about providing the knowledge base, specialized skills, and diverse worldviews needed to succeed in a global economy (Jordan, 2010). In the science classroom, equity allows all students to contribute, participate and perform equally. A hierarchy of race, class, gender, privilege, language, dialect, or difference does not exist (Brown, 2004; Carlone et al., 2011; Jayaratne, Thomas, & Trautmann, 2003; Lynch et al., 2005; Schademan, 2011). This includes the acceptance of diverse learners' ways of knowing, articulating, thinking and what they bring to science (Elmesky, 2011; Schademan, 2011; Warren et al., 2001).

Equity can be achieved through the identification, examination, and elimination of inequitable practices enacted, in educational environments, against minority learners in science classrooms (Carlone et al., 2011; Polman & Miller, 2010). Minority learners' "scientific literacy" has been a source of cultural conflict (Brown, 2004) as their science discourse may offer alternative perspectives than "mainstream" expectations.

Other equity issues relate to the curriculum and educational access. Conflicts exist in the one size fits all curriculums that do not meet the needs of diverse student populations (Lynch et al., 2005). Access to scientific knowledge has been denied to ethnic youth in US public schools. This denial is exhibited through the lack of access to high level science courses (Gollub & Spital, 2002), scientific literacy, and qualified science teachers (Barton et al., 2008).

Identity: Identity is tied to how learners perceive themselves amongst others. In the science classroom, these culturally produced meanings of self can be positive or negative and can influence scientific learning and interactions (Barton et al., 2008; Brown, 2004; Carlone et al., 2011; Polman & Miller, 2010; Schademan, 2011). That is, cultural conflict as manifested through science discourse can challenge or create conflicts that prohibit learning (Brown, 2004). Learners, in the science classroom, need to be able to see themselves as successful and as someone who can be identified as a "scientist" (Carlone et al., 2011; Elmesky, 2011; Warren et al., 2001). Learners cultural commodities are their forms of capital that needs to be respected and valued (Seiler, 2001). By example, Basu (2008) found that when given the freedom to create their own conceptions of physics, high school students situated their understandings of science in their identities; specifically, they enacted lessons through how they understood science and how science aided them in achieving their goals.

Agency: Agency in the science classroom is enacted through learners participation in the act of scientific thinking, being able to engage in science practices that promote learning, feeling comfortable enough to verbalize scientific understanding, and bringing the culture of themselves into the mix. Research studies report that agency is performed when learners feel empowered by their cultural knowledge (Schademan, 2011); express their identity through scientific enactments and articulations (Basu, 2008), and build cultural capital and affiliations with others based on engaging in the act of cultural practices (e.g., African American students used hip-hop culture and developed a rap about the speed of sound as a path to understanding science and expressing identity) (Elmesky, 2011).

These studies found equity, identity, and agency to be important issues in better meeting the academic needs of marginalized groups. This suggests that there are social, political, and economic issues that must be addressed concurrently with the academic issues in order to provide a learning environment where equity is provided, identity supported, and agency given.

Interventions in Science Education

Several studies conducted science interventions with ethnically diverse populations of learners to examine learning gains and considerations of culture in the design of a curriculum unit and professional development materials. Rivet and Krajcik (2004) developed the Big Things program that focused on a sixth grade project based science curriculum with learning technologies and real-world applications that would be of interest to urban youth. Students showed improvement; however, learning gains were not as high as expected.

Lynch et al. (2005) used a "highly rated" preexisting middle school science curriculum called Chemistry That Applies (CTA) with the goal of better understanding student learning and the implementation of CTA in an ethnically diverse setting. In the overall study, academic gains were realized in the content area assessed; however, the impact of the curriculum on a small group of ethnically diverse students was inconclusive.

Lee et al. (2008) developed a science and professional development intervention for elementary school teachers that sought to promote science achievement in English Language Learners. For example, the curriculum integrated science terms in English, Spanish, and Haitian Creole, included teacher guides about misconceptions and disconnects that students encountered with the curriculum, provided literacy development for English Language Learners in their native language, and used multiple modes of communication to educate the learner (e.g., visual, kinesthetic, textual). Overall, students demonstrated a significant improvement in science achievement and performed better on high stakes testing.

These science education interventions demonstrate the need to find new ways to educate all. In particular, the inclusion of more culture-specific content into academic disciplines like science have the potential to improve learning gains for ethnically diverse learners and provide an avenue to truly educate the underserved.

International Studies in Science Education

International studies in science education focused on how learners learned through scientific reasoning (Ozdemir & Clark, 2009; Robottom & Norhaidah, 2008), learning preferences (Chang, Hsiao, & Chang, 2011), and different learning environments (Chang, Hsiao, & Barufaldi, 2006; Chang & Tsai, 2005). Other studies examined affective factors related to beliefs, feelings (Robottom & Norhaidah, 2008), and attitudes (Caleon & Subramaniam, 2008; Chang, Hsiao, & Barufaldi, 2006) of learners engaged in science education.

Consistent across these studies is the use of large sample sizes of students from upper elementary to high school age levels (Caleon & Subramaniam, 2008; Chang, 2005; Chang, Hsiao, & Barufaldi, 2006; Chang, Hsiao, & Chang, 2011; Chang & Tsai, 2005; Robottom & Norhaidah, 2008). Further, the methodology sections of these papers reveal the development of an instrument to measure epistemological beliefs about science (Robottom & Norhaidah, 2008), actual and preferred learning environments and teaching methodologies (Chang, Hsiao, & Barufaldi, 2006; Chang, Hsiao & Chang, 2011; Chang & Tsai, 2005), general attitudes towards science (Caleon & Subramaniam, 2008), and understandings and appreciations of humans to nature (Chang, 2005).

International studies in science education advocate for a science curriculum that is indicative of learners lived experiences (Chang, 2005; Lewthwaite et al., 2010). By example, the Taiwanese Science and Life Technology Curriculum Standards and Earth Systems Education are curriculums that focus on helping learners apply science in their daily lives (Chang, 2005). Chang, Hsiao, & Barufaldi's (2006) findings argue that student's cultural histories and identity should be considered when designing learning environments. Chang and Tsai (2005) begin to exemplify the inclusion of the Chinese culture by redesigning an American instrument into the Chinese Constructivist Learning Environment Survey. Ozdemir & Clark (2009) found that Turkish elementary, middle, and high school aged students varied greatly in their understandings of the concept of force due to their diversity. That is, student's cultural diversities (i.e., language, understandings, education) attributed to their varied interpretations and meanings of science education content. Robottom and Norhaidah's (2008) research of Islamic learners further supports the notion that learners meanings of science are shaped and constrained by their culture.

The international studies in science education demonstrate a focus on how learners learn but in particular how learners feel about the learning experience. Further there is a focus on learners lived experiences. This suggests that there are psychological (i.e., beliefs, feelings, attitudes, reasoning) and anthropological (i.e., lived experiences) factors to better understanding learning. Studies about learning require more of a holistic orientation to get at the intricacies of human learning that manifest through learner's engagement with their culture.

Worldviews on Science Education

Worldviews on science education argue that there is a space and place for indigenous knowledge and global perspectives that get at other ways of knowing, being and seeing the world within science education. The point is to bring equity into science education through the inclusion of indigenous and marginalized groups' worldviews and perspectives of science and provide these groups with successful science learning opportunities (Aikenhead & Ogawa, 2007).

Studies in science education research argue that Western science education fails to serve the needs of indigenous and marginalized groups due to its (1) epistemological conflicts, (2) irrelevance to lived experiences, (3) domination of Western science and scientific thought (Brayboy & Castagno, 2008), and (4) inability to meet their social needs (Mutegi, 2011). A harmonizing science education that honors two ways of learning from the Western worldview and the indigenous worldview is believed to best serve the needs of the Inuit communities in the Northern Qikiqtani region of Nunavut (Lewthwaite & McMillan, 2007), Māori communities of Aotearoa New Zealand (Wood & Lewthwaite, 2008), and Zulu communities of Chibini, South Africa (Keane, 2008).

Emdin (2010) promotes the inclusion of students lived experience through hip-hop culture as a tool to connect learners to science education; his work continues to explore other urban science education conceptualizations such as neo-indigenous, communal practices and rituals (Emdin, 2007a, 2007b; 2009). Mutegi (2011) advocates for a socially transformative curriculum approach that is particular to the African Diaspora experience and at the core it asks African American students to understand their colonial status, colonialism, and their colonizers.

Lewthwaite et al. (2010) argue that expressions of local and indigenous content in science education can only come through policy and leadership that supports "culture-based education programs" (p. 1). Culture-based education, as endorsed by the Government of Nunavut, Canada, provides children with educational content and experiences that affirms and reflects the Nunavummiut culture; in particular this culture-based education should be integrated throughout the school management, operations, curriculum, pedagogy, and programs.

It is evident that indigenous and marginalized groups around the world are seeking to preserve and document their knowledge, ways of being, identity, etc.—that is their culture. Further, they seek to capture their culture and use it as an instructional tool to advance the academic achievement of children and youth. Some of these cultures chose to exclude all Westernized and Eurocentric interference others seek to find a middle ground where both indigenous and European worldviews can be learned in harmony.

International Perspectives in E-Learning

An analysis of empirical research in the areas of culture, learning, and e-learning reveals predominately a focus on international learners in higher education settings. These studies seek to quantify and qualify learners based on their perceptions about e-learning (Jung, 2011; Ku & Lohr, 2003; Liu & Magjuka, 2011; Wang, 2007), attitudes towards e-learning (Ku & Lohr, 2003; Thompson & Ku, 2005), behaviors (participation and usage) while engaged in e-learning (Yang, Olesova, & Richardson, 2010; Zhao & Tan, 2010), communication styles during e-learning (Yang et al., 2010), and critical thinking in an e-learning environment (Al-Fadhli & Khalfan, 2009).

The studies covered in this review all examined some aspect of culture; however, some research made explicit cultural concerns such as: cultural differences (Chase, Macfadyen, Reeder, & Roche, 2004; Yang et al., 2010), cultural influences (Hannon & D'Netto, 2007; Ku & Lohr, 2003; Zhao & McDougall, 2008), cultural barriers (Hannon & D'Netto, 2007), and cultural orientations (Wang, 2007). Ultimately, it seems that there is concern about how culture influences the learner and learning in an e-learning environment.

The methodological approaches of the e-learning research demonstrate the dynamics of evaluating culture within an e-learning environment. Across the studies, the participants varied greatly in terms of race and ethnicity (e.g., Chinese, Australian, Eastern Slavic, American, etc.); however, all of the studies focused on international higher education aged learners. Sample sizes varied from 6 to 299 participants. The analyses considered qualitative, quantitative, and mixed methods (Al-Fadhli & Khalfan, 2009; Chase et al., 2004; Hannon & D'Netto, 2007; Jung, 2011; Ku & Lohr, 2003; Liu & Magjuka, 2011; Thompson & Ku, 2005; Wang, 2007; Yang et al., 2010; Zhao & McDougall, 2008; Zhao & Tan, 2010). Most of the studies administered research specific surveys, except Liu and Magjuka (2011), Thompson and Ku (2005), and Zhao and McDougall (2008) who conducted interviews. Chase et al. (2004) analyzed content from the courses' online discussion board and Al-Fadhli and Khalfan (2009) administered a critical thinking test. This suggests that multiple methodologies of analyses have been effective in evaluating culture and learning within an e-learning environment.

The findings of culture, learning, and e-learning research indicate that learners are influenced by what they learn, how they learn, how much they learn, when they learn, where they learn, and their culture. The e-learning environment in-turn influences how learners reacted and responded through their perceptions, attitudes, and behaviors—ultimately their culture.

The most emphasized findings across the studies focused on technology, synchronous and asynchronous learning, communications, and the instructor. Overall, the technologies used in e-learning environments failed to support e-learners, serve the cultural and international needs of groups and only highlighted Westernized styles (Chase et al., 2004; Wang, 2007). Cultural issues such as technology experience and differences in cultural backgrounds were not addressed by the technology or through technological supports (Hannon & D'Netto, 2007). A more personalized technological environment is suggested to better improve e-learning environments (Jung, 2011).

Synchronous and asynchronous e-learning environments should better support users. E-learning environments should consider the cultural variability of learners and learning to better address the needs of learners (Jung, 2011; Liu & Magjuka, 2011; Wang, 2007; Yang et al., 2010; Zhao & McDougall, 2008). Asian students in particular found that asynchronous environments allow them time to reflect, think, and learn more (Wang, 2007; Zhao & McDougall, 2008).

Communicating in e-learning environments is a great concern of researchers because learning is supported through communication. Culture affected the way learners approached and responded in the e-learning environment, to classmates and with the instructor (Jung, 2011; Wang, 2007; Yang et al., 2010). Cultural issues were apparent in ways of communicating (Chase et al., 2004; Hannon & D'Netto, 2007; Liu & Magjuka, 2011; Wang, 2007; Zhao & McDougall, 2008), values, language, and learning preferences (Ku & Lohr, 2003); and participation behaviors (Yang et al., 2010).

The power dynamics between teacher and learner is culturally shaped and it influences learner's interactions with the e-learning environment (Chase et al., 2004). Several studies found that Chinese learners operated on the cultural belief of instructor as knowledge source and that these expectations carried into the e-learning environment. When instructors did not respond with these cultural expectations, the learner and learning experience were disengaged (Ku & Lohr, 2003; Wang, 2007; Zhao & McDougall, 2008).

Culture influenced how learners performed and persisted in an e-learning environment (Wang, 2007). Of note, the studies that focused on perceptions and attitudes included participants who were Asian (i.e., Chinese, Korean) (Jung, 2011; Ku & Lohr, 2003; Liu & Magjuka, 2011; Thompson & Ku, 2005; Wang, 2007; Yang et al., 2010; Zhao & McDougall, 2008). This may be significant in that this research finds the analysis of the psychology (e.g., perceptions, attitudes, beliefs) of the learner as important as the anthropology (e.g., behavior, etc.). That is, learning in an e-learning context may require both an analysis of psychological and anthropological factors to best access the intricacies of human learning.

Reviews in E-learning

Reviews of literature in e-learning focus on nation building, formulating frameworks that support sociocultural learning and considering diverse learning needs. Nation building through e-learning involves competing with global economies; educating, preparing, and supporting the countries human capital (Perkins, Gwayi, Zozie, & Lockee, 2005); building and supporting information technology infrastructures; and creating an environment that fosters knowledge construction (Kim & Santiago, 2005). Further, the act of nation building is very particular to the maintenance of culture. Frameworks, models, and guidelines that support e-learning center on knowledge development, building community, supporting learners, considering culture (Gunawardena et al., 2004; Gunawardena et al., 2006; Taylor, 2005), identifying manifestations of culture in e-learning (Gunawardena & LaPointe, 2008), and evaluating e-learning courses (Edmundson, 2007). Considering the needs of learners means making allowances for their diverse learning approaches (Alias, 2011); attributes and contexts and conditions for learning (Mitchell & O'Rourke, 2008).

It seems that this e-learning research is very much focused on the needs of the learner and how the learner can support country and ultimately their culture. This research suggests that there is much improvement needed to address the international higher education learner in an e-learning environment.

Implications

There are growing concerns across disciplines that learners, from children to adults, need a more specialized education to meet their academic needs. In the twenty-first century, this should not be an issue with the wealth of information, multiple means of literacy outlets and the technological resources available. The present methods and strategies that are being used fail to appropriately address the needs of all learners. Therefore, there is a need to rethink and rebuild curriculum, instruction, theories, methodologies, etc.

This research sought to examine international research in the areas of culture, learning, and mathematics, science and e-learning education to determine relevant instructional strategies in this context. The implications of this literature review indicate the following:

- Explicit instructional strategies that enable learning do not exist for ethnically diverse populations in the USA. Innovative instructional strategies must be derived from versus applied to learners.
- Research about learners should be more broadly structured to include anthropological and psychological factors to acquire a more holistic picture of the learner and their learning. This holistic picture aids in building learning applications that are culture-specific and more appropriately aligned to learner needs.
- Methodologies of analysis vary; however, ethnographies seem to capture a more holistic picture of the learner and more specifically their culture. By example, 10 of the 12 science education studies employed ethnographic methods to acquire information about the learner (Barton et al., 2008; Basu, 2008; Brown, 2004; Carlone et al., 2011; Elmesky, 2011; Lynch et al., 2005; Polman & Miller, 2010; Schademan, 2011; Seiler, 2001; Warren et al., 2001). The collection of ethnographic data can include videotapes, observations, assessments, interviews (Carlone et al., 2011), group interviews, content-based think-alouds, reflection notes, student work, informal conversations in and out of school; social gatherings (Barton et al., 2008); and archival documents (Basu, 2008).
- Multiple assessment methods may be needed to get at academic and affective learning. There is a need to determine if learning is happening and if so in what ways and why. Determining how learners feel about the academic experience may be as important as their academic progress.
- Instructional strategies that are derived from human interactions will prove the most valid in designing curriculum, improving e-learning environments, making learning happen, knowledge construction, and improving academic gains.
- Building on the life experiences of the learner seems to be the nexus of moving towards more culture-specific applications. This need to situate learning in the life experiences of the learner is supported by mathematics education research, science education research, and e-learning education research.

Conclusion

Culture matters in the selection of instructional strategies. However, it is better to assess the learner to let the educational strategies be derived from the learner versus applied arbitrarily to the learner.

A variety of research has been excluded because of space constraints or content. Studies that focused on teachers versus learners were excluded or minimally highlighted to maintain the focus of the chapter on learners. Some of this research examined what instructors should do in relation to culture, learning, and science education (Emdin, 2007a, 2007b; Lewthwaite et al., 2010; Milner, 2011; O'Neill, 2010), math education (Civil, 2002; Correa, Perry, Sims, Miller, & Fang, 2008; Gutstein, 2003; Lipka et al., 2005; Leonard, Brooks, Barnes-Johnson & Berry, 2010; Seah, 2002), and e-learning education (Burniske, 2003; Goold, Craig & Coldwell, 2007; Sánchez-Franco, Martínez-López, & Martín-Velicia, 2009).

Culture, learning and computer technology education offers another area for in-depth study. This research examines a variety of issues such as the following: global knowledge in local contexts, instructor focused concerns, perceptions of using technology, the role of technology in cultural change, ethnically diverse learners, technology enhanced learning, and technology integration (Aydin & McIsaac, 2004; Chitiyo & Harmon, 2009; Ezer, 2006; Gudmundsdottir, 2010; Heemskerk, Brink, Volman, & Dam, 2005; Hornik & Tupchiy, 2006; Lee, 2003; Lieberman, 2008; Lim, 2007; Luck & Peng, 2010; Olaniran, 2009; Robbins, 2007; Swigger, Alpaslan, Brazile, & Monticino, 2004; Zhang, 2007, 2010; Zhao, Zhang, & Tan, 2010).

The areas of culture, learning and instructional design provide guidance in educating diverse populations. This research examines a variety of issues such as: ethnically diverse learners, culture-specific curriculum content, multiculturalism, cultural diversity, culture-specific pedagogy, indigenous languages and knowledge, and designing in cross-cultural contexts (Amiel, Squires, & Orey, 2009; Campbell, Schwier, & Kanuka, 2011; Frederick, Donnor, & Hatley, 2009; Igoche & Branch, 2009; Joseph, 2009; Kinuthia, 2007; Leonard, 2008; Russell, 2011; Scott, Aist, & Hood, 2009; Thomas & Columbus, 2009; Young, 2009).

Future research in culture, learning, and a discipline might examine the literature coming from Human Computer Interaction and game design. These disciplines are growing in these areas and finding innovative ways to educate learners through information and communication technologies.

Of course, it is possible to miss some important studies or reviews of literature. This chapter has tried to locate a representative sampling of what has been published in the last decade.

If culture matters in educating learners in mathematics and science education, why has there been little movement in North America to design learning technologies to meet the needs of marginalized groups? If e-learning systems do not meet the needs of international populations why have not e-learning companies accommodated to the needs of these groups? Why has culture been ignored?

It seems that considering culture in the development of instructional strategies is only part of a complicated equation to educate learners. There are many factors that must be seriously considered. Situating the learner at the center of this nexus is a place to begin.

Learning Ability Development in Flexible Learning Environments

29

Saskia Brand-Gruwel, Liesbeth Kester, Wendy Kicken, and Paul A. Kirschner

Abstract

Education has come to recognise the importance of the development of learning ability, that is, the acquisition of self-directed learning (SDL) skills and self-regulated learning (SRL) skills, because these skills equip students for functioning in our constantly changing society as life long learners. To give students the opportunity to develop these skills a flexible learning environment is needed. Such an environment enables learners to determine more or less personalised learning trajectories for themselves. Moreover, a flexible learning environment should be designed in such a way that the acquisition of SRL and SDL skills is supported. In this chapter after addressing the concept of learning ability or more specifically the concepts of SRL and SDL and the way the two are intertwined, the basic elements needed in the design of a flexible learning environment are discussed. The need for well-structured learning materials, assessment criteria, portfolios, advisory models and instructional support for acquiring SRL and SDL skills is discussed.

Keywords

Learning ability • Self-direct learning • Self-regulated learning • Flexible learning environments

Learning Ability Development in Flexible Learning Environments

This chapter discusses flexible learning environments (FLEs) that foster the development of learning ability, that is, the acquisition of self-directed learning (SDL) skills and self-regulated learning (SRL) skills. A flexible learning environment refers to an environment in which learners are able to follow their own learning trajectory given the formal learning goals. Concisely stated (as this is discussed extensively in the rest of this chapter), SDL encompasses the ability to formulate learning need, determine learning goals and select learning resources. Moreover, SRL is the ability to monitor and steer own learning processes. Education has come to recognise the importance of SDL and SRL. It is important because these skills equip students for functioning in our constantly changing society as life long learners. To give students the opportunity to develop these skills in education a flexible learning environments is needed in which a student can follow their own learning trajectory and get the support needed to create the most optimal learning path. Such an environment enables learners to have choices in term of what, where, when, why and how they learn (Hill, 2006). Based on formulated learning needs and learning goals learners should be able to identify human and material resources for learning in a flexible learning environment. In this way, such an environment enables learners to determine personalised learning trajectories given the formal learning goals. But just given the learners the opportunity to choose is not

recommended, because research shows that learners are not always capable of making substantiated, appropriate, and effective choices (e.g. Williams, 1996), resulting in ineffective learning and low transfer of learning. So, we argue that a flexible learning environment can be a good starting point to encourage learners to become self-directed and self-regulated learners. But the support and guidance given in the environment to the learners in acquiring these skills and make appropriate choices seems essential.

A flexible learning environment differs from what is called an adaptive learning environment. In an adaptive environment the learning trajectory and learning materials are personalised, but the system does this for the learner. Adaptivity can be defined as the capability of *a system* to alter its behaviour according to the learners and other characteristics (Vandewaetere, Desmet, & Clarebout, 2011). The "system" could be a teacher, a trainer, an intelligent agent or tutor, etc. In any event, the system adapting the materials and trajectory to the learner is not the learner herself/himself and thus the learner cannot develop the needed SRL and SDL skills in such an environment, unless the "system" decides the environment should allow flexibility.

This chapter outlines the basic elements needed in the design of an FLE. The need for well-structured learning materials, assessment criteria, portfolios, advisory models and instructional support for acquiring regulation skills is discussed. But before we go into that, we address the concept of learning ability or more specifically the concepts of SRL and SDL and the way the two are intertwined. The chapter concludes with a discussion section in which theoretical and practical implications are addressed and directions for future research are given.

Learning Ability

Learning ability is related to SDL and SRL. The SRL and SDL skill can be referred to as higher-order skills, skills overlooking and governing the cognitive system, while simultaneously being part of it (Veenman, Van Hout-Wolter, & Afflerbach, 2006). In the literature, SDL and SRL are often difficult to distinguish from each other with confusion being the result. The constructs are regularly used interchangeably (Boekaerts & Corno, 2005; Bolhuis, 2003; Dinsmore, Alexander, & Loughlin, 2008), often no precise definitions are given and a variety of related terms (e.g. autodidaxy, SDL, independent study, SRL, self-planned learning, self-guided learning and learner control) is used to indicate both constructs (Brockett & Hiemstra, 1991). Moreover, SDL and SRL are complex constructs that focus on different aspects of the learner and her/his learning processes (e.g. motivational or cognitive processes, organisation of learning). Although the constructs are closely related, they differ in theoretical background as well as empirical methods to study them and, therefore, should not be used interchangeably.

Self-Directed Learning

SDL is described by Knowles (1975) as "a process in which individuals take initiative, with or without the help of others, in diagnosing their learning needs, formulating learning goals, identifying human and material resources for learning, choosing and implementing appropriate learning strategies, and evaluating learning outcomes" (p. 18). Although the concept of SDL was introduced in adult education, Knowles pointed out that SDL does not exclusively apply to adults. Brockett and Hiemstra (1991) developed a conceptual framework for understanding SDL called the "Personality Responsibility Orientation" with personal responsibility as the starting point for SDL. In their view, individuals need to be owners of their thoughts and actions and should have—or be willing to take—control over how to respond to a situation and make choices concerning their learning process without ignoring the social context. The freedom to make choices implies that learners need to be able to make good choices during their learning process (Brockett, 2006), and must be responsible for the consequences of their thoughts and actions. Self-directed learners, thus, are able, ready and willing to independently prepare, execute and complete learning (Van Hout-Wolters, Simons, & Volet, 2000).

Different authors have described characteristics of a skilful self-directed learner. These include initiative, intentions, choices, freedom, energy and responsibility (Tough, 1979, in Levett-Jones, 2005), the ability to learn on one's own, personal responsibility for the internal cognitive and motivational aspects of learning (Garrison, 1997), independence, autonomy and the ability to control one's own affairs (Candy, 1991). These characteristics stress a key aspect of SDL, namely, that the learner determines the planning and execution of her/his learning trajectory in the long term. Therefore, as stated by Jossberger, Brand-Gruwel, Van de Wiel, and Boshuizen (2010) SDL can be situated at the macro level and concerns the person's learning trajectory as a whole. Self-directed learners are able to decide what needs to be learned next and how their learning can best be accomplished. Skilful self-directed learners can—based on an evaluation of previous learning—diagnose their own learning needs, formulate learning goals, and identify and choose human and material resources for learning, and determine appropriate learning strategies (cf. Kicken, Brand-Gruwel, Van Merriënboer, & Slot, 2009; Knowles, 1975).

Self-Regulated Learning

SRL, in contrast, functions on a micro-level and concerns processes within the execution of a specific learning task. It is argued (Jossberger et al., 2010; Loyens, Magda, & Rikers, 2008) that while SDL includes SRL, the opposite is not the case. In other words, self-directed learners are supposed to be able to also self-regulate their learning, but a self-regulated learner is not necessarily able to self-direct her/his learning.

SRL deals with subsequent steps in a learning process (Loyens et al., 2008). However, in the SRL literature there is a variety of perspectives on how cognitive, meta-cognitive, motivational and contextual factors influence the learning process (e.g. Boekaerts, 1997; Pintrich, 2003; Zimmerman, 2002). A well known and often used perspective is that of Zimmerman (1989, p. 329) who states that "students can be described as self-regulated to the degree that they are meta-cognitively, motivationally, and behaviourally active participants in their own learning process". Important in this citation is the word degree. The more the learner is intrinsically motivated, is learning in an active way and is metacognitively involved in the process the more self-regulated the learner is.

Zimmerman (2000, 2006) describes three phases and underlying sub-processes that involve behavioural, environmental, and covert self-regulation. The *forethought phase* is a preparatory phase where learners orient themselves to the learning task and plan the steps that need to be taken to carry out the learning task. Self-regulated learners analyse the learning task, set a clear goal, make a plan and select strategies for achieving the goal. Task demands and personal resources must be considered before beginning a task so that potential obstacles can be identified (Ertmer & Newby, 1996; Zimmerman, 2000, 2006). In the *performance phase*, monitoring and adjusting are central skills during the learning process. Monitoring is essential, as learners should be constantly aware of what they are doing by looking back at the plan and looking forward at the steps that still need to be performed to achieve the goal in mind. When learners realise that things do not work out as planned, they need to adjust their approach. In the final *reflection phase*, assessing and evaluating are key skills. After having carried out the task, learners evaluate the effectiveness and efficiency of the plan and of their strategy use (Ertmer & Newby, 1996; Zimmerman, 2000, 2006). Evaluating the process and reflecting on experience can increase learning from actual experience and can possibly be used in the future (Ertmer & Newby, 1996; Fowler, 2008). Reflection is, therefore, critical for the link between previous learning experiences and future learning experiences because a learner can, by reflecting, draw upon previous knowledge to gain new knowledge (Ertmer & Newby, 1996).

To conclude, learning ability is related to both SDL and SRL which are two distinctive types of learning that describe learning processes on a macro level (SDL) and on a micro level (SRL). Learning ability includes both SDL skills (learning trajectory level) and SRL skills (learning task level). In Fig. 29.1, the way the two skills are interrelated is visualised. As can be seen, the two skills act on different levels but

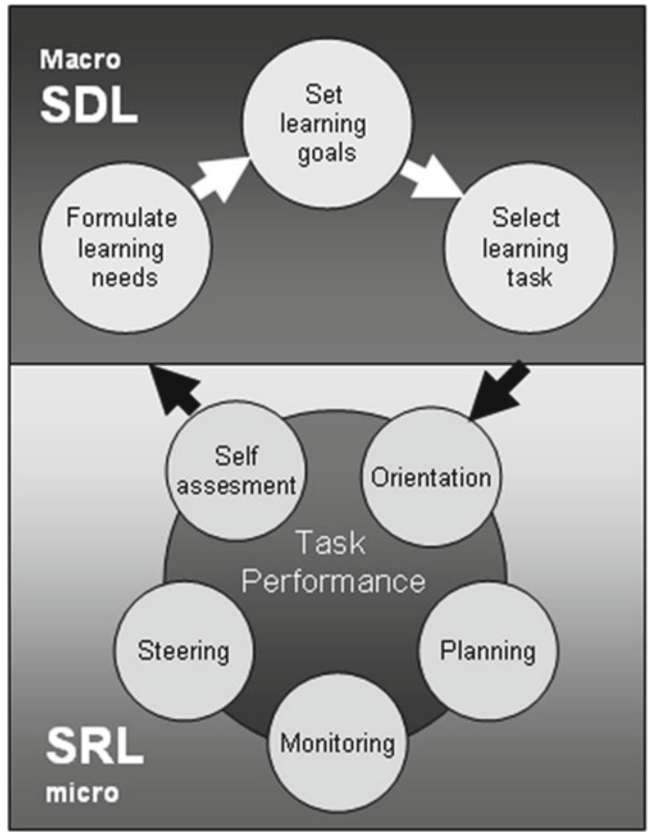

Fig. 29.1 Relation between self-regulated learning (SRL) and self-directed learning (SDL)

proper execution of both skills is needed to optimise the learning process. The outcome of the task performance and the assessment of the task helps learners to formulate learning needs and goals and to direct learning, and select tasks for future learning.

It is important to realise that guidance and support in these skills must be embedded in the domain specific content of the curriculum. As mentioned these skills are higher-order skills and Van Merriënboer (1997) assumes higher-order skills can only be trained in a particular domain. Furthermore he claims that "…if we want the strategic component of higher-order skills to transfer between domains, they should be trained in as many domains (or, courses) as possible and it should be made explicit to students that a higher-order skill that works in one domain may also work, or may not work, in another domain" (pp. 15–16). This promotion of mindful abstraction and decontextualisation of general principles of higher-order skills, is referred to as "the high road of transfer" (Perkins & Salomon, 1987). This assumption has its consequences for the way the instruction to acquire these skills should be designed. The next section discusses the design of an FLE and the instructional support that can be embedded in it to acquire these skills.

Flexible Learning Environments: Enabling Self-Directed Learning

As stated, a flexible learning environment is an environment that enables learners to make choices, select learning materials (e.g. subsequent learning tasks) and personalise their learning trajectory based on the formulated learning needs and learning goals. These needs and goals are based on the assessment of the previous performed learning tasks. Furthermore, we argue that a FLE should be designed in such a way that the acquisition of these skills is supported. The responsibility of the choices made in the learning environment can be gradually shift from the teacher (or intelligent agent) to a learner. When the learner acquired a set of well-developed SDL skills, the learner can be given full control and complete freedom to decide on the learning trajectory. But when the learner is not yet able to accomplish a self-assessment, formulate learning needs and goals, and select appropriate tasks, the teacher and learner should share the control. A flexible learning environment based on shared control is an environment where learners can learn to become self-directed in a guided way.

When designing a flexible learning environment the design elements necessary to foster SDL must be thoroughly considered. Based on the work of Knowles (1975) on SDL, of Zeichner and Wray (2001) on portfolio use, of Bell & Kozlowski, 2002 on enhancing self regulation, and of Tennyson (1980) on instructional strategies Kicken, Brand-Gruwel, and Van Merriënboer (2008) developed what they called the *informed self-directed learning* (ISDL) model in which three components or information resources are distinguished to support SDL skills development in an FLE. The elements are (1) learning tasks with metadata, (2) a development portfolio and (3) an advisory model. Figure 29.2 shows how these components are related in a learning environment with shared control. The components at the top of the figure (development portfolio, advisory model, task metadata) negate the major problem in many so-called flexible learning environments, namely, the learners' lack of information essential for successful SDL. The inclusion of the advisory model here is based on the empirical findings that learners often have not yet sufficiently developed their own SDL skills and, thus, need to be explicitly supported in developing them. The information provided by the development portfolio and task metadata is directly related to the activities of performance (self-) assessment, learning goal formulation, and resource selection (e.g. learning tasks) (Knowles, 1975). The rule bars indicate the amount of support given to the learner in order to perform the SDL-skills to a sufficient level and make adequate decisions on the learning trajectory. The model by Kicken et al. provides the basis for the development of a FLE.

The ISDL model implemented in an FLE supports a cyclical learning process. The learner selects one or more learning tasks from the task database, carries it/them out, gathers assessments of the task/tasks in the portfolio based on assessment criteria, selects one or more new learning tasks from the database taking the information in the portfolio into account, and so on. In each cycle, the updated information in the portfolio is used to formulate/reformulate individual learning

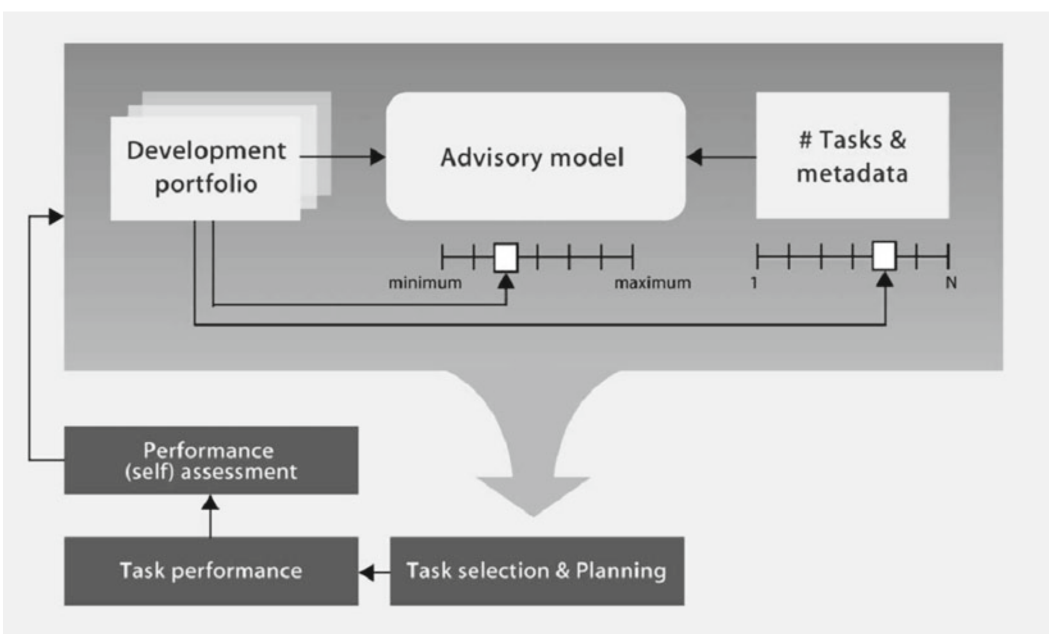

Fig. 29.2 The Informed Self-Directed Learning (ISDL) model (Kicken et al., 2008)

needs and set new learning goals to select suitable subsequent tasks. The teacher or computer system uses the coaching protocol based on the advisory model to support and guide the process of formulating learning needs, setting learning goals, and selecting new tasks and so optimises the development of both domain-specific skills and SDL skills. The model gives insight in the process of SDL but also provides information about the important design elements of the FLE. We briefly discuss the design elements and address research that has been conducted to concerning the models' elements.

Learning Tasks with Metadata

Learners should be supported in selecting new learning tasks according to their level of performance, because such a selection is a difficult aspect of SDL. When the learning environment is too open, providing learners with to many choices and too little guidance or advice to help them make appropriate decisions, it can lead to even negative effects on cognitive, metacognitive, and affective learning variables (Katz & Assor, 2007; Williams, 1996). Selecting new tasks or resources for learning must be learned by practising and receiving feedback on the quality of the selection process and the appropriateness of it. To help students to select appropriate tasks that fit their learning needs it is necessary that a large set of learning tasks is available. To select tasks from this set, learners should have the tasks' relevant metadata available (Bell & Kozlowski, 2002). These metadata can include the tasks' objectives, the skills that can be acquired, the task's level of difficulty and support provided, the applicable performance standards for determining whether the task has been carried out to a predetermined level, and the prerequisite skills, knowledge and attitudes necessary to perform it (Kicken et al., 2008). The goals and skills that can be acquired is of major importance, because taken the personal learning goals and learning needs one has to choose if the new tasks is in essence suitable.

Development Portfolio

A development portfolio, which can be electronic or paper-and-pencil, gives an overview of assessments of task performances and keeps track of the learning process by providing an overview (Kicken et al., 2008, 2009). Several studies reported that development portfolios are effective tools to help students reflect on their learning and to think about the development of their skills (Chen, Liu, Ou, & Lin, 2000; Driessen, van Tartwijk, Overeem, Vermunt, & van der Vleuten, 2005; Mansvelder-Longayroux, Beijaard, & Verloop, 2007; Zeichner & Wray, 2001). An important aspect in the assessments is the use of assessment criteria. These criteria should be specific and related to the learning goals of the task. The assessor(s) (e.g. teacher, coach, peer or intelligent agent) can put the assessment into the portfolio. In that case the learner and the teacher have an overview of the learners' progress. A development portfolio also allows the learner the opportunity—or can even require—that the learner bring his or her self-assessments into it. Finally, the portfolio can allow the comparison of these assessments. This kind of information make that learners acquire more experience in self-assessments, and can gain more insight in their progress or lack of progress (Birenbaum & Dochy, 1996; Falchikov & Boud, 1989). The assessments gathered in the portfolio and the information they provide on competency development offer a sufficient basis for identifying individual learning needs. The learning needs, formulated either by the learner or by the learner and the agent (e.g. teacher, tutor, peer, computer) in a shared control condition should also added into the portfolio. These learning needs can be related to the assessment criteria. Students are not used to think about or formulate their learning needs (Holme & Chalauisaeng, 2006), and therefore, it is important that learner perceive that assessments for a basis for formulating learning needs. Also the learning goals for future learning can be part of the portfolio; in this way the goals can be related to the learning needs and the tasks that can be selected to fulfil these learning needs.

Advisory Models

FLEs should make learners increasingly responsible for their own SDL process and advisory models can help teachers to integrate support on these skills in their education. Providing students with advice has shown to be an effective method to help students make better choices and develop their task selection skills (Bell & Kozlowski, 2002; Tennyson & Buttery, 1980). For giving advice the teacher can use different advisory models (Taminiau, Kester, Corbalan, Van Merriënboer, & Kirschner, 2010). A procedural advisory model provides the students with feedback on their self-assessment skills and formulated learning goals, by informing them whether the self-assessments are in line with expert assessments and the SMART rules. Feedforward is provided merely by informing learners which task(s) they could select in order to improve their performance. A strategic advisory model provides the learners with feedback on their self-assessments and self-formulated learning goals in terms of their accuracy and effectiveness, and provides directions for improvement of self-assessment skills and formulating learning goals. With respect to feedforward information, the directions for task selection are heuristic in nature and extend the basic information on suitable tasks with in-depth explanations and arguments for their suitability. A strategic model makes explicit how assessments of prior performance are interpreted and converted into directions for the selection of new learning tasks (Kicken et al., 2008).

Flexible Learning Environments in Practice

Kicken et al. (2009) investigated the effects of giving students specific portfolio-based advice on the development of their SDL skills in a flexible environment. In a flexible hairdressing programme in vocational secondary education, one group of students received feedback on their achievements while a second group received specific portfolio-based advice (i.e. feedback and feedforward) in regular supervision meetings. In the environment, learning tasks were of different complexity levels, were all authentic tasks and the tasks differed concerning the amount of support. To help students take responsibility for their own learning process and make effective choices, a web-based development portfolio called Structured Task Evaluation and Planning Portfolio (STEPP) was designed and implemented. STEPP has three functionalities, namely, helping students to (a) assess their own task performance using assessment standards and criteria, (b) formulate learning needs based on assessed shortcomings in task performance and (c) select future learning tasks with characteristics that help to fulfil the formulated learning needs. Figure 29.3 is a screen dump of this electronic portfolio.

On the left side of the screen, a hierarchical menu with all possible hairdressing skills and subskills are presented and on the right side students can add their self-assessment and their points of improvement. On another screen students were able to select future learning tasks, skills and subskills that need further practice to meet the formulated learning needs. Finally, STEPP provides three structured overviews with all portfolio data necessary for discussing a student's progress during supervision meetings. The first screen presents all learning tasks performed by the student, together with the corresponding self-assessments and, if applicable, teacher assessments. The second screen gives an overview of all formulated learning needs. The third screen presents the working plan for the forthcoming week.

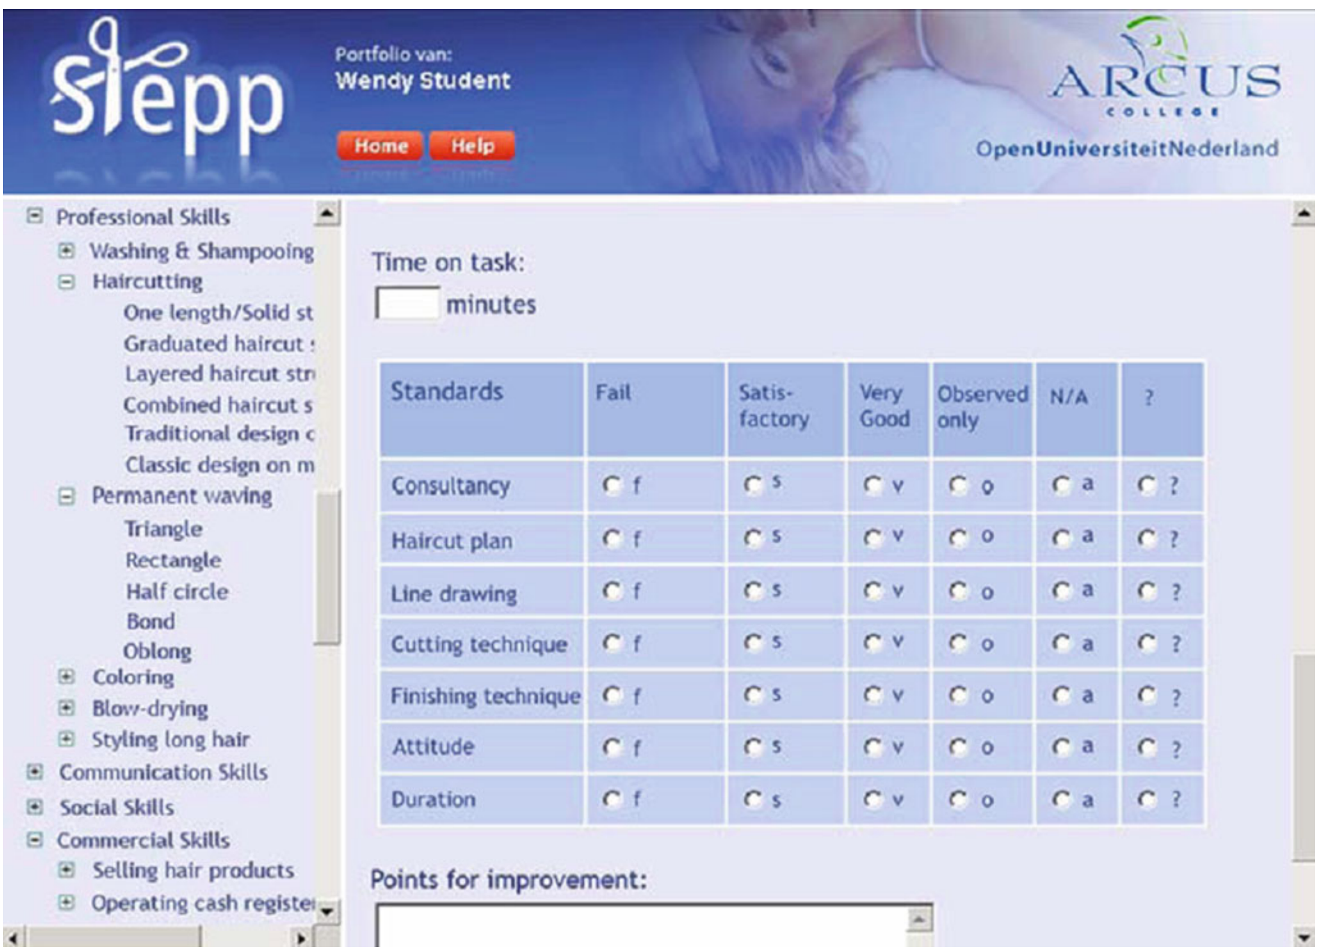

Fig. 29.3 Self-assessment and formulation of learning needs functionality in STEPP: Overview of skills (*left column*), standards for performance assessment (*table*) and possibility to formulate learning needs (*textbox*)

In both the advice and the feedback-only group, the supervisor provided feedback on the student's progress report and planning of learning over the previous 2 weeks, while discussing the three above mentioned STEPP overview screens in a fixed order. In the advice condition, the supervisor provided not only feedback but, in addition, advice on how to improve SDL skills.

Effects were studied on the development of SDL skills (i.e. self-assessment of performance, formulating learning needs and selecting new learning tasks), learning results, and student perceptions of the effectiveness of the supervision meetings. The effect of giving advice was evident in students' ability to formulate learning needs. Students who received advice were better able to diagnose possible cause(s) of their weaknesses and formulated relatively more diagnostic learning needs than students who only received feedback. With respect to task selection skills, providing feedback on task selection was to some extent effective, provided that students selected tasks from a limited number of available tasks. With respect to self-assessment skills, students did not reach a stage where they were able to assess their own performance at a sufficient level. So it can be concluded that the SDL skills of the students were to some extent improved, However, transfer to other learning situations and over time were not measured in this study. Further research should be conducted to gain insight in how transfer processes occur. Furthermore, students in the advice condition showed better learning results.

Flexible Learning Environments: Embedded Support on Self-Regulated Learning

When functioning in an FLE it is also important that learners receive support on the acquisition of SRL skills, because for functioning well in an FLE also requires regulation of learning processes when accomplishing learning tasks. In the following, four well-known instructional interventions that facilitate the acquisition of SRL skills and which can be embedded in the tasks used in the FLE are discussed. These are process worksheets (e.g. Nadolski, Kirschner, & Van Merriënboer, 2006), prompting (e.g. Stadtler & Bromme, 2008), modelling (e.g. Collins, Brown, & Holum, 1991) and feedback (e.g. Butler & Winne, 1995; Hattie & Timperley, 2007).

Process Worksheets

To help learners to attend to their micro level learning process providing general strategies and heuristics can enable them to carry out the task and meet the assessment criteria for the task (Van Merriënboer, 1997). According to Nadolski et al. (2006) a process worksheet provides a systematic approach to accomplish a learning task, presenting descriptions of the steps that need to be taken to carry out the task, and hints or rules of thumb that may help the learner to successfully complete the task. They support both the acquisition of domain-specific skills and SRL skills such as monitoring task performance and adjusting one's behaviour when task performance is not successful. Powerful scaffolds that can be added to a process worksheet are the presentation of keywords or leading questions reflecting a strategic approach to carrying out the task (Land & Greene, 2000). Wopereis, Brand-Gruwel, and Vermetten (2008) taught students to solve information-based problems while searching for information on the Internet, making use of process worksheets to structure and regulate the solution process. They found that, after the intervention, students who had received the process worksheets regulated their task performance, more often than the students who had not. In other words, using process worksheets enabled students to acquire SRL skills when accomplishing a similar task as during the intervention.

Prompts

A prompt is a cue given to someone to help or remember him or her to act on time or immediately. Prompts embedded in the learning context trigger the learner to execute specific SRL skills on a regular basis (Bannert, 2004) directing the learner's attention towards her/his own cognition during the learning process (Brown, 1997). Empirical evidence for the effect of using prompts on SRL skill acquisition has been found in a number of experimental studies. These studies have been carried out in different content domains such as mathematics (Gerjets, Scheiter, & Schuh, 2005; Kramarski & Gutman, 2006), psychology (Bannert, 2003), software programming (Schmidt & Ford, 2003), physics (Veenman, Elshout, & Busato, 1994), educational measurement (Kaufman & Lichtenberger, 2006) and biology (Lin & Lehman, 1999). Stadtler and Bromme (2008), for example, prompted students to monitor their comprehension process while studying multiple hypertext documents and found that repeated prompting assisted domain novices in detecting comprehension failures and inconsistencies in their text representation thereby enabling them to regulate their information processing accordingly (e.g. by re-reading difficult parts of the text or slowing down their reading speed). Further evidence showing that prompts indeed have a positive impact on SRL skill acquisition has been found in studies using think-aloud methodology (Bannert, 2004; Veenman et al., 1994).

Modelling

Modelling is an instructional strategy that can be seen as a first step in cognitive apprenticeship, "a model of instruction that works to make thinking visible" (Collins et al., 1991, p. 1). Modelling refers to the teacher or instructor (or actually any expert in a domain) demonstrating the carrying out of a task and also thinking aloud about what she/he is doing while performing that task. By verbalising her/his thoughts, the teacher makes it possible for learners to conceptually understand the task as well as observe the regulation aspects involved in carrying out the task. A teacher is likely to offer explicit description of each part of the process while performing the task, thus providing the learner with both a conceptual overall understanding and an analysis of the regulation processes involved. Effects of using modelling as an instructional measure to foster regulation have been studied for example by Brand-Gruwel, Aarnoutse, and van den Bos (1998). Primary school children learned to regulate their reading comprehension process during a 1-month intervention where the process of reading comprehension was modelled by both the teacher and peers. Compared to students in the control condition, students receiving the modelling intervention exhibited more regulation behaviour. Furthermore, when measuring transfer over time, the effects were not found anymore. It seems important to keep supporting the children in using these skills.

Feedback

According to Hattie and Timperley (2007), feedback is a powerful tool or teaching strategy in supporting learners in enhancing their learning performance. Feedback can be defined as "information provided by an agent (e.g. teacher, peer, book, parent, self, experience) regarding aspects of one's performance or understanding" (Hattie & Timperley, 2007, p. 81) and it is "information with which a learner can confirm, add to, overwrite, tune, or restructure information in memory, whether that information is domain knowledge, metacognitive knowledge, beliefs about self and tasks, or cognitive tactics and strategies" (Winne & Butler, 1994, p. 5740). Feedback aims to bridge the gap between the current level of performance/understanding and the learning goals. According to Hattie and Timperley, the effectiveness of feedback depends on its focus. Task mastery is especially promoted by feedback on process level and self-regulation level because this feedback is related to learning (Hattie & Timperley, 2007). Focusing feedback on the learning process can guide learners how to learn, set learning goals, choose and execute learning activities, diagnose and monitor the learning process, and evaluate learning results (Bolhuis & Voeten, 2001).

Discussion

To foster the acquisition of SRL and SDL skills, learning environments in which learners can develop these skills must be designed and developed. The environment should be flexible and learners should be able to direct their learning by formulating their own learning needs, setting their learning goals, and identifying resources for learning on the trajectory level supported by instructional measures embedded in the curriculum that stimulate acquiring necessary SRL skills.

Integrating support and guidance in acquiring SDL and SRL skills into a flexible learning environment is essential because these skills do not develop spontaneously (Zimmerman, 2002). Instructional strategies to foster SRL skills are the use of process worksheets, modelling and prompting (e.g. Bannert, 2004; Collins et al., 1991; Nadolski et al., 2006). As learners' SDL skills develop, the control over needs identification, goal setting, and task selection must gradually shift from the teacher to the learner. The learner, thus, takes increasing responsibility over her/his own learning process. Eventually, the learner must be able to identify her/his own concrete individual learning needs on the basis of self-assessments and—possibly deviant—assessments made by others who use given criteria and standards, set realistic and feasible learning goals to fulfil identified learning needs, and select appropriate new learning tasks that help reach the learning goals. Taking these aspects together and integrating them from an educational design perspective will provide insight into how learning environments should be designed to foster learning.

The practical implications of all of this are very demanding when designing a FLE. Although the environment seems loosely organised from the learner's perspective, the system itself should be very well organised. The learning tasks that the learners can or must accomplish should be well ordered (i.e. in complexity levels/task classes) and should be companied by necessary metadata such as goals, skills involved, kinds of support, and so forth. Furthermore, the assessment criteria must be clearly and transparently formulated for the learner. And finally, when guiding learners to become self directed learners, teacher/agent feedback and guidance in a shared controlled situation is indispensable.

Concerning directions for future research, more research is needed to determine and study the important elements in the design of a FLE and how these design elements function and what effects are on learners' performances and especially on their SDL and SRL skills. Research questions for the future concern how a database of tasks should be arranged to support learners in selecting tasks for future learning. How many tasks should be offered and of what complexity and support level to have an impact on the effectiveness on learners learning? Or research on how to gradually reduce the amount of support in a shared control environment and give more responsibility to the learner. Based on which criteria should a teacher decide that a learner is capable to self direct own learning? These kind of questions can give more insight in how to effective design flexible learning environment; environments that prepare learners to become self-directed and self-regulated learners and for the future also lifelong learners.

Instructional Message Design: Past, Present, and Future Relevance

30

M.J. Bishop

Abstract

Instructional message design explores how various media and delivery systems might be used more effectively to help optimize instructional communications within context-specific instructional situations and learner needs. But use of the term appears to have fallen out of favor over the years since the mid-1990s. A review of the historical and theoretical foundations of instructional message design reveals that, while instructional design generally has shifted from objectivist to more constructivist perspectives on learning theory, the instructional message design field remains firmly rooted in early "transmission oriented" communications models. It appears that instructional message design has also suffered from definitional problems as well, with more recent narrow views of the field focused on media attributes supplanting earlier broad views of the field as an applied "linking science" between theory and practice. And, finally, while findings from studies on media attributes provide designers with some guidance for generally what will *not work* in terms of cognitive processing, the guidelines seldom shed light on what one should actually *do* within a particular learning context. It appears that reestablishing instructional message design as a valid area of inquiry within the field of instructional design will require catching up with recent philosophical shifts in communication theory while adjusting our definitions and research foci accordingly. The chapter concludes with recommendations for a revised guiding theoretical framework based on conversation theory, a broader definitional focus that looks at more than just optimizing cognitive processing, and a new systems view of our approach to research in this area.

Keywords

Instructional message design • Instructional communications system • Message • Systems philosophy

Introduction

The research in educational media indicates that any medium used for teaching and learning is only as effective as the design of the message it is intending to communicate. Poorly designed instruction is poorly designed instruction, regardless of delivery mode (Cuban, 1986, 2001). In order to devise technologies that truly make a difference within an instructional communication system, instructional designers must

be supplied with development guidelines that are based on the unique ways specific groups of learners interact with various communication technologies and media presentations to construct knowledge. Instructional message design, therefore, explores how various media and delivery systems might be used more effectively to help optimize instructional communications within context-specific instructional situations and learner needs. As such, it applies learning theory, communication theory, and systems theory to the design and evaluation of instructional media.

Instructional message design has been described as the "next step" in the instructional design analytical process—moving beyond deciding what methods are best for bringing about desired changes in student knowledge (Reigeluth, 1983) toward specifying the exact form an instructional communication system should take for optimal learning (Grabowski, 1991). But since the mid-1990s, use of the term "instructional message design" appears to have fallen largely out of favor. Database searches for new literature on instructional message design come up more-or-less empty, referring repeatedly back to Fleming and Levie's earlier texts (1978, 1993). Even Wikipedia has no entry for it as of this writing.

So, what has happened to instructional message design? In 1995, Berry noted that some had begun arguing traditional instructional message design orientations were antithetical to the learner-centered approaches that were just emerging at the time. Could it be that instructional message design has become irrelevant as the field's philosophical focus shifted from *instruction* to *learning* instead? Or perhaps instructional message design has been supplanted by other areas of inquiry? While studies identified specifically as instructional message design research have been fairly sparse since the early 1990s (Molenda & Boling, 2007), vast empirical work in related areas termed "multimedia learning" and "cognitive load theory" has continued, for example. Or maybe there really is no problem at all but rather the guidelines derived from the instructional message design research done before 1995 are all we need?

This chapter examines these questions by reviewing the theoretical and historical foundations, discussing current issues, and exploring the potential future relevance of instructional message design research as a subdiscipline of our field.

Theoretical and Historical Context

Traditionally, instructional message design has explored the application of communication and learning theories to the design and development of media used for teaching and learning (Bishop, 2000; Bishop & Cates, 2001). This section briefly summarizes these theoretical foundations to provide a context for the discussion of current issues and future directions for instructional message design. For a more complete review of the evolution of learning and communications theories and their impact on the field, readers are encouraged to consult Driscoll (2005), Reiser (2001a, 2001b, 2012), Richey, Klein, and Tracey (2011), and Saettler (1990).

Communications Theory

Educational technologists have typically viewed teaching–learning problems as communication problems. The traditional instructional message design literature has, therefore, approached the instructional process as an instructional communication system with a set of interrelated parts working together to produce learning (Berlo, 1960).

Communication as Transmission

Early communications models focused on the way information is passed from one location to another and have been characterized as *transmission* models (Richey et al., 2011). Shannon and Weaver's *The Mathematical Theory of Communication* (1949) was particularly influential in shaping early thinking in the field about human communication.

The Shannon–Weaver model proposed that all communication processes begin when a source, desiring to produce some outcome, chooses a *message* to be communicated. A transmitter then encodes the message using a set of perceptual elements or cues that are assembled in a deliberate way to produce a signal appropriate for transmission over the channel that will be used. After the message has been transmitted, a receiver then decodes the message from the signal transmitted and passes it on to the destination.

According to the model, communication is "perfect" when the information contained in a message affects the receiver in exactly the way intended by the source. Communication is rarely perfect however; spurious information, or noise, can introduce errors at any point in the transmission that make the signal harder for the receiver to reconstruct accurately. Offsetting noise in communication involves adding redundancy to messages. Redundancy is the information that message cues share: the parts that "overlap" (Attneave, 1959). While the word "redundancy" has lately been defined as something that is superfluous or unnecessary (for example, see Chap. 31), in the Shannon and Weaver sense the surplus may not necessarily be uncalled-for. They posited that redundancy in communication systems that helps a receiver separate transmitted information from system noise increases understanding and is, therefore, desirable.

However, Shannon and Weaver (1949) also acknowledged that all channels have limited capacity. That means redundancy not needed by the receiver or that fails to increase understanding may actually impede the flow of new information and, consequently, decrease communication effectiveness. When redundancy exists at the expense of new information, it can introduce its own sort of noise into the system. Thus, while highly redundant messages can overcome noise in communications effectively, they are not very efficient. When a source anticipates problems in communication, the trick may be in knowing how much and which sort of between-cue message redundancy to include in order to counteract noise. According to the Shannon–Weaver model, striking the right balance in messages between redundancy and new information appears to be the key to successful communication (Reza, 1961/1994).

Communication as Interaction

In 1954 Schramm was among the first to alter the Shannon–Weaver model by conceiving of decoding and encoding as activities happening simultaneously by sender and receiver while messages are exchanged interactively and reciprocally. Schramm further suggested that the sender's and receiver's fields of experience play a large role in successful communication. The sender encodes messages based on what is known about the receiver's experience and the receiver's experience impacts message decoding. If there is no commonality in the sender's and receiver's fields of experience, communication does not occur.

In 1960, Berlo's Sender–Message–Channel–Receiver (S–M–C–R) model further expanded thinking about human interactions by focusing on "the ingredients of communication" within each of the four communications elements. Like Schramm, Berlo's model acknowledged the importance of shared experience between the sender and receiver (communications skills, attitudes, knowledge, social systems, and culture) and also emphasized the role of feedback from the receiver requesting clarification for how the message was decoded. But Berlo's model viewed the communications channel as the five human senses rather than a mechanical conduit for messages. Additionally, Berlo's model placed the message squarely at the center of the process and examined the extent to which content elements, treatment elements, and code structure affected communication outcomes.

Learning Theory

Berlo (1960) also suggested that the study of communication processes and the study of learning processes differ only in their point of view. While communication models most often begin with and focus on how messages are constructed and sent, learning models generally pick up with and focus on how messages are received and processed by learners. Designing optimally effective instructional messages must also, therefore, involve understanding learning theory. Thus, in addition to communication theory, traditional instructional message design thinking has also been firmly rooted in the behavioral and cognitive sciences as well.

From Behaviorism to Cognitivism

The behaviorist orientation prominent in psychology during the first half of the twentieth century viewed learning as the ability to perform new behaviors. Organisms respond to stimuli and, if repeated over time, eventually form stimulus–response bonds or chains. These responses can be strengthened or weakened as a result of whether they are positively or negatively reinforced. Behaviorists suggested, therefore, that knowing what might be going on in an individual's mind in terms of invisible mental processes such as thoughts and consciousness is less important than understanding observable behaviors in relation to the environmental events surrounding them (Driscoll, 2005).

When applied to human learning, the behaviorist orientation suggested that learning is a process of carefully planned steps under the direction of an educator (teacher, instructional designer) who either succeeds or fails at creating the conditions necessary for student learning. Among the critical elements for assuring learning success from this behaviorist perspective was providing immediate reinforcement for student responses. The automated "teaching machine" (Pressey, 1926, 1927) that delivered programmed instruction (Crowder, 1960; Skinner, 1958) promised a solution to the problem of supplying learners with timely feedback on their progress. The idea was to automate the process of teaching by setting up, in advance, the conditions under which learning will inevitably occur and delivering those stimuli—or messages—via a mechanical device. The machine then provided feedback on the learner's response and, if correct, the learner went on to the next step. If incorrect, however, the learner reviewed the previous material until she got it right. The teaching machine concept advanced further with the advent of early computers in the 1960s and 1970s, as most computer-assisted instruction continued to reflect a behaviorist orientation. While computerized drill-and-practice programs and tutorials did capitalize on the new technology's enhanced displays and improved learner interactions, they still presented material in a step-wise fashion, provided immediate reinforcement for learners' responses, and assumed a strong degree of program control over learner control (Saettler, 1990).

By the early 1980s, at roughly the same time microcomputers were also being introduced to the market, the cognitive model of learning began to replace the behaviorist model in the educational technology literature. Cognitivists emphasized knowing rather than responding and viewed learning as an active process of acquiring, organizing, and constructing new understandings from incoming stimuli. In the cognitivist view, therefore, understanding how knowledge is represented in memory is key to the development of instructional theory. Among the key assumptions of the cognitive sciences at this time was the idea that humans receive, process, and store information in ways analogous to computers.

Human Information-Processing

Like the Shannon–Weaver communications model, Atkinson and Shiffrin's (1968) three-stage information-processing theory has been particularly influential over the years among cognitivist learning theory models. In this explanation of human memory, stimuli coming in from each of the five senses are first handled by a *sensory register*, which filters and then routes the incoming signals to a second, *short-term store*. Short-term store (also sometimes called *working memory*) holds information temporarily while it is being encoded as *schema* for permanent storage in the *long-term store*. *Encoding* is the process of building relationships and connections within new material or between new material and existing knowledge structures. Long-term store is both the place where we hold newly encoded schemas and the place from which we retrieve well-established memories.

Information-processing theorists maintain that learning occurs when information that has been transferred to and stored in long-term memory can be retrieved when needed (Atkinson & Shiffrin, 1971; Phye, 1997). It appears, however, that limitations in each of these operations may restrict the amount of data one can consign to long-term storage. For example, in order to acquire or make sense of the constant barrage of sensory information, an individual must decide, often unconsciously, which information to attend to and which to ignore (Broadbent, 1958; Treisman & Gelade, 1980). There is also a limit to the amount of information, or maximal cognitive load, an individual can process in short-term store at any given time (Paas, Renkl, & Sweller, 2003; Sweller, Ayers, & Kalyuga, 2011). And, while there is some evidence to suggest that once information has been moved to long-term store it remains there forever (Nelson, 1971, 1978), it is equally clear individuals certainly can lose access to memories over time (Ausubel, Robbins, & Blake, 1957; Norman, 1969; Postman, 1961).

From this view then, instructional message design should be focused on helping learners process information rather than merely initiating behavioral responses (Saettler, 1990). Winn argued in 1993 that designers had "failed to consider how messages affect what they mean to the individual who receives them in interaction with each person's knowledge of the world" (p. 75). Therefore, to facilitate learners' acquisition, processing, and later retrieval of new material, designers should work to manipulate the attributes of an instructional message to make clear delineations among salient features, organize presentations hierarchically to show relationships, and provide meaningful connections to learners' existing knowledge structures (Salomon, 1979/1994).

In this way, instructional message design emerged as a subdiscipline of instructional design from the intersection of communication and learning theory. And, over the years, principles derived from research in this area have supplied instructional designers with a wealth of useful information important to support "a designer's decision of form" (Smith & Boling, 2009, p. 4).

Current Issues

However, despite considerable changes over the last 50 years in communications and learning theory as well as the available interactive technologies, it appears the underlying instructional message design concepts have remained essentially the same. In fact, even recent compilations of research-based principles for instructional media designers still rely principally on empirical work done before 1995 (for example see Lohr, 2008; Morrison, Ross, Kalman, & Kemp, 2011). Molenda and Boling (2007) noted that the emphasis continues to be on optimizing the instructional communications system by finding the most effective ways to transmit material to be learned from the source (teacher or designer) to the receiver (learner), with little concern for the more dynamically social and reciprocal nature of most communication transactions. In effect, the assumption is that "meaningfulness" can be determined in advance and—given the right combination of message cues—transmitted successfully to all learners (Sless, 1981).

Philosophical Mismatch

While the shift from behaviorism to cognitivism in the first half of the last century was a sea change in perspectives on learning, both theories were still based on an objectivist belief that knowledge exists independently of learners and learning is the process of transferring that knowledge "from outside to within the learner" (Driscoll, 2005, p. 387). More recently, constructivists have argued that knowledge does not exist independently but is, instead, constructed by learners as they actively seek to make meaning from their experiences. Thus, constructivists view instruction as a process of supporting active knowledge construction rather than transmitting knowledge into an empty vessel. In fact, constructivists like Duffy and Cunningham (1996) have contended that we cannot be certain that "perfect communication" with wholly shared meaning between a sender and receiver is even really possible.

> We can only evaluate whether meaning is shared by testing the compatibility of our individual meanings: exploring implications, probing more deeply. Of course, no matter how much we probe, we can never be sure that the meaning is shared (p. 171).

Instead, the authors suggested we must actively seek to understand the communicators' different perspectives and, in a learning context, seek to understand and challenge the learner's thinking—eschewing the transmission approach to instruction.

So, about the same time many of the seminal works in instructional message design were being produced, Cooper (1993), Jonassen (1990, 1991), Kember and Murphy (1990), and others were arguing that if learners actively construct their own understanding through interactions between their existing knowledge structures and authentic experiences with the world around them, then the field must move away from models based on an objectivist epistemology that places responsibility for learning on "pre-packaged" messages didactically designed to deliver content through some communications medium to passive recipients. Jonassen (1990) contented:

> It matters little how we represent ideas and less how we present it. *What matters is how the learner is thinking*. Since knowledge is mediated by thinking and not by technologies, our goal should focus on providing cognitive tools for helping learners to construct knowledge, that is, to think more productively (p. 34).

According to Januszewski and Molenda (2008) this philosophical shift to constructivism dramatically changed the orientation of the field. Research interest moved away from "the design of prespecified instructional routines" to be delivered in a variety of communication formats and toward "the design of environments to facilitate learning" (p. 2). Jonassen, Lee, Yang, and Laffey (2005) summed up the growing philosophical mismatch by observing "…the most obvious effect of this influence has been a shift from emphasis on instructional communication systems to an emphasis on practice-based collaborative learning systems" (p. 247).

Definitional Problems

In addition to the growing philosophical mismatch, instructional message design has suffered from definitional problems as well. Some have taken a very broad view of the field as a "linking science" between learning theory and instructional practice (Dewey, 1900 as cited by Fleming, 1993) whereas others have taken a much narrower view, choosing to focus on media attributes and their affordances for improving—or impairing—learners' cognitive processing.

Syntheses of Generalized Principles

Among the first major works attempting to synthesize basic research into applied instructional message design principles was Fleming and Levie's (1978) *Instructional Message Design: Principles from the Behavioral Sciences*. In it, the authors took a very broad view of instructional message design as the bridge between learning theory research and instructional practice. According to the preface, this text set out to formulate "sets of generalizations stated as principles" from research in the areas of perception, memory, concept formation, and attitude change in an effort to "narrow the gap between research and practice in instructional message design" (p. vii). The idea was to provide a research-based conceptual framework that might "inform the creativity of designers/teachers" but "not replace or lessen the need for innovation in instruction" (p. xiii).

Fleming and Levie's first edition was roughly organized around the functions of instructional messages within the instructional communications system and, therefore, included chapters on perception principles (helping learners acquire messages), memory principles (helping learners process message content), concept learning principles (helping learners relate new constructs to existing knowledge structures), and attitude change principles (assuring the delivered message has the desired effect). Fifteen years later the second edition was updated to reflect "the pervasive change in the research literature from the earlier behavioral emphasis to the current cognitive orientation" (Fleming & Levie, 1993, p. viii). Nonetheless, the update retained the first edition's organization around message functions, changing the earlier memory principles chapter to learning principles instead and adding three more chapters on motivation, psychomotor, and problem-solving principles.

Works Focused on Media Attributes

While some of the principles suggested in Fleming and Levie's two editions specifically addressed the use of graphics, text, sound, and the like, most of what the authors proposed there were principles that might apply generally to the design of instruction regardless of medium. In contrast, others over the years have approached discussions of instructional message design from the more specific focus on some media attribute (text, sound, color, images) and explored optimally effective ways to utilize the inherent codes or symbol systems possessed by the medium to facilitate cognitive processes (Jonassen, Campbell, & Davidson, 1994; Moore, Burton, & Myers, 1996). Interest at the time in media attributes likely emerged from—and contributed to—the media debates of the 1980s and early 1990s over whether media (television, film, radio) could influence learning in-and-of-themselves (for a complete review, see Clark, 2001). Contributions to the field that have taken this media attributes approach have included Jonassen's *Technology of Text* (1982, 1985), Hartley's *Designing Instructional Text* (1986), Houghton and Willow's *The Psychology of Illustration* (1987). Additionally, the first two editions of this *Handbook* included instructional message design sections organized from a media attributes perspective with chapters on static and visual representations, text, audio/sound, and multichannel/multimedia (Jonassen, 1996, 2000).

More recently, Mayer (2001, 2003, 2005, 2008, 2009, 2011) and his colleagues have extended this work by very systematically exploring how the brain processes the attributes of multimedia instructional messages based on three major principles of cognitive theory: the dual channel principle, the limited capacity principle, and the active processing principle (see also Mayer's many collaborations with Clark, Johnson, Moreno, and others). Based on the findings from these studies, Mayer has argued that the three goals of multimedia instructional message design should be to minimize extraneous cognitive processing by eliminating irrelevant presentation elements, manage essential processing, and foster generative processing during learning. To date, Mayer's and others' empirical work has focused primarily on deriving principles for minimizing extraneous cognitive processing and managing external processing. (For a more thorough review of the work being done in multimedia learning, see Chap. 31). Having adopted the umbrella term "multimedia learning" to refer to the work being done in this area, it is not altogether clear whether Mayer and his colleagues intend this to be a subset of instructional message design or, rather, perceive this to be what instructional message design has evolved into—particularly given that most instructional messages now entail multiple media.

Methodological Concerns

Thus, the term "instructional message design" as a subdiscipline of instructional design does not appear to have ever had a precise meaning or a discrete set of descriptive parameters that formed the boundaries for inquiry. At the very least, it appears the research in this area has focused increasingly on highly constrained comparison studies of media attributes. And, while the findings from these studies have given message designers an empirically tested set of guidelines for understanding the potential cognitive processing ramifications of making poor multimedia presentation design choices, Boling (2010), Krippendorff (2006), and others have argued that the principles derived from this research falls short of telling designers specifically what to do in any given situation (see also Archer, 2004; Cross, 2007; Lawson, 2004).

Britt (1997) explained that—through simplification, explicitness, and reformulation—theory-based models derived from a traditional "scientific approach" to inquiry can provide an effective way to sort out the chaos of systems that are too complex to deal with directly, like instructional communications (see also von Bertalanffy, 1950, 1962, 1968, 1975). Because such models show the repeating patterns and relationships among the parts, they can help one understand the true complexity of the problem or situation. However, according Banathy (1991), dynamic social systems such as education appear to have too many interacting variables to be reduced easily to a set of linear, cause-and-effect relationships (see also Banathy, 1996; Banathy & Jenlink, 2004). Changes to one element in the system can influence, to different degrees, many other elements of the system as well. Therefore, from this *systems philosophy* perspective, the nature of each individual system element can be understood only by looking at how it functions in relation to the whole system of which it is a part. Stated differently, systems philosophers contend that, outside of the laboratory's experimental control, there is no such thing as an independent variable.

It was from this viewpoint that Rieber (2005) concluded "Generalization of the results from educational multimedia research to the 'real world' of learning and performing in schools and the workplace should be viewed with considerable caution" (p. 551). Sless (1981) and others have also argued that, in fact, we cannot ever hope to *predict* the consequences of a particular instructional message:

> "Scientific" procedures cannot work because the systems under investigation are governed by meanings and rules related to meaning which cannot be reduced to cause and effect contingencies. The only way such a system can be controlled is by regulating the meanings in the system and rules governing their usage. …control of meanings is diffused within the culture, refracted by personal experience and focused differently within different contexts, all of which are only marginally controlled by the education process (p. 173).

Rowland (2008) suggested that, instead, "a fully developed system of inquiry for educational contexts" will need to exist at the intersection of research and design, with each transforming the other (p. 7). Unfortunately, as Smith and Boling (2009) noted, to date very little applied work has been done to provide concrete guidance in how to translate the designer's specifications into the tangible attributes of an instructional message (see also Gibbons & Yanchar, 2010).

Potential Future Directions

In 2009 Gibbons contended that good designs do not serve a theory, but rather a metaphor. Further, he maintained that the appropriate design metaphor for instruction is conversation—making the design of messages "one of the very most important layers in the future of designer's thinking." If that is true then perhaps instructional message design does still have an important role to play in the future of our field despite the paradigm shifts, definitional issues, and methodological concerns. But what guiding framework should we be following? What is the definition of "message design" within this new context? What questions should we be focusing on now and how should we be pursuing the answers to those questions?

A New Guiding Framework for Message Design

As discussed earlier, instructional message design has traditionally existed at the intersection of learning and communications theories. But while foundational learning theory has shifted to more constructivist approaches, there has not been a similar evolution in our thinking as a field about the nature of communication. Message design remains firmly rooted in the transmission oriented communications model first proposed by Shannon and Weaver in 1949. While there have been many communications models proposed over the years since then, one that appears to hold the most promise for message design within a constructivist paradigm is *conversation theory*.

In 2004 Boyd suggested that educational technology needed to move away from "the conventionally understood psychology of the individual" and, instead, understand the instructional communication system as a conversation among "a collection of psychological individuals… whose presence is variable and hierarchical" (p. 179). Between 1966 and 1996 Gordon Pask developed "conversation theory" as a framework for exploring the complexity of interactions necessary for learners to construct meaning and make knowledge explicit within real life sociocultural environments. According to Luppicini (2008), conversation theory emerged in opposition to earlier theories that viewed learning as "a set of mental structures and processes that can be analyzed separately and applied to learning and instructional applications" (p. 3).

Pangaro (1996) explained that, at the simplest level, learning from a conversation theory perspective begins with one participant in a group uttering a word like "cup," which is likely to have rather different meanings for the other participants. In order to clarify and agree upon the meaning, a conversation among the participants is necessary. This begins with the first participant clarifying how a cup is used, what it is for, and how it looks. The other participants listen to these views, consider that perspective, and come as close as they can to understanding the first participant's meaning, then share their understanding with the group. If there are conflicts between the other participants' views and the first presented, their views are discussed and considered as well. Once there is consensus among participants' views of "cup," there is said to be "agreement over an understanding." Thus, effective conversation occurs not when meaning is shared, but rather "when beliefs are negotiated through interaction and evolve via goals" (Pangaro, 2008, p. 35).

But conversations need not be only among humans for learning to occur—conversations can also involve technology-based communication systems as well, particularly as the rapid growth of interactive multimodal and social networking technologies offer opportunities not previously possible (Luppicini, 2008). Thus, Boyd (2004) suggested that conversation theory can serve as a framework for the design of technology-based constructivist learning support systems. However, we can no longer conceive of these technologies as the deliverers of a series of previously designed instructional messages but, instead, as tools that must be able to "adopt a role similar to that of action researcher, continually observing, reflecting, and adapting the process" (De La Cruz & Kearney, 2008, p. 124).

A Broader Focus for Message Design

Movement away from an objectivist, linear paradigm of instructional message design and delivery and toward creating technology-facilitated environments that support conversations among learners will likely also require message designers to think, once again, more broadly about the field. That means allowing for the entire process of "conversation" (not just the sender to receiver transmission) and developing the necessary tools to make meaningful, interactive dialog possible for all participants. Stated differently, we need to find ways to create the technology affordances necessary for participants other than the educator (teacher/designer) to support and represent their thinking while engaged in the discourse.

Like Fleming (1993), Gibbons and colleagues have taken a broader view of design as a "linking science" between theory and practice that focuses on the product rather than the process of design (see Gibbons, 2003, 2009a, 2009b; Gibbons, Nelson, & Richards, 2000; Gibbons & Rogers, 2009a, 2009b). Gibbons observed that many design process models do not provide much in the way of actual operational principles for decision-making when creating a design, often glossing over the "miracle box" labeled "design instruction," "write instruction," or something similar. While Gibbons does not contextualize his ideas within a conversation framework, he does conceive of design within the miracle box as being made up of multiple layers of decision making about what will be the artifact's functions—the content, strategy, control, message, representation, media-logic, and management of the conversation. According to Gibbons & Rogers, 2009a, the *Content* layer involves decisions about subject matter, how it will be structured, organized, divided, and the like. The *Strategy* layer comprises the "space, time, event, social, and interaction structures that define occasions through with the learner can experience the content structures" (p. 18). In the *Control* layer, the designer makes decisions about affordances the learner will have available to participate actively in the exchange. The *Message* layer, in this sense, involves the ways in which the system will respond adaptively to the learner's activity—based on predefined message generation and construction systems. *Representation* involves "the rules for converting abstract structures from all of the other domains (layers) into representations that have sensory properties" (p. 19). The *Media-logic* layer involves decisions made about the actual delivery system employed in the execution of the representations. And, finally, the *Data Management* layer involves the underlying collection, storage, and data analyses activities needed to support adaptivity of instruction within the system. Each layer is characterized by a set of unique design goals, constructs, theoretic principles for the selection and use of design constructs, design and development tools, and specialized design processes.

According to Gibbons and Rogers (2009b), the design process in this view involves design by "successive constraint placement" on the system rather than strict adherence to some prevailing doctrine. And, while well-known instructional theories have had a great deal to contribute to providing guidelines and rules for the content, strategy, and to some degree the control layers, there are very few formalized guidelines for structuring the message, media-logic, or data management layers.

A New Research Paradigm for Message Design

In addition to redefining the field more broadly to comprise the design of technology affordances aimed at enabling all involved in the conversation to actively participate, message designers also will need to become more mindful of the non-cognitive factors that contribute to meaning-making in human conversation so that we can design adaptive systems that respond appropriately. Grunert (1997) argued that "We must seek frameworks that acknowledge, as the technical framework does not, the social, political, emotional, moral, imaginative, and aesthetic complexity of human interaction in the world" (p. 44). Wilson (2005a, 2005b) agreed and offered four "pillars of practice" that he suggested should underlie a broader view of instructional design research and practice in the future: individual cognition and behavior, social and cultural learning, values, and aesthetics. Wilson suggested these four levels of analysis "reflect more than an expanded view of learning outcomes" and become, instead, "an expanded view of design processes themselves and criteria for evaluating designed products" (p. 10).

The first pillar, *Individual Cognition and Behavior*, requires understanding the way learners think and acquire knowledge and skill. This level has been and continues to be thoroughly researched in instructional design and technology and relies heavily on much of the earlier instructional message design research that has been done over the years. Wilson's second level of analysis, *Social and Cultural Learning*, "turns to issues of cultural context and social support, including peer-to-peer interactions; group identity and motivation; and participation within communities of learning and practice" (Wilson, 2005b, p. 245). Like the first of Wilson's pillars, this area of inquiry has historically been a primary focus of the field under terms such as "learning communities" (Lave & Wenger, 1991); "situated cognition" (Brown, Collins, & Duguid, 1989); "cognitive apprenticeships" (Collins, Brown, & Newman, 1989; Wertsch, 1998); and the like. *Values*, Wilson's third level of analysis, is less well researched in the instructional design field and deals with exploring the underlying values and mores that are communicated in our designed materials. This pillar, as suggested by Krippendorff (2006) as well, "is a turn toward considerations of meaning—*a semantic turn*" (p. xv) that focuses our attention on questions of social justice and equity. Wilson's fourth pillar, *Aesthetics*, involves exploring both the "shape and form of the learning experience, as well as the design of messages within that experience" (Wilson, 2005b, p. 245). Drawing largely from the arts—particularly literary criticism—Parrish (2005, 2008, 2009, 2010) has been exploring the aesthetics of learning experiences and has come up with a set of principles and guidelines for thinking about message design, some of which suggest alternative approaches to the problems of cognitive load and avoiding split attention.

According to Sless (1981), understanding how learners respond to instructional conversations that are sensitive to values and aesthetics will require a different approach to empirical research that focuses more on the semiotic quality of the exchange and less on its psychophysical qualities. He added:

> …the skilled practitioner is more likely to make sound judgments on the basis of years of experience than the positivist researcher on the basis of precise research. It is therefore imperative that the cumulative knowledge of practice be nurtured (p. 178).

Claiming that precision may be a false goal for the social sciences, Freedman (1985, 1987, 1991) and others who have adopted the systems view over the years suggest an alternative research design (see Ling, 1983; Platt, 1964; Uslaner, 1983; Zeisel, 1982). Rather than attempt to emulate the precision of the natural sciences by making the constraining assumptions necessary to analyze large samples using multiple regression, systems methodology begins by formulating the properties of systems in abstraction, then observes specific cases to test the assumptions made. Freedman contended that although this approach is potentially less precise, it usually will generate answers to the right questions rather than solve the wrong problem. When answers are not forthcoming, one always can go back and modify the original assumptions.

While the systems view adopts a holistic strategy, the primary purpose of this approach to inquiry is to find ways to eliminate the discrepancy between a system's stated goal and that system's actual output (Kidd & VanCott, 1972). Senge (1990) suggested that the systems approach to inquiry is primarily the science of managing the problems that arise in "real world" situations outside of laboratory controls. The systems approach is a means to organize complexity into a coherent story that can help identify the important variables, illuminate the causes of problems, and indicate potential solutions. Thus, it appears that explicating those features of technology most effective for supporting learning may require that we embrace a systems inquiry approach to research in this area (Banathy & Jenlink, 2004; Boling & Smith, 2012; Gibbons & Rogers, 2009a, 2009b; Rieber, 2005; Smith & Boling, 2009).

Conclusion

Sless (1981) observed that "…education is parasitic on the modes of communication available in our culture" (p. 41). Even as we move away from objectivist epistemologies toward more constructivist approaches, it seems communication will still play a central role in the learning environment and, therefore, so too will message design. Reestablishing this area of inquiry as a valid subdiscipline of instructional design, however, will require following the paradigm shifts of the field and adjusting our definitions and research foci accordingly. It may also benefit from a name change.

In 1991 Grabowski differentiated between message design for *instruction* and message design for *learning*. Message design for instruction, she suggested, "deals with attention, perception, and comprehension, as well as, but not necessarily, retention and retrieval" (p. 204). Message design for learning, on the other hand, "addresses the cognitive processes required of retention and retrieval and therefore would be most concerned with the inductive composition of the message" (p. 204). She added that: "Message design for instruction deals with those external factors out of control of the learner which can facilitate learning, while message design for learning deals with those strategies which activate internal factors to have learning actually occur" (p. 205). Perhaps the next edition of this *Handbook* should include a new section called "Message Design for Learning?"

Multimedia Instruction

31

Richard E. Mayer

Abstract

Multimedia instruction consists of instructional messages that contain words (such as printed or spoken text) and pictures (such as illustrations, diagrams, photos, animation, or video). The rationale for multimedia instruction is that people can learn more deeply from words and pictures than from words alone. Multimedia instruction began with the publication of Comenius' Orbis Pictus (The World in Pictures) in the 1600s, and has progressed to a wide array of computer-based multimedia learning experiences that are available anytime and anywhere. The science of learning—that is, a research-based account of how people learn—is necessary for designing effective multimedia instruction. Meaningful multimedia learning occurs when the learner engages in appropriate cognitive processing during learning, including attending to relevant words and pictures, organizing words and pictures into coherent representations, and integrating the representations with each other and with knowledge activated from long-term memory. Successful instructional methods for improving learning with multimedia include research-based principles for reducing extraneous processing during learning, managing essential processing during learning, and fostering generative processing during learning.

Multimedia learning • Science of learning • Extraneous processing • Essential processing • Generative processing

Introduction

What Is Multimedia Instruction?

Multimedia instruction is instruction that includes words (e.g., printed or spoken text) and pictures (i.e., static graphics such as illustrations, diagrams, charts, maps, and photos, or dynamic graphics such as animation and video). Multimedia instruction can be presented on paper (e.g., as printed text and figures), on a computer (e.g., as narrated animation or annotated graphics), on a handheld device (e.g., as a game involving printed words and graphics), or face-to-face (e.g., as a narrated slide presentation). For example, Fig. 31.1 presents an annotated diagram aimed at explaining how a car's braking system works, and Fig. 31.2 presents frames from a narrated animation aimed at explaining how a car's braking system works.

Rationale for Multimedia Instruction

The rationale for multimedia instruction is that people can learn more deeply from words and pictures than from words alone—a finding that has been called the *multimedia principle* (Fletcher & Tobias, 2005; Mayer, 2009). For example,

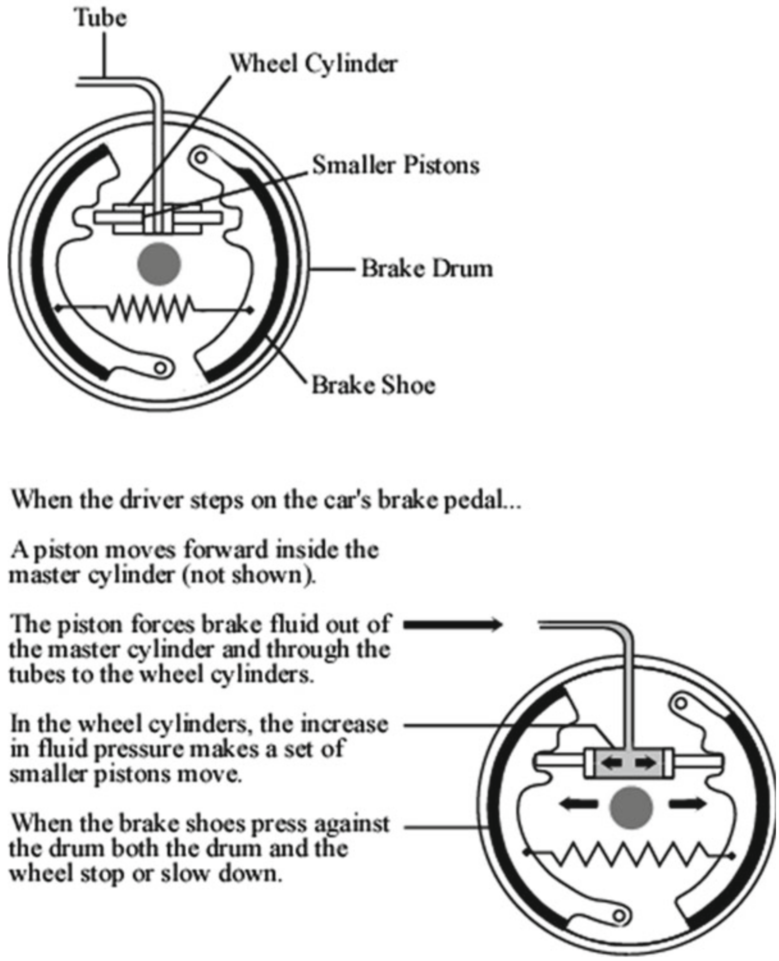

Fig. 31.1 Annotated diagram of a car's braking system

students who received text and illustrations explaining how a car's braking system works (such as in Fig. 31.1) performed better on a subsequent transfer test than students who received only the printed text (Mayer, 1989; Mayer & Gallini, 1990). Similarly, students who received a narrated animation explaining how a car's braking system works (such as in Fig. 31.2) performed better on a subsequent transfer test than students who received only narration (Mayer & Anderson, 1992). In short, under some circumstances, there is strong and consistent evidence that learning is improved when corresponding graphics are added to words (Mayer, 2009).

Not all multimedia lessons are equally effective, however, so research is needed to determine evidence-based principles for effective multimedia instruction. Some of these design principles are described in the third section of this chapter, and the underlying theory is described in the second section of this chapter.

Historical Overview of Multimedia Instruction

In the field of education, instruction has traditionally been based on verbal media, including spoken words (e.g., in lectures, discussions, or tutorials) and printed words (e.g., in textbooks). Yet over the past 350 years there have been visionaries who proposed an instructional approach that combined words and pictures, and scientists who investigated the effectiveness of such multimedia instruction for student learning.

The history of multimedia instruction has involved three major phases—the introduction of instructional illustrations beginning in the mid-1600s, the scientific study of learning with illustrations and text beginning in the mid-1900s, and the scientific study of multimedia learning in computer-based environments beginning in the late 1900s. The first phase is exemplified by the publication of John Comenius' *Orbis Pictus* ("The World in Pictures") in 1658—the world's first illustrated textbook. Each page consisted of an illustration of some aspect of the world ranging from birds of the field to bones of the human body to a bakery shop to a school, with a number next to each object in the illustration, along with a legend that gave the name and definition of each numbered object in Latin and in the student's native language. The editor of an English-language version of *Orbis Pictus* notes that "it was the first picture-book made for children and was for more than a century the most popular textbook in Europe" (Comenius, 1887).

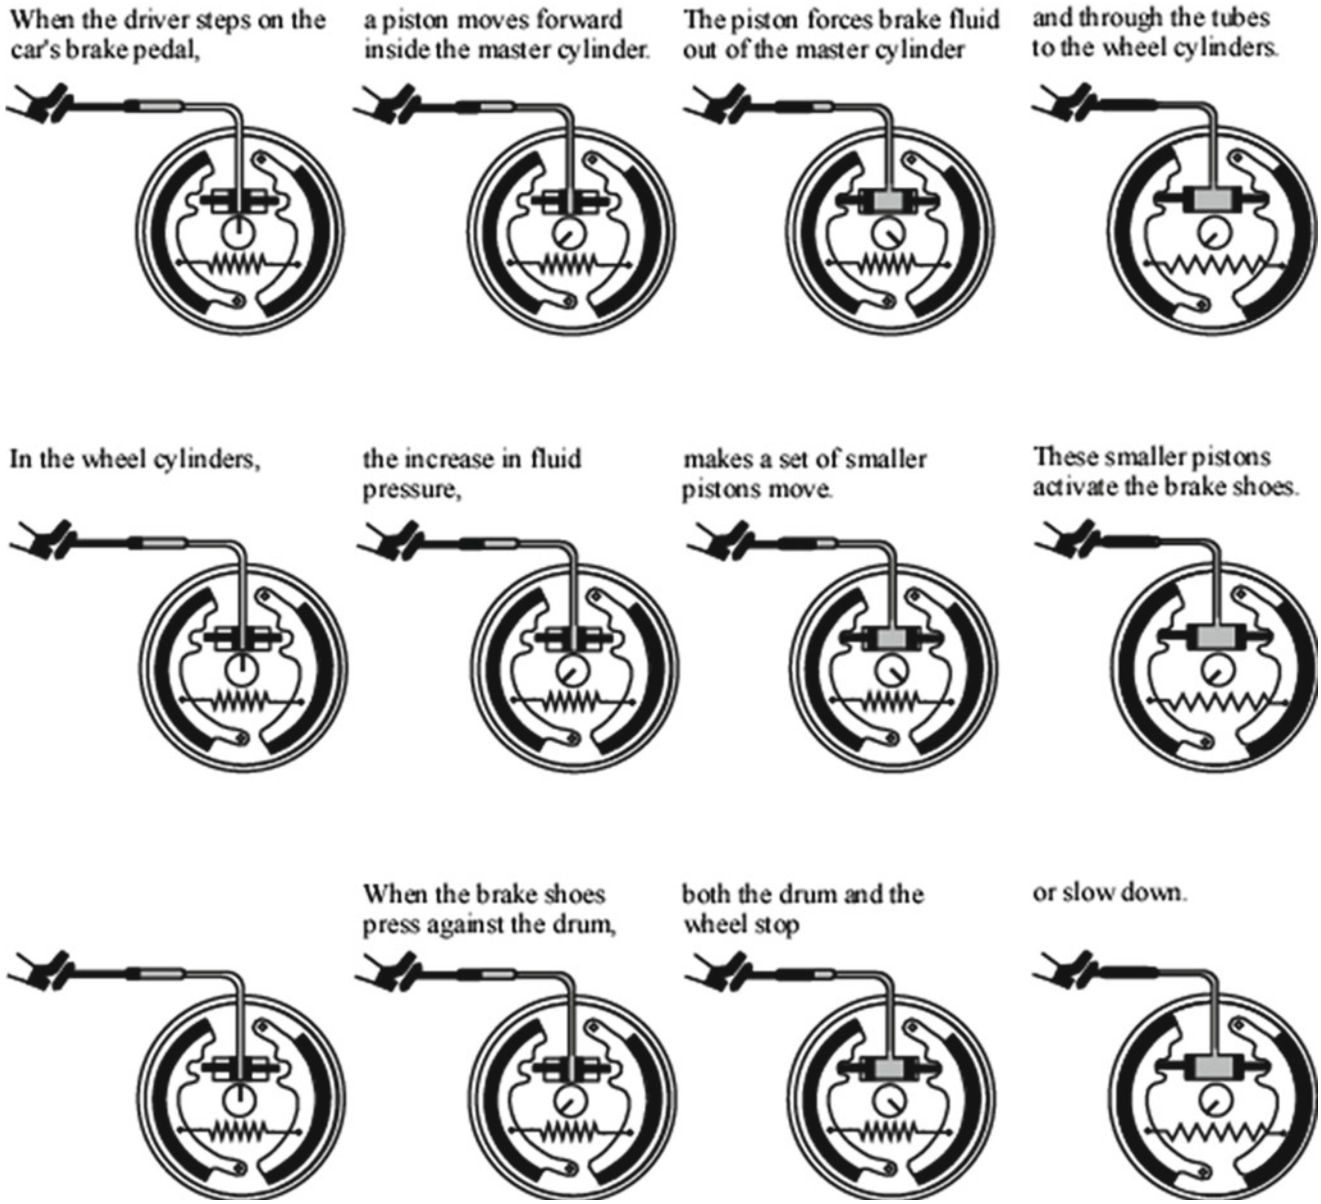

Fig. 31.2 Slides from a narrated animation of a car's braking system

In the field of engineering, machine books containing annotated illustrations of machines began appearing in the middle ages as a means of communicating between engineers and investors as well as between engineers and the artisans carrying out the work (Lefevre, 2004). In the field of business, William Playfield introduced the world's first books to use statistic graphics in 1786 and 1801 (Playfair, 2005), which revolutionized the way statistical information is communicated (Cleveland, 1985; Few, 2004; Kosslyn, 2006; Tufte, 2001).

Orbis Pictus, and other early books involving text and illustrations, can be seen as forerunners of today's textbooks, which devote up to half their space with graphics, though not as effectively as *Orbis Pictus* (Levin & Mayer, 1993; Mayer, Sims, & Tajika, 1995). Advances in technology enabled the spread of multimedia instruction in educational films in the 1920s, educational television in the 1950s, and computer-based instruction in the 1960s (Cuban, 1986). More recent advances in visualization technology have enabled the spread of multimedia instruction in e-learning environments (Clark & Mayer, 2008).

The second major phase in multimedia instruction involves the scientific study of how people learn with printed words and illustrations, which became popular in the mid-to-late 1900s (Flemming & Levie, 1993; Mandl & Levin, 1989; Moore & Dwyer, 1994; Paivio, 1971, 1986; Schnotz & Kulhahy, 1994; Willows & Houghton, 1987). For example, in a rigorous meta-analysis of the learning effects of adding illustrations to printed text, Levin, Anglin, and Carney (1987) reported a large effect size when the illustrations were designed to promote deep cognitive processing (with effect sizes greater than $d = 0.50$) but not when they served mainly to decorate the page (with effect sizes below $d = 0.00$). An important accomplishment of this work was the distinction between visual and verbal channels for processing information as depicted in Paivio's (1971, 1986) dual coding theory as well as preliminary design principles for using illustrations and text (Flemming & Levie, 1993; Moore & Dwyer, 1994).

The third major phase in multimedia instruction, which began in the late 1900s, extends the scientific study of how people learn to include computer-based multimedia instruction. For example, computer-based environments that support multimedia instruction include slide presentations, computer-based training, online multimedia lessons, narrated animation, hypermedia, interactive simulations, intelligent tutoring systems, animated pedagogical agents, virtual reality, and serious games (Atkinson, 2008; Clark & Mayer, 2008; Graesser, Chipman, & King, 2008; Kosslyn, 2007; Lowe & Schnotz, 2008). This third phase in multimedia instruction has both a theoretical goal of contributing to the science of learning by developing a cognitive theory of multimedia learning and a practical goal of contributing to the science of instruction by developed evidence-based principles for the design of multimedia instruction (Clark & Mayer, 2008; Mayer, 2005, 2009). The remainder of this chapter summarizes the progress being made in achieving these goals of building a theory of how people learn from multimedia instruction and compiling principles of multimedia instructional design.

Applying the Science of Learning to Multimedia Instruction

How Multimedia Learning Works

The science of learning is the scientific study of how people learn, that is, how the learner's experience causes a change in the learner's knowledge (Mayer, 2008, 2011). When applied to multimedia instruction, the goal is to understand how people learn from words and pictures. Three relevant principles about the human information processing system derived from research in cognitive science are as follows:

Dual channels—people have separate channels for processing verbal and pictorial material (Paivio, 1986, 2001)

Limited capacity—people can process only a few pieces of information in each channel at any one time (Baddeley, 1986, 1999; Sweller, 1999)

Active processing—meaningful learning occurs when people engage in appropriate cognitive processing during learning, including attending to the relevant information, mentally organizing it into coherent structures, and integrating it with other structures and with knowledge activated from long term memory (Mayer, 2009; Mayer & Wittrock, 2006; Wittrock, 1989)

Figure 31.3 presents a model of how multimedia learning works based on the cognitive theory of multimedia learning (Mayer, 2008, 2011; Mayer & Moreno, 2003). The model consists of two channels (i.e., a verbal channel on top and pictorial channel on the bottom), three memory stores (i.e., sensory memory, working memory, and long-term memory represented as boxes), and five cognitive processes represented as arrows (i.e., selecting words, selecting images, organizing words, organizing images, and integrating).

The learning process begins when the learner receives a multimedia instructional message—such as when the learner reads an illustrated textbook, attends a PowerPoint lecture, clicks on an online narrated animation, or plays an educational computer game. Spoken words and sounds impinge on the ears, resulting in their sounds being held in auditory sensory memory for a very brief period (i.e., <1 s); pictorial material and printed words impinge on the eyes, resulting in their images being held in visual sensory memory for a very brief period (i.e., <1 s). If the learner attends to the incoming sounds and images (indicated by the *selecting words* arrow and the *selecting images* arrow, respectively), some of the information is transferred for additional processing to working memory (which has limited capacity in each channel). In working memory, as indicated by the *organizing words* arrow, the learner arranges the incoming sounds into a coherent cognitive representation, which can be called a *verbal model*;

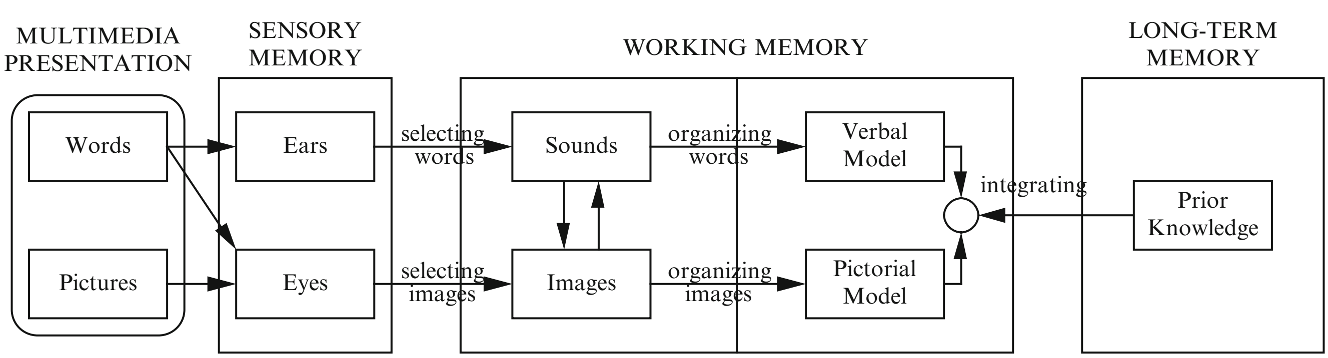

Fig. 31.3 A cognitive theory of multimedia learning

Table 31.1 Three demands on the learner's cognitive capacity during learning

Type	Definition	Cause	Arrows
Extraneous processing	Cognitive processing that does not serve the instructional goal	Poor instructional design	None
Essential processing	Cognitive processing for building a mental representation of the presented material as presented	Complexity of the material	Selecting (and initial organizing)
Generative processing	Cognitive processing aimed at making sense of the presented material	Learner's motivation to exert effort to learn	Organizing and integrating

and as indicated by the *organizing images* arrow, the learner arranges the incoming images into a coherent cognitive representation, which can be called a *pictorial model*. Finally, as indicated by the *integrating arrow*, the learner builds connections between corresponding aspects of the verbal and pictorial models and with relevant prior knowledge activated from long-term memory (which contains the learner's storehouse of knowledge). Once the knowledge is constructed in working memory, the learner can embed it in long-term memory for permanent storage. The learning process depicted in Fig. 31.3 also depends on the learner's motivation to want to make sense of the presented material and the learner's metacognition with respect to selecting, monitoring, and controlling appropriate cognitive processing during learning.

How to Design Multimedia Instruction that Fosters Multimedia Learning

The model of multimedia learning includes five cognitive processes for meaningful learning from multimedia instruction, as indicated by the five arrows in Fig. 31.3. Guiding these cognitive processes during learning is the primary focus of multimedia instruction. The major challenge for designing effective multimedia instruction is that meaningful learning requires that the learner engages in appropriate cognitive processing during learning, but the learner's capacity for processing information in each channel in working memory is extremely limited.

Drawing on Sweller's (1999, 2005; Brunken, Plass, & Moreno, 2010) cognitive load theory and Mayer's (2009; Mayer & Moreno, 2003) cognitive theory of multimedia learning, Table 31.1 lists three kinds of demands on the learner's cognitive processing capacity during learning. Extraneous processing is cognitive processing during learning that does not serve the instructional goal, and is caused by poor instructional design. For example, in a situation where an illustration is on one page and the text describing it is on a different page, the learner must engage in scanning back and forth between the corresponding words and graphics, which results in extraneous processing. Therefore, an important instructional goal is to design multimedia instruction in ways that reduce extraneous processing.

Essential processing is cognitive processing during learning that is required to mentally represent selected parts of the presented material as they were presented, and is caused by the inherent complexity of the material. For example, in a situation where a novice is learning a complicated concept, such as how a lightning storm develops, a great amount of cognitive processing is required to mentally represent the material. Therefore, an important instructional goal is to design multimedia instruction in ways that manage essential processing.

Generative processing is cognitive processing during learning aimed at making sense of the presented material by processing it more deeply, and is caused by the learner's motivation to exert effort to understand the material. For example, learners may explain a lesson to themselves, looking for inconsistencies with their prior knowledge. Therefore, an important instructional goal is to design multimedia instruction in ways that foster generative processing.

According to this triarchic theory, instructional designers must deal with situations in which learning tasks place three kinds of cognitive processing demands on learners (i.e., heavy processing demands) but learners possess limited capacity for cognitive processing during learning (i.e., limited processing capacity). Figure 31.4 summarizes three multimedia instruction scenarios, each requiring a different kind of multimedia instructional design solution.

In the extraneous overload situation (shown in the top of Fig. 31.4), the amount of extraneous, essential, and generative processing required for learning overloads the learner's available cognitive capacity (i.e., the amount of processing the learner can carry out at one time in working memory). If the learners are wasting precious cognitive capacity on extraneous processing, they may not have adequate capacity remaining for essential and generative processing, which are needed for meaningful learning. When an instructional scenario creates excessive extraneous cognitive processing, an important instructional goal is to design the lessons in ways that reduce extraneous processing.

In the essential overload situation (shown in the middle of Fig. 31.4), the need for extraneous processing has been eliminated or greatly reduced, but the amount of required essential processing still exceeds the learner's cognitive capacity. In this case it is not appropriate to reduce essential processing because essential processing is required for the

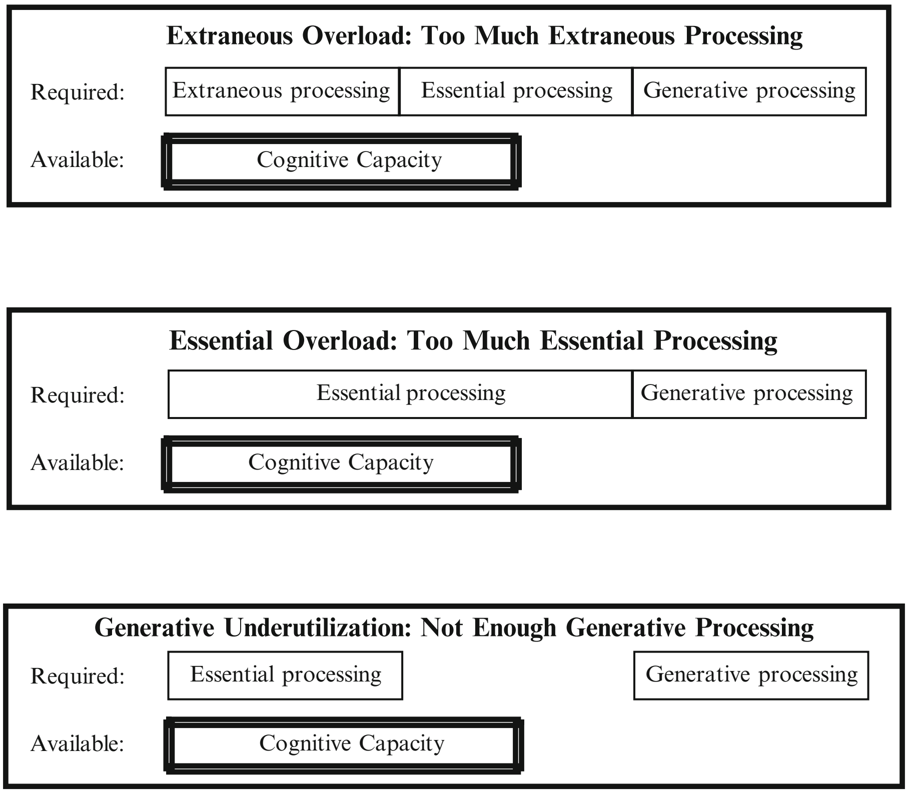

Fig. 31.4 Three demands on the learner's cognitive capacity during learning

learner to mentally represent the presented material (although with growing expertise learners will be able to chunk the incoming information in ways that minimize the demand for essential processing). When an instructional scenario creates excessive essential cognitive processing, an important instructional goal is to manage essential processing.

In the generative underuse situation (shown in the bottom of Fig. 31.4), extraneous load has been eliminated and essential load has been managed so the learner has cognitive capacity to engage in generative processing but chooses not to do so. In this case, an important instructional goal is to foster generative processing by designing instruction in ways that encourage the learner to engage in deeper processing (e.g., organizing and integrating) during learning.

Research-Based Principles of Multimedia Instruction

The triarchic theory suggests three instructional goals, each for a different instructional scenario—reduce extraneous processing for extraneous overload situations, manage essential processing for essential overload situations, and foster generative processing for generative underuse scenarios. This section explores some evidence-based principles for accomplishing each of these three goals. Most principles are based on research evidence as documented in one of three sources: (1) a handbook of research on multimedia learning (Mayer, 2005), (2) an Association for Psychological Science task force report on research-based learning principles applicable to education (Halpern, Graesser, & Hakel, 2007), and (3) a report issued by the US Department of Education on research-based learning principles applicable to education (Pashler et al., 2007). This section focuses on principles that consistently generate effect sizes greater than $d=0.40$, which Hattie (2009) argues is the level needed for practical relevance for education.

Principles for Reducing Extraneous Processing

Table 31.2 lists six principles for reducing extraneous processing—coherence, signaling, spatial contiguity, temporal contiguity, redundancy, and expectation principles.

The *coherence principle* is that people learn better from a multimedia lesson when extraneous material is excluded rather than included. For example, in a series of six experiments involving a multimedia lesson on lightning formation including both paper-based formats (Harp & Mayer, 1997, 1998) and computer-based formats (Mayer, Heiser, & Lonn, 2001) students performed better on a transfer posttest if they learned from a concise presentation than from an elaborated

Table 31.2 Evidence-based principles for reducing extraneous processing

Principle	Description	Example
Coherence (Halpern et al., 2007; Mayer, 2005)	Eliminate extraneous words and pictures	Cut out interesting but irrelevant anecdotes and cartoons
Signaling (Mayer, 2005)	Highlight essential words and pictures	Use an outline and headings; put key terms in bold font for a text lesson
Spatial contiguity (Halpern et al., 2007; Mayer, 2005; Pashler et al., 2007)	Place text next to the part of the graphic it describes	Embed each part of a caption next to the corresponding part of an illustration
Temporal contiguity (Halpern et al., 2007; Mayer, 2005)	Present corresponding graphics and spoken text at the same time	In a narrated animation, describe the events in audio at the same time they are depicted on the screen
Redundancy (Mayer, 2005)	Present graphics with spoken words rather than graphics with spoken and printed words	Do not add onscreen text to a narrated animation
Expectation (Halpern et al., 2007)	Present a preview of the test items or instructional objectives before the lesson	Before this section of the chapter, present the question: "What are the names, definitions, and examples of six principles for reducing extraneous processing?"

presentation containing added sentences, photos, or video clips that were interesting but not relevant to the explanation. The median effect size was $d=1.66$, which is large effect. In a follow-up study, students received a PowerPoint presentation on how a virus causes someone to catch a cold or on how the human digestive system works, which included inserted statements about the topic that were high or low in interest (Mayer, Griffith, Naftaly, & Rothman, 2008); the study showed that the low-interest group outperformed the high-interest group on a transfer posttest, with $d>0.80$ in both experiments.

Overall, these results are consistent with previous research showing that student learning from text is diminished when the text contains added *seductive details*—interesting but irrelevant sentences, such as amusing anecdotes or grizzly facts (Garner, Brown, Sanders, & Menke, 1992; Hidi & Baird, 1986; Mohr, Glover, & Ronning, 1984; Shirey, 1992; Shirey & Reynolds, 1988; Wade, 1992; Wade & Adams, 1990). For example, in a replication involving a text lesson on lightning formation, Lehman, Schraw, McCrudden, and Hartley (2007) found that adding interesting but extraneous sentences about lightning throughout a lesson resulted in significantly less learning ($d=0.88$) based on deep processing measures such as a holistic understanding score for student essays.

Adding background music or environmental sounds to a narrated animation on lightning or brakes also resulted in lowered transfer posttest performance, with a median effect size of $d=1.11$ based on two experiments (Moreno & Mayer, 2000a). Adding relevant factual or mathematical details to a multimedia lesson on how lightning works or how ocean waves work that are not needed to understand how the basic cause-and-effect system works also resulted in lowered transfer test performance, yielding a median effect size of $d=0.82$ across six experiments (Mayer, Bove, Bryman, Mars, & Tapangco, 1996; Mayer & Jackson, 2005). Overall, there is strong and consistent evidence for the coherence principle based on well-controlled laboratory studies. The effect may be diminished for high knowledge learners (Ploetzner, Fehse, Kneser, & Spada, 1999) or for high working memory capacity learners (Sanchez & Wiley, 2006).

The *signaling principle* is that people learn better when the essential material and its organization are highlighted. Verbal signaling can take the form of putting essential printed text in bold font (or giving vocal emphasis to essential spoken text), adding an outline or graphic organizer containing the same words as in the text, adding headings that correspond to the outline, or including pointer words such as "first…second…third." Visual signaling can take the form of adding arrows, flashing, or a spotlight that grays out the nonessential areas. In a series of six experiments involving paper-based multimedia lessons on lightning or biology (Harp & Mayer, 1998; Stull & Mayer, 2007) and computer-based narrated animations on how airplanes achieve lift (Mautone & Mayer, 2001), students performed better on a transfer posttest when the presentation included verbal signals, yielding a median effect size of $d=0.52$. These results help extend earlier research on learning from text showing that verbal signaling improves students' retention of a text passage (Loman & Mayer, 1983; Lorch, 1989; Lorch & Lorch, 1996; Lorch, Lorch, & Inman, 1993; Meyer, 1975; Meyer, Brandt, & Bluth, 1980).

Visual signaling involving arrows was not found to be effective in promoting transfer posttest performance with animations on how airplanes achieve lift (Mautone & Mayer, 2001) and on how a toilet tank flushes (Hegarty & Kriz, 2007). In some cases transfer test performance was improved when online multimedia lessons included an onscreen agent who pointed to essential material in a worked example (Atkinson, 2002), when the appropriate portion of a worked example flashed on the screen as a narrator described it (Jeung, Chandler, & Sweller, 1997), and when spreading color was used to indicate the flow of activity in narration on piano mechanisms (Boucheix & Lowe, 2010). Spotlighting the appropriate portion of a narrated animation on the human heart as the narrator described it (by decreasing luminance outside the spotlight) improved transfer performance in one study (de Koning, Tabbers, Rikers, & Paas, 2007) but not in another (de Koning, Tabbers, Rikers, & Paas, 2010). Overall, there is moderate evidence for the benefits of verbal signaling but continuing research is needed to establish principles for visual signaling. The effect may be diminished for high-knowledge learners (Meyer et al., 1980; Naumann, Richter, Flender, Cristmann, & Groeben, 2007) or when the material is simple for the learner (Jeung et al., 1997).

The *spatial contiguity principle* states that people learn better when corresponding printed words and graphics are presented near each other on the page or screen. In a core set of five experiments carried out in our lab involving paper-based multimedia lessons on brakes and lightning (Mayer, 1989; Mayer, Steinhoff, Bower, & Mars, 1995) and a computer-based multimedia lesson on lightning (Moreno & Mayer, 1999a), students performed better on a transfer posttest if words describing each step in the process were placed next to the portion of the diagram they described rather than as a caption at the bottom of the diagram, with a median effect size of $d=1.12$.

Similar results favoring integrated presentation over separated presentation of printed words and graphics were found with paper-based lessons on mathematics (Sweller, Chandler, Tierney, & Cooper, 1990), engineering (Chandler & Sweller, 1991, 1992; Tindall-Ford, Chandler, & Sweller, 1997), and how the heart works (Chandler & Sweller, 1991), and with computer-based lessons on how a tire pump works (Bodemer, Ploetzner, Feuerlein, & Spada, 2004), statistics (Bodemer et al., 2004), and physics (Kester, Kirschner, & van Merrienboer, 2005). In a recent meta-analysis of 37 experiments on spatial contiguity, Ginns (2006) reported an average effect size of $d=0.71$ favoring integrated over separated presentation, and the effect size was $d=1.07$ for published studies that used posttest measures of transfer.

Overall, there is strong and consistent evidence for the spatial continuity principle involving both paper-based and computer-based multimedia lessons. The effect may be diminished for high-knowledge learners (Mayer et al., 1995), when the material is very simple for the learner (Ayres & Sweller, 2005), or when the graphic can be understood without accompanying words (Ayres & Sweller, 2005).

The *temporal contiguity principle* is that people learn better when corresponding spoken text and graphics are presented simultaneously rather than successively. Across eight computer-based experiments carried out in our lab, students who received simultaneous presentations (i.e., narration and corresponding animation, video, or slides at the same time) performed better on transfer posttests than students who received successive presentations (i.e., narration before or after animation, video, or slideshow), including multimedia lessons on tire pumps (Mayer & Anderson, 1991, 1992; Mayer & Sims, 1994), brakes (Mayer & Anderson, 1992; Mayer, Moreno, Boire, & Vagge, 1999), lungs (Mayer & Sims, 1994), and lightning (Mayer et al., 1999). The median effect size was $d=1.31$, which is a large effect.

These findings mesh well with classic studies in which students remembered more from a narrated movie on carnivorous plants (Baggett & Ehrenfeucht, 1983) or toy construction (Baggett, 1984) than one in which the sound track was misaligned from the movie. In a recent meta-analysis of 13 experiments on temporal contiguity, Ginns (2006) reported an average effect size of $d=0.87$ on learning outcome measures favoring simultaneous over successive presentation.

Overall, there is strong and consistent evidence for the temporal contiguity principle. The effects may be diminished when learners have control over the pace and order of presentation (Michas & Berry, 2000) and when the segments are very short (Mayer et al., 1999; Moreno & Mayer, 1999a).

The *redundancy principle* is that people learn better from graphics with spoken words than from graphics with redundant spoken and printed words. In a set of five computer-based studies involving lightning (Mayer et al., 2001; Moreno & Mayer, 2002a) and an environmental science game (Moreno & Mayer, 2002b), students who received a narrated animation (or narrated slideshow) performed better on a transfer posttest than students who received the identical presentation with on-screen text added as captions. The median effect size was $d=0.72$.

Similar results yielding similar effect sizes were obtained with computer-based lessons involving human memory (Jamet & Le Bohec, 2007), lightning (Craig, Gholson, & Driscoll, 2002), and electrical engineering (Kalyuga, Chandler, & Sweller, 1999, 2000) as well as paper-based lessons on temperature graphs (Leahy, Chandler, & Sweller, 2003) and math problems (Mousavi, Low, & Sweller, 1995). In a recent review, Sweller (2005) used a somewhat broader definition of redundancy, but also concluded that there was empirical support for the redundancy principle.

Overall, there is strong and consistent evidence for the negative consequences of adding redundant onscreen text to a narrated animation, video, or slideshow. The redundancy effect may be diminished when the onscreen text is shorted to a few key words that are placed next to the corresponding part of the graphic (Mayer & Johnson, 2008). When there are no graphics, presenting concurrent spoken and printed text can result in better learning than printed words alone when the verbal segments are short (Moreno & Mayer, 2002a) but not when they are long (Diao & Sweller, 2007).

The *expectation principle* is that people learn better when they are shown the type of test items in advance of the lesson. For example, when Mayer, Dow, and Mayer (2003) presented sample pre-questions before a narrated animation on electric motors, students performed better on a transfer posttest (with different transfer questions) than when students did not receive pre-questions, with an effect size of $d=0.83$.

Table 31.3 Evidence-based principles for managing essential processing

Principle	Description	Example
Segmenting (Halpern et al., 2007; Mayer, 2005)	Break a complex lesson into manageable parts	Break a continuous narrated animation into small segments, each controlled by an onscreen "Continue" button
Pretraining (Mayer, 2005)	Before a lesson, provide training in the names and characteristics of key elements	Tell people the name, location, and actions of each part in braking system before showing a narrated animation on how brakes work
Modality (Mayer, 2005; Pashler et al., 2007)	Present graphics with spoken text rather than with printed text	Present a narrated animation on lightning rather than an animation with onscreen captions

This finding meshes with classic research on adjunct questions in learning from text, in which pre-questions produced positive effects on retention (Boker, 1974; Rothkopf, 1966; Rothkopf & Bisbicos, 1967). Overall, there is promising initial support for the expectation principle, but more research is needed, including additional research on providing students with a statement of the instructional objective.

Principles for Managing Essential Processing

Table 31.3 lists three principles for managing essential processing—segmenting, pretraining, and modality principles. The *segmenting principle* is that people learn better when a complex lesson is presented in manageable parts. Learners can fully digest one segment of the lesson before moving on to the next segment. For example, Mayer and Chandler (2001) found that compared to viewing a continuous 2.5 min narrated animation on lightning formation, students performed better on a transfer test after viewing a narrated animation on lightning formation that paused after each of 16 segments until the learner clicked a "Continue" button. Similarly, compared to viewing continuous narrated animation on how an electric motor works, students performed better on a transfer test in two experiments if they could see the presentation broken into five segments, each started by the learner's mouse click (Mayer et al., 2003). Overall, across three experiments conducted in our lab, the median effect size across these three experiments was $d=0.98$, favoring the segmented group over the continuous group.

Similar results were obtained in which students learned better when worked-out examples were broken into manageable steps for solving probability problems (Gerjets, Scheiter, & Catrambone, 2006) and for solving algebra equations (Ayres, 2006), and in which students learned better when a complex graph was broken into parts (Lee, Plass, & Homer, 2006; Mautone & Mayer, 2007). Overall, there is a growing base of support for the segmenting principle, with a median effect size of $d=0.82$ across nine experiments. Concerning boundary conditions, Ayres (2006) provides some evidence that the effects of segmenting may be strongest for low-knowledge learners.

According to the *pretraining principle*, people learn better from a complex lesson when they receive pretraining in the names and characteristics of the key concepts. Less processing is required when the complex lesson is presented because the learner already knows about the key concepts. In a core set of five experiments carried out in our lab, students performed better on a transfer test when a narrated animation on brakes (Mayer, Mathias, & Wetzell, 2002) or tire pumps (Mayer et al., 2002) or a geology game about geology formations (Mayer, Mautone, & Prothero, 2002) was preceded by a brief introduction to the names and characteristics of each key component of the system. The median effect size was $d=0.85$, which is considered to be a large effect. Similar results with large effect sizes were obtained in computer-based lessons on statistics (Kester, Kirschner, & van Merrienboer, 2004) and electronics (Kester, Kirschner, & van Merrienboer, 2006), as well as paper-based lessons on electrical engineering (Pollock, Chandler, & Sweller, 2002) and mathematics (Clarke, Ayres, & Sweller, 2005). Overall, there is strong and consistent evidence for the pretraining principle across ten experiments, yielding a median effect size of $d=0.88$. Concerning boundary conditions, preliminary evidence suggests that the effects of pretraining may be strongest for low knowledge learners (Clarke et al., 2005; Pollock et al., 2002).

The *modality principle* is that people learn better from a multimedia lesson when words are spoken rather than printed. Removing printed words from the page or screen frees up capacity in the visual channel allowing more processing of the graphics, and providing spoken words offloads some on the processing demands onto the verbal channel, which has capacity available. In a set of 17 experiments on modality, my colleagues and I have found strong and consistent evidence that learners perform better on transfer tests when words in a multimedia lesson are spoken (as narrated graphics, for example) rather than printed on the screen (as captioned graphics), with a median effect size of $d=1.02$. The findings include computer-based lessons on lightning (Mayer & Moreno, 1998; Moreno & Mayer, 1999a), brakes (Mayer & Moreno, 1998), electric motors (Mayer et al., 2003), and biology (Harskamp, Mayer, Suhre, & Jansma, 2007) as well as an environmental science game (Moreno, Mayer, Spires, & Lester, 2001; Moreno & Mayer, 2002a, 2002b) and an aircraft simulation (O'Neil et al. , 2000).

Similar results with generally strong effect sizes have been reported in paper-based lessons on how to solve geometry

Table 31.4 Evidence-based principles for fostering generative processing

Principle	Description	Example
Multimedia (Halpern et al., 2007; Mayer, 2005; Pashler et al., 2007)	Present words and pictures rather than words alone	Present a narrated animation on lightning rather than a narration
Personalization (Mayer, 2005)	Put words in conversational style	Say "I" and "you" rather than only use third person constructions
Voice	Use human speech rather than machine speech	Use recorded sound files of human voice rather than machine-synthesized voice

problems (Mousavi et al., 1995), how to solve electrical circuit problems (Tindall-Ford et al., 1997), and graph reading (Leahy et al., 2003), as well as computer-based lessons on lightning (Craig et al., 2002), electrical engineering (Kalyuga et al., 1999, 2000), and solving math problems (Atkinson, 2002; Jeung et al., 1997). In contrast to 35 experiments favoring the modality principle, with a median effect size of $d = 0.88$, the modality effect was not obtained in a study in which the pace of the lesson was slow and under learner control (Tabbers, Martens, & van Merrienboer, 2004), thereby suggesting a possible boundary condition. In a meta-analysis based on 39 between-subjects comparisons, Ginns (2005) reported a mean effect size of $d = 0.72$ favoring the use of spoken words over printed words in multimedia lessons.

Overall, the modality principle has been more widely tested than any other principle, and has achieved a high level of empirical support. Some important boundary conditions that warrant further study include that the modality effect may be stronger when the material is complex (Ginns, 2005; Tindall-Ford et al., 1997), the relevant portion of the graphic is highlighted (Jeung et al., 1997), the words are familiar to learners (Harskamp et al., 2007), and lesson is fast-paced and under system control (Ginns, 2005; Tabbers et al., 2004).

Principles for Fostering Generative Processing

Table 31.4 lists three principles for fostering generative processing—multimedia, personalization, and voice. The *multimedia principle* is that people learn better from words and pictures than from words alone. The rationale is that multimedia presentations encourage learners to build connections between corresponding words and pictures, thereby causing them to engage in one of the key cognitive processes in meaningful learning—the process of integrating. Across 11 experiments conducted in our lab, students performed better on transfer tests when their lesson contained printed words and corresponding illustrations rather than printed words alone (Mayer, 1989; Mayer & Gallini, 1990) or spoken words and corresponding animation rather than spoken words alone (Mayer & Anderson, 1991, 1992; Moreno & Mayer, 1999a, 2002b), yielding a median effect size of $d = 1.39$. Similar findings were reported for a computer-based lesson on lightning (Moreno & Valdez, 2005) and for a lecture on learning principles (Moreno & Valdez, 2007; Moreno & Ortegano-Layne, 2008). Overall, there is strong and consistent evidence for the multimedia principle. Some possible boundary conditions are that the multimedia effect may be stronger for low knowledge learners (Kalyuga, Chandler, & Sweller, 1998, 2000; Mayer & Gallini, 1990) and for high-quality graphics (Schnotz & Bannert, 2003).

The *personalization principle* is that people learn better when the instructor uses conversational style rather than formal style. The rationale is that people try harder to make sense of the presented material (i.e., engage in the cognitive processes of organizing and integrating) when they feel they are in a social partnership with the instructor. Across 11 experiments carried out in our lab, students performed better on transfer tests when they received a multimedia lesson in which the words were in conversational style (such as using "you," "I," and "we") rather than formal style, including computer-based lessons on lightning (Moreno & Mayer, 2000b) and the human respiratory system (Mayer, Fennell, Farmer, & Campbell, 2004), and games on environmental science (Moreno & Mayer, 2000b, 2004) and engineering (Wang, Johnson, Mayer, Rizzo, Shaw, & Collins, 2008). The median effect size was $d = 1.11$, which is a large effect. The effect also applies to polite wording of feedback and guidance by online tutors in an engineering game (Wang et al., 2008), but was not obtained with online chemistry tutors in classrooms (McLaren, Lim, Gagnon, Yaron, & Koedinger, 2006). Continuing research is needed to pinpoint the conditions most suitable for using conversational or polite wording.

The *voice principle* is that people learn better when an online instructor speaks with a human voice rather than a machine voice. The rationale is that an instructor using a human voice is more readily accepted as a social partner (Nass & Brave, 2005), thereby fostering deeper cognitive processing during learning. In a set of three experiments involving computer-based lessons on lightning formation (Mayer, Sobko, & Mautone, 2003) and mathematics word problems (Atkinson, Mayer, & Merrill, 2005), students performed better on transfer tests when the onscreen agent spoke in a friendly human voice rather than a machine-synthesized voice, yielding a median effect size of $d = 0.78$. These results provide promising preliminary evidence for the voice principle, but a larger evidence base is needed. A potential boundary condition concerns the role of the match between the learner's and instructor's gender, race, ethnicity, or emotional state (Nass & Brave, 2005).

Complementary evidence across nine experiments shows that adding the instructor's physical image on the screen (such as a talking head or a motionless cartoon character) does not substantially improve learning (Atkinson, 2002; Craig et al., 2002; Mayer et al., 2003; Moreno et al., 2001), yielding a median effect size of $d = 0.26$. Thus, the available evidence does not provide strong support for what could be called the *image principle* (Mayer, 2009). One possible suggestion may be that the onscreen agent would be more effective if it engaged in human-like gesturing (Goldin-Meadow, 2003; Hostetter, 2011; Lusk & Atkinson, 2007), an intriguing idea that warrants further study and could be called the *embodiment principle*.

Finally, some other candidates for fostering generative processing—also relevant to non-multimedia environments (Mayer, 2011)—are the concretizing principle, the anchoring principle, the testing principle, the self-explanation principle, the worked-out example principle, the guided discovery principle, the questioning principle, and the elaboration principle. The *concretizing principle* is that people learn better when unfamiliar material is presented in a way that relates it with the learner's familiar knowledge, such as using concrete examples and analogies. Research on concrete advance organizers provides encouraging evidence that students learn more deeply from a text lesson when it is preceded with a familiar concrete model or analogy (Mayer, 2008). Research on the use of concrete manipulatives in mathematics instruction offers another source of encouraging evidence (Lillard, 2005). In a multimedia learning environment, for example, allowing students to move an onscreen bunny along a number line helped students learn about addition and subtraction of signed numbers (Moreno & Mayer, 1999b).

The *anchoring principle* is that people learn better when material is presented in the context of a familiar situation, such as embedding a lesson on algebraic functions within the context of running a pizza business (Brenner et al., 1997). Research on multimedia learning also shows that anchoring a mathematics lesson within the narrative of a realistic practical problem can enhance learning (Bransford et al., 1996).

The *testing principle* is that people learn better when they take a practice test on the material have studied. Research using noneducational materials provides promising evidence (Roediger & Karpicke, 2006), as do some preliminary findings using educational multimedia in a computer-based environment (Johnson & Mayer, 2009). The *self-explanation principle* is that people learn better when they are prompted to explain lesson elements during learning, an idea that has preliminary empirical support in multimedia environments (Johnson & Mayer, 2010; Roy & Chi, 2005). The *worked-example principle* is that people learn better when they are shown a step-by-step example of how to solve a problem, with commentary—a principle that has extensive support including some multimedia learning environments (Renkl, 2005, 2011). The *guided discovery principle* is that people learn better when they are allowed to solve problems while receiving appropriate guidance, a technique that has been successful with computer simulation (de Jong, 2005, 2011). The *questioning principle* is that people learn better when they must ask and answer deep questions during learning and the *elaboration principle* is that people learn better when they outline, summarize, or otherwise elaborate on the presented material (Mayer, 2011). Finally, providing high quality feedback has long been recognized as one the most powerful instructional techniques for skill learning (Hattie & Gan, 2011; Shute, 2008), so its role in multimedia instruction warrants further investigation (Ido, Aleven, McLaren, & Koedinger, 2011).

Conclusion

Multimedia instruction involves instructional messages that consist of words (e.g., spoken or printed text) and pictures (e.g., drawings, charts, photos, animation, or video). The science of multimedia learning is concerned with developing a research-based theory of how people learn from words and pictures. Three major principles for a cognitive theory of multimedia learning are that learners have separate information processing channels for verbal and visual material (i.e., dual channel principle), that learners can engage in only a small amount of processing in each channel at any one time (i.e., limited capacity principle), and that meaningful learning depends on the learner's cognitive processing during learning (i.e., active processing principle). The science of multimedia instruction is concerned with developing design principles for multimedia instruction that are consistent with research evidence and grounded in cognitive theory.

Three kinds of goals of multimedia instruction design are to minimize extraneous cognitive processing during learning (i.e., cognitive processing that does not serve the instructional goal), to manage essential processing during learning (i.e., cognitive processing needed to mentally represent the essential material), and to foster generative processing during learning (i.e., cognitive processing aimed at making sense of the material). Research on instructional effectiveness pinpoints the degree to which students perform better on subsequent transfer tests when multimedia instruction is based on instructional design principles. Some principles for reducing extraneous processing during learning are coherence, signaling, redundancy, spatial contiguity, temporal contiguity, and expectation. Some principles for managing essential processing during learning are segmenting, pretraining, and modality. Some principles for fostering generative processing during learning are multimedia, personalization and voice.

A logical next step would be to explore what makes the difference between extraneous processing and generative processing, that is, what determines whether added material is relevant to the instructional goal. In addition, continuing research is needed to determine the boundary conditions for each principle in multimedia instruction, such as the degree to which principles apply to different kinds of learners, learning objectives, and learning contexts.
