Article Outline

Glossary

Azoic conditions Conditions that prevail when no organisms or their remains are found in a system as a consequence of stress on a system.

Biodeposition Organic matter deriving from (shellfish) species that falls to the seafloor. The matter can take the form of feces, pseudofeces, or the shellfish themselves.

Far-field effects The effects of impacts of activities measured at a predefined distance or time from the location of the pressure. The effects may or may not be distinguishable from other effects in the system leading to cumulative impacts.

Ecological aquaculture The implementation of aquaculture practices whose design and implementation result in economically viable and socially responsible aquaculture systems.

Integrated coastal zone management (ICZM) The management of activities in marine environments in a coherent and practical fashion so as to result in the most efficient use of resources and avoid conflicting claims on space and missed opportunities for more sustainable coastal development.

Performance standards Defined expectations represented by some measurable variable which reflects the impact an activity will have on the marine environment.

Best management practices A series of operating procedures, schedules of activities, and other management practices that aquaculture operations can use to prevent or reduce impact on the marine environment while retaining an economically viable operation.

Definition of the Subject

Worldwide aquaculture production of finfish and shellfish species is an ever-increasing sector of food production and now represents nearly half (48%) of all aquatic species intended for human consumption [1]. It is thought that the increased aquaculture production is driven primarily by the vacuum created as a consequence of the static (or declining) status of wild capture fisheries allied to an overall greater demand for fishfood products [1]. This generalization is broadly accepted as the primary driver for increased aquaculture production; however, more specific drivers may be, increased profit as a consequence of targeted marketing allied with development of new species in developing countries and as a means of providing more self-sufficient mechanisms to grow fishfood and provide a regular income in developing countries. Typically, aquaculture production has been dominated by the culture of finfish species; however, shellfish production has shown a steady increase in production over the last number of decades [1] and represents 27% by weight and 15% by value of worldwide aquaculture production. The culture of shellfish in aquaculture is comprised primarily of species of crustaceans (e.g., shrimp and crab) and molluscs (e.g., oysters, clams, mussels). A major distinction

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

between the crustaceans and molluscs is that crustaceans, as omnivores, typically require the input into their culture system of feed, usually derived from external sources (e.g., fish protein or oils). Consequently, issues surrounding the sustainability of crustacean culture as activities are more akin to those encountered with finfish aquaculture. Molluscs, particularly those identified above, are filter feeders. Filter-feeding organisms, for the most part, feed at the lowest trophic level, usually relying primarily on ingestion of phytoplankton. The process in extractive in that it does not rely on the input of feedstuffs in order to produce growth.

The steady increase in world aquaculture production over the last number of decades allied with greater environmental awareness has resulted in an increased level of scrutiny of these activities in relation to their interactions with the environment. The increased focus on environmental issues in the marine environment (driven by consumer demands and/or regulatory requirements) has resulted in a concomitant increase in efforts to identify methods to culture shellfish that are considered sustainable. Consequently, there is a move toward rearing aquatic shellfish species in the marine environment such that negative interactions are minimized. In addition, it has also become apparent that there are considerable marketing benefits that will accrue as a consequence of food being reared in an environmentally acceptable fashion. These efforts (to identify and activate more sustainable method of culture) have been driven both by industry and environmental nongovernmental organisations (e.g., Pacific Shellfish Growers Association and World Wildlife Fund) as well as regulatory drivers (e.g., Natura 2000 Legislation in the European Union). Notwithstanding the efforts to carry out shellfish aquaculture activities in a more sustainable fashion, there is still some confusion relating to the definition of sustainability and how an activity might be carried out in a sustainable fashion. At first, identifying if an activity and its consequences in the marine environment is acceptable or not will help define whether the activity is sustainable. Clarifying or clearing defining some of the terms utilized in this subject area will lend itself to a clearer and understandable of how the culture of shellfish can be managed to achieve sustainability goals.

Introduction

Worldwide aquaculture production has increased steadily since 1980 [1]. Production of aquatic products in 1980 accounted for 7% of food fish supply (five million tons), in 2007 this quantity had risen to 50 million tons. Based upon current trends, it is apparent that production of shellfish will continue to increase at a stable rate (6.5% per annum since 2002). This increase is fueled by an increase in market demand, adoption of more efficient and effective culture methods, and the financial rewards associated with the production of value-added products to higher end markets. Notwithstanding the important differences between finfish production and the majority of shellfish production methods, i.e., the introduction of feedstuffs into the environment, which has led to well-documented resource demands and impacts on the marine environment, shellfish aquaculture also has the potential to impact on the marine environment in a negative fashion if not carried out in a responsible manner. This is underpinned by a background of greater environmental awareness and increased legislative drivers toward maintaining biodiversity and minimizing negative interactions between a range of conservation goals and development activities. Some authors [2] correctly highlight that aquaculture cannot be considered as one single "monolith," which can be tarnished with the single level of criticism, as it reflects a diverse array of species, methods, and potential interactions. In addition to the differences highlighted above between those culture methods reliant on input of feedstuffs necessary for the culture of some species (finfish and crustaceans), the degree of structural input and environmental alteration is also highly varied among the different species cultured and the method employed. In short, this entry will identify some of the issues associated with sustainability of shellfish aquaculture and whether or not the efforts directed to date are considered to be on a trajectory toward sustainability [3].

Interactions of Shellfish Culture

Early incarnations of shellfish culture are considered not far removed from wild fisheries in that the activities were broadly extensive with only small-scale

manipulation of stocks (e.g., movement of wild seed to production areas; an activity still practiced today with on-bottom mussel and oyster culture). Over time, the industry has evolved with the development of more contained systems. With such intensification, the risk of detrimental environmental interactions increased, e.g., disease risks or greater deposition of organic matter beneath structures, as a consequence of higher holding densities of culture organisms. Notwithstanding density-related issues, in many instances, it is not the presence of the culture organisms that result in largely negative interactions but the activities associated with the culture mechanisms, e.g., dredging extensive culture systems, pesticides, or chemotheraputents in pond systems.

The culture of shellfish (bivalve molluscs) as distinct from finfish and crustaceans, for the most part, requires no input of feed to the culture process. Given this difference, this entry will focus primarily on the culture of molluscan shellfish (primarily bivalves). Under certain circumstances, e.g., hatchery production of shellfish, the input of feed in the form of phytoplankton is required to produce seed [4]. Thereafter, for the majority of their life cycle, shellfish consume at the lowest trophic level, feeding largely as herbivores and relying on ambient seston [5]. This distinction is important in that it highlights the fact the culture of shellfish, upon harvest, is considered a process that facilitates the net export of carbon (and other nutrients) from marine systems. While this may be considered an exploitation of a resource and detrimental to the system, there are situations where this is also inherently beneficial to the ecosystem. The impacts of shellfish culture have been well documented in research literature where specific interactions are described and quantified (Table 1). In addition, this topic has been a subject of numerous reviews highlighting similarities and differences inherent in culture methods and considers the factors governing any differences observed.

The extent of the interactions between shellfish culture and the environment are primarily a function of the type of species being cultured, the system of culture, and the properties of the receiving environment. Table 1 provides a summary of the interactions identified between shellfish culture practices and the environment. The interactions are summarised as the mechanism which acts on the system. For example, the dredging associated with the collection of mussel seed for aquaculture practices can have the effect of physically disturbing the seafloor and the organisms therein (the impact indicator). It has been demonstrated empirically that this activity can have an impact at the community level of marine ecosystems. The culture of shellfish species using structures presents a number of likely interactions. The use of structures, i.e., bags and trestles, longlines with droppers will increase the density of culture organisms above the seafloor, thus influencing the flux of material and nutrients to the seafloor and into suspension. This higher density can also modify water flow in and around the culture system. These and other more general interactions are discussed below.

Nutrients

Bivalve shellfish can function in the ecosystem by filtering seston and releasing nutrients in solid or dissolved forms. They are responsible for deposition onto the seafloor of particulate matter (as either feces or pseudofeces), thus influencing benthic-pelagic coupling of organic matter and nutrients. The deposition of organic matter by molluscs has been demonstrated to impact on the infauna organisms and communities found in sedimentary environments. The changes have broadly reflected the Pearson–Rosenberg [6] pattern of community development whereby moderate increases in organic matter stimulate species' richness and abundance. Further increases in organic matter could result in a reduction in species richness and abundance such that excesses result in azoic conditions as a consequence of protracted anoxic conditions. The effects of biodeposition are exacerbated by the increase in density of culture organisms above the seafloor. The use of bags on trestles (e.g., oyster culture) and longlines (with mussels) will increase the density of culture organisms over a particular point and increase the risk of impact due to biodeposition. While effects of organic loading have been demonstrated with shellfish culture activities, the impacts are considered relatively small when compared with other culture systems where externally derived organic matter, i.e., food, is inputted directly to the system, e.g., finfish culture. A number of factors mediate the level of impact on the seafloor.

Shellfish Aquaculture, Methods of Sustainable. Table 1 Interactions between shellfish culture methods and the environment identifying the interaction route and indicator

Culture type (species)	Interactions	Indicator	References
*Off-bottom – Suspended culture (*e.g.*, mussels, oysters) using longlines, rafts, floating bags*	Water flow alteration	Sediment particle size analysis (PSA) – increase in fine sediment composition due increased sediment deposition or increase in coarse sediment complement due to scouring	[7, 79–85, 163]
		Benthic infauna – adjustment in species composition and abundance; community composition	[86–89]
	Depostion of organic matter (feces and pseudofeces)	Increase in sulfide reduction, Decrease in REDOX depth; Sediment biogeochemistry changes	[84, 88, 90–93]
		Benthic infauna	[81, 86, 87, 94, 95]
	Shading	Condition of light-sensitive species (macroalgae, maerl, eel grass)	[96, 97]
	Habitat creation/fouling	Secondary production on culture organisms or structures. Increased nekton species	[22, 98–103]
	Seston filtration	Alteration of phytoplankton communities, impact on production/ecological carrying capacity; changes in zooplankton assemblages	[80, 104–107]
	Nutrient exchange	Ammonium, DIN – increased primary production, N2 removal via harvest or denitrification	[93, 108–111]
	Introduction of exotic species with culture organisms	Presence of non-endemic or exotic species	[22, 112, 151]
On-bottom (Mussels, oysters, clams)	Physical alteration, dredging, intertidal picking	Benthic infauna	[86, 114, 115]
	Monoculture	Epifuana community alteration: PSA alteration	[52, 86, 89, 91, 96, 115–118]
	Depostion of organic matter (feces and pseudofeces)	Increase sulfide reduction, Decrease in REDOX depth; sediment biogeochemistry changes	[119–126]
		Benthic infauna	[8, 127]
	Shading	Condition of light-sensitive species (macroalgae, maerl, eel grass)	[11]
	Habitat creation/fouling	Secondary production on culture organisms or structures	[78, 79, 89, 115, 127–129]
	Seston filtration	Alteration of phytoplankton communities, impact on production/ecological carrying capacity; increased light penetration	[11, 91, 106, 107, 109, 130–141]
	Nutrient exchange	Increased primary production, N_2 removal via harvest or denitrification; alteration of N:P ratios	[109, 110, 142–150]
	Introduction of exotic species with culture organisms	Presence of non-endemic of exotic species	[112, 113]

In addition to density of culture organisms, the hydrography of the system including residence time, tidal range, and residual flow will all dictate the likely influence the extent of an impact on the seafloor. The greater the residual flow and/or tidal regime, the risk of accumulation of organic material is reduced [7, 8] due to the dispersive regime. Similarly, the high density of structures can result in the impediment of water flow (baffling effect), slow it down, and cause localized deposition of suspended material on the seafloor. Depending on the extent of the structures, the effect can be localized or extensive [9] with concomitant impacts on sedimentary infauna.

Organic deposition by shellfish on the seabed can also influence the remineralization of nutrients in marine systems. This process as well as normal excretion (of ammonium NH_4^+) demonstrates that shellfish in both their natural state and in culture can influence nutrient dynamics in marine systems. In fact, in a coastal bay in France it has been estimated that between 15% and 40% of nitrogen in the system is derived from oysters in culture [10]. Notwithstanding the factors that govern extent of impacts on systems, molluscs are considered net consumers of particulate and dissolved nutrients, and, by virtue of the movement of product to market the nutrients are exported from the system. The area required to assimilate material is generally confined to the production area and as such the area required to assimilate material is less with culture than without.

Filtration

Bivalve shellfish (oysters and mussels) have a high filtration capacity and can respond rapidly to changes in phytoplankton abundance (as a result of eutrophication) in marine systems. In nearshore marine environments, the presence of large numbers of bivalve shellfish has provided the system with the ability to buffer the effects of large phytoplankton blooms. This phenomenon applies equally to shellfish in culture which likewise provides the system with resilience against natural or anthropogenically derived fluctuations in phytoplankton numbers (blooms) [11–14]. As a consequence of this phenomenon, the subsequent removal of natural bivalve populations from marine systems (e.g., by fishing) has resulted in well-documented ecological shifts in system processes. The dramatic reduction of oyster numbers in the Chesapeake Bay (USA) has coincided with a deterioration in water quality of the Bay; this situation was exacerbated by increased athropogenic pressures [15–17]. Shellfish in culture while having demonstrable localized effects do also appear to have the ability to moderate the effects of nutrients more broadly in marine systems [9, 18].

Exotic Species

The importance of aquaculture as a vector for the introduction and spread of exotic species has been well documented [19–23]. There are two broad classes of introductions that may result from bivalve aquaculture.

First, there is the establishment and spread of non-endemic species that have been intentionally introduced into an area for aquaculture purposes, the "target" species. Classic examples of this include the establishment of the Pacific oyster (*Crassostrea gigas*) on the Pacific coast of North America [24] and in various countries throughout Europe [25–27] and of the Mediterranean mussel (*Mytilus galloprovincialis*) in South Africa [28]. More recently, the large expansion of *C. gigas* in the Oosterschelde and the Dutch and German Wadden Sea have been a cause of concern in both countries from a fisheries, ecological, and human health perspective. Wild populations of the Pacific oysters have expanded from 15 ha in 1980 to 750 ha in 2005 in the Oosterschelde [29]. They have become a competitor (for space and food) with the commercially important mussel industry [25, 30]. In addition, they have become an increasing health risk associated with human encounters given the sharp nature of the shell [31]. Efforts to remove wild Pacific oysters from the Oosterschelde in the Netherlands are ongoing (Aad Smaal, IMARES, NL personnel communication). It is important to note that in the Netherlands, Pacific oysters were first introduced by broadcast spreading in an uncontained fashion on the seabed under the assumption that the summer temperatures were such that they would not successfully complete gametogenesis, spawn, and most importantly recruit.

Second, there is the establishment and spread of species that are associated with the introduced bivalves [32, 33]. These species may include both "hitchhiking"

species – animals, plants that grow associated with the bivalves and diseases or parasites that may cause outbreaks in the same or other species [34]. This acts at two spatial scales: at an interregional or international scale with respect to the initial introduction of hitchhiking species and also at a regional scale, where the transfer of stock among sites may be very important to the spread of established exotic species locally [35]. The provision of novel habitat by the species being cultured may also allow for the establishment or amplification of exotic species that may be introduced through other vectors or of native species that thrive in the novel habitat [36–38].

Introductions of the *C. gigas*, and to a lesser extent *C. virginica* and other oyster species, outside of their native range for aquaculture have been suggested to be one of the greatest single modes of introduction of exotic species worldwide [19, 39]. For example, transfer of organisms with bivalves has been suggested to be the most important source of exotic species in northern Europe [17, 40] and among the most important vectors elsewhere in that continent [17, 41, 42]. In the northeast Pacific, some authors suggest that oyster (*C. gigas*) introductions have even been the major source of introduction of exotic molluscs [14] and invertebrates in general [43], historically contributing at least as many of the exotic species in that area as has international shipping.

The slipper limpet (*Crepidula fornicata*), originally introduced into England with *C. virginica*, has had great impacts on some benthic communities in Europe, particularly in France [44] and the UK [45]. It has displaced important commercial bivalves, such as the great scallop (*Pecten maximus*) in some areas and native oysters beds in Normandy [46] and the south coast of England [39]; however, in other areas where it has not proliferated as much, it appears to have had little effect on overall macrobenthic community diversity [47].

Introductions have not just been confined to macrofaunal species. Oyster introductions have also been strongly implicated in the introduction of parasitic organisms and macroalgal species into novel regions [48–50]. Notwithstanding the records of aquaculture-mediated introductions of nonnative species into marine systems, there still appears to be a paucity of information and experimental evidence quantifying the impacts of nonnative oyster introductions on the receiving environment [13]. The structures associated with shellfish culture (e.g., ropes, bags, floats) in some areas provide novel habitat for the colonization and proliferation of exotic species [18]. In addition to the likely effects on system function, the colonization of structures associated with shellfish culture also presents practical problems for the aquaculturists from a husbandry perspective.

Biodiversity

The physical presence of large numbers of shellfish in culture can result in a monoculture which has a finite period of time in the system as a consequence of husbandry practices, e.g., thinning or harvesting. Given this constraint, the development of communities associated with the cultured shellfish will be restricted and hence biodiversity is likely to be reduced. This is particularly true if the culture period is short (i.e., approximately 1 year). The activities associated with shellfish culture can also be impacting. For example, dredging associated with on-bottom culture of mussels and oysters can cause damage to seabed (and organisms therein) and cause sediment plumes to be distributed beyond the culture environs [51, 52].

Structures

The culture of shellfish species using structures presents a number of likely interactions with the environment. The use of structures, i.e., bags and trestles, longlines with droppers will increase the density of culture organisms above the seafloor, thus influencing the flux of materials and nutrients to the seafloor and into suspension. The physical presence of the structures can also modify water flow in and around the culture system resulting in increased deposition of material or scouring in areas of higher flow. Either way there is a potential to impact on the sediment structure and associated communities. As stated above, shellfish aquaculture can also provide structures that can provide for the proliferation of individual (fouling) organisms in a system. Some of which might be new to the system. Finally, the physical presence of the structures and culture animals can have the effect of shading the seafloor and thus potentially impacting on species reliant on light (e.g., maerl or seagrasses).

The interaction of shellfish culture activities with the marine environment can be considered from the perspective of near-field and far-field impacts. While near-field effects are more easily measured (using many standard near-field impact indicators identified in Table 1) and mitigated, the measurement of far-field effects is more difficult to achieve, although some of the impacts might be lessened if near-field activities are reduced or mitigated. Other far-field effects may not be as easily measured and assigned to a specific causative activity (as there may be multiple causative factors) yet they all must be considered when managing marine systems. To this end, a number of authors (e.g., Tucker and Hargraves [163]; Costa-Pierce and Page [3]) have provided a good contextual presentation on the issues surrounding sustainability of aquaculture activities. They acknowledge that sustainability solutions can extend from ecological, technical, and socioeconomic and cover very small spatial scales to adjusting broader societal values.

It is important to appreciate that in order to manage activities in marine systems, it is imperative that there is a good understanding linking the culture practice to a specific environmental response. These interactions are important in order to coordinate management responses between regulatory agents and aquaculture operators, in order to minimize negative environmental effects while maintaining production returns and hence, profits.

Evolution of Sustainability for Shellfish Culture

It is widely accepted that most human activities in the marine environment will have some effect on marine species and habitats. The scale of these impacts depends on the nature of the activity, its intensity, and the sensitivity of the receiving environment. The degree of change that is considered permissible depends on a number of factors, not the least of which is public perception. Empirical data demonstrating change or impact is the most obvious basis on which to justify management actions or inactions. Equally important is linking the change observed directly to the process under consideration (e.g., bivalve molluscan mariculture). Best management practices (BMPs) and performance standards have been adopted as means of mitigating against unacceptable environmental interactions. The major categories of practices and standards include the following:

- Regulatory standards governing molluscan mariculture
- BMPs (or design standards or specifications) for bivalve growers, mariculture regulators, and managers
- Certification standards for molluscan products (e.g., organic, sustainable, fair trade, domestically or even locally grown)
- Other innovations, Integrated Multi-Trophic Aquaculture (IMTA)

Legislative Drivers Toward Sustainable Practices

As in many countries there is much national and internationally derived legislation governing the production and placement of aquaculture-derived food products on the market. These regulations consider the product primarily from a food safety perspective with the goal of protecting the consumer. In European Union member states, Regulation (EC) No 854/2004 [53] of the European Parliament and of the Council of 29 April 2004 laying down specific rules for the organization of official controls on products of animal origin intended for human consumption was implemented to ensure that consumers of shellfish products are not exposed to toxins that might have accumulated in shellfish flesh as a consequence of filtering phytoplankton species responsible for producing these toxins. Shellfish are effective bioaccumulators. Such regulation requires continual monitoring of shellfish products derived from marine waters. In the event of an excess of defined thresholds, the product is not placed on the market and monitoring continues. The broader environmental benefits of this legislation are that it can identify areas of risk (for harmful algal blooms) and has spawned research to identify factors governing the causes of bloom events including anthropogenic sources. How this impacts on sustainability of shellfish aquaculture? The persistence of HAB and toxic events can dictate the feasibility of locating or developing shellfish culture these areas. If areas are subject to prolonged closures, the product is generally restricted from being removed and can result in overload and subsequent impact on system processes.

The Water Framework Directive [54] is a legislative driver designed to improve surface and groundwater quality throughout the European Union. Allied with a full-risk assessment, each waterbody will be assessed for its condition in terms of ecological quality elements. This monitoring program focuses on a range of ecological quality elements (e.g., benthic invertebrates, phytoplankton, macroalgae, fish in transitional waters) for which a series of standards have been developed. The waterbodies included in the monitoring program were selected on the basis of no obvious pressures and site for which some pressure has been identified, e.g., aquaculture activities. The goal of the WFD is to ensure that all waterbodies achieve good ecological status by 2015.

The Habitats and Birds Directive [55] in EU member states is considered the cornerstone of Europe's nature conservation policy. The Directive requires that certain areas are designated as conservation sites (Natura sites) and that the conservation features therein managed such that they are preserved in a natural state. In many EU member states, licensed aquaculture activities take place in Natura sites. The designation does not preclude licensing activities in Natura sites but the licensing process must ensure that the proposed activities do not pose a significant risk to the conservation objectives of the site. In this regard, the licensing authority must be seen to carry out and appropriate assessment on the likelihood of these activities significantly impacting on the conservation features. If the activity is considered impacting, then the licensing authority or the applicant can mitigate with a view to reducing the significance of the impacts and still fulfill both conservation and aquaculture objectives. Similarly, in the USA, the Magnuson-Stevenson Fishery Conservation and Management Act, provides for the protection of essential fish habitat and the restoration of coastal habitats. Both objectives can cause the relocation of shellfish aquaculture operations to less ecologically sensitive areas (e.g., away from seagrass beds). However, the act also provides some opportunity for shellfish aquaculturists from the perspective of the benefits shellfish aquaculture can provide specifically as it relates to habitat restoration goals. The worldwide depletion of natural populations of shellfish in nearshore coastal areas has been well documented (reviewed in National Research Council [18]). The ability of aquaculture to fill the ecological niche previously provided by native populations has been postulated. At a minimum aquaculture has provided stock for the implementation of restoration projects in Chesapeake Bay in Virginia and Maryland [56].

The International Council Exploration of the Sea Code of Practice on the Introductions and Transfers of Marine Organisms [57] is not legislation per se; however, it is cited in legislation and is considered a good example of a guide/code of practice developed in response to particular pressures or risks identified with human activities including, *inter alia*, shellfish aquaculture. The ICES Code of Practice recommends a series of protocols with a view to mitigating any negative risks associated with intentional introductions and transfers of marine organisms and is targeted at individuals or organization that engages in such activities. As an example of specific legislation citing the ICES Code is the European Union regulation concerning use of alien and locally absent species in aquaculture (708/2007/EC). Specifically, the legislation is designed to avoid alterations to ecosystems, prevent negative biological interactions (including genetic change) with indigenous populations, and restrict the spread of nontarget species and detrimental impacts on natural habitats. This legislation directs member states to ensure that a full-risk assessment is carried out prior to the introduction of a nonnative species for aquaculture purposes. In order to facilitate any introduction, the regulator must ensure that the operator mitigate fully any negative interactions identified as a consequence of the risk assessment. The protocols identified in the ICES Code can provide an avenue toward this mitigation.

The Code is aimed at a broad audience since it applies to both public (commercial and governmental) and private (including scientific) interests. In short, any persons engaged in activities that could lead to the intentional or accidental release of exotic species should be aware of the procedures covered by the Code of Practice.

Notwithstanding the potential for regulation to positively guide the development and practice of shellfish aquaculture activities, there is also the risk that regulation can result in constraint of bivalve aquaculture development. This has been demonstrated in the

USA where a range of local, state, and federal ordinances govern the licensing of activities in nearshore waters (i.e., areas conducive to bivalve aquaculture). For example, while some coordination has occurred between state and federal agencies in the USA, it still requires up to 30 permits to establish a shellfish culture operation (National Research Council [18]). The complexity can result in a protracted and expensive application process on the part of the aquaculturist that can end with the permit application being refused. The conflict inherent in the regulatory processes is also reflected by conflicts of users in the coastal areas, e.g., wild fishery and aquaculture interests. As a solution to such conflicts, some jurisdictions have implemented zoning of activities where certain activities are only permitted. For example, in an effort to mitigate the conflicts between shellfish culturists and fisherman, some states (Massachusetts and North Carolina) allow shellfish culture in areas where bivalves do not naturally grow. While this offers a somewhat artificial solution to user conflicts, it would appear to favor fishermen, as shellfish typically grow best where they are found naturally in the wild and the availability of approved growing areas might be hard to locate if shellfish are ubiquitous.

Industry Solutions Toward Sustainable Practices

There have been a number of industry-led initiatives that have directly or indirectly led to the implementation of more sustainable practices relating to shellfish culture. As already stated, an important realization among promoters of aquaculture and/or regulatory bodies is that a good understanding of the likely interactions between culture practices and environmental concerns is paramount in order to structure management responses. From the industry perspective, these responses are structured with a view to minimizing the negative environmental interactions while maximizing profits.

Integrated Multi-Trophic Aquaculture

Integrated Multi-Trophic Aquaculture (IMTA) is based upon the principle that the coculture of aquaculture products in carried out in sequence and that one species production is dependent upon the outputs of another [58]. Integration at larger scales may address the optimization of shared resources among various aquaculture users (e.g., shellfish or seaweed culture near fish farms), but assumes that the integrated components (species) are situated within the influence of the system component upon which it directly depends for waste/energy transfer and utilization. In a well-balanced system this relationship provides the environmental benefits associated with polyculture, and is the basis of definitions such as sustainable, or ecological, aquaculture.

Initiatives on the east coast of Canada (New Brunswick) have recently evaluated the performance of mussels (*Mytilus trossulus*) and large macrophytes (*Laminaria*) cultured within the infrastructure of an open net-cage salmon (*Salmo salar*) aquaculture facility (see IMTA chapter) [58]. To date, there have been mixed results in terms of performance of secondary species, i.e., shellfish species in demonstration projects for IMTA; however, there are a number of other perceived benefits of location shellfish operations in the influence of finfish farms. Most notably is the effect of the shellfish on diseases and parasites of the fish species. Concern has been raised about the ability of the shellfish species of retaining and/or transmitting disease-causing organisms to fish species. The counterargument to these concerns is that the shellfish species is likely endemic to the area and may form part of fouling community on structures such that the risk is not magnified by the presence of the species in culture. In addition, a demonstrated benefit is that the blue mussel (*Mytilus edulis*) has been shown to destroy the virus for infectious salmon anemia (ISA) [59]. Furthermore, the blue mussel has also been demonstrated to eat copepodids (the larval stage of the sea louse, a parasite of salmon) [60] and represents a potential alternative control mechanism to sea lice to chemical treatment which have limited efficacy due to a buildup of resistance in the louse.

The environmental benefits of MTA are not constrained solely to the direct assimilation of waste constituents among the cocultured species, but will also be achieved indirectly through the physical design/configuration and orientation of such a system with respect to adjacent, and potentially sensitive marine habitats. Furthermore, there are a number of perceived social benefits associated with the development of marine integrated aquaculture including: (1) optimizing culture opportunities where space is constrained; (2) the provision of development opportunities in remote coastal regions; and/or (3) improving public

awareness of aquaculture or aquaculture subsequent environmental accountability. To this end, in the European Union, the Common Agriculture Policy and Common Fishery Policy requires primary users of the natural resources (e.g., agriculturists, fishermen, aquaculturists) to implement an ecosystem approach in the management and conservation of the environment and landscape. It considers polyculture (MTA) as a viable utilization approach for these areas that could provide restoration at a lower cost for society.

Certification Schemes

The increasing demand from consumers for information pertaining to the products they are consuming has been the primary driver for the development of aquaculture certification schemes. The schemes operate on the principal that aquaculture products are produced in fashion that considers a range of factors including, *inter alia*:

- Social responsibility and comply with laws such that they are produced in a legal, safe, and fair manner
- Environmentally responsible manner such that any negative impacts on the system are minimized
- That all food safety and quality standards are complied with in the member states
- That all animal health issues are considered and managed consistent with legislative requirements

To date, the most prominent schemes are overseen by the Global Aquaculture Alliance (GAA) [61], which is responsible for the development of best aquaculture standards for mostly "fed" aquaculture products, including shrimp hatchery and farm standards. It would appear that there are currently no plans for the GAA to develop standards for bivalve shellfish culture. The Aquaculture Stewardship Council is an association founded jointly by the WWF and Dutch Sustainable Trade Initiative with a view to ensuring aquaculture is carried out in an environmentally and socially sustainable fashion. The ASC has developed standards for the culture of bivalve shellfish products (on foot of the Bivalve Aquaculture Dialogues [62]). The standards are governed by a range of broad principles for addressing the environmental and social issues associated with bivalve aquaculture. These principles are consistent with those identified above. The principles provided the framework for developing the criteria, indicators, and standards applicable to bivalve farming. The standards attempt to provide quantitative performance levels that determine whether a principle is achieved or not. The ultimate goal of ASC is to have comprehensive participation in the certification scheme by shellfish aquaculturists, which is planned to be certified by a third party. In addition to bivalves (clams, oysters, mussels, and scallops) standards have also been established for abalone. In summary, certification standards have been developed by buyers, public agencies, nongovernmental organizations, or marketing groups as a means of providing consumers with information about a product. The ultimate goal of certification schemes is to persuade growers to modify culture practices by influencing consumer choice and market forces. However, pursuit of certification is voluntary for growers.

Best Management Practices

The origin of Best Management Practices (BMPs) dealing specifically with environmental interactions is primarily from broader land-based agricultural practices used to mitigate the effects of soil erosion and nutrient loading. Similarly, mariculture BMPs have been developed with a view to minimizing effects resulting from aquaculture culture practices (see Table 2). Best management practices often are developed or strongly supported by the industry group (e.g., oyster growers) to which they apply and as such, adoption of and adherence to these codes is usually voluntary. As with other practices (cited above) the adoption of BMPs tend to have multiple objectives including, for example, reducing the likelihood that shellfish farming will have unacceptable ecological effects. These effects relate primarily to changes in the ecology of the system and interactions with other stakeholders in the system. As highlighted in Table 2, some examples of BMPs relating to shellfish culture consist of outreach brochures on husbandry techniques (e.g., Washington Sea Grant, 2002; Alaska Sea Grant, 2009; University of Maryland, 2009) to identify the optimal ways to culture bivalve molluscs. While these publications focus on methodologies to maximize production, they can still be considered as rudimentary BMPs, in that they require, of the culturists or advisors,

a good understanding of the likely interactions between the specific culture methods and the environment (e.g., performance in light of productivity).

The development of BMPs with a view to managing environmental interactions should be considered a fluid or transitory process that should allow for feedback and subsequent modification of culture practices to mitigate negative effects associated with the shellfish culture.

Some BMPs are usually nontechnical wherein they identify a range of issues and present a framework of

general principles and solutions and as such, are unlikely to address the range of detailed and local in aspect, issues that present to regulatory agencies and the producers. Other BMPs do deal with more regional issues, and yet others specifically consider the day-to-day operations at farms and their interactions. These guidelines can provide important advice on pertinent laws and ordinances and focus on important local issues (e.g., environmental interactions, stakeholder interactions, community relationships). In addition, they can identify solutions that range from farm- or small-scale measures to broader societal solutions focusing upon competing uses and values. Toward this end, there are a number of general principles that have applied to the development of BMPs that have directed the practice of shellfish aquaculture toward producing molluscs under the broader umbrella of sustainability. These principles can be broadly categorized under the following headings [50, 63]:

1. Promote a good understanding of environmental and ecological processes, with the broader view of generating carrying capacity models for production areas. This can be further expanded including important socioeconomic considerations also (i.e., ecological and socioeconomic sustainability).
2. Utilize the BMP as a means of promoting the product, i.e., a marketing tool to target a niche market and/or premium price (i.e., economic sustainability).
3. Allow a staged increase in production and reduce uncertainty in terms of environmental interactions (i.e., ecological sustainability).
4. Provide an important communication tool to highlight issues and benefits of shellfish culture to relevant regulatory authorities as well other stakeholders (e.g., nongovernmental organizations) (i.e., social sustainability).

While a goal of implementing BMPs will undoubtedly be the improvement of environmental conditions or mitigation of negative effects caused by the aquaculture activity, there still remains a question of how the effects of the BMP are measured. There can be a sharp distinction between BMPs and performance standards. On the face of it, both schemes are broadly designed to limit risk of undesirable environmental impacts. Some authors [15, 64] correctly note, however, that BMPs are not a proxy for performance and that they may have little or no impact in terms of measurable environmental improvements. Typically there are no measures associated with BMPs to validate the claims about mitigating environmental effects. BMPs, in effect, are akin to design standards, whereby procedures and practices are strictly defined (e.g., number of longlines per hectare) which are relatively easily verified. BMPs, therefore, will have a lower administrative burden for demonstrating compliance by identifying easily measured metrics, but have the drawback that there is no guarantee of environmental benefit. Performance standards, on the other hand, measure specific environmental objectives, i.e., the effect on the activity on some aspect of the environment (e.g., free sulfide concentration in sediments). Performance standards relate more specifically to objectives focusing upon ecological integrity of a system [15]. However, performance standards have resource implications in terms of monitoring and enforcement; they are likely more expensive to administer and implement that BMPs.

Notwithstanding with distinction highlighted between BMPs and performance standards, it is still possible for managers to align husbandry practices with some measure of performance. For example, it is possible for managers to identify the carrying capacity of a system and subsequently advise on the design of husbandry systems. The process must be fluid and allow for changes in practices and standards as more information on effects is gathered and uncertainty is reduced. It also should allow for stakeholder participation to inform management decisions. In this regard, the science underpinning management actions is communicated concisely to all with an interest in the subject matter and that the views and experience of stakeholders are brought to bear on the process.

Measuring Sustainability: The Development of Indicators

Indicators are important management and communication tools used in order to

1. Inform and raise public awareness on environmental issues
2. Provide information linking driving forces and impacts

3. Develop policy responses. To this end, the indicators can be used:
   a. To supply information on environmental problems in order to enable policy makers to value their seriousness
   b. To support policy development and priority setting by identifying key factors that cause pressure on the environment
   c. To monitor the effects of policy decisions

Communication is a primary function of indicators – they should enable or promote information exchange regarding the issue they address. Communication, however, demands simplicity and therefore indicators should always simplify complex realities. Sustainability indicators are different from "impact" indicators in that they tend to be more inclusive and consider not only environmental issues but also social and economic features [3]. Based upon these broad criteria, sustainability indicators represent an amalgam of the Integrated Coastal Area Management (ICAM) guidance of the United Nations Educational, Scientific, and Cultural Organisation (UNESCO) recommends three basic categories of indicators:

1. Environmental: Reflect trends in the state of the environment; are descriptive in nature; and become performance indicators if they compare actual conditions to desired conditions expressed in terms of environmental targets.
2. Socioeconomic: Represent the demographics of humans in the coastal zone and measure quality of life issues.
3. Governance: Measure the performance of the state of implementation, measuring the progress and quality of interventions of the governance process in relation to program goals set at the outset.

To this end, sustainability indices (SIs) are needed by aquaculture resource managers who must sort through large amounts of information and make numerous decisions relating to environmental management and policy implementation. SIs, therefore, offer a means to prioritize those aquaculture systems most in need of immediate management attention and allow scarce management assets to be applied in the most cost-effective manner. The development and subsequent utilization of SIs are also valuable to owners of seafood businesses who wish to procure or develop "sustainable seafoods," i.e., as a marketing tool.

Well-developed and scientifically credible SIs are important tools which can make a range of ventures including monitoring, baseline data collection, research enterprises, and communications efforts better organized and targeted, and thereby, more cost effective. Therefore, indicators must be selected or developed and cover the three components of sustainability. It has been argued that indicators should be as quantitative as possible. While this is a practical goal, some descriptors do not lend themselves as easily to quantitative measurements and therefore qualitative descriptions may be more appropriate for describing, say, for example, the social aspects of sustainability [3].

Indicators must be measurable objects that can be simplified by aggregation and calculation. Outcomes from theoretical models cannot be considered as indicators. Nevertheless, models may help to indicate the most relevant factors to be monitored. Ideally, indicators might address the following issues:

- Continuity of supply (environmental, economic, and social services)
- Social, economic, and environmental costs to provide this continuity of supply
- Long-term aspects
- Financial viability
- Social and ecological impacts
- Global efficiency

Environmental Indicators

While there is considerable effort directed toward the development of indicators for coastal areas throughout the world, the focus primarily remains on environmental indicators that link specific pressures with impacts. The development in European Union Member States of indicators relating to the implementation of the Water Framework Directive [52, 65] is a clear example of one such endeavor. Indicators developed in response to this legislation, for the most part, are responsive to a range of pressures. The development of sustainability indicators (particularly those targeted at shellfish aquaculture) is at a more nascent stage. It is broadly accepted that sustainability indicators for shellfish aquaculture

(and aquaculture generally) should encompass the criteria outlined previously, i.e., track aquaculture's (positive and negative) impacts on the environment and be able to monitor economic, social, and cultural externalities, as well as evaluate governance impacts of policies and regulatory measures on aquaculture. Once accepted as practical tools, SIs need to be ultimately included in codes of best practices, decision support systems, and should be used by managers to steer aquaculture development and how it might interact with other activities and features in the marine environment.

Composite Sustainability Indices

While it is possible to assess sustainability with several indicators [66], it may sometimes be difficult to make decisions and comparisons among sectors, production systems, or companies based on a large number of performance measurements. To help decision makers in this respect, it may be useful to use composite sustainable development index, linking many sustainability issues and so reducing the number of decision-making criteria that need to be considered.

In recent years, research has focused on the development of composite indices mostly for cross-national comparisons of economic, societal, environmental, and/or sustainable progress of nations in a quantitative fashion [67]. Care must be taken in the development of composite indicators as, for example, weighting of constituent indicators can be applied subjectively without any clear quantitative basis. However, this may be corrected by the application of sensitivity analysis whereby weightings are adjusted to reflect the true influences of indicators (and by association, pressures). In addition, the selection of the indicators to be used in a composite indicator is crucial to the utility of a sustainability indicator. A solution to this is it requires a transparent and inclusive process to determine how and who will select the most appropriate indicators [50]. Such a process should avoid risks associated with too much complexity as well as concerns about the costs associated with monitoring multiple indicators that could be irrelevant to managers and the public. Usable indicators must be more than just a description of state and should have diagnostic properties that lead to some insights into processes taking place (i.e., provide a specific link to the pressure under consideration).

As previously stated, SIs for environmental and aquaculture management are still in the early stages of development. However, some investigators [68] have recommended a simple set of easily quantifiable indicators for sustainability in aquaculture (generally) and which broadly reflect the criteria outlined previously describing sustainability indicators:

- Biological: domestication, trophic level, nutrient/energy conversion
- Ecological: footprint, emissions, escapes
- Intersectoral: water sharing, diversity, cycling, stability, and capacity

The development of tool-box approach toward assessing sustainability for aquaculture has been proposed [60]. This approach has been taken further with the utilization of indicators specifically to shellfish culture operations [69] with the production of guidance for effective site selection and targeted approach to conducting environmental impact assessments and establishing monitoring standards. Furthermore, the incorporation of a stakeholder consultation process in order to identify the most pertinent indicators has also been incorporated into a variety of initiatives.

Notwithstanding the relatively slow progress toward the development of specific indicators of sustainability for shellfish aquaculture, there are still a number of clear criteria proposed that can help define and direct future development efforts. These are best elucidated by the International Council for the Exploration of the Sea [70] which has addressed the issue of sustainability in aquaculture over the last number of years. They offer some general principles on sustainability indices and how they relate to aquaculture activities (including shellfish culture). The basic points below summarize much of the previous discussion and are as follows:

1. It is important to discern the differences between "sustainability" indicators and "impact" indicators which are narrow in their focus. Sustainability indicators should be able to track more than aquaculture's impacts on the environment and be able to monitor economic, social, and cultural externalities, as well as evaluate governance impacts (e.g., policies and regulatory measures) on aquaculture and the environment broadly.

2. Once accepted, SIs should be ultimately included in codes of best practices (BMPs), decision support systems, and should be used to inform aquaculture development by the authorities (e.g., integrated coastal zone management systems, see below).
3. Sustainability indices must be of the highest scientific credibility and be accepted only after peer review of the chosen index, and analyses of precision, accuracy, reliability, and consistency are completed. It may be contrary to the criteria outlined above but the SIs must also be cost-effective and be applicable across a range of environments, habitat types, and activities.
4. SIs must be flexible enough to be adapted to the local environment in which they will be used. There is no chance that a single set of "generic" indicators may be universally applicable and used in all the situations in the aquaculture sector. In addition, SIs may be of use to address the interactions with other users of marine resources, locally or internationally because of the opening of global markets.
5. In the development of SIs for aquaculture it is important to develop them collaboratively and consider SIs from a managers' and other stakeholders' perspective. Managers are a critical link between the science community and the public. Collaborations between managers, scientists, and the public should be formalized to facilitate rapid decision-making and communication. It is important that levels that exceed those which are accepted by the society are scientifically credible so that managers can determine causative agents and what remediation actions are necessary.
6. SIs must be able to detect the linkages between the 3Ps – people, profit, planet – which suggests a development of a "sustainability indicator matrix." Such a matrix approach could allow flexibility and be able to address the sustainability factors more comprehensively for any given situation. Regular evaluation of SIs may be necessary among the various actors assessing aquaculture developments, e.g., producers, policy makers, consumers, NGOs, suppliers, since aquaculture technologies and site locations are constantly evolving.
7. To this end it is important to emphasize that SIs must be sustainable themselves. The production of information must be practicable at a low cost for the government, public, and the aquaculture sectors. Data from SIs must provide meaningful long-term data series. These time series will need to be housed in data management frameworks at the institutional level, but be universally accessible.

Progressing Sustainability in Shellfish Aquaculture

Heretofore, the difficulty in developing a single (composite) indicator relating to shellfish aquaculture remains and one has yet to be definitively proposed. This is borne out by the general conclusion that the majority of exercises examining the sustainability of aquaculture operations recommend only specific and localized "sustainability" (or impact) indicators, without fully addressing the sustainability of aquaculture from an interactive perspective. It is generally accepted that the main goal of these programs is to determine an acceptable aquaculture production capacity for a defined area. It is also accepted that aquaculture activities should be managed while fully cognizant of other activities in a particular area. Consequently, the likely impacts of aquaculture will, therefore, have to be assessed individually, cumulatively (with other aquaculture operations), and in combination with other activities, on the environment, ecosystem, and function of a system. The interactions and impacts of aquaculture have been well documented; it has been this information that has provided the framework for many monitoring programs for aquaculture operations. The notion of acceptability is critical to fully determining the sustainability of an activity in the marine environment. The term "acceptable" is governed primarily by social values, starting from a global to local perspectives. The social carrying capacity of aquaculture should be the basis of a sustainability program to assess the sum of activities, such as aquaculture, within a defined area. The principles of these programs could flow from global vision, with regionally based criteria. For example, no net loss or biodiversity may be a global vision.

Considering the goal of ensuring sustainable levels of activities in the marine environment, the application of Integrated Coastal Zone Management (ICZM) is likely to be an important tool toward achieving this objective. As already highlighted, the importance of

linking social, economic, and environmental aspects into the management of marine systems is critical as well as the need to have broad sectoral cooperation and input into the development of these practices.

ICZM facilitates a shift from management and regulation of activities in the marine environment in isolation to a system where all activities can be considered and the resource use is optimized with a view to maintaining the health and productivity of coastal ecosystems so that they can continue to supply resources that sustain different forms of activity, including mariculture. While these goals are lofty, the implementation will be challenging. Benthic and pelagic effects of shellfish culture are well documented in the literature (from both modeled and empirical studies). The risk posed by practices associated with aquaculture (both finfish and shellfish) have also been well documented and evaluated in the areas of disease transmission and introductions of exotic species to areas. The *in-depth* knowledge relating to these impacts and interactions have placed the pressures posed by mariculture to the forefront in terms of public awareness and criticism. Ironically the lack of information pertaining to other pressures may be a reason they have not been the focus of scrutiny or criticism (e.g., static gear fisheries, sewage effluent discharges over broad spatial scales). ICZM can be supported by the development of appropriate decision support systems (DSS), i.e., in the form of conceptual models allied with the presentation of geospatial data in geographic information systems (GIS) can be used to identify what would seem to be the most appropriate use of marine ecosystems. The term "use" also includes nonexploitive activities particularly in areas that have high intrinsic natural value or have some protection conferred by legislation (e.g., national parks).

The social science dimension is an important component on the issue of ICZM [50, 65]. Application of social science principles will facilitate a better understanding of the expectations of different stakeholders competing for space and resources in coastal areas and help establish a consensus among relevant users. More specifically, a recent initiative in France [71] called EVAD (ÉVAluation de la Durabilité des systemés aquacole) addressed the issue of aquaculture sustainability by examining the contribution that aquaculture systems make to the sustainability at regional levels. The first component of this approach much merit and could be an important component into an Integrated Coastal Zone Management program. Similarly an ecosystem approach to aquaculture management that is comprehensive and based on the best available scientific knowledge of the ecosystem and its dynamics is also proposed by numerous fora [72, 73]. Actions are designed to be taken on the influences of aquaculture developments that are critical to the health of ecosystems, thereby achieving sustainable uses of ecosystem goods and services and maintenance of ecosystem integrity. In these instances, the aim is to assess the sustainability of all the activities in an area where aquaculture is fully and fairly integrated rather than the sustainability of aquaculture in isolation. At that point, indicators can be developed, negotiated, and used to evaluate the effect or impact (positive or negative) of aquaculture and other activities (drivers) on the sustainable utilization of resources in a region, based upon the global principals and the regional-territorial criteria. Sustainability would thereby no longer be assessed by indicators of impacts, but mainly criteria based on objectives instead of thresholds. The sustainability of all activities within a region would thereby be evaluated on the merit of criteria developed under an Integrated Coastal Zone Management (ICZM) approach. It is important to note that assessment of sustainability at the activity level can lead to the establishment of thresholds that can be ineffective or even detrimental to the activity which may only contribute marginally to one or several criterion. In addition, smaller aquaculture operations would not be constrained by the responsibility of monitoring the sustainability of an area, because they are the newer addition to the coastal zone territory, already affected by numerous players.

Future Directions

Sustainability by definition and in application must include consideration of planning for multiple impacts and identifying the likely challenges posed by existing and future development and conservation (general sense) needs. To this end, sustainability therefore refers to the ability of a society to continue functioning in the future without being forced into decline through exhaustion or overloading of key resources upon which society's systems rely [74]. Proponents of

shellfish aquaculture [75] propose that the accelerated development of aquaculture in a sustainable fashion is a realistic goal going forward. Consistent with the broad view offered above, the focus for aquaculture development should be to manage existing activities and proposed expansions in coincidence with other activities in marine systems such that the management actions are fully integrated, and that any impacts will be at a minimum, neutral on both natural and social ecosystems [76]. It is appreciated that some codes of conduct and guidelines for certifying sustainability are sometimes too complex and narrowly focused. Therefore, there would be an imperative on the part of managers to see to it that inclusive yet simple and scientifically credible sustainability indices for mariculture activities are developed and are considered a cost-effective complement to any codes employed. This would be driven by the need of regulatory or licensing agents to have systems with which to take defendable decisions relating to management of marine issues. Furthermore, the need to communicate in a transparent, concise, and credible fashion the likely issues relating to shellfish culture activities to consumers is another important justification toward the development of sustainability indices for shellfish culture.

In summary, a SI applicable to shellfish aquaculture should be able to incorporate all information in a system, identify what the goals (global vision) for the system are, and evaluate both positive and negative aspects of any proposed development. It should be able to determine if the positive aspects outweigh the negative ones such that a decision to permit the activity can be taken. In other words, will the mitigation of eutrophication effects afforded by the filtration of shellfish outweigh the increased biodeposition beneath the culture structures? While these considerations apply generally to all activities and how they interact with the natural environment (both terrestrial and aquatic), they also provide a framework with which to focus more clearly on specific activities in the marine environment and how these activities interact with features therein. However, it has become clear that the application of these concepts have not been fully implemented because it is apparent that such generalities apply at the level of the (eco)system and are difficult to apply at the level of specific activities and/or environmental features. It is apparent that in order to fully implement these definitions and take a total view of sustainability in the marine environment, it is the job of managers to apply a system-wide view of sustainability. Such an initiative would have to take into account a broad range of pressures and would have to define clearly what might be permissible and acceptable (i.e., social carrying capacity guided by legislative or policy drivers). Such an initiative would have to consider both spatial and temporal considerations of pressures (activities) and sensitivities. Of considerable importance, however, is that the development of management systems must be informed by a clear notion of an acceptable endpoint that would be either defined as the level that a particularly activity (or range of activities) might be carried out in the marine environment or the maintenance of a specific condition of an environmental feature (environmental standard). It is important to point out that, to date, sustainability has been a much used word with abundant pedagogy but little practice [77] (this article is a case in point). It would appear that progression toward truly sustainable practices is hampered when there is a clear need for interdisciplinary actions but there is little scientific knowledge to inform these actions. This contribution highlights, we hope, that the mechanism toward identifying sustainable activities in the marine environment will be progressed when clear policies are elucidated and an inclusive approach is adopted reflecting fully legislative requirements and the views of all stakeholders.

Article Outline

Glossary

Strategic crop management Decisions with respect to agro-ecosystems on the basis of the expected long-term performance of these systems, as influenced by the natural resource base and the socioeconomic boundary conditions, independent of the current state of the system.

Tactical crop management Seasonal decision-making in reaction to the variable and unpredictable environment, with a time horizon of the order of 1 year, independent of the current state of the system.

Operational crop management Decisions concerned with daily activities of the farm, in response to the current state of the system and the (anticipated) environment.

Simulation Building a model and studying its dynamic behavior.

Model Simplified description of a system.

System A limited part of reality with well-defined boundaries, containing related elements.

Decision support system (DSS) A class of information systems (including but not limited to computerized systems) that support business and organizational decision-making activities. A properly designed DSS is an interactive software-based system, intended to help decision makers compile useful information from a combination of raw data, documents, personal knowledge, or business models to identify and solve problems and make decisions.

Farming system The particular mix of agricultural activities in which a farm household engages.

Definition of the Subject

Agricultural production can be defined as the transformation of sun energy in useful organic material in the form of food, feed, and fiber. The transformation requires in principle only limited resources: a piece of land, some seeds from a wanted plant species, some sun and rain, and some human labor. However, the transformation takes place under erratic and unpredictable conditions, as especially the availability and timing of the sun and the rain are extremely difficult, if not impossible to predict, while their effects are modified by the qualities of the land and the interventions of the farmer. Any methodology that would improve the predictability of the availability of the resources and their impact on the performance of the production system could in principle improve that performance and reduce the level of uncertainty. Crop growth simulation models that were developed from the late 1960s onward and that allowed exploration of the performance of plant production systems as governed by the properties of the plant species/variety in interaction with the environmental conditions, promised to be excellent tools for the reduction of this uncertainty. Following 40 years of experience in this realm of the application of crop growth simulation models in support of the management of plant production systems, the current situation is still highly ambiguous. On the one hand, some of the modelers still advocate the use of these tools in crop management, while many others have become disenchanted and emphasize their limited impact on crop performance. Although definitely the last word has not been said about their advantages and disadvantages, in this contribution an attempt will be made to summarize the past experiences and the current state of affairs, and to make an effort to identify their possible contribution in the future. As mentioned, there appear large differences among agricultural and systems-analytical specialists in judging the contribution and the

possibilities for application of crop growth models in support of crop management, and thus this contribution will not lead to unequivocal judgments and recommendations, but it should serve as a starting point for those interested in the subject.

Introduction

Crop Management

Performance of agricultural production systems at any given location is determined on the one hand by the agro-technical possibilities and constraints and on the other by the socio-economic conditions under which the farmer and his customers operate. The agro-technical possibilities are largely determined by the quality of the natural resources, most importantly, soil characteristics and the prevailing climatic conditions. Agricultural systems that have developed in various regions are therefore strongly linked to these characteristics of the environment. However, within comparable natural environments, the viability of various agricultural systems is dependent on the socio-economic environment, which can broadly be characterized by the prevailing price ratios of crop products and inputs, modified by other factors, such as the risk that can be accepted, access to credit facilities, and the relative importance attached to other objectives than purely economic, for example, environmental considerations. In agricultural production systems, decision making can be schematically subdivided in three hierarchical levels [1]. The first level is that of *strategic management*, that is, strategic decisions with respect to agro-ecosystems, made on the basis of expected long-term performance of these systems, determined by the (quality of the) natural resource base and the socio-economic boundary conditions, but independent of the current state of the system and its expected short-term performance. Strategic management is mainly oriented toward long-term planning and deals with the selection of farming systems, that is, the particular mix of agricultural activities in which the farm household engages (e.g., arable farming, horticulture, animal husbandry), and the associated investment decisions. The time horizon for such decisions varies therefore from more than 1 year up to 10 or 20 years, that is, the time it takes, for instance, for machinery to become technically obsolete, or for farmers to become acquainted with new production techniques.

Once the strategic decisions have led to the selection of a certain cropping system, the farmer, in actual practice, is faced with the task of implementing a certain number of crop systems. A conspicuous characteristic of agricultural production systems is that they operate in highly variable and hardly predictable natural environments [2]. Although climate for a given region may be characterized on the basis of long-term records, that hardly helps the farmer in his actual decision-making, as year-to-year variability is generally large and the actual performance of the system is dependent on weather conditions rather than on climate. Therefore, in most agricultural production systems, the quality of the *tactical decision-making process*, that is, the reaction to this variable and unpredictable environment, is a major factor in determining their success. The time horizon of tactical management, that is, seasonal decision making, is therefore in the order of 1 year, dealing with such issues as the selection of a specific crop (and/or variety) mix to be cultivated and the allocation of land, both in terms of how much and where, to the various crops.

Finally, decisions at the *operational level* are mainly concerned with daily activities on the farm, such as selection of sowing dates, water (irrigation), nutrient (fertilizer), and pest and disease management, and time horizons varying from days to, sometimes, hours in relation to decisions on spraying and harvesting.

Crop Modeling

Crop modeling as a scientific activity has been in existence now for almost 50 years, following among others, the pioneering work of De Wit (cf. [3–5]). Its history and its position within current agricultural research have been dealt with extensively in the last two decades from various angles [6–10]. An interesting analysis is that of Sinclair and Seligman [6], who draw parallels between the growth and development of crop simulation models and human development. Their overview ranges from *birth* and *infancy* of the discipline with the appearance of mainframe computers in the 1960s, via a *juvenile* stage in the 1970s, and an *adolescent* stage in the 1980s, to a *maturity* stage in the 1990s. The *infancy* and *juvenile* stages were characterized by the

expectation that crop modeling would provide the answers to questions in many areas of crop science, which led to the development of detailed "comprehensive" models, aiming mainly at increasing understanding of the interactions between the crop and its environment.

These development stages of the models were subsequently translated into functional categories [9], that is, in the 1960s and 1970s, the main aim of these modeling activities was to generate understanding at the crop scale, on the basis of the underlying processes and to test hypotheses on crop-physiological functioning, as illustrated among others in the series Simulation Monographs (cf. [11]). In the 1980s, major efforts were directed to obtaining full understanding of crop performance under a wide range of environmental conditions. In the 1990s, the focus shifted toward applications in agronomic practice and policy making. In the 1990s, crop models also found their application in studies at higher levels of integration, that is, farm and regional scale. In these studies, crop models were used to quantify a broad range of land use systems; subsequently, these land use systems were aggregated to farm or regional scale using various techniques (e.g., linear programing) or procedures. Studies on designing environmentally friendly systems for arable, dairy, and flower bulb farms were conducted, also enabling analysis of trade-offs between economic and environmental objectives.

Land use studies were carried out with a focus on interactive exploration of different strategies for the European Union, Mali, Costa Rica, and Southeast Asia. Finally, crop models were used to explore limits for food production capabilities at global scale.

In the beginning of the twenty-first century, all of the functions of crop growth models continued to be performed and improved, but the development efforts shifted to reuse of models and to their applications for policy support [12].

Crop simulation models were thus originally developed as research tools and have had their greatest usefulness and impact so far as part of the research process. The advantages of integrating simulation modeling approaches into a research program have adequately been summarized [13]: (1) identification of knowledge gaps; (2) generation and testing of hypotheses, as an aid to the design of experiments; (3) determination of the most influential parameters of a system (sensitivity analysis); (4) provision of a medium for better communication between researchers in different disciplines; and (5) bringing researchers, experimenters, and producers together to solve common problems.

In addition to their use as tools in research, almost from the beginning of their development, crop models have been advocated as tools to help in decision-making processes of practitioners, with the development of so-called decision support systems (DSSs) for crop management. DSSs have evolved over the years from rudimentary single-decision rules to multiple-criteria optimization software. In its simplest form, a DSS can be a pest management threshold, calculated using empirical relations and field data on a calculator. In a sophisticated form, it can be an interactive computer system that utilizes simulation models, databases, and decision algorithms in an integrative manner. DSSs typically have quantitative output (as opposed to an expert system with qualitative reasoning) and place emphasis on the end user for final problem solving and decision-making. There is often no clear-cut boundary between models used in research and those used in DSS, that is, in the literature, models used in research are promoted in terms of their potential to aid in decision-making, although there is not always evidence that they have been or are being used for this purpose!

Simulation Models in Support of Crop Management

Crop modeling has helped in finding improved ways to manage crops, fields, and farms in practice, but the pathway has been problematic. Early expectations of computerized decision support systems as the connecting vehicle between crop models and management practice have, to a large extent, been unrealized. Nonetheless, some lessons have emerged from the attempts. It has been argued that the most significant contribution of these attempts at decision support has not been the actual production of decision support systems, but rather the bringing together of researchers and farmers to improve farm management [14]. Alternatively, it has been argued that for successful development and adoption of simulation approaches: (1) issues to be addressed must be neither trivial nor

obvious, (2) a modeling approach must reduce complexity rather than proliferate choices in order to aid the decision-making process, and (3) the cropping systems must be sufficiently flexible to allow management interventions based on insights gained from models [15]. Despite the limited application of operational decision support systems in actual commercial farming at the moment, a wide variety of such systems have been described. Without trying to be exhaustive, a number of illustrative examples are given here, following the classification of strategic, tactical, and operational decisions, as explained earlier.

Strategic Management

Strategic management support does not aim at generating answers for management to practitioners, but focuses on facilitating and supporting the dialogue with various stakeholders. This has led to the development of "discussion" support software [16], systems designed to facilitate dialogue about management practice that is relevant and significant to the decision maker. There exist significant opportunities for current capabilities in cropping systems analysis and modeling to contribute better to discussions about long-term economic and ecological issues associated with agricultural production systems. A number of these opportunities have been explored during the 1990s and cropping system simulation tools, such as APSIM (Agricultural Production system SIMulator; [17, 18]), CropSyst [19, 20], STICS [21], and DSSAT (Decision Support System for Agrotechnology Transfer; [22]), were designed with these targets in mind.

Increasingly over the last decade, crop models have been used to explore and design options for farm and regional land use systems. Studies at farm and regional scale require proper coverage of the system's physical conditions and the agroecological production options. Once sufficient information on soils and climate of an agricultural production system is available, crop models are useful tools for assessing their performance, that is, quantifying the inputs and outputs of (new) production systems. Two ways of using crop-soil models for farm and regional scale studies have been developed and elaborated. In the first method, crop yields are simulated for a range of well-defined (by soil and climate) points in a region and a geographical information system (GIS) is used to interpolate input data and aggregate results for the entire region. This method is generally suited to analyze or evaluate a limited number of land uses with little or no spatial interaction, but if necessary, with significant physiological detail. Examples of such approaches are an agroecological zonation for potato production at global scale [23] and an assessment of potential global food supply for a number of scenarios with respect to food demand, using low and high external input production systems [24]. In the second approach, crop models, supplemented with empirical relations and expert knowledge, are incorporated in so-called technical coefficient generators (TCGs) for production activities (e.g., [25, 26]). In this approach, crop models are used to quantify a broad range of land use systems in terms of inputs and outputs, which are subsequently aggregated to farm or regional scale using bio-economic optimization models (e.g., [27–34]). Examples of such TCGs are PASTOR and LUCTOR [35] and TechnoGIN [36]. The use of TCGs in combination with optimization models is particularly helpful in situations where many alternative crops and production technologies must be evaluated concurrently, and where spatial or temporal interactions are limited or less relevant for the type of questions to be addressed. The approach has proven to facilitate effective cooperation between agro-ecological and economic disciplines, and enables analysis of trade-offs between economic and environmental objectives at farm and regional scales.

Tactical Management

Tactical management basically refers to the medium term and deals with decisions that are taken once during the growing season, with respect to such issues as crop/variety selection, allocation of land to various crops, and identification of the most appropriate sowing or planting date.

An early example of a tactical decision support system is the program TACT, targeted at farm advisers and consultants but as the authors assure, readily useable by farmers [37]. It includes a simulation model of wheat performance (development, biomass accumulation, and yield) with a user-friendly interface. It calculates probability distributions of yield and gross

margin, using data on location, soil type, wheat variety, sowing time, and weather conditions to date, and historical rainfall records. In addition to calculating expected crop performance, TACT can also be used for climatological analyses which have an impact on 'break of season' decisions, using criteria defined by the program user in combination with historical daily rainfall and temperature records to investigate, for example, the incidence of frost. Other suggested applications at the time were calculating the probabilities of sowing opportunities, given a sowing rule and the probability of a dry period after a given date. This kind of information aids tactical decisions by estimating the risks of replanting if crops are sown early and the penalties for missing an early sowing opportunity. Most of the analyses generate a distribution of expected outcomes, for example, yield, which is used to derive probabilities.

TACT could be tailored to individual circumstances in two ways. Users could select from a wide range of parameters from TACT program menus, such as location, soil type, and sowing rule. These parameters tailor either the simulation model or climatic analyses to the user's specifications. Users could also adopt a probability level in the output, consistent with their attitude to risk.

In the last decade, computer-aided support for tactical decision making has received substantial attention, especially since it appeared possible to generate a characterization of in-season rainfall in (semi-)arid regions on the basis of, for instance, the El Niño/Southern Oscillation (ENSO) phenomenon [38]. Especially in (northeast) Australia this procedure has been relatively successful, because of three factors: a highly variable environment, which heightened riskiness of crop production decisions [39]; some ability to anticipate risks by utilizing seasonal climate forecasting [40, 41]; and a research culture that fostered close linkages between researchers and decision makers [42]. To facilitate crop management discussions in farmer-driven workshops, using analyses of management options based on crop simulation and seasonal climate forecasts, the Whopper Cropper software tool was designed [43]. As an example of using Whopper Cropper in relation to an issue involving seasonal climate forecasting, consider farmers in the Callide valley of Central Queensland, Australia, planning summer cropping options. For this scenario, it is November and the SOI phase [40] for September–October was positive. The farmers have heard that a positive SOI at this time of year means an improved chance of a better-than-usual season in terms of rainfall, and are considering sowing sorghum earlier than usual. The clay soil on properties in this area has a plant available water-holding capacity (PAWC) of about 170 mm, and is two-thirds full of moisture after good spring rain. To start with, it was assumed that a medium-maturing hybrid of sorghum was sown at a density of 10 plants m^{-2} on November 15 and that total nitrogen available to the crop (the amount in the soil plus the amount applied) is 100 kg ha^{-1}. By conducting a simulation of this scenario with the 100-year historical climate record for the location, a 100-year time series of yield outcomes was generated, with each year differing only in the seasonal climate realized. Time series analysis showed the year-to-year variability in yield for this scenario, compared to the long-term median, and then compared to those years in which the September–October SOI phase was positive. For this scenario, a positive SOI phase is often, but not always, associated with higher-than-median yields. Similar graphs can be produced for each SOI phase. The value of seasonal climate forecasting based on SOI phases in crop management stems from the shift in the expected yield distribution associated with each of the five phases [44]. For the sorghum cropping scenario, the distribution of yield associated with years having a positive SOI phase at the end of September–October has higher median yield and reduced risk of low yield compared to the distributions associated with years in the other phase categories. Products such as Whopper Cropper can be used for discussions about tactical decision-making, but can also be used to encourage debate on the design of planned and flexible rotations.

The El Niño-Southern Oscillation (ENSO) also contributes to the vulnerability of crop production to climate variability in the Pampas region of Argentina. Predictability of regional climate anomalies associated with ENSO provides opportunities to tailor decisions to expected climate, either to mitigate expected adverse conditions or to take advantage of favorable conditions. Model analysis was used to explore the potential for tailoring land allocation among crops to ENSO phases at the farm scale in two subregions of the Pampas [45]. The model identifies, as a function of risk preferences and initial wealth, the crop mix that

maximizes expected utility of wealth at the end of a 1-year decision period, based on current costs and prices, and crop yields simulated for each year of historical weather. The model reproduced recent land allocation patterns at the district scale under moderate risk aversion, and predicted increasing diversification with increasing risk aversion. Differences in land allocation among ENSO phases were consistent with known climate response to ENSO, and crop response to water availability. The relationship between the potential value of ENSO information and risk aversion was not monotonic, and differed between locations. Crop mix and information value also varied with crop prices and initial soil moisture. There are potential financial benefits of applying this approach to tailoring decisions to ENSO phases.

It was also shown that a similar procedure yielded relevant results for Kenya [46], thus increasing confidence in the use of seasonal weather forecasts for tactical crop management.

Water Management Crop growth simulation models have been used extensively to analyze the effects of tactical crop water (irrigation) management. In most instances, various water management regimes are being tested under local conditions, sometimes with the aim of exploring the scope for improvements in actual management practices, sometimes with the aim of contributing to the discussion on water management. Without trying to be exhaustive, a few typical examples are given.

The ORYZA W model [47] was used [48] to evaluate alternative management options for rice production in the light of farmers' attitudes toward risk. The model was used to generate probability distributions of rainfed lowland rice yields under different management scenarios which included water management (bund height, puddled soil depth, planting density, seedling age at transplanting). Stochastic dominance analysis was applied to identify risk-efficient management options. It appeared not possible to evaluate to what extent farmers (or extension officers) actually (have) apply(ied) the methodology in decision-making in commercial farming.

The interactive computer program WIRROPT7, a modification of the CERES-Wheat model, was applied [49] to explore the possibilities for the intra-seasonal irrigation regime that maximizes total gross margin for particular soil, weather, and crop management combinations, within the constraints of land and water availability. The use of the system was demonstrated for two soils near Harare in Zimbabwe and for two strategies – maximizing gross margin per unit area with a frequent irrigation schedule, or maximizing overall profits by reducing the application per unit area by irrigating less frequently but growing a larger area. As the variability of yields and gross margins are higher with the second strategy, the farmer's attitude to risk will determine which strategy he or she adopts. The authors recommend that the model should be seen only as a guide to irrigation management due to its limitations such as lack of routines describing nutrients and pests and the need to use mean historical weather data. The actual irrigation strategy should take into account real-time estimates of water use as well. It is not stated if the system is actually being used by farmers or extension staff.

The Environmental Policy Integrated Climate (EPIC) model was used to evaluate its application as a decision support tool for irrigation management of cotton and maize under South Texas conditions [50]. Simulation of the model was performed to determine crop yield, crop water use, and the relationships between the yield and crop water use parameters such as crop evapotranspiration (ETc) and water use efficiency (WUE). On-farm simulation results in this study demonstrated that the EPIC model can be used as a decision support tool for crops under full and deficit irrigation conditions in South Texas. EPIC specifically appears to be effective in long-term (strategic) and preseason (tactical) decision making for irrigation management of crops. However, more studies are needed to employ the model as a decision support tool addressing other irrigation issues such as operational management, dealing with irrigation allocation and scheduling.

Within the Australian cotton industry, the imperative to reduce water use and optimize irrigation management through the understanding of risk, using information generated by computerized decision aids was identified and subsequently developed into the HydroLOGIC irrigation management software [51]. On-farm experiments throughout the development period allowed the validation of internal software

logic, irrigator decision processes, and the OZCOT cotton growth model [52]. The software demonstrated the ability to improve yield and water use efficiency by optimizing strategic and tactical irrigation decisions in the Australian furrow irrigation cotton production system. In 7 of the 11 on-farm experiments conducted, the use of HydroLOGIC helped improve overall field water use efficiency by optimizing the timing of irrigation events or by indicating further irrigations would not provide yield or maturity benefits. Using concise reports, users can easily assess the risk of different irrigation management options at any crop stage, from land preparation through to postharvest benchmarking. HydroLOGIC may also be used within an integrated whole farm water management planning process to provide information on the impact of water allocations and subsequent evaluation of water security, water cost, and risk.

Nutrient Management As a basis for formulation of crop nitrogen requirements for rice, the ORYZA 0 model was developed and tested [53, 54], a "parsimonious" model based on incident solar radiation, bulk leaf nitrogen, and a site calibration factor. The model was subsequently applied [55] to classify some irrigated rice soils in India into those in which the soil N supply was sufficient to meet crop demand up to the onset of flowering and those that required a basal dressing of N fertilizer. The results were then used to generate fertilizer N recommendation curves that identified different optimal timing of N application for the different soil N supply regimes. The model was also used in a similar exercise in China, where it was found that significantly higher yields were obtained by following the recommendations produced by the model compared to the local recommendations [56]. Whether the model is able to make significant improvements over local recommendations in a wider range of environments remains to be seen. A limitation of ORYZA 0 is that it must be calibrated for each site, in this case by measuring the seasonal pattern of crop N uptake, which, because of year-to-year variation, makes it difficult to use the model in a predictive way. Also, no account is taken of the ability of the soil to act as a reservoir or "bank" of nitrogen – that is, nitrogen applied earlier in the season can remain in the soil for uptake by the crop later, so that it is not critical when the fertilizer is applied. The model only indicates how much nitrogen must have been applied by a specific crop age, and not when and how (i.e., as a single dressing or as split doses) it should be applied.

In a study for Walbundrie in Southeast Australia, the Agricultural Production System Simulator (APSIM) was used to simulate crop production and drainage passing the crop root zone of wheat and canola crops in response to nitrogen application rates from 0 to 300 kg N ha^{-1} $year^{-1}$, using historical climate records from 1889 to 2002 and variable values of stored soil water at sowing time (SSMS) [57]. The capability of the Southern Oscillation Index (SOI) phases to forecast growing season rainfall and crop yield was analyzed. The results showed that the optimal N rates were 100, 150, and 200 kg N ha^{-1} $year^{-1}$ in the years when April/May SOI phases were falling/negative, near zero, and rising/positive, respectively. Combining April/May SOI phases and SSMS to manage N application increased wheat gross margin, and reduced deep drainage for wheat, compared with N management based on historical climate data only. Similar results were obtained for a continuous canola cropping system.

Pest Management InfoCrop, a generic crop growth simulation model [58] was applied to simulate rice planthopper damage on Pusa Basmati 1 rice [59]. The model was used to simulate economic injury levels (EILs) of planthoppers and iso-loss curves, depicting combinations of crop age and planthopper populations that resulted in similar yield losses. Combinations of EILs and iso-loss curves can be used in monitoring planthopper populations and promoting judicious pesticide applications to avoid unwarranted control expenditure and environmental contamination. The simulation models, based on detailed crop ecological and physiological processes and pest damage mechanism can thus aid in the development of location-specific decision support tools and ensure precision in pest management decisions.

Operational Management

Operational management refers to day-to-day management of agricultural production systems, and deals with decisions by individual farmers on timing and intensity of interventions in their crops. From the

very beginning of the development of crop growth simulation models, their capabilities for support in operational management have been recognized. In hindsight, it must be concluded that in actual practice, at the moment, only a very limited number of such operational support systems are actually being applied at large scale. The scope for the use of crop growth simulation models as part of operational decision support systems has been expanded in the last decade through integration of mechanistic crop growth simulation models with earth observation techniques. Both, simulation modeling and remote sensing have been shown to be valuable tools in separate applications in agriculture. Integration of both techniques can lead to improvements in the dynamic simulation of the crop-soil system and thus contribute to improvements in management decision support systems for environmentally sound agricultural production [60–63].

In this section, a number of the decision support systems for operational management are illustrated that have been proposed, subdivided in the categories derived from the production situations [25], that is, water management (including irrigation), nutrient management (including fertilizer application), and crop protection management (including weed control and pest and disease control).

Water Management In many agricultural production systems, availability of water is the yield-determining factor, and therefore water management is an important aspect of crop management. The objective generally is to supply supplementary water to the crop in such a way that the water constraint is alleviated, the applied water is used as efficiently as possible, and, in some cases, specific water quality criteria are met.

Irrigation scheduling is an area in which models have been used extensively as decision support systems. It has been claimed [64] that there are at least 140 models based on the use of the water production functions developed by FAO [65]. However, he cautions that such models do not correctly forecast the effect of water stress on crop growth, as they do not take into account the dynamic processes. In mechanistic crop growth models such as CERES–Maize [66], EPIC [67], and CROPSYST [20], the effects of soil water depletion in the course of the crop growth cycle are simulated. They can, therefore, be used as effective tools for forecasting the water content of the soil and the crop response to it [64].

As an early example, the use of the real-time crop growth model EPIC-PHASE is illustrated [68], functioning at a daily time step, as a new method that might support the irrigator in answering questions such as "how much" and "when" to irrigate. Their results showed the potential progress that the irrigator could make by scheduling irrigation according to the predictions of water stress intensities. However, the efficiency of this schedule is dependent on the accuracy of weather forecasts. The study noted that the simulations gave a large difference in the choice of operational irrigation, depending on whether weather forecasts or actual weather data were used. From an agronomic standpoint, it is necessary to test other methods such as updating the weather forecasts every 24 h, or determining, in terms of risk on yields, the weight of possible climatic errors according to the crop phase, thus allowing the irrigator to take his decision to irrigate or not with a full knowledge of the facts.

A pilot irrigation scheduling project was established in Northern Zululand in South Africa on a commercial estate [69]. Meteorological variables were measured with an Automatic Weather Station (AWS) and the data transmitted electronically to the experimental station every week. A model was used to estimate the soil water content on a daily basis. A report on the current soil water status was then generated and advice on when next to irrigate was sent to the irrigator.

In Denmark, irrigation scheduling based on local experience and rules of thumb proved inadequate to deal with the increasing complexity of water management. A PC-based DSS (MARKVAND) was developed in response to a need to find more efficient forms of irrigation due to increasing water demands in different sectors of society in Denmark [70]. It is being used to give daily information on the timing, amount, and economic net return of irrigation for a wide group of agricultural crops. The model includes conceptual and empirical sub-models for crop development, water balance, and crop yield.

In the United Kingdom, Irrigation Management Services (IMS) provided a consultancy service that gave farmers weekly advice on which fields to irrigate, when and how, based on the results of computer

simulation [71, 72]. IMS employs a simple water balance model with crop evapotranspiration estimated on the basis of soil, crop, and weather factors. It was used between 1984 and 1989 to provide an irrigation scheduling service to farmers and growers in eastern England in conjunction with in-field monitoring of soil water and crop cover [72]. When the service began in 1984, it operated on a bureau basis with communication by phone combined with farm visits. Farmers saw this personal touch as beneficial, since it gave them confidence in the service and enabled them to discuss broader issues with the adviser. However, by 1990, the use of microcomputers had become more common and farmers began to demand the scheduling packages themselves as this was greatly cheaper than paying for a consultancy service [72]. In time, some farmers eventually felt experienced enough in estimating when to irrigate such that they no longer needed to use the model. Despite the technological advancements in irrigation scheduling, most irrigators do not use the real-time procedures that have been developed by scientists. However, it has been argued [73] that if the efficiency of irrigation is to improve in order to help meet the increased demands for water from all sectors of society, such tools must be adopted. The challenge to researchers is to develop economically viable technology that is readily adaptable for use by farmers. This requires more interactive communication between researchers, extension staff, and farmers for improving the transferability and applicability of irrigation scheduling techniques [73].

Recently [74], an approach was presented to explore water management options in irrigated agriculture, combining remote sensing, crop growth modeling, and optimization, taking into account the constraints of water availability and the heterogeneity of irrigation system properties. The method contains two components: (i) system characterization using a stochastic data assimilation procedure where the irrigation system properties and operational management practices are estimated using remote sensing (RS) data; and (ii) water management optimization, exploring water management options under various levels of water availability. A soil–water–atmosphere–plant model (SWAP) is applied in a deterministic–stochastic mode for regional modeling. The distributed data, for example, sowing dates, irrigation practices, soil properties, depth to groundwater, and water quality, required as inputs for the regional modeling is estimated by minimizing the residuals between the distributions of field-scale evapotranspiration (ET) simulated by the regional application of SWAP, and a surface energy balance algorithm for land (SEBAL; [75]) using two Landsat7 ETM+ images. The derived distributed data were used as inputs in exploring water management options. A generic algorithm was used in data assimilation and water management optimizations.

The results showed that regional crop productivity can be improved by considering water and crop management practices as one, not as independent entities under limited water conditions. Adjusting sowing dates and their distributions in the irrigated area were found to impact positively the regional yield. This management option could complement the practice of deficit irrigation. On average, the farmers could allow their crops to experience water stress of about 27% before irrigation, with the current conditions in the study area. This could result in an increase of about 8.5% in the expected regional wheat yield and a regional water productivity of 1.6 kg m^{-3}. When water supply is very limited, high equity in water distribution could result in better performance of the irrigation system, and this should be also complemented by an earlier date of sowing in the growing season with wider distribution. This is also true when water is non-limiting but the farmers have higher degrees of freedom in their planting activities. There is an optimum point where the benefit would justify additional use of water for irrigation, beyond this point, water should be saved.

In a more proactive mode, if a seasonal climate forecast is available, the approach can be applied to explore water management decisions before the wheat-growing season [76].

Nutrient Management In the Netherlands, in an interdisciplinary project, nitrogen-fertilizer recommendations were formulated on the basis of results of a simulation model [77]. The model was initialized in early spring on the basis of field measurements of crop biomass and soil mineral nitrogen contents. Anticipated wheat yields were calculated on a weekly basis using measured weather data until the day of simulation and historical weather data for a 20-year period

prior to the season of prediction. Expected yield and its range were then calculated from the simulated yields for the 20-year period. Fertilizer recommendations were derived from these values on the basis of simulated N deficiencies in the crop. The results, following 3 years of testing on a number of experimental and commercial fields in the Netherlands, were rather disappointing, as final yield appeared strongly dependent on the actual weather conditions (temperature, determining the length of the grain filling period and radiation, determining the rate of grain growth) after flowering of the wheat crop. At that point in the crop's phenology, total crop nitrogen content can hardly be changed anymore (uptake takes place essentially before flowering), so that no adjustment was possible. The recommendations were therefore not better than those based on measured mineral nitrogen content in the soil profile in early spring, the common method at that time in the Netherlands.

AmaizeN [78] is a decision support system to help maize growers schedule nitrogen (N)-fertilizer applications for site-specific maize crops. It forecasts crop yields and N-fertilizer application rates for potential yield and best economic returns, and predicts the consequences of user management decisions. It takes into account both crop production and environmental impact. In an evaluation study with 16 field trials, covering a wide range of weather and soil conditions, AmaizeN-predicted maize yields (for both silage and grain) matched field measurements well, and gave a reasonably good indication of silage crude protein content and silage harvest date. The system was also capable of estimating N-leaching during the cropping season and predicting residual soil mineral-N at the end of the season, but more effort is needed to improve the accuracy of some predictions. In all instances, the AmaizeN-recommended N-fertilizer strategy was more efficient than the growers' practice. Recommended N-fertilizer rates were on average 85 kg ha^{-1} less than conventional application rates across ten crops, with no yield reduction. Its recommended higher-than-conventional application rate at another crop brought about a significant yield increase. System development was guided by an industry user group who requested the decision support system interface to be 'simple and easy to use'. To ensure user adoption of the system, some compromises in system prediction accuracy were required. Local agricultural production conditions were also incorporated.

Pest and Disease Management Because of the complex relationships between crops and their pests and diseases, and because populations of pests and diseases are dynamic in nature, a systems analysis approach is required to understand how pest and disease problems arise and how they may be tackled. In the case of pest and disease populations themselves, the approach bridges the gap between knowledge at the individual level and understanding at the population level.

The EPIPRE (EPIdemic PREvention) system was developed between 1977 and 1981 in the Netherlands as a system for supervised control of diseases and pests in winter wheat [79] and was intended to reduce the use of chemical crop protection agents. A major advantage of the system was that the farmers, recruited from Wheat Study Clubs, were able to learn as they went along and were always aware of how the system worked. They were trained to recognize disease symptoms, carrying out their own disease and pest monitoring, and sending their field observations to a central team who entered them on a daily basis into a computerized data bank. The system produced recommendations for treatment by optimizing financial returns for crop protection. There were three major decision options: (1) treat, (2) do not treat, and (3) make another field observation. When the season was over, every farmer received a record of his actions and the recommendations, as well as a financial account of the crop protection activities. The results were discussed with farmers in regional meetings. The farmers listened critically and often expressed appreciation of their improved expertise. Eighty-five percent of farmers participating in 1 year participated in the next. Complete adherence varied between 20% and 80%. Partial adherence was far greater than full adherence [79]. In 1981, 6% of Dutch winter wheat was covered by the system [80] saving on average £15 ha^{-1} [79]. In Belgium, the system functioned under the auspices of the National Soil Service, and in 1992, EPIPRE was used to advise on disease control in 500 fields in Belgium and northern France [81]. The research in Sweden (from 1982 to 1985) found that although EPIPRE was an interesting and useful system, it would require alteration if it were to

be introduced to farmers for routine use. There was a need to incorporate meteorological parameters into the model and to adjust the plant growth model to suit Swedish conditions, as the model was still recommending unnecessary spraying [82]. Experience in Switzerland found that EPIPRE-treated fields yielded 3% less than traditionally treated fields (0.5% with corrected gross return), but that farmers were able to reduce the spray frequency by 20–100%. The conclusion was that although the farmers did not make more profit, the new practice was ecologically beneficial and helped to reduce selection pressure for pesticide resistance [83]. It was calculated that in 1981, if all Dutch winter wheat would have been treated with the EPIPRE recommendations, the pollution load would have been reduced by 12 Mg [79]. Characteristic for the EPIPRE system was that there was an initial steady increase in membership, which resulted in an improvement in pest management. However, subsequently membership declined, as the growers felt that they had learned what the model would predict and therefore did not need it any more [6]. The system was successful in that it contributed to improved pest management by developing farmers' understanding and by helping them to interpret their own field observations more effectively.

A comparable system was developed in Australia, that is, SIRATAC, a dial-up crop management system to assist cotton growers in making good tactical decisions about the use of insecticides in irrigated cotton on a day-to-day basis [84]. It was run by SIRATAC Ltd., a nonprofit commercial company formed in 1981 to market the system to the cotton industry. SIRATAC aimed to reduce the risk associated with pesticide use by adopting Integrated Pest Management principles. It consisted of several simulation models and a decision model helping the grower decide whether or not to spray pesticide and which pesticide. The area managed using SIRATAC increased steadily during the early 1980s. In 1981–1982, there was demand for a tenfold expansion [14]. However, by 1985, it had reached a ceiling in adoption at 25% (by area) of the industry and its use declined after 1987 [85]. In 1989, SIRATAC Ltd. went into voluntary liquidation due to a predicted declining market share and cash flow problems, despite the fact that the area managed by SIRATAC was at a historical high [14]. It was replaced by an informal user group (SUG) that continued the program for a few more seasons, but by 1993 the group had ceased operation and the field-support system was no longer available. A moratorium on SIRATAC development meant that only minor changes were made to the program. Attempts to achieve similar functionality on a microcomputer failed. An in-depth participatory analysis found that many of the reasons for the poor adoption of SIRATAC were based on organizational issues rather than on problems with the model itself [84]. The important themes that emerged from their survey were:

- Widely held negative views against SIRATAC and SIRATAC Ltd. by nonusers.
- Many growers did not consider SIRATAC's intangible benefits to be worth paying for. They wanted to see tangible cost-saving benefits.
- Many people based their opinions on hearsay and did not really know what SIRATAC was or what it could do.
- Many felt that they were often overriding the system and so abandoned it. They felt uncomfortable with the recommendations of the system (e.g., expensive sprays when cheaper ones would do, not enough spraying – they felt it may put crops at risk).
- Practical limitations: no office or computer or reliable telephone service.
- Growers felt threatened – they saw it as a man versus machine issue and felt that their own experience and knowledge was being undervalued.

Hence, in both, the SIRATAC and EPIPRE cases, there was an initial steady increase in membership, which resulted in an improvement in pest management. However, both organizations then experienced a decline in membership as the growers felt that they had learned what the models would predict and therefore did not need them any more [6]. Both systems were successful in that they contributed to improved pest management by developing farmers' understanding and by helping them to interpret their own field observations more effectively.

Future Directions

Since the beginning of the development of crop growth simulation models, attention has been paid to application of these models in crop and farm management.

The possibility to quantitatively address, in an integrated fashion, many different aspects of decision-making and the expected consequences on crop and agricultural system performance, made such models attractive tools for such analyses.

With respect to *strategic management*, substantial progress has been made in methodological development in the last decade, and tools have been developed that (can) play a role as discussion and decision support systems in such areas as agricultural land use planning [86–88]. However, in a recent review on quantitative assessment of agricultural production systems, the remark was made: "The probably biggest challenge is to transfer the methodologies developed in land use studies to the unruly practice of land use policy formulation and implementation" [89]. "That requires close cooperation with the ultimate users of the methodologies, the various stakeholders, through the development of discussion and negotiation platforms" [90].

In the same sphere, it was concluded that the combination of the boundary arrangement perspective with critical leverage points presents a basis to design an institutional pathway for enhancing impact of modeling research in the policy sphere [91]. For researchers functioning in a science-domain-oriented environment, more options appear available than the frequently proposed 'more participation' for increasing the likelihood that their policy-oriented work is used. These include establishing contacts with research groups or institutes that are in a position to function as "stepping stones," or engaging with others to develop social networks in the policy sphere.

Following a critical evaluation of development and application of the Land Use Planning and Analysis System (LUPAS), it was concluded that its successful use is only possible if there is sufficient, shared awareness of problems and the need for solutions among the stakeholders [88]. Once a prototype of LUPAS was operational (preferably with a user-friendly interface) and stakeholders had the proper level of comprehension, LUPAS served as a vehicle to demonstrate potential conflicts, reveal strategic resource use options, and stimulate discussion among different stakeholder groups. However, presumably the project would have benefited from a more complete identification of problems and information needs as perceived by stakeholders and policy makers. A better contextualization (cf. [92]) would have been an asset in bridging the gap between the information supply of LUPAS and the needs of the stakeholders (cf. [93, 94]).

All of these experiences thus point in the direction of the fact that cooperation with the stakeholders, that is to say with the clients of the information, is critical in creating impact of the modeling work in the policy arena. This interaction with stakeholders should start at the beginning of the modeling work, so that problem identification and the associated design of the modeling tool should also be carried out jointly. The transition from the research field to the application field thus requires more attention than at the moment in general is being accorded.

In the area of *tactical management*, an extensive analysis of a long-term effort to develop in a multi-stakeholder setting an operational system was analyzed by the FARMSCAPE project team in Australia [95]. Their self-evaluation, supported by external evaluations, shows mixed feelings with respect to their success. Near the end of the first round of training and accrediting commercial agronomists in the application of FARMSCAPE tools, with the main focus on facilitating the agronomists involved in the application of these new skills and tools within their business systems, the team states "their success is our primary goal and our evaluation of how system monitoring and simulation is perceived and adopted within agribusiness and their clientele will continue as a key learning objective."

Looking ahead, they state that they are in serious negotiations with a consortium of agribusiness companies who wish to invest in a national delivery system for APSIM simulations targeted at farmer clients. This initiative was first mooted and is now being designed, promoted, and will be financed and implemented by the agribusiness consortium. APSRU (Agricultural Production System Research Unit)'s role will be to provide and support the APSIM software and train accredited users. The commercial system being proposed is well aligned with the FARMSCAPE approach to decision support, with emphasis on the need for simulations to be contextualized to the requests and circumstances of individual farmers. If established, this commercial delivery system could be an important market test for the applicability of computerized decision support to the industry.

While the operational focus is on facilitating development of delivery systems through commercial agronomic service providers, research continues to focus on learning about the market for decision support and its viable delivery, through (i) continued efforts at assessing the internet as a delivery vehicle [96] and (ii) addressing a market barrier to wide adoption of decision support. As pointed out [97], a major challenge to the delivery of DSSs is gaining the attention of farmers beyond "Innovator"/"Early Adopter" types to those who comprise the majority. Accordingly, research has been initiated aimed at penetrating the "Early Majority" market for improved risk management, by creating reference groups of satisfied adopters among the pragmatist category of farmers who are crucial to the diffusion process required for viable market volume. This new project is to be based on case studies built around farmer groups involving both innovative and pragmatist farmers, consultant agronomists, and key researchers.

FARMSCAPE has developed into a successful approach to systems research, specifically in the exploration of a role for computerized decision support. Its focus has been on dryland farming systems of northeast Australia with participant interest concentrating on decisions that impact on the economics of alternative cropping options. There is now interest, both within APSRU and from collaborating researchers, to expand and replicate the FARMSCAPE approach in other regions, and to address a broader range of issues. Research projects implementing the FARMSCAPE approach have already commenced elsewhere in Australia, as well as internationally. Collaborative projects have commenced to assess the role for APSIM in improving management practices in smallholder agriculture, such as a WifAD session successfully held with smallholder farmers in Zimbabwe [98]. Expanding the systems view to incorporate natural resource management, weed management and agroforestry systems are all new project initiatives being undertaken by the FARMSCAPE team.

When leaning backward, and trying to identify systems that at the moment actually are used in *operational farm management*, the results are on the whole disappointing.

Although crop-soil simulation models dealing with soil water balances and crop water used have proliferated and in general, the relevant processes are well understood, there are very few examples where these models are being applied at the individual plot level to guide irrigation scheduling. One of the reasons is no doubt the fact that there is always a substantial degree of uncertainty, because rainfall cannot be predicted with great accuracy, neither in timing nor in amount, an uncertainty that propagates into predictions of future irrigation requirements. An additional constraint on the use of these models is that individual farmers are often dependent on irrigation system management, that determines when and how much water is available.

Application of operational nutrient management systems (fertilizer recommendations) is hampered by a number of difficulties. As mentioned in the description of the wheat nitrogen-fertilizer recommendation system in the Netherlands, the "final" demand for nitrogen, governed by the realized yield level, is determined at a point in the crop's life cycle when uptake by the crop cannot any more be affected by management. An additional problem is that the fertilizer is added to the soil and that it is impossible to predict when and how much of the fertilizer nutrient is actually being taken up by the crop, because that depends, among others, again on the soil and crop water balance, almost impossible to accurately predict. The uncertainty associated with simulation of the nutrient supply from natural sources, particularly that from soil organic matter, in general the largest source, adds uncertainty to the accuracy of estimating fertilizer requirements, both in timing and in rate.

Crop protection systems in the field of pest and disease management have had substantial success in the past, in a combination of farmers' monitoring and simulation models. However, these systems have largely disappeared again, mainly as farmers indicated, because the learning associated with application of these systems made them redundant. Farmers felt that after a number of years, interpretation of the monitoring data did not require model results, but could be done by the farmers themselves. Whether crop growth simulation models can really provide added value in this area is difficult to foresee, although they could play a role in quantitative assessment of damage levels on the basis of famer-supplied incidence levels at different stages of crop development, with or without control measures. The farmer could then decide, taking into

account the level of risk that he is prepared to take, whether to implement control measures or not, very much in line with the original EPIPRE and SIRATAC decision support systems.

At present, there is an increasing demand for weed management systems with reduced use and reliance on herbicides, and the ecophysiological competition models have great potential for contributing to the design of such alternative weed management systems. In the near future, more attention should be given in these models to the accuracy with which growth, morphological development, and seed production of weed species are being simulated, as the long-term development of weed populations becomes increasingly important. In this way, a functional link can be established between crop-weed competition research and research on weed population dynamics. Continuous interaction between modeling and experimental research should support determination of the required level of detail in crop-weed competition models and will provide leads for focusing future weed ecological research.

In conclusion, the great expectations that originally existed with respect to the use of crop growth simulation models in crop management (cf. [6]) unfortunately have not materialized. There are a number of reasons for this disappointing development. One is doubtless the fact that crop production takes place in an uncertain environment and that meteorological sciences have as yet, not been able to predict weather conditions in the near future with any great accuracy. The performance of crops is to a large extent governed by these weather conditions and thus it remains difficult to recommend actual actions when the future weather conditions are uncertain. Another problem is that most simulation models have been developed, tested, and validated against data from experimental stations and commercial crops often perform differently from those in experimental stations. When sufficient time and capacity is available, this problem can to a large extent be overcome, as reported for the Australian situation [99], but such extended programs for the development of crop management systems are seldom if ever available.

In contrast, there appears to be ample scope for application of crop growth simulation models in strategic and tactical management, in which such models are part of so-called discussion support systems that can be used by farmers to explore "what-if" questions, based on explicit quantitative information [100]. It has been shown convincingly that the success of such discussion support systems is greatly enhanced when the relevant stakeholders ("clients") are from the very beginning involved in the design and development of these systems, so that the relevant questions and the available information can be dovetailed in the most efficient way [101].

Therefore, although substantial progress has been made in the last 3 years, the situation has not basically changed and that in order to effectively make use of crop growth simulation models in crop management, the biggest challenge is to transfer the methodologies developed in land use studies to the unruly practice of land use policy formulation and implementation. That requires close cooperation with the ultimate users of the methodologies, the various stakeholders, through the development of discussion and negotiation platforms [89, 91, 101].

Socially Affected Traits, Inheritance and Genetic Improvement

Piter Bijma
Animal Breeding and Genomics Centre, Wageningen University, Wageningen, The Netherlands

Article Outline

Glossary

Animal breeding The process of selection and mating of parents to produce the next generation of a population, aiming to genetically improve populations of livestock and fish.

Associative effect Heritable effect of an individual on the phenotypic of another individual.

BLUP (best linear unbiased prediction) a method to estimate breeding values of individuals, making use of their pedigree and observed phenotypes.

Breeding value Expected phenotypic trait value of an individual given its genes

Genetic parameters Genetic component of the variances and covariances of traits in a population. Also encompasses derived parameters such as heritability.

Heritability Magnitude of the heritable variation in a population, expressed as a proportion of the observed variation among individuals.

Phenotype Observable trait value of an individual.

Response to selection Change in mean value of a phenotypic trait due to genetic selection.

Selection The choice of individuals to become parents of the next generation. The selection determines which genes are passed on to the next generation.

Social interactions The social process between individuals, which may affect the phenotypic trait values of those individuals.

Definition of the Subject

Livestock genetic improvement, also known as animal breeding, refers to the selection and mating of parents to produce the next generation of a population. The aim is to genetically improve populations of livestock and fish so that they better meet the future needs of markets and societies. Genetic improvement programs gradually change the genetic composition of populations and may create large changes over time. The social environment that individuals experience profoundly affects their productivity, health, and welfare, but has largely been overlooked in animal breeding. There is, however, increasing evidence that traits of individuals are affected not only by the genes carried by those individuals, but also by genes in the individuals present in their social environment. Thus there is a need to generalize the classical theory of inheritance and response to selection to make optimum use of the genetic variation present in the social environment. This involves both the basic mathematical description of the inheritance of socially affected traits, and methods for statistical genetic analysis of populations and designs of breeding schemes.

Introduction

Classical breeding has been very successful [1]. In many species, yields have increased dramatically, particularly in species with short generation intervals in which the focus has been on traits of moderate to high heritability recordable on the selection candidate, such as growth rate in broiler chickens [2, 3]. In many cases, however, there has been a trend for aspects of fitness to decline. Balanced genetic improvement in multiple traits is hampered by trade-offs between those traits, which are observed as unfavorable genetic correlations. Typical examples are trade-offs between yield and fertility in dairy cattle, between litter size and piglet survival in pigs, egg size and egg number in laying hens, and between growth rates and female fertility in broilers. Particularly the widespread trade-off between production and reproduction traits appears to be a systematic biological phenomenon [4].

Genetic improvement in the presence of trade-offs has compromised animal welfare, at least in some livestock species. This has partly been due to a lack of tools

to efficiently breed for health-related traits. In many cases, production traits have been most easy to record, have higher heritabilities than reproduction or health-related traits, and are available earlier in life. Breeding for longevity in dairy cattle, for example, has long been hampered by the lack of suitable statistical tools to account for censored records [5]. Moreover, in cases where yield related traits have greater heritability and better or earlier available phenotypic information, selection for the economically optimal index tends to yield negative responses in traits related to fitness. In addition, there has been a difficulty to market traits related to health and welfare of livestock. Profit margins in livestock production are often narrow, so that there is a strong emphasis on the economics of production. Genomic selection [6] is a very promising tool for a more balanced genetic improvement of productivity versus health and welfare, mainly because it provides estimated breeding values early in life for all recordable traits. However, though genomic selection largely removes trade-offs related to breeding scheme design, it does not remove the biological trade-offs between traits. In the absence of genetic engineering, traditional genetic parameters, such as the genetic correlation, remain the key parameters reflecting the prospects for genetic improvement.

There are different levels of modeling the causal mechanisms underlying the observed trade-offs. From a physiological perspective, for example, trade-offs can be understood from a resource allocation point of view. When resource intake becomes increasingly limiting, traits sharing the same resources will show an increasingly negative relationship [7, 8]. This perspective suggests that breeding for increased efficiency, which should be the overall goal of livestock genetic improvement [9], will lead to increasingly negative relationships between traits. From a genetic perspective, systematic trade-offs are the result of unfavorable pleiotropic effects of segregating genes. Sustained multitrait selection will increase such trade-offs because genes with favorable pleiotropic effects will become fixed by selection, while genes with unfavorable pleiotropic effects will remain segregating for much longer. There is no contradiction between the physiological and the genetic perspective; they merely represent different levels of causality. The evolutionary history of a population represents the ultimate level of causality because millions of years of evolution have shaped the biology of current livestock species. Hence, an evolutionary perspective may help to identify new opportunities for genetic improvement because it provides some understanding of the forces that have shaped the current livestock populations.

Denison et al. [10] consider opportunities for genetic improvement of agricultural populations from an evolutionary perspective. They argue that breeders cannot compete with the natural selection that has occurred in the evolutionary history of livestock populations because of the difference in time scales, being years for breeders and millions of years for natural selection. Consequently, it is unlikely that breeders can improve traits that have always been a target of natural selection. Typical examples are general disease resistance and basic efficiencies of metabolic processes. Hence, rather than trying to mimic natural selection, breeders should investigate other directions for genetic improvement.

A second reason why breeders should not try to mimic natural selection is that they have a fundamentally different objective. While natural selection acts on individual fitness, breeders are interested in the average performance of groups of animals or entire populations. Because natural selection acts on individual fitness, it has the intrinsic tendency to increase competition among population members. Thus natural selection may result in selfish individuals that are successful at the expense of others, rather than in maximization of output on the population, flock, or herd level. A clear example comes from the difference between wild wheat and rice versus modern cultivars. In natural populations, individual plants compete for sunlight. Natural varieties and traditional cultivars, therefore, have long stems making them sensitive to lodging (falling over). Modern wheat and rice cultivars, however, owe their high-yield potential largely to their short stature, relative to traditional cultivars. Short stature reduces lodging and increases growth of grain at the expense of stems, but artificial selection for these traits has resulted in decreased individual competitiveness. Forced to compete with traditional, low-yielding cultivars, modern high-yield rice cultivars completely disappear within as few as three generations [10]. This result clearly demonstrates that natural populations do not provide a useful blueprint for agriculture.

Moreover, it illustrates the relevance of competition among individuals in natural populations, which may also be relevant for livestock genetic improvement.

Denison et al. [10], therefore, conclude that breeders should investigate directions of human interest that are not already exhausted by natural selection. They identify two such directions. First, since domestication has greatly changed the environment to which populations are exposed, certain traits that are essential in nature may no longer be useful in domestic populations. Thus this change in environment releases usable genetic variation. Most modern agricultural species do, e.g., not need the capacity to escape from predators, or to deal with seasonal starvation. Hence, to achieve progress in traits of human interest, breeders should provide good environments and accept sacrificing traits that are essential in natural populations, rather than trying to breed robust individuals that can deal with very challenging environments. This direction has already been exhausted to a great deal in livestock. Improvement of genetics, husbandry, and feeding have gone together ever since domestication, and classical selection strategies implicitly utilize the genetic variance released by improvement of the environment. This approach, however, is gradually reaching limits. Concerns about animal welfare are on the increase in Western societies, and producers sometimes have difficulty providing the environment allowing animals to express their full genetic potential (personal communication Egbert Knol (IPG) and Frans van Sambeek (ISA)). Hence, breeders already utilize opportunities arising from improved environments, and it seems unlikely that current rates of genetic improvement can be accelerated by further improvement of the environment.

Second, Denison et al. [10] argue that breeders should target traits beneficial to the population but not to the individual expressing the trait. This is because natural selection acts on individual fitness and does, therefore, not exhaust the genetic variance in the social effect that individuals have on each other. Hence, they suggest breeding for decreased competition among population members. Thus the quantity of interest here is the heritable effect of an individual on the trait values of its group mates, known as the associative or indirect genetic [11, 12], rather than on its own trait value. Most livestock populations are kept in groups, ranging from cages of four laying hens, groups of moderate size in pigs and beef cattle in feed lots, to large flocks of broilers, sheep or beef cattle. In those systems, performance of individuals may depend on (social) characteristics of the other individuals present in the same group. Well-known examples are mortality due to cannibalistic behaviors in non-beak-trimmed laying hens [13], and tail biting and aggression at mixing in swine [14]. Results in pigs, moreover, indicate that growth rate is affected by heritable social effects, even in ad libitum feeding [15]. Also aquaculture species provide a typical example of social effects, where variation among individuals is often considerably increased due to competition for feed [16].

When trait values depend on social interactions among individuals, selection of the best individuals may cause the average performance of a population to decline, rather than increase. In non-beak-trimmed laying hens, for example, selection of the survivors has decreased survival in the next generation because the survivors had a negative heritable effect on survival of their cage mates [17]. Results in plant breeding, however, illustrate that selection for increased yield in the presence of social interactions can be successful. Properties of modern crops show that plant breeders have successfully improved yields by decreasing competition (see above). Reasons for this success may be that plant breeders are more aware of competition among individuals, and that breeding for reduced competition is much easier in plants. (Theory shows that selection between clonal plots exploits the full heritable variance in traits, including the component due to competition; see below and in [18]). In livestock breeding, in contrast, relatively little is known of the magnitude of associative effects. With the exception of maternal genetic effects, breeders have hardly attempted to utilize associative effects for genetic improvement (But see Muir's selection experiments; [17, 19–21]). Hence, there is a need for further research on the magnitude of associative effects in livestock populations.

At first glance, breeding for improved social effects may seem difficult to apply in practice because social effects will often be the result of certain behaviors that may be difficult to record. Breeding for improved behavior is rarely applied in modern breeding practice

because recording behaviors is usually very labor intensive. [22], however, showed that heritable social effects can be estimated in a similar way as maternal genetic effects [23] without the need to record the behaviors underlying the associative effects. At present, flexible tools are available to estimate social genetic effects without the need to observe the traits underlying them (See section on "Estimation of Genetic Parameters" below). Hence, nowadays breeders have the opportunity to address improvement of social interactions in their improvement programs.

Whether or not social interactions are of interest to breeders will depend on the trait considered and on the environment in which individuals are kept. Selection experiments on mortality in non-beak-trimmed layers kept in cages illustrate the relevance of social genetic effects in that situation [17, 20, 21]. For non-beak-trimmed laying hens, Ellen et al. [24] found that more than half of the total heritable variation in survival days originated from social effects. Bergsma et al. [15] found that social genetic effects contribute to heritable variation in growth rate and feed intake in pigs. In contrast, results of Arango et al. [25] in growing pigs indicate that social genetic effects may be difficult to estimate and not deviate significantly from zero. At present, knowledge of the importance of social genetic effects in populations of livestock and fish is still limited. In aquaculture, the large size differences among individual fish indicate that competition is important and that it affects uniformity [16], but the heritable effects underlying such competition are largely unknown. It would be interesting to see whether fish breeders can achieve something similar as plant breeders, who have effectively reduced competition among individuals in wheat [10]. Though social genetic effects may not always be important and may be difficult to utilize in some cases, the promising results observed in layer chickens should be sufficient incentive for further research in this area. Moreover, genetic improvement of productivity resulting from improved social interactions may cause less trade-offs in health and welfare traits because it may reduce energy waste rather than shifting resources from fitness traits toward production traits [17]. This chapter summarizes the quantitative genetic theory of socially affected traits, covering the basic models, expressions for response to selection, and estimation of genetic parameters.

Quantitative Genetics of Socially Affected Traits

Quantitative Genetic Model

Classical Model In classical quantitative genetics and animal breeding theory, individual phenotypic values, P, are modeled as the sum of a heritable component, A, known as breeding value, and a residual, E, known as environment (Table 1) [26, 27],

$$P = A + E \tag{1}$$

The breeding value is the sum of the so-called average effects of the genes of the individual on its phenotype [28, 29]. It represents the heritable component of an individual's phenotype, whereas the "environment" comprises all non-heritable effects, including the non-heritable genetic effects arising from dominance and epistasis.

The absolute magnitude of the heritable effects is measured by the variance of the breeding values, σ_A^2, known as the additive genetic variance. The relative magnitude of the heritable effects is measured by the heritability, the ratio of heritable variance over phenotypic variance [26, 27],

$$h^2 = \sigma_A^2/\sigma_P^2 \tag{2}$$

Heritability expresses the relative contribution of heritable effects to phenotypic variance among individuals, taking values from 0 through 1. In the classical model, heritability also has the natural interpretation as the regression coefficient of offspring phenotype on mean phenotype of the parents; it is the proportion of phenotypic superiority in the parents that is recovered in the offspring. In the context of selection experiments, this quantity is known as the realized heritability [26].

Social Model As summarized in the Introduction, individuals may affect each other's phenotypes. The "environmental" component of the phenotype, therefore, also includes effects of the social environment provided by other individuals that interact with the focal individual. In contrast to the physical environment, however, the social environment is biological in origin and may therefore contain a heritable component. Hence, the E-term in Eq. 1 may contain heritable components due to other individuals. Such heritable effects on trait values of others are known as indirect genetic effects in the evolutionary genetic literature [12, 30],

Socially Affected Traits, Inheritance and Genetic Improvement. Table 1 Notation key

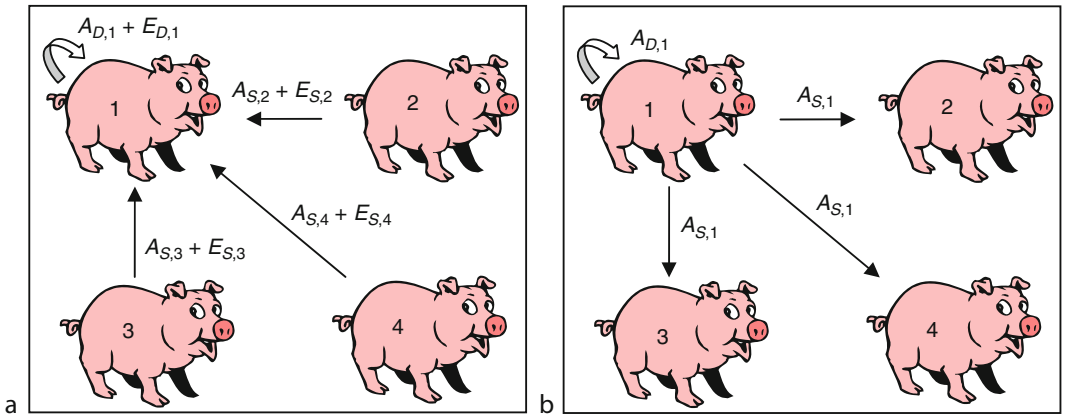
Symbol	Meaning
P, A, h^2	Phenotypic value, breeding value, heritability
i, j, n	Focal individual, group mate of focal individual, group size
$P_{D,i}$, $P_{S,i}$	Direct effect of i, (full) associative effect of i
$A_{D,i}$, $A_{S,i}$	Direct genetic effect of i, associative genetic effect of i
$E_{D,i}$, $E_{S,i}$	Direct non-genetic effect of i, associative non-genetic effect of i
$A_{T,i}$, T^2	Total breeding value of i, relative heritable variance
$A_{M,i}$, $E_{M,i}$	Breeding value for maternal effect of i, non-genetic maternal effect of i
R	Response to selection
ρ, ρ_T	Traditional accuracy of selection, total accuracy of selection
ρ_D, ρ_S	Direct and social accuracy of selection
g, r	Degree of between-group selection, relatedness between group mates
r_f, τ	relatedness between candidate and relatives, intraclass correlation between relatives
$\sigma^2_{A_D}$, $\sigma^2_{A_S}$	Direct genetic variance, associative genetic variance
$\sigma_{A_{DS}}$, r_g	Covariance and correlation between direct and associative genetic effects
$\sigma_{E_{DS}}$, r_E	Covariance and correlation between direct and non-genetic associative effects
σ^2_P, $\sigma_{P_{DS}}$	Phenotypic variance, full covariance between direct and associative effects
$\sigma^2_{A_T}$	Total heritable variance
σ^2_g, σ^2_e	Between-group non-genetic variance, residual variance
d	Degree of dilution of associative effects with group size
N_f, m	Number of families, effective number of records per family
σ^2_z, σ^2_f, σ^2_e	Full variance of records, between-family variance, residual variance
SE, $n_{opt,x}$	Standard error, optimum family size for parameter x

and as associative effects or social effects in the animal breeding literature [11, 17, 31]. Associative effects are of interest to animal breeders because they are heritable and thus can contribute to response to selection. Hence, for socially affected traits, the classical model in Eq. 1 needs to be modified because it treats associative effects as part of the non-heritable environment [11]. Also the definition of heritable variance may be modified because the classical additive genetic variance excludes the contribution of associative effects.

In most livestock and aquaculture populations, individuals are kept in groups, and interactions among individuals occur within group. In a population consisting of groups of n individuals each, the phenotype of an individual can be expressed as the sum of a direct effect rooted in the individual itself, and the associative effects of each of its $n-1$ group mates [11],

$$P_i = P_{D,i} + \sum_{i \neq j}^{n-1} P_{S,j}, \tag{3}$$

where $P_{D,i}$ denotes the direct effect due to the focal individual i, $P_{S,j}$ the associative effect of its group mate j, and the summation is over the $n-1$ group mates of the focal individual. Both the direct and associative effect may be decomposed into a heritable component, A, and a non-heritable component, E. The



Socially Affected Traits, Inheritance and Genetic Improvement. Figure 1

(**a**) The phenotype of individual 1 is the sum of its own direct effect plus the associative effects of its group mates, $P_1 = A_{D,1} + E_{D,1} + \sum_{j=2,3,4} \left(A_{S,j} + E_{S,j}\right)$. (**b**) The total breeding value of individual 1 is the sum of its heritable effects on all group members, including itself, $A_{T,1} = A_{D,1} + 3A_{S,1}$

phenotype, therefore, is the sum of the direct breeding value and direct environmental effect of the focal individual, and the summed associative breeding values and associative environmental effects of each of its $n - 1$ group mates [11, Fig. 1a],

$$P_i = A_{D,i} + E_{D,i} + \sum_{i \neq j}^{n-1} A_{S,j} + \sum_{i \neq j}^{n-1} E_{S,j} \qquad (4)$$

In this expression, $A_{D,i}$ is the direct breeding value (DBV) of individual *i*, and $A_{S,j}$ the associative breeding value (SBV) of its group mate *j*. The DBV corresponds to the classical (direct) breeding value, whereas the SBV is a generalization of a breeding value for maternal effect (See section on "A Special Case: Maternal Genetic Effects" below). An individual's DBV is the sum of the direct average effects of its genes, whereas its SBV is the sum of the associative effects of its genes. In total, the $A_{D,i} + \sum_{i \neq j}^{n-1} A_{S,j}$ is the best predictor of the phenotype of the focal individual from the average effects of its own genes and those in its group mates, obtained using the method of least squares [27–29, 32]. The $E_{D,i}$ and $E_{S,i}$ are the corresponding non-heritable effects ("environment").

At first glance, it seems that the summation in Eq. 4 implies additivity of associative effects, whereas, in reality, an individual's associative effect may depend on the individual it interacts with. For example, an individual may interact in a positive manner with a certain group mate, but have adverse effects on other group mates. Equation 4, however, considers the average associative effect of a genotype, which is additive by definition. This is an analogy of the average effect of an allele in, e.g., a single locus model [26, 29]. In the presence of dominance, the effect of an allele depends on the other allele at the locus. Nevertheless, one can still define the average effect of an allele, which is the effect relative for heritable variance and response to selection (at least in the short term). Hence, Eq. 4 does not assume additivity of the social interactions, but focuses on the heritable component of these interactions.

Breeding Value The objective of livestock genetic improvement is to generate response to selection, that is, to genetically change the mean trait values of the population. For this purpose, an individual's quality is measured by its heritable effect on the mean trait value of the population. In the classical model, an individual's heritable effect on the population mean simply equals the classical breeding value, *A*, as defined in Eq. 1. With associative effects, an individual's full heritable effect on the mean trait value of the population is the sum of its direct heritable effect on its own phenotype, plus its social heritable effect on the phenotypes of its group mates. Hence, an individual's total breeding value may be defined as [31; Fig. 1b]

$$A_{T,i} = A_{D,i} + (n-1)A_{S,i} \qquad (5)$$

In contrast to an individual's phenotype, its total breeding value is entirely a property of its own genes (Fig. 1a vs 1b). The total breeding value is a generalization of the classical breeding value and is the heritable property relevant for response to selection in socially affected traits. Taking the average phenotype of the population shows that response to selection equals the change in mean total breeding value,

$$R = \Delta \bar{A}_T \tag{6}$$

In contrast to the classical breeding value, however, the total breeding value contains a part that is not expressed in the individual's own phenotype, nor in the phenotypes of its offspring, but in the group mates of the individual and of its offspring.

Heritable Variance In the classical model, heritable variance equals the variance of the breeding values among individuals. By analogy, for socially affected traits, the total heritable variance may be defined as the variance in total breeding values among individuals [31],

$$\sigma^2_{A_T} = \sigma^2_{A_D} + 2(n-1)\sigma_{A_{DS}} + (n-1)^2\sigma^2_{A_S}, \tag{7}$$

where $\sigma^2_{A_D}$ is the variance in direct breeding values, $\sigma^2_{A_S}$ the variance in associative breeding values, and $\sigma_{A_{DS}}$ the covariance. The total heritable variance reflects the magnitude of the heritable differences among individuals that determine the potential of the population to respond to selection (See section "Response to Selection" below). The $(n-1)^2\sigma^2_{A_S}$ term represents the heritable variance present in the social environment. This term shows that even small associative effects can substantially increase the total heritable variance, particularly when groups are large. (But see the section "The Effect of Group Size on Heritable Variance" below.) This may explain the rapid response to group selection observed by Muir [19, 21]. The term $2(n-1)\sigma_{A_{DS}}$ shows that a negative genetic covariance between direct and associative breeding values reduces the total heritable variance. With negative $\sigma_{A_{DS}}$, individuals with positive breeding values for their own phenotype have on average negative associative effects on the phenotypes of their group mates, and vice versa. Thus a negative $\sigma_{A_{DS}}$ may be interpreted as "heritable competition." Heritable competition, therefore, reduces total heritable variance and thus the potential of the population to respond to selection. Heritable cooperation ($\sigma_{A_{DS}} > 0$), in contrast, increases total heritable variance.

The $\sigma^2_{A_T}$ expresses heritable variance in absolute units. The interpretation of the magnitude of the heritable variation is facilitated by expressing heritable variance relative to phenotypic variance, analogous to classical heritability (Eq. 2). By analogy, for socially affected traits, the ratio of total heritable variance over phenotypic variance equals [15],

$$T^2 = \frac{\sigma^2_{A_T}}{\sigma^2_P} \tag{8}$$

A comparison of h^2 and T^2 reveals the proportional contribution of associative to heritable variance. When group members are unrelated, phenotypic variance equals

$$\sigma^2_{P_{r=0}} = \sigma^2_{A_D} + \sigma^2_{E_D} + (n-1)\left(\sigma^2_{A_S} + \sigma^2_{E_S}\right) \tag{9}$$

With associative effects, phenotypic variance depends on relatedness between group members [15, 33]. As a consequence, T^2 depends on relatedness between group members when using the realized phenotypic variance in Eq. 8, which is inconvenient for a standardized parameter. Hence, to achieve standardization, it is preferable to scale total heritable variance by the phenotypic variance for populations with unrelated group members, using $T^2 = \sigma^2_{A_T}/\sigma^2_{P_{r=0}}$, rather than using the realized phenotypic variance in Eq. 8.

Comparison of Eqs. 7 and 9 shows that total heritable variance, $\sigma^2_{A_T}$, is not a component of phenotypic variance, illustrating that an individual's total breeding value is not a component of its trait value (Eq. 4 vs Eq. 5). Because an individual's total breeding value is dispersed over multiple individuals, it is hidden to direct observation. As a consequence, total heritable variance may exceed phenotypic variance, and T^2 may take values greater than one, whereas classical heritability has an upper limit of one. When group members are unrelated, the difference between the genetic component of phenotypic variance and total heritable variance equals (personal communication J. Bruce Walsh)

$$\sigma^2_{A_T} - \sigma^2_P = (n-1)\left[2\sigma_{A_{DS}} + (n-2)\sigma^2_{A_S}\right], \tag{10}$$

illustrating that heritable variance may substantially exceed phenotypic variance particularly when groups

are large. (But see the following section on "The Effect of Group Size".) Social interactions, therefore, result in hidden heritable variation. Empirical results indeed indicate that T^2 may considerably exceed h^2, but values greater than one have not been found so far (See Table 3 below). Note, however, that greater heritable variance than phenotypic variance does not necessarily imply that associative effects increase response to selection. Whether or not the available heritable variance translates into response to selection depends on selection criterion and on relatedness between group members [11, 18, 33] (See section on "Response to Selection" below).

The Effect of Group Size on Heritable Variance The careful reader will have noted that total heritable variance approaches infinity when groups become large (Eq. 7), which is unrealistic. Indeed, when $\sigma^2_{A_S}$ remains constant while group size increases, the $\sigma^2_{A_T}$ in Eq. 7 increases continuously. The magnitude of the associative genetic variance, $\sigma^2_{A_S}$, however, will probably also depend on group size because interactions between a specific pair of individuals are likely to be less intense in large groups [25]. The relationship between the magnitude of associative effects and group size is relevant because it affects the dynamics of response to selection, heritable variance, and group size. It determines, for example, whether or not selection is more efficient with larger groups.

Models accounting for the relationship between group size and associative effects have been provided in Refs. [25, 42, 43]. In [43], the relationship between associative effects and group size is modeled as

$$A_{S,i,n} = \left(\frac{\bar{n}-1}{n-1}\right)^d A_{S,i,\bar{n}}, \tag{11}$$

where $A_{S,i,n}$ is the associative effect of individual i when it would be expressed in a group of n members, $A_{S,i,\bar{n}}$ the associative effect of i when expressed in a group of the average size, $\bar{n}$, and d the degree of dilution. The degree of dilution measures the decrease of an individual's associative effect when group size increases.

With no dilution, $d = 0$, an individual's associative effect is the same for all group sizes, $A_{S,i,n} = A_{S,i,\bar{n}}$, so that its total associative effect summed over all group mates is proportional to the number of group mates, $(n-1)A_{S,i,n} = (n-1)A_{S,i,\bar{n}}$. This may occur, for example, in trees, where a large tree's associative effect may result from shading all individuals under its canopy, the effect on each individual being independent of the total number of individuals under the canopy (personal communication J. Bruce Walsh). With full dilution, $d = 1$, in contrast, an individual's total associative effect summed over all group mates is independent of group size, $(n-1)A_{S,i,n} = (\bar{n}-1)A_{S,i,\bar{n}}$, while its associative effect on each individual group mate is inversely proportional to the number of group mates, $A_{S,i,n} = [(\bar{n}-1)/(n-1)]\ A_{S,i,\bar{n}}$. This may occur, for example, with restricted feeding on group level, where an individual consuming 1 kg of feed has a total associative effect of -1 kg, and an average associative effect of $A_{S,i,n} = -1/(n-1)$ kg on each of its group mates. More generally, the magnitude of associative effects may be modeled as a function of the intensity of the interaction. In trees, for example, the associative effect of one tree on another may be modeled inversely proportional to the distance between both trees [17]. The degree of dilution of associative effects is an empirical issue, which may be trait and population specific, and needs to be estimated for the population of interest (See section on "Estimation of Genetic Parameters" below).

Dilution of associative effects alters the relationship between genetic variances and group size. The associative genetic variance for groups of $n$members equals,

$$\sigma^2_{A_S,n} = \left(\frac{\bar{n}-1}{n-1}\right)^{2d} \sigma^2_{A_S,\bar{n}}, \tag{12}$$

which decreases with group size for $d > 0$. The total heritable variance for groups of n members equals

$$\begin{aligned}\sigma^2_{A_T,n} = \sigma^2_{A_D} + 2(\bar{n}-1)^d(n-1)^{1-d}\sigma_{A_{DS},\bar{n}} \\ +(\bar{n}-1)^{2d}(n-1)^{2-2d}\sigma^2_{A_S,\bar{n}}\end{aligned} \tag{13}$$

(This expression may seem complex, but note that $\bar{n}$ is a constant for any particular population). Hence, for $\sigma_{A_{DS}} = 0$, total heritable variance increases with group size as long as dilution is incomplete ($d < 1$), and total heritable variance is independent of group size with full dilution ($d = 1$). Since total heritable variance depends on group size and on the degree of dilution, response to selection will also depend on those factors. To account for the effect of dilution on response to selection, the $\sigma^2_{A_S}$ and $\sigma^2_{A_T}$ should be substituted by Eqs. 12 and 13 in the expressions for response to selection provided below.

When genetic and non-genetic associative effects show the same dilution with group size, the phenotypic variance in populations of groups of $n$unrelated members equals

$$\sigma^2_{P,n} = \sigma^2_{P_D} + (\bar{n}-1)^{2d}(n-1)^{1-2d}\sigma^2_{P_S,\bar{n}} \qquad (14)$$

showing that phenotypic variance increases with group size for $d < 0.5$, is independent of group size for $d = 0.5$, and decreases with group size for $d > 0.5$. Hence, the relationship between phenotypic variance and group size provides an approximate impression of the degree of dilution.

Response to Selection

In a series of papers, Griffing [11, 33, 44–46] showed theoretically that associative effects on trait values alter response to genetic selection, not only in magnitude but potentially also in direction, and demonstrated that response depends strongly on relatedness among interacting individuals and on the selection criterion. Results of Griffing, however, do not fit easily in the common animal breeding framework for response to selection and have largely been overlooked. Griffing [44] summarized his results into a more common theoretical framework, but this work was published in a conference proceeding and was also largely overlooked. Muir [17] and Bijma et al. [31] rediscovered those results and expressed them in terms familiar to animal breeders. This section summarizes the resulting expressions for response to artificial selection, accounting for associative effects, genetic relatedness among interacting individuals, and selection acting on multiple levels, such as individual or group, or on an (optimum) index of both.

General Expression for Response to Selection In classical animal breeding theory, i.e., in the absence of associative effects, response to selection is commonly expressed as the product of the intensity of selection, $\imath$, the accuracy of selection, ρ, and the additive genetic standard deviation in the trait, σ_A [e.g., 47],

$$R = \imath\rho\sigma_A \qquad (15)$$

In this expression, R is the genetic change in mean trait value from one generation to the next. The selection intensity expresses the phenotypic superiority of the selected parents in standard deviation units, $i = S/\sigma$, where S is the superiority of the selected parents for the selection criterion and σ is the standard deviation of the selection criterion among the candidates for selection. The accuracy is the correlation between the value of the selection criterion (SC) and the additive genetic merit for the trait (the breeding value) in the candidates for selection,

$$\rho = \mathrm{corr}(A, \mathrm{SC}) \qquad (16)$$

Equation 15 partitions response to selection into three clearly distinct components; a scale-free measure of the strength of selection, $\imath$, a scale-free measure of how accurately the selection criterion resembles an individual's true breeding value for the trait of interest, ρ, and a measure of the magnitude of the heritable differences in the population, σ_A. The intensity of selection is largely determined by the reproductive potential of the species and the availability of reproductive technologies such as artificial insemination. The accuracy reflects the quality of the selection criterion, which depends on the type and amount of information collected. The genetic standard deviation is an intrinsic biological property of the population, reflecting its potential to respond to selection, and is outside human control. (Equation 15 can easily be extended to account for two sexes [26]).

The classical expression for response can be generalized to account for associative effects [48]. From the trait model (Eq. 4), it follows that response to selection equals the increase in mean direct breeding value plus the increase in mean associative breeding value weighted by the number of group mates, $R = \Delta[\bar{A}_D + (n-1)\bar{A}_S]$, which is the change in mean total breeding value, $\Delta\bar{A}_T$ (Eq. 5). The change in mean total breeding value equals the mean total breeding value of the selected parents expressed as a deviation from the overall mean and follows from regression of the total breeding value on the selection criterion, $R = b_{A_T,\mathrm{SC}}(\mathrm{SC} - \overline{\mathrm{SC}})$. From the definitions of regression and correlation coefficients, and using $\mathrm{SC} - \overline{\mathrm{SC}} = \imath\sigma_{\mathrm{SC}}$, it follows that

$$R = \imath\rho_T\sigma_{A_T}, \qquad (17)$$

where the total accuracy of selection, ρ_T, is the correlation between the selection criterion and the total breeding value in the candidates for selection, and σ_{A_T} is the total genetic standard deviation in the

trait (Eq. 7). Equation 17 applies to any selection strategy and inheritance model, as long as the total breeding value represents the average effects of an individual's genes on the mean trait value of the population. (See [49] for an application to maternal effects, and [49] for an application to both associative and maternal effects). Equation 17 corresponds to the first term of Price's Theorem [50] and represents the change in trait value due to change in allele frequency, keeping average effects of alleles constant for all elements of the inheritance model. Because intensity and accuracy are scale-free parameters depending on the breeding design, the total genetic standard deviation reflects the intrinsic potential of a population to respond to selection. Thus the total heritable variance defined in Eq. 7 bears a direct relationship to response to selection. In theory, σ_{A_T} may exceed σ_P (see above), suggesting that response in socially affected traits can be very large relative to phenotypic standard deviation. While this agrees with the very large response observed by Muir [19, 21] in cannibalistic laying hens, it is unlikely that this phenomenon is widespread in livestock. Nevertheless, the potential for genetic improvement of socially affected traits may be larger than suggested by classical theory (see Table 3 below).

Accuracies of Selection Traditional selection methods include mass selection, selection based on information recorded on relatives, mostly full sibs, half sibs, or progeny, index selection [51, 52], and selection on estimated breeding values (EBV) obtained using Best Linear Unbiased Prediction (BLUP, [53]). Those methods are aimed at the classical (direct) breeding value and do therefore not fully utilize the available heritable variation when trait values are affected by associative effects. Efficient improvement of socially affected traits, therefore, requires modification of classical selection methods. Research in the field of evolutionary biology [12, 18, 30, 54–57] and early work on associative effects [11, 33] indicates that genetic relatedness among interacting individuals and selection acting on the group rather than the individual level strongly affect response to selection. Relatedness between group members and selection between groups are, therefore, important factors in response to selection for socially affected traits.

The following summarizes the accuracies for direct, associative, and total breeding value for a number of selection strategies (Table 2). In all cases, the individuals that provide the information for selection are kept in groups of n members, but the selection criterion may differ. For any parameter, response to selection is the product of intensity ($\imath$), accuracy (ρ), and genetic standard deviation (σ_A) for the parameter of interest,

$$R_D = \imath \rho_D \sigma_{A_D} \tag{18a}$$

$$R_S = \imath \rho_S \sigma_{A_S} \tag{18b}$$

$$R = R_D + (n-1)R_S = \imath \rho_T \sigma_{A_T} \tag{18c}$$

Individual Selection (IS) With individual selection (also known as "mass selection"), the individuals with the best phenotypes are selected as parents of the next generation. The total accuracy of individual selection equals (Ellen et al. 2007),

$$\rho_{T,\mathrm{IS}} = \frac{r\,\sigma^2_{A_T} + (1-r)[\sigma^2_{A_D} + (n-1)\sigma_{A_{DS}}]}{\sigma_{A_T}\sigma_P} \tag{19}$$

In the numerator of Eq. 19, relatedness acts as a weighting factor; greater relatedness increases the $\sigma^2_{A_T}$ term, while decreasing the $\sigma^2_{A_D} + (n-1)\sigma_{A_{DS}}$ term (Fig. 2a).

When group members are unrelated, IS does not directly target the associative breeding value, as illustrated by the accuracy of associative effects, $\rho_{S,\mathrm{IS}}(r=0) = \sigma_{A_{DS}}/(\sigma_{A_S}\sigma_P)$ (Table 2). Hence, when group member are unrelated, response in associative effects is entirely dependent on the covariance between direct and associative effects (Fig. 2b). When this covariance is negative, IS yields a negative response in associative effects, meaning that competition among individuals increases. Moreover, with unrelated group members, the negative response in associative effects may exceed the positive response in direct effect, $-(n-1)R_S > R_D$, yielding a negative net response and a negative total accuracy. This occurs when $\sigma^2_{A_D} + (n-1)\sigma_{A_{DS}} < 0$. The risk of negative response is not merely a theoretical possibility, but has been observed for egg number in cannibalistic laying hens by Muir [17].

When relatedness between group members increases, components in the numerator shift away from a potentially negative term, $\sigma^2_{A_D} + (n-1)\sigma_{A_{DS}}$,

Socially Affected Traits, Inheritance and Genetic Improvement. Table 2 Accuracies of selection

[a]Individual selection.

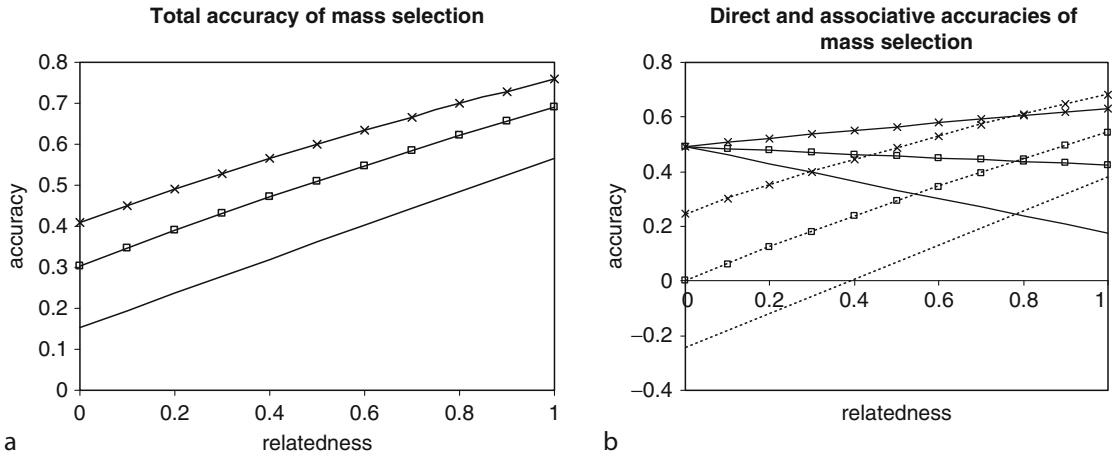
[b]Group selection; $\sigma_{\bar{P}}$ is the standard deviation of the group means (Eq. 20b).

[c]Index selection, $I_i = P_i + g\sum_{n-1} P_j$, g represents the degree of group selection, σ_I is the standard deviation of the index.

[d]Selection based on phenotypes of relatives; r_f is the additive genetic relatedness between the candidate and the relatives providing information, which equals 0.25 for half sibs, and 0.5 for full sibs and progeny; $\sigma_{\bar{P}_f}$ is the standard deviation of the family mean.

[e]The relatives of the selection candidate are mixed at random over groups, so that group members are on average unrelated.

[f]The relatives of selection candidates are kept together in groups, so that relatedness within groups equals within-family relatedness (r_w), which equals 0.25 for half sib families and 0.5 for full sib families. The m is the number of groups of relatives per candidate, so that mn is the total number of relatives per candidates. See Eq. 35 for η and τ.



Socially Affected Traits, Inheritance and Genetic Improvement. Figure 2
Accuracies of mass selection. (**a**) Total accuracy. *No symbols*: $r_{A_{DS}} = -0.5$; *boxes*: $r_{A_{DS}} = 0$; *crosses*: $r_{A_{DS}} = +0.5$. (**b**) Direct and associative accuracies. *Solid lines*: direct accuracy; *dotted lines*: associative accuracy. Symbols as in panel **a**. Other genetic parameters are $n = 8$, $\sigma^2_{A_D} = 1.5$, $\sigma^2_{A_S} = 0.05$, $h^2_D = h^2_S = 0.3$ and $r_{E_{DS}} = r_{A_{DS}}$. These parameters yield a phenotypic variance of $\sigma^2_P = 6.17$ when relatedness equals zero, and total heritable variances of $\sigma^2_{A_T} = 2.03$ for $r_{A_{DS}} = -0.5$, $\sigma^2_{A_T} = 3.95$ for $r_{A_{DS}} = 0$, and $\sigma^2_{A_T} = 5.87$ for $r_{A_{DS}} = +0.5$, respectively

toward a positive term, $\sigma^2_{A_T}$, which increases the accuracy (Fig. 2a). In the extreme case with fully related group members (clones), $\rho_{T,\mathrm{IS}}(r = 1) = \sigma_{A_T}/\sigma_P$, which is an analogy of the classical accuracy of individual selection, $\rho_{\mathrm{mass}} = h = \sigma_A/\sigma_P$ [26]. This illustrates that a population consisting of clone groups is genetically equivalent to a population consisting of noninteracting individuals with heritability $h^2 = \sigma^2_{A_T}/\sigma^2_P$. In other words, the "group becomes an individual" when group members are fully related. In summary, with individual selection, relatedness between group members can prevent negative accuracies.

Group Selection (GS) With group selection, selection is based solely on mean trait values of the groups, so that parents are selected from the best groups [33, 58, 59]. The accuracy of group selection equals [48]

$$\rho_{T,\mathrm{GS}} = \frac{[1 + (n-1)r]\sigma_{A_T}}{n\sigma_{\bar{P}}}, \tag{20a}$$

where $\sigma_{\bar{P}}$ is the standard deviation of the group means,

$$\sigma^2_{\bar{P}} = \frac{1}{n}\left[\sigma^2_P + (n-1)\mathrm{Cov}(P_i, P_j)\right] \tag{20b}$$

in which $\mathrm{Cov}(P_i, P_j)$ is the covariance between the phenotypes of two group members,

$$\begin{aligned}\mathrm{Cov}(P_i, P_j) = {} & 2\sigma_{P_{DS}} + (n-2)\sigma^2_{P_S} \\ & + r\left[\sigma^2_{A_D} + 2(n-2)\sigma_{A_{DS}}\right. \\ & \left. + (n^2 - 3n + 3)\sigma^2_{A_S}\right].\end{aligned} \tag{20c}$$

Because both the numerator and denominator of Eq. 20a are nonnegative, accuracy of group selection is nonnegative, irrespective of relatedness. Accuracy of GS has lower limit of zero, which occurs when all groups are composed in exactly the same manner; for example, when 10 clones are allocated to 10 groups, each group containing precisely one individual of each clone. In that case, $r = -1/(n-1)$ and accuracy is zero [60]. In this case, there is no between-group genetic variance, so that group selection cannot create response. In all other cases, GS directly targets the total breeding value, as illustrated by the σ_{A_T} in the numerator of Eq. 20a. This is because an individual's total breeding value surfaces in the group mean; the direct breeding value via its own phenotype and the associative breeding value via the phenotypes of each of its $(n-1)$ group mates. Group selection, therefore, also directly targets

both direct and associative breeding values, as illustrated by the $\sigma^2_{A_D}$ and $\sigma^2_{A_S}$ in the numerator of the direct and associative accuracy, respectively (Table 2).

When group members are unrelated, however, the n in the denominator causes accuracy to be low particularly when groups are large. This is because the between-group genetic variance is proportional to $1/n$ when group members are unrelated. Hence, with unrelated group members, the genetic variance that can be utilized by group selection decreases with group size, and approaches zero for large groups. Relatedness between group members considerably increases the accuracy of group selection because it increases the between-group genetic variance. In the extreme case of fully related group members (clones), $\rho_{T,\mathrm{GS}}\,(r=1)=\sigma_{A_T}/\sigma_{\bar{P}}$, which may be interpreted as the square root of the group heritability, $\sigma^2_{A_T}/\sigma^2_{\bar{P}}$. Note that GS outperforms IS when group members are fully related because $\sigma_{A_T}/\sigma_{\bar{P}} > \sigma_{A_T}/\sigma_P$. This occurs because GS does not waste effort on within-group selection, which is useless when group members are genetically identical. In summary, group selection prevents negative accuracy, but is efficient only when group members are sufficiently related.

Multilevel Selection Rather than selecting solely on individual or mean group phenotype, one may select on a linear combination of phenotypes of group mates and individual phenotype. In terminology used in evolutionary biology, this is an application of multilevel selection, where the levels of selection are the individual and the group. In natural populations, multilevel selection occurs when individual fitness depends on both properties of the individual itself and on properties of its groups. Multilevel selection is widespread in nature [61], but can also be applied as a breeding strategy in livestock and aquaculture [17, 31, 44].

Multilevel selection may be described by the following index [17, 31, 44]

$$I_i = P_i + g\sum_{n-1} P_j \tag{21}$$

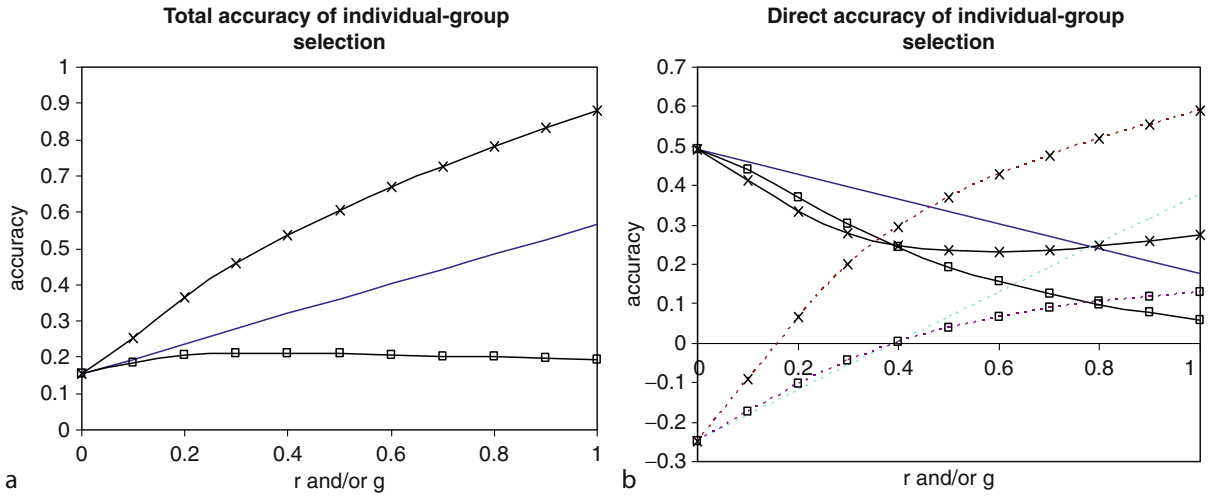
where g represents the weight on the summed phenotypes of the $(n-1)$ group mates. A $g=0$ corresponds to individual selection, whereas a $g=1$ corresponds to selection on $I_{i,g=1}=\sum_n P_j$, where the summation is over all $n$group members, including the individual of interest. Hence, a $g=1$ corresponds to between-group selection. Thus the $g$may be interpreted as a measure of the degree of group versus individual selection. A $g=-1/(n-1)$ corresponds to within-group selection, where individuals are selected based on the deviation of their phenotype from the mean phenotype of their group. (Interestingly, the value of $-1/(n-1)$ is also the lower bound for relatedness between group members, indicating a symmetry between $g$and r; [60]).

The accuracy of multilevel selection equals [62]

$$\rho_{T,I} = \frac{[g+r+(n-2)gr]\,\sigma^2_{A_T} + (1-g)(1-r)[\sigma^2_{A_D}+(n-1)\sigma_{A_{DS}}]}{\sigma_{A_T}\sigma_I} \tag{22}$$

Note that the numerator of this expression is fully symmetric in the degree of group selection, g, and relatedness, r, indicating that group selection and relatedness have precisely the same effect on the covariance between the index value and the total breeding value of selection candidates. The first term in the numerator, $[g+r+(n-2)gr]\,\sigma^2_{A_T}$, shows that group selection and relatedness cause selection to target the total breeding value. The second term, $(1-g)(1-r)[\sigma^2_{A_D}+(n-1)\sigma_{A_{DS}}]$, shows that the complement of group selection and relatedness acts on a term that is potentially negative. The $[\sigma^2_{A_D}+(n-1)\sigma_{A_{DS}}]$ is the numerator of the accuracy of individual selection with unrelated group members, which may indeed give negative response (See section on "Individual Selection" above). Hence, group selection and relatedness shift selection away from a potentially negative term toward the total genetic variance, thereby preventing negative response due to increased competition. Figure 3a illustrates this effect, showing that the combination of multilevel selection and relatedness may strongly increase accuracy. When group members are unrelated, the effect of multilevel selection on accuracy may be only moderate, and an intermediate value of $g$may be optimal. Figure 3b shows that multilevel selection and relatedness increase the accuracy of the associative effect, which may be at the expense of the direct effect when the direct-associative genetic correlation is negative.

Optimum Index Selection If the genetic parameters of direct and associative effects are known, then the degree of between-group selection, g, can be optimized using



Socially Affected Traits, Inheritance and Genetic Improvement. Figure 3

Accuracy of multilevel selection, $I_i = P_i + g\sum_{n-1} P_j$. (**a**) Total accuracy. *No symbols*: $g = 0$, $r \in [0, 1]$; *boxes*: $r = 0$, $g \in [0, 1]$; crosses: $r = g \in [0, 1]$. (**b**) Direct and associative accuracies. *Solid lines*: direct accuracy; *dotted lines*: associative accuracy. Symbols as in panel **a**. Other genetic parameters are $n = 8$, $\sigma^2_{A_D} = 1.5$, $\sigma^2_{A_S} = 0.05$, $r_{A_{DS}} = -0.5$, $h^2_D = h^2_S = 0.3$ and $r_{E_{DS}} = r_{A_{DS}}$. These parameters yield a phenotypic variance of $\sigma^2_P = 6.17$ when relatedness equals zero, and a total heritable variance of $\sigma^2_{A_T} = 2.03$

selection index theory [17, 44, 48, 51]. For this purpose, it is convenient to rescale the index to

$$I_i = b_1 P_i + b_2 \sum_{n-1} P_j \tag{23}$$

This index is equivalent to $I_i = P_i + (b_2/b_1)\sum_{n-1} P_j$, so that the optimum degree of group selection is

$$g_{\text{opt}} = \frac{b_{2,\text{opt}}}{b_{1,\text{opt}}} \tag{24}$$

From selection index theory, optimum index weights are [52]

$$\mathbf{b}_{\text{opt}} = \mathbf{P}^{-1}\mathbf{G}\mathbf{v}, \tag{25}$$

where $\mathbf{b}_{\text{opt}}$ is a column-vector of optimum index weights, $\mathbf{b}'_{\text{opt}} = [\, b_{1,\text{opt}} \quad b_{2,\text{opt}} \,]$, $\mathbf{P}$ is the symmetric matrix of covariances between the information sources in the index,

$$\mathbf{P} = \begin{bmatrix} \text{Var}(P_i) & \text{Cov}\left(P_i, \sum_{n-1} P_j\right) \\ \text{Cov}\left(P_i, \sum_{n-1} P_j\right) & \text{Var}\left(\sum_{n-1} P_j\right) \end{bmatrix},$$

$\mathbf{G}$ is the matrix of covariances between the information sources in the index (rows of $\mathbf{G}$) and the true direct and associative breeding values of the individual of interest (columns of $\mathbf{G}$),

$$\mathbf{G} = \begin{bmatrix} \text{Cov}(P_i, A_{D,i}) & \text{Cov}(P_i, A_{S,i}) \\ \text{Cov}\left(\sum_{n-1} P_j, A_{D,i}\right) & \text{Cov}\left(\sum_{n-1} P_j, A_{S,i}\right) \end{bmatrix},$$

and $\mathbf{v}$ is a vector of weights on direct and associative breeding values (also known as "economic values"). Because response equals $R = \Delta[A_D + (n-1)A_S]$, the weights required to optimize response to selection are given by $\mathbf{v}' = [1\, n-1]$.

Elements of $\mathbf{P}$ are

$$P_{11} = \sigma^2_P \tag{26a}$$

$$P_{12} = P_{21} = (n-1)\text{Cov}(P_i, P_j) \tag{26b}$$

$$P_{22} = (n-1)\text{Var}(P_i) + (n-1)(n-2)\,\text{Cov}(P_i, P_j), \tag{26c}$$

where $\text{Cov}(P_i, P_j)$ is the covariance between the phenotypes of two group members, which equals

$$\begin{aligned}\text{Cov}(P_i, P_j) = {} & 2\sigma_{P_{DS}} + (n-2)\sigma^2_{P_S} \\ & + r\left[\sigma^2_{A_D} + 2(n-2)\sigma_{A_{DS}}\right. \\ & \left. + (n^2 - 3n + 3)\sigma^2_{A_S}\right].\end{aligned} \tag{27}$$

The first two terms of this expression can be obtained from mixed model analysis using, $2\sigma_{P_{DS}} + (n-2)\sigma^2_{P_S} = 2\sigma_{A_{DS}} + (n-2)\sigma^2_{A_S} + \sigma^2_g$, where σ^2_g is the between-group non-genetic variance (See section "Estimation of Genetic Parameters" below). Elements of **G** are

$$G_{11} = \sigma^2_{A_D} + (n-1)r\sigma_{A_{DS}} \tag{28a}$$

$$G_{12} = \sigma_{A_{DS}} + (n-1)r\sigma^2_{A_S} \tag{28b}$$

$$G_{21} = (n-1)\left[r\sigma^2_{A_D} + \sigma_{A_{DS}} + (n-2)r\sigma_{A_{DS}}\right] \tag{28c}$$

$$G_{22} = (n-1)\left[r\sigma_{A_{DS}} + \sigma^2_{A_S} + (n-2)r\sigma^2_{A_S}\right] \tag{28d}$$

Using those **P** and **G**, the optimum weight on group versus individual, g_{opt}, follows from Eqs. 25 and 24. Note that g_{opt} may fall outside the 0–1 range. For example, when associative effects are large, g_{opt} may exceed one, indicating that the individual phenotype is weighted negatively relative to the overall group mean.

The accuracy of the optimum index can be obtained either by substituting g_{opt} into Eq. 22, or from

$$\rho_{T,I_{\text{opt}}} = \sigma_I/\sigma_{A_T}, \tag{29}$$

where σ_I is the standard deviation of the index,

$$\sigma_I = \sqrt{\mathbf{b}'\mathbf{P}\mathbf{b}} \tag{30}$$

For any index, i.e., for any combination of weights on the phenotype of the individual versus the summed phenotypes of its group mates, accuracy is given by

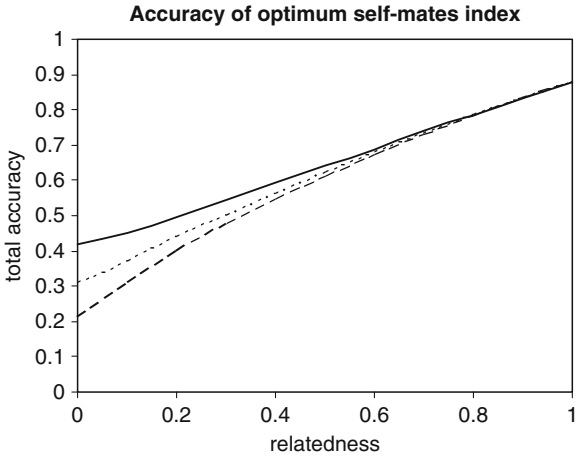
$$\rho_T(\mathbf{b}) = \frac{\mathbf{b}'\mathbf{G}\mathbf{v}}{\sigma_I\sigma_{A_T}} \tag{31}$$

This expression is equivalent to Eq. 22, where $g = b_2/b_1$. Total response to selection follows from Eq. 17, and responses in direct and associative effects are given by

$$\begin{bmatrix} \Delta\bar{A}_D \\ \Delta\bar{A}_S \end{bmatrix} = \mathbf{b}'\mathbf{G}\frac{\imath}{\sigma_I}, \tag{32}$$

where $\imath$ is the intensity of selection [26].

Figure 4 illustrates the accuracy of index selection, showing that accuracy is always positive and increases considerably with relatedness among group members.



Socially Affected Traits, Inheritance and Genetic Improvement. Figure 4
Accuracy of an optimum index of own performance and group mates, $I = b_1P_i + b_2\sum_{n-1}P_j$, as a function of relatedness among group members. For three genetic correlations between direct and associative effects; *dashed line* $r_{A_{DS}} = -0.5$, *dotted line* $r_{A_{DS}} = 0$, *solid line* $r_{A_{DS}} = +0.5$. Other genetic parameters are $n = 8$, $\sigma^2_{A_D} = 1.5$, $\sigma^2_{A_S} = 0.05$, $h^2_D = h^2_S = 0.3$ and $r_{E_{DS}} = r_{A_{DS}}$. These parameters yield a phenotypic variance of $\sigma^2_P = 6.17$ when relatedness equals zero, and total heritable variances of $\sigma^2_{A_T} = 2.03$ for $r_{A_{DS}} = -0.5$, $\sigma^2_{A_T} = 3.95$ for $r_{A_{DS}} = 0$, and $\sigma^2_{A_T} = 5.87$ for $r_{A_{DS}} = +0.5$, respectively

Hence, also when index weights are optimized, there is still a clear benefit of using groups composed of related group members. This result extends to selection on estimated breeding values using best linear unbiased prediction (see below).

Selection Based in Information of Relatives The above-mentioned selection methods rely on phenotypic information collected on the selection candidates themselves, which requires that the selection candidates are kept in groups (When selection candidates are housed individually, their phenotypes provide no information on their associative effect). Keeping selection candidates in groups, however, is often undesirable or difficult to apply in practice, particularly in laying hens and broilers. This is because group housing may interfere with recording data on an individual basis for important traits such as egg number or individual feed intake. Moreover, for behavioral traits

such as cannibalism, group housing may increase loss of selection candidates which is costly and reduces the intensity of selection. Also for veterinary reasons, it is often required that selection candidates are kept in clean conditions, such as Specific Pathogen Free environments, which are very different from the average production environment. Hence, response to selection based on information collected on the candidates themselves may be sensitive to genotype by environment interaction. Finally, recording of certain traits, such as carcass quality, may require sacrificing the individual, in which case selection cannot be based on own performance information.

For those reasons, selection decisions are often based on phenotypic information collected on relatives of the selection candidates, particularly sibs or progeny. Ideally, those relatives are kept in environments resembling commercial production environments, such as group housing and increased levels of disease. The following provides expressions for response to selection in socially affected traits when selection decisions are based on phenotypes of relatives kept in groups [48].

Consider selection on the average phenotype of relatives of the selection candidate, $\bar{P}_{\text{rels}}$. The phenotypic value of a relative j consists of the direct effect of j, and the summed associative effects of its group mates, $P_j = P_{D_j} + \sum_{n-1} P_{S_k}$, k denoting a group mate. When the group mates of the relative are unrelated to the candidate ($r_{ik} = 0$, $i$denoting the candidate), then the phenotype of the relative provides information only on the direct effect of the candidate, so that response in associative effect is entirely dependent on the genetic correlation between direct and associative effects. This is illustrated by the covariance between the total breeding value of the selection candidate and the phenotype of its relative, of which the component $\text{Cov}(A_{T,i}, \sum_{n-1} P_{S_k}) = 0$, so that $\text{Cov}(A_{T,i}, P_j) = r_{ij}[\sigma^2_{A_D} + (n-1)\sigma_{A_{DS}}]$ (Beware of a typo in this expression in [48]). In this case, accuracy is simply a scaled version of that with mass selection and unrelated group members,

$$\rho_{T,\text{rels}} = \frac{r_{\text{rels}}[\sigma^2_{A_D} + (n-1)\sigma_{A_{DS}}]}{\sigma_{A_T}\sigma_{\bar{P}_{\text{rels}}}}, \tag{33}$$

where r_{rels} is relatedness between the candidate and its relatives providing the information for selection. Hence, just as with mass selection, when using information recorded on sibs kept in groups with unrelated members, there is a risk of negative accuracy and thus negative response.

To capture the entire total breeding value of the selection candidates, relatedness between a candidate and the group mates of its relatives needs to be equal to relatedness between the candidate and its relatives, $r_{ik} = r_{ij}$, i denoting the candidate, j its relative, and k a group mate of j. In that case, $\text{Cov}(A_{T,i}, P_j) = \text{Cov}(A_{T,i}, A_{D,j} + \sum_{n-1} A_{S,k}) = r_{\text{rels}}\sigma^2_{A_T}$, showing that the phenotype of the relative captures the total breeding value of the candidate. This can be achieved by keeping relatives in family groups. For example, when selection is based on sib information, groups may be composed of full sibs of the candidate, so that $r_{ik} = r_{ij} = 0.5$. The following, therefore, describes the accuracy of selection based on relatives when they are kept in family groups.

The accuracy of selection based on the mean phenotypic value of relatives kept in family groups is an analogy of the classical expression for traits not affected by social interactions [48]. In the absence of social interactions, the accuracy of selection based on relatives is commonly expressed in terms of relatedness between the candidate and its relatives, r_{rels}, the square root of heritability, h, and the intraclass correlation t between the relatives (e.g., [63]),

$$\rho = \frac{r_{\text{rels}}h}{\sqrt{t + (1-t)/N}}, \tag{34}$$

where $t = r_w h^2$, being the product of mutual relatedness between the relatives, i.e., the within-family relatedness r_w, and heritability, and N is the number of records of relatives for each selection candidate. Note that there may be a difference between relatedness between the candidate and its relatives, r_{rels}, and mutual relatedness r_w within the group of relatives. For example, for half-sib progeny of the candidate, $r_{\text{rels}} = \frac{1}{2}$, whereas $r_w = \frac{1}{4}$. For full sibs of the candidate, $r_{\text{rels}} = r_w = \frac{1}{2}$, and for half sibs of the candidate, $r_{\text{rels}} = r_w = \frac{1}{4}$. When relatives are kept in family groups, with m groups per candidate each containing n members, yielding a total of mn records of relatives per candidate, the accuracy for socially affected traits equals,

$$\rho_{\text{rel}} = \frac{r_{\text{rels}}\eta}{\sqrt{\tau + (1-\tau)/mn}}, \tag{35a}$$

which is an analogy of Eq. 34 [48]. The Greek symbols in Eq. 35 are analogies of the "heritability" and the intraclass correlation;

$$\eta = \frac{\sigma_{\mathrm{TBV}}}{\sigma_{\mathrm{TPV}}} \tag{35b}$$

is an analogy of the square root of heritability, $h = \sigma_A/\sigma_P$, and

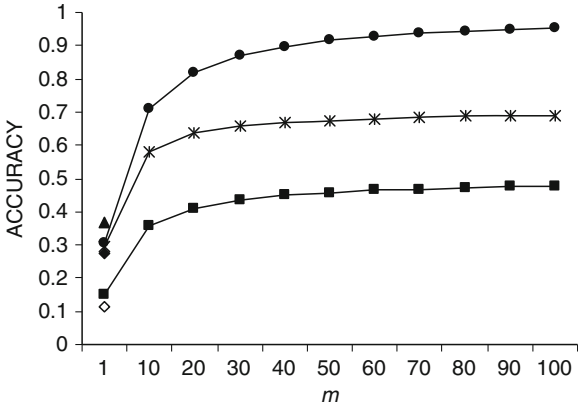
$$\tau = r_w \eta^2 \tag{35c}$$

is an analogy of the intraclass correlation between relatives $t = r_w h^2$. The η and τ account for interactions among individuals, and, therefore, depend on the total breeding value (TBV) and on the total phenotypic value (TPV) contributed by an individual. The TPV is the phenotypic analogy of the TBV (Eq. 5). It is not the observed phenotype of the individual, but represents an individual's effect on all phenotypes in the population, which is the sum of its direct phenotypic effect and $n-1$ times its associative phenotypic effect, $P_{T,i} = P_{D,i} + (n-1)P_{S,i}$, so that,

$$\sigma^2_{P_T} = \sigma^2_{P_D} + 2(n-1)\sigma_{P_{DS}} + (n-1)^2\sigma^2_{P_S} \tag{35d}$$

Thus, the TPV measures the total effect of an individual on performance of its group, the total breeding value is the heritable component of the TPV, and $\eta^2 = \sigma^2_{A_T}/\sigma^2_{P_T}$ is the proportion of the variance of the TPV which is heritable, analogous to the classical heritability. The intraclass correlation τ equals the correlation between TPVs of relatives, analogous to the classical intraclass correlation t, which equals the correlation between phenotypes of relatives for traits not affected by interactions [26]. In the absence of interactions, η reduces to h, τ reduces to t, and σ_{TBV} reduces to σ_A, so that Eq. 35a reduces to Eq. 34.

Hence, Eq. 35a shows that response to selection based on relatives kept in family groups can be obtained from the classical expression for response to selection based on relatives (Equation 34), when replacing heritability by $\sigma^2_{A_T}/\sigma^2_{P_T}$ and the intraclass correlation between relatives by $r_w\sigma^2_{A_T}/\sigma^2_{P_T}$. The key issue is that the sibs need to be kept in family groups. For example, when 16 half sibs are available and groups consist of 4 individuals, 4 groups of 4 individuals each should be used; the 16 half sibs should not be distributed over 16 groups each also containing 3 unrelated individuals.



Socially Affected Traits, Inheritance and Genetic Improvement. Figure 5

Accuracy of selection methods. The accuracy is shown for individual selection when the animals in a group are either full sibs (♦) or unrelated (◇), for group selection with groups of full sibs (▲), and for selection based on relatives kept in family groups, as a function of the number of groups per candidate (m), where relatives can be either half sibs (■), full sibs (✳) or half-sib progeny (●). (For $n = 4$; $\sigma^2_{P_D} = 1$; $\sigma^2_{P_S} = 0.33$; $h^2_D = 0.10$; $h^2_S = 0.10$; $r_A = r_E = 0$; Taken from Ellen et al. 2007)

Figure 5 illustrates the accuracy of selection based on relatives as a function of the number of groups of relatives per candidate. With many groups of relatives per candidate, $m \to \infty$, accuracy approaches

$$\max(\rho_{T,\mathrm{rels}}) = \frac{r_{\mathrm{rels}}}{\sqrt{r_w}}, \tag{36}$$

which is 0.5 for half sib information, $\sqrt{0.5}$ for full sib information, and 1 for information on half-sib progeny of the candidate [26]. Those values are the same as for classical selection based on relatives. Hence, with selection based on phenotypes of relatives, limiting accuracies for socially affected traits are the same as those for classical traits. For example, it is possible to obtain an accuracy approaching unity by using information on a large number of half-sib progeny kept in groups consisting of half sibs.

Selection on Estimated Breeding Values (EBVs) In animal breeding practice, breeding values are usually estimated using the so-called BLUP-procedure (Best Linear Unbiased Prediction; [53]. In the traditional

BLUP approach, phenotypes of individuals are analyzed using a mixed "animal model" containing fixed correction factors, such as herd, sex, or age of the individual, and a random genetic effect of the animal [27, 53, 64],

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Za} + \mathbf{e}, \tag{37}$$

where $\mathbf{y}$ is a vector of phenotypes, $\mathbf{b}$ a vector of fixed correction factors with incidence matrix $\mathbf{X}$, $\mathbf{a}$ a vector of random additive genetic effects ("breeding values") of individuals with incidence matrix $\mathbf{Z}$, and $\mathbf{e}$ a vector of residuals (Note that elements of $\mathbf{y}$ in Eq. 37 correspond to P_i in Eq. 4.). In animal breeding, interest is in the vector of estimated breeding values, $\hat{\mathbf{a}}$. Estimates for fixed effects and breeding values are obtained from the so-called Mixed Model Equations (MME). When residuals are independent and identically distributed, the MME are [27, 53, 64]

$$\begin{bmatrix} \mathbf{X}'\mathbf{X} & \mathbf{X}'\mathbf{Z} \\ \mathbf{Z}'\mathbf{X} & \mathbf{Z}'\mathbf{Z} + \alpha\mathbf{A}^{-1} \end{bmatrix} \begin{bmatrix} \mathbf{b} \\ \mathbf{a} \end{bmatrix} = \begin{bmatrix} \mathbf{X}'\mathbf{y} \\ \mathbf{Z}'\mathbf{y} \end{bmatrix}, \tag{38a}$$

so that the estimates follow from

$$\begin{bmatrix} \hat{\mathbf{b}} \\ \hat{\mathbf{a}} \end{bmatrix} = \begin{bmatrix} \mathbf{X}'\mathbf{X} & \mathbf{X}'\mathbf{Z} \\ \mathbf{Z}'\mathbf{X} & \mathbf{Z}'\mathbf{Z} + \alpha\mathbf{A}^{-1} \end{bmatrix}^{-1} \begin{bmatrix} \mathbf{X}'\mathbf{y} \\ \mathbf{Z}'\mathbf{y} \end{bmatrix}, \tag{38b}$$

where $\mathbf{A}$ is a matrix of relatedness coefficients between all individuals in $\mathbf{a}$, and $\alpha = \sigma_E^2/\sigma_A^2$. The use of BLUP requires knowledge of heritability of the trait to calculate the $\alpha = (1 - h^2)/h^2$. Further details and extensions are in [27, 64].

In contrast to selection index theory, BLUP is extremely flexible. It utilizes all available information, it allows correction for systematic non-genetic effects such as herd, sex or age, it allows for any degree of relatedness among individuals, any number of relatives, it provides also estimated breeding values for individuals without records, and it accounts for selection (under certain conditions).

Deterministic prediction of the accuracy of selection on BLUP-EBV is possible with selection index theory [65, 66], but is tedious, particularly when the model contains additional random effects such as maternal or associative effects. For this reason, consequences of selection on BLUP-EBV are often investigated using stochastic simulations. The following discusses the consequences of selection on BLUP-EBV when trait values are affected by associative effects, first when the mixed model ignores the associative effects, and afterward when accounting for associative effects.

BLUP Ignoring Associative Effects When only direct breeding values are modeled (i.e., when using Eq. 37), the consequences of selection on BLUP-EBV will depend critically on relatedness among group members [67]. When group members are unrelated, the EBV captures only the direct genetic effect of individuals, so that response in associative effects depends entirely on the genetic correlation between direct and associative effects. The accuracy derived from the MME, therefore, refers to the direct breeding value, not to the total breeding value. The actually achieved accuracy for the total breeding value is given by

$$\rho_{T,\mathrm{BLUP}}(r=0) \approx \hat{\rho}_{\mathrm{MME}} \left[\frac{\sigma_{A_D}^2 + (n-1)\sigma_{A_{DS}}}{\sigma_{A_D}\sigma_{A_T}} \right] \tag{39}$$

The $\hat{\rho}_{\mathrm{MME}}$ is the ordinary accuracy of BLUP-EBV derived from the diagonal elements of the inverse of the coefficient matrix of the MME [64], and the term in square brackets is the correlation between the direct and total breeding value (Note that this result reduces to $\rho_{T,\mathrm{BLUP}}(r=0) \approx \hat{\rho}_{\mathrm{MME}}$ when associative effects are absent). This result shows that BLUP selection with unrelated group member yields a negative accuracy when $\sigma_{A_D}^2 + (n-1)\sigma_{A_{DS}} < 0$, which is the same condition as for mass selection with unrelated group members (Table 2). When $\sigma_{A_D}^2 + (n-1)\sigma_{A_{DS}} < 0$, the correlated response in associative effects is negative and greater in absolute magnitude than the direct response, yielding a negative net response. Results of Muir [17] in cannibalistic quail illustrate that this is not merely a theoretical possibility, but may indeed occur in practice. (See section "Results of Social Selection Experiments" below.)

When groups are composed of families, the EBV of the traditional BLUP model implicitly captures the total breeding value of individuals, even though the associative component of trait values is not explicitly included in the model (Eq. 37; [67]). The reason is that the covariance between family members equals $r\sigma_{A_T}^2$, where $r = 0.5$ for full sibs and 0.25 for half sibs, when

groups consist of family members (When groups are composed at random with respect to family, the covariance between sibs equals $r\sigma^2_{A_D}$). Consequently, the accuracy of BLUP-EBV obtained from data containing groups of family members is approximately equal to the ordinary accuracy derived from the MME,

$$\rho_{T,\mathrm{BLUP,fam}} \approx \hat{\rho}_{\mathrm{MME}} \tag{40}$$

Moreover, the estimated additive genetic variance from an ordinary mixed model as in Eq. 37 will yield an estimate of $\sigma^2_{A_T}$ rather than $\sigma^2_{A_D}$. This occurs because the covariance between relatives equals $r\sigma^2_{A_T}$ rather than $r\sigma^2_{A_D}$ when groups consist of family members. Hence, the accuracy of BLUP-EBVs will always be positive when it is obtained from data consisting of family groups. This theoretical prediction agrees with results of Muir et al. [67] in quail, who found a negative response with BLUP selection and unrelated group members, but a positive response to BLUP selection when group members were related (referred to as Kin-BLUP in [67]).

BLUP Including Associative Effects Muir and coworkers [17, 22] extended the traditional mixed animal model to include Griffing's associative effects. In this model, the phenotype of each individual contains two separate components: a direct breeding value of the individual itself and the summed associative breeding values of its group mates,

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_S\mathbf{a}_S + \mathbf{e}, \tag{41}$$

where $\mathbf{y}$ is the usual vector of observations, $\mathbf{b}$ a vector of fixed effects with incidence matrix $\mathbf{X}$, $\mathbf{a}_D$ a vector of direct additive genetic effects with incidence matrix $\mathbf{Z}_D$ linking phenotypes of individuals to their own direct genetic effect, and $\mathbf{e}$ a vector of residuals. (Note that elements of $\mathbf{y}$ in Eq. 41 correspond to P_i in Eq. 4.) The $\mathbf{Z}_S\mathbf{a}_S$ represents the associative additive genetic effects, where $\mathbf{a}_S$ is a vector of associative effect, with incidence matrix $\mathbf{Z}_S$ linking phenotypes of individuals to the associative effects of their group mates. For example, for a population of 8 individuals kept in two groups of 4 individuals, individuals 1 through 4 in the first group and 5 through 8 in the second group, where individuals 2, 5, and 8 are female and the rest is male, a mixed model with a separate mean for both sexes and direct and associative effects for all records is

$$\begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \\ y_5 \\ y_6 \\ y_7 \\ y_8 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 1 & 0 \\ 1 & 0 \\ 0 & 1 \\ 1 & 0 \\ 1 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \mu_m \\ \mu_f \end{bmatrix} + \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} a_{D,1} \\ a_{D,2} \\ a_{D,3} \\ a_{D,4} \\ a_{D,5} \\ a_{D,6} \\ a_{D,7} \\ a_{D,8} \end{bmatrix}$$
$$+ \begin{bmatrix} 0 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 0 \end{bmatrix} \begin{bmatrix} a_{S,1} \\ a_{S,2} \\ a_{S,3} \\ a_{S,4} \\ a_{S,5} \\ a_{S,6} \\ a_{S,7} \\ a_{S,8} \end{bmatrix} + \begin{bmatrix} e_1 \\ e_2 \\ e_3 \\ e_4 \\ e_5 \\ e_6 \\ e_7 \\ e_8 \end{bmatrix}$$

The covariance structure of the random genetic terms is: $\mathrm{Var}\begin{bmatrix} \mathbf{a}_D \\ \mathbf{a}_S \end{bmatrix} = \mathbf{C} \otimes \mathbf{A}$, where $\mathbf{C} = \begin{bmatrix} \sigma^2_{A_D} & \sigma_{A_{DS}} \\ \sigma_{A_{DS}} & \sigma^2_{A_S} \end{bmatrix}$, $\mathbf{A}$ is a matrix of relatedness coefficients between individuals, and $\otimes$ denotes the Kronecker product of matrices. Thus, Eq. 41 is involves

three genetic variance components, $\sigma^2_{A_D}$, $\sigma_{A_{DS}}$ and $\sigma^2_{A_S}$. (See section "Estimation of Genetic Parameters" below for more details, such as the residual variance structure.)

The estimated breeding values for the direct and associative effects follow from the solution of the mixed model equations,

$$\begin{bmatrix} \hat{\mathbf{b}} \\ \hat{\mathbf{a}}_D \\ \hat{\mathbf{a}}_S \end{bmatrix} = \begin{bmatrix} \mathbf{X}'\mathbf{R}^{-1}\mathbf{X} & \mathbf{X}'\mathbf{R}^{-1}\mathbf{Z}_D & \mathbf{X}'\mathbf{R}^{-1}\mathbf{Z}_S \\ \mathbf{Z}_D'\mathbf{R}^{-1}\mathbf{X} & \mathbf{Z}_D'\mathbf{R}^{-1}\mathbf{Z}_D + g^{11}\mathbf{A}^{-1} & \mathbf{Z}_D'\mathbf{R}^{-1}\mathbf{Z}_S + g^{12}\mathbf{A}^{-1} \\ \mathbf{Z}_S'\mathbf{R}^{-1}\mathbf{X} & \mathbf{Z}_S'\mathbf{R}^{-1}\mathbf{Z}_D + g^{21}\mathbf{A}^{-1} & \mathbf{Z}_S'\mathbf{R}^{-1}\mathbf{Z}_S + g^{22}\mathbf{A}^{-1} \end{bmatrix}^{-1} \times \begin{bmatrix} \mathbf{X}'\mathbf{R}^{-1}\mathbf{y} \\ \mathbf{Z}_D'\mathbf{R}^{-1}\mathbf{y} \\ \mathbf{Z}_S'\mathbf{R}^{-1}\mathbf{y} \end{bmatrix} \tag{42}$$

where $\mathbf{R}$ is the covariance matrix of the residuals, $\mathbf{R} = \mathrm{Var}(\mathbf{e})$, and the g^{ij} denote elements of the inverse of the genetic covariance matrix, $\begin{bmatrix} g^{11} & g^{12} \\ g^{21} & g^{22} \end{bmatrix} = \begin{bmatrix} \sigma^2_{A_D} & \sigma_{A_{DS}} \\ \sigma_{A_{DS}} & \sigma^2_{A_S} \end{bmatrix}^{-1}$. The elements of $\mathbf{R}$ are given in the section on "Estimation of Genetic Parameters" below.

When fitting Eq. 41, fixed effects and potential additional random effects must be chosen carefully because not only an individual's direct effect but also its associative effect may be affected by fixed and random factors. Hence, in addition to the ordinary fixed effects, which refer to effects on the individual producing the record, one may need to fit fixed effects for its group mates. For example, when groups consist of mixed breeds, one may fit a fixed associative effect for the breed of each group mate. When associative breed effects are omitted, they may inflate the estimated associative effects and their variance. Similarly, when groups consist of mixed sexes, one may fit a fixed associative effect for the sex of each group mate. Moreover, when common-litter effects play a role, one may fit a random common-litter associative effect [41]. An example is given in the section on "Estimation of Genetic Parameters" below.

Deterministic prediction of the accuracy of selection on BLUB-EBV obtained from Model 41 is very tedious. In principle, selection index theory can be used to derive that accuracy, using the pseudo-BLUP selection index methodology suggested by [66]. However, for a population consisting of full and half sib families, a pseudo-BLUP selection index for a single trait contains 24 distinct sources of information. Hence, the variance matrix of the index contains 24^2 elements. Thus the use of stochastic simulation is more practical.

Some insight in the factors determining accuracy of BLUP selection can be obtained from a simplified index. The selection index of Muir et al. [67] shows that relatedness between group members may have greater impact on accuracy than extension of the mixed model to account for associative effects. They compared Kin-BLUP, in which the mixed model contained direct effects only (Eq. 37) and group members were related, to C-BLUP, in which the mixed model contained both direct and associative effects (Eq. 41), but group members were unrelated. The accuracy of Kin_BLUP exceeded that of C_BLUP, and the correlation of the true associative BV with the EBV of Kin_BLUP was greater than that with the associative EBV of C_BLUP. Hence, though Kin_BLUP does not explicitly account for associative effects, it can have greater accuracy for associative effects than C_BLUP. This result agrees with the empirical observations of Muir et al. [67] who observed greater response with Kin-BLUP than with C-BLUP in cannibalistic quail. Kin_BLUP picks up associative effects because they are hidden in the own performance and FS-performance when group members are related.

In conclusion, both empirical and theoretical results indicate that relatedness within groups is the key factor for response to selection; the use of C_BLUP does not make relatedness superfluous. C_BLUP, however, will always outperform Kin_BLUP when applied to the same breeding structure because it explicitly models the associative effects. When both methods are applied to data with full-sib groups, for example, C_BLUP will outperform Kin_BLUP [67].

A Special Case: Maternal Genetic Effects Maternal genetic effects are a common case of social interactions among individuals, where the mother affects the trait values of her offspring. Maternally affected traits usually depend on both the genes for maternal effect in the mother and genes for direct effect in the offspring [23, 27, 68, 69]. Preweaning growth rate and survival of piglets, for example, will depend on maternal milk yield and behavior of the sow, but also on the direct effect of the piglets for growth rate. Other

examples are calving ease in dairy cattle [70], and preweaning survival in sheep [71].

Maternal effects should not be confused with the genes for direct effect that the offspring inherits from its mother, but refers to the effect of the mother on her offspring that arises through the environment, for example, due to maternal care. Hence, direct and maternal effects are genetically distinct traits. For growth rate in piglets, for example, genes for direct effect will relate to juvenile growth rate, whereas genes for maternal effect may relate to milk yield or behavior of sows.

Maternal effects may be modeled as [68, 69]

$$P_i = A_{D,i} + E_{D,i} + A_{M,j} + E_{M,j}, \tag{43}$$

where i is the offspring, j the mother, P_i is the phenotype of the offspring, A_D and A_M the direct and maternal breeding values, and E_D and E_M the non-heritable direct and maternal effects, respectively. From Eq. 43, response to selection equals the sum of the changes in mean direct and mean maternal breeding value [68, 69],

$$R = \Delta\bar{A}_D + \bar{\Delta}A_M, \tag{44}$$

Based on Eq. 44, Eaglen and Bijma [49] defined a total breeding value for maternally affected traits, being the sum of an individual's breeding values for direct and maternal effect,

$$A_T = A_{D,i} + A_{M,i}, \tag{45}$$

so that response to selection equals $R = \Delta\bar{A}_T$. In contrast to the phenotypic value, the total breeding value includes the individual's own breeding value for maternal effect, rather than that of its mother. This is because an individual transmits its own genes for maternal effects to its offspring, not those of its mother. The total heritable variance that can be used to generate response to selection in maternally affected traits equals the variance in total breeding values among individuals,

$$\sigma^2_{A_T} = \sigma^2_{A_D} + 2\sigma_{A_{DM}} + \sigma^2_{A_M} \tag{46}$$

From Eq. 17, response to selection equals [49]

$$R = \imath\rho_M\sigma_{A_T}, \tag{47}$$

where ρ_M is the accuracy of selection for maternally affected traits, which is the correlation between the selection criterion and the total breeding value of an individual.

A number of studies have referred to a "total heritability" [72, 73], citing Willham [69],

$$h^2_r = \frac{\sigma^2_{A_D} + 1\frac{1}{2}\sigma_{A_{DM}} + \frac{1}{2}\sigma^2_{A_M}}{\sigma^2_P} \tag{48}$$

Willham [23, 69] referred to h^2_r as the "fraction of the selection differential realized if selection were on P_x" (P_x being the offspring phenotype). Hence, h^2_r represents the realized heritability for mass selection, $h^2_r = R/S$, the ratio of response over the selection differential, rather than the ratio of heritable variance over phenotypic variance [68]. Thus response to mass selection can be predicted as $R = h^2_r S$. Equation 47 yields the same result for mass selection, but applies to any selection strategy.

Maternal genetic effects can be estimated using mixed models that include both a direct and maternal genetic effect [64]. Issues related to the estimation of maternal genetic effects are discussed in [23, 64, 74–78].

Results of Social Selection Experiments Only a few social selection experiments have been applied in livestock. Muir [19] selected laying hens, housed in half-sib groups, based on total egg production per group. Hence, this experiment combined group selection with relatedness. In six generations, mortality decreased from 67% to 8%. Most of the response occurred within the first few generations of selection. Eggs per hen housed increased from 91 to 237 eggs, mainly as a result of increased survival. In the seventh generation, the group selected and control lines were compared to the commercial line from which the group selected line was derived [20, 79, 80]. In single-bird cages, egg production was significantly greater for the commercial line. In 12-bird cages, however, the reverse was seen. The most remarkable difference was for mortality at 58 weeks of age, which was 89% for the commercial line, 20% for the group selected line and 54% for the control. These results confirm the theoretical expectation that group selection with related group members yields large response to selection when associative effects are important.

The changes in mortality were accompanied by changes in behavior, stress physiology, and immunology [81, 82].Under conditions of social stress, birds from the low mortality population were more hesitant to attack other birds, showed less feather pecking, had a lower H/L ratio and had lower dopamine and corticosterone blood concentrations, indicating lower stress levels [83, 84]. Cheng and Muir [82] suggested that these changes in birds from the low mortality population may reflect a greater ability to cope with novel environments and to have a greater resistance to stressors than birds from the high mortality population.

Muir and coworkers [17, 22, 67] presented results of 25 cycles of selection for body weight in quail housed in groups of 16 birds. Three selection programs were compared. First, selection on conventional animal model BLUP EBV considering direct effects only (AM_BLUP, Eq. 37). Second, selection on estimated total breeding values derived from a mixed model, including both direct and associative effects (C_BLUP, Eq. 41). Group members were unrelated in those selection programs. The third selection program used groups consisting of half-sibs families, and selection on conventional animal model BLUP EBV considering direct effects only (Kin_BLUP). Results showed that the AM_BLUP program decreased body weight and increased mortality, whereas the Kin_BLUP program increased body weight and decreased mortality. The C_BLUP program was intermediate. Those results agree with expectations based on the theory presented above.

At Wageningen University, Ellen and coworkers initiated a selection experiment in laying hens, combining individual selection for egg number and group selection for low mortality in non-beak-trimmed kin-groups, based on the method of [48]. Selection candidates were housed individually, allowing recording of individual egg number. Non-beak-trimmed full sibs of these selection candidates were housed in family groups in which mortality was recorded. Selection was for a combination of egg number and mortality. Rodenburg et al. [85, 86] and Bolhuis et al. [87] investigated the behavioral and physiological consequences of this selection program in the second generation. Animals of the selected line were less fearful and less sensitive to stressors in a range of behavioral tests. Consistent results were found both in young chicks [87] and in adult birds [88] in two environments (cages and floor pens).

A number of group selection experiments have been performed in laboratory species, particularly in flour beetles (*Tribolium castaneum*). Wade [58, 59] was the first to demonstrate the power of group selection experimentally. Goodnight [89] reviewed 12 group selection experiments. Without exception, all group selection experiments showed a significant response to selection both in animals, plants, and microbial communities. Similar results have been found in bacteria [90]. Again, those results demonstrate that selection between groups and use of related group members increases response to selection in traits affected by social interactions, which agrees with theoretical expectations (see above).

Estimation of Genetic Parameters

Statistical Methodology

Some of the selection methods described above can be applied without knowledge of the genetic parameters, such as mass and group selection. Without knowledge of the genetic parameters, however, it is unclear whether associative effects are present and whether those selection strategies are needed and/or efficient. Moreover, most applied breeding programs make use of Best Linear Unbiased Prediction [53] for estimating breeding values, e.g., to correct for systematic environmental effects, which requires knowledge of the genetic parameters. Knowledge of the genetic parameters is also needed to quantify the expected response to selection, which may be required to make decisions on investment in breeding programs. Moreover, there is a wider biological interest in the heritable components affecting individual trait values and responses to selection, both in agriculture and in other fields of biology such as evolutionary genetics [30, 62]. Thus there is a need to estimate the genetic parameters for socially affected traits, which are the additive genetic variances of direct genetic effects, $\sigma^2_{A_D}$, the additive genetic variances of associative effects, $\sigma^2_{A_S}$, and the additive genetic covariance of direct and associative effects, $\sigma_{A_{DS}}$. This section addresses the estimation of those parameters, starting with a review of existing results.

Empirical Estimates of the Associative Variance Table 3 summarizes estimates of direct and associative heritabilities. Brichette et al. [37] were the first to publish estimates of the associative genetic variance. They analyzed growth in mussel cultures and found strongly significant direct and associative effects. Their model is somewhat different from the mixed models discussed in this chapter, and estimates may not be directly comparable. In each group, they tested a single focal family against a mixed reference set containing members of all families. In this design, the effect of the focal family on the mean phenotype of the reference group represents the associative effect of that family. Hence, in this setup, the associative effect is defined for a set of family members, rather than for a single individual, and the factors $(n-1)$ and $(n-1)^2$ in the total genetic variance do not apply (Eq. 7). Brichette et al. [37] obtained direct heritabilities of 0.104 and 0.232 for length measures, and 0.097 and 0.234 for area measures. Corresponding estimates for associative heritability were 0.010 and 0.087 for length and 0.220 and 0.082 for area. Direct-associative genetic correlations were negative, averaging −0.2. These results suggest that $\sigma^2_{A_t}/\sigma^2_P \approx 0.24$, and that associative effect contributed ∼1/3 of heritable variance in growth of mussel cultures.

Later studies focused primarily on laying hens and pigs. Particularly in pigs and beef cattle, it has proven

difficult to reliably estimate the associative genetic variance. Often the estimates suggested a considerable contribution of associative effects to total heritable variance ($T^2 >> h_D^2$), but the estimated associative genetic variance was nevertheless not significantly different from zero (Table 3). This occurred particularly when group sizes were relatively large, so that the number of groups was fairly small [25]. These observations agree with theoretical predictions, which indicate that the number of groups is the major determinant of statistical power, and that designs with small groups are often superior ([32]; see section on "Power and Optimum Designs" below). Hence, in large groups, even small values of the associative heritability can make a major contribution to total heritable variation (Eq. 7), but this contribution is difficult to estimate accurately, as reflected by the large standard errors of $\hat{\sigma}_{A_T}^2$. Estimates in laying hens, which come from data containing groups of four individuals, have been more accurate [24, 36].

Several studies have shown that the estimated associative genetic variance is very sensitive to the choice of the statistical model. Models not accounting for non-genetic associative effects, i.e., models that fit neither environmental associative effects nor pen effects or correlated residuals, generally yielded strongly inflated estimates [34, 40, 91, 92]. Hence, the choice of the statistical model requires careful consideration. To properly estimate the genetic variance components, additional fixed and random associative effects may be required to account for other sources of variation, such as litter environment or group size (see below).

QTL: There appears to be only a single QTL-study involving associative effects. Biscarini et al. [93] performed an association study to map direct and associative QTL for feather damage across nine different genetic lines of laying hens. A total population of 662 hens were genotyped for 1022 SNPs. Eleven significant SNPs were detected for direct effect and 81 for associative effect. From the significant associative SNPs, six were located at the sex chromosome. The SNPs identified suggest a relationship between behavior and immunology, and a role of the serotonergic system in feather pecking.

Mixed Models Muir and coworkers [17, 22] extended the traditional mixed animal model to include Griffing's associative effects (See Eq. 41 above). The following describes an extension of their model, taking the basic model as a starting point. In the basic model (Eq. 3), observed trait values are the sum of direct and associative effects, $P_i = P_{D,i} + \sum_{j=1}^{n-1} P_{S,j}$. The full direct and associative effects are not solely genetic, but may depend also on fixed effects, random genetic effects, and other random effects such as permanent or litter effects,

$$P_{D,i} = \text{fixed}_D + A_{D,i} + E_{D_P,i} + E_{D_C,i} + E_{D,i} \quad (49a)$$

$$P_{S,i} = \text{fixed}_S + A_{S,i} + E_{S_P,i} + E_{S_C,i} + E_{S,i}, \quad (49b)$$

where subscripts P and C indicate permanent and common-litter effects, respectively. (Note that Eqs. 49a and b are not exhaustive; they may be extended with, e.g., maternal genetic effects.) Just as in classical mixed models, omission of associative permanent effects or associative common-litter effects may lead to overestimation of $\sigma^2_{A_S}$. In pigs, for example, two full sibs may develop similar social skills because they experienced the same litter environment. In the fattening period, this similarity in social skills will create a covariance between the pen mates of both full sibs. When not accounted for, this covariance will largely be attributed to the associative genetic variance because the mixed model implies that $\text{Cov}(\bar{P}_{\text{pen mates}(FS1)}, \bar{P}_{\text{pen mates}(FS2)}) = \frac{1}{2}\sigma^2_{A_S}$ when associative litter effects are not included. A similar reasoning applies to permanent effects. For example, when an individual has been member of two distinct groups, the covariance between the phenotypes of two group mates, one taken from each group, equals $\sigma^2_{A_S} + \sigma^2_{E_S}$. When permanent associative effects are omitted from the mixed model, this covariance will be fully attributed to associative genetic effects, leading to overestimation of $\sigma^2_{A_S}$.

In general, therefore, the mixed model for socially affected traits is given by

$$\begin{aligned}\mathbf{y} = &\{\mathbf{X}_D\mathbf{b}_D + \mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_{D_P}\mathbf{e}_{D_P} + \mathbf{Z}_{D_C}\mathbf{e}_{D_C} + \cdots + \mathbf{e}_D\} \\ &+ \{\mathbf{X}_S\mathbf{b}_S + \mathbf{Z}_S\mathbf{a}_S + \mathbf{Z}_{S_P}\mathbf{e}_{S_P} + \mathbf{Z}_{S_C}\mathbf{e}_{S_C} + \cdots + \mathbf{e}_S\}\end{aligned} \quad (50)$$

where subscripts D and S indicate direct and associative effects, P and C indicate permanent and common-litter effects, $\mathbf{X}$ and $\mathbf{Z}$ denote incidence matrices, and $\mathbf{e}$ the residual. Whether or not a specific model component needs to be included will depend on the data structure. Direct and associative fixed effects may often be fully confounded, so that fitting a single effect is sufficient. For example, group members will usually be in the same herd at the same time. Hence, the direct and associative herd-year effects will be fully confounded, so that fitting a single herd-year effect suffices. In some cases, therefore, the simplest model, $\mathbf{y} = \mathbf{Xb} + \mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_S\mathbf{a}_S + \mathbf{e}$, may be appropriate. (But see the section on "Non-Genetic Associative Effects" below.)

In other cases, however, additional fixed or random associative effects may be required. Consider, for example, a pen of four beef cows, the first individual being a Hereford, and individuals two through four being Charolais. In this situation, fitting both a direct and an associative fixed breed-effect may be appropriate,

$$\begin{aligned}\mathbf{y} &= \mathbf{X}_D\mathbf{b}_D + \mathbf{X}_S\mathbf{b}_S + \mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_S\mathbf{a}_S + \mathbf{e} \\ \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \end{bmatrix} &= \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 1 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} H_D \\ C_D \end{bmatrix} + \begin{bmatrix} 0 & 3 \\ 1 & 2 \\ 1 & 2 \\ 1 & 2 \end{bmatrix} \begin{bmatrix} H_S \\ C_S \end{bmatrix} \\ &\quad + \mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_S\mathbf{a}_S + \mathbf{e}\end{aligned}$$

where H_D and C_D are the fixed direct breed effect of Hereford and Charolais, respectively, and H_S and C_S are the fixed associative breed effect of Hereford and Charolais, respectively. The record of individual 1, for example, contains three fixed Charolais associative effects, because its three pen mates are all of the Charolais breed. When associative breed effects are omitted, they may partly end up in the estimated associative genetic variance. Moreover, when groups consist of mixed sexes, fitting a fixed associative effect for sex of the group mates may be appropriate.

As a second example, consider social interactions in fattening pigs. Because litter-mates may develop similar social skills, fitting a common-litter associative effect is of interest in this case [15]. Consider a pen of 8 individuals originating from three distinct litters; individuals 1 through 3 are born in litter 1, individual

4 is born in litter 2, and individuals 5 through 8 are born in the third litter. The mixed model for this pen is

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_S\mathbf{a}_S + \mathbf{Z}_{C_D}\mathbf{e}_{C_D} + \mathbf{Z}_{C_S}\mathbf{e}_{C_S} + \mathbf{e} \tag{51}$$

$$\begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \\ y_5 \\ y_6 \\ y_7 \\ y_8 \end{bmatrix} = \mathbf{Xb} + \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} a_{D,1} \\ a_{D,2} \\ a_{D,3} \\ a_{D,4} \\ a_{D,5} \\ a_{D,6} \\ a_{D,7} \\ a_{D,8} \end{bmatrix}$$

$$+ \begin{bmatrix} 0 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 0 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 0 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 0 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 0 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 & 0 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 & 1 & 0 & 1 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 0 \end{bmatrix} \begin{bmatrix} a_{S,1} \\ a_{S,2} \\ a_{S,3} \\ a_{S,4} \\ a_{S,5} \\ a_{S,6} \\ a_{S,7} \\ a_{S,8} \end{bmatrix}$$

$$+ \begin{bmatrix} 1 & 0 & 0 \\ 1 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} e_{C_D,1} \\ e_{C_D,2} \\ e_{C_D,3} \end{bmatrix}$$

$$+ \begin{bmatrix} 2 & 1 & 4 \\ 2 & 1 & 4 \\ 2 & 1 & 4 \\ 3 & 0 & 4 \\ 3 & 1 & 3 \\ 3 & 1 & 3 \\ 3 & 1 & 3 \\ 3 & 1 & 3 \end{bmatrix} \begin{bmatrix} e_{C_S,1} \\ e_{C_S,2} \\ e_{C_S,3} \end{bmatrix} + \begin{bmatrix} e_1 \\ e_2 \\ e_3 \\ e_4 \\ e_5 \\ e_6 \\ e_7 \\ e_8 \end{bmatrix}$$

The $\mathbf{Z}_S$ links the record of each individual to the associative genetic effect of its group mates, whereas $\mathbf{Z}_{C_S}$ links the record of each individual to the litter of its group mates. Hence, with groups of 8 individuals, each row of both $\mathbf{Z}_S$ and $\mathbf{Z}_{C_S}$ has a sum of 7, because each individual has 7 group mates. For this model, the variance structures for genetic effects is $\text{Var}\begin{bmatrix} \mathbf{a}_D \\ \mathbf{a}_S \end{bmatrix} = \mathbf{G} \otimes \mathbf{A}$, where $\mathbf{G} = \begin{bmatrix} \sigma^2_{A_D} & \sigma_{A_{DS}} \\ \sigma_{A_{DS}} & \sigma^2_{A_S} \end{bmatrix}$, $\mathbf{A}$ is the usual numerator relationship matrix [27], and $\otimes$ denotes the Kronecker product of matrices. The variance structure of the common-litter effects is $\text{Var}\begin{bmatrix} \mathbf{e}_{C_D} \\ \mathbf{e}_{C_S} \end{bmatrix} = \mathbf{C} \otimes \mathbf{I}$, where $\mathbf{C} = \begin{bmatrix} \sigma^2_{E_{C_D}} & \sigma(E_{C_D}, E_{C_S}) \\ \sigma(E_{C_D}, E_{C_S}) & \sigma^2_{E_{C_S}} \end{bmatrix}$, and $\mathbf{I}$ is an identity matrix of dimension equal to the number of litters. The $\sigma^2_{E_{C_D}}$ is the variance of the (usual) direct litter effects, $\sigma^2_{E_{C_S}}$ the variance of the associative litter effects, and $\sigma(E_{C_D}, E_{C_S})$ the covariance between the direct and associative effect of a litter. Hence, Eq. 51 involves the estimation of six variance components and the residual variance. (See below for the variance structure of the residual). Canario et al. [38] showed that an associative common-litter effect may be required to prevent overestimation of the associative genetic variance in fattening pigs.

Non-Genetic Associative Effects In both above examples, the direct residual effect of the focal individual and the associative residual effects of its group mates have been summarized into a single residual, $e_i = E_{D,i} + \sum_{j=1}^{n-1} E_{S,j}$. This is because the non-genetic parameters $\sigma^2_{E_D}$, $\sigma_{E_{DS}}$ and $\sigma^2_{E_S}$ are not uniquely identifiable when group size is constant [39, 40, 92]. Hence, a model including both E_S and a (direct) residual is overspecified. Nevertheless, non-genetic associative effects have consequences for the variance structure of the residuals. First, the residual variance becomes dependent on group size [39, 92],

$$\sigma^2_e = \sigma^2_{E_D} + (n-1)\,\sigma^2_{E_S}, \tag{52}$$

Hence, when group size varies in the data, it may be appropriate to fit a separate residual variance for each group size. Second, the residuals of group mates become correlated [39, 92],

$$\text{Cov}(e_i, e_j) = 2\sigma_{E_{DS}} + (n-2)\sigma^2_{E_S}, \tag{53}$$

where i and j are group mates. Equations 52 and 53 illustrate that the non-genetic variance components are

non-identifiable because there are only two observable (co)variances in the data, but three unknowns. In other words, there is an infinite number of combinations of $\sigma^2_{E_D}$, $\sigma_{E_{DS}}$ and $\sigma^2_{E_S}$ that yield the same values of σ^2_e and $\mathrm{Cov}(e_i, e_j)$ [15, 39, 92]. (This becomes different when group sizes vary; see below).

Equation 53 shows that the residual covariance may take negative values, particularly when groups are small. In that case, it may be required to allow for correlated residuals within group in the mixed model, using [92] $\mathrm{Var}(\mathbf{e}) = \mathbf{R}\sigma^2_e$, with

$$R_{ii} = 1, \tag{54}$$

$R_{ij} = \rho_e$ when i and j are group mates, and $R_{ij} = 0$ when i and j are in different groups.

This results in a block-diagonal structure for the correlation matrix of residuals, **R**. For two groups of four individuals, for example, the correlation matrix of residuals equals

$$\mathbf{R} = \begin{bmatrix} 1 & \rho_e & \rho_e & \rho_e & 0 & 0 & 0 & 0 \\ \rho_e & 1 & \rho_e & \rho_e & 0 & 0 & 0 & 0 \\ \rho_e & \rho_e & 1 & \rho_e & 0 & 0 & 0 & 0 \\ \rho_e & \rho_e & \rho_e & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & \rho_e & \rho_e & \rho_e \\ 0 & 0 & 0 & 0 & \rho_e & 1 & \rho_e & \rho_e \\ 0 & 0 & 0 & 0 & \rho_e & \rho_e & 1 & \rho_e \\ 0 & 0 & 0 & 0 & \rho_e & \rho_e & \rho_e & 1 \end{bmatrix}$$

The correlation between residuals of group mates equals $\rho_e = \left[2\sigma_{E_{DS}} + (n-2)\sigma^2_{E_S}\right] / \left[\sigma^2_{E_D} + (n-1)\sigma^2_{E_S}\right]$. This structure can be fitted in ASREML using the CORU statement in the description of the R-structure [94].

When groups are reasonably large, the residual correlation is likely to be positive because the $(n-2)\sigma^2_{E_S}$ becomes the dominant term in Eq. 53. In that case, one can account for residual correlations by adding a random group effect to the model and fitting independent residuals [15, 34, 39]. Fitting a random group effect is computationally easier than fitting correlated residuals and is therefore preferable when the correlation between residuals of group mates is positive. This leads to the model

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_S\mathbf{a}_S + \mathbf{Z}_g\mathbf{g} + \mathbf{e}, \tag{55}$$

where **g** is a vector of random group effects, with incidence matrix $\mathbf{Z}_g$ linking phenotypes of individuals to their group, $\mathrm{Var}(\mathbf{g}) = \mathbf{I}\sigma^2_g$, $\mathrm{Var}(\mathbf{e}) = \mathbf{I}\sigma^2_e$, **I** denoting an identity matrix, σ^2_g the between-group non-genetic variance and σ^2_e the residual variance. With Eq. 55,

$$\sigma^2_g = 2\sigma_{E_{DS}} + (n-2)\sigma^2_{E_S}, \text{ and} \tag{56a}$$

$$\sigma^2_e = \sigma^2_{E_D} - 2\sigma_{E_{DS}} + \sigma^2_{E_S} \tag{56b}$$

Note that, in contrast to Eq. 41, the residual variance of Eq. 55 is independent of group size, whereas the between-group variance depends on group size. Hence, when group size varies in the data, it may be appropriate to fit a different group variance for each group size. (But see the section "Accounting for Variation in Group Size" below.)

Ignoring non-genetic associative effects, e.g., by omitting a group effect and fitting a simple residual, may inflate the estimated genetic variance components by as much as 200–300% [39, 40, 92]. In this case, the covariance between trait values of group mates, which equals $2\sigma_{P_{DS}} + (n-2)\sigma^2_{P_S}$, is attributed entirely to the genetic components because the model implies that $\mathrm{Cov}_{\text{group mates}} = 2\sigma_{A_{DS}} + (n-2)\sigma^2_{A_S}$.

Accounting for Variation in Group Size The above has ignored variation in group size within a population, which will be very common in practice. When group sizes vary in the population, merely fitting a fixed effect for group size may not be sufficient because variance components may also differ between group sizes. For example, interactions among individuals may be less intense in large groups, meaning that the associative genetic variance decreases with group size.

When the underlying parameters, $\sigma^2_{A_D}$, $\sigma_{A_{DS}}$, $\sigma^2_{A_S}$, $\sigma^2_{E_D}$,$\sigma_{E_{DS}}$ and $\sigma^2_{E_S}$ are assumed to remain constant, variation in group size requires only modifying the variance structure of the non-genetic part of the model. In the genetic part of the model (Eq. 51), $\mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_S\mathbf{a}_S$, variation in group size is automatically accounted for in $\mathbf{Z}_S$. Consequences for the non-genetic part of the model will depend on the model. When fitting a model with correlated residuals, both the residual variance and the residual within-group correlation will vary among group sizes (Eqs. 52–54). When fitting a model with random group effects, the group variance will be heterogeneous among group sizes while the residual variance is homogeneous

(56 and Eqs. 57). Hence, when the underlying variance components are assumed constant, a model including a random group effect is more easily adapted to account for varying group size.

However, assuming that the underlying parameters remain constant with varying group size is a strong a priori assumption. In many cases, associative effects may become smaller in larger groups because they are distributed over more group mates, a phenomenon known as "dilution" [25, 42, 43]. In principle, one could estimate separate genetic parameters for each group size. However, this would be a waste of information, and require large data sets for each group size. A simpler solution is to scale the magnitude of associative effects by a factor depending on the inverse of the number of group mates (Eq. 11),

$$A_{S,i,n} = \left(\frac{\bar{n}-1}{n-1}\right)^{d} A_{S,i,\bar{n}},$$

where $A_{S,i,n}$ represents the associative effect of individual i when expressed in a group of n members, $A_{S,i,\bar{n}}$ the associative effect when expressed in a group of the average size, and d the degree of dilution. Further details on dilution of associative effects are summarized above in the section "The Effect of Group Size on Heritable Variance".

The degree of dilution can be estimated from data containing variation in group size by using a mixed model with Restricted Maximum Likelihood and evaluating the likelihood for different fixed values of d [25, 38]. Estimates of A_S, $\sigma^2_{A_S}$ and $\sigma_{A_{DS}}$ referring to the average group size may be obtained from the following mixed model [38, 43],

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_{S(d)}\mathbf{a}_{S,\bar{n}} + \mathbf{Z}_g\mathbf{g} + \mathbf{e}, \tag{57}$$

where $\mathbf{y}$ is the vector of observations, $\mathbf{Xb}$ are the usual fixed effects, $\mathbf{Z}_D\mathbf{a}_D$ are the direct genetic effects, $\mathbf{Z}_g\mathbf{g}$ are random group-effects, and $\mathbf{e}$ is a vector of residuals. The $\mathbf{a}_{S,\bar{n}}$ is a vector of associative effects referring to the average group size, and $\mathbf{Z}_{S(d)}$ is the incidence matrix for associative effects, which depends on the degree of dilution. Elements of $\mathbf{Z}_{S(d)}$ are

$$\mathbf{Z}_{S(d)}(i,j) = \left(\frac{\bar{n}-1}{n_i-1}\right)^{d} \text{ when } j \text{ is a group member of } i,$$
$$\mathbf{Z}_{S(d)}(i,j) = 0 \text{ otherwise,} \tag{58}$$

where $\bar{n}$ denotes the average group size, and n_i the size of the group of individual i. This model yields estimates of genetic parameters and breeding values referring to the average group size because the $[(\bar{n}-1)/(n_i-1)]^d = 1$ when $n_i = \bar{n}$.

When non-genetic associative effects depend on group size in the same manner, also the group and residual variance for the model in Eq. 57 will depend on group size [43],

$$\sigma^2_{g,n} = 2\left(\frac{\bar{n}-1}{n-1}\right)^{d}\sigma_{E_{DS},\bar{n}} + (n-2)\left(\frac{\bar{n}-1}{n-1}\right)^{2d}\sigma^2_{E_S,\bar{n}} \tag{59a}$$

$$\sigma^2_{e,n} = \sigma^2_{E_D} - 2\left(\frac{\bar{n}-1}{n-1}\right)^{d}\sigma_{E_{DS},\bar{n}} + \left(\frac{\bar{n}-1}{n-1}\right)^{2d}\sigma^2_{E_S,\bar{n}} \tag{59b}$$

Hence, to obtain unbiased estimates of the genetic parameters and d, it may be required to fit a separate group and residual variance for each group size. An alternative solution is to explicitly model E_S. When group size is constant, the non-genetic parameters cannot be estimated, and a model including both E_S and a residual is overspecified (See below Eq. 53). When group size varies, however, $\sigma^2_{E_D}$, $\sigma_{E_{DS}}$ and $\sigma^2_{E_S}$ may be identifiable (unless $d = 1$), and it may be possible to fit the model

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_{S(d)}\mathbf{a}_{S,\bar{n}} + \mathbf{Z}_{S(d)}\mathbf{e}_{S,\bar{n}} + \mathbf{e},$$

with $\mathrm{Var}\begin{bmatrix}\mathbf{e}_{S,\bar{n}}\\ \mathbf{e}\end{bmatrix} = \mathbf{E}\otimes\mathbf{I}$, where $\mathbf{E} = \begin{bmatrix}\sigma^2_{E_S,\bar{n}} & \sigma(E_D,E_{S,\bar{n}})\\ \sigma(E_D,E_{S,\bar{n}}) & \sigma^2_{E_D}\end{bmatrix}$.

However, it may not be possible to implement the nonzero $\mathrm{Cov}(\mathbf{e}_{S,\bar{n}},\mathbf{e})$ of this model in standard software.

Canario et al. [38] present estimates for the degree of dilution of both associative genetic effects and associative common-litter effects in fattening pigs, with group sizes varying from 5 through 15 individuals. Their results suggest that both effects are fully diluted with group size ($\hat{d} = 1$). Their results also indicate that the estimate of the associative variance may depend on whether or not the analysis accounts for dilution.

Hadfield and Wilson [42] presented an alternative approach to account for the relationship between associative effects and group size. They fit an additional

associative genetic effect that is proportional to the inverse of the number of group mates. Bijma [43] compares their model to Eq. 57, and concludes that it has greater flexibility, but is also less tractable.

Identifiability of the Associative Genetic Variance

Not all data structures are equally suited for estimating the genetic variance of associative effects. A particularly critical aspect is group composition. When groups are composed of equally related individuals, for example, full or half-sib families, then direct and associative effects are fully confounded and cannot be estimated [34, 92, 95]. Also the use of specific distributions of families over groups may cause non-identifiability of the associative genetic variance [92]. Genetic parameters are identifiable when groups are composed at random with respect to family, but the standard error of $\hat{\sigma}^2_{A_S}$ may be large. Groups composed of members of two distinct families yield more precise estimates of $\sigma^2_{A_S}$ (See section "Statistical Power and Optimum Designs" below).

Moreover, the associative genetic variance is not identifiable when a fixed group-effect is fitted [96]. When fitting group as a random effect, however, $\sigma^2_{A_S}$ is identifiable and simulations with normally distributed group effects indicate that estimates are unbiased [92]. Nevertheless, the non-identifiability of $\sigma^2_{A_S}$ when using fixed group effects indicates that the information for estimating $\sigma^2_{A_S}$ is closely linked to variation in the group means, suggesting that estimates may be sensitive to the distribution of group effects. The importance of the group agrees with the observation of Bijma [97], who found that number of groups, rather than number of individuals, is the main determinant of the standard error of $\hat{\sigma}^2_{A_S}$. Cantet and Cappa [96] present methods to investigate whether variance components are identifiable from a particular data set.

Statistical Power and Optimum Designs

Standard Errors of Estimated Variance Components

Optimization of experimental designs and evaluation of the power of experiments aiming to estimate genetic parameters for socially affected traits requires knowledge of the factors determining the standard errors (SE) of estimated parameters. Accurate prediction equations for those SEs are available for balanced designs containing N_f families with n_f members each,

Socially Affected Traits, Inheritance and Genetic Improvement. Table 4 Example of the design with groups composed of two distinct families

	Family B				
Fam. A	2	3	4	5	6
1	2/2	2/2	2/2	2/2	2/2
2		2/2	2/2	2/2	2/2
3			2/2	2/2	2/2
4				2/2	2/2
5					2/2

Group size equals n= 4. Each group consists of members of two distinct families, each family contributing two individuals. Family size equals n_f = 10, so that each family can be combined with 10/(½ × 4) = 5 other families. Thus a block consists of six families, each being combined with each of the five other families in that block. Hence, there are 5*6/2 = 15 groups per block, 15*4 = 60 individuals per block, and $N_t/60$ blocks, N_t denoting the total number of individuals in the experiment.

yielding a total of $N_t = N_f\, n_f$ individuals in the experiment [97]. Two group compositions have been investigated; groups composed at random with respect to family, and groups composed of two families. In the latter design, each group is composed of members of two distinct families, each family contributing ½n individuals. This design leads to a block structure (Table 4), where each of the families within a block is combined with each of the other families in that same block, each combination occurring precisely once.

For both designs, the SEs of estimated genetic variances follows from

$$\mathrm{SE}(\hat{\sigma}^2_A) \approx \frac{1}{r}\sqrt{\frac{2}{N_f-1}\left[\sigma^4_f + \frac{2\sigma^2_f\sigma^2_e}{m} + \frac{\sigma^4_e}{m(m-1)}\right]}, \tag{60}$$

where N_f is the number of families, m the effective number of records per family, σ^2_f the between-family variance, and σ^2_e the residual variance,

$$\sigma^2_e = \sigma^2_z - \sigma^2_f, \tag{61}$$

where σ^2_z is the variance of an "effective record" [97]. Equations 60 and 61 allow prediction of $\mathrm{SE}(\hat{\sigma}^2_{A_D})$, $\mathrm{SE}(\hat{\sigma}^2_{A_S})$ and $\mathrm{SE}(\hat{\sigma}^2_{A_T})$. Application of those Equations requires knowledge of m, σ^2_z and σ^2_f, which

	$\sigma_P^2 = \sigma_{P_D}^2 + (n-1)\,\sigma_{P_S}^2$	
	$\mathrm{Cov}_\omega = 2\sigma_{P_{DS}} + (n-2)\,\sigma_{P_S}^2$	
$\hat{\sigma}_{A_D}^2$	$\sigma_z^2 = \sigma_P^2$	$\sigma_f^2 = r\sigma_{A_D}^2$
$\hat{\sigma}_{A_S}^2$	$\sigma_z^2 = \frac{\sigma_P^2 + (n-2)\mathrm{Cov}_\omega}{n-1}$	$\sigma_f^2 = r\sigma_{A_S}^2$
$\hat{\sigma}_{A_T}^2$	$\sigma_z^2 = n\left[\sigma_P^2 + (n-1)\mathrm{Cov}_\omega\right]$	$\sigma_f^2 = r\sigma_{A_T}^2$

[a]SEs for the estimated genetic variance of interest follow from substituting σ_z^2 and σ_f^2 for that parameter into Eq. 60.

depend on the parameter and experimental design of interest, and are given in Table 5 for schemes with groups composed at random, and in Table 6 for schemes with groups composed of two distinct families.

The SE of the estimated genetic covariance, $\mathrm{SE}(\hat{\sigma}_{A_{DS}})$ follows from

$$\mathrm{SE}(\hat{\sigma}_{A_{DS}}) = \sqrt{\frac{\mathrm{SE}(\hat{\sigma}_{A_D}^2)\ \mathrm{SE}(\hat{\sigma}_{A_S}^2)}{2} + \frac{\sigma_{A_{DS}}^2}{N_f - 1}}, \qquad (62)$$

where $\mathrm{SE}(\hat{\sigma}_{A_D}^2)$ and $\mathrm{SE}(\hat{\sigma}_{A_S}^2)$ follow from Eq. 60.

The SE of the ratio of total heritable variance over phenotypic variance follows from

$$\mathrm{SE}(\hat{T}^2) \approx \frac{\mathrm{SE}(\hat{\sigma}_{A_T}^2)}{\sigma_P^2}, \qquad (63)$$

where $\mathrm{SE}(\hat{\sigma}_{A_T}^2)$ follows from Eq. 60. An accurate prediction equation for the SE of the estimated genetic correlation between direct and associative effects is available only for cases where the true value of this correlation is near zero. Designs with two families per group yield lower $\mathrm{SE}(\hat{\sigma}_{A_S}^2)$ than schemes with groups composed at random with respect to family, except when group size equals two individuals, in which case both designs are nearly equivalent [97].

For designs with group composed at random, the optimum family size for estimating a genetic variance is

$$n_{f\,\mathrm{opt},\sigma^2,\mathrm{random}} \approx \sigma_z^2/\sigma_f^2 \qquad (64a)$$

For designs with group composed of two families, the optimum family size for estimating a genetic variance is

$$n_{f\,\mathrm{opt},\sigma^2,2\mathrm{fam}} \approx \frac{1}{2}\,n\,\sigma_z^2/\sigma_f^2 \qquad (64b)$$

These expressions can be applied for the genetic variance of interest by using the appropriate σ_z^2 and σ_f^2 from Tables 5 or 6. Results of Eqs. 64a and b show that optimum family size for estimating $\sigma_{A_S}^2$ may be very large when group are composed at random and may differ considerably from optimum family size for estimating $\sigma_{A_D}^2$. When groups are composed of two families, optimum family size for estimating $\sigma_{A_S}^2$ is smaller, and more similar to that for $\sigma_{A_D}^2$. Thus the scheme with two families per group may be a good compromise to estimate both the direct and associative genetic variance [97].

Expressions for optimum group sizes for estimating $\sigma_{A_S}^2$ are not available. Numerically obtained results in [97] indicate that optimum group sizes are small ($\leq$3–4) in most cases. Optimum group sizes are large only for designs with two families per group, and only when the number of groups, rather than the number of individuals, is the limiting factor in the experiment. An R-package named SE.IGE is available, which calculates SEs and optimum family and group sizes, and can be downloaded from the repository of R-packages, CRAN, at http://cran.r-project.org/package=SE.IGE, following the usual method to install R-packages.

Future Directions

This chapter has summarized the quantitative genetic theory of traits affected by social interactions among individuals and reviewed the existing empirical evidence for such effects. The theoretical framework is now well developed, both in the field of artificial selection and in evolutionary biology [18, 56, 57]. The theory of genetic variance, inheritance, and response to selection has been developed [17, 31], and statistical methodology to estimate associative variance components has become available [17, 22, 25, 39, 92, 98]. Selection experiments and data analysis provide convincing evidence of substantial associative effects on survival time in cannibalistic laying hens and quail [17, 19, 21, 24, 36, 67, 93]. The evidence is less strong for other livestock species, such as pigs and beef cattle,

Socially Affected Traits, Inheritance and Genetic Improvement. Table 6 Components of SEs[a] with group composed of two distinct families (See Table 4)

Parameter	Expression	
All VC	$m = 2n_f/n$	
	$\sigma_P^2 = \sigma_{P_D}^2 + (n-1)\sigma_{P_S}^2 + 2r\left(\frac{1}{2}n-1\right)\left[\sigma_{A_{DS}} + \left(\frac{1}{2}n-1\right)\sigma_{A_S}^2\right]$	
	$\mathrm{Cov}_{\omega,\mathrm{fam}} = 2\sigma_{P_{DS}} + (n-2)\sigma_{P_S}^2 + r\left[\sigma_{A_D}^2 + 2(\frac{1}{2}n-2)\sigma_{A_{DS}} + (\frac{1}{2}n^2-2n+3)\sigma_{A_S}^2\right]$	
	$\mathrm{Cov}_{\omega,\mathrm{nonfam}} = 2\sigma_{P_{DS}} + (n-2)\sigma_{P_S}^2 + 2\,r(\frac{1}{2}n-1)\left[\sigma_{A_{DS}} + (\frac{1}{2}n-1)\sigma_{A_S}^2\right]$	
	$\mathrm{Var}(\bar{P}_{\mathrm{fam}}) = \dfrac{\sigma_P^2 + (\frac{1}{2}n-1)\mathrm{Cov}_{\omega,\mathrm{fam}}}{\frac{1}{2}n}$	
$\hat{\sigma}_{A_D}^2$	$\sigma_z^2 = (1+\varphi^2)\,\mathrm{Var}(\bar{P}_{\mathrm{fam}}) - 2\varphi\,\mathrm{Cov}_{\omega,\mathrm{nonfam}}\varphi = \dfrac{\frac{1}{2}n-1}{\frac{1}{2}n}$	$\sigma_f^2 = r\sigma_{A_D}^2$
$\hat{\sigma}_{A_S}^2$	$\sigma_z^2 = \frac{4\,\mathrm{Var}(\bar{P}_{\mathrm{fam}})}{n^2}$	$\sigma_f^2 = r\sigma_{A_S}^2$
$\hat{\sigma}_{A_T}^2$	$\sigma_z^2 = \frac{4}{n}\left[\sigma_P^2 + (\frac{1}{2}n-1)\mathrm{Cov}_{\omega,\mathrm{fam}} + \frac{1}{2}n\mathrm{Cov}_{\omega,\mathrm{nonfam}}\right]$	$\sigma_f^2 = r\sigma_{A_T}^2$

[a] SEs for the estimated genetic variance of interest follow from substituting σ_z^2 and σ_f^2 for that parameter into Eq. 60.

where some studies have found large effects [15], but others none or only small effects [25, 95]. Further research is required on those species. Associative effects appear to be very relevant for aquaculture populations as well (see below), but estimates of the associative genetic variance are almost completely lacking at present.

Genetic improvement of associative effects has the potential to contribute significantly to animal welfare because a significant proportion of welfare issues is related to mutual behaviors [99]. Well-known examples are feather pecking and cannibalism in laying hens [100], and fighting after mixing and tail biting in pigs [14]. In the past, genetic improvement of behaviors has been hampered by the cost and labor involved in routine collection of behavioral data. As a consequence, breeding for improved behavior is rare in livestock genetic improvement. The use of associative-effect models offers the potential to solve this problem because they estimate the associative effect from the resulting phenotype without the need to observe the causative behavior. Biscarini et al. [93], for example, identified 81 QTL for associative effect on plumage condition, without observing feather pecking behavior.

Not all welfare problems are related to behavioral interactions among animals. Welfare is also threatened by metabolic stress related to high efficiency of production [4]. Results in quail [17] and in Medaka [101, 102] suggest that a genetic reduction of agonistic behaviors may produce strains that waste less resources on competitive behaviors. This suggests that genetic improvement of associative effects may have the potential to increase the efficiency of production without increasing metabolic stress. Whether this phenomenon is widespread awaits further empirical testing.

Though the statistical methodology to estimate associative variance components is available, application is practice has many pitfalls, particularly in pigs, and careful model comparison is required to assess the stability of the estimates [15, 34, 39, 91]. The omission of random group effects from the statistical model, for example, may yield a strongly overestimated associative genetic variance. Interpretation of early results has been hampered by the lack of a proper theoretical framework to judge the relevance of the estimated associative genetic variance, which is often very small compared to phenotypic variance, but can nevertheless contribute substantially to heritable variance. The definition of

a total heritable variance facilitates interpreting the relevance of associative effects for livestock genetic improvement [31]. If current estimates of the associative genetic variance in pigs and laying hens reflect the true parameters, then selection for associative effects can increase rates of genetic improvement considerably. Particularly in pigs and aquaculture, there is a need for validation by means of selection experiments.

A challenging problem is the improvement of associative effects when populations are kept in large groups, which is increasingly the case. When groups are large, the number of groups is usually small, which hampers the estimation of genetic parameters. Investigation of optimum designs to estimate genetic parameters shows that the number of groups, rather than the number of individuals, is the primary determinant of statistical power [97]. Moreover, in large groups, the intensity of the interactions is probably less, as found in pigs [38], which reduces the accuracy of estimated genetic parameters and breeding values. This issue requires further investigation.

Optimum designs for maximizing response to selection suggest a trade-off between improvement of associative effects and rates of inbreeding. The key factor to increase response to selection is the use of related group members (see above). However, such designs will probably increase the correlation between EBVs of relatives, which in turn increases rates of inbreeding when selection is based on EBVs. Rates of inbreeding can be restricted by using flexible selection algorithms, such as optimum contribution selection [103–105]. Hence, high rates of inbreeding can be avoided, but this may be at the expense of response to selection. This issue has not yet been investigated; it probably becomes less relevant when breeders start using genomic selection (see below and in [106]).

Particularly interesting is the relationship between competition and variability. Breeders have long been interested in increasing uniformity. However, though animal breeders have successfully increased the average performance of livestock, genetic improvement of uniformity has proven difficult. In the classical model, where $P = A + E$, opportunities for genetic changes in variability are very limited [107]. At best, breeders can achieve $\sigma_A^2 \approx 0$, which reduces phenotypic standard deviation by only ~16% when heritability equals 0.3. There is, however, increasing evidence that the environmental variance is under direct genetic control [e.g., 108, 109], and theoretical models for inherited variability have been developed [110–112]. Results suggest a substantial genetic coefficient of variation in the environmental variance, but also a difficulty to obtain reliable estimated breeding values for environmental variance [112].

The mechanisms underlying such inherited variability are largely unknown at present. In aquaculture, competition for feed is believed to inflate size variation among individuals. In carp, for example, Moav and Wohlfarth [16] found greater variability in ponds of mixed genetic strains than in ponds of a single genetic strain. Results in Medaka [101, 102] suggest that behavioral consequences of selection for growth depend on whether or not there is competition for feed in the selection environment. To limit size variation among individuals, regular grading of fish is common practice in aquaculture. Because group selection has the potential to reduce competition among individuals (see above), it seems to be a promising tool for reduction of variability in aquaculture. At present, however, there appear to be no studies on the consequences of group selection for variability in aquaculture. Current models of associative effects (see above) cannot explain a relationship between competition and variability because the phenotypic variance is independent of the average social breeding value. Hence, extension of current models is required to theoretically link variability and competition. The link between competition and variability may, however, largely be an empirical, rather than theoretical, issue.

At present, the use of genome wide marker information is rapidly increasing in livestock genetic improvement. A method know as Genomic Selection [6], which estimates effects of markers covering the entire genome, has become a routine tool in dairy cattle breeding and will soon be adapted by breeders of other livestock species. Genomic selection extends readily to socially affected traits, which seems particularly useful for crossbreeding schemes. A comparison of estimated genetic parameters for direct and associative effects for survival in cannibalistic laying hens shows large differences between purebred parental lines [24] and their crossbred offspring [36]. The genetic correlation between direct and social effects appears to be strongly negative in crossbreds, while around zero in purebreds.

Moreover, estimated parameters differ between reciprocal crosses. Those results indicate considerable "GxE-interaction" between purebreds and crossbreds. Genomic selection based on phenotypes recorded on crossbreds can be used to predict breeding values of nucleus individuals for direct and social effects referring to crossbred performance. Hence, combining genomic selection with associative-effect models seems promising to reduce mortality due to cannibalism in commercial crossbred herds.

Article Outline

Glossary

Competition Refers to the process whereby plants share resources (e.g., mineral nutrients, water, and light) which are in insufficient supply for their joint requirements [71].

Crop structure Refers to the spatial, temporal, and genetic arrangement of a particular crop species or genotype within a sown area.

Density Is the number of individuals of a plant species in a unit of area within a crop.

Facilitation Is the process whereby one crop species provides some sort of benefit for another species when in a polyculture. Usually, when facilitation occurs, at least one crop may positively alter the environment for the other crop [77].

Policulture (also intercrop) Refers to crop arrangements that include more than one crop species or genotypes grown together partially or totally during the growth period of a particular area.

Potential yield Is the crop yield obtained when available resource use is maximized in a particular environmental condition and limiting factors, such as soil nutrients, or reduction factors, such as insect and plant pests and diseases, are absent [41, 78].

Rectangularity Is a measure used to describe the spatial distribution of individual plants in crops sown in rows. It is the ratio of the mean distance between rows and the distance between individual plants within a row.

Resource complementarity Is a measure of the extent to which the crop species components in a polyculture share common limiting resources, i.e., plant components in a crop that show complete resource complementarity do not compete [71].

Spatial arrangement Refers to the way that crop plants are distributed in a field. For example, they may be randomly distributed, when seeds or propagules are randomly broadcast or they may be sown in rows, in a regular pattern when drillers are used.

Definition of the Subject

Crop yields mostly depend on the growth rate experienced by the plant during particular critical periods. The amount of the resources captured and the resource use efficiency determine the growth rate of the crop plants at those crucial stages for yield determination. Since plants stand still in the land, the way they are distributed greatly influence the ability of a crop to capture and use environmental resources (radiation, water, and nutrients), which are necessary for growth and yield. The spatial arrangement of plants and the temporal development of their structures (mainly leaves and roots) define the crop structure. Crop structure may be then analyzed and described in many ways. However, most effort has been concentrated on describing the size and distribution of leaves, which capture the radiant energy, since they are aboveground and easy to measure. The study of yield response to crop structure has conformed to the scientific basis for important technical management decisions and technologies involving crop density, and distance between rows and rectangularity in both mono- and polycultures in various agricultural systems of the world. Crop structure, as a research topic, is one of the few examples in which science dynamically contributes to develop crop management strategies and to guide genetic improvement among crop species. At present, the manipulation of crop structure is not only explored in controlled, semi-controlled, and field

research experiments, but also in mathematical modeling, which evidences the complexity of the interactions that need to be explored and, at the same time, the maturity of the knowledge reached in this area.

Introduction

Crop structure is one of the major determinants of the ability of a crop to capture resources and to produce high yields. It has received much attention from producers, agronomists, and researchers because it is under fairly close control by the farmer in most crop systems of the world. Crop structure is a complex crop attribute, determined by the crop genotype, its sowing date, density (i.e., the number of plants per unit area), and the spatial plant arrangement. Therefore, crop structure in general has a genetic, temporal, and spatial component. However, the spatial component determined by the plant density and spatial arrangement of the plants are largely considered the main modifier of crop resource capture and use and, therefore, a strong determinant of crop yield. For this reason, just for simplicity, in this entry, attention will be centered on the spatial structure of crops, since it would be very difficult to cover all the effects and interactions from other factors, such as temporal ones, in a single entry.

The structural component of a crop may be seen as determining its potential yield in any particular region. Decisions affecting the structure of the crop and so its ability to capture light and other resources may modify the potential yield of the crop. The potential yield is the yield attainable by the crop when its growth is only limited by the radiation and carbon dioxide available, and so is only affected by the temperature of the site and the crop structure. Crop structure factors may directly (for example, in the case of density) or indirectly (for example, in the case of the genotype sown, due to its length or appropriate sowing date) modify the potential yield of a crop. Although actual (real) yields harvested may usually be lower than potential yields due to the effect of limiting (i.e., water or nutrients) and reducing (i.e., diseases, pests, and weeds) factors [78], the interaction of crop structure with environment and other crop management decisions are crucial to produce high yields efficiently.

Most crops in mechanized agriculture are sown in monocultures, i.e., single-species stands are grown every growing period in the same region. However, in most subsistence and few mechanized modern agricultural systems, crops are sown in polycultures, i.e., more than one species are grown in the same area during each growing period. Crop structure characteristics are crucial in determining crop yield responses both in single species and polycultures. Usually, the interest was concentrated in defining the relationships between density and crop yield quantitatively in order to establish optimum crop populations and maximum attainable yields under various situations. As a result, the effect of density on crop productivity in mono- and polycultures has been deeply studied since mid last century [22, 34, 82]. However, due to the high contribution of single-species crops to grain crop production, the study of spatial crop structure determinants has called the attention of researchers all over the world, particularly under this modern and technologically advanced crop production system.

Crops in monocultures are usually heavily selected for uniformity so that most individuals are genetically and phenotypically similar or even identical because of the uniformity of seed size and the fact that sown seeds tend to germinate synchronously. In such crops stands, intraspecific competition (competition between plants of the same species) may be intense and is largely the process commanding crop responses and yield. When in polycultures, intra- and interspecific competition together with resource complementarities or facilitation processes determines yield of each crop species in the stand. For most of the modern agricultural systems, plant competition is therefore the ecological process largely determining the yield response to spatial crop structure arrangements.

Crop density largely determines interplant competition causing a reduction in survival, dry-matter growth, and grain yield of individual plants. Despite the fact that interplant competition causes a negative effect in the individual plants, the management of crop competition through density selection may allow maximum yields per unit area to be achieved. Identifying and understanding crops yield-density response allow researchers to predict the effect of crop management practices on yield and help farmers, agronomists, and consultants to properly design crop production structure under various ecological conditions. Spatial arrangement also determines not only interplant

competition at any density (since it may modify the competition between plants within a row with respect to plants in different rows) but also resource use efficiency. Therefore, crop-plants arrangement or crop structure affects intraspecific competition and resource use efficiency, allowing a full or partial use of available resources and how they are transformed during the various stages of crop growth. In this entry, I will discuss how density and spatial arrangement affects crop functioning and how some environmental conditions or crop management decisions may affect those relationships. Most of the information comes from crops in monocultures, but the performance of these spatial components of crop structure in polycultures will be also briefly addressed.

Ecophysiological Basis of Response to Crop Structure

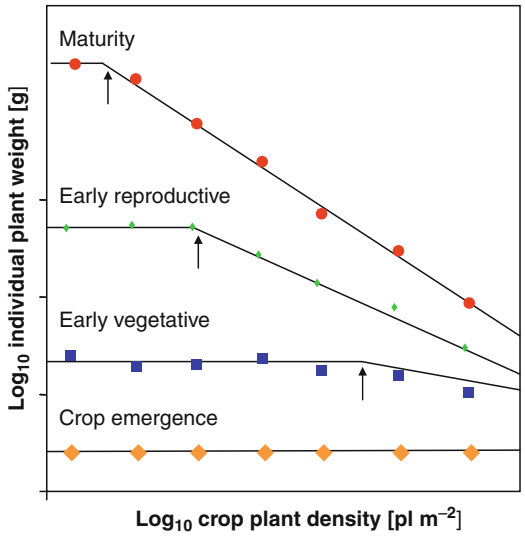
Resource Use and Dry-Matter Production

Crop dry-matter production under potential conditions is determined by the intercepted solar radiation and the radiation use efficiency of the crop canopy. From both aspects, crop density mainly affects the ability of the crop to intercept radiation (or to capture the light resource, from an ecological perspective) since there is little evidence on the effects of density on resource use efficiency. However, spatial arrangement may modify both the capture and use efficiency of resources [42, 83].

It is known that much of the incident solar radiation is not available for annual crop species growth during the early stages, due to the fact that low leaf area expansion determines low light interception. At early crop stages, increasing density may contribute to increase Leaf Area Index (LAI) of the crop (i.e., the green leaf surface per unit of area) and the amount of light intercepted. For this reason, there is a strong positive, although nonlinear, relationship between density, LAI, and the proportion of the incident light that is intercepted in early stages of crop development. When the crop grows, light resource capture increases as leaves expand and LAI increases, and a nonlinear relationship establishes among both variables. Although density may modify the number of leaves, particularly at early crop stages, the relationship between density and leaf area becomes weak when the crop advances in its development. Improving plants spatial distribution (for example, by changing the distance between rows) may also help to intercept more light at early stages of crop growth, when Leaf Area Index (LAI) values are low. To illustrate these points, early results from Puckridge and Donald in wheat [56] clearly showed that density manipulation in the range 1.4–1078 pl/m^2 could successfully increase light interception of wheat crops under the Western Australia conditions. The greater proportion of intercepted light in high-density crops explained most of the differences in early crop growth rates calculated from the results of that research; i.e., early crop growth rates were greater in crops sown at the higher densities. Similar results were also obtained with other crops, such as those reported in recent experiments for maize (e.g., [79], soybean, and sunflower [76]. There are experimental evidences that increasing density not only improve light capture early in the season but also the uptake of soil resources such as water [75]). For example, in a Mediterranean environment, high crop-sowing densities contributed to reduce soil evaporation and to increase biomass production and water use in the early phases of wheat growth [16].

During the early stages of development, competition among small crop plants may be evident only at very high densities; therefore, young individual plants tend to have similar dry-matter production, while crop productivity per unit area tends to increase linearly with density. Plotting the logarithm of plant dry matter against the logarithm of density as suggested by Kira et al. [39] helps to show the way individual plants and crops would tend to respond as they grow (Fig. 1). It is clear from the figure that, as time goes by and crop development progresses, plants increase in size and leaf area, and the onset of competition is evident even at low densities; i.e., individual plant size is continuously reduced as density increases above a density threshold (Fig. 1, see arrows). As plant size increases, crop growth rate may depend more on resource availability than on plant density; therefore, crop growth rates may be only influenced by density if plant number is below the competition threshold. This density threshold varies according to the crop or genotype characteristics and the environmental conditions.

For any crop, when crop stands are above the threshold density, LAI tends to allow full light interception and



Spatial Crop Structure in Agricultural Systems. Figure 1 Influence of density on individual plant weight at various stages of crop development, following Kira et al. [39] proposal. *Arrows* indicate competition thresholds at the various crop stages (see text for details)

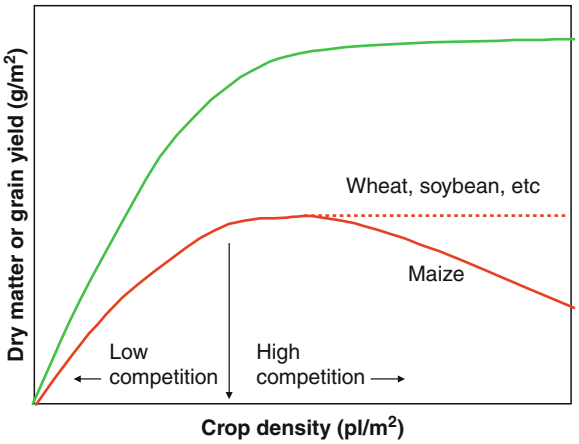
use of the available resources; therefore, crop growth rate will be maximum for the set of environmental conditions explored by the crop. At this stage, any crop density above the competition threshold (Fig. 1) would maximize crop growth rate per unit area. Sustaining maximum crop growth rates is important for high yields to be obtained, especially when that occurs during the critical period for yield determination of the crop.

The phenological period that is critical for yield determination varies among species; i.e., the period when reductions in crop growth rate significantly reduce grain number or yield depends on the species considered. For example, for wheat, it extends from the beginning of ear growth to the beginning of grain growth [29, 68], but for maize, it is considered to be centered 15 days before and after crop silking [3]. High crop yield per unit area would then be expected when crop structure, density, and plant arrangement have been suitable for the crop to reach 95% light interception, which allows maximum crop growth rate when non-limiting or reduction factors are present, before the beginning of the critical period and during it. Environmental and management practices such as fertilizer application or disease control could alter the crop yield-density response, altering the density above which crop growth rate is maximum.

In general, crop structures are aimed to use above- and belowground resources completely, allowing the crop to maximize its growth rate during critical stages. However, it has to be mentioned that increasing early resource capture through great plant densities may not necessarily maximize growth rate at critical crop stages. For example, large quantities of water use by a crop in the early phases of growth may reduce soil-water availability late in the season, leading to biomass yields similar to those obtained with lower plant densities [20, 51]. In temperate subhumid areas, this pattern of crop water use may led to reduce crop sowing rates, as in wheat in the southern pampas of Argentina [32] or the semiarid Brown soil zone of Canada during dry years [45].

Due to the relationship described in Fig. 1, the total shoot weight of a crop per unit area of land usually increases asymptotically as density increases (Fig. 2). Therefore, the performance of crops sown at low densities may depend on their ability to compensate for low plant populations by producing more tillers, branches of bigger leaves. Tillers offer vegetative plasticity in the case of barley or wheat, while branches do so in the case of soybean. Crops that do not produce tillers or branches may express some vegetative plasticity by altering leaf size or height as in the case of maize or sunflower. Moreover, in some crops, the dry-matter asymptote in Fig. 2 extends over a wide range of densities, due mainly to the large plasticity of individual plant size which determines that mean plant weight declines to exactly compensate for increases in density; i.e., proportionate reductions in plant weight occur as densities increase above the normal sown density [22, 35, 69]. Examples of such phenotypic plasticity may be found in crop species, such as wheat, soybean, or barley. Forty-fold differences in plant weight have been reported to occur between widely spaced wheat plants and plants growing in stands at normal seed rates [9, 56].

The supply of limiting resources and the genetic ability to capture and use them largely determine the maximum total biomass yield per unit area of any particular crop in a particular environment [82]. Environmental factors such as temperature or daylength, which may affect the length of the growing season, can also



Spatial Crop Structure in Agricultural Systems. Figure 2 Influence of density on crop dry matter (*green line*) and grain yield (*red line*). Low and high competition range is indicated, together with the expected response of yield to density in maize (*solid red*) and wheat or soybean (*dotted red*)

affect maximum shoot weight (Potential yield) by modifying the ability of the crop to capture resources. For example, in the case of wheat, a crop with large vegetative plasticity (see Fig. 2), long days at high latitudes reduce wheat tillering, which determines that sowing rates of 500–700 pl/m^2 are commonly used for spring wheat crops in places such as Finland [55] in contrast with the 200–300 pl/m^2 used in temperate areas. In some cases, the relationship between density and total shoot weight per unit area is better described by a parabolic model; i.e., there is a distinct maximum yield at a particular density, and shoot yield declines as density increases above this point. In these cases, it is expected that crowding reduces the efficiency of the crop to capture or use environmental resources [22].

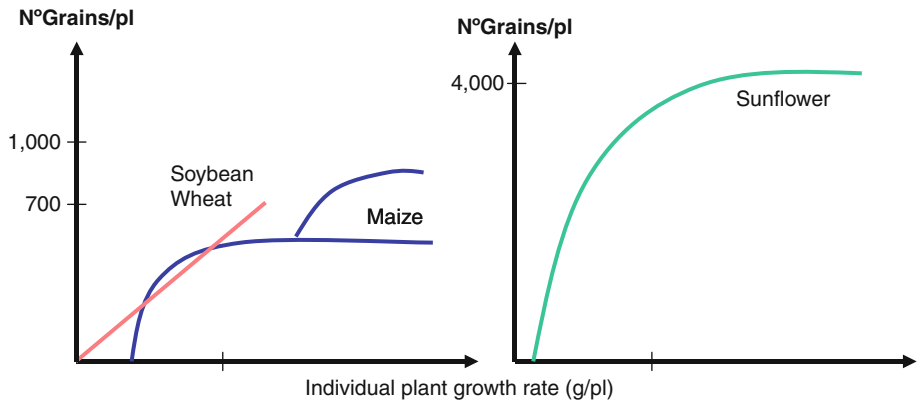
Grain Yield Production

Grain yield increases as density increase up to a value which determines maximum use of available resources (i.e., at suboptimal densities). However, performance of yield at supraoptimal densities may vary among species. It has generally been accepted that the response to density of harvest or storage organs (e.g., grains) is better described by a parabolic model [35]; i.e., grain yield decreases at higher or supraoptimal plant densities due to the fact that the allocation of resources to storage organs or grains is greatly altered by competition [34]. In general, the proportion of the total biomass allocated in the grains, i.e., harvest index (HI), declines progressively with increasing density [23]. Despite the fact that parabolic responses are generally accepted for grain yield–density relationships, some studies indicate that yield–density relationships for grain may sometimes be better described by asymptotic models (e.g., [38, 43]). In this case, the range of densities that maximize grain yield could be wide and strongly dependent upon crop genotype and environmental characteristics.

When crop plants are under severe competition due to relatively high crop densities, they show a reduction in individual growth rate. This will markedly affect grain number determination of any grain crop, particularly if the per plant low growth rates occur during its critical period. Therefore, shoot growth may become less affected than grain yield, causing a reduction in harvest index. Crops such as maize, with low reproductive plasticity, may experience severe grain yield reductions at high crop densities, mainly under limiting environments, such as with low water availability. Grain yield reductions at supraoptimal densities depend on how crops determine yield. In most grain crops, the number of grains per plant, firstly, and per unit area, lately, is strongly related to yield. However, the relationship differs between crop species (Fig. 3).

In the case of maize and sunflower, a minimum plant growth rate is necessary to fix grains, and the relationship is not linear, while in the case of soybean or wheat, it is linear, and the minimum plant growth rate necessary to fix grains is very close to zero (Fig. 3; [5, 79]). It is clear from much data that the number of grains fixed per unit area is the main factor controlling the grain yield-density response of grain crops and, since number of grains determination varies between species, density rules and decisions have to be carefully explored in any particular case. In high-yielding environments or cropping systems (i.e., with irrigation and high fertilizer rates), it appears that large plant populations will determine large number of grains per unit area and high yields.

Low seeding rates or low crop stands may be compensated by the contribution of tillers or branches. Therefore, in low-density crops, either tillering, branching, or the reproductive plasticity of the species is an



Spatial Crop Structure in Agricultural Systems. Figure 3
Expected relationship between the individual grain number and growth rate of four grain crops

essential component in determining the number of grains per unit area at harvest. However, tillering and branching have been recognized as complex phenomenon, controlled by endogenous (genetically) and environmental factors [60]. It has been accepted that a large number of tillers or branches are produced by plants when the availability of resources is high. However, recent studies have found that light quality may affect tiller or branch responses. Light composition with low Red/Far Red ratio in a crop canopy reduces tillering or branching of individual plants [13]. These results indicate that, within a wide range of resource availability, photomorphogenic reactions mediated by light quality may also affect responses to various crop structures. Therefore, density and plant arrangement responses will ultimately be the result of the interaction between resource-based and non-resource-based environmental signals.

High density in crops may produce adverse agronomic effects, such as lodging or higher susceptibility to pest or disease damage. Although different plant densities may have little effect on carbon photoassimilation in top plant structures, including reproductive structures, high densities may tend to reduce partitioning to the stem internodes and to increase leaf senescence among other effects [61, 80, 81]. For example, when stems export photoassimilates due to high competition pressure by crop plants, the rate of leaf senescence is increased and basal nodes weaken, which contributes to increase lodge susceptibility and to reduce grain yields under high sowing rates.

Crop Structure Responses in Monocultures

The Effect of Soil Resources

As mentioned above, the supply of limiting resources, i.e., water, light, and nutrients may affect the form and parameters of the biomass and yield–density relationships, largely through their effect on the maximum yield per unit area that can be achieved at very high densities. Resources have little effect on the yield of widely spaced plants, i.e., yield per plant at very low densities, since in that case, biomass and yield productivity is limited by the possibility to capture resources due to the low-density crop structure. For example, nitrogen fertilizer applications tended to increase maximum wheat yields per unit area under field conditions, but only slightly affect the maximum yield per plant when plants were sown widely spaced [9]. However, in most agricultural conditions, the response to density is dependent upon the supply of limiting resources since it is competition for limiting resources the driving process in crop stands. Generally, increasing the availability of soil resources through fertilizer applications (nutrients) of irrigation (water) will relax or reduce the interplant competition so that the environment may support a higher number of plants. This will be so if the addition of a limiting factor does not affect the competition or availability of other competition factor; i.e., increasing the availability of soil resources, such as water or nitrogen, may reduce competition for soil factors, but it may increase competition for aboveground resources, such as light [22].

Nitrogen, a major soil limiting factor, strongly interacts with density in most grain crop species [70]. The optimum density and, therefore, the maximum grain yield tend to be greater by increasing nitrogen applications if nitrogen is a yield limiting factor. For example, optimum maize crop density tends to be higher as nitrogen [47, 49] or water [3] availability increases. When supplies of the major limiting resource (either water or nitrogen) are made, the crop system might be enabled to sustain a higher crop density and hence a greater grain yield. Since individual plant growth is reduced as density increases within the range of crop densities that allow maximum grain yields, the overall demand of growth resources per unit of area will tend to be similar; therefore, the nitrogen application rate or water provision required will tend to be similar between the lowest and highest density that allow maximum yields [59].

Nitrogen or water availability have a great impact on early vegetative growth by promoting plant tillering or branching, or by increasing leaf area and its activity; However, while this increases the shoot weight of the crop plants in most species, it may reduce the harvest index, particularly at high crop density (see above) if resources during the critical period of yield determination are scarce.

Crop species and genotypes within species may present different responses to density at various soil resource conditions. Differences are usually associated to the way resources are partitioned between vegetative and reproductive structures within the plant, to the ability to produce tillers or branches, and to the morphological and geometrical characteristics of their canopies. Sowing date and plant arrangements may modify the performance of the plants under various crop structures by altering the phenotypic plasticity of the crops.

The Effect of Plant Arrangement

Among the management factors that determine crop structure and that may affect crop yield–density relationships, the planting arrangement of the crop is the most important. Plant spatial arrangement, usually the distance between rows, is under close control by farmers. At any given crop density, sowing patterns can be considered random, clumped, or regular; extensive and mechanized grain crops are normally sown in rows, i.e., in a clumped arrangement, although in some cases regular patterns may be found. Historically, planting arrangement in a crop was determined to allow mechanical weed control or other labor, i.e., to let the tractor, the animal, and the tool to do its labor on the weeds between rows of the crop. However, in various parts of the world, herbicide technology and the tolerance of modern genotypes to herbicides have allowed modifying planting arrangements since no secondary, mechanical weed control labors are necessary. The planting arrangement of crops is often described by its "rectangularity," i.e., the ratio of the distance between rows to the distance between plants within a row. In general, crop yield tends to be the greatest, at any density, if the plants are arranged regularly, i.e., the rectangularity is 1 [10, 30, 33, 36, 53]. However, the effect of planting arrangement is often not significant if densities are at or above those required to achieve maximum use of resources and yield [3, 10, 50]. The extent to which rectangularity affects the yield of a crop is dependent on the plasticity of the individual plants of any particular genotype, variety, or hybrid and the environmental conditions. Grain crops yield patterns are not consistent through literature when rectangularity is analyzed. In maize crop, [17] found that contrasting crop genotypes regularly sown in narrow rows (38 cm between rows) produced significant higher yields than crops in a more rectangular pattern (70 cm between rows) in 2 years. They observed that crop growth rate was higher early, and light interception was greater at the critical period of maize (flowering) when crops were sown regularly spaced. However, Cirilo [20] found no significant differences between maize crops sown at 52 vs 70 cm between rows, since at the critical period of yield determination (see above), crop growth rate was similar among cropping patterns. Similarly, in the case of wheat crops, Holliday [36] reported yield increases between 8% and 33% due to reducing row spacing from 20 to 10 cm. In the case of wheat crop, most research worldwide has shown that closer row spacing (15–18 cm) gave higher grain yields than wider row spacing (usually greater than 23 cm; [32, 54, 73, 52]), though a few experiments showed that wider row spacing did not result in wheat yield losses [40]. Differences in cycle length among varieties or sowing dates may help to explain such results, as in the case of soybean in the

Southern Pampas. When long-cycle soybean varieties are sown, no yield differences between various row widths may be found (i.e., 52 vs 35 cm between rows). However, when short-cycle soybean varieties are sown, yields tend to increase consistently as distance between rows is reduced. Similarly, consistent yield increases are found when soybean varieties are sown late in the season at narrow rows, while no differences may be found, particularly in long cycle varieties, at optimum sowing dates among various row distances.

Planting arrangement may be used in crops to overcome water plant stress. For example, in the case of wheat, in some subhumid areas with late water stress periods, wide cropping patterns (for example, 52 cm between rows) proved to be more stable and productive than narrow ones, mainly due to a better water use efficiency in those environments. This sowing pattern is presently used in the low-producing areas of the Northwest of Argentina under a monsoonal climate. However, also in wheat crops, several experiments reported that there was a consistent yield depression at low sowing rates as rectangularity was increased [10, 26]. In some other cases, wheat crop yields per unit area gradually declined as rectangularity increases either by increasing plant density or increasing row width, though yield declines at high density were greater than at low-density crops [82]. When crops have enough phenotypic and reproductive plasticity, results are consistent in showing that there are better possibilities to equal high-density crop yields if low-density crops are sown in a square pattern; i.e., a better plant spatial distribution may promote grain yield advantages when crops are sown at low density rather than at high density.

The reported evidence suggests that any advantage derived from spatial arrangement is brought about by improving crops ability to exploit available resources (e.g., [84]). Low rectangularity crops increase yield due to the its effect on (1) improving the capture of incident radiation, particularly in early crop stages; (2) allowing the crop to reach 95% light interception during the critical period of yield determination (see above and [4]); (3) improving resource use efficiency, for example, water use efficiency by reducing water-soil losses through direct evaporation; and (4) improving weed control or reducing weed competition. Therefore, it may be also inferred that positive effects of improving plant arrangement by reducing rectangularity is particularly important when productive conditions may reduce plant growth due to limiting factors (i.e., low-resource availability, late sown crops under short growth periods, short cycle varieties, etc.) and when environmental or management conditions may affect crop resource capture during the critical periods.

Rectangular, more clumped, arrangements possibly cause an early reduction of crop growth rate, which in some cases may delayed or even avoid use of distant resources. On the other hand, as mentioned above, reducing the distance between rows and rectangularity and increasing plant density contributes to rapidly exploit resources by intercepting more light or capturing more water or soil resources which in most crops enhance the competitiveness of the crops against weeds [8, 31, 58, 65, 66, 72]. For example, Solie et al. [72] concluded that wheat yield increases of 18% could be obtained when row spacing was reduced from 23 to 7.5 cm when cheat (Bromus secalinus)-free and cheat-infested fields were evaluated. Similarly, [14] found that weed yield reduction was lower when soybean crops were sown at narrow rows than when they were sown widely spaced. Conversely, weed production increases with increasing weed density, or by increasing crop rectangularity or by reducing crop density. For example, Felton [28] found that increasing the row spacing in soybeans from 50 to 100 cm increased weed yield 3.5 times.

Mathematical Relationships Between Plant Yield and Density

Since density is a main determinant of crop structure responses, mathematical models have been proposed for interpreting and predicting the effect of density on yield. Interest in quantitative relationships between crop yield and density was largely stimulated by the need to clearly define optimum sowing densities for crop production. Such relationships should, ideally, take account of environmental factors, such as limiting resources, or spatial arrangement (rectangularity) which may affect the response to density. Willey & Heath [82], Mead [46], and Ratkowsky [57] among others made a comprehensive review of the various models used to describe yield–density relationships pointing out the advantages and disadvantages of the

various mathematical functions proposed. Several types of equations have been described, but only the so-called reciprocal equations for yield per plant have proved to be satisfactory for a wide range of crops and conditions. Some forms of the reciprocal equation that have been proposed are:

$$\text{Yield} = \text{density}/(\text{a} + \text{b}^{*}\text{density}) \quad (1)$$

In Eq. 1, yield is the shoot or grain yield per unit area and density is number of crop plants per unit area, and "a" and "b" are parameters of the equation. This is the simplest equation and describes only the asymptotic model; i.e., yield increases asymptotically toward a maximum yield as density increases. A basic form of Eq. 1 was first proposed by Shinozaki and Kira [69], and its beauty relies on the fact that parameters ("a" & "b") have biological meaning [82]. In this equation, parameter "a" is the reciprocal of the yield per plant (w^{-1}) when a crop genotype is sown at an infinitely low density, i.e., it is an estimation of the yield of wide-spaced plants, in competition-free conditions. This may be regarded as a measure of the "genetic potential" of individual plants of the crop. The fitted value of "a" indeed largely depends on the genetic characteristics of a particular genotype. If the yield–density relationship is truly asymptotic, parameter "b" is inversely related to the value of the asymptote, i.e., the maximum yield per unit area at very high densities; Willey & Heath [82] regarded this parameter as a measure of the "environmental potential," i.e., as an estimator of the maximum crop yield that can be attained in a particular environment and crop production system.

Other reciprocal equations incorporate a third parameter so that they can also describe parabolic yield–density relationships, i.e., the possibility of a reduction of shoot or grain yield at high densities. For example, Holliday [35] proposed the expression:

$$\text{Yield} = \text{density}/\left(\text{a} + \text{b}^{*}\text{density} + \text{c}^{*}\text{density}^{2}\right) \quad (2)$$

In Eq. 2, the quadratic term accounts for parabolic relationships; if the parameter "c" is equal to 0.0, then the equation reduces to that of Shinozaki & Kira [69]. Similarly, Farazdaghi and Harris [25] proposed the expression:

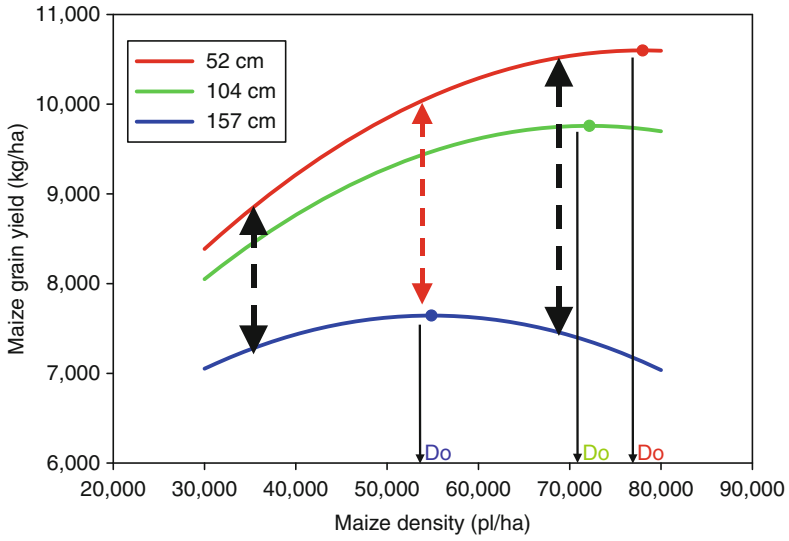
$$\text{Yield} = \text{density}/(\text{a} + \text{b}^{*}\text{density}^{z}) \quad (3)$$

Like in Eq. 2, this becomes identical to Eq. 1 when $z = 1$.

In spite of the good fit provided in several cases by these mathematical approaches [57], the reciprocal equations have some statistical limitations. However, novel statistical techniques, using data transformation and nonlinear procedures, have improved the statistical treatment of these models [57].

For modeling purposes, the response of crops to plant density should be also defined in terms of the spatial arrangement of the plants. Few researchers have intended to distinguish between density and plant arrangement (rectangularity) when modelling crop response, since usually responses to different densities have been studied at a constant row width. Although the extent to which spatial arrangement may affect the yield of crops is strongly dependent on the plasticity of the genotype [82] and the availability of environmental resources (see above), it appears to be important to consider the effect of rectangularity on the yield-density equations, particularly when crops may be sown at various densities and distances between rows. In these cases, equations should be able to describe the effects of density as well as those of rectangularity. For this purpose, it has been proposed to include intrarow and interrow spacing (rectangularity) as variables in Eqs. 1–3 [82]. However, there has been insufficient research on the effect of rectangularity on yield-density responses, and the yield-density-arrangement equations have been only tested on wheat and maize crops in few cases. Recently, Satorre [64] suggested that optimum density decreases as rectangularity increases in maize crops sown at 53, 104, and 157 cm between rows (Fig. 4). Moreover, and more important, the authors found that the magnitude of the yield increase obtained due to improving plant arrangement, by reducing rectangularity or the distance between rows, was greater in high-yielding environments than in low yielding, since vegetative growth at early crop stages was unaffected.

The reciprocal equations have proved to be robust and provide a tool to describe asymptotic or parabolic yield–density relationships. However, despite these efforts to describe the effect of crop structure on crop yield, there is still a huge work to be done since, also for modeling purposes, the response of crops to plant density should be also defined in terms of the planting



Spatial Crop Structure in Agricultural Systems. Figure 4
Yield density response in maize crops sown at 52, 104, 157 cm between rows. Optimum density (Do) at each planting arrangement is indicated by solid vertical rows. Optimum density (Do) decreases 214 plants/ha for every centimeter of increase in the distance between rows above 52 cm. Nonsolid vertical *arrows* indicate the magnitude of resource reduction found between extreme plant arrangements due to plant rectangularity increment

arrangement and management, and environmental conditions that may modify them. In this case, the effect of environmental conditions on the performance of the yield-density model parameters also needs to be described.

Crop Structure Responses in Polycultures

Crops, in developed countries, are normally grown in single-species stands or monocultures. As was discussed above, in such crop structures, there is little or no interspecific competition, but usually intense intraspecific competition. However, in the tropics and at present in some temperate areas, mixed crops are very common [7]. The concept of mixed crop or polycultures refers to the practice of growing more than one specie or genotype in the same land at the same time [6]. In such polycultures, competition occurs between plants of different species or genotypes, as well as between plants of a single genotype. In this general concept, the space and time component of the mixture allows the recognition of a whole gradient of intensity of interactions among component crops. For example, crops may be sown in sequence, i.e., a second crop is sown in the growing period immediately after a first crop is harvested, or partially or totally overlapped (i.e., two or more crops are sown and grown simultaneously in the same field). Similarly, crops may be sown in strips or in alternate rows. As the overlap of time or space between individuals of the various crop species increases, the opportunity to capture positive interactions among crop components also increases if they complement or facilitate the use of environmental resources. By this means, mixed crops or polycultures have showed some evidence of greater yield, greater stability of yield, and lower pest and disease damage than monocultures [1, 2]. Particularly, mixes of legumes and non-legumes species have shown greater yield when sown together than when they are sown alone [74].

Mixed crops are far less common in temperate areas under mechanized agricultural systems than in tropical subsistence farming [37]. However, recent biotechnological advances which helped to improve weed control with the use of previously nonselective herbicides in crops such as soybean, maize, and sunflower has opened new alternatives for the development of polycultures in extensive grain crops. For example, this increasing

interest in exploring the performance of mixtures of cultivars and species in modern, mechanized grain-cropping systems has been slowly expanding in some regions of the Pampas. In the Argentinean Pampas, one of the most productive areas of the world, mixed grain crops may be found in various patterns depending on the component crops species, the degree of temporal overlap among species, and on the spatial arrangement and relative density of the plants [62, 85].

Within the concept of polycultures, successive crops is defined when two or more species are grown in the same land in the same cropping or calendar year but without any overlapping; i.e., a second crop is sown immediately after harvesting the previous crop. In this plant arrangement, the use of resources is intensified per unit of time when compared to a single crop per year, but the interaction between crop species is reduced to the interference produced by the use of resources by one species on the resources available to the following crop [6]. As mentioned before, in the Pampas, nearly three million hectares are sown every year in a successive crops planting pattern. Wheat/double-cropped soybean, maize, or sorghum, and Barley/double-cropped soybean are examples of such extensive crops planting arrangements. In such systems, wheat crop structure (variety, density, distance between rows, and sowing dates) remains unaffected, while the soybean structure is usually modified by reducing the distance between rows and by increasing the plant density [11, 19, 67]. Wheat/double-cropped soybean, the more extensively used successive multiple-crop pattern, has proved to be more productive in terms of total yield and income per hectare and less variable than either sole wheat or sole soybean crops in the same unit of land.

As previously mentioned, the term intercrop is applied when two or more species or genotypes are grown simultaneously during part or the whole crop growing period in the same land. Intercrops are also used in the Pampas in a wheat/soybean mixture when the soybean growing period left by the wheat is short enough to affect its productivity, i.e., the yield of the second crop. In the case of such intercrops, the wheat (winter crop) and the soybean (summer crop) crop structures are both modified. The soybean is sown in spaces previously unsown with wheat, usually after wheat flowering and well before it is harvested. In wheat/soybean intercrop, wheat crop is sown in rows widely apart (for example, at 52 cm between rows) or in a variable spatial pattern, some rows are left unsown, and others follow the usual planting pattern for the region (i.e., 17.5 or 19 cm between rows; see Pictures 1 and 2). In intercrops, the soybean varieties are frequently sown at 52, 38, 35, or 19 cm between rows. Therefore, one row of wheat remains unsown in every three rows when at 17 cm between rows (i.e., 66% wheat, 100% soybean), or 1 every other row is sown when the wheat is at 19 cm between rows (i.e., 50% wheat, 100% soybean). Since the wheat plants tend to compensate with a higher vegetative and reproductive growth in the absence of crop plants, wheat yield is reduced by only 20–25% when compared to 100% monocultures (e.g., [24]). Successive and partially overlapped winter–summer intercrops increase the radiation use efficiency [86] and the weed and soil erosion control. However, it increases management complexities and requires well-trained people to conduct mechanized operations.

More recently, summer–summer crop species intercrops have been also evaluated in mechanized temperate agriculture. Intercrops of soybean in maize crops or soybean in sunflower crops have been evaluated at commercial fields in various regions of the Pampas in Argentina [18, 19]. The release of transgenic glyphosate-resistant soybean and maize has been crucial to explore this planting arrangement at commercial fields. Similarly, biotechnology and the release of imidazolinone resistant sunflower have been crucial to explore sunflower–soybean intercrops. A less complex intercrop may be obtained when each crop species is sown in wide strips in the field. Some yield and pest control advantages have been reported in maize–soybean strip patterns, although they are dependent on the width of the strip and its orientation, among other factors [48]. It is well documented that yield advantages (greater grain yield and yield stability) were often found when, particularly, grass and legume crops were mixed [74] mainly due to the complementary use of belowground resources. In such cases, it has been proposed that legume plants may use both soil and atmospheric nitrogen, while grass species may only use soil nitrogen; in such circumstances, both species complementary use nitrogen. However, it has also been proposed that in some cases, atmospheric nitrogen

previously fixed by the legume species may be transferred to the belowground environment of the grass species. In such cases, growth of grasses in the presence of legumes tends to be greater than when they are alone. In this case, facilitation tends to be the dominant process. It has been also found that the incidence of pest and diseases have sometimes been reduced when species or genotypes are grown in mixtures [12, 27, 77]. Such advantages may support the interest and promote the increase of area sown with more complex crop structures.

Future Directions

Attaining high yields per unit area requires that individual crop plants may usually experiences a competitive stress. Therefore, highly productive crops depend on crop structure by controlling the amount of resources used and their use efficiency which will determine the extent of competition experienced by the crop plants. In this respect, the discussion in this entry has deliberately concentrated on the effect of density and plant arrangement on crop growth and yield determination, and it has avoided any discussion on the effect of crop structure on the mortality of plants since this hardly occurs, at least as a density dependant process, in most crop production conditions. Interpreting the response of crops to crop structure from an ecophysiological and ecological approach was aimed to help construct a framework in which the temporal and spatial aspects of crop structure may be understood. Plant functional responses, determining individual species' requirements and critical periods for yield determination, and competitive interactions are responsible of the effects of density and plant arrangement on yield under various environments and crop management situations. The conceptual framework built may provide a rationale for predicting and manipulating crop structure under various conditions since modifying crop structure (density, plant arrangement, genotype) may be seen as a way to change crop spatial and temporal structure and, by this means, the use of crop resources. Although high densities for any particular environment should provide a greater use of early available environmental resources, yield-density responses still rely strongly on the way resources are used during the critical periods of yield components determination of the various crops. Taking this into account, density or plant arrangement manipulation should be effective only when it assures that the crop must be able to achieve high plant growth rates during those periods. Moreover, since genetic improvement has successfully widened the adaptation of crop species and genotypes to various production conditions, genotype specific interactions and characteristics need to be individually considered within the framework presented here to develop effective crop structures.

Although interspecific plant interactions, such as crop–weed interactions, are frequent in extensive grain crops. Polycultures increase the complexity of crop structures by adding the influence of crop plant–crop plant interactions and new crop management complexities to the result of the cropping system. Analysis of the "ecological combining ability" of crop species and genotypes in modern agriculture opens a whole new world to explore more productive and sustainable cropping practices, partially resembling the complexity and functioning of natural systems. The evaluation of the yield advantages of mixtures or polycultures compare to pure-stand yields or monocultures is also crucial. It has for long been based upon the absolute or relative yield differences between mixtures and polycultures [34, 44], but other criteria including resource use efficiency and environment health will surely need to be considered. In any case, the design and management of crop structure remains one, perhaps the most, important decision that farmers and agronomists face every time they plan to grow a grain crop.

Article Outline

Glossary

Alternative energy Is a generic term that refers to any source of usable energy intended to replace fuel sources without the undesired consequences of the replaced fuels. It is typically used to describe renewable forms of energy that can be used in place of fossil fuels and thereby reducing, mitigating, or eliminating the negative environmental consequences associated with the traditionally used fuels.

Aquaculture Is the farming of aquatic organisms and represents a controlled approach to the production of marine or freshwater species – differentiating it from fishing, which is the harvest of wild organisms.

Integrated multi-trophic aquaculture (IMTA) An ecologically designed recycling process in which the organic wastes generated from one species become inputs (food or nutrients) for another. A fed aquaculture species, such as fish or shrimp, are combined with inorganic extractive (e.g., seaweed) and organic extractive (e.g., shellfish) aquaculture to create an ecologically "balanced" food production system.

Ocean ranching A seafood production approach that combines aquaculture techniques with traditional fishery methods. Juveniles are produced in hatchery and controlled rearing facilities, and then released to the ocean environment where they grow under natural (no containment) conditions to harvest size and then captured (fished) using standard industry methods (e.g., trolling, seining, divers, etc.).

Polyculture An agriculture or aquaculture approach that uses multiple crops (or species) in the same space, typically in an effort to avoid the production issues (e.g., disease susceptibility) associated with single-species, or monoculture production. Differentiated from IMTA, which selects species based upon ecosystem function (trophic relationships), polyculture simply supports species diversification within the production model.

Sustainability Meeting the environmental, social, and economic needs of the present generation without compromising the ability of future generations to meet their needs.

Definition of the Subject and Its Importance

An increasing global demand for seafood has resulted in considerable and increasing pressure on world fisheries, with a number having already collapsed and others in serious decline [1]. Satisfying the growing seafood demand has seen aquaculture production increase significantly over the past few decades, with the current contribution of aquaculture to the global seafood supply equal to or exceeding that of the wild fisheries. However, commensurate with this controlled, although often intensive, approach to seafood production are a number of environmental consequences that have called into question, as with the pressured growth in the wild fisheries, the ultimate sustainability of these approaches.

Sustainable ecological aquaculture (SEA) systems endeavor to address the socioeconomic and environmental facets of sustainability by integrating ecological and engineering system design with comprehensive best management practices. Operational efficiency is considered a keystone element in such designs, and one which will ultimately demonstrate that an industry focus on sustainability can also be profitable – a critical argument in encouraging innovation and facilitating long-term change within the corporate environment of global food production.

Introduction

The United Nations Food and Agriculture Organization (FAO) defines sustainability as "*Meeting the needs of the present without compromising the ability of future generations to meet their needs*" [2]. This definition

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

requires that mankind keeps population densities below the carrying capacity of a region, facilitates the *renewal* of renewable resources, conserves and establishes priorities for the use of nonrenewable resources, and keeps environmental impact below the level required to allow affected systems to recover and continue to evolve.

In a simple, yet technical-based definition, sustainability – in reference to natural resource management – has also been described as the "*long-term maintenance of ecosystem components and functions for future generations*" [3]. Linking economic, social, and environmental aspects of human society this concept is intended to configure civilization and human activities so that society, its members and its economies are able to meet their needs and express their greatest potential in the present, while preserving biodiversity and ecosystem integrity, and planning and acting for the ability to maintain these ideals indefinitely [4].

Although sustainability values may vary greatly among cultures, there is a fundamental commonality among these details that is best described as a "*parallel care and respect for the ecosystem and for the people within*." From these common values emerges the goal of sustainability – to concurrently achieve human and ecosystem well-being. It thus follows that the measure of sustainability for any activity (including aquaculture) be the achievement of, or the contribution to, human and ecosystem well-being together. In this way, the concept of sustainability can be considered a positive concept that has as much to do with achieving well-being for people and ecosystems as it has to do strictly (as is often the focus) with environmental protection.

In general, society has been moving steadily toward sustainable industrial activities for a number of decades, recovering "waste" in an effort to recycle and reuse such materials [5]. Industry and government have both recognized that these waste streams are in fact a valuable resource, and society now expects the use of recoverable materials and the integration of natural design into most product development. These ideals are further promulgated through initiatives such as eco-labeling, eco-certification, eco-design, etc. – all of which are becoming more prevalent in the seafood production industry [6].

Consumers now use their purchasing power to ensure that the products they acquire meet these ever-changing social criteria. A growing awareness of sustainability issues has placed pressure on business (industry) to shift or to modify their production processes to accommodate the eco-ethical consumer needs [7]. This has become increasingly critical to both the wild fisheries and the aquaculture industry sectors as demand for a high quality, and sustainable supply of seafood continues to rise.

While it is indisputable that the achievement of sustainability for coastal aquaculture – embracing social, economic and environmental objectives – is necessary, the motivation for fundamental change in current industry production approaches, where required, has not yet been clearly established. The development of sustainable ecological aquaculture (SEA) systems represents a movement toward this goal, and commercialization efforts are now in place to provide working models and the basis for future innovations [8]. The following sections provide an example of SEA-System development in coastal British Columbia, a region renowned for the social conflicts associated with open netcage (finfish) aquaculture. The environmental issues associated with this approach to finfish aquaculture are summarized and then used to exemplify how a sustainable ecological aquaculture (SEA) system approach can be developed to resolve these issues, and further to illustrate how a comprehensive approach to SEA system design and operation can satisfy the environmental, economic, and social aspects of aquatic food production sustainability.

Sustainability Issues in Coastal Aquaculture Production

The development of coastal aquaculture, and the subsequent increase in its global role for seafood production, has not been without its environmental and socioeconomic risks and negative impacts [9]. The rapid development in Asian shrimp production through pond culture, for example, stimulated significant socioeconomic activity in traditionally poor, rural coastal communities – resulting, as envisioned, in increased livelihood opportunities in the wake of declining subsistence fisheries. Although successful in

addressing a number of social issues associated with the coastal fisheries situation, the inherent value in shrimp production and the local and regional wealth it generated facilitated the tendency to further increase production, despite exceeding environmental sustainability criteria, to support further wealth creation, with a predictable result – catastrophic production collapses with serious socioeconomic and environmental consequences [10]. The three pillars of sustainability – environmental, social, and economic – are truly in balance, and ignoring one can have serious consequences to this integral relationship.

In the global salmon aquaculture industry, with farm production originating in Norway, Chile, United Kingdom, Canada, United States, Australia, and New Zealand, a standardized production approach, including infrastructure configuration and general management practices, has resulted in a common suite of sustainability issues associated with the industry. The net-cage aquaculture operational procedures that will ultimately influence whether this approach is considered environmentally sustainable will also form the basis upon which social and economic criteria for sustainability are determined. As with many new coastal activities, social "acceptance" of open net-cage aquaculture has, in many jurisdictions, waned as inherent environmental issues have been identified during the early stages of its development. Issues that currently jeopardize the sustainability of this form of coastal aquaculture include the following.

Species selection is typically seen as a serious risk when exotic (non-indigenous) species are used [11]. Should escapes occur, the potential for disruption of ecosystem structure through displacement of indigenous species, or the potential for interbreeding that could weaken the natural, resident populations are associated with use of such species – despite their selection and obvious benefits as farm stock (disease resistance, faster growth rates, etc.). Farming of high densities of animals in proximity to wild populations of similar phylogeny may also pose threats of disease and/or parasite transfer both to and from the farm facility.

Stock escapes have occurred both incidentally, as a result of human error during the husbandry process, or catastrophically due to containment system failure during extreme weather episodes, and marine mammal interactions causing severe subsurface net damage. The risks associated with stock escapes include interactions with wild populations – genetic dilution – as well as those associated with the escapes of farm stock comprised of non-indigenous species (referenced above) [12, 13].

Chemotherapeutic compounds represent a wide range of complex chemical and antimicrobial compounds that have been developed to manage farm stock disease and parasite issues. Their use is considered a site management activity, and is recognized as a stressor due to the periodic release of the respective compounds (and residues) into the environment [14]. The environmental effects of this stressor could manifest itself in a number of ways – changes to contaminant concentrations (partitioned in various ways within the ecosystem), and through a suite of potential effects determined by the bioavailability of these residues to nontarget organisms within the ecosystem.

Chemicals used in net-cage aquaculture comprise a variety of compounds and include the micronutrients of fish feed (trace metals), disinfectants, anaesthetics, and antifoulants. All are released to the marine environment, albeit typically in very low concentrations and at differing release rates. The fate and effects of these residues within the environment, like that of the chemotherapeutic compounds, pose a risk to a variety of ecosystem components through environmental partitioning, accumulation and persistence, and the bioavailability and effects to nontarget species [15].

Organic fish wastes are a natural product comprised of fecal material and incidental wasted feed. These materials are released from the fish and enter the environment where they can have localized impacts to benthic habitat, changing biophysical conditions and displacing or disrupting species composition of these communities [16, 17]. While localized in nature, these impacts are of considerable concern when considered with respect to aquaculture expansion and the potential for broader, cumulative effects.

Inorganic fish wastes, comprise of dissolved nutrients (e.g., nitrogen, nitrate/nitrites, ammonium, phosphorus) are excreted as a result of fish metabolism and primarily released to the environment through the urine [18–20]. While localized effects of nutrient release are often associated with enrichment effects, nutrient loading from large or multi-farm operations have been implicated in potential eutrophication

processes, with speculation that harmful algal blooms can be generated and sustained as a result of the cumulative nutrient enrichment (far-field) effects from such aquaculture facilities.

Energy consumption, and particularly that component generated from hydrocarbon-based (fossil) fuels, is currently a globally recognized sustainability issue – regardless of the associated activity [21]. Salmon, and other temperate finish aquaculture, currently operate in remote coastal areas and as a result, rely upon off-grid source of power for much of the required operational needs. Expansion of these industry sectors to satisfy increasing seafood supply will likely result in further use of such coastal areas and thereby increase the use and hence the broader scale effects associated with this use.

The significance of these open net-cage aquaculture issues, in terms of impact upon environmental and socioeconomic sustainability, varies among the farm operational regions and reflects local concerns, values, and hence how, where, and what priority research effort is focused. Many of these sustainability issues are addressed independently, through a variety of ongoing private sector and/or academic-based research initiatives, and usually in an effort to continually improve environmental and economic performance of the present production model [22].

While a continual improvement paradigm is a recognized and essential component to maintain sustainability, typically characterized with ongoing and relatively minor changes to operational procedures or infrastructure design (e.g., materials use), a more dramatic step in the development of sustainable aquaculture will be required in order to supply increasing demands for seafood. The evolution toward sustainable ecological aquaculture (SEA) systems considers the array of stressor-impact concerns associated within current production models with the objective of designing an approach that incorporates innovative infrastructure and proactive operational controls [23].

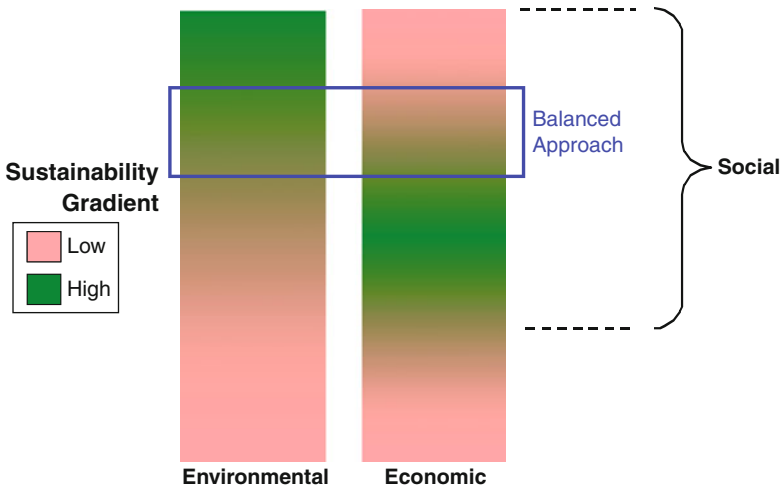
Design and Operational Framework for SEA Systems: Considerations for Socioeconomic Sustainability

A sustainable ecological aquaculture (SEA) system can be defined as *a holistic aquaculture approach that uses the principles of ecology to achieve the goal of sustainability*. It is essentially a blend of two developmental pathways for aquaculture systems, whether referring to a freshwater or to a marine environment scenario, i.e., sustainable aquaculture and ecological aquaculture. In terms of the *sustainable* aquaculture component, a sustainable ecological aquaculture system endeavors to satisfy the perpetual needs of society (e.g., ensuring food security, maintaining livelihoods) while protecting the environment – and do so in a manner that is efficient and hence economically viable [22].

Figure 1 illustrates the relationship among the three facets of sustainability. While the range of Social acceptance may vary considerably among communities, and/or given a specific form of aquaculture, the balance between environmental and economic sustainability is much more objective in nature with their concurrent evaluation typically resulting in a compromise that may in fact represent a narrow range of opportunity. If, for example, all of the criteria considered necessary to achieve environmental sustainability (top portion of the left gradient) is the goal, then the associated economic costs may increase and actually exceed the ability to accomplish the environmental objectives (illustrated with a pink portion at the top of the right gradient). Hence, to achieve economic sustainability, a sacrifice along the environmental gradient of sustainability may be required in the short-term. As system innovation addresses operational efficiencies and costs, then the balanced approach shown with the blue box (Fig. 1) will move toward the top of both gradients – improving environmental performance while remaining, and potentially increasing, social acceptance.

Environmental Sustainability: The Ecological Design of SEA Systems

The configuration and operational design of many current aquaculture systems are, or could with minor modifications, be considered environmentally sustainable. Minor ongoing operational improvements, typically introduced as efficiencies in husbandry practices, have and will continue to result in the reduction of environmental effects. For example, the development and introduction of effective vaccines has



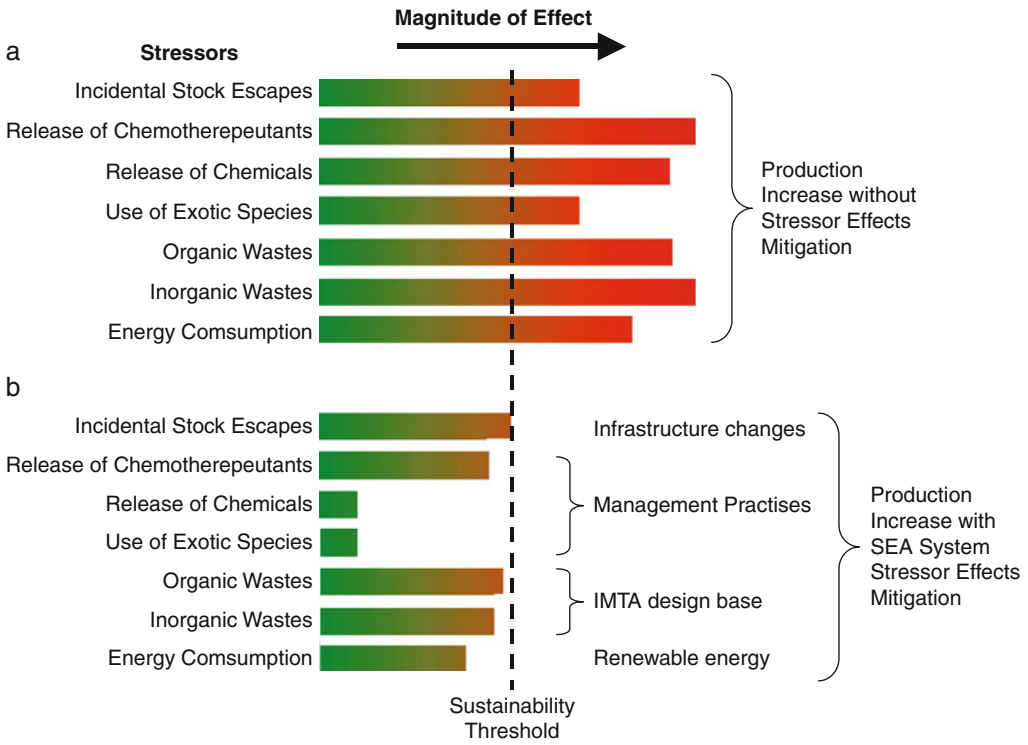
Sustainable Ecological Aquaculture. Figure 1
The inherent balance between environmental and economic sustainability gradients, based upon a comprehensive suite of sustainability factors/indicators, the associated need for compromise, and the relationship to social acceptance

dramatically reduced the use of antibiotics, the residues from which are released to the environment and presumably neutralized through natural assimilative processes. The engineering and introduction of new structural materials (e.g., netting), with greater breaking strengths and increased antifouling properties, prevent negative interactions with predators and reduce maintenance (net washing) costs while optimizing water quality and flows through the cages.

However, as the demand pressures on current seafood supply continues to rise, the scale of coastal production (individual farm configuration and/or regional allocation of farming units) will need to increase at a rate faster than minor adaptive changes to existing system design will be able to occur to remain environmentally sustainable. Figure 2 illustrates the hypothetical impacts of increased production on sustainability using seven environmental stressors – stock escapes (and use of exotic species), release of therapeutic and chemical residues, discharge of organic and inorganic wastes, and energy use.

Scenario I in Fig. 2 (upper portion) represents the projected effects of present farm operational models given a dramatic increase in production with a limited adaptive response to mitigate the associated environmental impacts. At present, the magnitude of independent environmental effects resulting from each of these seven stressor effects is likely to the left of the vertical dashed line, which represents the sustainability threshold for each stressor effect. As production is increased, through increased farm size and/or the number of farms within an operational area (density), the magnitude of stressor effects of any number of these (and other) operational factors will exceed the environmental, and eventually the social and economic sustainability thresholds.

Scenario II in Fig. 2 (lower portion) suggests how a sustainable ecological aquaculture approach, representing a significant shift in fundamental system design and operational considerations, would proactively mitigate (or eliminate) the impacts of the example stressor effects and thereby accommodate increased production needs. First – use of an *integrated multitrophic aquaculture (IMTA)* production model provides an inherent increase in system productivity (and product diversification), yet represents a design and change in *infrastructure configuration* that facilitates interception and use of the organic and inorganic wastes, generated and released from the fed (fish) component, by extractive species such as shellfish, echinoderms and seaweeds/kelps [24–27]. Second – revised *management practices* that comprise protocols committing to best (e.g., *organic)* practices/standards result in strict control over all operational



Sustainable Ecological Aquaculture. Figure 2
Anticipated sustainability impacts of increased farm/regional production based on two developmental scenarios: (**a**) magnitude of individual environmental stressor effects without the introduction of appropriate mitigation measures; and (**b**) potential mitigation of these stressor effects using a sustainable ecological aquaculture approach to production

inputs, including elimination of therapeutics and other process chemicals, restricted introduction/use of non-indigenous species, and sourcing of feeds. Third – integration of renewable energy into system operations provides a significant and ongoing reduction in the use of fossil fuels and hence the carbon foot-print of the operation.

Example: Commercialization of the SEA-System Approach

The principles of sustainable ecological aquaculture are currently being applied by the SEA-Vision Group of companies of western Canada (www.SEAvisiongroup.ca) in the development and commercialization of its own SEAfood System. This unique coastal aquaculture production system is based on the predominant open netcage approach used in finfish aquaculture but incorporates engineering and ecological design components that facilitate a scalable transition from single to multiple species production. In the development of this new system, the SEA-Vision Group has considered the social, environmental, and economic pillars of sustainability – resulting in an environmentally efficient, cost-effective production system that meets the scrutiny of both the local community and the consumer. A description of the key socioeconomic and environment design aspects of the SEAfood System are provided in the following sections.

Social Sustainability Considerations Social sustainability is based on *acceptance* and on *involvement*. Introduction and commercialization of the SEAfood System in coastal British Columbia considered three levels of social engagement – community design input, operational involvement, and satisfaction of consumer demand.

Community design input was considered essential in establishing the conceptual framework upon which the local coastal community would be willing to accept and support the introduction of a new commercial-scale production system/operation – one intended to address the ongoing controversies associated with coastal aquaculture in the region. In British Columbia, the aquaculture industry comprises two independent sectors – shellfish and finfish. Shellfish, which primarily encompasses self-feeding extractive species such as oysters, scallops, mussels, and intertidal clams, also includes (and refers to) other extractive invertebrates that have had their historical use as a harvest fishery and have recently garnered attention as potential culture candidates, for example, urchins, sea cucumbers, geoduck clams, and abalone. The finfish sector was developed with salmon (indigenous and introduced species) but has begun to diversify with the introduction of marine species such as sablefish and rock cod.

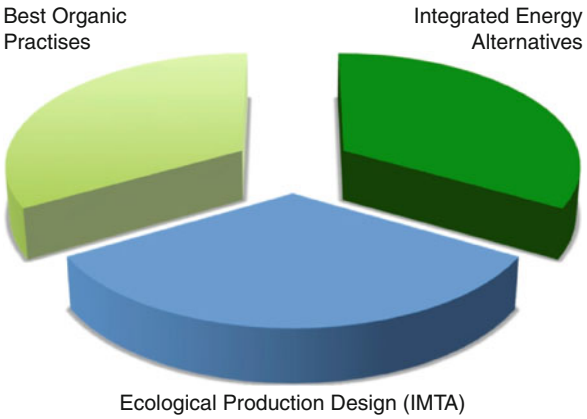
Sites best suited to aquaculture in British Columbia are generally located in remote coastal areas, substantially removed from urban centers and populations. These areas remain resource-based and under joint management control of Provincial/Federal governments and the local aboriginal (First Nation) peoples that maintain claim over their traditional coastal territories. In soliciting *community design input* for the new SEA-Vision Group production model, the integration of traditional ecological knowledge (TEK) of the residing coastal first nation community (the Ka:'yu:'k't'h'/Che:k:tles7et'h' First Nation = KCFN) was a critical social engagement step [28] in the commercialization process. Discussion of the SEAfood System conceptual design with the KCFN allowed input as to species selection that satisfied the ecological design criteria of the system yet met the needs and concerns of the local community. The KCFN conveyed their specific concerns regarding coastal aquaculture, identified a suite of indigenous species candidates for the system design, and provided valuable input into which of these species would be of most value to their people's tradition. A formal agreement as to species use, restrictions, and other operational criteria was prepared and has formed the basis for local social acceptance of the SEA-system approach in this case – one that also supports the social sustainability issues of the community.

Operational involvement has also been an important social sustainability factor for the SEAfood System development, providing and supporting direct and indirect coastal community livelihoods – for example, farm staff, contract services (divers, harvest vessels), investment. Integration of local workers into the business, including those from the KCFN, further supports the social acceptance of the approach, allowing ongoing input into system operational improvements. A continuing working partnership with the local community is critical to the success of current operations and the potential for future operational expansion and corporate growth.

Consumer demand for seafood sustainability was also an important consideration of the social engagement process. Many of the environmental issues associated with open netcage aquaculture have had a direct influence on consumer acceptance of the product (farmed salmon), and with an associated and growing demand for wholesome, sustainably produced seafood, the design and operational attributes of the SEAfood System deliberately focused on these consumer criteria to provide a supply of seafood that would satisfy these demands. By systematically addressing this range of environmental concerns, and by continually and immediately addressing new issues/concerns as they are realized, the sustainable ecological approach allows the consumer to be integrated into the continual improvement paradigm of the approach – and thereby further supporting the sustainability of the SEAfood System.

Environmental Sustainability Attributes In order to address, and facilitate improvement among all of the socio-environmental issues of open netcage aquaculture in the region, the SEA-Vision Group system focuses on three design components – its production model, energy needs, and operational practices (Fig. 3). This combination effectively encompasses ecological design (multispecies, IMTA approach) to reduce the waste/nutrient foot-print, integrated energy alternatives to reduce the carbon foot-print; and implementation of best, organic practices to mitigate the potential effects of antibiotics and chemical use.

Production Model The ecological production design of the SEAfood System is based on that of an Integrated



Sustainable Ecological Aquaculture. Figure 3
The SEAfood System™ addresses the majority of socio-environmental issues of open netcage aquaculture using an effective combination of ecological (multispecies, IMTA) system design, integrated energy alternatives, and a suite of best organic practices

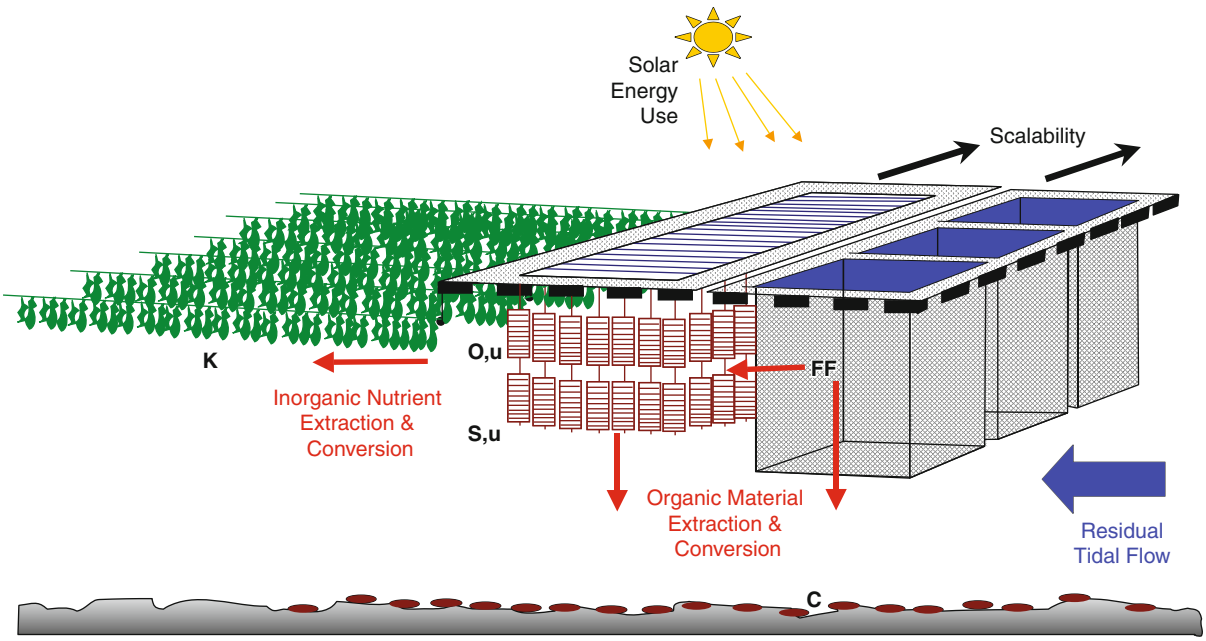
Multi-Trophic Aquaculture (IMTA) model [29]. This multispecies approach expands upon the monoculture model for fed (fish) production by integrating a number of extractive species to intercept and remove the organic and inorganic wastes generated by the fish. Two simple criteria are used in the selection of species for the SEAfood System: (a) each species must fill an ecological role in the removal of organic and/or inorganic wastes; and (b) each must have economic value – a marketable and profitable product [30, 31].

The SEAfood System model developed in British Columbia combines a single fed species – sablefish (*Anoplopoma fimbria*) or Chinook salmon (*Oncorhynchus tshawytscha*), with a variety of extractive species positioned deliberately to facilitate interception and removal of the organic and inorganic fish wastes that are released into the environment as particulates and dissolved nutrients. Downstream of the fish component is a shellfish (bivalve mollusk) system that is situated and configured to maximize the extraction of the fine particulate fraction of the organic waste streams [32]. Further downstream is a series of kelp/seaweed grids (*Saccharina lattisima* or *Porphyra sp.*) that are positioned to intercept and capitalize on the enriched dissolved nitrogenous wastes. Beneath the entire floating infrastructure of the farm, sea cucumbers (*Parastichopus californicus*) are grown in an ocean-ranching style – released as juveniles, these animals consume the rich settleable organic material that would otherwise accumulate over the seafloor.

Figure 4 illustrates the infrastructure configuration and spatial relationship of the SEAfood System species. The various extractive components of the SEAfood System are situated in such a manner so as to maximize receipt of the organic and inorganic wastes originating from the fish. SEAfood System sites – SEAfarms – are configured with the extractive species downstream and to one side of the fish component to allow for operational logistics around the cages (e.g., vessels used for net changes, harvesting, etc.). Site selection and subsequent system orientation thus requires a thorough physical oceanographic assessment to ensure that system component placement is in the direction of the residual tidal flow (downstream).

The total length and production capacity of a SEAfarm is scalable and is determined by the finfish production component. In the initial model each SEAfarm is 200 m in length and includes twelve 15-m square cages or six 30-m cages. This small operational foot-print for the fish production component (by current industry standards) is considered an additional environmental benefit to the SEAfood System design, allowing for better water flow, waste transfer, and overall assimilative efficiencies among the species components.

Infrastructure compatibility between the extractive components and that of the base finfish production system is considered key to SEAfood System production capacity and operational efficiencies. A new suspended shellfish aquaculture system was therefore designed and engineered to meet the unique needs of multispecies production. The system, shown in Fig. 5, uses similar construction materials to that of the finfish cage (e.g., galvanized steel, high-density polyethylene flotation billets), provides a production platform with a number of benefits: (a) strong connection points for securing to the finfish cage system, (b) a very high floatation capacity that supports considerable shellfish production – both in surface area and in depth, (c) a moving *SEA-Tram* system that supports multiple, wind/solar-powered winch systems for on-system handling of shellfish product, (d) adjustable cross-beams to allow changes to spacing of the shellfish droplines,



Sustainable Ecological Aquaculture. Figure 4

Infrastructure configuration, orientation with respect to tidal flow, and the spatial relationship of the SEAfood System™ species. The integrated multi-trophic aquaculture (IMTA) design aspects of the system support a single-fed component (**FF** – sablefish or salmon), a 2-tiered shellfish component (**O** – oysters; **S** – scallops) to extract fine organic particulates, a deposit feeding component comprised of sea cucumbers (**C**) to remove settleable organics, and a large kelp/seaweed component to assimilate dissolved nutrients. Urchins (**u**) are integrated with the shellfish to reduce biofouling and solar energy is used to power operational components of the system

and (e) standardized outboard attachment points for kelp/seaweed lines.

The shellfish component of the first SEAfood System production model, shown in Fig. 5, comprises Pacific oysters (*Crassostrea gigas*) in the surface layer (1–4 m) and Pacific scallops (*Patinopecten yessoensis*) in the lower (5–10 m) portion of the water column. With 1.0 m spacing between vertical lines of shellfish trays/nets, the overall 2-tiered shellfish system comprises a biofiltration component that is 15 m wide (immediately downstream of the fish), 10 m deep, and extends parallel to the finfish cages and the entire length of the farm (200 m). A SEAfarm of this size thus has the capacity to physically support approximately 2,600 vertical shellfish lines with each line comprised of 8 oyster trays and 12 scallop nets – a total of 52,000 shellfish production units.

Kelp lines are attached to the downstream side of the shellfish component, with a 1.0-m spacing, which in the current British Columbia SEAfarm model results in a total of 200 kelp/seaweed production lines. These lines run perpendicular to the shellfish system with the production grid extending 80 m downstream of the shellfish structure (although length is only limited by available space).

The sea cucumber component of the SEAfood System is managed using an ocean-ranching approach that makes it independent of the floating aquaculture production units that support the finfish, shellfish, and kelp/seaweed. Cucumber seed (small juveniles: 2–3 cm) are sowed over the ocean floor (5–10 m^2) and allowed to move freely in the vicinity of the farm structures, taking advantage of the continual input of organics originating from the overlying species assemblage – fed and extractive components. Once achieving market size these animals are harvested using divers, and although a somewhat labor-intensive method, this extensive approach allows for waste management

Sustainable Ecological Aquaculture. Figure 5
Left photograph: a segment of the SEAfood System's shellfish component showing the powered SEA-Tram and gantry for hoisting shellfish droplines. *Right photograph*: SEA-Tram gantry showing author lifting dropline of scallop nets using one of the winch components; these six winches have subsequently been changed to electric units with a solar panel system mounted at the top of the gantry. Battery storage is at the base of the gantry

across the entire farm rather than just below the source of the settleable organics (the finfish).

Energy Needs Widespread recognition and growing concern over fossil fuel consumption trends, associated carbon emissions, and the global/regional climatalogical effects of these atmospheric loads are also reflected at the aquaculture farm scale, representing a significant environmental as well as economic (business) impact. For example, in remote coastal aquaculture operations, the reliance on diesel fuel to power boats and associated equipment (hydraulic pumps, winches) represents a significant impact on operations. In an analysis of the current shellfish aquaculture industry, it has been estimated that to produce a dozen [12] oysters using a suspended (raft) culture approach requires 0.24 l of diesel fuel over the entire production cycle – this includes on-farm activities only and does not account for seed and harvest transport to/from the farm.

Integration of sustainable energy alternatives (SEA-Power) within the SEAfood System design was envisioned as another approach to improve upon environmental performance (reducing the carbon footprint) while addressing this inherent and increasing operational cost of aquaculture production. As alternative energy systems continue to increase in efficiency, their unit size, weight, materials use, and life cycle characteristics now lends itself to uses other than satisfying the energy needs of large facilities (e.g., homes, commercial buildings).

Following a detailed site-specific meteorological assessment, selection, and integration of a solar energy system has been used within the first SEAfood System operation to operate the winch systems within the shellfish production component. Panels at the top of the SEA-Tram collect solar-derived electrical energy to maintain a battery storage unit at the base. The 2.0-kW system for the first SEAfarm site has been designed for independent operation of six electric winches, each capable of lifting a maximum of 240 kg (shellfish droplines). The energy use pattern for the SEA-Tram is unique, in terms of typical alternative energy system uses, in that operation of the winch units occur over a 10–12-h working day, and comprise a series of long-lift (entire dropline) retrieval as well as short lifts (vertical moves from one layer of shellfish to the next for product handling).

Each proposed SEAfarm site will have different alternative energy sources and will require different

energy extraction and storage configurations. The shift between small solar and wind power units, or using a combination of the two, may be needed to maintain operational energy needs for this intended use within a SEAfarm. The size of the farm may also dictate the need for additional SEA-Tram (and associated energy units) in order to efficiently manage shellfish production levels within this SEAfood System component. The current model considers a SEA-Tram for each 100-m length of farm – a total of two for the one discussed in this example (one operating on each end of the SEAfarm).

Operational Practices Application of organic operational standards is considered an effective approach by which many of the other environmental issues associated with coastal aquaculture, including food formulations, use of antibiotics and other chemicals, animal welfare (stocking density), etc., can be addressed [33]. While certified organic standards are currently under development in North America, it is anticipated that these operational protocols will be similar to Standards that are currently in practice in other jurisdictions (e.g., *Naturland organic standards* in the EU).

Organic standards include strict operational requirements for all aspects of the food production. In aquaculture, the standards dictate specifications for environmental management, prohibitions on use of antibiotics and chemicals, animal welfare (stocking densities, humane forms of dispatch), feed composition and sources, product handling (husbandry, harvesting, transport), biosecurity, emergency protocols, auditing requirements, staff training, branding, sales, etc.

Integrating these rigorous practices within the ecologically designed SEAfood System further supports the goal of achieving environmental as well as socio-economic sustainability. As a third-party-verified (audited) operational program, a certified organic aspect provides an important linkage between environmental sustainability practices and the inherent and ongoing need for social acceptability – a level of assurance to the consumer and to other coastal stakeholders. The implementation of a certified organic approach is also beneficial from a business/economic perspective, in that the approach will allow for further product differentiation and market access.

Economic Sustainability: The Business Model As discussed above, the ecological design and operational practices associated with the SEAfood System address many of the environmental issues/stressors associated with current methods of coastal aquaculture production, and in doing provides an additional measure of social acceptability (and sustainability) for this growing seafood producing sector. However, the sustainable ecological aquaculture (SEA) system approach is also inherently more complex than that of traditional production approaches – and with increased complexity comes increased operational (and business) risk. A cost-benefit analysis of the SEAfood System production model, implemented during the early design stage of system development, is thus an essential exercise in terms of achieving economic (and business) sustainability [30, 31]. Basic criteria that have been incorporated into this assessment include the following: (a) species selection, value and production capacity, (b) operational efficiencies; (c) economy of scale; and (d) vertical integration.

Species Selection, Value, and Production Capacity The choice of species used in the SEAfood System developed for British Columbia considered social sustainability, ecological function within the production model, and market value (profitability). First, all species used in the system are native (or long established through introductions), and thereby satisfy the social issues and potential ecological risks of using exotic species – particularly in regard to the fed (finfish) component of the system. Sablefish and Pacific salmon, although slightly more difficult to culture than the Atlantic salmon, receive a significantly higher farm-gate value given the comparatively lower regional supply but increasing demand for these particular species. This inherent price premium, coupled with the *green* nature of the SEAfood System approach, offsets the cost of implementing and maintaining the operational standards required for *organic* certification – adding additional value to the fish and offering a variety of new market segment opportunities.

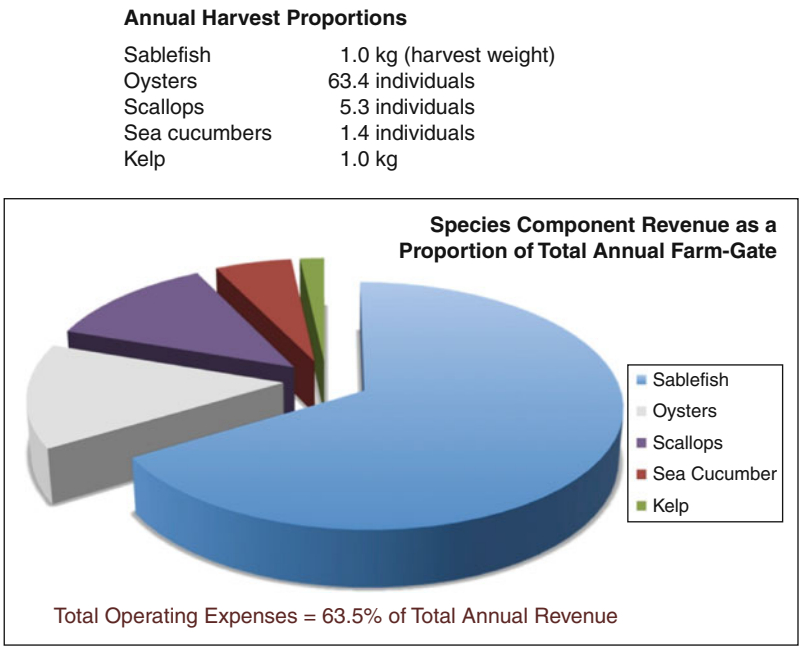
The selection of the organic extractive species is a much more difficult task given the number of species available to satisfy this role within the SEAfood System [34–37]. Choice of appropriate species ultimately requires a compromise between extractive efficiency

and product value. For example, although blue mussels (*Mytilus edulis*) are known to be the most efficient shellfish species in terms of filtration capacity, their commercial value is much lower than that of other shellfish species candidates. Therefore, to maximize the profitability of the shellfish extractive component, a 2-tiered approach was introduced into the design – oysters in the surface layer (replacing a mussel) and scallops in the lower portion of the water column. The combination of the two extractive species not only increases the operational efficiency for this component but also provides a significantly higher farm-gate value to the overall seafood production model.

The business decision to adapt a much more complex, multispecies production system, and ultimately the economic sustainability of this approach, will be determined not only by the values of the individual species but also by the level of combined production that can be achieved for the additional, extractive species, the cost of production (CoP) for these integrated components, and continued consumer demand for the products.

Assuming that consumer demand remains constant (although it will likely continue to grow), Fig. 6 illustrates the relative proportions of annual production (harvest volumes) among the system components, as well as the farm-gate value for the various SEAfood System species in the first SEAfood System operation established on the Canadian west coast. For each kilogram of sablefish produced from the system, approximately 5 dozen half-shell oysters, 5–6 scallops, 1–2 sea cucumbers, and a kilogram of kelp are harvested. It should be noted that this proportion of species represents a starting commercial balance for the SEAfood System and one that will be refined over time to ensure extractive efficiency of the system. These values also represent the proportion of annually harvested stock, and the SEAfood System maintains multiple year classes of each species.

The pie chart in Fig. 6 illustrates the proportion (percent) of farm-gate revenue generated annually from each of the component species. These values were generated from total annual revenue projected for four regional SEAfarms, and averaged to provide standardized estimate of farm-gate sales for a single facility. The fed component of the system (e.g., sablefish) remains the highest value (66.4%), with oysters



Sustainable Ecological Aquaculture. Figure 6
Annual harvest proportions and the individual species component revenues represented as a proportion of her total annual farm-gate sales

contributing 13.9%, scallops 12.5%, sea cucumbers 5.5%, and kelp 1.8% of the total annual sales revenue. With operating expenses of 63.5% of the total sales, the Net Revenue (Total Expenses – Total Gross Revenue) is 36.5%. This analysis indicates that from a business/economic perspective the SEAfood System is potentially quite profitable, and given these margins would not only be considered sustainable but would also support future growth.

Operational Efficiencies The SEAfood System maintains multiple-year classes for each component species, ensuring an annual balance between seed entry and product removal (harvest) for each of these species. Although intuitively a much more complex management challenge than a process involving a single species/product, there are inherent operational efficiencies – and economic (profitability) gains – that can be realized within this type of operational system.

The infrastructure design and configuration of this multispecies SEAfood System represents an adaptation of the galvanized steel netcage array used in the finfish aquaculture industry. The majority of species components (fish, shellfish, urchins, and attachment points for the kelp/seaweed) are directly accessible from the consolidated SEAfood System infrastructure components and thus do not require transportation of staff, materials, and vessels among what might otherwise comprise independently moored structures. The operational efficiencies gained through this design are significant, and are associated primarily with savings in labor and the requirement for dedicated working vessels (with fuel and equipment costs). Development of unique infrastructure (e.g., the shellfish SEA-Tram component) has further reduced the Cost of Production (CoP) within the consolidated multispecies SEAfood System model. By introducing alternative energy components to power shellfish winches, the saving in fuel (estimated from traditional shellfish production methods) is projected at over 43,000 l annually for each SEAfarm (based on 0.23 l/dozen shellfish produced). Fuel costs have continued to burden CoP over the past decade, and the present and future projections for the cost of fuel is a continual increase. The shift from fossil fuels to wind/solar energy is therefore readily justified, and in fact, represents a significant reduction in CoP and in business (economic) risk.

A shared labor pool will also result in a significant reduction in overall CoP. While each farm will require staff for finfish husbandry (feeding, net maintenance, grading, harvesting, etc.) as well as for the additional, extractive species component (shellfish grading, net maintenance, harvesting, etc.), in a consolidated multispecies system, there is opportunity for staff to assist in all tasks and thereby eliminate traditional slow periods in workloads. It is estimated that the SEAfood System will require 75–80% of the staff that would be cumulatively needed to independently operate the various production components.

While these inherent operational efficiencies are evident within the single SEAfarm operation, further CoP reductions can be realized through economy of scale – the addition of multiple SEAfarm sites.

Economy of Scale Compatibility and scalability were the key design criteria in developing the SEAfood System. Engineering of unique extractive species infrastructure, using comparable materials and assembly lengths, makes the system compatible with most of the current finfish cage system designs. Further, and as illustrated in Fig. 4, this manufacturing flexibility allows scalability in each SEAfarm. The configuration described in this chapter, for example, is based on a single array of 12 steel fish cages – approximately 200 m in length – with the extractive system components paralleling these structures. Other farms may choose to use large fish cages, perhaps with a fewer number, while others may establish very long farms with greater numbers of fish cages.

Economy of scale for the present *SEA*food System production operation is further realized through the development of a vertically integrated *SEA*farm Cluster – an operational aggregate of 4–5 production SEAfarm sites and an affiliated seed (hatchery) facility (see following section). Each of the production sites is configured identically as per the first *SEA*farm – the operational template – including infrastructure configuration and species composition and stocking densities. The joint management/operation of the *SEA*farm Cluster facilities allow increased production with a commensurate reduction in the cost of operations resulting regional efficiencies. Spatial distribution of a number of smaller SEAfarm units, rather than establishing large farm facilities, is considered an additional

design feature in reducing the environmental footprint of the commercial production system.

Vertical Integration One of the greatest operational risks associated with a multispecies production model is the assurance of annual seed supply. While this is always a challenge for aquaculture (fish, shellfish) companies, this becomes even more difficult when the function of the ecological production system relies on an established biomass for each species component – fish, shellfish, echinoderms, and kelp/seaweed.

To optimize and fully control the *SEA*food System production model, vertical integration within the operational framework includes a small, floating *"marine species"* hatchery. The *SEA*food-Hatchery capacity is small by comparison to the current hatchery model, and is designed to accommodate seed/juvenile production for no more than 4–5 *SEA*farm sites – allowing control of seed production of all marine component species (if salmon is used, these are acquired through other commercial facilities). The floating (barge-based) design of the *SEA*food-Hatchery supports placement of this aspect of the overall aquaculture production system directly *within* a *SEA*farm cluster (4–5 farms in an operational area), facilitating use of farm infrastructure for broodstock management, juvenile rearing, and other activities that would otherwise be conducted within a land-based hatchery – saving capital infrastructure costs, operational expenses, and lowering the overall cost of production for these integrated aquaculture systems. This becomes particularly relevant in remote coastal areas where transportation expenditures for all aspects of production can be limiting.

Summary of Cost–Benefits Risk associated with any form of aquaculture, including that of the SEAfood System approach, the business risks, and hence the determinants of economic sustainability, are mitigated largely by the inherent ecological design and business framework established for this new aquaculture approach. In addition to the intuitive environmental benefits associated with the SEAfood System approach, which directly address societal concerns associated with traditional aquaculture, this new production model provides significant economic benefits/incentives for future industry commercialization efforts. Specifically, the mitigation of these risks increase profitability of this ecological approach that stem jointly from the:

- Selection and integration of high-valued commercial species to the SEAfood System, thereby ensuring a higher combined farm-gate value
- Coproduction of multiple species, providing an inherent product diversification and reducing the potential operational or financial risks associated with single species production
- Reduced Cost of Production, resulting from a shared labor pool, integrated infrastructure, and lower per-unit production expenditures for the SEA-system components
- Inherent, potentially higher margins associated with a sustainable ecological aquaculture (SEA) system production approach that is viewed by consumers as *natural*, and that follows the operational standards established for organic certification

Future Directions

The sustainability of aquatic food production systems is currently recognized as a critical issue in global seafood supply and demand. Environmental effects resulting from many aquaculture approaches may represent ecosystem stressors that will not support long-term sustainability goals given the inherent and increasing need for marine protein. With the dramatic shift from a reliance on global fisheries to the production of seafood through controlled aquaculture systems, innovation in design and operational practices will facilitate the sustainable growth of global aquatic food production.

The vision for sustainable ecological aquaculture (SEA) systems is one that will continue to evolve under a *continual improvement* paradigm. All three pillars of sustainability – social, economic, environmental – and how these will effectively be integrated into the global seafood production process will necessarily require a multi-disciplinary and collaborative approach of science. Ongoing social pressures including demand for seafood, concerns over environmental degradation, and growing competition for space by other coastal foreshore stakeholder will further dictate the need for increased production

efficiency. Modifications to SEA system design, improvements to infrastructure, and integration of new species, will all support a long-term sustainable ecological aquaculture (SEA) vision.

Sustainable Herbicide-Resistant Crops

Jonathan Gressel
Plant Sciences Department, Weizmann Institute of Science, Rehovot, Israel

Article Outline

Glossary

Gene stacking Developing transgenic crops containing two or more transgenes, either by simultaneous transformation or by hybridizing plants with different transgenes.

Graminicide A herbicide that specifically controls weeds in the grass family (Graminae – Poaceae).

Harvest index The ratio of grain to total biomass in a crop.

Herbicide hypersensitivity The property of certain genetically engineered crops to be susceptible to herbicides to which the wild type is naturally resistant.

Herbicide resistance The ability to withstand a critical level of herbicide with little or no effect on yield. Resistance can be natural, evolved, or generated by mutagenesis as well as by using recombinant DNA technology (genetic engineering).

Selectivity The ability to differentially control weeds with little or no effect on a specific crop.

Shattering Premature dropping of seeds before they can be harvested.

Systemic herbicide A herbicide that is applied to the leaves but spreads to underground plant organs, and affects these parts of the plant as well as leaves, or is applied to the soil and also affects leaves.

Target site The specific site to which a herbicide binds, beginning the cascade leading to plant death.

Transposon A DNA element that can move from one location in the genome to another.

Volunteer weed Weeds of a plant species that had been a crop in a previous season.

Definition of the Subject

While transgenic herbicide-resistant crops have been a boon to agriculture, reducing both production costs and ecological impacts of farming, weeds have rapidly evolved resistance to the major herbicide used in transgenic crops (glyphosate) [1], rapidly rendering the technology less sustainable than had been thought [2]. While no practice in agriculture has been sustainable forever, the period of sustainability can be extended. Methods are outlined to extend both the usefulness to crops where needed as well as the sustainability of transgenic herbicide technologies such as rotations of crops and herbicides, increasing the targets of herbicide action, suppressing herbicide targets in rotation. Transgenically inducing hypersensitivity to herbicides can be considered as an option for some weeds.

Introduction

Chemical weed control with herbicides has been a major quantum step that has allowed agriculture to supply food to a rapidly growing population, decreasing the drudgery of mechanical and manual (too often fe-manual) control of weeds. It allowed the switch in the direction of crop domestication from selection of ever taller grain crops (with lower harvest index) that were more competitive with weeds, to dwarf "green revolution" high harvest index crops. This broke the cycle of weeds continuing to evolve taller forms as a consequence of farmer and breeder selecting for height in crops so that the crop would compete with weeds.

The amount of additional arable land that would have been needed to feed the present populations of India and China just does not exist in these countries, and there would have been massive famine had it not been for the green revolution dwarfing wheat and rice, and the availability and use of herbicides to control the highly competitive, taller weeds. There would have

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

Robert A. Meyers (ed.) Encyclopedia of Sustainability Science and Technology, © 2012, DOI 10.1007/978-1-4419-0851-3

been this famine even if all available natural wild ecosystems were brought under the plow. Still, the chemical industry has not been able to generate new herbicides needed for each cropping situation where they are needed. Some of the older generation herbicides were found to have environmental or toxicological issues and have been de-registered as regulatory standards change. Additionally, weeds continue to evolve, just as they had to previous efforts to deal with them. Agriculture is not statically sustainable. New strategies must continuously be developed as previous ones are lost. So far, agricultural scientists have been successful at this continuing exercise, coming up with new technologies to replace lost ones, and delaying Malthus's nineteenth century predictions that due to population increasing at a higher rate than yields, there would be starvation. Indeed, typical annual yield increases would not keep up with population increases, but in every generation or so a new technology appears, providing quantum leaps. These included the use of hybrid vigor, tractors, selective herbicides, the green revolution, etc., all leading to major jumps in yield.

Genetically engineered herbicide resistance was another quantum leap; it allows taking a desired herbicide with limited use because it is not selective with a particular crop and then expand its use by transgenically rendering the crop resistant [3]. The major herbicide being used transgenically, glyphosate, indeed has excellent properties; no mammalian toxicity in realistic amounts; little environmental toxicity, it kills most weeds, including many that are hard to control [4]. The latter include weeds that have hidden buds and/or underground organs that require that a herbicide be systemic and penetrate to all parts of a plant to prevent resprouting.

Successes of Transgenic Herbicide-Resistant Crops

It has been argued that no technology has been taken up as rapidly and as massively as transgenic herbicide resistance to the herbicide glyphosate [5, 6]. This resistance has only been released in four crops: soy, maize, cotton, and oilseed rape (canola). Over 80% of the world's soybean and most of the maize and oilseed rape are glyphosate resistant, as is most of the North American cotton [5]. In the latter case, farmers had a choice of herbicide-resistant cotton with or without a transgene encoding the Bt insecticidal gene, and more farmers cultivated transgenic cotton with herbicide resistance than with the insecticidal gene. This rapid adoption by growers occurred despite high "technology fees" for the seeds, the availability of non-transgenic varieties, and a predominantly bad public perception generated by antitechnology, anti-multinational, and antiglobalization groups. The reasons are simple; the herbicide is inexpensive and the control package costs less, a larger spectrum of weeds is controlled, and the farmers had more flexibility in application timing than with previous herbicides [3, 6]. This had a major (positive) environmental impact. Many of the previous herbicides used were applied to cultivated bare ground before planting and much herbicide washed (with soil) into rivers or percolated into underground aquifers. The rapid dissipation of glyphosate allowed farmers to apply herbicide to standing weeds before planting, without cultivation, and then plant into soil-holding stubble. Spraying requires far less energy than plowing followed by disk cultivating, with considerable saving in fossil fuels. It has been estimated that the amount of fossil fuel saved per year is equivalent to that which would be saved from removing over five million automobiles from the roads [6]. This lack of preplant cultivation (no-, minimum, or eco-tilling) reduces soil erosion by 95% [6, 7]. It was not just in industrial USA and Canada where the technology was rapidly adopted. Argentina had a problem with a mistake made generations ago; they repeated an earlier mistake of a Mr. Johnson in the USA who introduced a Middle-Eastern weed, *Sorghum halepense* to the USA as a pasture grass. This "johnsongrass" turned out to be a poor pasture grass in both countries, but especially in Argentina, an excellent weed that propagates by seed as well as by underground buds on rhizomes. Other herbicides would burn off the tops only to have it resprout; cultivation cut the rhizomes into multiple propagules, spreading the weed. Transgenic glyphosate-resistant soybeans, planted into "johnsongrass" and other weed stubble that kept the soil from overheating, became a hit [7]. This transgenic soybean spread rapidly to neighboring Brazil where it was cultivated illegally until the government changed its policies due to massive farmer civil disobedience.

Countries in Europe, though reluctant to allow farmers the choice to cultivate transgenic herbicide-resistant maize and soy, have had no choice but to import them to feed their livestock. The claim that European agriculture is sustainable without cultivation of transgenic crops is only correct when the importation of transgenic feed grains to sustain European livestock is politely ignored.

There are those who argue that transgenic crops are not needed; modern breeding using DNA marker-assisted techniques can meet all needs. This author knows only of cases where marker-assisted breeding has allowed more rapid stabilization of inherent traits, such as a naturally occurring mutation for herbicide resistance that also occurs in weeds at a high frequency. Breeding cannot bring in herbicide resistance traits that do not exist in that crop species. This can only be done with recombinant technologies. Mutation breeding is counter-indicated with crops having related weeds, as this is not even sustainable in the short term, as discussed below.

Problems with the Present Transgenic Herbicide-Resistant Crops

There has never been a rapidly adopted technology that is not without drawbacks, despite widespread use. A case in point is the Model T Ford that revolutionized personal transport, cityscapes, suburbia, and lifestyles. It was inexpensive and met unforeseen needs. Still, it could never meet present day fuel, pollution, or safety standards with its arm breaking hand crank, poor suspension, steering and brakes, and tires that rapidly blew out. Early cars had detractors who passed regulations such as to have flagmen run in front of cars so as not scare horses, not too unlike some of the irrelevant regulatory requirements for transgenics (e.g., knowing flanking sequences of insertion sites). Such detractors rarely call for the rational and much needed regulation concomitant with all technologies.

The next generations of herbicide-resistant crops need to evolve to meet new needs and higher standards. They will be more sophisticated, more efficient, and their use far more complex than the present ones. The author hopes that he will not be misconstrued from the following sections: he is clearly not against the use of transgenic herbicide-resistant crops, but there are far too many cases where they are being used injudiciously, compromising the long-term effectiveness of the technology. The agronomic, economic, environmental, and toxicological benefits discussed above should make it clear that they are needed. Just for those reasons it is discussed at length how to sustain such useful products.

There Are Not Enough Herbicide-Resistant Crops

Industry has decided for its own (arguably misdirected) reasons to both limit the crops rendered herbicide resistant, as well as the markets where they are sold. Weeds are a major problem in "truck" crops (intensively cultivated fruit and vegetable crops). There are very few herbicides registered for use in these crops and most such crops are hardly competitive with weeds (imagine un-weeded lettuce or radishes). They must be intensively mechanically and manually cultivated. Many such crops have already been transformed using resistance to the herbicide glufosinate as the selectable marker. Despite the need for these crops in the field, the company that owns patent rights to both the gene and the herbicide steadfastly refuses to register the use of their gene and herbicide in such crops.

Hand weeding is de rigueur in much of the developing world, especially Africa due to the small farm sizes, lack of capital for machinery as well as chemicals. When transgenic glyphosate-resistant maize was finally released in South Africa (and marketed to rich, large-scale farmers) adoption was rapid among resource-poor farmers. A lady farmer could spray down weeds on 2 ha with a backpack sprayer in a day, where she could only hoe weeds on 1 ha in a month, with much weeded too late. There has been no major effort to market this maize in other African countries, despite its potential use in controlling parasitic weeds [8]. Parasitic weeds that attach to roots of major crops and suck the crops dry before emerging from the soil and flower are a scourge of major crops in Africa, the Mediterranean basin, and eastern Europe. They cannot be controlled by cultivation or conventional herbicides, facilitating their spread and gain in importance. Fifteen years ago, it was demonstrated that transgenic crops with resistance to systemic herbicides with three different targets sites of action could be successfully used to

control parasitic weeds [9]. No transgenic crop has yet to be marketed with this use in mind. Non-transgenic maize [10, 11] and sunflowers [12, 13] with mutant acetolactate synthase genes have been marketed, and can be used for this purpose. A similar herbicide-resistant sorghum is also being developed for use in *Striga* control in Africa [14]. Parasitic weeds have not rapidly evolved resistance in maize because at the high local herbicide levels used with maize seed dressings, resistance is recessive [15]. At the levels used in field spraying sunflowers, both parasitic weeds and regular weeds are rapidly expected to evolve resistance.

Wheat and rice are humanity's two major food crops. Before the advent of selective herbicides, wheat fields were biodiversely multicolored red (from poppies) or white or yellow (various mustards or other weeds). These weeds severely reduced yields and grain quality. The advent of the herbicide 2,4-D after World War II rid wheat and rice fields of broad leaf weeds that made fields so pretty to city folk, but devastated farmers. No real sustainable fit resistance has evolved to 2,4-D among the weeds it so successfully controlled. Grass weeds, which could not compete with broad leaf weeds, quickly filled the ecological vacuum for weeds in wheat and rice. Industry countered by developing selective graminicides that could control the grass weeds in wheat and rice, grasses themselves. One by one grass weeds evolved resistance to the various graminicides, most often by using the same enzymes the crops uses to degrade and detoxify the herbicide. Initially, the weeds had too low a level of these enzymes and they slowly evolved upregulated levels, probably by gene duplication or modifications in controlling elements such as promoters and enhancers of gene expression [3]. Thus, wheat and rice are ideal targets for transformation with genes endowing resistance to general broad spectrum herbicides such as glyphosate. Such new transgenic wheat or rice varieties could then be treated with a single broad spectrum herbicide instead of 2,4-D (or a related herbicide) together with a graminicide, a more expensive technology. Both transgenic glyphosate- and glufosinate-resistant rice and wheat have been generated and tested, but neither has been marketed.

There is good evidence that transgenic herbicide resistance, as presently generated, may well not be sustainable, even in the short term in wheat and rice. This is rather certain for rice on a broad scale and for wheat on a more limited scale. This is due to two particular weeds, one more limited in distribution (*Aegilops cylindrica*) in wheat, and weedy rice in rice. Neither weed can be controlled by the selective herbicides in these crops, as each is too closely related to the crop, and are naturally resistant to the same herbicides. Wheat and rice are thus problematic targets for transgenic herbicide resistances that can then provide selectivity between weed and crop. Both weeds are able to introgress genes (hybridize and then internalize genes) from the respective crop. *Aegilops cylindrica* is a weed composed of two related but distinct genomes and wheat is made up of three. One genome is common to both wheat and its hard-to-control weed. When one mutant non-transgenic herbicide-resistant (Clearfield™) wheat was developed, the resistant gene quickly appeared in *Aegilops cylindrica* in the USA [16], and other herbicide resistances were shown to move from wheat to two other *Aegilops* species in Europe [17, 18]. Thus, instead of being controlled by the herbicide, these weeds could again become uncontrollable problems.

Weedy rice (also called feral rice or red rice) is a large group of varied de-domesticated rice strains, but almost all are the same species as cultivated rice [19]. The consistent trait of weedy rice is that it shatters seed; a dominant back mutation from the recessive non-shattering of the crop. Weedy rice can have other dominant mutations rendering it ever more feral and weedy, a regain of secondary dormancy such that some seeds remain dormant for a few seasons; a dominant mutation to reddish or purple seed color; long awns, a dominant mutation to height and to tillering [19]. Weedy rice had been controlled by transplanting nursery-grown non-weedy domestic rice into cultivated paddies, giving the crop a month head start. This labor intensive, backbreaking process is rapidly being replaced by direct seeding, and weedy rice is celebrating. The only chemical answer has been a non-transgenic Clearfield™ rice, and the mutant gene quickly moves into weedy rice [20]. The Clearfield™ technology quickly became "passé" in tropical Latin America where it had been used season after season even during the same years [21, 22].

Thus, it can be seen that where a crop has a related introgressing weed in the same agroecosystem,

transgene flow from crop to weed can be a real issue, especially with a trait such as herbicide resistance. Transgene flow from crop to related wild species would be an ecological nonissue as herbicides are not used in the wild, so there would be no selective advantage to resistance. One must carefully read and interpret the literature claims of gene flow from transgenic crops to "wild" relatives, (for example, [23]). A close perusal of the data quickly reveals that there was no gene flow to wild relatives, but that all the gene flow was to weeds of agroecosystems or of ruderal (human disturbed) ecosystems such as roadsides. There are many basic differences between weedy species and wild species [24].

There are many crops with weedy or feral relatives in the same agroecosystems, and these weeds are major problems in those crops. They include weedy beets, weedy radish, weedy sunflowers, and especially weedy sorghum (shattercane) [23, 25–28]. All the weeds are the same botanical species as the crop, even if botanists have tagged them with different Latin binomials. There are no known weedy forms of cotton, maize, or soybeans in the vast majority of the areas where these crops are cultivated. There are no weedy relatives of oilseed rape in the western provinces of Canada where transgenic herbicide-resistant oilseed rape was initially introduced, but there are in the eastern provinces and gene flow is a problem there. Thus, there is a Catch 22 situation with many crops: transgenic herbicide resistance is needed to control weeds related to the crop, but the transgene will quickly hybridize into the weed, abrogating the utility of the technology. As will be discussed in a later Section, the problem can be overcome by more sophisticated transgenic technologies.

The Evolution of Weed Resistance

More than 90% of the area covered by transgenic herbicide-resistant crops is devoted to one gene (CP4 type EPSP synthase) and the herbicide glyphosate (Roundup Ready™) [5, 6]. When this was just released and being rapidly adopted, the manufacturer saw no reason to institute any strategies that might delay resistance from evolving, and the company scientists claimed that the nature of the herbicide and its mode of action precluded the evolution of resistance, a view they maintained well after the first cases of evolved resistance were confirmed [2]. This was despite ample evidence that there was diversity in the level of resistance among weeds due to a multiplicity of factors, and these factors could either combine to provide resilient resistance or any given factor could intensify with the same result [29]. Nature has a way of making fools of those who claim that something cannot evolve, and has done so with a vengeance. There has been a propensity of some of the most pernicious weeds to have the variability and mutability to rapidly evolve resistance to many different herbicides.

It may be a question of numbers, these are weeds that shed thousands of seeds where one or two would be enough for replacement of parents or it could be that they are more mutable than others. Thus, weeds in the genus *Amaranthus* and *Lolium* have rapidly evolved resistance to most herbicides controlling them [3, 30], and they proceeded to evolve resistance to glyphosate in various locations around the globe [1], often with different populations evolving differing modes of resistance. Some of the weeds that evolved resistance were those where glyphosate was most needed; those requiring a systemic herbicide. Some of these weeds evolved a "phoenix" resistance. The leaves burnt off and new shoots emerged from the ashes in a manner similar to the mythical bird. In *Conyza*, they emerged from dormant buds at the base of the rosette of leaves [31]; in *Sorghum halepense* (johnsongrass) in Argentina and the USA from the underground rhizomes [30, 32, 33]. In many of these cases, glyphosate was the herbicide of last resort, the weeds had evolved resistance (or were naturally resistant) to other herbicides.

Very Few Herbicide-Resistant Genes Have Been Commercialized

The ease of use, the low price of herbicide, the broad spectrum of weed control quickly rendered glyphosate resistance the choice of farmers. The farmers either believed or wished that weeds would not evolve resistance to glyphosate. Worse yet, competitors of the producers of glyphosate believed this hype and severely cut back on research on discovery of new herbicides and on developing transgenic resistances to their own preexisting herbicides, which they thought could never compete with glyphosate, and by not bringing

new products to market self-fulfilled their predictions. The options available to farmers were further reduced when it came time for industry to reregister older herbicides. Many companies decided that they could not justify the outlay for renewed registration because they thought that other herbicides will never again compete with glyphosate. Many transgenic herbicide resistances under development that had value were never released and at least one that had been commercialized was withdrawn. When glyphosate resistance was initially released, seed companies continued to breed conventional varieties to provide farmers with choice. The less farmers chose conventional varieties, the less incentive remained to breed them.

The lack of alternatives clearly exacerbated the rate at which glyphosate resistance evolved and spread. This in turn was made worse by policies of the manufacturer who convinced many that resistance could not be an issue and no management strategies were needed that might involve competitors' products that could assist in sustaining their own technology.

Non-transgenic Strategies to Sustain Transgenic Herbicide Resistances

There are a series of strategies used to sustain the useful lifetime of conventional herbicide technologies. These can extend the useful lifetime of the transgenic herbicide only where there is a no similarity between the transgenic crop and the weed; that is, such technologies are poor at dealing with problems such as transgene flow from crop to related weed. One strategic mistake with glyphosate-resistant crops was the promotion of glyphosate for all applications, including preplant where crop herbicide resistance is not required. There are other herbicides such as paraquat and inhibitors of protoporphyrinogen oxidase that provide rapid burn down of most weeds; with the notable exception being those that require a systemic herbicide. Thus, any weeds that might have evolved glyphosate resistance in previous seasons and germinate before planting would be controlled by these preplant herbicides. At least by changing the preplant herbicide, glyphosate-resistant weeds will not have a head start on the crop.

Crop and herbicide rotations have always been excellent tools to delay herbicide resistance using conventional herbicides, and they could have delayed glyphosate resistance, had they been applied. The best herbicides for use in rotation are those that exert negative cross-resistance; that is, they are more effective at controlling resistant individuals that in controlling the wild type [34]. Still, there have been no reports about herbicides that preferentially control glyphosate-resistant weeds. Most cases of glyphosate resistance evolved following the sole use of glyphosate, season after season, with no other herbicide that controls the target weeds used in the interim.

Some herbicide mixtures have been highly effective in delaying resistance in the past. Resistance evolved to atrazine in maize where atrazine was used alone, but not where it was mixed with herbicides in the chloroacetamide group inhibiting long-chain fatty acid biosynthesis [35]. These chloroacetamide herbicides even prevented the evolution of resistance in weed species that they did not control; but they must have weakened them to the point that they were unable to compete. Not all mixtures work equally well, and there are some rule-of-thumb criteria for choosing good mixtures, such as having the same persistence, different targets of action, overlapping weed control spectra, etc. [36].

Genetic Engineering Strategies to Extend the Sustainability of Transgenic Herbicide Resistances

From the foregoing, it is clear that many of the problems with what had been and still is a most useful agricultural tool, transgenic herbicide resistance, are derived from the overreliance on a single technology. If there were more transgenic herbicides to rotate, the risk would have been spread and each would last for much longer, and each in turn would have controlled resistance to the previous one. There are herbicide chemistries that have less propensity to having herbicide resistance evolve, and should be used more often in rotations and mixtures. The chloroacetomide herbicides inhibiting long-chain fatty acid biosynthesis have been heavily used for over 4 decades. The only major case of resistance reported for this group was when a rice weed evolved resistance to one herbicide in the group [37]. The cross-resistance of the weed to herbicides of a different group suggests that resistance probably was not at the target site of herbicide action. These chloroacetamide herbicides inhibit more than one fatty

acid elongase, and resistance at all the target sites would require the exceedingly rare confluence of a few mutations appearing simultaneously. Resistance due to catabolism could continue to evolve to members of this group of herbicides, but the diversity of chemistries preclude the probability of a single metabolic system degrading them all.

Industry has dedicated most of its efforts to finding herbicides that affect single targets of action. Nature has been wiser; it evolved natural herbicides (allelochemicals) as part of one of its strategies of using chemical warfare for one plant species to compete with others. Many of these allelochemicals inhibit more than one target site [3]. For example, sorghum secretes the phytotoxin sorgoleone that inhibits two separate targets in plants, the psbA protein in photosystem II and the enzyme HPPD (4-hydroxyphenylpyruvate dioxygenase) [38], which are key targets of two separate groups of commercial herbicides. Two targets would have to simultaneously mutate for target site resistance to evolve. If the chemical industry could find such multisite inhibitors, the biotech industry could find or generate genes encoding enzymes that will degrade them to provide crops with selective transgenic herbicide resistance. Technologies such as gene shuffling allow researchers to take genes that encode enzymes that inefficiently degrade a herbicide and turn them into usable genes. This has been elegantly used to generate herbicide-resistant maize, but so far only published for generating metabolic resistance to the herbicide glyphosate [39], where additional resistant genes are redundant.

There are ways to extend useful life of the present and future transgenic herbicide resistances by stacking genes. There are also ways to deal with crops where gene flow is an issue, as well as to develop sophisticated systems using herbicide hypersensitivity to both prevent volunteer weeds and crop × weed hybrids from going feral. One can even envisage ways of overcoming weed resistance after it has evolved, all as outlined below.

Stacking Herbicide Resistances

Two companies have announced that they are stacking herbicide resistances to preclude some of the problems that at least one [2] had denied would occur. This will require the farmer to use both herbicides, effectively raising production costs. Convincing them to do so may not be easy. One company is stacking glyphosate resistance with resistance to dicamba, a herbicide similar to 2,4-D in structure and mode of action [40]. Another is stacking glyphosate resistance with resistance to acetolactate synthase inhibiting herbicides [41]. These may solve many problems, but not all. Dicamba controls only broad leaf weeds so it may be effective against the *Amaranthus* species that evolved resistance to glyphosate [30], but will have no effect on the populations of grass weeds such as johnsongrass and *Lolium* spp. that have already or will evolve resistance to glyphosate. At high rates, dicamba will kill some perennial broad leaf weeds, but a high level of transgenic resistance will be required.

The choice of acetolactate synthase inhibiting herbicides as a mixing partner for stacked-gene crops raises questions, even though these are systemic herbicide. Too many weeds that have evolved glyphosate resistance such as *Lolium* spp., the *Amaranthus* spp., *Conyza* spp., as well as the *Sorghum halepense* have already evolved resistance to these acetolactate synthase herbicides [30, 32], the most resistance-prone group of herbicides known. Even if this has not occurred in all populations, it easily can.

The best stacking partners will be with genes encoding resistance to systemic general herbicides with multiple target sites of action (mostly yet undiscovered), and/or with genes encoding resistance to graminicides, as these are cases where the needs are the greatest.

Mitigating Gene Flow with Tandemly Coupled Genes for Herbicide Resistance and Non-weediness

As discussed above, there is a major reservation to conferring transgenic herbicide resistance on major crops such as rice, wheat, sorghum, sunflowers as well as others having related weeds. This is because such herbicide resistances would be non-sustainable. The ability to control the closely related feral, weedy forms of these crops or other closely related weeds residing in the same agroecosystem as the crop, will soon be lost due to gene flow. This problem can be precluded by assuring that any hybrid and future offspring from a cross of a transgenic herbicide-resistant crop with an interbreeding weed will lose at least one weediness

trait, rendering it less fit to compete with its wild-type brethren, as well as less fit to compete with other species. In highly competitive ecosystems such as agricultural fields, where hundreds of weed seeds germinate in a small area, and competitive "self thinning" leaves a single survivor, "less fit" usually means "unfit." Thus offspring having lost a weediness trait are offspring that cannot establish as a majority of a population; at worst, these offspring will remain in an insignificant frequency in the population, at best, they will die off completely. This use of a tandem construct of a herbicide resistance gene coupled with an anti-weediness gene or genes is the basis of the concept of transgenic mitigation [42]. The mitigating genes used can be those genes causing dwarfing, genes preventing seed shattering, genes preventing secondary dormancy, and with "root" or "head" crops, genes preventing "bolting" (premature flowering) [26]. The result is offspring that are more like the crop and cannot compete with weeds. Because a tandem construct is used, the herbicide resistance and the mitigating genes are genetically linked and will not segregate from each other. Where goes resistance, so goes mitigation. That this strategy might work has been demonstrated with transgenically mitigated tobacco competing with wild-type tobacco as a model system [43, 44], and with oilseed rape in the screenhouse [45, 46] as well as in the field [47].

A Special Endogenous Mitigator for Wheat Wheat has a propensity to naturally introgress genes into wild and weedy *Aegilops* species [16–18], including those with which it has no homologous chromosomes, such as *Aegilops peregrina* [48]. It transfers such genes by the process of homoeologous recombination by which similar but not identical (homoeologous) chromosomes recombine. This recombination does not occur in the F_1 generation, only in backcrosses after some wheat chromosomes are lost, most notably chromosome 4B. Homoeologous recombination would be deadly to wheat itself; the chromosomes of its three different genomes would pair with each other during meiosis causing a spaghetti-like mess. There is a gene *ph*1 on this long arm of chromosome 4 in the B genome (4BL) that prevents homoeologous recombination, and thus this type of gene flow from wheat to related *Aegilops* species can occur only after 4BL is lost. Thus, it was suggested to insert the gene of choice (herbicide resistance) on 4BL near *ph*1 so that they will remain together, either by homologous recombination onto 4BL or by random insertions and cytologically determining which occurred onto 4BL [49]. Thus, while the F_1 and some backcrosses with *Aegilops* could be resistant to herbicides, it is unlikely that the resistance gene could ever integrate into the *Aegilops* genome by homoeologous recombination.

Mitigating Volunteer Weed Establishment Gene Flow by Engineering Hypersensitivity to Herbicides

An interesting tandem construct was demonstrated to work in rice to assure that transgenically glyphosate-resistant rice volunteers cannot survive. This was achieved by spraying the next crop of (non-glyphosate-resistant) rice with the herbicide bentazon. Bentazon is a selective herbicide that can be used in conventional rice, because rice has an enzyme that degrades bentazon to nontoxic products. The transgenic glyphosate-resistant rice contained the glyphosate-resistant gene in tandem with an antisense (reverse direction) form of the gene encoding bentazon resistance [50]. This antisense form suppresses the expression of the bentazon resistance rendering rice to be hypersensitive to bentazon. When bentazon is used, glyphosate-resistant volunteer rice and any hybrids with weedy rice die.

This strategy has been theoretically extended to other crops and other herbicide resistances to develop a seemingly complicated and sophisticated strategy [51]. Still, such strategies can easily be implemented if there is an agreement among farmer groups, chemical producers, biotech and seed companies. The strategy is to have a series of transgenic varieties with opposing metabolic herbicide resistances and hypersensitivities cultured in rotation so that volunteers and hybrids with weedy forms are killed in alternate generations, and weedy forms that did not introgress the transgene are also controlled in each generation. For example, variety 1 contains a gene encoding glyphosate metabolism (glyphosateR) in tandem with the antisense form of the gene degrading glufosinate. Thus, variety 1 is glyphosate resistant and hypersensitive to glufosinate. Variety 2 has a gene encoding glufosinate metabolism (glufosinateR) and an antisense form of the gene

encoding glyphosate resistance. Thus variety 2 is glufosinate resistant and is hypersensitive to glyphosate. Thus, when the herbicides and varieties are used in rotation, glyphosate use with variety 1 will kill volunteers of and hybrids with variety 2, as well as the weedy wild type. Glufosinate with variety 2 will kill volunteers and hybrids with variety 1 as well as the wild-type weed [51]. Other mitigator genes can be added in tandem to further preclude gene flow. This type of stacking has the advantage of requiring the use of a single herbicide during each cropping generation.

As complicated as the strategy may sound, it requires only that the herbicide and crop seed be bundled (sold together) and that only a single variety is available each cropping season. Not only does such a strategy deal with gene flow to weedy rice, it also will delay the evolution of both glyphosate and glufosinate resistances. From past experience with herbicide resistances, such rotations extend the total expected useful lifetime of both herbicides well beyond the sum of expected lifetimes of each, if each had been used as the sole herbicide without rotation.

Implementation of such sustainability extending practices is not unknown even though industry typically cites antitrust laws as preventing joining forces for such strategies. For example, Australian cotton growers joined forces with academic experts on resistance management and industry and decided which insecticides may and may not be used at different times during the growing season to delay the evolution of all resistances [52].

Overcoming Transgenic Herbicide Resistance Once It Has Evolved in Weeds (Science Fiction?)

The following are strategies proposed (for the first time) for controlling herbicide-resistant weeds once they have evolved. The first strategy is an extension of a concept suggested on how to cause insects to commit chemical suicide [53], which was modified to have parasitic *Striga hermonthica* [54], and other outcrossing weeds such as *Lolium* spp. [26] commit chemical suicide. The proposal is as follows: after an outcrossing weed has evolved herbicide resistance, either via gene flow from the crop or by natural means of evolution, the gene(s) responsible must be isolated. The gene(s) in the antisense form is/are inserted into a transposon (a DNA element that can move from one location in the genome to another) that is compatible with the weed, and multiple copies of the transposon are transformed into the weed and seeds bulked up. The weed seeds are sown into a field where resistance is a problem. For 4–6 generations, alternative crops and herbicides are used. It is rare that any herbicide kills more than 95% of weeds. The remaining weeds will interbreed. All offspring of a weed crossing with others bearing multicopies of the transposon will also contain the trait and the trait will quickly spread. If the trait were to be spread by nuclear, Mendelian genetics, only 50% of offspring would bear the trait. Transgenic traits are functionally dominant in plants, so even heterozygous plants with the transgenic override of resistance are now sensitive to the herbicide, and the herbicide again can be used. Because of the antisense, none of the transposon-bearing weeds are now resistant to the original herbicide, and the original transgenic herbicide-resistant crop can be grown again. This strategy is limited to obligate outcrossing weeds, and would be lost when/if the outcrossing species evolved self-compatibility. Transposons normally move genes around a genome, and presumably have moved some transgenes in the crops already commercialized. Thus, it might be hard to find scientific regulatory concerns about such a technology.

Alternatively, the antisense form of the gene overriding resistance can be inserted into a disarmed (no longer pathogenic) systemic virus that is specific to the weed, and the weeds inoculated by virus-coated grit applied by commercial sandblasting equipment. The virus would spread and the weeds would be functionally susceptible to the herbicide. This use of viruses was initially suggested for producing vaccines to animal diseases in fodder crops [26]. Most viruses do not reach generative (sex) cells, which means that every generation of weed would have to receive such an application, as the trait will not be inherited. There should be few regulatory biosafety concerns about the use of a virus that does not insert DNA into generative cells in seed-propagated crops, as the trait will not be inherited through seeds. If a virus can be found that does insert its nucleic acid into generative cells, a combination of the above two strategies could be considered; the antisense gene in a multicopy transposon could be transmitted by such a virus, and herbicide sensitivity would be conferred on the virus/transposon infected weed, but also on all its

offspring. Here, there may well be biosafety concerns that must be ascertained and dealt with if indeed this strategy can be determined to be worthwhile.

Future Directions

The present use of transgenic herbicide resistance has proven itself to be non-sustainable for long periods as a stand-alone technology without instituting meaningful strategies to keep these technologies in the farmers' arsenal of weed control options. Similarly and even less sustainable, is the practice of mutating crops to herbicide resistance, where the crops have interbreeding-related weeds in the same fields. Both governments and industry have failed to institute management strategies to sustain such technologies. The lack of government regulatory intervention is surprising and disturbing. The regulatory systems required management strategies to delay resistance to transgenic Bt insect-resistant crops, a small fraction of the transgenic crops released, but ignored such issues with herbicide-resistant crops, including the deregulation (i.e., permission for commercial cultivation) of transgenic herbicide-resistant oilseed rape, beets, and rice, all crops with interbreeding weeds. Governments have questionable regulatory authority over the non-transgenic herbicide resistances released in rice, wheat, sunflowers, and oilseed rape, all crops with related interbreeding weeds, and a demonstrated ability to lose sustainability. Perhaps, they should assist sustainable agriculture by obtaining such regulatory authority.

The first priority for the future is to learn from the past and rapidly institute strategies to keep the present herbicide resistances useful. Unfortunately, neither industry nor farmers have long-term considerations; this year's profitability is all that seems to matter. Long-term sustainability of profitability is more an interest of governments, and the regulatory regimes must be set up to attain sustainability through requiring innovations. Goals and milestones must be set for instituting management strategies, and then support academia and industry in testing which are the most cost-effective strategies for maintaining long-term sustainability of herbicide-resistant crops, both of transgenic and non-transgenic herbicide-resistant crops. Such crops must be available in the future and are imperative for food security.

Article Outline

Glossary

C_3 photosynthetic system In which the enzyme rubisco is responsible for the initial fixation of carbon dioxide. All tree and vine crops, all cool-season-adapted annual crops, and most warm-season-adapted annual crops have this photosynthetic system.

C_4 photosynthetic system In which the enzyme PEP carboxylase is responsible for the initial fixation of carbon dioxide. A few tropical grasses (e.g., maize, sorghum, pearl millet, and sugarcane) and a very few warm-season-adapted herbaceous dicotyledonous crops (e.g., grain amaranth) have this photosynthetic system.

CTD Plant canopy temperature depression, the number of degrees Celsius the plant canopy is cooler than air temperature.

FACE Free-air CO_2 enrichment is a system for studying crop responses to elevated [CO_2] under natural open-air field conditions.

Harvest index The ratio of grain yield to total aboveground biomass at harvest.

Heat resistance A cultivar is heat-resistant if it has greater yields of economic product, such as the weight of grain or fruit per unit land area, than standard cultivars in hot environments.

Heat tolerance A cultivar is heat-tolerant if it has a specific process such as germination, vegetative survival, pollination, or fruit set that withstands heat better than the process does in standard cultivars.

Subtropical zones Are where the coldest month has a mean air temperature $<18°C$, there is a long period (8–12 months) when plants can actively grow (mean monthly air temperatures $>10°C$), and only occasional frosts occur. This zone is located at low elevations in latitudes between 20° and 30° [26].

Temperate zones Are where there are only 4–7 months when temperatures are high enough for plants to actively grow (mean monthly air temperatures $>10°C$), and there is a long, cold winter. This zone is located at either high latitudes or at high elevations in more equatorial latitudes [26].

Tropical zones Are where all monthly mean air temperatures are $>18°C$, and there is no frost and minimal chilling. This zone is located at low elevations between the Tropic of Cancer and the Tropic of Capricorn [26].

Definition of the Subject and Its Importance

As a consequence of global climate change, air temperatures are predicted to increase by about 4°C during the twenty-first century. Plant physiological and developmental processes respond to temperature by increasing at low temperatures, responding only slightly at optimum temperatures and decreasing at high temperatures. At high temperatures, the processes can become irreversibly damaged. Of particular concern for crop production are the substantial decreases in grain or fruit production caused by experimentally induced increases in air temperature that have been observed in field conditions. In addition, in some zones and years some crop species already are being subjected to temperatures that are above optimal. In a small number of cases, crop cultivars have been bred with developmental and physiological processes that can tolerate a few degrees higher temperature, such that they are heat-resistant and produce more economic yield than standard cultivars in hot environments. Consequently, it is important to determine the circumstances where future breeding of cultivars with heat-tolerant processes, such that they are more heat-resistant than current cultivars, can contribute to the sustainability of crop production during future global warming.

Introduction

During the 1990s, accelerating increases in atmospheric carbon dioxide concentration [CO_2] have occurred leading to the current concentration of 380 ppm and a predicted level greater than 600 ppm by the end of the twenty-first century. As a consequence of the increases in [CO_2] and other gases that absorb infrared radiation, global warming probably already has begun. It has been predicted that temperature increases of about 4°C will take place by the end of the twenty-first century in crop production areas. In some circumstances, these increases in air temperature could result in substantial decreases in economic yield if cultivars, management methods, or crop species are not changed. In contrast, the many crop plants with the C_3 photosynthetic system could exhibit a tendency for increases in photosynthesis and productivity as [CO_2] continues to increase. Consequently, it is important to determine whether elevated [CO_2] can reduce the potentially detrimental effects on productivity of increases in air temperature.

Up to now there has been relatively little emphasis on breeding for heat tolerance in either the public or the private sector but significant progress has been made with a small number of crop species [24]. Breeding the first heat-resistant cultivars by incorporating heat tolerance has taken at least 10 years with annual crop species that are relatively easy to breed. The approach taken has involved incorporating heat tolerance during pollination and seed or fruit set [24]. Breeding heat-resistant cultivars of hard-to-breed perennial species, such as trees or vines, likely would take several decades and many resources. The effects of high temperature, elevated [CO_2], and their interaction on crop plants will be examined. Circumstances where heat-resistant cultivars could help to sustain productivity in the future will be discussed, including consideration of potential negative effects of genes that confer heat tolerance. In addition, circumstances will be described where attempting to incorporate heat tolerance may not be justified and alternative mitigation procedures will be needed.

Climate Change Effects on Crop Plants

Increased Temperature Effects on Crop Plants

From 1950 through 1979, daily minimum temperatures increased more than daily maximum temperatures. However, from 1979 through 2004, there were comparable increases in daily maximum and minimum temperatures [75]. Models predict that daytime and nighttime temperatures will both increase by about 4°C in the twenty-first century. This is important because in some cases high nighttime temperatures have been more damaging to crop productivity than high daytime temperatures [24]. There is some uncertainty with respect to how fast air temperatures may increase and how much they may increase in different parts of the world and seasons of the year.

Higher temperatures can have complex effects on plants. The approach taken in this analysis is to determine: what aspect of temperature is most damaging to productivity (Is it high day temperature or high night temperature or both and at what stage of development?); what developmental stage or physiological process is most damaged by heat stress; and what extent is economic yield (i.e., grain or fruit yield) decreased when the developmental or physiological process is damaged. Answers to these questions provide the information needed to design efficient programs for breeding heat-resistant plants.

The most reliable method to determine the effects of increases in temperature on productivity is to subject different plots of crop plants growing in the field to increases in temperature. Unfortunately, only a few studies of this type have been conducted. In one of these studies, plots of cowpea that were flowering were enclosed with plastic only during the nighttime hours and a system involving a fan, air-distribution system, heater, and differential thermostat were used to raise the air temperature in the enclosure a fixed number of degrees above ambient air temperature [53]. With this system, daytime conditions on the treated and control plots were not changed, so it is likely that the differences in productivity between the plots were caused by the differences in nighttime temperature. The cowpea plants exhibited a 4.4% decrease in grain yield per degree Celsius increase in nighttime temperature above a threshold daily minimum temperature of 15°C [54]. The lower yields were due to reductions in the proportions of flowers producing pods. In another field study, sorghum exhibited a 28% decrease in grain yield and a 30% decrease in seed number when night

temperatures were increased 5°C for 1 week during floret differentiation [17]. When rice plots were subjected to a 4°C increase in temperature both day and night using open-top chambers, there was a decrease in grain yield of 18% [47] due to reductions in spikelet and pollen fertility [45].

Another approach involves growing a crop cultivar with similar management methods in field environments with contrasting thermal regimes. A major problem with correlation studies of this type is that the different field environments also differ with respect to factors other than nighttime temperature, although an attempt was made to minimize these differences in the following examples. When cowpea was grown in four locations in a subtropical zone with contrasting thermal regimes over 2 years a 13.6% decrease in grain yield per degree Celsius increase in average minimum night temperature above a threshold of 16°C between emergence and first flowering was observed [32]. The reduction in productivity was mainly due to reductions in pod set and harvest index (HI is the ratio of grain yield to total shoot biomass). Correlation studies also have been conducted where the productivity of a rice cultivar was examined over 12 years during which time the temperature varied in a tropical zone [60]. In this case, grain yield decreased 10% per degree Celsius increase in minimum night temperature.

A third approach involves studies using glasshouses or growth chambers with artificial lighting systems. While these types of studies can produce information on the mechanisms of heat stress effects because many factors can be kept constant and the studies can be repeated, they tend not to produce reliable data concerning the yield losses due to heat that might occur in field conditions. Studies with cowpea will be discussed because much research on heat-stress effects has been conducted with this crop species and there are indications that some other crop species are affected in a similar manner. Growth chamber studies demonstrated that high night temperatures can reduce pod set of cowpea due to impaired pollination [79], whereas much higher temperatures during the day did not reduce pod set [78]. Artificial pollination studies demonstrated that the female part of the flower, the pistil, was not damaged by high night temperatures [77]. Reciprocal transfers of plants between growth chambers with high or optimal night temperatures demonstrated that the stage of floral development most sensitive to heat stress occurred 9–7 days before anthesis [1]. This stage is after meiosis, which occurs 11 days before anthesis. Damage occurred at the time that the tetrads are released from the microspore mother cell sac [1, 48, 79]. Premature degeneration of the tapetal tissue and lack of endothecium formation were observed which could have been responsible for the low pollen viability, low anther dehiscence, and low pod set under high night temperatures [1]. Tapetal tissue plays an important role in providing nutrients to developing pollen grains and its premature degeneration could thereby stunt pollen development. Based on studies with contrasting cowpea genotypes, Mutters et al. [49] proposed that heat injury during floral development of sensitive cowpea genotypes may be due to reduced translocation of proline from anther walls and tapetal tissue to developing pollen. Tapetal malfunction has been considered to be the causal mechanism of much of the cytoplasmic and genetic male sterility occurring in plant species [16, 51]. Growth chamber [50] and glasshouse studies [19] have shown that high night temperatures can be more damaging to reproductive development of cowpea under the long days typical of subtropical zones than under the short days that can occur in tropical zones.

Why is pod set in cowpea sensitive to high night temperature while it is not sensitive to much higher temperatures during the day? Growth chamber studies demonstrated that pod set of cowpea is sensitive to heat during a particular time in the night, the last 6 h and not the first 6 h of a 12-h night [48]. The greater sensitivity of pod set to heat under long days was shown to be a phytochrome-mediated effect [50]. Phytochrome-mediated events have a degree of circadian control occurring at a particular time in the 24-h cycle. Mutters and Hall [48] hypothesized that there is a heat-sensitive physiological or developmental process in pollen development that is under circadian control. Natural selection would have favored plants in which this process takes place during the coolest part of the diurnal period, which is the late night and early morning.

As with cowpea, day length also can influence the effect of high temperature on pollination of rice

[83]. In addition, glasshouse studies have shown that higher nighttime temperatures that reduced grain yield of rice also reduced percentage of pollen germination and spikelet fertility [46]. Studies in sunlit growth chambers demonstrated, however, that both high day and high night temperature can reduce spikelet fertility in rice [84]. If there is a heat-sensitive process in pollen development that occurs in the coolest period in the 24-h cycle, it could be affected by both late night and early morning temperatures.

From the field and controlled-environment studies, it is apparent that, depending on the crop species, increases in night or day temperature of 4°C during early flowering could cause substantial reductions in fruit or grain yield. The reductions in yield in cowpea and rice appear to have been mainly caused by reduction in pollination. Similar effects have been seen in some other annual crop species including common bean [23]; peanut [72, 73]; tomatoes [59]; pepper [81]; and cotton [70]. The species that appear to be particularly sensitive to high night temperature include: cowpea, common bean, pepper, cotton, sorghum, and possibly rice. Few controlled-environment studies have been conducted of high temperature effects on perennial crops. In one case, for peach, higher temperatures resulted in reduced pollen viability, lack of synchronization in fertilization, reduced fruit set, and reduced fruit yield [52].

Where heat stress is most damaging to economic yield by reducing fruit set and/or seed set, it is a case of the reproductive sink suffering greater damage than the photosynthetic source of carbohydrates. Alternative possibilities for the effects of heat stress include the photosynthetic source suffering significant damage that then reduces economic yield, and cases where both the reproductive sink and the photosynthetic source suffer significant damage.

For Irish potatoes, economic yield may be reduced because of heat-induced reductions in photosynthesis [67]; although initiation of tuberization may be even more sensitive to heat stress than photosynthesis [66]. Grain yield of wheat may be reduced in hot environments because of heat-induced reductions in photosynthesis and stomatal conductance [68]. However, high temperatures during the early floral development can result in infertile pollen and low grain set in wheat [14]. Consequently, reductions in grain yield of wheat in hot environments may be due to both reductions in photosynthesis and damage to reproductive development.

Elevated Atmospheric Carbon Dioxide Concentration [CO_2] Effects

Analyses of air trapped in polar ice indicates that, prior to the year 1800, the [CO_2] fluctuated between 180 and 290 ppm for at least 220,000 years [29]. Since 1800, ice core data indicate increases in [CO_2] from 280 to 315 ppm by 1958. Direct measurements of [CO_2] indicate accelerating increases since 1958 from 315 to 380 ppm by the early 2000s. Predictions indicate [CO_2] could exceed 600 ppm by the end of the twenty-first century.

Plants with the C_4 photosynthetic system evolved during an early period after the [CO_2] became low, and this system represents a specific adaptation to the low [CO_2] environments of the last 200,000 years. The yield responses of C_4 species to elevated [CO_2] are small, and will not be considered in this analysis. The extent and nature of the evolution of plants with the C_3 photosynthetic system, with respect to low [CO_2], are not known. It is likely that low [CO_2]s over 220,000 years resulted in evolutionary modifications to whole plant processes, such as increases in the ratio of photosynthetic source to carbohydrate sink tissues. Consequently, some C_3 plants may not be well adapted to either future or even present-day levels of [CO_2] due to inadequate investment in sink tissues [30]. Photosynthetic rates of these plants may increase when [CO_2] is increased from the current level of 380 ppm to say 600 ppm but the rates may not increase as much as they would if the whole plant system was adapted to function optimally at a [CO_2] of 600 ppm. Progress during the twenty-first century in increasing the productivity of several C_3 crops through plant breeding was estimated as mainly (77%) resulting from increases in HI with only 23% due to increases in total shoot biomass [22]. This indicates these crop species had an inadequate reproductive sink, for agricultural purposes, and with increasing [CO_2] the reproductive sink may become even more inadequate to support the full photosynthetic potential.

In early studies using controlled-environment enclosures, doubling [CO_2] increased grain yield of various small grain cereals by 32% and various grain legumes by 54% at intermediate temperatures [36]. More recent studies with free-air [CO_2] enrichment (FACE) experiments under field conditions, however, gave grain yield responses to elevated [CO_2] that were about 50% lower than those obtained using enclosures [39]. FACE experiments provide responses that farmers are more likely to get because the crops are grown under natural open-air field conditions. Yield increases in the FACE studies were less than the increases in photosynthesis that occurred with short-term doubling of [CO_2] at the same temperature [3, 61]. A possible explanation for the smaller yield responses to long-term [CO_2] enrichment is the downregulation of photosynthetic capacity that occurred in the FACE experiments [39]. This downregulation has been attributed to feedback mechanisms that operate when the supply of carbohydrates from photosynthesis exceeds sink demands for carbohydrates [3]. Limitations by sink demand were apparent in those FACE experiments where only a small proportion of the increase in photosynthate supply was partitioned to grain [39]. The results of the FACE experiments support the hypothesis that crop plants are not well adapted to the higher [CO_2]s likely to occur by the end of the twenty-first century.

Interactive Effects of Increases in Temperature and [CO_2]

The interactive effects of elevated [CO_2] and higher temperatures on plants are complex [13]. They can be simplified if one separates cases where heat stress limits the reproductive sink from cases in which heat stress limits the photosynthetic source. In many cases, reproductive development is more sensitive to heat stress than overall biomass production resulting in a decrease in HI. For soybean grown under controlled-environment field conditions, HI progressively decreased with increasing temperature under either 330 or 660 ppm [CO_2] and HI was lower with elevated [CO_2] indicating a more severe imbalance between the reproductive sink and the photosynthetic source [6]. Reproductive development of Pima cotton can be so sensitive to high temperatures that the plants do not produce either fruiting branches or bolls [63]. Studies in naturally sunlit, controlled-environment chambers demonstrated that elevated [CO_2] of 700 ppm did not ameliorate this problem [64, 65]. Controlled-environment field studies with rice demonstrated that grain yield decreased 10% per degree Celsius in average temperature above 26°C at [CO_2]s of either 330 or 660 ppm [5]. The decrease in grain yield was mainly due to fewer grains per panicle. High day and high night temperatures can cause decreases in viability of pollen grains at anthesis, increases in floret sterility, and decreases in seed set in rice [84]. Elevated [CO_2] aggravated the heat stress effect on pollen, causing a 1°C decrease in the threshold maximum canopy surface temperature after which the percentage of spikelets having ten or more germinated pollen grains exhibited a precipitous decline [45]. Heat-induced increases in floral sterility may have been responsible for the downregulation of photosynthesis observed in rice under high temperatures and elevated [CO_2] through indirect effects associated with reductions in reproductive sink strength [40].

A study with genotypes that are either heat-tolerant or heat-sensitive during reproductive development has provided unique insights into the interactive effects of high night temperature and elevated [CO_2]. With high night temperatures, many cowpea genotypes do not produce flowers, while others produce flowers but no pods and the few with total heat tolerance produce flowers and pods [18]. In growth chamber studies with contrasting genotypes in pots under high night temperature, a totally heat-sensitive genotype did not produce any flowers and a partially heat-sensitive genotype did not set any pods under either 350 or 700 ppm [CO_2] [2]. A heat-tolerant genotype had greater pod production under elevated [CO_2] at both high and more optimal night temperatures than a genetically similar cultivar that does not have the heat-tolerance genes [2]. These results indicate that for those many annual crops that are sensitive to heat during reproductive development, incorporating heat tolerance may also enhance their yield responses to elevated [CO_2] over a range of temperatures [29, 30]. This important hypothesis should be more completely tested using other cultivars of cowpea and other crop species.

For cases where the photosynthetic source is particularly sensitive to heat stress, the interactive effects with elevated [CO_2] are less clear. The review of [3] indicates that for C_3 plants, photosynthetic responses to elevated [CO_2] of individual leaves often increased with

increasing temperature, up to some maximum temperature, and in some cases biomass responded in the same way. In field studies with wheat using temperature-gradient plastic tunnels, the response of grain yield to elevated [CO_2] of 700 ppm increased from 8% at low seasonal mean temperatures of 10°C to 58% at the highest mean air temperature of 24°C [62]. Other studies with wheat have not exhibited this interactive effect on grain yield of elevated [CO_2] and high temperature [38]. Irish potato responses to elevated [CO_2] of 700 ppm were determined in field canopy chambers maintained at either moderate temperatures or heat-stress temperatures [58]. Tuber yield and total biomass were increased substantially by elevated [CO_2] in the moderate-temperature chambers. In contrast, tuber yields in the heat-stress chambers were very low and there was no effect of elevated [CO_2]. Total biomass production was not affected by the heat-stress treatment. The authors stated that "These results should be viewed as preliminary since they are based on a single growing season and one variety, but they suggest that elevated [CO_2] will not mitigate the negative effects of high-temperature stress on tuberization and yield."

Mitigating Effects of Global Warming on Crop Plants

Circumstances Where Heat-Resistant Cultivars May Help to Sustain Productivity

For some of those annual crops in which reproductive development is particularly sensitive to high temperatures, breeding to incorporate heat tolerance during reproductive development has produced cultivars that are heat-resistant in that they have greater grain or fruit yields than other cultivars in hot environments. Some examples are provided of where breeding heat-resistant cultivars may help to sustain productivity as [CO_2] and temperatures increase including some crop species where heat-resistant cultivars already have been bred, and rice and wheat because of their global importance.

Cowpea and Common Bean Some emphasis is given to cowpea because much has been published on breeding for heat tolerance in this crop. A heat-resistant cowpea cultivar was bred for use during warm seasons in subtropical zones by incorporating heat tolerance during reproductive development [20]. Developing this cultivar required 18 years of breeding. The approach was to take an overall process, heat resistance, that has complex inheritance and divide it into a developmental sequence of simpler heat-tolerant processes which individually were shown to be conferred by one or two major genes [25]. This sequence involved tolerance at the early floral bud stage that conferred the ability to produce flowers under hot long-day conditions; tolerance during pollen development that conferred the ability to set pods under high night temperature; and tolerance during embryo development that conferred the ability to produce large numbers of seeds per pod under high day or high night temperatures. A pedigree breeding program based on this approach and heat-tolerant germplasm are available that would enable additional heat-resistant cowpea cultivars to be bred for use in subtropical zones in about 6 years [28]. The University of California at Riverside has heat-tolerant cowpea lines that are available for use as parents. In breeding for heat resistance, one of these lines could be crossed with the best available cultivar for the target production zone. Heat tolerance could be incorporated by subjecting a large F_2 generation to a long-day field environment with very high night temperatures (or a glasshouse with very high night temperature and long days) and selecting plants with abundant flower production and pod set. The major gene responsible for heat tolerance during early floral development and the ability to produce flowers is recessive [25], and can be fixed by this selection. A major gene responsible for some of the heat tolerance during pod set is dominant [44]; consequently, selection during additional generations is required to fix this trait. During the fall and winter, one could either select for low leaf-electrolyte-leakage, as a measure of cellular membrane thermostability, to indirectly select for heat tolerance during pod set in the F_3 and F_4 generations in moderate-temperature glasshouses or simply advance two generations using single-seed decent. Many earlier studies have been conducted using leaf-electrolyte-leakage as a measure of cellular membrane thermostability with several crop species [10]. Definitive genetic selection studies with cowpea have demonstrated that low leaf-electrolyte-leakage can be associated with heat tolerance during pod set [71]. Individuals selected for low

leaf-electrolyte-leakage under heat stress also tended to have high pod set in hot environments. Individuals selected for high pod set in hot environments also tended to have low leaf-electrolyte-leakage under heat stress. During the next summer, replicate F_5 families could be grown in the extremely hot field nursery (or the glasshouse with very high night temperature) and in parallel nurseries to screen for agronomic traits. Families would be chosen that have abundant flower production, pod set, and number of seed per pod under high night temperature, and suitable agronomic traits in parallel nurseries. The best individual plants would be chosen from within these families. In the following fall and winter, two generations could be advanced in moderate-temperature glasshouses or in a suitable off-season field nursery. While making these generation advances, an adequate quantity of seed should be produced to enable the F_8 lines to be tested for yield and other agronomic traits in several hot, long-day, commercial production environments during the third summer. Potential new cultivars would be selected from these lines and then subjected to one more years yield testing on experiment stations followed by 2 years of yield testing on both experiment stations and farmers' fields.

Most cowpea is produced in tropical zones, such as in the Savanna and Sahelian zones of Africa and in Brazil. Progress has been made in breeding heat-tolerant cowpea cultivars for use in Africa [56, 57]. The approach used involved crossing heat-resistant cowpea parents from the University of California at Riverside with cultivars from Ghana. Selection for heat tolerance during reproductive development was conducted in subtropical long-day environments in California. Final selection for agronomic traits was conducted in northern Ghana. A modified breeding method, however, may be more effective for breeding heat-resistant cowpea cultivars for the tropics than was used for subtropical zones [28]. Heat-resistant African breeding lines could be used as parents and all selection, including that for heat tolerance, should be conducted in Africa. Selection would emphasize ability to set pods and maintenance of large numbers of seeds per pod. Many cowpea cultivars have the ability to produce about 15 ovules per pod, but they rarely produce this many seeds per pod. Under optimal field conditions, the average number of seeds per pod is about 10. In short-day conditions typical of the tropics, heat-sensitive cowpea genotypes produced 50% fewer seeds per pod in a glasshouse with high night temperatures than in a glasshouse with moderate night temperatures [19]. In these studies, several cowpea breeding lines from West Africa were shown to either have high pod set or maintain large numbers of seeds per pod under high night temperatures. These lines could be used as parents to combine heat-tolerance genes and thereby breed cowpea cultivars for Sub-Saharan Africa with greater heat resistance.

Future breeding of heat-resistant cowpea cultivars likely will be done by public plant breeders since as of 2009 there were no significant private breeding programs for cowpea in the world. Some collaborative support for breeding heat-resistant cowpea cultivars can be provided by the University of California at Riverside [31] and the Kano station of the International Institute of Tropical Agriculture in Nigeria. Breeding heat-resistant cowpea cultivars for Africa likely will proceed slowly because national programs have relatively few resources and other high priorities, such as the need to breed cowpea cultivars with resistance to various pests and diseases.

There are many similarities in the responses to heat of common bean and cowpea [27]. Progress has been made in breeding snap bean types of common beans with heat resistance through incorporating heat tolerance during reproductive development by selecting for high pod set in glasshouses with high night temperatures over two generations [15]. In addition, heat-resistant cultivars of dry bean types of common bean have been bred [7] by selecting for grain yield in hot commercial production environments [8].

Tomato Major contributions to the breeding of heat-resistant tomato cultivars for tropical zones have been made by the Asian Vegetable Research and Development Center in Taiwan [55]. This tomato improvement program gave high priority to incorporating genes for heat tolerance during fruit set. This was achieved by selecting for high fruit set in field nurseries with a sowing date that resulted in strong reductions in fruit set due to heat in sensitive materials. This program has produced open-pollinated and hybrid cultivars with heat resistance, and breeding lines that have

been released in at least 32 countries. For subtropical zones, initially, heat-resistant cultivars of tomato were bred by public programs that selected for fruit set in very hot summer field conditions, such as in the Lower Rio Grande Valley in Texas. Subsequently, since the late 1960s, several private breeding programs have been breeding heat-resistant hybrid tomato cultivars for use in the Central Valley of California and elsewhere. For understandable reasons, these private breeding programs have not divulged the methods they have used to incorporate heat tolerance.

Rice A large area of rice is grown in tropical zones at low elevation between the tropics of Cancer and Capricorn. As further warming occurs in this area the major practical solution is to develop heat-resistant rice cultivars. Breeding heat-resistant rice cultivars has received much less attention than breeding for other abiotic stresses [80] and biotic stresses or yield potential. Pollen development, pollination, and spikelet fertility are particularly sensitive to high temperatures. Rice accessions have been discovered that have heat tolerance during flowering, and potentially useful selection criteria have been determined including: flowering earlier in the morning to escape heat; substantial pollen shed (i.e., a large number of pollen grains on the stigma); and high spikelet fertility [80]. Significant research on breeding for heat tolerance in rice has been conducted by the International Rice Research Institute (IRRI) in the past (e.g., [43]). Public rice breeding programs, such as those in China and India, should be able to develop heat-resistant rice cultivars for use in tropical zones by using morphological selection criteria related to pollen and spikelet fertility. National programs in China already have bred heat-sensitive rice lines that are male sterile in hot long-day environments for use in achieving outcrossing in field environments to facilitate the production of hybrid cultivars of rice [83]. All that is needed now is for the national programs in China and elsewhere to select in the opposite direction and breed rice that is not male sterile in hot environments by incorporating greater heat tolerance.

Pima Cotton and Upland Cotton Under high temperatures, cotton plants may not produce fruiting branches or set bolls with Pima cotton being more sensitive to heat stress than upland cotton [37]. Since the early 1960s, selecting for high boll set on low nodes in very hot field conditions has been an important component of the public American Pima cotton breeding program [37]. This program has released a series of six heat-resistant cotton cultivars that have produced progressively higher lint yields under hot field conditions [42]. Surprisingly, these heat-resistant cultivars had progressively higher stomatal conductances as measured in the early afternoon on hot days during peak flowering and fruiting [42]. The authors argued that the adaptive advantage of the higher stomatal conductance appears to be associated with leaf cooling. A tendency to maintain higher stomatal conductances may be even more important in the future since elevated [CO_2] can cause stomata to partially close.

Heat-resistant upland cotton cultivars have been and are being bred for use in subtropical zones by private breeding programs. Several public programs are breeding heat-resistant cotton cultivars for use in tropical zones [70].

Wheat A large area of wheat is grown in both temperate and subtropical zones. As temperatures increase, some of this production could concentrate in temperate zones; however, heat-resistant wheat cultivars will be useful in many areas as temperatures increase. Due to current farmer interest in growing wheat in hot irrigated conditions, the International Maize and Wheat Improvement Center (CIMMT) has conducted a research program to breed cultivars for this environment. Comparisons of spring wheat cultivars with contrasting heat resistance growing in hot, irrigated environments demonstrated that grain yield was positively correlated with photosynthetic rate and leaf conductance of flag leaves, and canopy temperature depression [68]. Canopy temperature depression (CTD) is the number of degrees Celsius that the crop canopy is cooler than air temperature. Since CTD is dependent on transpiration rate, it provides an alternative to measuring leaf conductance which determines transpiration rate. The CTD is more effective for use in selection in that it can be measured more quickly and covers a larger foliage area than do measurements of leaf conductance. For environments with

sunny conditions and a large vapor pressure deficit, CTD was proposed to be a useful trait for selecting for heat tolerance in wheat grown under irrigated conditions that is correlated with higher stomatal conductance and greater photosynthesis [4]. Progress has been made in using measurements of CTD in breeding programs to enhance heat tolerance in spring wheat [69]. In a different approach, studies with genetic lines of wheat that varied in heat resistance demonstrated that low leaf-electrolyte-leakage, as a measure of cellular membrane thermostability, may provide a useful selection criterion for heat resistance in wheat [11]. The authors pointed out, however, that it may only be valuable as a supplemental selection criterion in final breeding stages or as a rough selection tool to reduce a large population into the most likely heat-tolerant core at the early stages of a breeding program. Similarly, selection for CTD may only be useful as a supplemental selection criterion [69]. For a while at least, breeding heat-resistant wheat cultivars likely will mainly depend on empirical selection for grain yield in hot commercial production environments [9].

Do Heat-Tolerance Genes Have Any Negative Effects on Crop Plants?

Genes can have negative as well as positive effects on crop performance due to either pleiotropy, where a single gene has multiple effects, or genetic linkage. One method for evaluating the negative as well as the positive effects of genes is to use backcross breeding to create pairs of near isogenic lines with and without the trait. Ideally this should be done by creating several pairs of lines with different genetic backgrounds to test for potential gene interactions. The performances of the pairs of lines are then compared in contrasting environments to document any positive and negative effects. Six pairs of cowpea lines with differences in heat tolerance during reproductive development have been compared in eight field environments with average night temperatures ranging from being cool to very hot in a subtropical zone [32]. Positive effects were apparent in that the heat-tolerant lines had greater pod set and grain yield than the heat-sensitive lines in the very hot environments. A potential negative effect was detected in that all of the heat-tolerant lines exhibited a progressive dwarfing with increases in night temperature due to shorter main-stem internodes. Performances of the semidwarf heat-tolerant lines and the standard-height heat-sensitive lines were compared at different row spacings with moderate temperatures in a subtropical zone [34]. The semidwarf heat-tolerant lines produced greater grain yields than the standard-height heat-sensitive lines when grown under narrow row spacing and similar grain yields under wide row spacing. In the good growing conditions of these experiments, the semidwarf habit of the heat-tolerant lines appears to be advantageous. In more stressful field conditions and hotter (i.e., tropical zone) environments, the dwarfing would be greater and could seriously reduce the competitiveness of the plants against weeds. The dwarfing associated with heat tolerance may have been due to genetic linkage with the recessive gene that confers heat tolerance during early floral development, and lines are available with heat tolerance during floral development that are not dwarfed [33]. Consequently, it should be possible to breed heat-tolerant cowpea lines that are not dwarfed. It should be noted, however, that the dwarfing is associated with greater HI [32] and may be responsible for the greater yield response of the heat-tolerant semidwarf line to elevated [CO_2] [2].

Potential negative effects of genes may be discovered by theoretical analysis. Heat tolerance during pod set has been associated with low membrane leakage in hot temperatures [71]. Membrane fluidity and function depend on their chemical composition and temperature [76]. Membranes with a chemical composition that is suited to function in hot conditions may not function as well in cool conditions. No evidence for this effect has been reported for cowpea. The heat-tolerant lines had similar grain yields as the heat-sensitive lines in cool field environments [32]. Lines have been bred at the University of California, Riverside that have both chilling tolerance during emergence, associated with low membrane leakage in chilling temperatures [35], and heat tolerance during pod set showing that it is possible to combine these two membrane-dependent traits. In germplasm screening studies, no association was seen between heat tolerance during emergence, chilling tolerance during emergence, and heat tolerance during flowering [21].

Circumstances Where Attempting to Incorporate Heat Tolerance into Cultivars May Not Be Justified and Alternative Mitigation Procedures Will Be Needed

There are many crop species where attempting to incorporate heat tolerance into cultivars may not be effective in sustaining productivity as temperatures increase. Tree and vine crops are difficult to breed using crossing and selection among progeny, and no models are available for incorporating heat tolerance using molecular transgenic methods that have been proven to be effective in enhancing heat resistance.

With crossing and selection, it is necessary to evaluate large numbers of progeny to find individuals that have many of the desired traits. In particular, fruit quality traits are critical for consumer acceptance and must be maintained. This phenotyping takes extensive land area and many years with tree or vine crops.

Much molecular work on heat stress has focused on heat-shock proteins. The classical studies of [82] demonstrated that leaves subjected to high temperatures (50°C) for short periods (15–30 s) tolerated high temperatures (55°C) longer than untreated leaves. Since then there have been many molecular studies of these heat-shock responses that associated them with specific proteins [74]. These proteins have been shown to play a role in enabling seedlings to survive extreme heat shock but they have not been associated with heat tolerance during reproductive development [74]. For example, cowpea genotypes with contrasting heat tolerance during reproductive development [18] have been examined by several laboratories but no differences in heat-shock proteins were detected among them. The heat-shock proteins have not been shown to be useful in enhancing heat resistance, the economic yield of crops in hot environments (e.g., reviews by [12, 76]).

Impacts of future climate changes on some perennial crops in California have been modeled [41]. The authors concluded that climate change in California is very likely to put downward pressure on yields of almonds, walnuts, avocados, and table grapes by 2050; although, they did not include effects of elevated [CO_2] in their analysis. FACE studies with tree species showed an average 28% increase in aboveground biomass production under elevated [CO_2] [39]. Given the long timescales for orchards and vineyards of about 30 years, temperature increases should be considered when selecting perennial cultivars for new plantings. Temperature effects on tree crops can be complex. For example, some deciduous tree crops have a chilling requirement that must be met during the winter to overcome bud dormancy. Insufficient chilling due to warming in winter could result in delayed opening of leaf buds and delayed bloom, and the flowers could be abnormal such that fruit set is reduced [26]. Cultivars of tree crops are available that have smaller chilling requirements but removing an orchard and then replacing it with another cultivar would incur considerable costs since the new orchard would not produce many fruit for several years [41].

Future Directions

For several important annual grain and fruit crops, incorporating heat tolerance during reproductive development by selecting for seed or fruit set under hot conditions can be used to breed heat-resistant cultivars that will help to sustain productivity as air temperatures increase. These cultivars also may be more responsive to the elevated [CO_2] that will occur in the future. For cases where private plant breeding companies are unlikely to do the necessary breeding, such as with rice and cowpea, more funding and resources should be provided to the public national and international programs that could do this breeding.

For annual crops that produce neither grain nor fruit or for which the main lesion due to heat stress is reduced photosynthetic function, more efficient selection methods could facilitate breeding for heat resistance. More efficient selection methods might be developed if more funds were provided for applied research on heat tolerance in plants. Over the last three decades, relatively little research funding has been devoted to the physiology and genetics of breeding for heat tolerance. In contrast, during this same period, substantial funding has been devoted to molecular studies of heat-shock proteins which, as of 2009, has not produced a documented practical benefit to crop breeding.

For perennial crops, breeding for heat tolerance is extremely difficult. In this case, alternative mitigation methods should be pursued. Predictive methods

should be developed and applied to assist farmers to determine when orchards should be removed and what crop and cultivar should be grown instead.

Article Outline

Glossary

CRE/*loxP* A site-specific recombination system in which the CRE recombinase catalyzes recombination between *loxP* sequences. A *loxP* sequence is 34 bp long and consists of two inverted repeats of 13 bp and one spacer region of 8 bp. The orientation of the *loxP* sequence is determined by the spacer region.

Inverted T-DNA repeat Repeat obtained from the integration of two T-DNA copies at one genetic locus, but with one T-DNA integrated in inverted orientation compared to the other.

Position effect Influence of the position of a gene in the genome upon its expression.

Posttranscriptional gene silencing (PTGS) Silencing mechanism leading to the sequence-specific degradation of target mRNAs and sequence-specific suppression of translation.

Single-copy transformant Transgenic plant harboring only one copy of the introduced DNA segment.

Transcriptional gene silencing (TGS) Silencing mechanism that targets homologous DNA sequences in the promoter, suppressing transcription and correlating with promoter sequence methylation.

Transfer DNA (T-DNA) The DNA fragment that is delineated by the right and left border repeats and is transferred from *Agrobacterium* to the plant cell by the type-IV secretion system.

Transgene expression variability Variability that is higher in a population of transformants than expected based on gene dosage effects.

Transgenic plant Plant harboring one or more external DNA segments that had been introduced and stabilized by integration into the plant genome. The foreign DNA is transferred to the plant cell via *Agrobacterium*-mediated transformation or direct gene transfer.

Definition of the Subject

To define the subject in relation to the title, we would like to emphasize that most of the results and conclusions described below were obtained in the model plants *Arabidopsis thaliana* and *Nicotiana tabacum* after *Agrobacterium*-mediated transformation, and in a limited number of crops, such as wheat, rice, and soybean, after direct gene transfer. Additionally, most of the transgenes described below are transcriptional fusions with the 35S promoter from the cauliflower mosaic virus. Indeed, to obtain transgenic plants with high and constitutive expression of a transgene, the 35S promoter is commonly used. This 35S promoter is very powerful, because it generally leads to constitutively high transcript and protein levels of the transgene in most dicot plants and is not greatly influenced by

environmental conditions or tissue types. However, over the years, it became clear that 35S-driven transgene expression is very variable in the different transformants of a transgenic plant population with the same construct. For most analyzed overexpression constructs containing this 35S promoter, more than a 100-fold difference in protein accumulation levels has been observed. Approximately 20% of the transformants have high recombinant protein accumulation levels, but approximately 80% display an intermediate or low and unstable transgene expression. Additionally, high-expression transformants often segregate progeny plants with low recombinant protein accumulation levels. Thus, it is imperative that for scientific analysis and applications, the variability of 35S-driven transgenes is known in different transformants and generations. In this contribution, the possible causes of variation in transgene expression in a population of transgenic plants are discussed and several approaches to diminish the variability are reviewed.

Introduction

From the mid-1980s on, transgenic plants were generated by adding one or more genes to a plant's genome. Transformation was usually achieved with gold-particle bombardment or through the gene transfer process via *Agrobacterium tumefaciens*, a soil bacterium carrying an engineered T-DNA vector. The inserted gene sequence, known as the transgene, can be derived from any living prokaryotic or eukaryotic organism. Transgenic plants were originally engineered to address specific scientific questions and to investigate the plant biology in general. However, the ability to create transgenic plants also opened the way to manipulate crop plants for better characteristics, such as increased yield, enhanced quality, pest or disease resistance, superior tolerance to heat, cold, and drought, and nutritional improvement. In addition, transformation of plants allows molecular farming of many limiting components, such as proteins, metabolites, fatty acids, and bioenergy precursors.

To generate transgenic plants, transformation methods had to be explored and ameliorated. Furthermore, the vectors and expression cassettes for controlled integration and expression of the introduced transgenes had to be worked out. Once the *Agrobacterium*-based system for T-DNA transfer had been unraveled, the simple view was that a particular T-DNA sequence could be constructed to be integrated as a single copy into the plant genome. However, it turned out that transformants quite often integrate two to ten T-DNA copies at one locus or dispersed over several loci [1]. Moreover, the transferred DNA is integrated randomly and, thus, every transformant containing the same transgene differs regarding the integration site and the transgene copy number [2]. Concerning transgene expression, in principle, it is very straightforward to combine particular gene-controlling elements with a coding sequence of interest to obtain a predictable level of transgene expression. The most frequently used promoter elements are the promoter of the nopaline synthase gene (pNOS), driving weak and constitutive expression of the downstream transcribed sequence, and the promoter of the cauliflower virus 35S transcript (p35S), driving in general at least 20-fold higher expression levels. Whereas the majority of transformants with transgenes controlled by the pNOS promoter display the same mRNA level, independent transgenic lines generated with a p35S-controlled transgene construct show variable transgene expression with more than 100-fold difference in recombinant protein levels. In the latter case, frequently the recombinant protein accumulation levels in the different transformants are distributed bimodally [3]. Low p35S transgene expression occurs regularly in transgenic lines with multiple T-DNA copies, particularly when they are integrated into inverted orientation. As a consequence, the transgenes are transcribed convergently [4]. However, also single T-DNA copies can result in low or even no transgene expression [5]. Originally, the mean of recombinant protein accumulation levels in different transformants was considered to represent the expression strength of a particular transgene construct. Afterward, it was realized that the class of transformants with high transgene expression correlated better with the transgene expression capacity [6], implying that all transformants with intermediate and low transgene expression have controlling mechanisms that result in transgene suppression or transgene silencing.

A first and visually dramatic example of transgene silencing was found in plants that overexpressed gene constructs coding for pigment production in

wild-type petunia (*Petunia hybrida*) with purple flowers [7, 8]. Contrary to their expectations, the flowers of the transgenic petunia exhibited reduced and variable instead of increased pigmentation. As both the expression of endogenes and transgenes were suppressed, this phenomenon was called cosuppression [7, 8]. Later on, the transgene silencing mechanisms were divided into three groups [9]. One group harbors the transgene silencing events based on position effects and heterochromatization. As transgenes integrate randomly, different transformants contain the transgene at a different chromosomal position and nearby located chromatin-controlling elements, enhancers and silencers, are expected to influence the activity of the integrated gene. The other two groups of silencing mechanisms operate via homology between the silencer sequences and the target silenced genes, do not depend on position, and exert their effects *in trans* [9, 10]. Transcriptional silencing (TGS) refers to the silencing process that suppresses transcription of the silenced genes based on homology in the silencer locus-containing promoter region. TGS functions at the level of prevention of transcription initiation of the silenced genes; is often accompanied with concomitant DNA methylation, altered histone modifications, and heterochromatin formation; and is stably inherited through meiosis and mitosis [11]. In contrast, post-transcriptional gene silencing (PTGS) needs homology in the transcribed region, results in specific transcript degradation and/or specific repression of translational initiation, and resets through sexual propagation [10, 12].

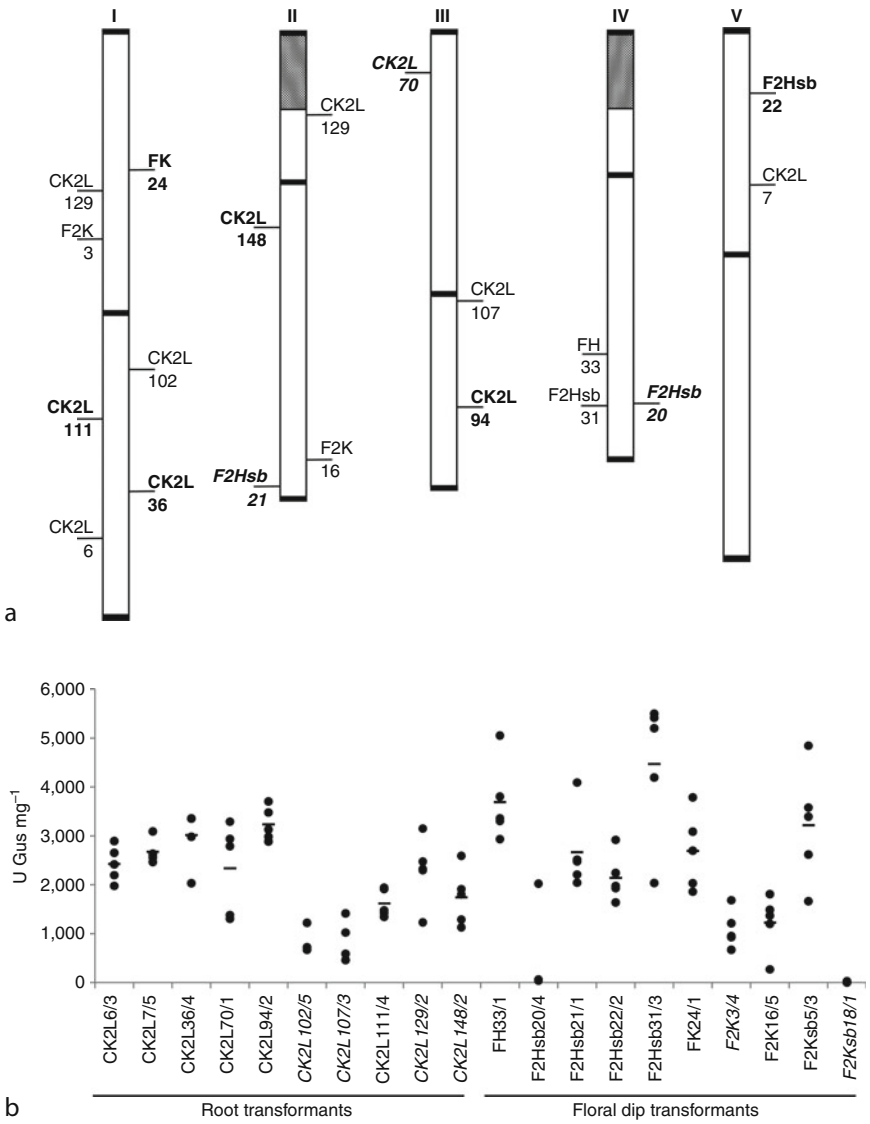
Here, different parameters that influence transgene expression in plants are described: (1) the transformation process, which results in plants with transgene loci that can be either simple or complex; (2) the different regulatory sequences used in the transgene expression construct; (3) the position of the integrated transgene into the plant genome; and (4) the correlation between repeat structures and transgene silencing. Several approaches to minimize the transgene expression variability are discussed: (1) the resolution of complex integration loci by the CRE/*loxP* recombination process, (2) site-specific or site-directed integration, and (3) the use of gene silencing mutants to create a population of transgenic plants with high and stable transgene expression.

Generation of Transgenic Plants by *Agrobacterium*-Mediated Transformation or Direct Gene Transfer

Agrobacterium-mediated transformation is the most widely used method to generate transgenic plants [13, 14], although direct transformation methods are still very important for certain crop plants (see below). During *Agrobacterium* transformation, the transferred DNA (T-DNA), delineated by the right border (RB) and left border (LB) repeats, is integrated into the plant genome by illegitimate recombination. Overall, approximately one half of the transformants contains only one T-DNA copy and the other half multiple T-DNAs (two to ten), integrated at one or several independent loci [2, 15].

The T-DNA integrates at random in any chromosome [2] (Fig. 1) and is as efficient in all five chromosomes of *Arabidopsis thaliana* as in intergenic and intragenic sequences and in exons and introns (Fig. 1) [16, 17]. With promoterless selectable markers and consecutive selection on those markers, many transformants could be recovered, indicating that T-DNAs frequently integrate in transcriptionally active regions [18, 19], but in the absence of transcriptional activation selection, many transformants integrated the T-DNA between genes and in repetitive DNA. Under nonselective conditions, silent T-DNA insertions were found in heterochromatic regions, centromeres, telomeres, and rDNA repeats [20, 21]. T-DNA integration is accompanied with small deletions of the plant target DNA and/or T-DNA ends. Very often, microhomology of 2–10 bp is observed between the plant pre-insertion site and the T-DNA ends, suggesting that T-DNA integration occurs via the nonhomology-dependent double-stranded break repair [2, 15, 22].

In theory, only the T-DNA, delineated by the LB and RB, is transferred to the plant cell, but in many plants, vector backbone sequences are transferred and integrated into the genome as well [23–26]. Two mechanisms might account for this vector backbone transfer. First, the LB repeat could mistakenly be recognized as initiation site for T-strand production and, as such, result in the transfer of vector backbone sequences. Second, the consequence of inefficient recognition of the LB repeat might be read-through from the T-DNA into the vector sequences [23, 27]. Both mechanisms



Transgene Expression in Plants, Control of. Figure 1

Random integration of single-copy T-DNAs into the *Arabidopsis* genome and the similar GUS activity levels yielded by single-copy 35S-*GUS* transgenes in the different transformants (Adapted from [17]). (**a**) Distribution of 18 single-copy T-DNA transformants on the five chromosomes of the *Arabidopsis* genome. In nine transformants, the T-DNA is integrated into an intergenic region and nine in a transcribed annotated gene (indicated in *bold*). Of these nine intragenic inserted T-DNAs, six were integrated into an exon and three into an intron (indicated in *italics*). Centromeres and telomeres are indicated in *vertical black boxes* and rDNA repeats in *gray boxes*. For transformant CK2L129, the LB and RB regions were fused to sequences of chromosomes 1 and 2. (**b**) GUS activity analysis in the T2 generation of 20 different single-copy T-DNA transformants. GUS activity was measured in the leaves of five 6-week-old seedlings per transformant (represented as a *dot*). All transformants were homozygous for the T-DNA insertion, except for the transformants indicated in *italics*. The average GUS activity level in the five seedlings of the homozygous transformants is marked by a *line*. The intra-transformant variability in GUS activity was as high as the inter-transformant variability, except for two transformants without detectable GUS activity. GUS activity levels are given as units GUS mg^{-1} of total soluble protein. For transformants F2Ksb5 and F2Ksb18, the integration position into the genome could not be determined (see **a**)

can be distinguished by analyzing whether or not the LB T-DNA sequences are directly linked to the vector sequences. The vector backbone transfer and integration is seemingly not influenced by the plant species, the explant type used for transformation, the T-DNA vector replicon type, or the selection [25]. Molecular DNA blot and polymerase chain reaction analyses revealed that the vector backbone sequences were mostly linked to both the LB and RB T-DNAs. In fact, the complete vector backbone sequence was integrated between two in tandem oriented T-DNAs, emphasizing the importance of the second mechanism in which the integration of complete vector backbone sequences results from a conjugative transfer initiated at the RB, followed by copying of the T-DNA, the vector, and again a T-DNA from a circular template due to read-through of consecutively the LB and RB [25]. Furthermore, the results demonstrated that neither the RB nor the LB was efficiently recognized as termination and initiation sites, respectively [25]. Additional evidence that the surrounding regions of the border repeats are important for the recognition of the repeat as initiation or termination site was obtained from hybrid border regions. In the absence of the surrounding border regions, the LB repeat was not recognized as T-DNA termination site; addition of the natural LB inner region and occurrence of both the octopine and nopaline LB regions with their repeats, improved the correct recognition of the LB repeat when compared to an LB with only the LB outer region [26].

A number of agronomically important plant species are still recalcitrant for *Agrobacterium*-mediated transformation and are, therefore, transformed with direct gene transfer methods, such as particle bombardment or biolistics, electroporation, and polyethylene glycol transformation [28]. A disadvantage of these techniques is that transformants tend to have multiple transgene copies integrated as a concatemeric array at one locus, and contain inverted repeats [29–33]. However, several approaches have been described to circumvent this problem (see below).

Transgene Loci Can Be Either Simple or Complex

Upon *Agrobacterium*-mediated transformation, a significant number of transformants contain a single-copy T-DNA insert, but, dependent on the transformation method used, a high percentage of transformants contain multiple T-DNAs integrated into the plant host genome. These multiple T-DNA copies are mostly clustered in one genetic locus, but they can also be present in two or more loci. Multiple T-DNAs integrated at one genetic locus are organized as direct and/or inverted repeats of the T-DNA segment. Complex T-DNA loci were found in many plant species, such as *Arabidopsis*, tobacco (*Nicotiana tabacum*), petunia, and potato (*Solanum tuberosum*) [34–38]. As direct and inverted T-DNA repeats were not found in the bacteria, they are believed to be formed in the plant cell prior to or during the T-DNA integration [34, 35, 39, 40].

Two models have been proposed for the formation of multicopy T-DNA loci upon *Agrobacterium*-mediated transformation: the replication and the ligation models [38]. In the replication model, the repeats originate from a single T-DNA copy that is replicated after introduction in the plant cell and before or during integration into the genome. This hypothesis is favored because all T-DNAs involved in repeat structures had analogous breakpoints in a restriction analysis and because three identical T-DNA copies were observed after transformation with a library of T-DNAs containing different promoters [38, 41, 42]. However, cotransformation experiments with different T-DNAs originating from different agrobacteria gave, with a similar frequency, rise to T-DNA loci with different T-DNAs in direct or inverted orientation [1, 34, 35, 43–46]. As these T-DNA structures cannot be formed by replication, but only by ligation of the cotransformed T-DNA copies before or during integration [34, 35], the ligation model postulates that repeats originate from extrachromosomal ligation of two or more individual T-DNAs prior to or during integration into the genome [34] and even that repeat structures are formed by the cointegration of several T-strand intermediates in one target site rather than by ligation of T-strands [39]. In any case, T-DNA inverted repeats about the RB, an integration structure that is frequently observed upon *Agrobacterium*-mediated transformation, can only be formed after duplication of the transferred single-stranded T-DNAs. Sequence analysis of T-DNA junctions revealed that, during the formation of T-DNA repeat structures, end-to-end ligation of double-stranded T-DNAs occurs especially between right T-DNA ends, whereas recombination based on microhomology regions and insertions of filler

DNA was more frequent at LB junctions [22, 35]. None of the sequenced T-DNA/T-DNA junctions contained plant DNA, suggesting that T-DNA recombination and ligation occurred in the majority of cases before integration [35].

Analysis of which parameter determined the structure and complexity of the transgene locus indicated a possible correlation with either the used *Agrobacterium* strain, the titer, or the physiology of the bacterial inocula, bacterial vectors, plant species, or ecotype, but overall no clear picture was obtained [1, 34, 38, 44, 47, 48]. Single-copy T-DNA insertions were found predominantly upon *Arabidopsis* root transformation, whereas multiple insertions, especially organized in T-DNA repeat structures over the RB occurred in transformants generated by leaf disc transformation [48]. However, this was not found in root and leaf disc transformants in an independent experiment (M. De Neve and A. Depicker, unpublished results), indicating that other parameters had to be involved. Nevertheless, a detailed study revealed that the structure of the T-DNA integration locus is especially determined by the transformed target cell [1, 48]. Whereas 20 years ago, *Agrobacterium*-mediated transformation of *Arabidopsis* was achieved mainly by in vitro tissue explant methods, such as root transformation [49], nowadays floral dip is commonly used [50], but the obtained T-DNA copy number in transformants obtained after both transformation methods varies much. To analyze whether this difference was due to cotransformation frequencies or to replication in the plant cell, several floral dip and root transformations were done with mixtures of *Agrobacterium* strains, each carrying one or two different T-DNA vectors, allowing to trace back the origin of complex T-DNA loci [1]. Although the cotransformation frequencies of T-DNAs originating from different agrobacteria after floral dip and root transformation were comparable, and the frequencies of T-DNA originating from one bacterium only slightly higher than those after floral dip transformation, the T-DNA copy numbers in the transformants differed completely. Upon floral dip transformation, on average T-DNA copies were integrated at one genetic locus versus one to three after root transformation [1]. The cotransformation frequencies might explain the T-DNA copy number in most root transformants, but not in floral dip transformants. Therefore, it was postulated that T-DNA replication of a single T-strand occurs in the plant cell before or during T-DNA integration and that its frequency is much higher upon floral dip than upon root transformation [1]. Because the same *Agrobacterium* strains had been used in both transformation methods, not the bacterium but the type of target cell determined the complexity of the T-DNA pattern [1].

In general, transformants obtained after direct gene transfer contain more transgene copies than after *Agrobacterium*-mediated transformation [30–32]. In maize (*Zea mays*), comparison of transgene copy numbers and RNA expression levels upon transformation via direct gene transfer and *Agrobacterium*-mediated transformation revealed that more than 90% of the transformants obtained after *Agrobacterium*-mediated transformation harbored fewer than three T-DNA copies, while most of the transformants obtained after particle bombardment contained more than three copies [32], of which some of the transformants contained as many as 100 copies of the transgene [32]. Another observation was that the transformants obtained after *Agrobacterium*-mediated transformation displayed a higher transgene expression than after particle bombardment. Besides the expected positive correlation between transgene copy number and transgene expression, frequently a negative correlation between gene dosage and transgene expression was observed (see below) [51].

Recent research revealed that more single-copy integrants could be obtained by particle bombardment when a limited quantity of DNA was used for bombardment [52, 53]. A decrease in DNA from 1.5 to 2.5 ng per shot resulted in an increase of single-copy transformants from 30% to 70% [52, 53]. The 10% reduction in transformation efficiency was more than compensated by the more efficient screening for single-copy transformants [53]. Additionally, complex integration patterns could also be avoided when cassette DNA, harboring a promoter, a coding region and a 3′ end region, instead of whole plasmids were used for bombardment [52, 54–56].

Regulatory Sequences Have a Major Impact on Transgene Expression and Expression Variability

To obtain transformants with high and stable transgene expression, the construct should be designed carefully

because several sequences might have a great impact on the transgene expression and expression variability. Especially, the selected promoter that drives the transgene expression will determine the accumulation levels of the transgene transcript and, indirectly, of the transgene-encoded protein. Since the beginning of chimeric gene constructions, plant scientists predominantly chose the 35S promoter of the cauliflower mosaic virus as a strong and constitutive promoter to overexpress a coding sequence of interest [57] and for the promoters of the nopaline (pNOS) and octopine (pOCS) synthase-encoding genes, as weak promoters, for instance to drive the selectable marker genes in dicots.

The strength of the 35S promoter increases when upstream activator sequences are added [58], but as a consequence, single-copy transgenes driven by a 35S promoter with two upstream activator regions are more prone to gene silencing [59–61]. In general, silencing frequency correlates positively with the promoter strength [61–64]. Indeed, silencing did not occur frequently when a weak pNOS promoter was used [62], whereas the 35S promoter is very prone to transgene silencing, most probably because the high expression leads to transgene RNA accumulation levels above a certain threshold that triggers RNA degradation [65]. Strikingly, promoters do not only influence the levels, but also the variability of expression in a population of independently transformed plants with the same transgene [66]. Transformation of *Arabidopsis* plants with a p35S-*β-glucuronidase* (*GUS*) construct resulted in a bimodal expression pattern, with more than 80% of the primary transformants showing a very low and less than 20% a high GUS accumulation [3, 66]. The mannopine synthase promoter (pMAS) yielded gene expression levels that were only slightly lower than those of the 35S promoter, but the variation in transgene expression was at least eightfold lower [66]. The bimodal character of the p35S promoter versus the normal distribution of the pMAS-driven gene expression suggests that silencing phenomena occur less frequently in plants transformed with pMAS than with p35S.

Not only the promoter, but also the codon usage might play a role in determining the transcript stability and/or translation efficiency. For *Arabidopsis*, highly expressed endogenous genes seem to contain a C at the third codon position, whereas genes with low expression levels have predominantly a T in that position [67]. By adapting codon usage in the green fluorescent protein (GFP)-encoding gene toward a higher proportion of codons with a C or a G in the third position, more highly *GFP*-expressing plants were generated [68]. Additionally, the nature of the coding sequence and the sequence composition seem to be important parameters in determining the transcript accumulation and/or threshold above which silencing is initiated [62, 69]. The transcript levels of the three reporter genes *GUS*, *GFP*, and streptomycin phosphotransferase (*SPT*) controlled by the same p35S, varied, reflecting the expected dissimilar transcript stability and turnover for different sequences. Furthermore, other effects also determined the transcript accumulation because the steady-state transgene transcript levels in transformants containing two copies of the *GUS* transgene were lower than in those carrying only one copy, while in transformants with two copies of the *SPT* or the *GFP* genes, the levels were higher than those with only one of the respective genes. The transcript length and GC content of the coding sequences were unlikely to be primary determinants for the gene-specific threshold for the silencing trigger [69]. Indeed, although the *GFP* and *SPT* transgenes have almost identical transcript lengths and similar GC content, silencing was activated at a different copy number. Silencing of *GUS* expression was already observed in plants with three P35S-*GUS* copies, while *GFP* and *SPT* expression were only reduced in plants carrying five or more 35S-*GFP* and nine or more 35S-*SPT* copies.

In tobacco plants, different 5′ leader sequences were modulated by P35S-driven expression [6]. A 31-nucleotide random leader stimulated translation 20- and 100-fold compared to the nine- and four-nucleotide synthetic leaders, respectively. However, the 30-nucleotide satellite tobacco necrosis virus leader and both the 79-nucleotide tobacco mosaic virus (TMV) and the plant chlorophyll *a/b*-binding protein (66-Cab22L) leaders were approximately two- to threefold and fivefold stronger than this 31-nucleotide random leader, respectively [6]. On the contrary, the 5′-untranslated regions (5′ UTRs) of MAS and TMV did not influence the transgene expression variability [66]. Similarly, also four terminators (tMAS, tNOS,

tG7, and tOCS) were analyzed for their effect on transgene expression, but none affected levels and variability [66]. That especially certain combinations of different elements can lead to high and stable transgene expression was clearly demonstrated [70]. The combination of the strong *ß-phaseolin* promoter, with the 5′ and 3′ regulatory sequences of the *arceline 5-I* gene and efficient endoplasmic reticulum-targeting signals boosted the expression of an antibody fragment to 36% of the total soluble protein in *Arabidopsis* seeds. Furthermore, the variation in transgene expression was very low [70].

A significantly increased level of transgene expression can be observed for particular intron-containing transgenes when compared to their respective intronless constructs. This phenomenon, designated "intron-mediated enhancement," has been demonstrated both in monocots and dicots [71–74]. The ability of an intron to enhance transgene expression depends on the sequence and position of the intron within the transgene [72, 75]. Generally, stimulation of mRNA accumulation decreases with increasing distance of the intron from the promoter and its effect is greatly diminished or entirely lost when the intron is placed in the 3′ UTR [71, 75]. The mechanism of intron-mediated enhancement is largely unknown, but has been postulated to be due to an increased accumulation of mRNA, enhanced transcript stability, and/or an enhanced translation [71, 72, 74, 76].

The effect of matrix attachment regions (MARs) on transgene expression levels and stability is still unclear and contradictory results have been obtained [66, 77–79]. In some studies, MARs significantly increased the average protein accumulation levels in transgenic plants and reduced the transgene expression variability [80–83]. For instance, the chicken lysozyme MAR (chiMAR) reduced the expression variability by seven- to eightfold in transgenic potato [83], whereas this chiMAR had no influence on the transgene expression levels and variability in *Arabidopsis* transformants, unless the gene silencing mutants were used as genetic background for transformation [3, 66, 78, 84]. The lack of positive effect of the MARs was caused neither by the transformation method, nor by the plant species used for transformation, because this chiMAR did not influence the *Arabidopsis* transformants obtained after root or floral dip transformation and the tobacco transformants [78]. Moreover, a tobacco-derived MAR sequence had no positive effect on transgene expression in the *Arabidopsis* wild-type Columbia-0 transformants [78].

The Influence of the Integration Position on Transgene Expression

Although the presence of multiple transgene copies, especially in inverted orientation, is the major trigger to induce transgene silencing (see below), also single-copy plants can show variation in transgene expression and undergo transgene silencing [5, 17, 60, 85–88]. Two general explanations for the inactivation of single-copy transgenes have been proposed that are not mutually exclusive: recognition of a transgene as foreign DNA and subsequent TGS and neighborhood of spreading heterochromatin domains. In the first explanation for position effects, transgenes might be recognized as nonself sequences, and especially the difference in GC content of the transgene versus the flanking sequences might induce chromatin changes and epigenetic variation [12, 89]. Indeed, a single copy of the GC-rich *A1* gene from maize became specifically methylated in transgenic petunia (*Petunia hybrida*), while the homolog of gerbera (*Gerbera hybrida*), with a GC content similar to that of petunia, remained unmethylated [89, 90]. In the second explanation, position effects result from heterochromatization of the transgene integrated close to heterochromatin domains, which is similar to the position effect variegation, extensively studied in fruit fly (*Drosophila melanogaster*). Thus, also in plants, the chromosomal position of a transgene is expected to cause variability in transgene expression [9, 91]. In petunia, single-copy transgenes were strongly silenced when they were integrated into a highly repetitive region [5]. Likewise, two single-copy transformants were identified with unstable transgene expression that were integrated into intercalary and paracentromeric locations [85], while the two stably expressing loci were integrated into the vicinity of telomeres and flanked at least on one side by plant DNA with AT-rich regions. However, the number of examined cases is limited and T-DNA insertion into heterochromatic regions has been demonstrated not to be necessarily associated with transgene silencing [16].

To determine whether the integration position had a major effect on transgene expression variability, a large transformant population had been screened for single-copy T-DNA transformants and the transgene accumulation levels were compared [17]. Twenty single-copy transformants were selected based on antibiotic resistance marker expression and in all of them the T-DNA integration was characterized at the sequence level in the *Arabidopsis* genome (Fig. 1a). In 18 of the 20 transformants, the p35S-driven *GUS* expression was high and stable in two subsequent generations. Furthermore, the GUS activity levels in these 18 different transformants could be considered as similar, because the intra-transformant variability was as high as the inter-transformant variability (Fig. 1b). Integration into an intergenic or genic region and into an exon or intron did not result in differential transgene expression (Fig. 1) and, additionally, integration into a gene in sense or antisense orientation had no influence on the transgene expression, indicating that overlapping transcription from the endogene and transgene did not induce transgene silencing in *Arabidopsis* [17].

Another hypothesis was that transgene expression might be reduced by the absence of MAR sequences near the T-DNA integration site or by the presence of neighboring highly methylated sequences [92, 93]. However, no general correlation with these factors was observed [17]. There has also been some debate on the influence of vector backbone sequences, cointegrated into the plant genome on transgene expression. In a first report based on the observation that two unstably expressed loci harbored binary vector sequences directly contiguous to the right T-DNA border, whereas two stably expressed loci contained no vector backbone sequences, vector sequences were postulated to trigger TGS [85]. Later, several studies showed that the integration of vector sequences, even with a GC content strongly diverged from that of the plant genome, had no negative influence on transgene expression [17, 94, 95].

In general, one can conclude that in *Arabidopsis*, the integration position of single-copy T-DNAs does not strongly influence transgene expression [17, 62, 94], but one should take care not to extrapolate this finding too far. The *Arabidopsis* genome is small (125 Mb) and has a low amount of heterochromatic DNA, while the genome of *Drosophila*, in which position effect variegation is often observed, is comparable in size, but consists for one third of centric heterochromatin [96]. Also, one should be aware that all the above-described observations were based on transformants that were selected on the expression of one selectable marker on the same T-DNA, implying that silenced heterochromatic T-DNA insertions were not recovered. Indeed, an increased number of T-DNA integrations into heterochromatic regions were found without selection in *Arabidopsis* [20, 21]. Apparently, the kanamycin selection had failed to identify approximately 30% of all integration events, because the expression of the selectable marker was absent or very low [21]. Analysis revealed that not PTGS, but TGS, caused this discrepancy in transformation efficiency. Furthermore, the integration sites of the lines with silenced transgenes mapped to heterochromatic regions, including telomeres, centromeres, and rDNA repeats [20, 21], which are regions that are significantly underrepresented in T-DNA integration studies with transformants identified by selection [21].

Nevertheless, the holy grail of plant biotechnology is to integrate the transgenes into the plant genome via homologous recombination. Indeed, in contrast to yeast and the moss *Physcomitrella patens*, the frequency of transgene integration via homologous integration is extremely low. When compared to random integration, targeted integration of a transgene into the homologous sequence of the plant genome occurs in the range from 0.01% to 0.1% [97, 98]. Several approaches, with variable success, have already been applied to detect gene targeting events among the random integration events: (1) application of gene-specific selection or screening for the target genes; (2) use of positive–negative selection and, hence, reduction of the transformants with randomly integrated transgenes; and (3) overexpression of genes involved in homologous recombination in yeast, such as the *RAD54* gene [99–101]. Additionally, induction of double-stranded breaks in the genome has been reported to result in an increased targeted integration frequency [102, 103]. Nowadays, these double-stranded breaks are produced by zinc finger nucleases (ZFNs) [104–106]. These ZFNs are synthetic restriction enzymes that can be specifically designed to cleave virtually any long stretch of double-stranded DNA sequence [107]. A defective *GUS:NPTII* reporter gene, carrying a recognition site for ZFN and integrated at

various chromosomal sites in ten different tobacco lines, was restored via homologous recombination in 10% of the transformed protoplasts, regardless of the chromosomal position of the reporter gene [105]. Approximately 20% of the *GUS:NPTII* reporter gene was repaired solely with homologous recombination, but the other events still contained additional DNA insertions and deletions [105]. Moreover, ZFNs are probably a promising tool to efficiently achieve targeted integration into plants. Once this procedure is optimized, plants with high, stable, and predictable accumulation levels of important heterologous proteins might be obtained with an increased frequency.

Correlation Between T-DNA Locus Structure and Homology-Based Silencing

Based on the gene dosage rationale, screening for transgenic plants with multiple transgene copies might be predicted to result in plants with high transgene expression. A direct correlation between transgene copy number and expression level has indeed been reported [51, 62]. However, also the inverse correlation is observed with p35S-driven transgenes inserted as convergently transcribed inverted repeats: the reproduction of the expression of the inverted repeat transgene copies is much lower than that of a single-copy transgene [51, 108].

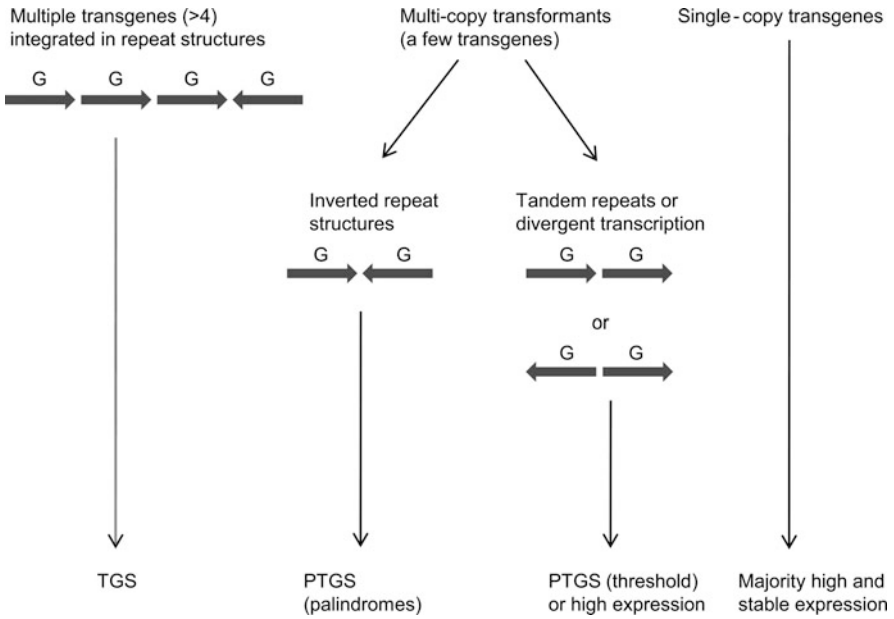
Increased Transgene Dosage Can Result in PTGS

Below a certain number of identical p35S-driven transgenes, gene copy number and expression correlated positively [62]. Transgene expression seemed stable and high over all generations analyzed and a comparable expression level was obtained for all independent lines harboring the same copy number of a certain transgene. However, once above a certain copy number, gene silencing occurred, implying that silencing was triggered by threshold concentrations of either transgene transcript or another product of transgene expression (Fig. 2) [62]. In many reports, the correlation between high transgene copy number and transgene expression was negative: the higher the copy number, the lower the expression level per gene copy [59, 61, 109]. Not the copy number per se, but especially the arrangement of the transgene copies in one genetic locus, seemed responsible for the low transgene expression. Indeed, as described above, multiple T-DNAs at one genetic locus are frequently integrated as a direct or an inverted repeat (Fig. 2) [1, 34, 35].

Several other examples show a correlation between transgene silencing and the presence of tandem repeats, which might be linked to exceeding the mRNA threshold level above which PTGS is initiated (Fig. 2) [59, 110, 111]. The same is true for transgene loci that are not silenced under hemizygous, but become silenced under homozygous conditions, as, for instance, in tobacco and *Arabidopsis* [60, 87, 112, 113].

Convergent Transcription from Inverted T-DNA Repeat Structures Is a Strong Trigger for PTGS

Invariably, convergently transcribed 35S-driven transgenes from invertedly repeated T-DNAs are posttranscriptionally silenced to a level that is only 1% or less of the single-copy transgene (Fig. 2) [4, 51, 59, 61, 108, 113–118]. Additionally, invertedly repeated transgenes can very efficiently silence *in trans* homologous sequences located elsewhere in the genome [51, 108, 117, 119]. This direct correlation between invertedly repeated trangenes and transgene silencing has been demonstrated experimentally by the deletion of one of the transgenes from the inverted repeat that released transgene silencing and a 100-fold increase in expression [108]. Indeed, in two parental lines, harboring two invertedly repeated 35S-driven *GUS* genes, the GUS activity was low and both the coding sequences and the center of the inverted repeat were densely methylated. Homologous transgenes at other chromosomal positions were silenced *in trans* by the inverted repeat silencer locus [108, 118]. Removal of one of the *GUS* copies from this silencer locus by the CRE recombinase resulted in all cases in constitutively high *GUS* expression, a significant decrease in methylation and lack of *in trans* silencing capacity [108, 118]. Strikingly, the spacer region in-between the two invertedly repeated transgenes seemed to determine the efficiency of transgene silencing. The presence of an 826-bp non-repetitive spacer region in-between the invertedly repeated transgenes strongly decreased the degree and the stability of silencing [108], but in another system, inverted repeats interrupted by a non-palindromic spacer region varying from 500 bp to 1,022 bp still gave efficient silencing [120].



Transgene Expression in Plants, Control of. Figure 2
Relation between locus structure and the expression of a p35S-driven transgene. Upon transformation, both single-copy and multicopy transformants are generated. Both single-copy plants and plants with multiple T-DNAs arranged in tandem repeat or in repeats giving rise to transgene divergent transcription generally display high and stable transgene expression. Plants carrying convergently transcribed transgenes show low transgene expression as a result of PTGS, whereas plants harboring multiple transgenes integrated into a concatemeric array frequently result in TGS. Abbreviations: *G* gene, *TGS* transcriptional gene silencing, *PTGS* posttranscriptional gene silencing

Multiple T-DNA Copies at One Locus Tend to Become Transcriptionally Silenced After Several Generations

Multiple T-DNA repeats not only induce PTGS, but also TGS. Induction of TGS occurs especially when a concatemeric array or inverted repeats of transgenes are formed and when different genes are regulated by the same promoter [119, 121–124]. The 271 locus, consisting of multiple T-DNAs with an antisense nitrite reductase driven by the 35S promoter, is transcriptionally silenced and is also able to very efficiently *in trans* silence another single-copy p35S-driven transgene [119]. Transgene expression is seemingly less stable over sexually than over vegetatively propagated generations [125]. Indeed, expression of the sulfur-rich sunflower (*Helianthus annuus*) seed albumin (*SSA*) and the phosphinothricin (*BAR*) genes, all driven by p35S, progressively decreased in transgenic clover (*Trifolium subterraneum*) [122]. The expression of both genes was stable until the T3 generation, but in the T7 generation, all plants were completely susceptible to the herbicide and the mean level of the SSA protein was much lower than those observed in the T3 generation. This progressive decrease in expression correlated with the reduced transcription level of both genes and strong CpG methylation in the promoter [122]. Not only the strong 35S promoter, but also the weak pNOS can trigger TGS. The H2 locus, a locus harboring six copies of pNOS, all transcriptionally silenced loci, strongly methylated the promoter regions [121]. Also, transcription of an inverted repeat of pNOS could trigger TGS and methylation of pNOS *in trans*, and this progressively decreased through generations [124].

How to Prevent Transgene Silencing?

To prevent transgene silencing, single-copy transgene inserts should be screened (see below) and inclusion of identical sequences in different transgene constructs

should be avoided [126]. Even a homology of 90 bp in the promoter region can be sufficient to trigger TGS [119]. Additionally, the use of multiple identical 3′ end regions can result in low transgene expression levels. A homology of 239 nucleotides in the 3′ UTR is sufficient to be recognized efficiently by the homology-based RNA degradation machinery [117] and also a homology of approximately 204 nucleotides in the 3′ UTR is enough for a single-copy transgene to activate the *in trans* silencing of another transgene with the same 3′ UTR [113]. Also designing transgenes without any inverted repeat is important to guarantee high and stable expression. Indeed, upon transcription of these inverted repeats, hairpin structures and double-stranded RNA are formed initiating transgene silencing [127]. Almost complete cosuppression of an endogenous gene in tomato (*Solanum esculentum*) was obtained after transformation with a homologous transgene construct that harbored two upstream inverted repeats in the 5′ UTR.

Control of Gene Expression by the Generation of Single-Copy Transformants

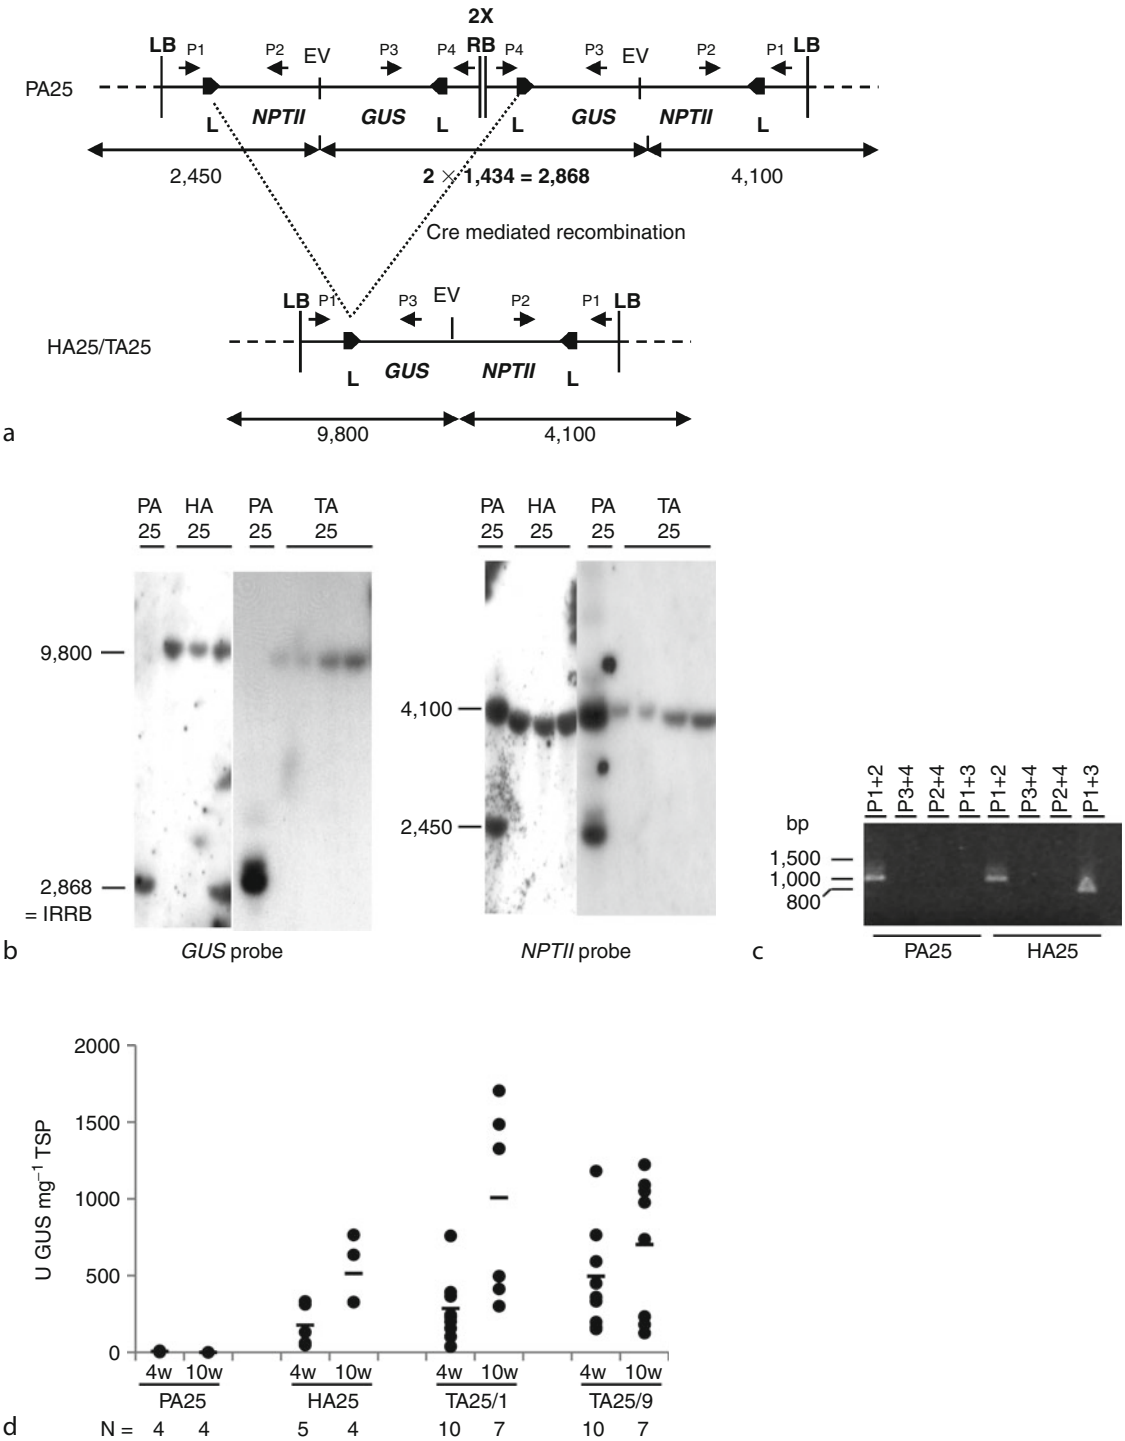
As mentioned above, transformants obtained after *Agrobacterium*-mediated gene transfer often contain multiple T-DNA copies in direct or inverted orientations, and the frequency of single-copy transformants is rather low [1, 17]. Because screening for single-copy T-DNA transformants strongly enriches for transformants with stable and high transgene expression [17], single-copy transformants need to be identified in a large pool of plants. Currently, conventional, but time-consuming and labor-intensive methods, such as DNA gel blot analysis and T-DNA fingerprinting are used [128]. Recently, transformation technologies and vectors have been developed to increase the frequency of single-copy transformants during or after transformation with site-specific recombination.

Generation of Single-Copy Transformants by Resolution of Complex Integration Loci by Site-Specific Recombination

A T-DNA construct, harboring site-specific *loxP* recombination sites, was designed to reduce complex T-DNA loci into a single T-DNA insert (Fig. 3a) [129]. This T-DNA harbored two invertedly oriented *loxP* recombination sites inside and immediately adjacent to the left and right T-DNA border ends [129]. Recombination between the outermost *loxP* sequences in direct orientation should resolve multiple copies into a single T-DNA copy, regardless of the number and orientation of the *loxP*-derived T-DNA copies inserted at one locus.

In a first approach, seven *Arabidopsis* transformants with multiple T-DNA inserts on a single locus were crossed with a homozygous *CRE*-expressing line [129]. In three hybrids, the complex T-DNA locus was reduced efficiently to a single-copy locus and in two of them, the resolution of the inverted repeat locus was accompanied by an at least tenfold-enhanced and stable transgene expression (Fig. 3a–d). In the progeny plants, only the simplified T-DNA locus was detected upon segregation of the *CRE* recombinase gene, proving that excision took place in the progenitor cells of the gametes (Fig. 3b and c) [129]. Unfortunately, in four of the seven transformants, the complex T-DNA locus could not be resolved by CRE-mediated transformation to a single T-DNA copy, although some rearrangements occurred as demonstrated on DNA gel blots. Strikingly, these complex T-DNA loci that were not resolved, had variable expression levels in different progeny plants with the same complex locus, implying some epigenetic imprints imposed by the interaction with the CRE recombinase. Possible reasons for the lack of resolution in these transformants might be deletion of the most extreme *loxP* sequences, too low CRE activity, or inaccessibility of the *loxP* sequences due to heterochromatinization of the complex locus [129]. Indeed, a correlation between the efficiency of CRE-mediated recombination and the CRE mRNA levels had been demonstrated [130].

In a second approach, the T-DNA vector with oppositely oriented *loxP* sequences was transformed into *CRE*-expressing *Arabidopsis* plants [88] and 55% of the primary transformants were single-copy T-DNA plants versus only 15% in control plants. Most of the single-copy transformants in *CRE*-expressing background (70%) displayed a continuous somatic inversion of the DNA fragment between the two inverted *loxP* sequences. To avoid this phenomenon, a new T-DNA vector, harboring only one *loxP* sequence adjacent to the LB or RB, was transformed in a *CRE*-expressing



Transgene Expression in Plants, Control of. Figure 3

Single-copy T-DNA transformants with high and stable transgene expression as a result of CRE/*loxP* recombination-mediated resolution (Adapted from [129]). (**a**) Schematic representation of the CRE/*loxP*-mediated resolution of a complex locus to a single T-DNA (not on scale). Parental (P) plant PA25 contained two T-DNAs in inverted orientation. After the plant

plant and up to 70% of the transformants were single copy. As resolution to single-copy plants is only efficient when the outermost *loxP* sites are in direct orientation, inverted T-DNA repeats might be mostly internal to multiple T-DNA copy arrays and they rarely occur at the ends after floral dip transformation in *Arabidopsis* [88]. Most single-copy transformants, obtained with both T-DNA vectors, displayed high and stable transgene expression. Strikingly however, the transgene expression in the majority of multicopy CRE transformants was stable and uniform, suggesting that the CRE recombinase prevented also the generation of inverted T-DNA repeats or modified the chromatin structure of the locus, so that it became less sensitive for gene silencing [88]. In both strategies, the *CRE* expression cassette is still present after resolution of the complex T-DNA locus, which can be a disadvantage, because, except for *Arabidopsis*, high *CRE* expression can result in severe growth phenotypes and reduced fertility in some plant species [131]. To avoid this drawback, *loxP*-containing T-DNAs could be transformed into hemizygous *CRE*-expressing plants, with 25% of the transformed progenies without *CRE* expression cassette as a consequence [88]. Also backcrossing of a homozygous *CRE*-expressing line with a wild-type plant would result in transformants without the *CRE*-containing T-DNA. Alternatively, the CRE recombinase protein could also be transiently introduced into the plant cell nucleus. Vergunst et al. [132] developed a VirB/D4-dependent translocation system in which the CRE recombinase was fused with the VIRE2 or VIRF proteins of *A. tumefaciens*. Together with the VIR proteins, the CRE recombinase was transferred to the plant cell and site-specific recombination took place. This recombination did not require any transferred DNA [132], but the question remains whether this CRE recombinase activity would be high enough to mediate complex T-DNA loci resolution and to transfer the CRE recombinase very efficiciently.

Simplification of complex T-DNA loci was also observed by Verweire et al. [133]. To ultimately develop a T-DNA vector that generates homozygous marker-free transgenic *Arabidopsis* plants without the need of additional transformation rounds or crosses, a germline-specific auto-excision vector was designed that harbored both the selectable marker and the *CRE* expression cassette between two *lox*P sequences in direct repeat. Additionally, the *CRE* recombinase was driven by the germline-specific 2.2-kb promoter fragment of the *SOLO DANCERS* gene, which is active in both the male and female meiocytes of *Arabidopsis*. In this manner, the transgenic plants become genetically programmed so that the marker

DNA was digested with the *Eco*RV (EV) enzyme, a fragment of 2,868 bp after hybridization with the *GUS* probe is indicative for the inverted T-DNA repeat about the RB, while two T-DNA/plant junctions of 2,450 bp and 4,100 bp were observed after hybridization with the *NPTII* probe, revealing the left T-DNA/plant DNA junctions. The hybrid (H) HA25 was obtained after crossing the parental plant with a *CRE*-expressing plant. CRE/*loxP*-mediated resolution between the two outermost *loxP* sites resulted in a new T-DNA harboring two LB regions in HA25 and the F2 progeny plants TA25. The primers P1, P2, P3, and P4 are indicated, showing homology with the LB region, the *GUS*-coding sequence, the *NPTII* coding sequence, and the RB region, respectively. (**b**) DNA gel blot analysis on *Eco*RV-digested DNA of PA25, HA25, and TA25. After CRE/*loxP*-mediated resolution, only one original LB-T-DNA/plant junction fragment was detected after hybridization with the *NPTII* probe fragment. Additionally, as expected, one new T-DNA/plant junction was observed after hybridization with the *GUS* probe. (**c**) Polymerase chain reaction (PCR) analysis on PA25 and HA25 transformants to identify the newly formed T-DNA configurations. Primer combination P1+2 amplified an LB/NPTII junction of 1,142 bp; primer combination P1+3 amplified an LB/GUS junction of 914 bp (*arrow 2*). With primer P4, no PCR fragment was obtained in PA25, because no inverted repeats could be amplified by PCR. Upon CRE/*loxP*-mediated resolution, the RB inverted palindrome was deleted, and only PCR products with the LB region of primer P1 were obtained. (**d**) GUS activity analysis in leaves of 4- and 10-week-old PA25, HA25, and TA25 seedlings. The measurements and the mean are indicated by *dots* and *line*, respectively. GUS activity levels are given as units GUS mg^{-1} of total soluble protein. The number (*N*) of the analyzed seedlings is indicated

gene is lost after the initial selection of the primary transformants. Surprisingly, not only marker-free homozygous progenies were obtained very efficiently, but also the locus structure in these progeny plants was simplified [133].

A similar approach to resolve complex transgene loci had been developed previously for the generation of single-copy transgenic wheat plants after direct gene transfer. In this case, the selectable marker was removed simultaneously with the resolution of the complex locus [134]. The transformation vector consisted of a transgene flanked by two *lox511* sites, a mutant variant of the wild-type *loxP* sequence, in inverted orientation. Additionally, the selectable marker gene was flanked by two wild-type *loxP* recombination sites in the same orientation. Two correct and independent recombination reactions could take place, because *lox511* and *loxP* did not recombine, with transformants with a marker-free, single-copy insertion of the transgene in the plant genome as a consequence. Crossing of four wheat transformants, harboring a multicopy locus, with a *CRE*-expressing wheat transformant, resulted in 62/72 F2 plants with a single-copy, marker-free, transgene locus [134]. Because the resolved locus still contained two *lox511* sites in inverted orientation, the CRE recombinase could still mediate inversion of the transgene between these two sites. Therefore, all F1 plants were chimeric for the inversion and harbored both transgene orientations.

To avoid crossing with a *CRE*-expressing plant, the transgene, flanked by the oppositely oriented *loxP* sites in maize cells, was cobombarded with a *CRE*-expressing construct [135]. This cotransformation resulted in 85% primary transformants harboring one or two copies of the introduced gene, of which 38% harbored a single copy. Of these single-copy plants, 60% lacked also the recombinase gene, because during cobombardment a molar ratio of 3:1 transgene to CRE construct was used. In this manner, an overall efficiency of 23% of plants with only one copy of the transgene construct was obtained [135]. This cotransformation strategy requires that the selectable marker is retained in the primary transformants. However, a strategy with two different recombination systems and two different selectable markers could result in the integration of one transgene without the incorporation of additional unneeded DNA in the transgenic plant [135].

Besides the use of the CRE/*loxP* recombination system to obtain efficiently single-copy transformants, other strategies have been proposed and evaluated. A site-specific recombination strategy was described in which two sets of directly repeated FLP recognition target (FRT) sites [136] flanked a "to-be-removed" (TBR) region. The FRT sites flanking one TBR are inverted in relation to the sites flanking the other TBR. Each TBR can be excised independently, because only recombination between directly repeated FRT sites can cause excision. Furthermore, one site-specific recombinase reaction could simultaneously induce double excisions, resulting in the resolution of complex T-DNA loci. Indeed, the progenies of 70% of the *Arabidopsis* transformants harbored only one or two copies of the transgene, while 40% contained only one T-DNA copy. This frequency of transformants with a simple T-DNA integration pattern is significantly higher than the 5–20% single-copy transformants normally obtained after floral dip transformation [1, 17]. Most interestingly, the reduced copy number was also strongly associated with increased expression [137].

Generation of Single-Copy Transformants by Site-Specific or Site-Directed Integration

Besides the use of site-specific recombination to resolve complex transgene loci into simple loci before, during or after integration, this site-specific recombination system can also be applied to produce plants with a simple integration pattern through site-specific integration [86, 138–141]. In addition, with this technology, transgenes can be targeted to a specific preselected chromosomal site to eliminate variation in gene expression. The strategy to obtain single-copy transformants via site-specific integration consists of two transformation rounds. In the first round, a target line is generated, harboring a target *lox* site between the promoter and the *CRE* gene. In the second transformation, the vector carrying the gene of interest and two *lox* sites is introduced into the target line. When the gene of interest is integrated into the *lox* site of the target line, the expression of

the recombinase gene is stopped. Site-specific gene integration in plants has been described with various DNA delivery methods, such as polyethylene glycol-mediated tobacco protoplast transformation [86], *Agrobacterium*-mediated transformation of *Arabidopsis* [138], and biolistic-mediated transformation of rice [139, 141]. After *Agrobacterium*-mediated transformation, the frequency of *CRE*-mediated gene integration was very low (approximately 2%) compared to the DNA delivery via direct gene transfer, probably because the transferred DNA during *Agrobacterium* transformation is single stranded, which is not a substrate for the CRE recombinase [139, 140].

By combining site-specific gene integration with gene expression analysis, the absolute level of transgene expression could be shown to vary up to tenfold, depending on the target site in the tobacco genome, indicating that the chromosome position can affect the level of transgene expression [86]. Additionally, despite the identical integration pattern, half of the transgenic tobacco lines showed the expected expression of the transgene and the other half very low *GUS* expression. This low *GUS* expression was due to transgene silencing, because it was correlated with DNA methylation and low transcript levels. Furthermore, this DNA methylation was specific for the newly introduced DNA sequences. Also in independent experiments, regenerants could be divided also upon site-directed integration in two categories: the single-copy lines that contained one site-specific insert without additional sequence integration and multicopy lines in which, besides the site-specific integration, additional transgene copies were integrated into the plant genome [140, 141]. The transgene expression of the single-copy rice transformants was high and stable and the variation was lower than that of the multicopy lines. In approximately half of the multicopy lines, expression of the site-specific integrated transgene could be reactivated and stabilized when the illegitimate integrated inserts were segregated away. In the remaining half, the expression could not be restored, because the random integrations were genetically linked to the site-specific integration event [141].

A site-directed integration system for *Agrobacterium*-mediated transformation of tobacco was developed in which a single transgene copy could be integrated precisely into a predefined target locus by recombinase-mediated cassette exchange (RMCE) [142]. In the RMCE-based site-directed integration strategy that uses the R-RS system from *Zygosaccharomyces rouxii*, a single-copy of the target cassette, surrounded by two oppositely oriented RS sites, is randomly integrated into the plant genome. The exchange cassette contains the selectable marker gene and the gene of interest between two opposite RS sites, and the recombinase gene, the selectable marker gene, and the gene of interest between directly oriented RS sites. This third RS site excluded random integration events. The recombinase will catalyze a double crossover between the two RS sites, replacing the target cassette by the exchange cassette and removing the recombinase gene. Expression analysis revealed that the obtained site-specific recombined plants from the same target line had approximately the same transgene expression level and less transgene expression variability than the random-integration transgenic plants and no transgene silencing [142]. Strikingly, transgenes in the same direction at the same target locus had the same level of activity, in contrast to transgenes in different directions, indicating that the surrounding genome DNA sequence outside the target locus might affect the activity of the gene. Also after direct gene transfer of soybean (*Glycine max*), site-specific integration via RMCE occurred efficiently and stable transgene expression was stable [143].

Another approach to obtain single-copy transgenic lines is the "Agrolistic" method, in which the advantages of *Agrobacterium*-mediated transformation and biolistics were combined [144, 145]. The *VIRD* genes were cobombarded with the T-DNA borders, flanking the introduced transgene. Approximately, 20% of the transformed tobacco calli contained only the T-DNA with correctly processed border sequences and no integrated vector backbone sequences [144], whereas 10–35% of transgenic maize calli contained one to two transgene copies. The addition of *VIRE2* genes even doubled this transformation efficiency [145]. Finally, the application of niacimide, a product that reduces recombination of extrachromosomal molecules, resulted in the generation of single-copy transformants in wheat with an efficiency of 8% [146].

Use of Gene Silencing Mutants to Overcome Transgene Expression Variability

Variation in transgene expression in a population of plants is frequently due to PTGS of the transgenes. Several genes are involved in PTGS and mutant screens revealed that the RNA-dependent RNA polymerase (RDRP6, SGS2) is essential for PTGS to occur [147, 148]. Therefore, a logical approach to overcome PTGS in a population of transgenic plants was to generate transformants in an *rdr6* mutant background, impaired in PTGS [3, 84]. Introduction of p35S-*GUS* or p35S-*GFP* transgenes into the *Arabidopsis sgs2* and *sgs3* mutants (two different alleles of *RDR6*) resulted in stable and high expression of these transgenes in 100% of the transformants analyzed [3], while, similarly, the outcome of introduction of a cyclin-dependent kinase inhibitor 6 gene under the control of p35S was a clear overexpression phenotype, typical for high expression of the kinase inhibitor, in all transformants. Also the transgene expression in transformants with convergent transcription of invertedly repeated T-DNAs was high. Interestingly, immediate transgene silencing in the F1 progeny plants occurred by backcrossing of these high-expressing transformants containing an inverted repeat T-DNA locus with a wild-type nontransformed plant. This observation clearly demonstrates that RDRP6 is required for the generation of double-stranded RNA, also from inverted repeat loci, and that not the read-through transcripts from the convergently transcribed genes generate the double-stranded RNA, as is widely believed. Similar results were obtained when the transgenes were driven by the pCAS promoter, a strong constitutive promoter derived from the cassava vein mosaic virus [149]. On the contrary, expression variability was not significantly reduced in the plants transformed with *sgs2* and *sgs3* when the transgenes were under control of the hybrid pOMA1 promoter, a hybrid promoter consisting of parts of the pMAS and pOCS, which might be too weak to trigger PTGS [3], in contrast to the strong p35S and pCAS. When the T-DNA constructs were flanked by MARs of the chicken lysozyme gene, the GUS activity was boosted fivefold and 12-fold in *sgs2* and *sgs3* background, respectively, in contrast to the wild-type background, making this PTGS-MAR expression system very attractive for the production of heterologous proteins in plants [3, 84].

Future Directions

The ultimate aim is to generate transgenic plants with a predictable, well-controlled, and stable transgene expression over many generations. As described above, to achieve this goal, many parameters should be taken into account. Most importantly, the transgene construct should be optimally designed: a suitable promoter should be selected that drives transgene expression in the desired way, multiple homologous sequences should be avoided in the transgene construct, and foreign unnecessary DNA should be as much as possible prevented to be integrated into the plant genome. Until now, the transgene construct was integrated via illegitimate recombination, but recent reports on site-specific integration let one assume that targeted integration via ZFNs will soon become feasible routinely [105]. At the same time, this method will enrich for single-copy transformants ensuring stable transgene expression. Importantly, the majority of the above-described observations and conclusions are all based on genes driven by the strong constitutive p35S. Therefore, it is perfectly conceivable that all these observations are typical for this promoter, but cannot be extrapolated to other promoters. In the future, the use of strong plant promoters instead of the 35S promoter in transgene constructs might be a big improvement to obtain controllable and stable high transgene expression. Indeed, in general, plant promoter–gene fusions show limited quantitative and qualitative variations in transgene expression in different transformants. Analysis of the expression profile of the *ARCELIN-5* regulatory sequences in *Arabidopsis* seeds revealed that, surprisingly, the *Arabidopsis* seeds accumulated ARCELIN-5, an abundant protein found in common bean (*Phaseolus vulgaris*), to 15% of the total soluble protein content [150]. All transformants had low plant-to-plant variation and even in plants harboring a complex T-DNA integration pattern, with invertedly and directly repeated T-DNAs, the transgene expression was high and stable [150]. Similar results were found for genes driven by the *ß-PHASEOLIN* promoter of common bean [70].

However, to really control transgene expression in plants, the underlying triggers that initiate PTGS and TGS have to be understood in much more detail. Do all plant promoters give less variation in transgene expression compared to viral and bacterial promoters? Do plant promoters also induce silencing and with which frequency? Intriguingly, why do certain loci with multiple p35S-driven transgene copies provoke silencing and why others not? Silencing is often triggered when gene expression rises above a certain threshold, but what is the nature of this threshold and how is the threshold measured? Can transcript levels be increased by the insertion of particular stabilizing elements? To answer all these questions, an integrated approach will have to be followed, including the use of well-designed transgene constructs differing only in a single transgene element in combination with different mutants. Molecular characterization of the transgene locus, the transcript steady state and turnover levels, and the translation efficiency should allow to unravel the network of gene expression control and identify the most important master elements. The ultimate goal is to be able to construct transgenes with a predefined expression pattern in a reliable way.

Article Outline

Glossary

Bacterium A unicellular, prokaryotic microorganism with a wide range of shapes that is surrounded by a lipid membrane and a cell wall made of peptidoglycan, and has few intracellular structures, no nucleus but a single circular chromosome located in the cytoplasm and reproduces by binary fission.

Fungus A eukaryotic organism such as a yeast or a mold, with cell walls that contain glucans and chitin, membrane-bound nuclei with chromosomes and cytoplasmic organelles, soluble carbohydrates, and storage compounds, and exhibits enormous diversity in life cycle strategies, morphologies, and ecologies.

Pathogen An infectious agent that causes disease to its host.

Pathogenicity The capacity of a pathogen to cause disease.

Pathogenicity factors Products encoded by a pathogen that are crucial for the establishment of disease, e.g., proteins involved in the attachment of the pathogen to the plant surface or penetration and colonization of the host.

Resistance The reaction of a host to a pathogen that derives from preformed defenses and/or defense responses induced following infection.

Systemic acquired resistance (SAR) A mechanism of induced defense that acts nonspecifically throughout the plant, is associated with the accumulation of pathogenesis-related proteins and requires the signal molecule, salicylic acid.

Transgenic plant A plant that results from the application of recombinant DNA and plant tissue culture technologies.

Virus A small obligate parasite that utilizes the cellular metabolic pathways of its host organism to replicate its genes which are made up of deoxyribonucleic or ribonucleic acid and are encapsidated in a protein coat.

Definition of the Subject

Loss of crops due to fungal, bacterial, and viral diseases can have a large impact on human food supplies and local economies, as well as on the social stability of rural communities. It is conservatively estimated that diseases, insects, and weeds together cause 30–40% loss of all crops worldwide [1]. Annual losses worldwide due to plant diseases are estimated to ~14% of total losses and about $220 billion. In addition, the need for measures to control diseases limits the acreage of land available for cultivation, restricts the crops that can be grown in fields already contaminated with certain pathogens and necessitates the use of agrochemicals for treating seeds, fumigating soils, spraying plants, and applying fruit postharvest treatments. Such control measures add to the cost of food production and toxic chemicals can be harmful to human health and the environment [1].

Since the beginning of agriculture, crop plants have been domesticated and improved for various traits such as increased yield, improved nutritious composition, enhanced disease resistance, and tolerance to abiotic factors, among others. The selection and use of resistant crop cultivars is the most efficient and most environmentally friendly strategy to mitigate the impact of

fungal, bacterial, and viral diseases. Resistance to pathogens can be achieved by application of disease-suppressing cultural practices, use of plant defense-promoting substances, deployment of biological agents antagonistic to the pathogens that cause disease, agrochemicals, conventional breeding strategies, and genetic engineering [1]. The need for controlling plant diseases effectively is not only a major challenge, but also a necessity to reduce food losses while improving food quality and safeguarding the environment.

The advent of molecular genetics and plant transformation, in combination with an increased understanding of pathogen–host interactions, has opened new avenues for the development of disease-resistant crops through genetic engineering. Research groups from academia and industry created the first transgenic plants in the early 1980s [2–5]. These early transgenic plants were laboratory specimens (tobacco, petunia, and sunflower). Subsequent research developed transgenic plants, including horticultural crops, with useful traits such as disease resistance. Transgenic crops resistant to fungal, bacterial, and viral diseases were created following extensive research. The first disease-resistant transgenic crop, i.e., a virus-resistant transgenic summer squash, was deregulated in the USA in 1994. Several cultivars derived from the deregulated transgenic summer squash lines were commercialized in the USA in 1996 [6]. The adoption rate of virus-resistant transgenic summer squash has been increasing steadily since the initial releases. Other commercially available virus-resistant transgenic crops include papaya in the USA, and sweet pepper and tomato in the People's Republic of China. Transgenic crops resistant to fungal and bacterial diseases have been developed and evaluated under field conditions. However, in spite of remarkable progress, their development and release lags behind virus-resistant transgenic crops.

Introduction

Plants provide microorganisms, including viruses, with a diversity of habitats [7]. Ensuing interactions are either detrimental or beneficial and are classified as neutralism, commensalism, synergism, mutualism, amensalism, or parasitism. It is the latter association that has been a major challenge to crop production for centuries.

In the parasitic interaction, an organism lives within the plant host or on its outer surfaces and obtains its nutrients from the latter [1]. The removal of nutrients often affects normal growth and development of the plant and may be associated with pathogenicity. Virus infections commonly result in the inhibition of plant growth as well as the development of undesirable morphological changes and decreased yield [8]. Unlike fungal and bacterial pathogens, viruses induce disease in plant hosts primarily by utilizing cellular components and disrupting cellular processes. Fungi are responsible for diseases referred to as blight, gray mold, bunts, powdery, and downy mildews. These microbes have evolved at least three strategies that lead to less-than-healthy plants; enzymes that breakdown the plant cell wall and cuticle, toxins that either reduce the activity of the host cells or inhibit it completely, and plant-specific hormones that interfere with the hormonal equilibrium of the plant cell [9]. Bacterial pathogens cause pre- and post-harvest diseases that are characterized by cankers, galls, wilts, spotting of leaves, and stem or fruit rots of various vegetable and fruit crops. The invasion of healthy plant tissue through a wound or an area of dead or dying tissue is generally followed by the initiation of infection, which is similar to that of fungi, and is associated with the breakdown of cell walls, the production of toxins, exo-polysaccharides or proteins that mimic plant hormones.

Plant diseases, whether initiated by viruses, bacteria, or fungi, are of paramount importance because of the destruction they cause to plants and plant products. The effects not only threaten crop productivity and reduce farmers' net income, but also the food supply, and by extension, the economies of rural areas and even countries [10]. Zadoks and Schein [11] differentiate between primary and secondary losses and direct and indirect losses. Primary losses refer to those sustained because of plant disease (before or after harvest) in yield or wages, while secondary losses are losses of future production capacity. On the other hand, losses in quality, quantity, and production capacity, and socioeconomic losses are classified as direct and indirect losses, respectively.

Disease control efforts to date have focused on various crop husbandry techniques including crop rotation, and the avoidance of spread of infested soil

and pathogen-carrying plant materials. The most widely used management strategy is the application of agrochemicals, particularly against fungal pathogens. Chemical protection against bacterial pathogens is not as evolved as that against fungi, and is not applicable to viruses. The most widely used methods against bacterial diseases primarily center on phytosanitary practices, harvesting techniques, and storage conditions, and eventually on the use of antibiotics. However, the intensive use of agrochemicals has led to the development of resistance in various microbial populations and in some cases the chemicals are no longer used because of their high toxicity or problems with persistence in the soil. Nowadays, the focus is on strategies that allow for crop production with minimal use of agrochemicals. The most effective strategy to mitigate the impact of diseases on agriculture involves breeding-resistant crop cultivars. The majority of the cultivars available today have been generated through the classical method of hybridization [12] and the introgression of genes responsible for resistance. Resistant plants ward off pathogen attack by an innate immunity of each cell, systemic signals emanating from infection sites and a suite of cellular responses that follow the activation of the gene for resistance. However, there are many pathogens for which no effective sources of disease resistance have been identified. Technologies such as genetic engineering and gene transfer methods offer an alternative means for the development of disease resistant cultivars. In contrast to conventional breeding which involves the random mixing of the tens of thousands of genes present in both the resistant and susceptible plant, the latter technology allows the transfer of only the resistance gene to the susceptible plant and the preservation of its valuable economic traits. Moreover, the genetic sources for disease resistance are not limited to closely related plant species. During the last decade, considerable progress has been made in the development of virus resistant transgenic plants, while the development of fungal- and bacterial-resistant transgenic plants has lagged behind.

This chapter examines the different strategies devised for the development of resistance to fungal, bacterial, and viral diseases through genetic engineering. A description of the genes employed to confer resistance against given pathogens and the mechanisms underlying engineered resistance are provided. Emphasis will be on horticultural crops and the recent applications of transgenic resistance to agriculture. Factors affecting the development, release, and adoption of transgenic crops with resistance to fungal, bacterial, and viral diseases will be identified and discussed. The final sections offer overall conclusions, cover the impending direction of the development of transgenic disease resistance and some reflection on the impact of transgenic crops resistant to fungi, bacteria, and viruses in terms of effective disease management, mitigation of disease impact on agriculture, improved production of quality food, and better preservation of the environment.

Transgenic Resistance to Fungal Pathogens

Plants have evolved a complex pathogen defense system that is driven by tight balances between the induction of specific defense pathways and cell death. Much progress has recently been made in identifying and understanding a number of the genes and gene products involved in these defenses as well as the signaling pathways. The findings have prompted the development of a variety of strategies for producing fungus-resistant transgenic plants that are based on the manipulation of the plant's innate defense system, the production of antifungal proteins or the neutralization of fungal pathogenicity factors.

The earliest strategy employed in the development of resistance against fungal pathogens involved the enhancement of the plant's natural defenses through the overexpression of pathogenesis-related proteins (PR- proteins). PR- proteins form part of the general resistance mechanism in plants, that is, systemic acquired resistance (SAR), which is induced by necrotizing pathogens or by treatment with chemicals such as salicylic acid. Initial studies on the development of fungus-resistant transgenic plants examined the effects of expressing a single PR-protein gene in transgenic plants, while later studies looked at the co-expression of combinations thereof, in an attempt to improve on the levels of resistance, to target a wider spectrum of fungal pathogens and to provide longer-term protection.

In 1991, Broglie and coworkers [13] reported on the first fungus-resistant transgenic plants. Transgenic tobacco and rapeseed plants, transformed with a chitinase gene isolated from bean, exhibited enhanced

resistance against the soil-borne fungus, *Rhizoctonia solani*. Presumably, expression of the chitinase transgene played a dual role in protecting against infection; that is, the enzyme inhibited growth of the pathogen by cell wall digestion and the released pathogen-borne elicitors induced additional defense reactions in the plants. Following the first pioneering work of Broglie et al. [13], Lorito et al. [14] showed that an endochitinase gene (*ThEn-42*) from the mycoparasitic fungus, *Trichoderma harzianum*, conferred similar resistance to the fungal pathogens, *Alternaria alternata, A. solani, Botrytis cinerea*, and *Rhizoctonia solani* in transgenic tobacco and potato (cv. 'Desiree'). The effectiveness of glucanase, another PR-protein, in transgenic plants was demonstrated in banana transformed with β-1, 3 glucanase from soybean. Increased protection was observed when transgenic banana was infected with *Fusarium oxysporum* f. sp. *cubense* [15]. Further, the combinatorial expression of two chitinase genes [16] or chitinase and glucanase genes was found to give increased levels of protection than the expression of the PR-proteins in single transformants [17]. Subsequent strategies employed the co-expression of transgenes encoding differently acting antifungal proteins with similar results. For example, ÓBrian et al. [18] confirmed protection against *Rhizoctonia solani* in transgenic tobacco carrying three barley proteins; chitinase, β-1, 3 glucanase, and plant ribosome-inactivating protein (RIP). While the first two enzymes targeted the cell wall of the pathogen, RIP targeted and inactivated fungal ribsomes. RIPs possess N-glycosidase activity and catalyze the removal of an adenine residue from the 28S rRNA, thus inhibiting protein elongation.

Another emerging strategy against fungal pathogens involves the use of genes encoding small cysteine-rich antifungal proteins. These proteins play a role in the plant's innate defense mechanism and include thionins, defensins, and lipid transfer proteins.

The antimicrobial activities of thionins are well known, particularly those found in barley. Antimicrobial action, most likely based on the induction of membrane permeabilization resulting in cell disruption and death, is not limited to fungi and these proteins are effective against bacteria and oomycetes. Given this growth inhibition activity, transgenic plants overexpressing thionins have been generated to provide fungal resistance. Epple et al. [19] overexpressed an endogenous endothionin *Thi2.1* gene in *Arabidopsis thaliana* and observed enhanced resistance against *Fusarium oxysporum* f. sp. *matthiolae*. Similar levels of resistance were obtained with *Thi2.1* transgenic tomato against bacterial and Fusarium wilt [20].

Other small cysteine- rich proteins referred to as defensins are increasingly becoming recognized as candidates of defense transgenes. Defensins were originally called γ-thionins due to similarities to *a*- and *b*-thionins, but it was later shown that the former proteins shared appreciable structural and functional commonalities to insect and mammalian defensins, hence the name change. As with thionins, the mechanism of action has yet to be confirmed. However there is strong evidence of the induction of ion fluxes across the plasma membranes of living fungal hyphae followed by interactions with glycosylceramides at the fungal cell surface. Expression of single-protein defensin gene constructs has been deployed in transgenic plants as well as cleavable, chimeric polyprotein constructs in an attempt to increase expression levels in planta and to introduce broad-spectrum resistance. The constitutive expression of a mustard defensin conferred resistance to *Fusarium moniliforme* and *Phytophthora parasitica* pv. *nicotianae* in tobacco and *Pheaoisariopsis personata* and *Cercospora arachidicola*, which jointly cause late leaf spot disease in peanuts [21]. François et al. [22] engineered a polyprotein construct using defensin genes *DmAMP1* from *Dahlia merckii* seeds and *Rs-AFP2* from *Raphanus sativus* seeds. The genes were joined by a linker peptide obtained from *Impatiens balsamina* seeds [22] and used for the transformation of *Arabidopsis*. Antifungal activity was obtained against *Fusarium culmorum* in in vitro assays using purified fractions from extracellular fluids of the transgenic plants.

Lipid transfer proteins (LTPs) are the third group of small cysteine-rich antifungal proteins (ca. 10 KDa) found in higher plants. As the name implies, LTPs are involved in shuttling phospholipids and other fatty acid groups between cell membranes and bind acyl chains; culminating in membrane permeabilization and a direct cytotoxic effect on fungal cells. Constitutive expression of pepper (cv. Habanero) LTPs, *CALTPI*, and *CALTPII*, in tobacco conferred enhanced resistance to *Phytophthora nicotianae* and the bacterial pathogen, *Pseudomonas syringae* pv. *tabaci* [23].

When a wheat LTP (*Ltp3F1*) was linked with a chitinase gene from barley (*chi2*) and transformed into carrots, reduced disease symptoms against necrotrophic foliar fungal pathogens, *Alternaria radicicola* and *Botrytis cinerea*, were obtained; 95% for *Botrytis* and 90% for *Alternaria* infection compared to 40–50% for single-gene transformants [24].

Phytoalexins are another group of plant secondary metabolites with primarily antifungal activity that have been exploited in the development of fungus-resistant transgenic plants. These metabolites are of low molecular weight (ca. <1,000 Da) and are synthesized or accumulated in response to infection or stress related to infection. Resveratrol is the best studied phytoalexin of grapevine that is synthesized from the precursors, malonyl-CoA and *p*-coumaroyl-CoA, by the action of stilbene synthase. Apparently, the accumulation of resveratrol upon infection triggers the synthesis of a fungal phenol oxidase that results in self-intoxication through the conversion of resveratrol to a more toxic dimmer, viniferin. Grapevine stilbene synthase transformation of tomato and papaya [25] introduced increased protection against *Botrytis cinerea* and *Phytophthora palmivora*, respectively. However, in other cases, e.g., strawberry, increased resistance was not obtained [26].

Increased evidence in recent years indicate the possibility of achieving improved resistance in transgenic plants expressing transcription factors that participate in the regulation of plant defense responses. Five major families of plant transcription factors have been described; basic region/leucine zipper motif (bZIP), zinc finger motif WRKY, MYB, ethylene-responsive element binding proteins (EREBP), and homeodomain proteins. Transcription factors play a crucial role in the transmission of pathogen-derived defense signals. They are involved either in the activation or suppression of downstream defense gene expression or the regulation of cross-talk between different signaling pathways. Presumably the mode of action is by binding promoter elements (W-box) of SAR gene promoters. Thus, the strategy is particularly attractive as the constitutive expression of a transcription factor may also modify the expression of all genes under its regulation. Solano et al. [27] engineered transgenic *Arabidopsis* plants with the ethylene-response-factor 1 (*ERF1*), an early ethylene-response gene that is regulated by the ethylene-insensitive gene EIN3 and, which in turn, regulates the expression of several pathogen responsive genes. The transgenic plants showed a clear reduction in *Botrytis cinerea* infection, with 40–70% of plants remaining symptomless after challenge and never developing macroscopic or microscopic necrosis. *ERF1* also mediated *Arabidopsis* resistance against the soil borne fungi, *Fusarium oxysporum* sp. *conglutinans* and *F. oxysporum* f. sp. *lycopersici* [28]. An ERF transcription factor (*GbERF2*) gene derived from cotton enhanced the resistance of transgenic tobacco to fungal infection by *Alternaria longipes* [29]. The accumulation of *GbERF2* transcripts along with transcripts of PR-proteins, such as *PR-1b*, *PR2*, and *PR4*, were detected.

Rather than using strategies based on the overexpression of PR-proteins or transcription factors that are induced during SAR for enhanced fungal resistance, other researchers have examined the effects of the constitutive expression of signaling molecules that play an important role in the induction of defense proteins. Components of the elicitor-receptor system were used to generate these transgenic plants. The system, explained by the gene-of gene-model, is the major line of plant defense against pathogens. Essentially, a pathogen protein encoded by an avirulence gene (*Avr*) is recognized by a plant protein encoded by a resistance gene (*R*), resulting in the activation of a number of defense mechanisms including the hypersensitive reaction and the restriction of the pathogen at the site of infection. Thus resistance against fungal pathogens carrying a particular *Avr* gene is introduced via the transfer of the corresponding *R* gene from a resistant plant to a susceptible plant. The success and durability of the strategy correlates strongly on the ability of the *R* gene product to recognize *Avr* proteins secreted by most if not all of the races of the pathogen. During the last decade, several sequences of *R* genes have been characterized into five classes according to their functional domains. Three classes contain leucine-rich repeats. The most common class encodes proteins with an amino-terminal nucleotide-binding site (NBS) and a carboxy-terminal leucine-rich repeat (LRR) and confers resistance against nematodes, sucking insects, viruses, bacteria, oomycetes, and fungi. The proof of concept has been conducted with the model system, tobacco, as well as various economic

crops. Rice plants transgenic for the *R* gene alleles, *Pi9*, *Pi2*, and *Piz*, against the rice blast fungus, *Magnaporthe grisea,* were reported highly resistant to 43 isolates collected from 13 countries [30]. In flax, three alleles of the flax rust resistance gene, *L* (*L2*, *L6,* and *L10*) when transformed into a highly susceptible rust cultivar, unequivocally demonstrated resistance against strains of pathogen (*Melampsora lini*) with the corresponding *Avr* gene [31]. Increased resistance was also obtained when transgenic tobacco transformed with the same three flax genes was challenged with two pathogens of tobacco. Increased resistance was conferred against *Cercospora nicotianae* and the oomycete, *Phytophthora parasitica* pv. *nicotianae* in *L6* transgenics and one *L10* transgenic plant [32]. Resistance was attributed to the constitutive expression of defense genes rather than recognition of the pathogens by the *L6* gene product. Of note, the *L6* transgenic plants exhibited a stunted phenotype.

Another arm of the plants' innate defense that is being investigated is that of RNA silencing. Accumulating evidence suggests the involvement of small interfering RNAs (siRNAs) and microRNAs (miRNAs) in the response to fungal pathogens. The involvement of plant siRNAs, short, noncoding RNAs between 20 and 24 nucleotides (nt) in length, have been implicated in the defense against viruses, and more recently bacterial pathogens, and is discussed in a later section of the chapter. miRNAs comprise the 21-nt class of siRNAs and short-interfering RNAs comprise the 24- nt class of siRNAs. Work with pine and the canker- forming rust fungus, *Cronartium quercuum* f. sp. fusiforme, identified 82 putative miRNA targets, including NBS-LRR proteins, receptor-like kinases, laccases, and MYB transcription factors, which are most likely associated with disease responses that restrict fungal growth [33]. Ellendorff et al. [34] showed that RNA silencing plays a role in the defense against *Verticillium* in *Arabidopsis*, but the siRNA involved were not identified. Further research into the targets and processes will invariably have broad implications in potentiating basal defenses against fungal phytopathogens.

Other strategies have explored the development of enhanced resistance through the expression of gene products that target components of the arsenal of the fungus. One approach employed the transformation a susceptible cultivar with sequences encoding polygalacturonase inhibiting proteins (PGIPs). PGIPs, proteins structurally related to several resistance gene products, are expressed in the cell wall of a number of plants and belong to a superfamily of LRR proteins, suggesting involvement in pathogen recognition. These proteins inhibit the activity of fungal endo-polygalacturonases presumably by binding at either the substrate binding site or the underside of the endo-polygalacturonase. The resulting oligogalacturonides induce a range of defense responses. *Arabidopsis* plants overexpressing *PGIP* isolated from pear showed decreases in disease symptoms produced by *Botrytis cinerea* [35]. Similarly, transgenic wheat accumulating bean PGIP developed smaller lesions when challenged with the necrotropic fungus, *Bipolaris sorokiniana* [36]. In earlier studies with transgenic tomato carrying a PGIP transgene isolated from bean, enhanced resistance against *Fusarium oxysporum* f. sp. *lycopersici, Botrytis cinerea,* and *Alternaria solani* was not obtained [37].

Another component of the arsenal that some fungi (e.g., *Sclerotinia sclerotiorum*) use to infect plants that is regarded as a pathogenicity factor is oxalate. Oxalic acid apparently assists in initiating infection through acidification, which facilitates cell wall–degrading enzyme activity, through pH-mediated tissue damage, or via the sequestration of calcium ions. Evidence for the utility of hydrogen peroxide–generating enzymes in protective plant responses was provided by the expression of oxalate oxidase, which catalyzes the degradation of oxalic acid to produce carbon dioxide and hydrogen peroxide (H_2O_2). Essentially increased H_2O_2 production limits the growth of the invading pathogen in planta and triggers the activation of a range of defense responses. Sunflower and tomato transformed with a wheat oxalate oxidase gene exhibited increased resistance to *Sclerotinia sclerotiorum* [38, 39]. Potato (cv. Bintje) and poplar expressing the same gene showed increased resistance to *S. musiva* [40] and the oomycete, *Phytophthora infestans* [41], respectively.

Transgenic Resistance to Bacterial Pathogens

Knowledge of bacteria–host interactions, in particular of the mechanisms of pathogenesis, and efforts to bolster plant defense mechanisms, has provided a strong basis for implementing transgenic approaches for bacterial disease management. Several strategies aiming at

the lysis or prevention of bacterial growth have been investigated based on the use of bacterial-resistance genes, avirulence genes, expression of antibacterial peptides that act as bactericidal or bacteriolytic agents, and the application of the concept of pathogen-derived resistance. The latter describes the use of genetic elements from a pathogen's own genome to confer resistance in an otherwise susceptible host via genetic engineering [42].

Members of the NBS-LRR class of disease *R* genes have been employed to provide effective protection against bacteria when transferred into new species. Transformation of a susceptible rice cultivar with the resistance gene *Xa21* that was isolated from a resistant rice line and characterized by positional sequencing and functional genetics conferred resistance to *Xanthomonas oryzae* [43]. Field tests of *Xa21* transgenic rice have shown satisfactory results in the Philippines, India, and the People's Republic of China [44], but deregulation of transgenic *Xa21* rice is still pending. It should be noted that hybrid rice containing *Xa21* was developed by conventional breeding [45]. Similarly, *Xa1* provided resistance to *Xanthomonas oryzae* pv. *oryzae* in transgenic rice [46]. Rice expressing an *R*-gene from maize were resistant against *Xanthomonas oryzae* pv. *oryzicola* [47]. Also, *Bs2* of pepper confers resistance to *Xanthommonas campestris* pv. *vesicatoria* in transgenic tomato [48]. Tomato plants expressing *Pto* showed resistance to *Pseudomonas syringae* pv. *tomato* and *Xanthomonas campestris* pv. *versicatoria* [49]. The transgenic approach based on *R*-genes circumvents tedious crosses and backcrosses of conventional breeding as well as linkages to undesired traits.

Another approach to confer resistance to bacterial diseases is based on the use of lytic peptides from insects that form pores in bacterial membranes. For example, cecropins are bactericidal peptides from the giant silk moth, *Hyalophora cecropia*, which interact with bacterial membranes and form transient ion channels. The peptides are active against a wide range of plant pathogenic bacteria including *Erwinia carotovora*, *E. amylovora*, *Pseudomonas syringae*, *Ralstonia solanacearum*, and *Xanthomonas campestris*. Native, mutant (SB37 and MB39) or synthetic polypeptides (Shiva-1 and D4E1) that are designed for increased activity have been used for engineered resistance against bacterial diseases. Infection caused by *Erwinia carotovora* sp. *atroseptica* is reduced in transgenic potato expressing the Shiva-1 and SB-37 lytic peptide analogs [50]. Transgenic apple trees expressing SB-37 showed increased resistance to *E. amylovora* in field tests [51]. Poplar expressing D4E1 had more resistance to *Agrobacterium tumefaciens* and *Xanthomonas populi* than control nontransformed trees [52, 53]. Attacin is another small protein from the giant silk moth with antibacterial activity that inhibits synthesis of the outer bacterial membrane. Transgenic potato attacin expression has enhanced resistance to *Erwinia carotovora* sp. *atrospetica* [50]. Attacin [54] as well as lactoferrin [55] provide enhanced resistance against *Erwinia amylovora* in pear. Similarly, transgenic apple expression of the attacin E gene exhibit enhanced resistance to *Erwinia amylovora* [56] even under field conditions [57].

Lysozymes from various sources have been exploited in the development of transgenic resistance against bacterial diseases. Lysozymes are ubiquitous bacteriolytic enzymes that cleave the murein layer of bacterial petidoglycan, resulting in a weakening of the bacterial cell wall. A chimeric bacteriophage T4 lysozyme fused to a plant signal peptide reduces the susceptibility of transgenic potato plants to *Erwinia carotovora* spp. *atroseptica* [58]. Transgenic apple trees with the bacteriophage T4 lysozyme exhibited significant resistance to fire blight infection [59] and the bovine lysozyme isozyme was shown to confer resistance to *Xanthomonas campestris* in tomato, rice, and potato [60].

Tachyplesin, an antibacterial peptide isolated from the horseshoe crab (*Tachypleus tridentatus*), reduces the incidence of rubber rot caused by *E. carotovora* in transgenic potato [61].

Reactive oxygen species play important roles in various defense responses of plants, including pathogen infection. A prolonged local oxidative burst is one of the earliest events correlated with plant resistance at the site of pathogen invasion; see the previous section for detailed information on the role of oxalate oxidase in plant defense responses. Transgenic potato tubers expressing a glucose oxidase from *Aspergillus niger* for the production of large amounts of hydrogen peroxidase exhibit strong resistance to *Erwinia carotovora* [62].

Many bacteria control virulence factor expression by a cell-to-cell communication system referred to as quorum sensing. Disruption of bacterial quorum sensing has been proposed as a disease management strategy and several techniques with the potential to disrupt quorum sensing have been investigated. The enzyme *N*-acyl homoserine lactone (AHL)-lactonase (AiiA) isolated from the soil-borne *Bacillus* sp. 240B1, which catalyzes the degradation of AHL and attenuates symptoms caused by plant pathogens by degrading the quorum-sensing autoinducer AHL of the soft rot pathogen, *Erwinia carotovora*, induces enhanced resistance in transgenic potato [63].

Several pathovars of *Pseudomonas syringae* produce extracellular toxins that often increase their virulence toward plants. Phaseolotoxin is one such example. Phaseolotoxin is a modified tripeptide that inhibits the plant enzyme, ornithine carbamoyl transferase (OCTase), and is produced by the *P. syringae* pvs. *phaseolicola* and *actinidiae* as well as by a single strain of *P. syringae* pv. syringae, CFBP3388. Transgenic bean expressing *argK* that codes for a phaseolotoxin-insensitive OCTase show resistance to *Pseudomonas syringae* pv. *phaseolicola* [64].

An example of pathogen-derived resistance against a bacterial disease, crown gall, is reported by Krastanova et al. [65]. Based on an earlier report on the use of a truncated virE2 gene construct lacking the 215 C-terminal amino acids to confer resistance to grown gall disease in tobacco [66], these authors used a truncated form of *virD2* from *Agrobacterium tumefaciens* strains C58 and A6, and *Agrobacerium vitis* strain CG450 to engineer resistance to crown gall disease in transgenic grape rootstocks. Resistant lines show a substantial reduction in tumoreginicity and develop very small sized galls [65].

Other researchers used a different approach against the soil-borne bacterium, *Agrobacterium tumefaciens,* that utilized oncogenes of the phytopathogen. *Agrobacterium tumefaciens* possesses several oncogenes (e.g., *iaaM* and *ipt*) that trigger de novo synthesis of auxins and cytokinins to generate tumors following horizontal gene transfer into the plant genome. By expressing two self-complementary RNA constructs designed to initiate RNA interference (RNAi) of the *iaaM* and *ipt* oncogenes of *A. tumefaciens*, resistance to crown gall disease development was achieved in transgenic tomato plants. Transformed tomato lines display between 0.0% and 24.2% tumorigenesis, whereas controls averaged 100% tumorigenesis following stem inoculation with various strains of *A. tumefaciens* [67]. This mechanism of resistance is based on RNA silencing rather than the highly specific receptor–ligand-binding interactions characteristic of traditional plant resistance genes.

Manipulation of the plant's innate defense signaling pathways offers an alternative approach to conferring resistance against bacterial diseases by controlling a large number of induced genes either directly or indirectly. The nonexpressor of PR genes, *NPR1*, is a key regulatory gene of the salicylic acid-mediated systemic acquired resistance in *Arabidodpsis thaliana.* Moreover, *NPR1* plays a key role in ethylene and jasmonic acid signaling pathways that are involved in induced systemic resistance. Plants expressing *AtNPR1* are resistant to bacterial, fungal, and viral pathogens [68–70]. Similarly, transgenic carrots expressing *AtNPR1* are resistant to *Xanthomonas hortorum* as well as to fungal pathogens [71] and transgenic tomato plants expressing *AtNPR1* show enhanced resistance to *Ralstonia solanacearum* and to a lesser extent *to Xanthomonas campestris* [68]. When introduced into rice, *AtNPR1* confers resistance to the bacterial pathogen, *Xanthomonas oryzae* pv. *oryzae* [72]. Overexpression of the rice *AtNPR1* homolog, *OsNPR1*, also enhances resistance to *X. oryzae* pv. *oryzae* in rice [73] and overexpression of an apple *NPRI* confers increased resistance to *Erwinia amylovora* in transgenic apple cultivar 'Galaxy' and transgenic apple rootstock M26 [74].

The involvement of endogenous siRNA and miRNAs in mediating the triggering of defense mechanisms against bacteria is an area of considerable interest. In spite of tremendous progress at identifying and sequencing siRNAs and miRNAs, information available on the involvement of endogenous small RNAs at mediating defense regulation is scarce. One miRNA (miR393) was recently shown to contribute to basal defense against bacteria by targeting auxin-signaling components [75]. Agorio and Vera [76] characterized an *Arabidopsis* ocp (overexpressor of cationic peroxidase) mutant that overexpresses the H_2O_2-responsive Ep5C promoter. The ocp11 mutant exhibits enhanced disease susceptibility to several virulent and avirulent

Pseudomonas syringae strains. OCP11 was cloned and found to encode ARGONAUTE4 (AGO4), a component of the pathway that mediates the transcriptional gene silencing associated with siRNA. The mutant allele, ago4–1, was examined and found to be compromised in resistance to *P. syringae* [76]. This work provided insight into the involvement of small RNA gene silencing pathways in resistance to bacterial pathogens. Silencing the expression of key genes involved in pathogen–host interactions and disease susceptibility is opening new avenues for bacterial disease management.

Transgenic Resistance to Viral Pathogens

Transgenic resistance generally complements conventional breeding methodologies for the development of virus-resistant crops; however, the approach devised to engineer resistance against viral diseases differs from strategies employed in engineering resistance against fungal and bacterial diseases. This is due to the fact that viruses utilize cellular organelles and metabolic pathways for their replication. As such, they interfere with the basic functions in a living cell, unlike fungi and bacteria, which produce specialized reproductive structures or reproduce by binary fission. The approach to engineering resistance to viral diseases in crops essentially consists of activating anti-viral pathways of a natural, innate, and potent defense mechanism against viruses called RNA silencing [77–82].

Prior to the discovery of RNA silencing in the late 1990s and early 2000s, the concept of PDR [42] was commonly applied to engineering resistance against viral diseases. Initially, the viral coat protein gene was the preferred construct used to confer resistance to viruses in plants. However, it soon became apparent that almost any sequence derived from a viral genome, i.e., coat protein gene, movement protein gene, proteinase gene, RNA-dependent RNA polymerase gene, 5′ and 3′ noncoding regions, satellite RNA, defective interfering RNA, could provide resistance. Validated first in tobacco plants expressing the coat protein gene of *Tobacco mosaic virus* (TMV) [83], PDR was subsequently applied to horticultural crops for engineered resistance against viral diseases. In the first field trial of transgenic plants engineered for virus resistance, tomato plants expressing the coat protein gene of TMV were evaluated for resistance to mechanical inoculation by TMV [84]. Only 5% of the transgenic plants were symptomatic at the end of the trial compared with 99% of the nontransformed control plants. This study indicated that overexpression of the coat protein gene provided practical control of TMV under field conditions. Also, inoculated transgenic and uninoculated nontransformed plants had identical fruit yield, indicating that the transformation process and expression of the TMV coat protein gene did not alter the horticultural performance of the transgenic tomato plants.

The efficiency of viral genes at conferring resistance against vector-mediated virus transmission was first shown with cucumber plants engineered for resistance to *Cucumber mosaic virus* (CMV). Plants expressing the coat protein gene of CMV showed a significantly reduced incidence of CMV and a lower percentage of symptomatic plants than nontransformed control plants following CMV inoculation via aphid vectors [85]. In these studies, mechanically inoculated cucumber plants dispersed throughout the field provided reliable sources of inoculum for natural aphid populations to vector CMV. This approach coupled with the fact that field trials were established at a time of abundant endemic aphid flights caused sufficient disease pressure to make inferences about disease progress, resistance, and yield [85]. Subsequently, many other studies have confirmed the usefulness of engineered resistance at providing practical control of aphid-transmitted virus diseases [6].

PDR offers unique solutions to infection by multiple viruses, for example, by co-engineering and co-transferring genes from several viruses into a single host plant. The usefulness of multiple viral genes to control mixed virus infections was demonstrated early on with potato plants expressing the coat protein genes of *Potato virus X* (PVX) and *Potato virus Y* (PVY) [86, 87]. Potato line 303 was highly resistant to infections by PVX and PVY in the field [87]. Later, summer squash plants expressing coat protein gene constructs of CMV, *Zucchini yellow mosaic virus* (ZYMV) and/or *Watermelon mosaic virus* (WMV) were engineered for resistance to single viruses or combinations of these three viruses [88]. Among summer squash engineered for multiple virus resistance, line ZW-20 expressing the coat protein genes of ZYMV and WMV was highly resistant, regardless of whether the infections were

initiated by mechanical inoculations or mediated by aphid vectors [88, 89]. Similarly, transgenic line CZW-3 expressing the coat protein genes of CMV, ZYMV, and WMV was highly resistant to mixed infections by these three viruses following aphid transmission [88, 90].

Following the initial discovery by Powell Abel et al. [83], the viral coat protein gene from various viruses was introduced into numerous economically important crop species with the aim of achieving resistance. It was initially believed that resistance was provided by the viral protein itself via a mechanism involving excess plant-expressed coat protein that interfered with the uncoating step in viral replication [91]. However, it soon became apparent that resistance could be achieved in transgenic plants producing low or undetectable levels of coat protein [92]. The mechanism underlying the engineered resistance involved degradation of the transgene-derived mRNA into small fragments in a sequence-specific manner. This phenomenon was subsequently referred to as RNA silencing [78–82]. This antiviral plant defense mechanism is initiated by double stranded RNA (dsRNA) structures that are identical to the RNA to be degraded [93]. Silencing is associated with the production of 21–24 nt duplexes called small interfering RNAs (siRNAs) [94, 95]. The siRNAs are produced from dsRNA precursors by an endonuclease known as Dicer and become incorporated and converted to single stranded RNAs (ssRNAs) in an Argonaute-containing-RNA-induced silencing complex (RISC) that targets RNA for cleavage [80, 82, 96, 97].

RNA silencing is an innate and potent plant response to virus infection and a natural example of the concept of PDR that has provided new and unprecedented insights into virus–host interactions. Several approaches have been used to express dsRNA cognate to viral RNA for activation of RNA silencing. Expressing sense and antisense viral genes or inverted repeat viral genes to express hairpin RNAs (hpRNA) for the formation of duplex RNA are some of the most recent strategies used to engineer resistance against viruses [81]. For example, intron-spliced hairpin RNA (ihpRNA), ihpRNA overhang, and ihpRNA spacer were evaluated for resistance to PVY [98, 99]. The ihpRNA was found to be the most efficient construct to conferring resistance to PVY with 90% of the plants exhibiting RNA silencing [99]. The same strategy based on the use of highly conserved genetic segments of several viruses into a single transgene construct achieved multiple virus resistance [100].

Artificial plant micro RNAs (amiRNAs) have been used also to engineer virus resistance in plants. The *Arabidopsis thaliana* pre-miR159a precursor was used to generate two amiRNAs^{159} (amiR-P69^{159} and amiR-HC-Pro^{159}) with sequences complementary to *Turnip yellow mosaic virus* (TYMV) and *Turnip mosaic virus* (TuMV), respectively [101]. The amiR-P69159 was designed to target the viral suppressor P69 of TYMV while amiR-HC-Pro^{159} targeted the viral suppressor HC-Pro of TuMV. Transgenic plants carrying both transgenes expressed the corresponding amiRNAs and showed specific resistance to TYMV and TuMV. Low temperatures had no substantial effect on miRNA accumulation [101]. Similarly, the miR171 of *Nicotiana benthamiana* was used to target the 2b gene of CMV and confer resistance to CMV [102]. Although very promising, amiRNAs have not been used yet in crops for virus resistance.

Strategies other than PDR and RNA silencing have also been applied to confer resistance to viral diseases in plants. Peptides or protein microdomains designed to block protein-binding sites have been used. For example, peptide aptamers designed to microdomains of the nucleoprotein of *Tomato spotted wilt virus* (TSWV) that interact with one of the N-protein homomultimerization domains confer resistance to TSWV and other tospoviruses in *Nicotiana* species [103]. Similarly, antibody-based resistance has been investigated as an innovative strategy to confer virus resistance in plants. Hybridoma-derived single-chain variable antibody fragments (scFv) were engineered for resistance to various viruses in model plants [104–108]. A number of plant proteins with antiviral activity have been identified and exploited for engineered resistance to viruses in plants. A class of proteins termed ribosome-inactivating proteins [109], protease inhibitors (cystatins) [110], and the interferon-regulated 2–5A system [111, 112] were used successfully to confer virus resistance.

Status of Commercialized Disease Resistant Transgenic Crops

Since the early studies of Powell Abel and coworkers [83], numerous cereal, vegetable, legume, flower,

forage, turf, and fruit crops expressing virus-derived gene constructs have been created [6]. Many have been tested under field conditions and shown to be highly resistant to virus infections. Among the transgenic crops produced and evaluated in the field, two lines of transgenic summer squash, i.e., line ZW-20 resistant to ZYMV and WMV, and line CZW-3 resistant to ZYMV, WMV, and CMV [88], and papaya resistant to PRSV [113] have been deregulated and released for commercial use in the USA. Summer squash line ZW-20 received exemption status in 1994 and was the first disease-resistant transgenic crop to be commercialized. Summer squash line CZW-3 was deregulated and commercialized in 1996. Five transgenic zucchini cultivars and six transgenic straightneck or crookneck yellow squash cultivars derived from lines ZW-20 and CZW-3 were developed by conventional breeding. Their adoption is increasing steadily since their initial release in 1996. In 2006, the adoption rate was estimated to 22% (3,250 ha) across the country with an average rate of 70% in New Jersey and 20% in Florida, Georgia, and South Carolina [114]. Papaya expressing the coat protein gene of PRSV was deregulated and commercialized in Hawaii in 1998. PRSV is a major limiting factor to papaya production in Hawaii and around the world. After extensive testing, PRSV-resistant papaya was released in 1998 as devastation caused by the virus reached record proportions in the archipelago's main production region [113]. The impact of PRSV-resistant papaya on the papaya industry in Hawaii is evidenced by its rapid adoption rate. In 2000, the first wave of transgenic papaya bore fruit on more than 42% of the total acreage, and by 2009, transgenic papaya cultivars were planted on more than 90% of the total papaya land in Hawaii (780 of 866 total hectares) ([114], D. Gonsalves, personal communication October 2009).

Tomato and sweet pepper resistant to CMV and papaya resistant to PRSV are also released in the People's Republic of China [115, 116]. Limited, if any, information is available on their adoption rate. Two virus-resistant potato lines were deregulated also in 1998 and 2000 in the USA. After failed attempts to create a potato line resistant to *Potato leafroll virus* (PLRV) by coat protein gene expression, lines expressing a PLRV replicase gene were created, field tested, deregulated, and commercialized [117]. Resistance to PLRV was stacked with the coat protein gene of PVY. Many growers in the Pacific Northwest, Midwest USA and Canada are growing virus-resistant transgenic potato, and a breakdown in resistance has not been reported, neither any detrimental impact on the environmental or human health. Nonetheless, virus-resistant potato was withdrawn from the market after the 2001 growing season due to the reluctance of large processors and exporters to adopt these products [117].

Although not released yet, the transgenic plum cultivar 'Honeysweet' resistant to *Plum pox virus* (PPV) and another PRSV-resistant papaya are under consideration for deregulation in the USA. Plum trees expressing a coat protein gene of PPV are highly resistant to PPV infection [118–121]. The US Department of Agriculture (USDA) Animal and Plant Health Inspection Service (APHIS) granted this plum cultivar deregulated status [122] and the Food and Drug Administration (FDA) has deemed a premarket review of the 'Honeysweet' unnecessary. Presently, the Environmental Protection Agency (EPA) is examining deregulation petitions for 'Honeysweet'. Papaya line X17-2 is also being considered for deregulation in the United States. Line X17-2 differs from the previously deregulated Hawaiian papaya in that it expresses the coat protein gene of a Florida isolate of PRSV and is suitable for cultivation in Florida [123]. APHIS and FDA granted X17-2-deregulated status and EPA is presently reviewing a deregulation petition [124].

Despite considerable progress in identifying genes that confer resistance against fungal and bacterial pathogens and testing their efficacy in transgenic plants under greenhouse conditions, it appears that the challenge is to translate the results to an effect in the field under continuous pathogen pressure. A search of the field testing release permit database in the USA reveals over 25 applications for field testing fungus-resistant transgenic soybean, corn, grape, strawberry, tobacco, lettuce, wheat, and American elm between 1993 and 2009. Both single traits such as resistance to Dutch Elm disease, ear mold, or downy mildew, were assessed as well as multiple traits against *Botrytis cinerea*, bacterial pathogens, nematodes, abiotic tolerance, glyphosate tolerance, and altered nutritional properties (oil and seed composition). Based on the FAO Biotechnology in Developing Countries Database (FAO-BioDeC), field

trials have been conducted in South Africa with transgenic strawberry expressing a phytoalexin synthesis gene and transgenic cotton with resistance to *Verticillium* and *Fusarium* in China. A few countries in Latin America, namely, Argentina, Brazil, and Cuba, are working on transgenic fungal resistance in tropical fruit trees, with some results already in the field. Apart from small projects in China, Thailand, and Pakistan addressing potato and wheat wilt, tomato wilt, and blight in rice, far fewer initiatives have been devoted to the development of transgenic cultivars with resistance against bacterial diseases.

To date, no transgenic cultivar with fungal or bacterial resistance has been released into commerce. The outcomes of field experiments have been variable and not in all cases is the resistance observed in the greenhouse extended to the field [125, 126]. In general, the constitutive expression of antimicrobial proteins in the transgenic host appears to confer partial resistance against these pathogens or increased tolerance at best, rather than absolute resistance. It is also clear that the resistance is limited to a few pathogens. The findings of Punja and Raharjo [127] further suggest that the levels of resistance in transgenic plants are influenced by interactions between endogenous and transgene defense compounds. These authors showed that transgenic carrots carrying a chitinase gene from tobacco exhibited enhanced resistance against *Botrytis cinera*, *Rhizoctonia solani*, and *Sclerotium rolfsii*. However, the transgenic plants reacted similarly to *Alternaria radicini* and *Thielaviopsis basicola* as nontransgenic carrots. Further, improved resistance was not obtained against the same sleuth of pathogens and transgenic carrots expressing a chitinase gene from petunia. Indistinguishable disease reactions to *A. cucumerina, B. cinera, Collectotrichum lagenarium*, and *R. solani* were observed with transgenic and nontransgenic cucumber plants transformed with the chitinase gene from three sources, tobacco and petunia, as above, as well as bean.

Conclusions

Plant diseases caused by fungi, bacteria, and viruses are responsible for enormous losses in cultivated crops worldwide. Disease management relies on prevention, cultural practices, biological control, use of chemical pesticides and insecticides, antibiotic sprays, and selection of host resistant genotypes. These approaches have had limited success in the prevention or cure of diseases. Moreover, the frequent use of biocides, especially in subtherapeutic doses, is leading to the rapid development of resistance in certain fungi and bacteria. In addition, preventing fungal infection not only helps in combating yield losses but also keeps crops free of toxic compounds that are produced by some pathogenic fungi and referred to as mycotoxins. These compounds can affect the immune system and disrupt hormone balances or can be carcinogenic. Therefore, there is an urgent need to develop alternative ways to control infections caused by fungal, bacterial, and viral pathogens in agriculture.

The incorporation of specific disease-resistant traits in plants through genetic engineering offers a means to prevent disease-associated losses. For viruses, the concept of PDR [42] provided unique opportunities for innovative solutions to control virus diseases by developing resistant crops expressing genetic elements derived from a virus's own genome. Thirty years after the inception of PDR, various transgenic crops have been engineered for virus resistance and virus-resistant papaya, summer squash, sweet pepper, and tomato have been deregulated and released commercially. Applying the concept of PDR and the antiviral pathways of RNA silencing provides unique opportunities for developing virus-resistant crops and implementing efficient and environmentally sound management approaches to mitigate the impact of viral diseases. Based on the tremendous progress, the prospects of further advancing this innovative technology for practical control of virus diseases are very promising.

Engineered resistance to fungal and bacterial diseases is more complex than engineered resistance to viral diseases. This is due to the complex nature of fungi and bacteria, as well as complex interactions with their hosts. Therefore, in spite of remarkable progress and promising reports from greenhouse evaluations and field tests, no cultivar with engineered resistance to fungi and bacteria have been deregulated yet or commercially released. The fact that transgenic crops with resistance to fungi or bacteria might not have provided equivalent levels of plant protection compared to conventional management strategies in practice could account for the reluctance to deliver

transgenic plans or seeds to growers. Also, the degree of resistance to fungal and bacterial diseases achieved so far might be of limited practical use for disease management. However, new insights into pathogen–host interactions and the application of siRNA and microRNA technologies will undoubtedly identify new targets and open new horizons for the management of fungal and bacterial diseases.

Future Directions

Transgenic virus resistance is undoubtedly the most advanced of the applications of biotechnology for the management of plant pathogens. There is the documented safe release of virus-resistant transgenic crops over the past 14 years in the USA, in addition to a significant amount of evidence that these crops have little to no detrimental impact on animal health and the environment beyond those of conventional agricultural crops [6]. Given the discovery and elucidation of the antiviral pathways of RNA silencing, various new approaches have been used to develop transgenes more likely to stimulate RNA silencing via the design of transgenes that will form dsRNA structures in planta. These approaches seemingly have an advantage over a full-length coat protein gene in the sense orientation as they are generally unable to produce a functional protein, thus alleviating concerns arising from the presence of the coat protein in plant material. Some nonviral sources of virus resistance, such as host resistance genes and the silencing of host genes that are necessary for viral replication [81] have also been investigated and could theoretically alleviate concerns about synergism, recombination, and transencapsidation. Work with transcription factors, in particular the ERF subfamily transcription, provided evidence of increased resistance to bacterial, fungal, and viral pathogens as well as abiotic stress via overexpression of the soybean *GmERF3* transcription factor in tobacco [128]. The mechanism of the effect remains unknown; it is likely that a range of effects such as elevated antioxidant capacity, induced expression of chitinases, or antimicrobial compounds in *GmERF3* transgenic plants and the suppression of viral spread as a consequence of the reduced virus propagation are responsible. The commercial potential of these technologies remain largely undiscussed and untested.

On the other hand, engineering resistance to fungal and bacterial diseases has proven more recalcitrant. Whereas crops engineered for resistance against viral pathogens are in the market, no commercial transgenic product with enhanced resistance against fungal or bacterial diseases is currently available. These organisms have developed numerous survival strategies and more complex interactions with the plant host. As a result, it has proven more difficult to engineer resistance against these pathogens; far beyond designing a simple defense strategy involving the use of a single gene.

Strides in deciphering the siRNAs that are induced or repressed in response to pathogen attack will invariably contribute to new technologies for the development of transgenic resistance against fungal and bacterial pathogens. Microarray analysis with more wild-type plants and RNA-silencing mutants should reveal the relationship between the physiological processes and the associated disease-resistant phenotype. In the interim, the use of stacks or pyramids of *R* genes either from self or non-host plant species is perhaps the best approach available for the development of transgenic resistance against these pathogens. Presumably, this strategy would not affect resistance to nontarget pathogens while providing durable and broad-spectrum resistance and not interfering with the tight controls of the plants' defense systems. But the full potential of *R* gene expression to provide wide range resistance cannot be realized as long as its use is clouded by controversy over what it does and how well it works. The major limitation of the use of *R* genes in the development of transgenic resistance lies in the durability of the resistance, which is driven by the highly specific recognition of the elicitor molecule of the pathogen. Pathogens are usually able to overcome *R* gene–mediated recognition through the accumulation of mutations or through the loss of the elicitor gene [129, 130]. Moreover, not in all cases is resistance obtained after transfer to species that are not closely related [32]. Although a plethora of data is available on the identity of genes and gene products involved in plant resistance, knowledge of pathogenesis is relatively primitive. Continued sequencing of crop plant genomes as well as pathogen genome analysis will invariably lead to decoding of the functions of various defense genes as well as pathways and the isolation of more *R* genes. With this knowledge, the precise

manipulation of *R* genes to permit binding to proteins of pathogens and the activation of defense responses will be possible, and facilitate the design of synthetic *R* genes with desired specificities. For example, work with 13 alleles (*L*, *L1* to *L11*, and *LH*) from the *L* locus from flax suggests a role for the TIR region and LRR region of L proteins in the flax–flax rust interaction [131]. Most of the sequence variation between the three resistance genes, *Pi9*, *Pi2*, *and Piz*, is confined to the LRR domains, indicating that this domain plays a major role in determination of *Magnaporthe grisea* resistance specificities [30]. Further, Jia et al. [132] provided evidence that a single amino acid change in the *Pi-ta* LRD (leucine rich domain) or the *AVR-Pita*$_{176}$ protease motif disrupted interaction between the two and subsequent a loss of resistance against *M. grisea*, the etiological agent of rice blast disease. As more data become available on the structural information and on the interactions between resistance proteins and pathogen ligands, the tweaking of *R* gene domains to accommodate resistance of pathogens infecting distantly related crop species will be likely possible. Moreover, this could be extended to antimicrobial proteins that target components of the pathogen's arsenal, e.g., PGIP. Manipulation of their primary structure and hence determinants of specificity could theoretically generate novel recognition specificities.

Multiple races and range in plant hosts are major issues facing the development of durable disease resistance against fungal and bacterial pathogens. Moreover, in some instances, the expression of enhanced resistance is accompanied by reduced growth or altered morphology or development, given that the plant has been reprogrammed into defense mode. Precise control of transgene expression is thus pivotal; restricted expression at the site of infection and quick induction is crucial as well as a quick response to a wide variety of pathogens [133]. One option is to use pathogen-inducible promoters. Given that the available pathogen-inducible promoters show some patterns of background expression, trancriptomics will play an important role in the identification of more suitable promoters. Work with *Arabidopsis* has already identified potential candidates [134], as have investigations into synthetic promoters combining *cis* elements (W box and GCC-like box) that are conserved across species for restricted expression exclusively at the site of attempted pathogen invasion [135]. Other approaches are considering defensin promoters [136], while others have utilized tissue-specific promoters with some success [137]. The endogenous endothionin *Thi2.1* gene in *Arabidopsis thaliana* gene in tomato under the control of a fruit-inactive promoter (RB7) provided significant levels of enhanced resistance to bacterial and Fusarium wilt [137]. More recently, one study targeted the expression of the PR-protein in leaf trichomes, the preferential port for plant colonization by fungi. The gene encoding an exo α-1, 3-glucanase from *Trichoderma harzianum* was fused to the ATP promoter that confers high expression levels in trichome cells and transferred to *Arabidopsis* [138]. Increased resistance was obtained against *Botrytis cinerea* in needle-wounded and spray assays with transgenic plants. Up to 20% fewer total leaf infections were observed.

In summary, transgenic resistance against viral, fungal, and bacterial pathogens is being addressed on many fronts. The challenge is to develop durable, broad-spectrum resistance, given the diversity of strategies that pathogens deploy and their ability to rapidly adapt. Clearly, an integrated approach based on the knowledge of the defense system of the plant, the arsenal of the pathogen to cause disease and the key genes involved in pathogenesis is required for the design of effective transgenic management strategies. To date, tremendous progress has been made for viruses. Encouraging results have been obtained for various fungi and bacteria. The prospects of further advancing transgenic crops for practical control of fungal, bacterial, and viral diseases are very promising.

Definition of the Subject

Agriculture is the production of food and commodities through farming. Since its dawn some 10,000 years ago, humankind has had an ever increasing impact on the environment. With the increasing intensification of agriculture, particularly during the twentieth century, this impact has become even more pronounced, often with undesirable or unacceptable consequences, including water pollution, soil erosion, and loss of habitat, often accompanied by a loss of biodiversity. Pests, particularly weedy plants, demonstrate a remarkable ability to adapt to agricultural production systems. The practice of growing monocultures, typically used in intensive agriculture, increases the number of pests; these are currently predominantly controlled through use of pesticides. However, with increasing exposure to pesticides, many pest populations are evolving resistance to these compounds. An additional problem encountered with many pesticides, and particularly insecticides, is their non-target effects on beneficial insects. Transgenic crops expressing genes conferring either resistance to insect pests and/or herbicides are becoming increasingly more widely grown. However, in many parts of the world, before such crops are commercialized, they have to be assessed for their potential environmental impact which measures the impact they will have on non-target species and their ability to outcompete native species. Environmental risk assessments cover both the transgenic crop concerned and the potential impacted environment. The assessment process includes evaluation of the characteristics of the crop and its effect and stability in the environment, combined with ecological characteristics of the environment in which the introduction will take place. The assessment also includes unintended consequences that could result from the insertion of the new gene. For all transgenic crops, the direct and indirect effects they have on non-target organisms must be considered. Furthermore, issues relating to potential gene flow to other non-transgenic cultivars and/or wild near-relatives also must be addressed.

Introduction

Food security figures are high on both the political and social agenda [1]. This is not surprising given that the global population increased fourfold during the last century, with current estimates suggesting that it will reach approximately 9.2 billion by 2050 (Fig. 1). However, this increase has primarily been seen in the developing regions of the world, with population remaining relatively static in the developed world. As expected, it is those countries least able that need to significantly

Project world population increase from 1950 to 2050 showing an overall fourfold increase in population. During this period, population growth in the more developed regions of the world are predicted to remain moderately static

increase food production, with an estimated increase in productivity of 300% for Africa and 80% for Latin America; even so, it is estimated that North America will need to increase productivity by some 30% [2]. Without an increase in "farm productivity," this required increase in food production equates to an additional 1.6 billion hectares of arable land by 2050, a scenario that is becoming increasingly less sustainable or, indeed, achievable. An immediate priority for agriculture is thus to achieve increased crop yields in a sustainable and cost-effective way in order to avoid a Malthusian disaster.

The concept of utilizing a transgenic (biotech) approach was realized in the mid-1990s with the commercial introduction of genetically modified crops. In 2009, it was estimated that some 14 million farmers planted 134 million hectares (330 million acres) of biotech crops in 25 countries, representing a 7% increase over the preceding year [3]. Interestingly, 90% of these farmers were small and resource-poor farmers from developing countries. In economic terms, the global market value for biotech crops in 2009 was US$10.5 billion; this figure represents 20% of the US$52.2 billion global crop protection market and 30% of US$34 billion commercial seed market. Of this US$10.5 billion biotech crop market, approximately 50% was accounted for by biotech maize, with soybean, cotton, and canola (oilseed rape) accounting for 37.2%, 10.5%, and 3%, respectively.

Although transgenic crops have only been available since the 1990s, they have dramatically changed the face of world agriculture and are likely to represent the most rapidly adopted technology in agriculture [4]. This trend is largely attributed to one herbicide, glyphosate (*N*-(phosphonomethyl)glycine), and crops that are genetically modified to have selectivity (resistance) to the glyphosate when the herbicide is applied topically to them. However, many new transgenic crops have been introduced that include multiple transgenic traits, thus providing greater value to agriculture. The reported increased economic profitability attributable to transgenic crops is a major factor that provides the impetus for the increasing adoption of these crops worldwide, both in developing as well as industrialized nations [5]. Despite their benefits, not least in increasing crop yield in a more sustainable and environmentally benign way compared to intensive agriculture (Tables 1 [6] and 2 [6–20]), neither the technology, nor the crops, are universally perceived as of benefit to humankind. There are fears that all questions of risk attributable to the wide-scale growing of such crops have not been adequately addressed, or perhaps even identified [21]. While many of these fears may be unfounded, public debate concerning potential environmental and public health risks is crucial.

This chapter will provide a brief overview of first-generation transgenic crops. Specifically, it will discuss the environmental impact of the wide-scale growing of such crops both in terms of their potential non-target effects and the potential for gene flow.

Insect-Resistant Transgenic Crops

Insect-resistant transgenic crops, also known as Biotech crops, were first commercialized in the USA during the mid-1990s with the introduction of genetically modified corn (maize), potato, and cotton plants expressing genes encoding the entomocidal δ-endotoxin from *Bacillus thuringiensis* (*Bt*; also known as crystal/Cry proteins). In terms of *Bt*-expressing maize and cotton,

the current market is estimated at US$2.3 billion and US$0.9 billion, respectively. Detailed knowledge on the mode of action of these Cry proteins is not only essential to optimize their efficacy against target insects, but also to predict the potential for non-target effects on beneficial insects. On ingestion, *Bt* toxins are solubilized in the midgut where they are proteolytically cleaved at the N-terminal to a 65–70-kDa truncated (active) form. The active molecules then exert their pathological effects by binding to a specific receptor (s) in the midgut epithelial cells and insert into the membrane where they form pores, this results in cell death by colloid osmotic lysis, followed by death of the insect [22]. In most commercial crop varieties, these Cry proteins are expressed in the active form and as such differ from those used in biopesticide formulations where the Cry proteins are present as protoxins.

Early commercial varieties of insect-resistant transgenic crops expressed single crystal (Cry) proteins with specific activity against lepidopteran pests as illustrated by Bollgard® cotton expressing Cry1Ac developed by Monsanto and Attribute® maize expressing Cry1Ab developed by Syngenta. Subsequently, other lepidopteran-active *Bt* toxins, such as Cry1F and Cry2Ab2, were introduced, and often presented as pyramided genes in a single variety (Widestrike® cotton expressing both Cry1F + Cry1Ac developed by Dow Agrosciences and Bollgard II® cotton expressing Cry1Ac + Cry2Ab2 developed by Monsanto). Transgenic crops, particularly maize, expressing Cry3 proteins to protect against coleopteran pests such as chrysomelid root-worms have also been commercialized (e.g., Monsanto's Yieldgard Rootworm® maize expressing Cry3Bb1, Dow Agrosciences' Herculex RW® maize expressing Cry34Ab1 and Cry35Ab1, stacked with a HT gene, and Syngenta's Agrisure RW® maize expressing a modified version of Cry3A). In 2009, SmartStax, a novel biotech maize containing eight different

genes for insect and herbicide resistance, was granted approval in the USA. Furthermore, Syngenta has recently launched Agrisure Viptera trait-stacked corn, the first commercially available variety to exploit a non-cry *Bt* protein (Vip3) for the provision of multiple pest resistance. In China, *Bt* cotton cultivars expressing Cry1Ac together with a modified cowpea trypsin inhibitor (CpTI) were commercially released in 2000 [23], and in 2005, accounted for approximately 15% of the cotton crop [24]. The major reason for co-expressing *Bt* and CpTI in cotton was to reduce the likelihood of the insects becoming resistant to this cultivar, thus extending its effective life.

While it is clear that *Bt*-expressing crops have made a significant beneficial impact to global agriculture, not least in terms of pest reduction, improved quality, and increased yield (Table 1 [6]), it is also becoming increasingly evident that there is a need to develop alternative strategies, not least because of the potential for pest populations to evolve resistance [25], and to the lack of effective control of homopteran pests. Recently, crops expressing vegetative insecticidal proteins (VIPs) have been commercialized (see above). However, alternative approaches based on the use of plant-derived or animal-derived genes, including those from insects (such as those encoding immunosuppressive proteins), are being investigated and developed. More recently, the potential to identify and exploit endogenous resistance genes using functional genomics and the use of RNAi are actively being investigated [26–30]. However, if these novel approaches are to play a useful role in crop protection, it is desirable that they do not have a negative impact on beneficial organisms at higher trophic levels since this would inevitably affect agro-ecosystem function. This is equally true for *Bt*-expressing crops.

Herbicide-Tolerant/Resistant Transgenic Crops

From the first commercialization of transgenic crops, to date, herbicide tolerance has consistently been the dominant trait and, as a consequence of its rapid and widespread adoption, has made an immeasurable change to global agriculture. In 2009, herbicide tolerance deployed in soybean, maize (corn), canola (oilseed rape), cotton, sugarbeet, and alfalfa occupied 62% (83.6 million hectares) of the global biotech area of 134 million hectares. Furthermore, in 2009, the stacked double and triple traits occupied an area of 28.7 million hectares (equivalent to 21% of global biotech crop area), much larger than the insect-resistant varieties which occupied 21.7 million hectares (15%). Interestingly, stacked trait products and herbicide-tolerant products grew at the same rate of 6%, while insect resistance as a trait grew at 14% [31].

While there are a number of herbicide-tolerant transgenic crops that have been developed to several herbicides with different modes of phytotoxic action, the primary influence in world agriculture is glyphosate [32, 33]. This preference for glyphosate is based on (1) the target site, (2) the ability of this compound to translocate in plants, and (3) the inability of plants to rapidly detoxify it. Glyphosate controls weeds by inhibiting 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS; EC 2.5.1.19), a key enzyme in the shikimate biosynthetic pathway which is necessary for the production of the aromatic amino acids, auxin, phytoalexins, folic acid, lignin, plastoquinones, and many other secondary plant products. Over 30% of the carbon fixed by plants may pass through this pathway. Inhibition of EPSPS by glyphosate deregulates the pathway, leading to even more carbon flowing through the pathway with accumulation of shikimate and shikimate-3-phosphate. Up to 16% of the plant's dry matter can accumulate as shikimate. Glyphosate occupies the binding site on EPSPS for phosphoenolpyruvate, a substrate of EPSPS, by mimicking an intermediate state of the enzyme-substrate complex. There are two forms of EPSPS in nature, EPSPS I, which is found in plants, fungi, and most bacteria, and is sensitive to glyphosate. The second form is EPSP II, which is found in glyphosate-resistant bacteria and is not inhibited by glyphosate. It is thus the gene encoding an EPSPS II that has been used to genetically engineer crops to confer resistance/tolerance to this particular herbicide [34].

Environmental Impact of Transgenic Crops

The adoption of transgenic crops, and in particular herbicide-tolerant crops, has resulted in significant changes in agronomic practices. Many clear benefits to both the grower and consumer can be identified with transgenic crops that are currently grown, not least in the often significant increases in productivity

accompanied by reductions in synthetic pesticide usage (Tables 1 [6] and 2 [7–20, 35–37]), thus making transgenic crops more environmentally sustainable. Despite the fact that such crops have now been commercialized for some 15 years, alongside these benefits, concerns are still being expressed as to their safety, particularly in terms of their impact on human health and the environment. It is imperative that these concerns are addressed in a scientifically sound and appropriate manner. Thus, assessing the environmental consequences of transgenic crops is an important prerequisite to their commercialization.

In many regions of the world, regulatory frameworks are in place to ensure that all pre-commercial transgenic crops are evaluated for potential impacts on human health, animal health, and the environment according to established standards of risk assessment and current scientific knowledge, prior to authorizations for import or planting being granted. The environmental risk assessment for such crops follows the same fundamental principles as other risk assessment schemes, i.e., risk is a function of hazard and exposure. However, one of the main differences that sets risk assessment of transgenic crops apart from other risk assessment procedures is that it is highly dependent on the crop and the introduced trait; hence, a case-by-case approach is required [38].

Impact of Insect-Resistant Transgenic Crops on Beneficial Insects

For any technology to be acceptable to the public at large, the perceived benefits have to outweigh any potential/perceived risk – this requirement is equally true for transgenic crops [39]. Common to all transgenic crops currently grown, general environmental concerns relate to the potential for horizontal gene transfer, gene flow, and invasiveness to occur both in managed and natural environments. However, in the case of insect-resistant transgenic crops, perhaps, the greatest concerns relate to their non-target effects and, in particular, their effects on beneficial insects such as natural enemies (predators and parasitoids) and pollinators.

An important consideration is the likelihood of exposure of the transgene product to the non-target insect, and indeed the different routes of exposure. The most obvious exposure route for non-target herbivores is through direct ingestion of plant material, although this will be influenced by the mode of insect feeding and spatial and temporal expression patterns of the transgene product within the plant. While exposure to pollinators is via the nectar and pollen, exposure routes to natural enemies are more diverse. Although many predators and parasitoids, particularly in the adult stage, are facultative herbivores and thus can be exposed to transgene products directly from consuming plant tissues (pollen, nectar), the larval stages are more likely to be exposed from consuming insects that have themselves fed on plant tissues where the transgene product has been expressed and accumulated. It is pertinent to point out that in some cases, particularly when the host is a sap-sucking insect such as aphids, that the natural enemy is rarely exposed to the transgene product; however, the scenario is quite different when the host is a chewing insect, in which case the likelihood of the natural enemy being exposed is very high.

Impact on Natural Enemies Agro-ecosystems consist of complex trophic interactions, with many aspects of the physiology, ecology, and behavior of the organisms present being governed by interactions with organisms from the same or different trophic levels. Since plants are the basis of these food webs on which all organisms at higher trophic levels depend, and since herbivorous insect species at the second trophic level have an important position in food webs, together with the fact that approximately 50% of all insect species are plant feeders, the potential for exposure to non-targets, either directly (bi-trophic) or indirectly (tri-trophic), is high. This is particularly true for predators and parasitoids which play an important role in suppressing insect pest populations both in the field and under specialized cultivation systems. Because of this important role and because expression of transgenes that confer enhanced levels of resistance to insect pests is of particular relevance (since they are aimed at manipulating the biology of organisms in a different trophic level to that of the plant), these beneficial insects have been the focus of numerous major studies to evaluate the non-target effects of transgenic crops. The nature of these investigations has been very varied ranging from detailed studies at the molecular/biochemical level

under controlled environmental conditions, to glasshouse trials using deliberately infested plants and released natural enemies, to effects at the population level in the field. Further, they have involved delivering the transgene product both in artificial diet and *in planta* and either directly (at the bi-trophic level) or via a tri-trophic (plant-pest-natural enemy) interaction. Recent studies relating to both the effects of *Bt*-expressing crops and crops expressing molecules still under development are summarized in Tables 3 [40–72] and 4 [50, 51, 73–102] for predators and parasitoids, respectively.

As mentioned above, prior to their commercialization, all transgenic crops have to undergo rigorous risk assessment. However, despite a global commodities market, the risk assessment process itself varies from region to region, as does the non-target organisms selected for testing. Obviously, the latter will vary depending upon geographical and climatic regions; however, there are concerns that there should be greater uniformity in the species selected; these should at least be representative of the major ecosystem functions. In an attempt to address this short-coming, Romeis et al. [103] have recently refined the 3-tier risk assessment to evaluate potential adverse impacts of insect-resistant transgenic crops on non-target arthropods, with specific recommendations for early-tier laboratory studies used in the risk assessment process. Although this risk assessment protocol has been primarily developed for crops expressing *Bt* toxins, the concepts put forward apply to other arthropod-active proteins. Typically, the risk assessment follows a tiered approach that starts with laboratory studies under worst-case exposure conditions; such studies have a high ability to detect adverse effects on non-target species, if present. Clear guidance on how such data are produced in laboratory studies assists the product developer and risk assessors. The need for a high level of reproducibility and clearly defined risk hypotheses contribute to the robustness of, and confidence in, the environmental risk assessments of transgenic plants. Further, these authors emphasized that confidence in the results of early-tier laboratory studies is a precondition for the acceptance of data across regulatory jurisdictions and should encourage agencies to share useful information and thus avoid redundant testing. When evaluating potential risks of a given technology, it is important to use relevant comparators. This holds true for risk assessment of transgenic crops. Few studies have actually been designed to directly compare recombinant DNA technology with conventional pest control strategies, although recent studies by Mulligan et al. [68, 69] directly compared the non-target effects of the synthetic pesticide cypermethrin with oilseed rape plants expressing a cysteine protease inhibitor against two predators. While neither form of pest control treatment negatively affected the carabid, the effects of the transgenic crop on the lacewing were significantly lower than with the commonly used pesticide.

Recent studies have performed meta-analyses on a modified public database [104] to synthesize current knowledge about the effects of *Bt* cotton, maize, and potato on the abundance and interactions of arthropod non-target functional guilds [105]. Overall, they show no uniform effects of *Bt* cotton, maize, and potato on the functional guilds of non-target arthropods. In fact, use of and type of insecticides influenced the magnitude and direction of effects; and insecticide effects were much larger than those of *Bt* crops. Similarly, Duan et al. [106] performed meta-analyses comparing results for non-target invertebrates exposed to *Bacillus thuringiensis* (*Bt*) Cry proteins in laboratory studies with results derived from independent field studies examining effects on the abundance of non-target invertebrates. In this case, the findings support the assumption that laboratory studies of transgenic insecticidal crops show effects that are either consistent with, or more conservative than, those found in field studies.

In combination with robust field data [107], the evidence strongly supports *Bt* crops as an environmentally neutral technology, especially in comparison to insecticides. These findings are thus in agreement with those of Mulligan et al. [68, 69].

Impact on Pollinators Many of the world's crops depend on insects for pollination and it is critically important that agricultural biotechnology does not disrupt this essential "ecosystem service" – as such, pollinators are critical to agriculture, in addition to their vital role in helping maintain biodiversity. Thus, representative pollinators form an important part of the risk assessment process and much of what has been stated for natural enemies applies to these species too. In common with natural enemies, transgenic plants can

Transgenic Crops, Environmental Impact. Table 3 Impacts of transgenic crops and transgene products on predators

Protein [1]	Transgenic plant or diet	Pest	Natural enemy	Effects on natural enemy	Reference
Bt	Corn (Cry1Ab)	Direct feeding (pollen)	Several (Coleoptera, Heteroptera, Neuroptera)	No effects on predators in both laboratory and field experiments	[40]
	Corn (Cry3Bb1)	*Diabrotica* spp. (Col: Chrysomelidae)	Several (Araneae, Carabidae, Staphylinidae)	No consistent negative effect	[41]
	Corn (Cry1Ab)	*Ostrinia nubilalis*; *Spodoptera littoralis* (Lep: Noctuidae)	*Caladenia carnea*	*Bt*-fed prey increased predator mortality and development times	[42]
		S. littoralis	*C. carnea*	Negative effects, as observed previously, determined to be due to reduced prey quality	[43]
		Tetranychus urticae (Acari)	*Stethorus punctillum* (Col: Coccinellidae)	No effects in both laboratory and field experiments	[44]
		Direct feeding (pollen)	Spiders (Araneae)		[45, 46]
	Corn (Cry3Bb1)	*Rhopalosiphum maidis* (Hom: Aphididae)	*Coleomegilla maculate* (Col.: Coccinellidae)	No effects when fed non-target aphid prey	[47]
	Corn (VIP3A + Cry1Ab)	Lepidoptera pests	Several (13 arthropod orders)	Large-scale study showed no negative effects of stacked traits over conventional corn	[48]
	Cotton (Cy1Ac)	*Aphis gossypii* (Hem. Aphididae)	*Chrysopa pallens* (Neu: Chrysopidae)	No effect	[49]
	Cotton (Cry1Ac)	Several	Predators (several)	Minor reductions in predator density in the field	[50, 51]

OCI		Direct feeding	*C. carnea*	No effect via contaminated pollen	[68]
	Oilseed rape	*Deroceras reticulatum* (Mollusca)	*Pterostichus melanarius* (Col. Carabidae)	No effects on beetle mortality, weight gain, or food consumption	[69]
	Oilseed rape	*P. xylostella* (Lep: Plutellidae)	*H. axyridis*	No effect on survival or development of ladybird	[70]
	Potato	*L. decemlineata* (Colorado potato beetle)	*Perillus bioculatus* (Het: Pentatomidae)	No effects	[71]
Soybean trypsin inhibitor (SBTI)	Diet	Direct feeding	*C. carnea*		[72]

Transgenic Crops, Environmental Impact. Table 4 Impacts of transgenic crops and transgene products on parasitoids

Protein [1]	Transgenic plant or diet	Pest	Natural enemy	Effects on natural enemy	Reference
Bt	Corn (Cry1Ab)	*Chilo partellus* (Lep: Crambidae)	*Diaeretiella rapae* (Hym: Braconidae)	Reduced survival due to host mortality, smaller cocoons and adults	[73]
	Corn (Cry1Ab) (field)	*Ostrinia nubilalis* (Lep: Crambidae)	*Macrocentrus cingulum* (Hym: Braconidae)	Reductions of 29–60% is numbers of wasps found in the field	[74]
	Corn (Cry1Ab)	*Spodoptera frugiperda* (Lep: Noctuidae)	*Campoletis sonorensis* (Hym: Ichneumonidae)	Wasps were significantly smaller when developing in *Bt*-fed hosts	[75]
		Eoreuma loftini (Lep: Pyralidae)	*Parallorhogas pyralophagus* (Hym: Braconidae)	Various aspects of parasitoid biology (not all) negatively affected	[76]
	Cotton (Cry1Ac)	*Helicoverpa armigera* (Lep: Noctuidae)	*Microplitis mediator* (Hym: Braconidae)	Wasp survival and development negatively affected	[77, 78]
		Pseudoplusia includens (Lep: Noctuidae)	*Cotesia marginiventris* (Hym: Braconidae), *Copidosoma floridanum* (Hym: Encyrtidae)	Development times for both wasp species negatively affected. Adult longevity for *C. marginiventris* reduced	[79]
	Cotton (Cry1Ac) (field)	Hemipteran pests	Aphelinid parasitoids	Small reduction of parasitoid population density relative to non-*Bt* cotton	[50, 51]
	Diet (Cry1Ac)	*Spodoptera litura*/*H. armigera* (Lep: Noctuidae)	*Meteorus pulchricornis* (Hym: braconidae); *Cotesia kazak* (Hym: Braconidae)	Survival of both unaffected in *Bt*-fed *S. litura*. *M.pulchricornis* negatively affected by *Bt* –fed *H. armigera*	[80]
	Oilseed rape (Cry1Ac)	*Plutella xylostella* (Lep: Plutellidae)	*Cotesia plutellae* (Hym: Braconidae)	No effect when *Bt*-resistant hosts were parasitized	[81]
	Broccoli	*P. xylostella*	*Diadegma insulare* (Hym: Ichneumonidae)	No effect on parasitoid when exposed by *Bt*-resistant hosts	[82]
	Pine (Cry1Ac)	*Pseudocoremia suavis* (Lep: Geometridae)	*M. pulchricornis*	No effect on parasitoid developmental parameters	[83]
	Diet (Cry9Aa)	*Galleria mellonella* (Lep: Gelechiidae)	*Exorista larvarum* (Dip: Tachinidae)	No effect on fly parasitoid when exposed to facticious *Bt*-fed hosts	[84]
	Tobacco (Cry1Ab) (field)	*Heliothis virescens* (Lep. Noctuidae)	*C. sonorensis*	Rates of parasitism increased	[85]
CpTI	Diet or potato	*Lacanobia. oleracea* (Lep: Noctuidae)	*Eulophus pennicornis* (Hym: Eulophidae)	Fewer hosts parasitized, no effects on parasitoids	[86]

Transgenic Crops, Environmental Impact. Table 4 (Continued)

Protein [1]	Transgenic plant or diet	Pest	Natural enemy	Effects on natural enemy	Reference
CpTI	Diet	Direct feeding (adult wasps)	*E. pennicornis*	No effects	[87]
CpTI and *Bt*	Cotton	*H. armigera*	*Microplitis mediator* (Hym: Braconidae)	No greater effects than with *Bt*-cotton	[78]
	Cotton pollen	Direct feeding	*Trichogramma chilonis* (Hym: Trichogrammatidae)	No adverse effects due to CpTI	[88]
OC1	Diet	*Macrosiphum euphorbiae* (Hom: Aphididae)	*Aphelinus abdominalis* (Hym: Braconidae)	Parasitoid fitness impaired	[89]
	Potato	*M. euphorbiae*	*Aphidius nigripes* (Hym: Braconidae)	Wasp size and fecundity increased on OC1 line	[90]
	Oilseed rape	*Myzus persicae* (Hom: Aphididae)	*Diaeretiella rapae* (Hym: Braconidae)	No consistent effects on adult wasp emergence and sex ratio; no effects on control of aphids	[91]
OC1 IΔD86 (for nematode control)	Potato (field)	*M. euphorbiae*, *M. persicae*	*Aphidius ervi* (Hym: Braconidae)	No effects on percent parasitism, adult wasp emergence, parasitoid communities more diverse on GM plants	[92]
Con A	Diet	Direct feeding	*E. pennicornis*	Higher doses reduced adult longevity and reproductive fitness	[87], [93]
GNA		*M. euphorbiae*	*A. abdominalis*	No effect via host feeding on aphids Reduced size and longevity of adults when exposed via host	[94, 95]
		Direct feeding (adult wasps)	*Aphidius colemani* (Hym: Braconidae)	Higher doses reduced adult longevity	[96]
	Honeydew	Direct feeding (adult wasps)	*A. ervi*	Indirect negative affect potentially due to altered honeydew composition	[97]
	Potato/diet	*M. persicae*	*A. ervi*	No effects via potato, dose-dependent effects on development via diet	[94, 95]
	Sucrose diet	Direct feeding	*Cotesia glomerata* (Hym: Braconidae)	Higher doses reduced longevity	[96]
	Diet/ Sugarcane	*Diatraea saccharalis* (sugarcane borer)	*Cotesia flavipes* (Hym: Braconidae)	Small negative effects on parasitism. No effects on host location of prey or parasitism	[98, 99]
	Potato/Diet	*L. oleracea*	*E. pennicornis*	No effect on parasitism success	[100]
	Diet	Direct feeding		Reduced adult longevity and reproductive fitness	[87], [93]

Transgenic Crops, Environmental Impact. Table 4 (Continued)

Protein [1]	Transgenic plant or diet	Pest	Natural enemy	Effects on natural enemy	Reference
	Host diet/host injection	*L. oleracea*	*E. pennicornis*	Negative effects on the survival of parasitoid larvae	[93]
	Sugarcane	*E. loftini*	*P. pyralophagus*	Reduced size and longevity of adult wasps	[101]
	Tomato/ potato/diet	*L. oleracea*	*Meteorus gyrator* (Hym: Braconidae)	No effects	[102]
	Sucrose diet	Direct feeding (adult wasps)	*Trichogramma brassicae* (Hym: Trichogrammatidae)	Antifeedant; high dose reduced longevity	[96]

impact on pollinators in two ways, either directly (via the transgenic plant itself posing a hazard to the pollinator), or indirectly (via the use of a transgenic crop affecting other ecological requirements of the pollinator). Of the extensive field trials carried out to date with either *Bt*-expressing crops, or HT transgenic crops, no deleterious effects on pollinators have been reported [108]. Furthermore, results from the many studies carried out to date on transgenic plants still under development suggest that only a few of the lectins and protease inhibitors tested could present dose-dependent hazards to bees, and then only if expressed in the pollen at sufficiently high levels; most current promoters used, albeit constitutive promoters, only express at very low levels, if at all, in the pollen.

In addition to evaluating the potential impacts of transgenic crops on pollinator species, it is also important to address issues relating to the ability of these species to collect and transport pollen between transgenic and non-transgenic crops, i.e., their role in pollen dispersal and hence gene flow. Recombinant proteins are usually expressed at low levels in the pollen of transgenic plants due to the use of specific "constitutive" promoters in the gene constructs. However, the transgenes themselves are present in DNA contained in the pollen, and therefore may be transferred to other related plants via the activities of the pollinator species.

Impact of Herbicide-Tolerant Transgenic Crops

The wide-scale growing of glyphosate-tolerant crops has resulted in an increase in glyphosate usage at the expense of other herbicides [4, 109–111]. However, despite this increase in glyphosate use, overall, the use of HT crops has resulted, overall, in a significant reduction in pesticides. This has been accompanied by a reduction in tillage which has an additional benefit of reducing the use of petroleum-based fuels as well as an implicit gain in time-use efficiency by growers [112]. Furthermore, HT crops have dramatically changed the crop cultivars selected by growers and has hastened the development of new transgenic crops for commercial distribution worldwide [32, 113].

Weed control based on HT crops is efficient and cost effective and provides considerable savings in terms of both time and labor [114]. However, despite this and other obvious benefits of the technology (see above), there is much opposition in some quarters to these crops – possibly more so than for insect-resistant transgenic crops. One of the reasons for this opposition stems from a lack of effective communication and understanding between the general public and the scientific and agricultural communities [21, 115]. Designing a risk assessment to test specific questions to also address societal concerns may help address this issue since it would provide an opportunity for society to participate in the regulatory decisions affecting HT crops [116]. It is possible that a major part of the concern expressed about HT crops is that the technology is associated with herbicide use, which in itself is perceived as risky by the public sector [117]. The mode of action of glyphosate is well understood and in fact was one of the first commercially successful herbicides to have an identified enzymatic site of action in plants.

The selective and specific interaction of glyphosate with EPSPS accounts for its potent herbicidal properties and low toxicity to other life forms; as such, this will significantly reduce the potential for direct non-target effects and should negate many of these concerns.

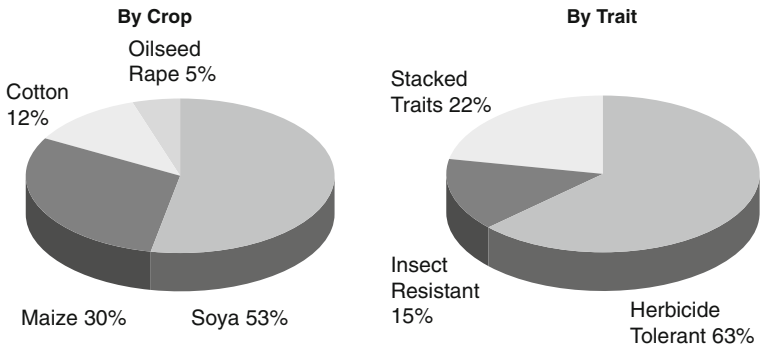
Despite their undoubted success and major contribution to global agriculture, potential risks associated with the technology must be assessed, not least in terms of the increased use of glyphosate [112, 118–121]. However, this apart, the primary environmental risk associated with HT crops relates to their impact on weed population shifts, whether expressed as the rise in economic prominence of a new weedy species or the evolution of glyphosate-tolerant weed biotypes. This position is supported by the herbicide resistance risk analysis which suggests that glyphosate-based systems are at high risk of selecting for glyphosate-tolerant weeds [122], although not all research supports this view point [123].

Impact on Biodiversity Agriculture itself has had a major impact on biodiversity, often manifested in a marked decline in the abundance of species [124–126]. While it is suggested that the ecosystem effects of HT crops have been minimal [127], the indirect impact of these crops on the agro-ecosystem, particularly as a result of changes in tillage and weed management tactics, is important [128]. There is conflicting evidence in the literature with some reports suggesting an increase in species diversity in HT-based systems while other reports suggest a reduction [129–133]. These apparent contradictions may be due to the fact that effects are often specific to the crop in question and dependent on the different weed management tactics used for HT crops compared to non-transgenic crops [134, 135]. For example, deployment of HT crops was shown to have a negative impact on butterfly population densities as an indirect effect of good weed control, reflecting a lack of nectar availability [136]. In contrast, little effect was observed for bees, gastropods, and other invertebrates. Furthermore, the effects of such crops on the soil biota were found to be negligible [132]. Thus, there appears to be both favorable and unfavorable data on the effects of HT crops on biological diversity [32]. The critical consideration is that these effects are highly dependent on specific crop and management tactics. It is likely that any unfavorable effect on biological diversity could be ameliorated by subtle manipulation of the HT-based system.

Gene Flow Another pervasive problem with HT crops is their coexistence with non-GM crops. Three important considerations have to be addressed: (1) introgression of the trait via pollen (pollen drift); (2) containment of plant products during the production year (grain segregation); and (3) volunteer HT plants in following years [115]. While HT crops and their non-transgenic counterparts can, and do, coexist, and while grain segregation and controlling volunteers is feasible [115, 137], controlling/preventing introgression of the HT trait via pollen movement in open-pollinated crops such as maize is considerably more difficult [138–141]. A number of factors affect the success of maize pollen movement and subsequent pollination, and generally, the greater the distance between the pollen source and donor, the less likely is the introgression of the transgenic trait [139, 140]. Given the tolerance levels established for some transgenic traits in non-transgenic crops, the isolation distances required to mitigate the risks of gene flow may be too great to be realistic in commercial maize production systems [142]. Other open-pollinated crops have also been scrutinized with significant legal ramification [143–146]. However, because of the possibility of "contamination" as a consequence of gene flow, many countries require buffer zones between fields growing transgenic crops and their non-transgenic counter parts; the size of these buffer zones will vary, depending upon a number of different factors including the crop itself. It is suggested that the issues of the coexistence of such crops with non-transgenic crops will continue to be a concern as long as there are economic differences between the crop cultivar types [147–149].

Future Directions

The major traits currently commercialized predominantly confer resistance to biotic stress, with herbicide-tolerant (HT) crops occupying the market share (Fig. 2). In 2009, SmartStax, a novel biotech maize containing eight different genes for insect and



Transgenic Crops, Environmental Impact. Figure 2
Global status of biotech crops for 2008

herbicide resistance, was approved for commercialization in the USA. These so-called first-generation transgenic crops, expressing improved agricultural traits are often perceived as being of benefit to the grower rather than to the consumer *per se*. Although the seed is more expensive, such crops lower the costs of production by reducing inputs of machinery, fuel, and chemical pesticides. In addition, due to more effective pest control, crop yields are often higher (Tables 1 [6] and 2 [7–20]). However, it is important to appreciate the environmental and health benefits of growing these first-generation transgenic crops, many of which are associated with reduced spraying of highly toxic chemical insecticides and herbicides. In terms of environmental benefits, these include controlling farm runoff that otherwise pollutes water systems and reduced mechanical weeding, so reducing loss of topsoil [150], while the major health benefits are a consequence of reduced pesticide exposure for farmers and rural laborers, and lower pesticide residues for consumers.

In addition to transgenic crops with increased tolerance to biotic stress, drought-tolerant maize is expected to be deployed in the USA in 2012 and sub-Saharan Africa in 2017. Other transgenic crops on the horizon include adoption of Golden Rice by the Philippines in 2012 and Bangladesh and India before 2015. Other smaller hectarage crops are also expected to be approved by 2015, including potatoes with pest and/or disease resistance, sugarcane with quality and agronomic traits, and disease-resistant bananas [3]. Interestingly, wheat remains the last major staple crop without approved biotech traits. However, political will for the crop is growing globally and many authorities suggest that China may be the first country to approve biotech wheat as early as 5 years from now.

As the science develops, so does the technology, but irrespective of which particular generation of transgenic crops is being considered, their environmental impact is of prime importance. Any risk assessment process must thus keep pace with the changing technology and the development of novel crops expressing novel traits.

Conclusion

Although one of the major concerns of recombinant DNA technology relates to its impact on non-target organisms, and thus on biodiversity, these fears have not, in the main, been realized, although there have been some well-publicized cases to the contrary. Concern over the potential for *Bt*-expressing maize to have negative effects on the Monarch Butterfly (*Danaus plexippus*) population was voiced following the publication of lab-based studies that demonstrated that unrealistically high levels of pollen from such plants had a deleterious effect [151]. However, subsequent large-scale field trials demonstrated this not to be the case, one factor being that when the maize was in flower, the Monarchs were not present [152–157]. Thus, in this instance, while the potential hazard was high, exposure was negligible resulting in effectively zero risk. Other examples include reports of initial studies concerning toxicity of *Bt* maize–fed hosts toward the predator *Chrysoperla carnae* (the green

lacewing) via a tri-trophic interaction [42]. However, subsequent studies demonstrated that *Bt* Cry1Ab was not toxic to the larvae but that the effects reported were mediated by prey quality [158]. Studies of this type emphasize the need not only to place them within an ecological context, but also to use appropriate comparators in the risk assessment process. Studies such as those carried out by Hilbeck [42] and colleagues emphasize the importance of scientific rigor and the need for demonstration of "cause and effect."

While numerous studies have now been carried out to evaluate the environmental safety of transgenic crops on beneficial insects such as natural enemies that play an important role in biological control and pollinators, in the vast majority of cases, few negative effects have actually been demonstrated. Interestingly, in the majority of cases studied to date regarding natural enemies, it is apparent that the predator/parasitoid is often able to avoid the toxic effects of the different insecticidal proteins being expressed, despite exposure at physiologically relevant levels. Further, there is evidence that the transgene product is diluted as it passes through the different trophic levels. For pollinators, this lack of toxicity is attributed to lack of receptors, in the case of *Bt*, and lack of exposure when expressed in the transgenic plant.

In addition to their potential impact on biodiversity, other environmental concerns relating to the deployment of transgenic crops are the potential for gene flow, particularly in the case of HT crops. However, the potential for gene flow is highly dependent upon the plant species [159]. Gene flow in crops can occur via pollen and via seed, the latter potentially affecting agriculture temporally and on a much larger scale than gene flow attributable to pollen [160]; in general, it is acknowledged that the risks of unintended trait movement are difficult to assess [161]. It is, however, important to point out that gene flow is no different in transgenic crops than in non-transgenic cultivars and that gene flow from transgenic crops is a reality [162]. To expect compliance of zero gene flow is neither reasonable nor realistic, and an acceptable tolerance must be established for the coexistence of transgenic crops with their non-transgenic counterparts.

Transgenic Crops, Next Generation

Martina Newell-McGloughlin
Department of Plant Pathology, University of California Davis, Davis, CA, USA

Article Outline

Glossary

Abiotic stress External (nonliving) factors which can cause harmful effects to plants, such as soil conditions, drought, and extreme temperatures.

Acclimatization Adaptation of an organism to a new environment.

Adaptation In the evolutionary sense, some heritable feature of an individual's phenotype that improves its chances of survival and reproduction in the existing environment.

Additive genetic variance Genetic variance associated with the average effects of substituting one allele for another.

Agronomic performance/trait Pertains to practices of agricultural production and its costs and the management of crop land. Examples of agronomic traits include yield, input requirements, stress tolerance.

Agrobacterium tumefaciens A bacterium normally responsible for causing crown gall disease in a variety of plants. A plasmid has been isolated from this bacterium that is useful in plant genetic engineering. This plasmid, called the Ti plasmid, has been modified so that it does not cause disease but can carry foreign DNA into susceptible plant cells.

Aldolase An enzyme, not subject to allosteric regulation, that catalyzes in a reversible reaction the cleavage of fructose 1,6-biphosphate to form dihydroxyacetone phosphate and glyceraldehyde 3-phosphate. The enzyme catalyzing the fourth reaction in the glycolytic pathway, which splits a monosaccharide into two 3-carbon units.

Allele Any of several alternative forms of a given gene.

Allele frequency Often called gene frequency. A measure of how common an allele is in a population the proportion of all alleles at one gene locus that are of one specific type in a population.

Allelic exclusion A process whereby only one immunoglobulin light chain and one heavy chain gene are transcribed in any one cell; the other genes are repressed.

Allogenic Of the same species, but with a different genotype.

Allopolyploid Polyploid produced by the hybridization of two species.

Allopolyploid Plants Plants having more than two sets of haploid chromosomes inherited from different species.

Allosteric Regulation Regulation of an enzyme's activity by binding of a small molecule at a site that does not overlap the active site region.

Anabolic The part of metabolism that is concerned with synthetic reactions.

Aneuploid Having a chromosome number that is not an exact multiple of the haploid number, caused by one chromosome set being incomplete or chromosomes being present in extra numbers.

Aneuploidy The condition of a cell or an organism that has additions or deletions of a small number of whole chromosomes from the expected balanced diploid number of chromosomes.

Antibiotic Chemical substance formed as a metabolic by-product in bacteria or fungi and used to treat bacterial infections. Antibiotics can be produced naturally, using microorganisms, or synthetically.

Antibody A protein produced by the immune system in response to an antigen (a molecule that is perceived to be foreign). Antibodies bind specifically to their target antigen to help the immune system destroy the foreign entity.

Antinutrients Substances that act in direct competition with or otherwise inhibit or interfere with the use or absorption of a nutrient.

Robert A. Meyers (ed.) Encyclopedia of Sustainability Science and Technology, © 2012, DOI 10.1007/978-1-4419-0851-3

Antisense RNA RNA produced by copying and reversing a portion of an RNA-encoding DNA, usually including a protein-specifying region, and placing it next to a transcription-control sequence. This cassette can be delivered to the target cell, resulting in genetic transformation and production of RNA that is complementary to the RNA that is produced from the original, not reversed, DNA segment. This complementary, or antisense, RNA is able to bind to the complementary sequences of the target RNA, resulting in the inhibition of expression of the target gene.

Antiserum Blood serum containing specific antibodies against an antigen. Antisera are used to confer passive immunity to diseases and as analytical and preparative reagents for antigens, for example, to determine potential allergenicity.

Avirulent Unable to cause disease.

Bacillus thuringiensis (Bt) A naturally occurring microorganism which produces a toxin protein that only kills organisms with alkalineing stomachs, such as insect larvae. As and when delivered as a part of the whole killed organism, this toxin protein has been used for biological control for decades. The genetic information that encodes the toxin protein was identified and was moved into plants to make them insect tolerant.

Bioconversion Chemical restructuring of raw materials by using a biocatalyst.

Biodegradable Capable of being broken down by the action of microorganisms, usually by microorganisms and under conditions generally in the environment.

Bioinformatics The discipline encompassing the development and utilization of computational facilities to store, analyze, and interpret biological data.

Biomass The totality of biological matter in a given area. As commonly used in biotechnology, it refers to the use of cellulose, a renewable resource, for the production of chemicals that can be used to generate energy or as alternative feedstocks for the chemical industry to reduce dependence on nonrenewable fossil fuels.

Bioprocess A process in which living cells, or components thereof, are used to produce a desired end product.

Biosynthesis Production of a chemical by a living organism.

Biotechnology Development of products by a biological process. Production may be carried out by using intact organisms, such as yeasts and bacteria, or by using natural substances (e.g., enzymes) from organisms.

Biosynthetic The formation of complex compounds from simple substances by living organisms.

Biotic Stress Living organisms which can harm plants, such as viruses, fungi, and bacteria, and harmful insects. (See Abiotic stress).

Callus A cluster of undifferentiated plant cells that can, for some species, be induced to form the whole plant.

Calvin Cycle A series of enzymatic reactions, occurring during photosynthesis, in which glucose is synthesized from carbon dioxide.

Catalyst An agent (such as an enzyme or a metallic complex) that facilitates a reaction but is not itself changed at the completion of the reaction.

Catabolic The part of metabolism that is concerned with degradation reactions.

Chloroplast A chlorophyll-containing photosynthetic organelle, found in eukaryotic cells that can harness light energy.

Cistron A length of chromosomal DNA representing the smallest functional unit of heredity, essentially identical to a gene.

Clone A group of genes, cells, or organisms derived from a common ancestor. Because there is no combining of genetic material (as in sexual reproduction), the members of the clone are genetically identical or nearly identical to the parent.

Codon A sequence of three nucleotide bases that in the process of protein synthesis specifies an amino acid or provides a signal to stop or start protein synthesis (translation).

Coenzyme An organic compound that is necessary for the functioning of an enzyme.Coenzymes are smaller than the enzymes themselves and may be tightly or loosely attached to the enzyme protein molecule.

Cofactor A nonprotein substance required for certain enzymes to function. Cofactors can be coenzymes or metallic ions.

Comparative genomics The comparison of genome structure and function across different species for further understanding of biological mechanisms and evolutionary processes.

Composition analysis The determination of the concentration of compounds in a plant. Compounds that are commonly quantified are proteins, fats, carbohydrates, minerals, vitamins, amino acids, fatty acids, and antinutrients.

Conventional breeding Breeding of plants carried out by controlled transfer of pollen from one plant to another followed by selection of progeny through multiple generations for a desirable phenotype. This method has also often included irradiation or mutation of plants or seeds to induce extra variation in the donor material.

Complementary DNA (cDNA) DNA synthesized from an expressed messenger RNA through a process known as reverse transcription. This type of DNA is used for cloning or as a DNA probe for locating specific genes in DNA hybridization studies.

Coumarins White vanilla-scented crystalline esters used in perfumes and flavorings and as an anticoagulant. Formula: C9H6O2.

Crossbreeding Interbreeding (of animals or plants) using parents of different races, varieties, breeds, etc.

Cyto- A prefix referring to cell or cell plasm.

Cytokines Intercellular signals, usually protein or glycoprotein, involved in the regulation of cellular proliferation and function.

Diet A specific allowance or selection of food or feed that a person or animal regularly consumes.

Diploid A cell with two complete sets of chromosomes. Cf. Haploid.

DNA sequencing Technologies through which the order of base pairs in a DNA molecule can be determined.

Enzyme A protein catalyst that facilitates specific chemical or metabolic reactions necessary for cell growth and reproduction. Cf Catalyst.

Epigenetics The study of changes in gene expression caused by mechanisms other than changes in the underlying DNA sequence – hence the name epi- (Greek: επί- over, above, outer) -genetics. Examples of such changes might be DNA methylation or histone deacetylation, both of which serve to suppress gene expression without altering the sequence of the silenced genes.

Event The term used to describe a plant and its offspring that contain a specific insertion of DNA. Such events will be distinguishable from other events by their unique site of integration of the introduced DNA.

Exposure assessment The qualitative and/or quantitative evaluation of the likely exposure to biological, chemical, and physical agents via different sources.

Feedstock The raw material used in chemical or biological processes.

Flavonoids Any of a group of organic compounds that occur as pigments in fruit and flowers.

Food additive Any substance not normally consumed as a food by itself and not normally used as a typical ingredient of food, whether or not it has nutritive value, the intentional addition of which to a food for a technological (including organoleptic) purpose in the manufacture, processing, preparation, treatment, packing, packaging, transport, or holding of such food results, or may be expected to result (directly or indirectly), in it or its by-products becoming a component of or otherwise affecting the characteristics of such foods. The term does not include "contaminants" or substances added to food for maintaining or improving nutritional qualities.

Fructan A type of polymer of fructose, present in certain fruits.

Functional foods The Institute of Medicine's Food and Nutrition Board defined functional foods as "any food or food ingredient that may provide a health benefit beyond the traditional nutrients it contains."

Functional genomics The development and implementation of technologies to characterize the mechanisms through which genes and their products function and interact with each other and with the environment. The science that is usually applied to the studies of gene and the expression (mRNA) of usually large numbers of genes simultaneously.

Gene expression The process through which a gene is activated at particular time and place so that its functional product is produced.

Gene flow The exchange of genetic traits between populations by movement of individuals, gametes, or spores. It involves the spread of new variants among different populations through dispersal.

Gene silencing (See RNAi) A method usually performed by the expression of an mRNA of complementary or the same nucleotide sequence in a cell such that the expression of the mRNA causes the downregulation of the protein which is being targeted.

Gene transfer The transfer of genes to an organism. Usually used in terms of transfer of a gene to an organism other that the original organism, through the tools of biotechnology.

Gene A segment of chromosome that encodes the necessary regulatory and sequence information to direct the synthesis of a protein or RNA product. (*See also* Operator Regulatory g. Structural g. Suppressor g).

Gene mapping Determination of the relative locations of genes on a chromosome.

Gene sequencing Determination of the sequence of nucleotide bases in a strand of DNA.

Genetic engineering A technology used to alter the genetic material of living cells in order to make them capable of producing new substances or performing new functions.

Genetic map A Map showing the positions of genetic markers along the length of a chromosome relative to each other (genetic map) or in absolute distances from each other (physical map).

Genome The total hereditary material of a cell, comprising the entire chromosomal set found in each nucleus of a given species.

Genomics Science that studies the genomes (i.e., the complete genetic information) of living beings. This commonly entails the analysis of DNA sequence data and the identification of genes.

Genotype Genetic makeup of an individual or group. Cf. Phenotype.

Germplasm The total genetic variability, represented by germ cells or seeds, available within a particular population of organisms.

Gene pool The total genetic information contained within a given population.

Glycoalkaloid toxins Steroid-like compounds produced by plant members of the botanical family Solanaceae, most notably "solanine" present in potato tubers.

Golden rice In 1999, Swiss and German scientists announced the development of a genetically engineered rice crop that produces beta-carotene, a substance which the body converts to vitamin A. This improved nutrient rice was developed to treat individuals suffering from vitamin A deficiency, a condition that afflicts millions of people in developing countries, especially children and pregnant women.

Haploid A cell with half the usual number of chromosomes, or only one chromosome set. Sex cells are haploid. Cf. Diploid.

Hazard characterization The qualitative and/or quantitative evaluation of the nature of the adverse health effects associated with biological, chemical, and physical agents. For chemical agents, a dose-response assessment should be performed if the data are obtainable.

Hazard identification The identification of biological, chemical, and physical agents capable of causing adverse health or environmental effects.

Hazard A biological, chemical, or physical agent, or condition, with the potential to cause an adverse health or environmental effect.

Hereditary Capable of being transferred as genetic information from parent cells to progeny.

Heterozygote With respect to a particular gene at a defined chromosomal locus, a heterozygote has a different allelic form of the gene on each of the two homologous chromosomes.

Homologous Corresponding or alike in structure, position, or origin.

Homologous recombination Rearrangement of related DNA sequences on a different molecule by crossing over in a region of identical sequence.

Homozygote With respect to a particular gene at a defined chromosomal locus, a homozygote has the same allelic form of the gene on each of the two homologous chromosomes.

Hormone A chemical that acts as a messenger or stimulatory signal, relaying instructions to stop or start certain physiological activities. Hormones are synthesized in one type of cell and then released to direct the function of other cell types.

Horizontal gene transfer Transmission of DNA between species, involving close contact between the donor's DNA and the recipient, uptake of DNA by the recipient, and stable incorporation of the DNA into the recipient's genome.

Host A cell or organism used for growth of a virus, plasmid, or other form of foreign DNA, or for the production of cloned substances.

Hybridization Production of offspring, or hybrids, from genetically dissimilar parents. The process can be used to produce hybrid plants (by cross-breeding two different varieties) or hybridomas (hybrid cells formed by fusing two unlike cells, used in producing monoclonal antibodies). The term is also used to refer to the binding of complementary strands of DNA or RNA.

Hybrid The offspring of two parents differing in at least one genetic characteristic (trait). Also, a heteroduplex DNA or DNA-RNA molecule.

Identity preservation The segregation of one crop type from another at every stage from production and processing to distribution. This process is usually performed through audits and site visits and provides independent third-party verification of the segregation.

Immunoassay Technique for identifying substances based on the use of antibodies.

Immunogen Any substance that can elicit an immune response, especially specific antibody production. An immunogen that reacts with the elicited antibody may be called an antigen.

Inbred Progeny produced as a result of inbreeding.

Inducer A molecule or substance that increases the rate of enzyme synthesis, usually by blocking the action of the corresponding repressor.

Inserted DNA The segment of DNA that is introduced into the chromosome, plasmid, or other vectors using recombinant DNA techniques.

Introgressed Backcrossing of hybrids of two plant populations to introduce new genes into a wild population.

Inulins A fructose polysaccharide present in the tubers and rhizomes of some plants. Formula: $(C_6H_{10}O_5)_n$.

In vitro Literally, "in glass." Performed in a test tube or other laboratory apparatus.

In vivo In the living organism.

Invertase activity Enzyme activity occurring in the intestinal juice of animals and in yeasts, that hydrolyses sucrose to glucose and fructose.

Isoflavones Water-soluble chemicals, also known as phytoestrogens, found in many plants and so named because they cause effects in the mammalian body somewhat similar to those of estrogen. The most investigated natural isoflavones, genistein and daidzen, are found in soy products and the herb red clover.

Knock in Replacement of a gene by a mutant version of the same gene using homologous recombination.

Knock out Inactivation of a gene by homologous recombination following transfection with a suitable DNA construct.

Linkage The tendency for certain genes to be inherited together due to their physical proximity on the chromosome.

Locus (Plural loci) The position of a gene, DNA marker, or genetic marker on a chromosome. (See gene locus).

Macronutrient Any substance, such as carbon, hydrogen, or oxygen, that is required in large amounts for healthy growth and development.

Marker Any genetic element (locus, allele, DNA sequence, or chromosome feature) which can be readily detected by phenotype, cytological or molecular techniques, and used to follow a chromosome or chromosomal segment during genetic analysis.

Marker assisted selection or marker aided selection (MAS) A process whereby a marker (morphological, biochemical, or one based on DNA/RNA variation) is used for indirect selection of a genetic determinant or determinants of a trait of interest (i.e., productivity, disease resistance, abiotic stress tolerance, and/or quality). This process is used in plant and animal breeding.

Mass spectrometry Analytical technique by which compounds in a vacuum compartment are ionized, eventually fragmented, accelerated, and detected based upon the mass-dependent behavior of the ionized compounds or their fragments in response to the application of a magnetic or electric field in a vacuum.

Messenger RNA (mRNA) Nucleic acid that carries instructions to a ribosome for the synthesis of a particular protein.

Metabolism All biochemical activities carried out by an organism to maintain life.

Metabolite A substance produced during or taking part in metabolism.

Metabolomics "Open-ended" analytical techniques that generate profiles of the metabolites, that is, chemical substances within a biological sample. Commonly differences between profiles of different (groups of) samples are determined and the identity of the associated metabolites elucidated. Contrary to targeted analysis, these techniques are indiscriminate in that they do not require prior knowledge of every single substance that is present.

Microarray A microscopic, ordered array of nucleic acids, proteins, small molecules, cells, or other substances that enables parallel analysis of complex biochemical samples. There are many different types of microarrays both from a biological and production system perspective. The generic terms "DNA array," "GeneChipTM," or "hybridization array" are used to refer broadly to all types of oligonucleotide-based arrays. The two most common are cDNA arrays and genomic arrays. cDNA array: A microarray composed of grid of nucleic acid molecules of known composition linked to a solid substrate, which can be probed with total messenger RNA from a cell or tissue to reveal changes in gene expression relative to a control sample.

Micronutrient Any substance, such as a vitamin or trace element, essential for healthy growth and development but required only in minute amounts.

Mini-chromosome Contains only centromeres and telomeres with little additional DNA. This provides the ability to accept multiple genes coding for stacked traits. They are particularly useful because they allow scientists to add numerous genes onto one mini-chromosome and manipulate those genes easily because they are all in one place.

mRNA Messenger RNA.

Multigenic Of hereditary characteristics one that is specified by several genes.

Mutant A cell that manifests new characteristics due to a change in its DNA.

Mutation A structural change in a DNA sequence resulting from uncorrected errors during DNA replication.

Mutation Breeding Genetic change caused by natural phenomena or by use of mutagens. Stable mutations in genes are passed on to offspring unstable mutations are not.

Nitrogen fixation A biological process (usually associated with plants) whereby certain bacteria convert nitrogen in the air to ammonia, thus forming a nutrient essential for growth.

Nucleic acid Large molecules, generally found in the cell nucleus and/or cytoplasm, that are made up of nucleotide bases. The two kinds of nucleic acid are DNA and RNA.

Nucleotides The building blocks of nucleic acids. Each nucleotide is composed of sugar, phosphate, and one of four nitrogen bases. If the sugar is ribose, the nucleotide is termed a "ribonucleotide," whereas deoxyribonucleotides have deoxyribose as the sugar component (i.e., adenine, cytosine, guanine, and thymine in the case of DNA). The sequence of the nucleotides within the nucleic acid determines, for example, the amino acid sequence of an encoded protein.

Nucleus In eukaryotic cells, the centrally located organelle that encloses most of the chromosomes. Minor amounts of chromosomal substance DNA are found in some other organelles, most notably the mitochondria and the chloroplasts.

Nutritionally improved Improving the quantity, ratio, and/or bioavailability of essential macro- and micronutrients and other compounds for which the clinical and epidemiological evidence is clear that they play a significant role in the maintenance of optimal health and are limiting in diets.

Nutraceutical The term was coined by the Foundation for Innovation in Medicine in 1991 and is defined as "any substance that may be considered a food or part of a food and provides medical or health benefits, including the prevention and treatment of disease."

Organoleptic Able to perceive a sensory stimulus such as taste.

Operon Sequence of genes responsible for synthesizing the enzymes needed for biosynthesis of

a molecule. An operon is controlled by an operator gene and a repressor gene.

Pathogen Disease-causing organism.

Peptide Two or more amino acids joined by a linkage called a peptide bond.

Pesticide Any substance intended for preventing, destroying, attracting, repelling, or controlling any pest including unwanted species of plants or animals during the production, storage, transport, distribution and processing of food, agricultural commodities, or animal feeds, or which may be administered to animals for the control of ectoparasites. The term includes substances intended for use as a plant-growth regulator, defoliant, desiccant, fruit-thinning agent, or sprouting inhibitor, and substances applied to crops either before or after harvest to protect the commodity from deterioration during storage and transport. The term normally excludes fertilizers, plant and animal nutrients, food additives, and animal drugs.

Phenotype Observable characteristics, resulting from interaction between an organism's genetic makeup and the environment. Cf. Genotype

Phenylpropanoids Especially the derivatives of the cinnamyl alcohols and of cinnamic acids, isolated from medicinal plants due to the interest as the source for the preparation of the remedies.

Photosynthesis Conversion by plants of light energy into chemical energy, which is then used to support the plants' biological processes.

Phytate (phytic acid) A phosphorus-containing compound in the outer husks of cereal grains that, in addition to limiting the bioavailability of phosphorous itself, binds with minerals and inhibits their absorption.

Phytochemicals Small molecule chemicals unique to plants and plant products.

Plasmid Circular extrachromosomal DNA molecules present in bacteria and yeast. Plasmids replicate autonomously each time the organism, a bacterium, divides and are transmitted to the daughter cells. DNA segments are commonly cloned using plasmid vectors.

Plasticity The quality of being plastic or able to be molded, changed.

Plastid Any of various small particles in the cytoplasm of the cells of plants and some animals that contain pigments (see chromoplast), starch, oil, protein, etc.

Pleiotropic Genes or mutations that result in the production of multiple effects at the phenotypic level. It is the consequence of the fact that biochemical pathways starting from different genes intersect in many places, inhibiting, deflecting, and variously modifying each other. Introduced genes may also insert into sites that effect phenotypic changes other than the one desired.

Polyclonal Derived from different types of cells.

Polymer A long molecule of repeated subunits.

Polypeptide Long chain of amino acids joined by peptide bonds. *Post-Transcriptional Gene Silencing* Post-transcriptional gene silencing (PTGS) is a sequence-specific RNA degradation system designed to act as an antiviral defense mechanism. A form of PTGS triggered by transgenic DNA, called co-suppression, was initially described in plants and a related phenomenon, termed quelling, was later observed in the filamentous fungus *Neurospora crassa*.

Posttranscriptional modification A series of processes through which protein molecules are biochemically modified within a cell following their synthesis by translation of messenger RNA. A protein may undergo a complex series of modifications in different cellular compartments before its final functional form is produced.

Profiling Creation of indiscriminate patterns of the substances within a sample with the aid of analytical techniques, such as functional genomics, proteomics, and metabolomics. The identity of the compounds detectable within the pattern need not be known.

Promoter A DNA sequence that is located near or even partially within encoding nucleotide sequences and which controls gene expression. Promoters are required for binding of RNA polymerase to initiate transcription.

Protein Proteins are biological effector molecules encoded by an organism's genome. A protein consists of one or more polypeptide chains of amino acid subunits. The functional action of a protein depends on its three-dimensional structure, which

is determined by its amino acid composition and any posttranscriptional modifications.

Proteomics The development and application of techniques used to investigate the protein products of the genome and how they interact to determine biological functions. This is an "Open ended" analytical technique that generates profiles of the proteins within a biological sample. The technique is commonly used to find differences between profiles of different (groups of) samples are and determined and the identity of the associated proteins elucidated. Contrary to targeted analysis, these techniques are indiscriminate in that they do not require prior knowledge of every single substance protein present that is analyzed beforehand.

Protoplast fusion The fusion of two plant protoplasts that each consists of the living parts of a cell, including the protoplasm and cell membrane but not the vacuoles or the cell wall.

Protoplast The cellular material that remains after the cell wall has been removed. A plant cell from which the cell wall has been removed by mechanical or enzymatic means. Protoplasts can be prepared from primary tissues of most plant organs as well as from cultured plant cells.

Quantitative trait loci The locations of genes that together govern a multigenic trait, such as yield or fruit mass.

Recombinant DNA Any DNA molecule formed by joining DNA segments from different sources (not necessarily different organisms). This may also be a strand of DNA synthesized in the laboratory by splicing together selected parts of DNA strands from different organic species, or by adding a selected part to an existing DNA strand.

Regeneration Laboratory technique for forming a new plant from a clump of plant cells.

Regulatory gene A gene that acts to control the protein-synthesizing activity of other genes.

Regulatory sequence A DNA sequence to which specific proteins bind to activate or repress the expression of a gene.

Replication Reproduction or duplication, as of an exact copy of a strand of DNA.

Rhizobium A class of microorganisms that converts atmospheric nitrogen into a form that plants can utilize for growth. Species of this microorganism grow symbiotically on the roots of certain legumes such as peas, beans, and alfalfa.

Ribonucleic acid (RNA) A molecule similar to DNA that functions primarily to decode the instructions for protein synthesis that are carried by genes. (*See also* Messenger RNA Transfer RNA).

Ribosome A cellular component, containing protein and RNA, that is involved in protein sythesis.

Ribozyme Any of the RNA molecules possessing catalytic activity and acting as biological catalysts.

Risk A function of the probability of an adverse health effect and the severity of that effect, consequential to a hazard(s).

Risk analysis A process consisting of three components: risk assessment, risk management, and risk communication.

Risk assessment A scientific process consisting of the following steps: (1) hazard identification, (2) hazard characterization, (3) exposure assessment, and (4) risk characterization.

Risk characterization The qualitative and/or quantitative estimation, including attendant uncertainties, of the probability of occurrence and severity of known or potential adverse health effects in a given population based on hazard identification, hazard characterization, and exposure assessment.

Risk communication The interactive exchange of information and opinions throughout the risk analysis process concerning hazards and risks, risk-related factors, and risk perceptions, among risk assessors, risk managers, population, industry, the academic community, and other parties, including the explanation of risk assessment findings and the basis of risk management decisions.

Risk management The process, distinct from risk assessment, of weighing policy alternatives, in consultation with all interested parties, considering risk assessment and other factors relevant for the health protection of population and for the promotion of fair practices, and if needed, selecting appropriate prevention and control options.

RNAi RNA Interference (RNAi), a term coined by Fire et al. in 1998, is a phenomenon whereby small double-stranded RNA (referred as small

interference RNA or siRNA) can induce efficient sequence-specific silence of gene expression.

SAFOTEST EU project on new methods for the safety testing of transgenic food.

Scale-up Transition from small-scale production to production of large industrial quantities.

Secondary metabolites Chemical substances within a biological organism sample that are not necessary for, or concerned with, primary cellular functions. Examples of secondary metabolites are Secondary metabolism proceeds by modification of the primary metabolites of photosynthesis, respiration, etc., by four main pathways. The malonate/polyketide pathway leads to the production of fatty acids and naphthoquinones. The mevalonate/isoprenoid pathway leads to the various terpenes (such as menthol), carotenoids and steroids. The shikimate pathway leads to aromatic amino acids and the phenolics and the final group of metabolites is a nonspecific mix of amino-acid derivatives including the and alkaloids (such as solanine) and others of mixed biogenesis.

Selectable marker A gene, often encoding resistance to an antibiotic or an herbicide, introduced into a group of cells to allow identification of those cells that contain the gene of interest from the cells that do not. Selectable markers are used in genetic engineering to facilitate identification of cells that have incorporated another desirable trait that is not easy to identify in individual cells.

Selective breeding Making deliberate crosses or matings of organisms so the offspring will have particular desired characteristics derived from one or both of the parents.

Selective medium Nutrient material constituted such that it will support the growth of specific organisms while inhibiting the growth of others.

Sequence homology The measurable likeness degree of identity or similarity between two nucleotides or amino acid sequences.

Sera-binding tests Immunological assays that evaluate for the presence of antigen-specific IgE in blood serum obtained from individuals allergic to food, pollen, or other environmental antigens. Sera-binding tests include assays such as western blotting, ELISA, ELISA-inhibition, RAST, and RAST-inhibition techniques.

Shikimate pathway Pathway in microorganisms and plants involved in the biosynthesis of the aromatic amino acid family (phenylalanine, tyrosine, tryptophan) with a requirement for chorismate as well as shikimate. Secondary metabolites such as lignin, pigments, UV light protectants, phenolic redox molecules, and other aromatic compounds, such as folic acid and ubiquinone, are postscript products of the shikimate pathway.

Signal transduction The molecular pathways mechanism through which a cell senses changes in its external environment and changes its gene expression patterns in response.

Signal sequence The N-terminal sequence of a secreted protein, which is required for transport through the cell membrane.

Small interfering RNA (siRNA) Small Interfering RNA (siRNA) is 21–23-nt double-stranded RNA molecules. It guides the cleavage and degradation of its cognate RNA.

Site-specific recombination A crossover event, such as the integration of phage lambda, that requires homology of only a very short region and uses an enzyme specific for that recombination. Recombination occurring between two specific sequences that need not be homologous, mediated by a specific recombination system.

Somaclonal selection Epigenetic or genetic changes, sometimes expressed as a new trait, resulting from in vitro culture of higher plant cells. Somatic (vegetative nonsexual) plant cells can be propagated in vitro in an appropriate nutrient medium. The cells which multiply by division of the parent somatic cells are called somaclones and, theoretically, should be genetically identical with the parent. In fact this process occasionally in vitro cell culture of somatic cells, whether from a leaf, a stem, a root, a shoot, or a cotyledon, frequently generates cell plants which are significantly different, epigenetically and/or genetically, from the parent in a stable fashion and such progenies are called somaclonal variants and may provide a useful source of genetic variation.

Stilbenes A colorless or slightly yellow crystalline water-insoluble unsaturated hydrocarbon used in the manufacture of dyes trans-1,2-diphenylethene. Formula: C6H5CH:CHC6H5. It forms the

backbone structure of several compounds with estrogenic activity. Trans-3,4′,5-trihydroxy-stilbene also known as resveratrol, has been found in some experiments to inhibit cell mutations, and stimulate at least one enzyme that can inactivate certain carcinogens, and may contribute to a low incidence of cardiovascular disease.

Structural gene A gene that codes for a protein, such as an enzyme.

Substantial equivalence In the report of the 1996 FAO/WHO Expert Consultation, substantial equivalence was identified as being "established by a demonstration that the characteristics assessed for the genetically modified organism, or the specific food product derived therefrom, are equivalent to the same characteristics of the conventional comparator. The levels and variation for characteristics in the genetically modified organism must be within the natural range of variation for those characteristics considered in the comparator and be based upon an appropriate analysis of data." In the Codex Guideline for the Conduct of Food Safety Assessment of Foods Derived from Recombinant-DNA Plants (2003), the concept of substantial equivalence is described as "a key step in the safety assessment process. However, it is not a safety assessment in itself rather it represents the starting point which is used to structure the safety assessment of a new food relative to its conventional counterpart. This concept is used to identify similarities and differences between the new food and its conventional counterpart. It aids in the identification of potential safety and nutritional issues and is considered the most appropriate strategy to date for safety assessment of foods derived from recombinant-DNA plants. The safety assessment carried out in this way does not imply absolute safety of the new product; rather it focuses on assessing the safety of any identified differences so that the safety of the new product can be considered relative to its conventional counterpart."

Substrate Material acted on by an enzyme.

Synteny All loci on one chromosome are said to be syntenic (literally on the same ribbon). Loci may appear to be unlinked by conventional genetic tests for linkage but still be syntenic.

Systems biology A biology-based interdisciplinary study field that focuses on complex interactions in biological systems claiming that it uses a new perspective (holism instead of reduction). Particularly, from year 2000 onward, the term is used widely in the biosciences, and in a variety of contexts. An often stated ambition of systems biology is the modeling and discovery of emergent properties, properties of a system whose theoretical description is only possible using techniques which fall under the remit of systems biology.

Tannins Any of a class of yellowish or brownish solid compounds found in many plants and used as tanning agents, mordants, medical astringents, etc. Tannins are derivatives of gallic acid with the empirical formula $C_{76}H_{52}O_{46}$.

T-DNA The segment of the Ti plasmid of *A. tumefaciens* that is transferred to the plant genome following natural infection.

Ti Plasmid A plasmid containing the gene(s) responsible for inducing plant tumor formation transfer of genes from *A. tumefaciens* to plant cells.

Tissue culture In vitro growth in nutrient medium of cells isolated from tissue.

Traditional breeding Modification of plants and animals through selective breeding. Practices used in traditional plant breeding may include aspects of biotechnology such as tissue culture and mutational breeding.

Transcription The process through which a gene is expressed to generate a complementary messenger RNA molecule. Synthesis of messenger (or any other) RNA on a DNA template.

Transcription activator–like effector nucleases (TALENs) Transcription activator–like effector (TALE) proteins from Xanthomonasare nucleases that cleave unique genomic sequences in living cells and can be used for targeted gene editing and mutagenesis.

Transcriptome The total messenger RNA expressed in a cell or tissue at a given point in time.

Transgene A gene from one source that has been incorporated into the genome of another organism.

Transgenic plant A fertile plant that carries an introduced gene(s) in its germ line.

Transformation Change in the genetic structure of an organism by the incorporation of foreign DNA.

Transgenic organism An organism formed by the insertion of foreign genetic material into the germ line cells of organisms. Recombinant DNA techniques are commonly used to produce transgenic organisms.

Translation Process by which the information on a messenger RNA molecule is used to direct the synthesis of a protein.

Transmissible spongiform encephalopathy A disease that can be transmitted from one animal to another and will produce changes in the brain that appear similar to a sponge (i.e., some of the cells are clear when seen down the microscope).

Transposon A segment of DNA that can move around and be inserted at several sites in the genome of a cell possibly altering expression. The first to be described was the Ac/Ds system in maize shown by McClintock to cause unstable mutations.

Trypsin inhibitors Antinutrient proteins present in plants such as soybeans that inhibit the digestive enzyme, trypsin if not inactivated by heating or other processing methods.

Unintended effect An effect that was not the purpose of the genetic modification or mutation. An unintended effect may be either predictable or unpredictable, based on the knowledge of, among other things, the function of the introduced DNA and of the native DNA affected by the genetic modification. A predicted unintended effect would be, for example, variations in metabolic intermediates and endpoints, and an unpredicted effect might be turning on of unknown endogenous genes.

Variety A subdivision of a species for taxonomic classification also referred to as a "cultivar." A variety is a group of individual plants that is uniform, stable, and distinct genetically from other groups of individuals in the same species.

Virulence Ability to infect or cause disease.

Virus A submicroscopic organism that contains genetic information but cannot reproduce by itself. To replicate, it must invade another cell and use parts of that cell's reproductive machinery.

Wildtype The form of an organism that occurs most frequently in nature.

Definition of the Subject

New and innovative techniques will be required to improve the efficiency of the global agriculture sector to ensure an ample supply of healthy food. To confound this situation the inequity between the affluent and developing countries will continue to grow and only a handful of technologies are sufficiently scale neutral to help with redressing this imbalance. Biotechnology is one such technology which offers efficient and cost-effective means to produce a diverse array of novel, value-added products and tools. The first generation of biotechnology products commercialized were crops focusing largely on input agronomic traits whose value was often opaque to consumers. The coming generations of crop plants can be grouped into four broad areas each presenting what, on the surface, may appear as unique challenges and opportunities. The present and future focus is on continuing improvement of agronomic traits such as yield and abiotic stress resistance in addition to the biotic stress tolerance of the present generation; crop plants as biomass feedstocks for biofuels and "bio-synthetics"; value-added output traits such as improved nutrition and food functionality; and plants as production factories for therapeutics and industrial products. From a consumer perspective the focus on value-added traits, especially improved nutrition, is undoubtedly one of the areas of greatest interest.

Introduction

During the coming decades, food and agricultural production systems will need to be significantly enhanced to respond to a number of remarkable changes, such as a growing world population; increasing international competition; globalization; shifts to increased meat consumption in developing countries and rising consumer demands for improved food quality, safety, health enhancement, and convenience. The 2008 World Bank Development Report emphasized that "Agriculture is a vital development tool for achieving the Millennium Development Goals that call for halving by 2015 the share of people suffering from extreme

poverty and hunger [1]." The Report notes that three out of every four people in developing countries live in rural areas and most of them depend directly or indirectly on agriculture for their livelihoods. It recognizes that overcoming abject poverty cannot be achieved in sub-Saharan Africa without a revolution in agricultural productivity for resource-poor farmers in Africa, many of whom are women.

New and innovative techniques will be required to ensure that this revolution produces an ample supply of nutritious food by improving the efficiency of the global agriculture sector. Innovation is essential for sustaining and enhancing agricultural productivity. This involves new, science-based products and processes that contribute reliable methods for improving quality, productivity, and environmental sustainability. Biotechnology has introduced a new dimension to such innovation, offering efficient and cost-effective means to produce a diverse array of novel, value-added products and tools. It has the potential to improve qualitative and quantitative aspects of food, feed, fiber, and biofuel production; reduce the dependency of agriculture on chemicals and fossil fuels; diminish overcultivation and erosion; and lower the cost of raw materials, all in an environmentally sustainable manner. Commercialization of the first generation of products of recombinant DNA technology was another facet in a long history of human intervention in nature for agricultural and food production purposes. As such, the same parameters of risk-based assessment should apply. Commercialization of products must be undertaken within a regulatory framework that ensures adequate protection of the consumer, the environment, and alternate production systems while not stymieing innovation.

In a world whose population is increasing disproportionally in disadvantaged regions, it is hard to envisage feeding and sustaining these numbers in a livable environment without the use of biotechnology. From 1800 onward, more food was simply produced by plowing up virgin land and forest. The land area used for farming increased about fivefold up to the middle of the twentieth century in step with population increases. The Green Revolution put a brake on this expansion, increasing yields threefold with limited need for further expansion. Since 1950, the proportion of the land devoted to farming has barely increased, even though the world population doubled over the same period. At least half the available good quality soil is currently used for agriculture, with the remainder under tropical forests. Coupling this with the ever diminishing nonrenewable resources and the compounding effects of climate change on the limitation of land usage leads to an obvious dilemma. Unless a second Green Revolution is carried out, increasing yield but limiting it to land currently used for farming, there will be further deterioration of natural habitats and biodiversity that may threaten more than our lifestyles.

During the most recent global food crisis in 2008 which was erroneously laid disproportionately on the shoulders of biofuel production, most especially grain ethanol, the Gates Foundation announced $306 million in grants to boost agricultural yields in the developing world, with nearly $165 million to replenish depleted soils in Africa. As noted by US News and World reports these efforts are not without controversy as they charge that critics consider that western philanthropists are violating African "food sovereignty" and promoting American at the expense of peasant farmers who are knowledgeable about local practices [2]. But local practices have yielded scarcity. A farmer in India grows three to four times as much food on the same amount of land as a farmer in Africa; a farmer in China, roughly seven times as much.

As noted, the FAO reports that global demand for food could easily double over the period 2000–2050, with a two-and-a-half- threefold increase in the poorest countries [2]. They found that biotechnology and genetic engineering of crops hold great promise for agriculture in developing countries. The report noted that more than 70% of the world's poor still live in rural areas and depend directly on agriculture for their survival. The WHO estimates that 800 million people worldwide suffer from malnutrition. It is difficult to imagine a promising alternative to biotechnology and industrial agriculture that will sustain such numbers without catastrophic consequences. As far back as 2004 the Economic and Social Council of the United Nations (ECOSOC) noted that most developing countries are unlikely to meet the Millennium Development Goals without a clear political commitment to making science and technology among top priorities in their development agenda [3]. FAO members called for

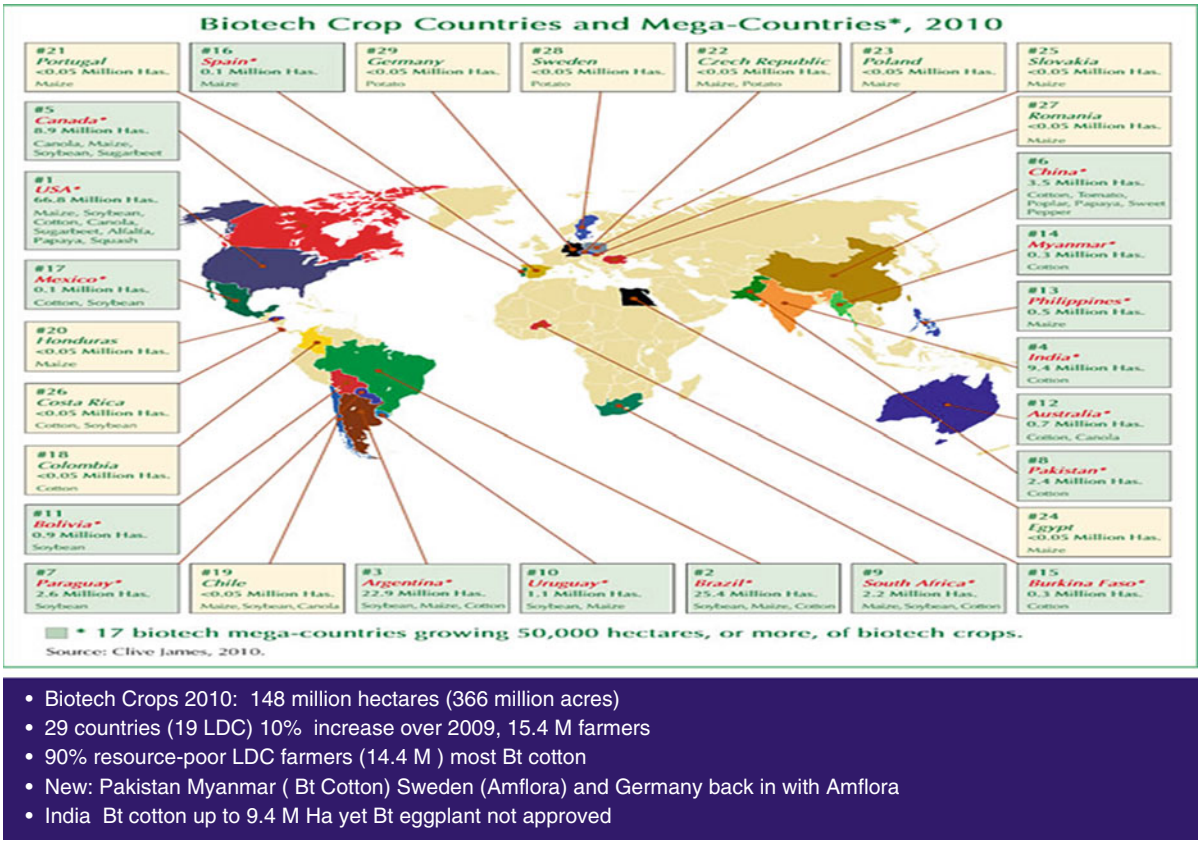
strengthening efforts in maximizing the benefits and minimizing the potential adverse consequences of biotechnology, through the Committee on Agriculture, the Council and the Conference, the development of a multidisciplinary, cross-sectoral program. In response, the Biotechnology Applications in Food and Agriculture, Forestry and Fisheries Priority Area for Interdisciplinary Action (Biotech-PAIA) was established and an Inter-Departmental Working Group on Biotechnology was set up to oversee its planning and implementation [4]. And prior to that the US National Academy of Sciences, joined by six other academies from around the world (Royal Society of London, Third World Academy of Sciences, and National Academies of Brazil, China, India, and Mexico) issued a report in 2000 declaring that biotechnology should be used to increase the production of main food staples, improve the efficiency of production, reduce the environmental impact of agriculture, and provide access to food for small-scale farmers [5]. Agricultural research of all forms holds an important key to meeting their needs, as the FAO noted biotechnology can speed up conventional breeding programs and may offer solutions where conventional methods fail. This is a positive outcome for consumers and the environment.

Progress to Date

Modifications of crop plants can be organized into two broad-based non-mutually exclusive categories: those that benefit the producer and those that benefit the consumer. Modifications that protect the crop from either biotic or abiotic stress (biotic stress being damage by predators such as insects and nematodes and disease agents such as viruses, fungi, bacteria, and weeds, and abiotic stress in the form of drought, cold, heat, and poor soils), or increase in total crop yield benefit the producer and are called "input traits." The majority of modified crops in commercial use fit in this group. Scientists have just begun to tap the large potential of biotechnology to produce varieties of plants that confer a wide spectrum of advantages to consumers. These varieties are modified with "output traits." Developing and commercializing plants with these improved traits involves overcoming a variety of technical, regulatory, and perception challenges inherent in perceived and real challenges of complex modifications. Both the panoply of traditional plant breeding tools and modern biotechnology-based techniques will be required to produce plants with the desired quality traits. In addition to the older gene transfer technology where mostly single genes were modified, newer techniques such as the use of RNA interference to manipulate endogenous genes and especially the use of transcription factors to modulate whole suites of genes and metabolic networks will become increasingly important tools in the effort to introduce valuable traits. The later approach is already a major focus in multigenic and quantitative traits such as developing stress tolerance crops and modifying paths for improving nutritional characteristics.

Since the first biotech crop was commercialized in 1996, genetically modified (GM) crops are now grown commercially by 15.4 million farmers in 29 countries on 366 million acres [6] (Fig. 1). More than half of the 63 countries engaged in biotech research, development, and production are developing countries. While North America still leads with US acreage accounting for about 45% of the total acreage worldwide, nevertheless, 19 of the 29 countries are developing countries and of the 15.4 million farmers that grew these crops, a full 14.4 million (90%) are resource-poor LDC farmers. The most recent countries to join this group were, in 2009, South America (Uruguay, Paraguay, and Bolivia) and Africa (Egypt and Burkina Fosa) and in 2010, three countries planted approved biotech crops for the first time and Germany resumed planting. Pakistan planted Bt cotton, as did Myanmar, and notably Sweden, the first Scandinavian country to plant a biotech crop, planted "Amflora," a potato with high amylase starch for industrial applications. Germany also resumed adoption of biotech crops by planting "Amflora" for a net gain of four countries in 2010 [6]. The first generation of such crops focused largely on input agronomic traits, and the next generation will focus more on value-added output traits. In the next decade, some studies estimate, the global value of biotech crops will increase nearly fivefold to $210 billion [7].

Agricultural biotechnology has helped farmers around the world boost their productivity and grow crops in more ecologically healthy fields while allowing much more efficient use of resources. This technology allows reduced tillage, which cuts down on greenhouse gas emissions, water runoff, machinery use, and soil



Transgenic Crops, Next Generation. Figure 1
Global map of biotech crop countries and mega-countries in 2010

erosion. Meanwhile, the benefits experienced by larger-scale farmers in both industrialized nations and lesser-developed countries are already considerable [6]. Research by Brookes and Barfoot [8, 9] shows in the first 11 years of GM crop cultivation that global net farm income increased by $33.8 billion since 1996; the environmental footprint associated with pesticide use was reduced by 15.4%; and there was a reduction in carbon dioxide emissions in 2006 equivalent to taking nearly 6.6 million cars off the road for a year.

An earlier study by researchers at Denmark's National Environmental Research Institute (NERI) monitored the fields of conventional and glyphosate-tolerant sugar beet. They found that the GM plots supported more plant species and insects than the conventional plots, thus providing more food for birds, and other types of wildlife use of transgenic crops increased biodiversity compared to traditional herbicide treatments [10]. Proper measurements in the UK indicate that no-till, (directly compared with plowed organic fields on the same farm and using the same farmer) uses only one third fossil fuel, uses land much more efficiently, reduces nitrate (and pesticide) runoff by at least half, and increases soil carbon which is lost when plowed. In addition, bird territories are orders of magnitude higher, soil erosion almost vanishes, and soil invertebrates such as earthworms soar in numbers, as do predatory arthropods to keep pests down. Organic fields in the UK see a threefold rise in weeds on conversion that necessitates use of the plow [11].

Therefore, reduced-till agriculture means healthier soil, with reduced erosion and far less carbon dioxide release. Soil carbon sequestration will be an important part of any international strategy to mitigate the increase in atmospheric CO_2 concentrations. By

adopting more sustainable management practices, agriculture may play a large part in enhancing soil carbon sequestration across the globe. One way is by reducing the amount of conventional tillage, after long-term tillage soil carbon stocks are depleted. In general, cultivation is not a sustainable practice. It is energy intensive and exposes soil to wind and water erosion. It allows rain to compact the soil and increases the oxygen content thus allowing organic matter to oxidize away. In turn, lower organic matter in the soil allows more compaction and more nutrient loss. Additionally in warmer and drier climates, evaporative water loss may be reduced as residue remains on the soil surface creating a wetter and cooler soil microclimate.

The Brooks and Barfoot study indicates that pesticide use fell by over 286 million kg (−7.8%: equivalent to about 40% of the annual volume of pesticide-active ingredient applied to arable crops in the European Union). Less spraying means fewer tractor passes, contributing to lower carbon dioxide emissions. Insect-resistant maize also has a collateral effect – less insect damage results in much less infection by fungal molds which reduces mycotoxins that are known health risks causing such problems as liver cancer to humans and animals. Bt corn resulted in a 90% reduction in mycotoxin fungal fumonisins [12]. In addition to the obvious health benefits, the total US economic benefit is estimated to be approximately $23million annually [6]. The only "natural" way to control those fungi is the use of copper sulfate which has one of the highest toxic hazard ratings of acceptable pesticides and selects for antibiotic-resistant bacteria in the soil.

A 2005 paper from the Royal Society suggests that intensive high-yield farming on less land is better for wildlife than "wildlife-friendly" less-efficient farming [13]. They provide convincing evidence that without yield increase, land use will double by 2050 and that this effect will be especially significant in developing countries where, without greater productivity China and India will need four times the land area to support their expanding populations. They show that in Latin America, where increased productivity was achieved, there was a significant decrease in deforestation; those producers with greatest yield increase had lower land use.

While North America remains the epicenter for cutting edge GM research, other regions, namely, China are emerging as contenders on the global stage. Agricultural science is now China's fastest-growing research field with China's share of global publications in agricultural science growing from 1.5% in 1999 to 5% in 2008 [6]. China's early experience with Bt cotton demonstrated the direct and indirect benefits of its investment in plant biotechnology research and product development. In 2002, Bt cotton was grown in 2.1 million hectares by around five million farmers. At that time the average Bt cotton farmer had reduced pesticide sprayings for the Asian bollworm from 20 to 6 times per year, reduced applications by 59–80% compared to conventional cotton (assessed in 3 years of use), and produced a kilogram of cotton for 28% less cost than the farmer using non-Bt varieties. Net revenues increased by 357–549 USD/ha compared to conventional cotton (assessed in 3 years of use) [14]. Ultimately, however, it is the social benefits from reducing exposure to insecticides and saving lives which is the real payoff.

The demand for productivity-enhancing technologies by farmers and for cost savings by consumers, the rate of increase in research investments, and success with Bt cotton suggest that products from China's research program will 1 day become widespread inside China. Indeed China is emerging as one of the trend-setters in the adoption of novel traits as more recently China is setting the pace for new approvals, with Bt rice and phytase maize approved on November 27, 2009. Rice is the principal staple for much of the world and maize is the largest animal feed source. Bt rice has the potential to increase yields up to 8%, decrease pesticide use by 80% (17 kg/ha), and generate US$4 billion in benefits annually [6]. The phytase approval is a major step forward in approvals as it is the first since the FLAVR SAVR tomato focusing on a "quality" trait. However, it is far more than this, both literally and figuratively since this single trait addresses several issues from nutritional to environmental as expanded on later.

The first GM crop to be released for commercial cultivation in India was Bt cotton, developed by the Maharashtra Seed Company (Mahyco) in partnership with Monsanto. The approval, which was given in 2002, came after several years of field trials following the

biosafety procedures laid down by the government. Three cotton hybrids were granted permission for field sowing in six states for 3 years. For the first season, farmer demand for Bt cotton seed was very high; it is estimated that 44,500 ha of certified Bt cotton were planted by nearly 55,000 farmers. However, the initial events thrived in regions that resembled the area in which they were originally developed but did not perform as well in growing regions with disparate climate challenges. It was not until the trait was introgressed into locally adapted varieties that Bt cotton thrived in all growing regions. Between 2005 and 2006 the biggest impact of this approach was realized. From 3 Bt cotton hybrids in 2002 to 62 in 2006 the rapid deployment of Bt cotton hybrids based on different agro-climatic conditions resulted in decreased insecticide sprays by 39%, and increased yield of 31%, resulting in increased profit per hectare of 88% or $ 250. Over this period of rapid deployment the average cotton yields increased from 308 to 450 kg/ha of lint (of this increase 50% could be attributed to Bt technology). Over the same period raw cotton exports rose from 0.9 million bales in 2005 to 4.7 million in 2006 and had achieved 5.9 million by 2007 [15]. By 2009, 5.6 million resource-poor farmers in India planted 8.4 million hectares of Bt cotton, equivalent to 87% of the 9.6 million hectare national cotton crop. The increase from 50,000 ha when Bt cotton was first commercialized in 2002 to 8.4 million hectares in 2009 represents an unprecedented 168-fold increase in 8 years. Between 2002 and 2008, Bt cotton generated economic benefits for farmers valued at US$5.1 billion, halved insecticide requirements, contributed to the doubling of yield and transformed India from a cotton importer to a major exporter. Choudary contends that the deployment of Bt cotton over the last 8 years has resulted in India becoming the number one exporter of cotton globally as well as the second largest cotton producer in the world [15].

However, despite the success of Bt cotton the expected successful commercialization of Bt eggplant never materialized as an effective opposition managed to scupper its approval. Bt eggplant, or brinjal as it is referred to in India, was found to be effective against fruit and shoot borer (FSB), with 98% insect mortality in shoots and 100% in fruits compared to less than 30% mortality in non-Bt counterparts. The multi-location research trials confirmed that Bt brinjal required, on average, 77% less insecticides than non-Bt counterparts for control of FSB, and 42% less for the control of all insect pests of brinjal. The benefits of Bt brinjal translate to an average increase of 116% in marketable fruits over conventional hybrids, and 166% increase over popular open-pollinated varieties [16]. Furthermore, the significant decrease in insecticide usage reduced the farmers' exposure to insecticides and resulted in a substantial decline in pesticide residues on brinjal fruits. Scientists have estimated that Bt brinjal will deliver farmers a net economic benefit ranging from $330 to $397 per acre with national benefits to India exceeding $400 million per year. However in February, 2010, the environmental minister announced a 6-month moratorium citing that "There is no overriding food security argument for Bt brinjal. Our objective is to restore public confidence and trust in Bt brinjal" [17], clearly articulating the fact that the decision was not based on scientific analysis or risk assessment.

A number of other multi-institutional projects have also been launched, including the development of transgenic plants for resistance to geminiviruses in cotton, mungbean, and tomato, resistance to rice tungro disease, development of a nutritionally enhanced potato with a balanced amino acid composition, and development of molecular methods for heterosis breeding. Other transgenic crops that are awaiting approval for commercial cultivation include transgenic herbicide-tolerant mustard hybrids and nutritionally enhanced potato varieties. However, despite the resounding success of Bt cotton, given the experience with Bt brinjal it is difficult to be optimistic about the prospects for commercialization of food crops.

A somewhat similar but even more insidious situation was experienced by Egypt. In 2008, Egypt became the first country in the Arab world (and only one of three in Africa) to commercialize biotech crops by planting 700 ha of Bt yellow maize. The variety commercialized, Ajeeb-YG, is a cross between MON 810 and an Egyptian maize variety with resistance to three corn borer pests. The reason that the amount was so low can in part be attributed to political pressure from their EU market.

The Next Generation

The vast majority of products approved to date are in the area of agronomic traits, most specifically biotic stress. The principal focus in the immediate future will remain on agronomic traits especially the area of pest control but with an increasing interest in abiotic stress tolerance which is gaining prominence as external pressures from climate change to land use change.

On the biotic stress tolerance side the focus is expanding to multi-tiered control systems. This in theory serves a double advantage, primarily expanding the effectiveness of the broad-based resistance events but also allowing more effective management of the resistance trait since there is less selective pressure when genes are stacked. SmartStax, an eight-trait event developed through collaboration between Monsanto and Dow takes advantage of multiple modes of insect protection and herbicide tolerance against above and below ground insects and provides broad herbicide tolerance, including Yieldgard VT Triple (Monsanto), Herculex Xtra (Dow), Roundup Ready 2 (Monsanto), and Liberty Link (Dow). It is currently available for corn, but cotton, soybean, and specialty crop variations are to be released [18]. It is estimated that this should require only 5% refuge acres as opposed to the 20% mandated for older technologies to mitigate against pest tolerance [15].

On the second area of agronomic traits, namely abiotic stress, there is a meta-issue that overlays much of the individual efforts, which is climate change. This poses a real challenge in terms of available agricultural land and freshwater use. Apart from the obvious effects of climate change, the decline of crop yields, ocean acidification, poor nutrition and abiotic stress, population displacement, and threatened ecosystems are effects underlined by the Stern Report [19] as potential consequences of climate change. In addition there are also broader, more systemic effects of drought beyond food insecurity such as decreased household income, the loss of assets due to slaughter of livestock, health threats due to the lack of water for hygiene and household uses, environmental degradation, and less-sustainable land management.

These effects should be considered in the light of growing population levels. In order to feed the overall population, the world will have to double its rate of agricultural production over the next 25 years, despite having already quadrupled it in the last 50 years. Severe drought accounts for half the world's food emergencies annually [1]. In 2003, the World Food Program spent US$565 million in response to drought in sub-Saharan Africa (SSA). In this context, solutions must be developed to adapt crops to the existing but also evolving conditions, such as marginal soils or harsher conditions such as cold, heat, drought, and salinity. The agriculture sector is both a contributor and provider of potential solutions to this phenomenon. It impacts two of the principal components of climate change greenhouse gases and water. Agriculture is a major source of the former emissions. Practices – such as deforestation, cattle feedlots, and fertilizer use – currently account for about 25% of greenhouse gas emissions. When broken down this amounts to 14% of carbon dioxide emission, 48% of methane, and 52% of nitrous oxide emissions [19]. In addition, this sector uses a significant amount of available freshwater – approximately 70% of the water currently consumed by humans is used in agriculture – and this is likely to increase as temperatures rise.

Given the potential impacts of climate change on the range and extent of agricultural productivity and the impact of agriculture practices itself on global warming, techniques should play a substantial part in mitigating against climate change. Green biotechnology offers a set of tools which can help producers limit greenhouse gas emissions as well as adapting their agricultural techniques to shifting climates. The three major contributions of green biotechnology to the mitigation of the impact of climate change are greenhouse gas reduction, crop adaptation (environmental stress, changing niches) and protection, and yield increase in less desirable and marginal soils.

On the first of these issues greenhouse gas reduction in addition to carbon dioxide agriculture contributes two of the other major gases indeed one of them nitrous oxide has a global warming potential of about 300 times that of carbon dioxide. In addition, nitrous oxides stay in the atmosphere for a considerable period. Nitrous oxide is produced through bacterial degradation of applied nitrogen fertilizer. In addition, fertilizer can contribute to eutrophication at ground level so its reduction is desirable on several levels. However, nitrogen is essential for crop production since it is quantitatively the most essential nutrient for plants and

a major factor limiting crop productivity. One of the critical steps limiting the efficient use of nitrogen is the ability of plants to acquire it from applied fertilizer. Therefore, the development of crop plants that absorb and use nitrogen more efficiently can serve both the plant and the environment. Arcadia Biosciences of Davis, CA, developed nitrogen-efficient crops by introducing a barley AlaAT (alanine aminotransferase) into both rice and canola. Arcadia's Nitrogen Use Efficiency (NUE) technology produces plants with yields that are equivalent to conventional varieties but which require significantly less nitrogen fertilizer because the AlaAT gene allows more efficient use. Compared with controls, transgenic plants also demonstrated significant changes in key metabolites and total nitrogen content, confirming increased nitrogen uptake efficiency. This technology has the potential to reduce the amount of nitrogen fertilizer that is lost by farmers every year due to leaching into the air, soil, and waterways. In addition to environmental pressures, nitrogen costs can represent a significant portion of a farmer's input costs and can significantly impact farmer profitability. Farmers spend $60 billion annually for 150 million tons of fertilizer [20]. The technology has been licensed to Dupont for maize and Monsanto for application in canola.

The second area where green technology can help in a changing climate is crop adaptation to environmental stress and changing niches. Under stress plants will divert energy into survival instead of producing biomass and reproduction, so addressing this impact should have substantial effect on yield. In addition, improved stress tolerance allows expanded growing season especially earlier planting and further reduces yield variability and grower financial risk. The most critical of these stresses is water. One of the most effective methods of addressing water limitation problems, namely, irrigation, unfortunately is also one of the major causes of arable land degradation. It is estimated that 24.7 million acres of farmland worldwide is lost each year due to salinity build up resulting from over irrigation. In fact crops are now limited by salinity on 40% of the world's irrigated land (25% of the USA). To address the extreme end of irrigation impact Eduardo Blumwald at UC Davis used AtNHX1, the most abundant vacuolar Na+/H+ antiporter in Arabidopsis thaliana which mediates the transport of Na+ and K+ into the vacuole. By overexpressing this vacuolar Na+/H+ antiporter, transgenic tomatoes were able to grow, flower, and produce fruit in the presence of 200 mM sodium chloride [21]. Arcadia Biosciences had now introduced this gene into economically important crops.

Even at a more moderate level of impact it is estimated that about 70–80 million acres in USA suffer yield losses due to moderate water stress. The most critical time for water stress is near-pollination and flowering where yields with or without irrigation can vary by up to 100%. This effect is clearly demonstrable in dry land production where yields can be cut in half in the absence of irrigation. At this time about 15% of US maize acres are irrigated. Given the negative effective and cost of irrigation it is estimated 20 million acres in USA would benefit from a drought tolerance gene that gives a 10% yield increase. It would also allow shifting of high-value crops into production on more marginal land.

One of the first commercialized products to have included a "yield gene" is Monsanto's second generation Roundup Ready 2 Yield® Soybeans which include not only the glyphosate-tolerant trait but also that which was developed using extensive gene mapping to identify specific DNA regions that segregated with yield increase. It is a perfect example of the power of combining recombinant DNA technology with genomics tools. The company claims that following 4 years of field trials across six US states showed 7–11% higher yields, compared to the first generation of Roundup Ready soybeans. At the National Technical Biosafety Committee (CTNBio) meeting in Brazil in August 2010, the committee approved the Bt enhanced version of this product for planting in Brazil [18].

As noted transcription factors are some of the most versatile tools being employed in developing stress-tolerant plants. One of the most versatile classes of transcription factors in so far as environmental response is concerned is the DREB (dehydration-responsive element binding protein) transcription factors which are involved in the biotic stress signaling pathway and can activate as many as 12 resistant functional genes relying on DREmembers of cis regulation under adverse conditions, for instance, rd29, cor15, and rd17, cause proline content to rise so as to enable plants to improve in many resistances such as drought, freezing, and salt tolerance. It has been possible to engineer stress tolerance in transgenic plants by

manipulating the expression of DREBs [22]. One isolated from Arabidopsis has improved drought tolerance increasing productivity by at least twofold during severe water stress. In Monsanto field trials using this approach, maize yields have increased under-water stress by up to 30% [22].

Other approaches include modification of individual genes involved in stress response and cell signaling. For example, drought-tolerant canola engineered to reduce the levels of PARP [poly(ADP-ribose) polymerase], a key stress-related protein in many organisms, shows relative yield increases of up to +44% compared to control varieties. A subset of the transcription factors homeodomain leucine zipper proteins (HDZip) play a role in regulating adaptation responses including developmental adjustment to environmental cues such as water stress in plants [23]. One of these effectors is abscisic acid (ABA), an important plant regulator controlling many environmental responses including stomata movement which is itself modulated by the DREB elements. Some work is being done on modifying HDZip directly and others are working indirectly, for example, down regulating farnesyltransferase, a signaling system in the production of abscisic acid and stomata control, which results in stomata closure and water retention.

Investigators are also working on modifying basic acid to enhance the tolerance of plants to water-deficit by delaying the drought-induced leaf senescence and abscission during the stress episode. Using tobacco plants expressing an isopentenyltransferase (IPT) gene under the control of a stress- and maturation-induced promoter (PSARK) it was shown that delayed drought-induced leaf senescence resulted in remarkable drought-tolerant phenotypes, as well as minimal yield loss when plants were watered with only 30% of the water used under controlled conditions [24]. This is now being introduced into rice among other crops. This work is being done in conjunction with Arcadia Biosciences. In addition, Bayer CropScience, Pioneer Hi-Bred, BASF and Dow among others are conducting research on maize, cotton, canola, and rice, to develop a new generation of stress-tolerant, high-performance crop varieties. Clearly stress-tolerant traits are of paramount importance in LDCs especially sub-Saharan Africa and Asia. Major efforts are already underway on this front. The partnership, known as Water Efficient Maize for Africa (WEMA), was formed in response to a growing call by African farmers, leaders, and scientists to address the devastating effects of drought on small-scale farmers. Frequent drought leads to crop failure, hunger, and poverty. Climate change can only aggravate this situation [25].

On the other end of the spectrum of climate change impact is flooding due to changing rain patterns and rising sea levels. This is already a major cause of rice crop loss. It is estimated that four million tons of rice are lost every year because of flooding which is sufficient to feed 30 million people. Rice is not grown in flooded fields through necessity but rather to control weeds, however, most rice varieties die after more than 3 days of complete submergence. Researchers know of at least one rice variety FR13A that can tolerate flooding for longer periods, but conventional breeding failed to create an event that was acceptable to farmers. The Ronald laboratory at UC Davis cloned the submergence tolerance (Sub1) locus from this resistance variety using a map-based cloning approach. The Sub1 locus encodes three putative transcription regulators one of which increases dramatically in response to oxygen deprivation in sub1 seedlings, whereas Sub1C levels decrease. Transgenic lines over-expressing the Sub1A-1 gene have been introgressed into a submergence-intolerant line and display-enhanced submergence tolerance [26].

There is also some research in the final abiotic stress focus area, namely, expansion of crops into and increased yield in less desirable and marginal soils. For example, a gene that produces citric acid in roots can protect plants from soils contaminated with aluminum as it binds to the contaminant preventing uptake by the root system [27]. Genes such as these can allow crops to be cultivated in hostile soils and temperatures increasing geographic range while reducing potential impact on fragile ecosystems.

While exciting and very relevant, research in abiotic stress tolerance is still an input trait. The first generation of biotechnology crops focused largely on those input agronomic traits; the next generation will focus more on value-added output traits. This will include identifying and isolating genes and metabolites that will make possible the enhancement of valuable traits, with some of the later compounds being produced in mass quantities

for niche markets. Two of the more promising markets are improved nutrition including nutraceuticals, or so-called functional foods, and plants developed as bioreactors (production factories) for the commercial-level production of valuable proteins and compounds, a field known as plant molecular farming [28]_ENREF_24.

While the correlative link between food and health, beyond meeting basic nutrition requirements, has only been unequivocally proven in a number of cases, a growing body of evidence indicates that food components can influence physiological processes at all stages of life [29]. Nutrition intervention from a functionality perspective has a personal dimension. Determining individual response is at least as complex a challenge as the task of increasing or decreasing the amount of a specific protein, fatty acid, or other components of the plant itself. There is also evidence that early food regimes can effect later life health, for example, some children that survived famine conditions in certain regions of Africa grew into adults battling obesity and related problems presumably due to the selective advantage of the thrifty gene in their early food-stressed environment becoming a hazard during more abundant times especially if later diets are calorie-dense.

Functional foods are defined as any modified food or food ingredient that may provide a health benefit beyond the traditional nutrients it contains. Scientific evidence is accumulating to support the role of phytochemicals and functional foods in the prevention and treatment of disease. Functional food components are of increasing interest in the prevention and/or treatment of a number of the leading causes of death including but not limited to cancer, diabetes, cardiovascular disease, and hypertension. Many food components are known to influence the expression of both structural genes and transcription factors in humans. Examples of these phytochemicals are listed in Table 2. The large diversity of phytochemicals suggests that the potential impact of phytochemicals and functional foods on human and animal health is worth examining as targets of biotechnology efforts. Developing plants with improved quality traits involves overcoming a variety of technical challenges inherent to metabolic engineering programs. Both traditional plant breeding and biotechnology techniques are needed to produce plants carrying the desired quality traits [29] (Table 1).

From a health perspective, plant components of dietary interest can be broadly divided into four main categories, which can be further broken down into positive and negative attributions for human nutrition, macronutrients (proteins, carbohydrates, lipids [oils], and fiber), micronutrients (vitamins, minerals, phytochemicals), anti-nutrients (substances such as phytate that limit bioavailability of nutrients), allergens, intolerances, and toxins [29]. Developing and commercializing plants with these improved traits involves overcoming a variety of technical, regulatory, and perception challenges inherent in perceived and real challenges of complex modifications. Both the panoply of traditional plant breeding tools and modern biotechnology-based techniques will be required to produce plants with the desired quality traits. Table 2 presents examples of crops that have already been genetically modified with macro- and micronutrient traits that may provide nutritional benefits.

In addition to functional foods, this area has the potential to address both nutrition and environmental impact. A good example of this is the addition of transgenic phytase enzymes to crops to reduce the need to add phosphate to feed [6]. Most of the phosphate is added to counteract the non-bioavailability of phosphorus in phytic acid and the sequestering effect of phytic acid on uptake of divalent mineral ions such as iron, calcium, and zinc. Unfortunately excess phosphate is excreted causing major environmental impact through eutrophication and fish kills in regions with intense pig and poultry farming [28, 29]. In addition, in humans, such mineral deficiencies due to phytate binding are estimated to afflict two to three billion people, primarily in the developing world. Several studies have shown that Aspergillus-derived phytases can be produced in large quantities in a range of plants including cereals with clear-cut positive effects on phytate degradation, and phosphate and mineral bioavailability in animal-feeding trials [104]. It is thus conceivable that genetic engineering of staples for increased phytase expression could have potential for improving iron and zinc bioavailability alleviating the need for supplementation in all monogastrics and consequent reduction in polluting runoff in non-ruminant animals [105]. As noted earlier China has led the way

Transgenic Crops, Next Generation. Table 1 Examples of crops in research with nutritionally improved traits[a]

Trait	Crop (trait detail)	References
Protein and amino acids		
Protein quality and level	Bahiagrass (protein↑)	Luciani and Wofford [30]
	Canola (amino acid composition)	Roesler et al. [31]
	Maize (amino acid composition; protein↑)	Cromwell et al. 1969, [32], Yang et al. [33], O'Quinn et al. [34], Young et al. [35]
	Potato (amino acid composition; protein↑)	Chakraborty et al. [36], Li et al. [37], Yu and Ao [38], Atanassov et al. [39]
	Rice (protein↑; amino acid)	Katsube et al. [40]
	Soybean (amino acid balance)	Rapp [41]; Dinkins et al. [42]
	Sweet Potato (protein↑)	Prakash and Jaynes [43]
	Wheat (protein↑)	Uauy et al. [44]
Essential amino acids	Canola (lysine↑)	Falco et al. [45]
	Lupin (methionine↑)	White et al. [46]
	Maize (lysine↑; methionine↑)	Agbios 2006, Lai [47]
	Potato (methionine↑)	Zeh et al. [48]
	Sorghum (lysine↑)	Zhao et al. 2003
	Soybean (lysine↑; tryptophan↑)	Falco et al. [45], Galili et al. [49]
Oils and fatty acids		
	Canola (lauric acid↑; γ-linolenic acid↑; + ω-3 fatty acids; 8:0 and 10:0 fatty acids↑; lauric + myristic acid↑; oleic acid↑)	Del Vecchio [50], Froman [51], James et al. [52], Ursin [53], Dehesh et al. 1996, Agbios 2006, Roesler et al. [31]
	Cotton (oleic acid↑; oleic acid + stearic acid↑)	Chapman et al. [54], Liu et al. [55]
	Linseed (+ ω-3 and -6 fatty acids)	Abbadi et al. [56]
	Maize (oil↑)	Young et al. [35]
	Oil Palm (oleic acid↑ or stearic acid↑; oleic acid↑ + palmitic acid↓)	Parveez [57], Jalani et al. [58]
	Rice (α-linolenic acid↑)	Anai et al. [59]
	Soybean (oleic acid↑; γ-linolenic acid↑)	Kinney [60], Reddy and Thomas [61]
	Safflower (γ Linoleic Acid GLA↑)	Arcadia [62]
Carbohydrates		
Fructans	Chicory, (fructan↑; fructan modification)	Smeekens [63], Sprenger et al. [64], Sevenier et al. [65]
	Maize (fructan↑)	Caimi et al. [66]
	Potato (fructan↑)	Hellwege et al. [67]
	Sugar beet (fructan↑)	Smeekens [63]
Frustose, Raffinose, Stachyose	Soybean	Hartwig et al. [68]

in the approval of this "output trait" in Maize being the first country to approve commercialization in November 2009 [6]. Continuing improvements in molecular and genomic technologies are contributing to the acceleration of such product development. One estimate states that foods that are used for functional purposes made up 10% of the $503 billion total US retail food market [106].

In addition to being a source of nutrition, plants have been a valuable wellspring of therapeutics for

Transgenic Crops, Next Generation. Table 2 Examples of plant components with suggested functionality[a]

Class/components	Source[b]	Potential Health Benefits
Carotenoids		
Alpha-carotene	Carrots	Neutralizes free radicals that may cause damage to cells
Beta-carotene	Various fruits, vegetables	Neutralizes free radicals
Lutein	Green vegetables	Contributes to maintenance of healthy vision
Lycopene	Tomatoes and tomato products (ketchup, sauces)	May reduce risk of prostate cancer
Zeaxanthin	Eggs, citrus, maize	Contributes to the maintenance of healthy vision
Dietary fiber		
Insoluble fiber	Wheat bran	May reduce risk of breast and/or colon cancer
Beta glucan[c]	Oats	May reduce risk of cardiovascular disease (CVD)
Soluble fiber[c]	Psyllium	May reduce risk of CVD
Whole grains[c]	Cereal grains	May reduce risk of CVD
Collagen Hydrolysate	Gelatin	May help improve some symptoms associated with osteoarthritis
Fatty acids		
Omega-3 fatty acids – DHA/EPA	Tuna; fish and marine oils	May reduce risk of CVD and improve mental, visual functions
Conjugated linoleic acid (CLA)	Cheese, meat products	May improve body composition, may decrease risk of certain cancers
Gamma linolenic acid	Borage, evening primrose	May reduce inflammation risk of cancer, CVD disease and improve body composition
Flavonoids		
Anthocyanidins: cyanidin	Berries	Neutralize free radicals, may reduce risk of cancer
Hydroxycinnamates	Wheat	Antioxidant-like activities, may reduce risk of degenerative diseases
Flavanols: catechins, tannins	Tea (green, catechins), (black, tannins)	Neutralize free radicals, may reduce risk of cancer
Flavanones	Citrus	Neutralize free radicals, may reduce risk of cancer
Flavones: quercetin	Fruits/vegetables	Neutralize free radicals, may reduce risk of cancer
Glucosinolates, indoles, isothiocyanates		
Sulphoraphane	Cruciferous vegetables (broccoli, kale), horseradish	Neutralizes free radicals, may reduce risk of cancer
Phenolics		
Stilbenes – resveratrol	Grapes	May reduce risk of degenerative diseases; heart disease; cancer. May have longevity effect
Caffeic acid, ferulic acid	Fruits, vegetables, citrus	Antioxidant-like activities; may reduce risk of degenerative diseases; heart disease, eye disease
Epicatechin	Cacao	Antioxidant-like activities; may reduce risk of degenerative diseases; heart disease

Transgenic Crops, Next Generation. Table 2 (Continued)

Class/components	Source[b]	Potential Health Benefits
Plant stanols/sterols		
Stanol/sterol ester[c]	Maize, soy, wheat, wood oils	May reduce risk of coronary heart disease (CHD) by lowering blood cholesterol levels
Prebiotic/probiotics		
Fructans, inulins, fructo-oligosaccharides (FOS)	Jerusalem artichokes, shallots, onion powder	May improve gastrointestinal health
Lactobacillus	Yogurt, other dairy	May improve gastrointestinal health
Saponins	Soybeans, soy foods, soy protein-containing foods	May lower LDL cholesterol; contains anticancer enzymes
Soybean protein	Soybeans and soy-based foods	25 g/day may reduce risk of heart disease.
Phytoestrogens		
Isoflavones – daidzein, genistein	Soybeans and soy-based foods	May reduce menopause symptoms, such as hot flashes, reduce osteoporosis, CVD
Lignans	Flax, rye, vegetables	May protect against heart disease and some cancers; may lower LDL cholesterol, total cholesterol, and triglycerides
Sulfides/thiols		
Diallyl sulfide	Onions, garlic, olives, leeks, scallions	May lower LDL cholesterol, helps to maintain healthy immune system
Allyl methyl trisulfide, dithiolthiones	Cruciferous vegetables	May lower LDL cholesterol, helps to maintain healthy immune system
Tannins		
Proanthocyanidins	Cranberries, cranberry products, cocoa, chocolate, black tea	May improve urinary tract health May reduce risk of CVD, and high blood pressure

[a]Examples are not an all-inclusive list

[b]US Food and Drug Administration approved health claim established for component. Modified from Newell-McGloughlin [29] (25)

centuries. During the past decade, however, intensive research has focused on expanding this source through rDNA biotechnology and essentially using plants and animals as living factories for the commercial production of vaccines, therapeutics, and other valuable products such as industrial enzymes and biosynthetic feedstocks [28].

More pressingly, with the increasing costs in economic and environmental terms of our dependency on fossil fuels, biotechnology offers innovative means to improve plant material for biomass conversion and enzymes to do the converting. There are two principal classes of biofuels: bio-alcohol (initially bio-ethanol but with increasing interest in higher-energy alcohols such as bio-butanol) and bio-diesel.

The first generation of biofuels was fermented from easy sources of simple sugars such as sugarcane and simple polymers primarily from grain starch. This source of bio-ethanol is unsustainable on many levels including the fact that its sources compete with food and especially feed grains for markets, land, and water. The focus for second generation bio-alcohols is mostly on complex polymers, primarily cellulosic ethanols and what are being termed third generation bio-alcohols such as bio-butanol [107]. From a biotechnology perspective work is being carried out on the biomass component focusing on increased production in such sources as switchgrass and miscanthus by among other things modifying photoperiodicity genes to switch energy to vegetative tissue production and improved biomass conversion by such

approaches as reducing lignin composition and incorporating self-activating enzyme digestion upon harvesting. On the enzyme component companies including Novozymes (Davis, CA) and Danisco (Palo Alto, CA) are making considerable strides in improving the effectiveness, specificity, and cost of cellulosic enzymes and increasing the conversion range especially for the more difficult pentose sugars such as xylose. Protein engineers are taking a synthetic biology approach with recent progress in engineering more stable and effective enzymes such as cellobiohydrolases by researchers at Caltech [108] and completely novel metabolic pathways by the Berkeley company, Amyris [109].

Biodiesel is defined by the National Biodiesel Board as a mono-alkyl ester. It is basically vegetable oil or animal fat–based diesel fuel consisting of long-chain alkyl (methyl, propyl, or ethyl) esters. Biodiesel is typically made via a trans-esterification process reacting lipids (vegetable oil, animal fat) with an alcohol.

Biodiesel per se can be used by standard diesel engines and is therefore qualitatively distinct from the vegetable, animal, and other waste oils used to fuel-converted diesel engines. Biodiesel can be used alone, or blended with petrodiesel. Biodiesel has better lubricating properties and much higher cetane ratings than today's lower sulfur diesel fuels but is still not economical as an alternate stand-alone fuel. Although still carbon-based, it is suggested by some that in terms of biofuels the algal biodiesel approach is much more sustainable than either the cellulosic or other land-based sources with DOE claiming that algae fuel yields have not yet been accurately determined, but DOE is reported as saying that algae yield 30 times more energy per acre than land crops such as soybeans [110].

From a biotechnology perspective the main focus for expanding interest in this area is increasing lipid production and modifying lipid composition for optimum performance. Work is being done to modify algae for increased production of desirable medium chain fatty acids (MCFA) which abrogates the requirement for cracking and isomerizing of long chain fatty acids (LCFAs). The advantages of MCFAs over LCFAs are high energy density, low fuel viscosity, low flash point, and low freezing point. The real issue with algal production systems is the scale-up step for commercial-level production where contamination, dewetting, and lipid isolation are still economically prohibitive. In February 2010, the Defense Advanced Research Projects Agency announced that the US military was about to begin large-scale production of jet fuel from algal pond isolates [111].

Barriers to Introduction

Most of the crops approved to date do appear to support the notion that the deregulation process is prohibitive for any but well-financed companies whose focus is primarily on the large commodity crops as just discussed. Worldwide there is clear asymmetry and lack of consensus in regulatory systems [112]. This discourages research on anything but the most mundane of crops and traits and is a real disincentive to creative research. For all intent and purposes there is just one trait from a public institution that has successfully traversed the regulatory minefields and been translated into a commercially viable commodity and that is the viral coat protein protection system initially developed for the papaya ringspot virus pandemic in Hawaii. This crop, papaya is a major tropical fruit crop in the Asian region. However, production in many Asian countries is set back by the prevalence of the PRSV disease as well as post-harvest losses. The PRSV-resistant papaya, based on RNAi suppression of the coat protein expression, literally saved the $17 M economy in Hawaii and is of significant importance in Taiwan and other SE Asian countries. Coat protein-based resistance is a demonstration of what is known as post-transcriptional gene silencing (PTGS). RNA interference (RNAi) in animals and basal eukaryotes, quelling in fungi, and PTGS in plants are examples of a broad family of phenomena collectively called RNA silencing. This system has now been applied to many species. A 5-year effort to combat plum pox virus disease through PTGS resistance paid off. In 1990, USDA/Agricultural Research Service (ARS) scientists began their efforts with a papaya ringspot virus coat protein gene obtained from Dennis Gonsalves [113]. This gene shows 70% homology to the plum pox gene and has been used to control other viruses similarly related to papaya ringspot. However, irrespective of the mechanism, it is important that resistance based on a single gene is managed well and alternate control mechanisms are introduced to reduce pressure on the development of viral resistance. Other approaches

include expression of the RNA replicating enzymes of the virus, expression of satellite RNA, replicating RNA molecules that are molecular parasites of the virus, or the use of protease inhibitors to interfere with processing of the viral proteins.

While translation of biotech research into value-added products for producers and consumers is a challenge in the USA, it is exponentially more difficult in LDCs [112]. A problem facing Africa in particular is the lack of a dynamic private sector to take technologies to the farmer. It has also been estimated that regulatory costs might exceed the costs of research and experimentation needed to develop a given GM crop, which is a major problem in releasing such crops to the market. A way to reduce the costs of generating food and environmental safety data is to develop regional "centers of excellence" with complementary facilities where food safety testing can be done reliably and regulatory costs could be reduced. The economic gains from using genetically modified crop technology in sub-Saharan Africa (SSA) are potentially large according to the World Bank Group [114]. The results suggest that the welfare gains are potentially very large, especially from golden rice and nutritionally enhanced GM wheat, and that those benefits are diminished only slightly by the presence of the de facto European Union's current ban on imports of GM foods.

The authors used the global economy-wide computable general equilibrium model known as GTAP. They specifically noted that if SSA countries impose bans on GM crop imports in deference to EU market demand for non-GM products, the domestic consumer loss net of that protectionism boost to SSA farmers would be more than the small gain derived from greater market access to the EU.

Problems cited for the slow passage of GM crops from experimental, to trial, to commercial stage especially in LDCs include the lack of capacity to negotiate licenses to use genes and research techniques patented by others, especially for crops with export potential [28]. In addition, there are difficulties in meeting regulatory requirements and a lack of effective public commercialization modalities and working extension networks. Biosafety and IPR regulations still have to be enforced in many countries for an effective and safe use of genetically engineered crops, especially if their production is meant for the export market.

Scientific, civic, and religious opinion leaders from all over the world have expressed support for the value of this technology. Florence Wambugu (CEO, Africa Harvest Biotech Foundation International, Kenya) states that the great potential of biotechnology to increase agriculture in Africa lies in its "packaged technology in the seed," which ensures technology benefits without changing local cultural practices [115]. For example, over 120 million children worldwide are deficient in vitamin A. In the late 1990s, Potrykus [108] group engineered rice to accumulate provitamin A (b-carotene). Incorporation of this trait into rice cultivars and widespread distribution of this "packaged technology in the seed" could prevent one to two million deaths each year. She observes that in the past, many foreign donors funded high-input projects, which have not been sustainable because they have failed to address social and economic issues such as changes in cultural practice [115]. In concurrence with this, Ismail Serageldin, former Chairman of the CGIAR (Consultative Group on International Agricultural Research) noted that, a priori, biotechnology could contribute to food security by helping to promote sustainable agriculture centered on smallholder farmers in developing countries [104].

US Consumer attitudes also tend to be relatively positive on the whole about agricultural biotechnology. In a 2010 IFIC survey, consumers were determined to be largely familiar with the term "biotechnology" [116]: More than two thirds of consumers (69%) have read or heard at least "a little" about the concept. Half (51%) of consumers say they are favorable toward farmers using biotechnology to grow more crops that would help meet food demand. In addition, significantly more consumers this year (28% vs. 23% in 2008) believe foods produced through biotechnology are available in the supermarket today, although this figure is still relatively low. Certain benefits of biotechnology are found to resonate better with consumers than others. These tend to be consumer-facing qualities such as improved health or better taste. For example, the majority of consumers say they are somewhat or very likely to purchase foods produced through biotechnology to provide more healthful fats like Omega-3 s (76%), to avoid trans fat (74%), and to make foods taste better/fresher (67%). This is consistent from 2008. Additionally, more than three quarters (77%) of

consumers say they would be likely to purchase foods produced through biotechnology for their ability to reduce pesticide use, and 73% of consumers said they would be likely to purchase bread, crackers, cookies, cereal, or pasta made with flour from wheat that had been modified by biotechnology to use less land, water, and/or pesticides. Of the 18% who would like to see additional information on the FDA label, only 3% mentioned anything about biotechnology.

But what of the context in which these crops are grown? Can all cropping systems co-exist in harmony? According to Brookes and Barfoot, [8, 117] it is important to determine the relative importance of different crop production systems based on planted area, production, and economic value to the region in question. The issue is what, if any, are the economic consequences of adventitious presence of material from one crop system within another based on the notion that farmers should be able to cultivate freely the crops of their choice using whichever production system works best in any given context (GM, conventional, or organic). It is never a food or environmental safety issue but rather a production and marketing matter. The heart of the issue is assessing the likelihood of adventitious presence of material from one production system affecting another and the potential impacts. This requires consistency when dealing with adventitious presence of any unwanted material including, but most definitely not limited to, biotech-derived material. Adventitious presence is simply the unintended incidence of something other than the desired crop such as small quantities of weed seeds, seeds from other crops, dirt, insects, or foreign material (e.g., stones). It is unrealistic to expect 100% purity for any crops, or products derived therefrom, so thresholds that are consistent across all materials should be set and should not discriminate (e.g., thresholds for adventitious presence of biotech material should be the same as applied to thresholds for other unwanted material and vice versa). All measures should be proportionate, non-discriminatory, and science-based.

The issue of economic liability provisions that compensate growers for adventitious presence of biotech material is often raised [117]. Historically, worldwide the market has adequately addressed economic liability issues relating to the adventitious presence of unwanted material in any agricultural crop. For example, for certified seed the onus is on the producers, who require isolation from undesired pollination for the purity of their product, to insure such purity; this is not their neighbor's problem. By extension the onus is on growers of any specialty crops to take action to protect the purity of their crops since these are self-imposed standards for and by that market. Growers who have themselves chosen a more stringent standard than that established in EU legislation should not expect their neighbors to bear the special management costs of meeting that self-imposed standard; to do so would reverse fundamental freedoms of economic activity and would establish a dangerous precedent. To allow specialty operators to formulate unrealistic standards for GM in their own produce would impose impossibly high standards on neighbors and would effectively impose a ban on the choice of other producers. Such growers usually are rewarded by higher prices and niche markets for taking such actions. Their neighbors enjoy no such advantage.

Existing legislation in North America and the EU is more than adequate to protect all grower and consumer interests but if new regulations were considered to address economic liability provisions for any negative economic consequences of adventitious presence of unwanted material, the same principle should apply to all farmers regardless of their chosen production methods. On equity grounds, biotech growers should have equal access to compensation for adventitious presence of material from conventional or organic crops (such as fungal contamination) as conventional and organic producers have from biotech growers. No one sector should be able to unfairly prohibit another – access and choice work both ways. All co-existence measures should be based on legal, practical, and scientific realities and not on commercial or niche marketing objectives. Where unintended presence has occurred on a number of occasions to date such as the presence of minute levels of Bayer Crop Sciences–regulated material LLRICE 604 found in Clearfield 131 (CL131) rice seed in 2007 and Mycogen's event "32" in maize in 2008, the agencies cooperated and determined that these events did not prove any risk as they carried similar constructs to those already having achieved non-regulated status.

According to Brookes and Barfoot, [8, 117] biotech crops co-exist successfully with conventional and

organic crops in North America (where, as noted, biotech crops account for the majority of acreage of important arable crops like soybeans, cotton, and maize) Spain, and more recently the Czech Republic. The market has developed practical, proportionate, and workable coexistence measures without new regulations or indeed any government intervention. Where isolated instances of adventitious presence of biotech material have been found in conventional or organic crops these have usually been caused by inadequate implementation of good coexistence practices (e.g., inefficient segregation of crops in storage and transport, nonuse of tested, certified seed). Under civil liability (i.e., tort damages) and for intellectual property infringement (except for the unauthorized StarLink), there have been no lawsuits brought by any parties for adventitious presence. Every case brought by a seed company for infringement has involved a claim that the farmer charged with infringement was an intentional infringer (i.e., adventitious presence was not the issue). And, to date, each of these cases was upheld by the courts. Indeed, all except one notable exception in North America has conceded to this claim. The exception is Percy Schmeiser who famously was found by a number of courts to have infringed Monsanto's glyphosate-tolerant patent by deliberately spraying and subsequently saving seeds from resistant sport canola plants found growing near his property. He initially claimed adventitious contamination but upon losing all the way to the Canadian Supreme court he changed tact to try to take advantage of Canadian patent law which prohibits patenting of higher organisms. While the court upheld this they determined that the construct within the plant was subject to IP protection and so Schmeiser was found to have infringed a patentable article under Canadian law.

Virtually all EU member states have transcribed EU Directive 2001/18 and implement EU regulations on traceability and labeling. Within the EU, provision has been made for a de minimis threshold for unavoidable presence of GMOs but no actual threshold has been set. Therefore, the default state of the 0.9% on labeling and traceability is the one enforced. In the USA, organic products cannot be (legally) downgraded or the producer decertified by unintentional presence when all required measures and best practices are adhered to and no producer has been so impacted to date [118].

Going forward there are four major stanchions to the furtherance of co-existence and all of them are incumbent on cooperation.

1. Monitoring: Verify the models and predictions about cost, isolation standards, and generally to learn how the farming community copes with the requirements for keeping the product streams separated.
2. Dialog: Strategy development takes place in a dialog between the scientific and technical community and all relevant stakeholders. (The Czech Republic [119].)
3. Stewardship: Stewardship programs should take into account the interests of both GM and non-GM farmers. Existing product stewardship programs for non-GM crops in farming should be a starting point for developing stewardship schemes for GM crops.
4. Research: The scientific community should be encouraged to fill the knowledge gaps that have been identified. Projects are needed to validate models and guidelines, including long-term studies. Building up mechanistic, probabilistic, and predictive models of gene flow etc. Methods for restricting gene flow by eliminating the fertility of pollen or seeds (apomixis, cytoplasmic male sterility, plastid transformation, Genetic Use Restriction Technology (GURT), etc.).

The World Trade Organization ruled in 2006 that a 6-year European ban on genetically engineered crops violates international trade. The three-person panel issued its decision ruling in favor of the three countries, USA, Canada, and Argentina, on a large majority of the 25 crops under dispute in the case while issuing mixed rulings on a few crops. The panel also ruled in favor of challenging national bans on specific biotech crops issued by Austria, France, Germany, Greece, Italy, and Luxembourg. The EU had argued that it did not have a moratorium but that it just took more time to weigh the possible risks to health and the environment posed by genetically engineered foods. It said it needed to take a "precautionary" approach to regulation, which is different from what it called Washington's "laissez-faire" stance.

The trade organization panel appears not to have challenged Europe's regulatory process for biotech

crops. Rather, it said Europe failed to follow its own procedures, resulting in undue delay of decisions. Interestingly one of the most comprehensive assessments on the technology was conducted by EU scientists. An EU Commission Report [120] that summarized biosafety research of 400 scientific teams from all original 15 EU countries conducted over 15 years stated that research on biotechnology-derived plants and products so far developed and marketed, following usual risk assessment procedures, has not shown any new risks to human health or the environment beyond the usual uncertainties of conventional plant breeding. Indeed, the use of more precise technology and the greater regulatory scrutiny probably make them even safer than conventional plants and foods. If there are unforeseen environmental effects – none have appeared as yet – these should be rapidly detected by existing monitoring systems. This analysis was repeated in a 2008 EU Joint Research Centre (JRC) Report commissioned by Members of the European Parliament (MEPs) conducted by world experts including the European Food Safety Authority (EFSA), the World Health Organization (WHO), and others [120]. Their report concluded that there is no evidence that genetically modified foods have any harmful effects; a declaration signed by over 3,500 scientists including 25 Nobel Laureates reiterates this position [28].

Future Directions

As agriculture must adapt to rapidly changing needs and growing conditions it is important to become more effective at producing more or less with limited resources and only the tools of biotechnology will allow us to bypass physiological and environmental limitations to produce sufficient food, feed, fuels, and fiber on ever diminishing arable land to meet ever increasing demand. The challenges going forward are foremost technical as one strives to modify qualitative as opposed to quantitative traits and intricates metabolic pathways and networks as opposed to single genes; the scientific hurdles to achieve these aims are not trivial. However, with the tools now coming online in the fields of genomics, proteomics, metabolmics, and bioinformatics, there is the potential to make major modifications to introgress desirable traits. For example, tools such as next generation sequencing, RNA interference (RNAi), transcription factors (Tfs), transcription activator-like effector nucleases (TALENs), mini-chromosomes, combinatorial transformation, epigenetic modification, network engineering, and systems biology will allow us to apply both reductive and holistic approaches to identify, modify, introgress, and subsequently and simultaneously study the expression and interaction of transgenes on tens of thousands of endogenous genes in elite germplasm backgrounds. With these newly evolving tools, one is beginning to dissect the global effects of metabolic engineering on metabolites, enzyme activities, and fluxes. With rapidly emerging technologies, the increase in our understanding of and ability to manipulate plant metabolism during the coming decades should place plant researchers in the position of being able to modify crop traits to respond to the diversity of needs from minimizing environmental impact to optimizing productivity and quality output.

Non-technical limitations include intellectual property restrictions which may limit translation of public research if not managed judiciously; secondly, liability concerns over abuse or misuse of constructs; thirdly prohibitive and asymmetric biosafety regimes and finally public acceptance. The latter two in many ways are the most insidious of limitations as they have little basis in rational process and thus are difficult to redress effectively – the last in particular is often predicated on how much of the former is perceived to be of concern, and how positions are presented by the opposing factions. It is often easier to appeal to emotion and self-fear than it is to present reasoned and judicious scientific rational for basing risk analysis. Indeed the actual commercialization of biotech products may have little to do with technical limitations and more to do with these external constraints primarily the process of regulatory approval. The flagship of improved nutritional varieties, namely, beta carotene–enhanced rice commonly referred to as golden rice, despite being under consideration since the late 1990s and subject to a barrage of risk assessments is unlikely to be approved until 2012 at the earliest. Ingo Potrykus, the developer, says an unreasonable amount of testing has been required without scientific justification. In a recent *Nature* article [121], he lays the blame largely on the regulatory process which he considers excessive observing that unjustified and impractical legal requirements are preventing genetically engineered crops from saving millions from starvation and malnutrition.

In the final analysis, resources are finite and true sustainability can come only from an enlightened philosophy that promotes the development of resource-enhancing technologies. Antithetically, those who claim to be the stalwarts of sustainability are, on occasion, the very ones who oppose the development and application of those tools that can help to insure such sustainability. The only sure way to insure food security and protect the planet's resources is not to settle into the complacency of maintaining the status quo but to engage in continual, constructive change based on scientific knowledge. Thus, if one is to be accountable to posterity it is not just the choice but one's duty to promote and apply responsible science and technology in all endeavors.

Article Outline

Glossary

Biodiversity Biodiversity is the quantity and variability among living organisms within species (genetic diversity), between species and between ecosystems. Biodiversity is not itself an ecosystem service, but underpins the supply of services. The value placed on biodiversity for its own sake is captured under the cultural ecosystem service called "ethical values" (according to the Economics of Ecosystems and Biodiversity report [1]).

Deliberate release Any intentional introduction into the environment of a genetically modified organism (GMO) or a combination of GMOs for which no specific containment measures are used to limit their contact with, and to provide a high level of safety for, the general population and the environment (according to Directive 2001/18/EC on the deliberate release into the environment of GMOs [2]).

Ecosystem An ecosystem is a dynamic complex of plant, animal, and microorganism communities and their non-living environment interacting as a functional unit. Examples of ecosystems include rainforests, grasslands, urban parks, and cultivated farmlands. Ecosystems can be relatively undisturbed by humans, such as virgin rainforests, or can be modified by human activity (according to the Economics of Ecosystems and Biodiversity report [1]).

Ecosystem services Ecosystem services are the benefits that people obtain from ecosystems. Examples include food, freshwater, timber, climate regulation, protection from natural hazards, erosion control, pharmaceutical ingredients, and recreation (according to the Economics of Ecosystems and Biodiversity report [1]).

Environmental harm Environmental harm can be defined as a measurable adverse change in a natural resource or measurable impairment of a natural resource service which may occur directly or indirectly (according to Directive 2004/35/EC on environmental liability [3]).

Genetically modified/transgenic organisms Organisms, such as plants, animals, and microorganisms (with the exception of human beings), in which the genetic material (DNA) has been altered in such a way that does not occur naturally by mating and/or natural recombination (according to Directive 2001/18/EC on the deliberate release into the environment of GMOs [2]).

Living modified organism Any living organism that possesses a novel combination of genetic material obtained through the use of modern biotechnology (according to the Cartagena Protocol on Biosafety [4]).

Modern biotechnology The application of (1) *in vitro* nucleic acid techniques, including recombinant deoxyribonucleic acid (DNA) and direct introduction of nucleic acid into cells or organelles, or (2) fusion of cells beyond the taxonomic family, that overcome natural physiological reproductive or recombination barriers and that are not techniques used in traditional breeding and

Robert A. Meyers (ed.) Encyclopedia of Sustainability Science and Technology, © 2012, DOI 10.1007/978-1-4419-0851-3

selection (according to the Cartagena Protocol on Biosafety [4]).

Organism Any biological entity capable of replication or of transferring genetic material (according to Directive 2001/18/EC on the deliberate release into the environment of GMOs [2]).

Placing on the market Making available to third parties, whether in return for payment or free of charge (according to Directive 2001/18/EC on the deliberate release into the environment of GMOs [2]).

Risk assessment Process of evaluation of risk, including the identification of scientific uncertainties, of the likelihood and severity of an adverse effect(s) or event(s) occurring to human and animal health or the environment following exposure under defined conditions to a risk source(s). A risk assessment comprises problem formulation (or hazard identification), hazard characterization, exposure characterization, and risk characterization (according to [5]).

Definition of the Subject

This contribution describes the risk assessment principles and the regulatory framework for transgenic (genetically modified (GM)) crops in the European Union (EU).

While the global cropping area of GM crops reached 148 million hectares in 2010, the total area cultivated with GM crops in the EU was less than 100,000 ha. Most GM crops are thus cultivated outside the EU, but might subsequently be imported and eventually further processed in the EU, mostly for animal feed purposes.

It is globally accepted that agro-food biotechnology could contribute to achieving the objectives (conservation of biological diversity, sustainable use of its components, fair and equitable sharing of the benefits arising out of the utilization of genetic resources) laid down in the Convention on Biological Diversity, if developed and used with adequate safety measures for both the environment and human health. Generally, the safety measures are embedded in process- or product-based regulatory framework. The EU regulatory framework is process-based, precautionary, and includes mandatory labeling and traceability requirements for GM crops and their derived food and feed products. During its development, the EU regulatory system has become increasingly more stringent.

GM crops and their derived food and feed products are generally subject to a risk analysis before they can be commercialized. In the EU, the risk analysis consists of three components: risk assessment, risk management, and risk communication. In risk assessment, potential adverse impacts associated with a specific activity are scientifically characterized on a case-by-case basis, while in risk management, policy alternatives to accept, minimize, or reduce the characterized risks are weighed and, if needed, appropriate prevention and control options are selected. Risk management is functionally and temporally separate from risk assessment in order to reduce any conflict of interest and to protect the scientific integrity of risk assessment. Risk communication is defined as an interactive exchange of information and opinions on risk throughout risk analysis, between risk assessors, risk managers, and other interested parties.

When analyzing potential risks, it is important to bear in mind that the real choice is not between GM crops that are inherently risky and traditionally bred ones that are completely safe. The cultivation of existing crops and those with novel traits (including GM crops) will have both positive and negative consequences. To fully acknowledge the overall outcome of adopting specific crops, and to assess and manage more effectively the environmental footprint of agriculture as a whole, the conclusion is that broader and more balanced legislative oversight is needed in the EU.

Introduction

The global cropping area of GM crops (including soya bean, maize, cotton, oilseed rape, and sugar beet) has consistently increased each year since they were first commercially cultivated in 1996. While the global cropping area of GM crops reached 148 million hectares in 2010, the total area under GM cultivation in the European Union (EU) was approximately 91,400 ha [6]. Most approved GM crops worldwide are thus currently cultivated outside the EU, but might subsequently be imported and eventually further processed in the EU, mostly for animal feed purposes.

The disparity in adoption rates of GM crops between the EU and the rest of the world is generally attributed both to societal and political opposition toward agro-food biotechnology, and to complex regulatory approval procedures in the EU [7, 8]. In the mid-1990s, the advent of GM crops aroused strong societal concerns [9–12]. Fostered by several highly publicized and successive food safety crises (e.g., bovine spongiform encephalopathy, dioxins, emergence of pathogens such as *Escherichia coli* 0157), public suspicion toward regulatory authorities, scientists and technocratic decision making grew [13]. The media, which was explicitly involved in framing public perception and societal image-building of agro-food biotechnology [14, 15], exacerbated the social amplification of risk [16]. In the late 1990s, increasing societal and political opposition contributed to a *de facto* moratorium on new GM crop market approvals. This was adopted at a meeting of the EU Council of environmental Ministers in June 1999, where five EU Member States indicated that they would oppose any new approvals pending a revision of the legislation [17]. The moratorium did not have a formal status and did not revoke pre-1999 approvals of GM crops or food products, nor did it officially prevent new approvals of GM food products. However, the moratorium was *de facto* effective since a sufficient number of Member States ensured a blocking majority of the legislative process [18]. As a consequence, several GM crop market applications remained blocked in the EU regulatory system for over a decade.

From 1999 onward, policy makers started to continuously revise the legal conditions under which GM crops and derived food and feed products were to be allowed to be used in the EU, in order to slow down further erosion of public and market confidence (reviewed in [10]). These various legal and institutional reforms, although leading to the upheaval of the *de facto* moratorium in 2004 and a regulatory regime that imposes the most stringent criteria for their approval worldwide (cf., WTO dispute between the US and EU), did not dissipate societal concerns. As Gaskell et al. [19] put it "the new regulatory frame appears to have done little to allay the European public's anxieties about agro-food biotechnology," and "the years of controversy have led many people in Europe to believe that anything that has to do with GM food is undesirable". Member States continue to raise safety objections during the approval process for the placing on the market of GM crops. While the new EU regulatory system should guarantee a harmonized and science-based process, none of the GM plant market applications that were positively evaluated by the EU authority responsible for providing advice on the safety of GMOs, the European Food Safety Authority (EFSA), have attained the necessary qualified majority (neither in favor nor against the approval of GMOs) from the relevant regulatory committees or the Council of Ministers, both for exhibiting substantial abstentions in voting [18, 20]. In most cases, the European Commission has adopted favorable decisions that are not endorsed by a qualified majority of Member States, whereas in other cases, decisions are still pending.

In response to the European Commission approvals for the marketing of GM crops, several Member States invoked national safeguard measures to provisionally restrict or prohibit the use and/or sale of approved GMOs in their territory. Even though EFSA concluded that, in terms of risk to human and animal health and the environment, no new scientific evidence had been presented that would invalidate former risk assessments, the Council of Ministers rejected the proposals of the European Commission to repeal invoked safeguard measures. To reduce the recourse of Member States to safeguard measures and to facilitate the decision making process, the European Commission proposed in July 2010 to confer to Member States the freedom to allow, restrict, or ban the cultivation of GMOs on part or all of their territory [21, 22]. In addition, the European Commission issued a new Recommendation on coexistence of GM crops with conventional and/or organic crops [23] that replaces the previous recommendation from 2003. Whether these proposals will help to unlock the European legal gridlock is debatable. The European Parliament and Council are expected to discuss the proposals, with a view to legal implementation, in the autumn of 2010 [24]. However, several Member States have already notified the European Commission of their intention to prohibit the cultivation of the Amflora® starch potato, which was approved for cultivation in March 2010. It was the first EU approval for cultivation of a GM crop in the past decade. This approval has garnered considerable public controversy [25] and is illustrative of the

lasting skeptical and/or ambivalent attitude of the European society toward agro-food biotechnology.

Regulatory Oversight of GM Plants and Their Derived Food and Feed Products

Heightened global awareness and concern over accelerating environmental degradation during the latter quarter of the twentieth century resulted in a desire by the international community to push the protection of the environment higher up the political agenda. These efforts came to fruition in 1992 when the Convention on Biological Diversity (CBD) came into force. Its objectives include "the conservation of biological diversity, the sustainable use of its components and the fair and equitable sharing of the benefits arising out of the utilization of genetic resources" [26]. During the elaboration of the Convention, negotiators recognized that biotechnology could contribute to achieving these objectives, if developed and used with adequate safety measures for both the environment and human health. Accordingly, procedures were developed to address the safe transfer, handling, and use of any LMO (used interchangeable with GMO in this contribution) resulting from biotechnology that may have an adverse effect on the conservation and sustainable use of biological diversity (Article 19.3, CBD). These procedures formed the Cartagena Protocol on Biosafety (CPB; 4), which came into force in 2003 and has 160 signatory countries to date (October 2010). Parties lacking a cohesive biosafety policy undertook, or are currently undertaking, a number of initiatives to put a national framework in place in order to comply with the CPB.

This period of heightened political activity in environmental protection has coincided with a concomitant rise in GM crop cultivation. The number of countries opting to grow GM crops has increased steadily from 6 in 1996, the first year of commercialization, to 18 in 2003 and 25 in 2009 [27]. Among the top 10 GM crop-growing countries by area, the USA, Argentina, Canada, Uruguay, and Australia are currently not Parties to the CPB. At the same time, many developing countries that have ratified the CPB are still in the process of elaborating a regulatory framework governing the import or cultivation of GM crops. This has led to the current situation where different strategies and standards have been adopted at the national level, caused by the different infrastructures available in developed and developing countries, and has resulted in much confusion and difficulty in harmonizing environment and trade agreements and regulations.

The Cartagena Protocol on Biosafety

The CPB has been the primary driving force behind many countries establishing national biosafety regulatory systems for GM crops and animals. Attempts have been made under the CPB, as an international legally binding treaty, to set forth the scientific and legal boundaries for those systems, and establish a minimum set of rules and procedures to "ensure an adequate level of protection to avoid or minimize potential adverse effects on the conservation and sustainable use of biological diversity, taking into account human health". The CPB also sets minimum standards for regulating certain aspects concerning the safe transfer, handling, and use of LMOs [28].

The necessary set of techniques to produce GMOs has been defined not only by the CPB, but also by other relevant international treaties, guidelines, and standards, including the Principles for the Risk Analysis of Foods Derived from Modern Biotechnology [29], and the International Standards for Phytosanitary Measures [30]. The application of modern biotechnology allows the intentional crossing of natural breeding barriers, the underlying molecular processes of which are qualified as sufficiently "new" so that they and the resulting organisms can be patented as inventions.

In many countries, the terms "genetically modified organism," "genetically engineered organism," and "transgenic organism" are widely used, including in domestic legislation, to describe LMOs covered by the CPB [31]. Different countries therefore have biosafety regulations to guide the development of GM crops. Such regulations are key to ensuring the environmental and human safety of GMOs and give the public confidence in GM products [28].

Although the CPB covers all LMOs, it primarily addresses two particular uses of LMOs: [1] those that will be intentionally introduced into the environment and [2] those used for food, feed, or processing (FFP).

For LMOs used for other purposes, such as LMOs used in the laboratory, the Protocol leaves any regulation to the discretion of the individual country. The CPB also does not cover products derived from LMOs, such as processed foods that have ingredients that came from LMOs.

To ensure the safe transfer, handling, and use of LMOs, the CPB sets up two separate procedures. The first time that an LMO is to be intentionally introduced into the environment, the CPB sets up an Advanced Informed Agreement (AIA) procedure (Article 7). This procedure requires that an exporter of an LMO provides a notice with detailed information about the LMO to the importing country (Article 8). The importing country then reviews the information, conducts a risk assessment, and decides, based on the risk assessment results, whether to approve or reject the LMO (Articles 10 and 15). In deciding whether to accept the LMO, the importing country can invoke risk management measures to address issues that arise from the risk assessment (Article 16). The importing country also can err on the side of precaution (discussed below) and not approve an LMO if there is insufficient information to adequately assess its particular potential risks (Article 10 [6]).

The second procedure set up by the CPB is for LMOs for FFP (such as maize, soya bean, wheat, or other grains that will be fed to humans or animals). For these LMOs, the AIA procedure is not required (Article 11). Instead, the CPB establishes a simpler system which reflects the decreased likelihood that these LMOs will affect the biodiversity of the exporting country. Before the LMO can be exported to another country, the safety decision in the exporting country is communicated to other countries through the Biosafety Clearing-House (BCH; http://bch.cbd.int/). A country may require prior consent, however, under its domestic regulatory framework, as long as that requirement has been posted on the Biosafety Clearing-House (Article 11).

The CPB also contains numerous other provisions that complement the review procedures for LMOs discussed above and address issues important to a uniform and comprehensive biosafety regulatory process. There are provisions on reviewing decisions for new information (Article 12), simplified procedures for certain LMOs that do not present risks (Article 13) and emergency procedures for unintentional releases of LMOs (Article 17). The CPB also addresses issues such as public awareness and participation (Article 23), and what to do about confidential information (Article 21). Thus, the Protocol attempts to establish a complete and comprehensive set of procedures and legal obligations to assess and manage the potential risks of LMOs on biological diversity, also taking into account risks to human health.

While proponents of modern biotechnology state that no new risks are associated with GMOs, others feel that the new methods of producing organisms might be associated with new risks. Premarket procedures have therefore been established by many regulatory authorities around the world, and are applied to assess how the organisms may behave and evolve in the environment, and how they may interact with other species. The CPB sets forth the information about an LMO that is needed before it is released into the environment or used for FFP. Annexes I and II contain detailed lists on the major categories of information needed to assess the potential risks of an LMO. They provide models which a national biosafety regulatory system can use as standard data requirements. Of course, individual countries may add to the list of required information, depending on particular environment issues within their country or if they choose to address other risk areas (such as food safety or socioeconomic concerns).

The CPB also attempts to explain what a scientific risk assessment of an LMO should entail. Annex III sets forth the objective of the risk assessment, what the risk assessment will be used for, the general principles that the risk assessment must follow, the methodology of the risk assessment, and particular points to consider when assessing the potential risks of an LMO. The Annex provides a clear explanation to interested parties about what is expected in the risk assessment, what will guide the risk assessment, and how it will be used. Therefore, the Protocol's Annexes attempts to provide sufficient information and details so that countries which adopt those provisions will establish harmonized and standardized procedures that will be transparent and understandable.

Precaution and the CPB

Based on the reaffirmation of the precautionary approach contained in Principle 15 of the Rio Declaration on Environment and Development (1992), Articles 10 (para. 6) and 11 (para. 8) of the CPB both state that

- "Lack of scientific certainty due to insufficient relevant scientific information and knowledge regarding the extent of the potential adverse effects of a living modified organism on the conservation and sustainable use of biological diversity in the Party of import, taking also into account risks to human health, shall not prevent that Party from taking a decision, as appropriate, with regard to the import of the living modified organism . . .. in order to avoid or minimize such potential adverse effects".

However, ever since the CPB came into force, government regulators and their technical experts, political activists, and GM product developers have debated this inclusion of the precautionary approach. Disagreements have raged over whether such an approach is a useful tool for managing the risks of biotechnology and its products. Resolving these disputes is made difficult by the lack of a formal, established definition, making it unclear exactly what it means in practical terms and what it requires of governments and innovators. Therefore, governments may act at their discretion to restrict or ban products or activities even before obtaining proof that a harm is imminent, although no obligation to do so seems to be implied in the CPB. This had led opponents of such actions to argue that conversely, such decisions can also jeopardize human health and the environment at large, for example, during the severe food shortage of 2002 in Southern Africa when food aid shipments containing transgenic maize were rejected on the basis of potential harm. Until clarity is forthcoming, this will remain fertile ground for dispute and open for possible abuse.

Process-Based Versus Product-Based Approach

In Europe, as in all Parties of the CPB, a *process-based* regulatory system governs the regulation of GMOs, as the techniques used for their production were considered new and raised specific safety concerns. A GMO is thus mainly characterized by the technique used to produce it, and is defined as an organism in which the genetic material has been altered in a way that does not occur naturally by crossing and/or natural recombination [2]. Directive 2001/18/EC, on the deliberate release of GMOs into the environment, provides a list of techniques in Annexes IA and IB that: (1) result in genetic modification; (2) are not considered to result in genetic modification; or that (3) result in genetic modification, but yield organisms that are excluded from the scope of the Directive [2, 32]. Production techniques falling under the EU GMO definition are:

- Recombinant nucleic acid techniques involving the formation of new combinations of genetic material by the insertion of nucleic acid molecules produced by whatever means outside an organism, into any virus, bacterial plasmid, or other vector system and their incorporation into a host organism in which they do not naturally occur but in which they are capable of continued propagation
- Techniques involving the direct introduction into an organism of heritable material prepared outside the organism including microinjection, macroinjection, and microencapsulation
- Cell fusion (including protoplast fusion) or hybridization techniques where live cells with new combinations of heritable genetic material are formed through the fusion of two or more cells by means of methods that do not occur naturally

In vitro fertilization, natural transformation processes (e.g., conjugation, transduction, transformation), and polyploidy induction are not considered to result in genetic modification and are, therefore, currently excluded from the GMO definition. Techniques of genetic modification yielding organisms that currently are excluded from the GMO definition are mutagenesis and cell fusion of plant cells of organisms which can exchange genetic material through "traditional" production techniques [2].

In the USA and Canada, a *product-based* regulatory approach is followed for the regulation of GMOs [33–35]. Legislation focuses on the risks of products, and not the techniques of production, as genetic modification *per se* is not considered inherently risky. Because the focus is on novel traits or attributes introduced into a plant, rather than the method of

production, both plants and their derived food and feed products are regulated under the existing regulatory system.

Whether legal regimes using production techniques instead of the product itself as a trigger for regulatory oversight provide the best framework for an adequate safety assessment of GMOs is at best debatable. On the one hand, it is questionable whether newly developed crop improvement techniques will outgrow the current EU GMO legislation [36, 37]. On the other hand, it is not intuitively obvious why conventionally bred plants and their derived products are not subject to a similar safety assessment as those obtained through genetic modification [38, 39] or, conversely, why GM plants are regulated more strictly than conventionally bred ones in the EU [40, 41]. With techno-scientific advances and innovations, the knowledge about plant genes and their regulation and functions has increased, while new plant production techniques have emerged to induce or select desired plant characteristics, such as RNA interference and oligonucleotide-mediated mutagenesis (see, e.g., [32, 42–44]). These new techniques may challenge the current regulatory definition of a GMO, because it is not always clear whether the products obtained through these techniques would be captured by, or excluded from, the EU GMO definition [36]. The current EU regulation is therefore heavily reliant upon the need to regularly update the list of techniques and their possible uses; otherwise, it runs the risk of quickly becoming obsolete, as the rate of innovation and advances in the field of biotechnology marches on. In addition, the ability to detect products of such emerging technologies will be severely challenged, and as such, there will need to be a greater emphasis placed on traceability mechanisms for this approach to be practically regulated. In recognition of this, EU Member States and the European Commission are considering recent developments in plant breeding and are discussing if the current EU legalization appropriately covers these new techniques and their application, and whether they should be subject to regulatory requirements. Recently, in an answer to a parliamentary question, the European Commission stated that a specific working group of external experts has been put in place to determine which of the newly developed plant production techniques would result in genetic modification and would thus be captured by, or excluded from, the EU GMO definition (cf., Parliamentary question P-6606/07 2008).

Regulatory Framework for GMOs in the EU

The EU has the most stringent and wide-ranging regulations on GM products and commodities in the world. Their development can be traced back to the aforementioned food safety incidences in the mid-1990s that affected European consumer confidence in government regulatory agencies and agribusiness groups. These concerns have developed to include a negative view of GM products and of the companies that develop and market these products. Furthermore, the ongoing maintenance of trade barriers against agricultural imports in general has resulted in strong political pressure to regulate GM products [45].

The EU regulatory approach is precautionary, process-related, and includes mandatory labeling and traceability requirements for food and feed crops, unprocessed or processed. Only non-food GM products (unseeded), such as textile or other industrial products, are not subject to any requirement.

EU legislation is adopted through a system of interactions between the three main EU institutions: the European Parliament; the Council of the European Union (i.e., representatives of all the EU Member States at the ministerial level); and the European Commission. In most cases, the European Commission initiates legislative proposals that are decided jointly by the Council and the European Parliament; the most common legislative measures are Regulations (acts that are binding in their entirety and are immediately applicable throughout the EU) and Directives (acts that require the modification or establishment of national measures, generally for harmonization purposes). Legislation pertaining to GMOs in the EU is further elaborated below.

Contained Use and Deliberate Release Directives

In the early 1990s, two European Directives for the use of GMOs were adopted: to ensure the protection of human and animal health and the environment; to guarantee consumers' freedom of choice without

misleading consumers/users; and to create an internal market that makes the free movement of GMOs possible within the EU without unequal competition and impediments between and within Member States. Directive 90/219/EEC, which has since been amended by Directive 98/81/EEC, regulated the contained use of GM microorganisms, while Directive 90/220/EEC regulated the deliberate release of GMOs into the environment, covering both the release for research purposes (part B) and for commercial use as or in products (part C). This triad reflects the stepwise process GM crops go through, beginning with experiments under contained use (e.g., laboratory, greenhouse), through experimental release, up to the placing on the market. According to the step-by-step principle, the containment of GMOs can be reduced and the scale of release increased gradually, if assessment of earlier steps indicated that the next step can be taken.

Novel Food Regulation

On 15 May 1997, Regulation (EC) No 258/97 – the so-called *Novel Food Regulation* – removed food products derived from GM plants from the scope of Directive 90/220/EEC on the deliberate release of GMOs into the environment. The new regulation covered risk assessment procedures and the marketing and labeling of all types of novel foods, including those produced by new plant production techniques such as genetic engineering, as well as food without a history of safe use in the EU. Under the Novel Food Regulation, the safety assessment of GM food was based on the principle of *substantial equivalence* between the GM food and its traditionally cultivated non-GM counterpart. The non-GM counterpart was generally taken to have a history of safe use, allowing it to serve as baseline in the comparison of its chemical composition and phenotypic characteristics to those of GM food [46–48].

According to the *labeling provisions* of the Novel Food Regulation, labeling was not required when a GM raw material had been treated technically in such a way that neither the new DNA, nor the protein could be detected in the end product. Since May 1997, processed oil from GM oilseed rape, maize, and cotton, and processed food and food ingredients derived from GM maize have been notified as being substantially equivalent and thus approved for human consumption under the simplified procedure of the Novel Food Regulation. Moreover, labeling did not apply to food already used for human consumption in the EU prior to the establishment of the Novel Food Regulation. Food already marketed, such as GTS40-3-2 soya bean and Bt176 maize, were not considered as novel. With the adoption of Regulations (EC) No 1813/97 and 1139/98, the labeling of GTS40-3-2 soya bean and Bt176 maize foodstuffs also became compulsory. From that moment on, the label literally had to contain the words "produced from GM soya bean" or "produced from GM maize" when the new protein or transgene was detectable in the end product intended for consumption. A final product needed no label when a GM raw material had been technically treated in such a way that neither the new protein nor the transgene could be detected (e.g., hydrolyzed soya bean proteins, refined oils). With Regulation (EC) No 50/2000, the labeling provisions were extended to additives and flavorings that have been genetically modified or that have been produced from a GMO.

Revised Deliberate Release Directive

On 17 October 2002, Directive 2001/18/EC replaced (the older) Directive 90/220/EEC. With it (1) the precautionary principle was explicitly adopted as a guide; (2) risk assessment criteria were broadened to include direct, indirect, immediate, delayed, and cumulative long-term adverse effects; (3) post-market environmental monitoring (PMEM) became compulsory; (4) the need for a common methodology for the environmental risk assessment was established; (5) the requirement of reexamination of risk assessment and management conclusions in light of new scientific evidence was strengthened by limiting the duration of market consents to a maximum of ten years; (6) specific considerations related to the use of antibiotic resistance marker genes were introduced; (7) existing labeling provisions applying to GM food were extended to all marketed products containing GMOs; (8) the general concept of traceability at all stages of commercialization was introduced; (9) transparency in the decision making process was increased; (10) consultation of the public became mandatory in the approval procedure; (11) the possibility to consult an ethics committee was confirmed; and (12) the

implementation of national cultivation registers was required, recording the locations where GM plants have been grown for experimental purposes.

General Food Law and Establishment of the European Food Safety Authority

Adding to Directive 2001/18/EC, Regulation (EC) No 178/2002 – the so-called *General Food Law* – laid down general principles of food law and procedures in food and feed safety. It defines food and feed and other agricultural inputs at the level of primary production, as well as hazard, risk, risk analysis, risk assessment, risk management, and risk communication. Furthermore, the General Food Law sets food and feed safety requirements in order to determine whether any food or feed may be injurious to human and animal health. With this Regulation, the application of the precautionary principle was further extended to risk analysis of all food and feed in the EU, whether of GM-origin or not.

In response to a multiple wave of food crises that caused considerable public concern in Europe about food safety and the ability of regulatory authorities to fully protect consumers, the *European Food Safety Authority* (EFSA) was created as a European-wide risk assessment body. EFSA is tasked: (1) to provide science-based advice at the request of the European Commission on any matter within its mission, or in the framework of Community legislation; (2) to issue scientific advice on its own initiative; and (3) to issue advice upon request of the European Parliament or a Member State on matters falling within its mission (Article 29 of the General Food Law). By providing "independent, objective, and transparent" science-based advice, EFSA aims to ensure a high level of consumer protection and to restore and maintain confidence in the EU food supply.

EFSA has ten Scientific Panels addressing food safety issues in the different sectors of food and feed production, and a Scientific Committee. The EFSA Scientific Panel on Genetically Modified Organisms (EFSA GMO Panel) consists of 21 scientific experts from European research institutes, universities, or risk assessment bodies. The EFSA GMO Panel issues: (1) *scientific opinions* on the safety of GMO market approval dossiers and on national safeguard clauses invoked by Member States; and (2) produces *guidelines* for the risk assessment of GMOs upon request of the European Commission in the framework of Directive 2001/18/EC and Regulation (EC) No 1829/2003. These guidelines provide assistance to those preparing and presenting GMO market applications, by describing principles, concepts, data requirements, and issues to be considered in the frame of risk assessment. So far, the following guidances have been issued:

- Guidance document for the risk assessment of GM plants and derived food and feed (issued in 2004; published in 2006; revised in 2008 and 2011)
- Guidance document for the risk assessment of GM microorganisms and their derived products intended for food and feed use (issued in 2006; revised in 2011)
- Guidance document for the renewal of authorizations of existing GMO products (issued in 2006)
- Guidance document for the risk assessment of GM plants containing stacked transformation events (issued in 2007; replaced by the latest revision of the Guidance document for the risk assessment of GM plants and derived food and feed, see above)
- Guidance for the risk assessment of GM plants used for non-food or non-feed purposes (issued in 2009)
- Guidance on the environmental risk assessment of GM plants (issued in 2010)
- Guidance on selection of comparators for the risk assessment of GM plants (issued in 2011)
- Guidance on the PMEM of GM plants (issued in 2011)

Scientific opinions and reports are also issued on specific risk assessment issues regarding food, feed, and environmental safety related to GMOs, such as: the safety of antibiotic resistance marker genes; the use of animal feeding trials for testing of whole GM food and feed; the statistical analysis of results of field trials; the evaluation of GM plants cultivated for non-food/feed purposes; PMEM; statistical considerations for the safety evaluation of GMOs; and the assessment of allergenicity of GM foods. A scientific opinion on the environmental risk assessment of non-target organisms exposed to GM plants was recently adopted, as well as a scientific opinion on the annual PMEM report on the cultivation of maize MON810 in 2009. The EFSA GMO Panel is continuously considering new scientific

information and recent developments in the field of GMO risk assessment, and as such, it has undertaken several initiatives to incorporate them into its operational procedures (see [49, 50] for further details).

GM Food and Feed Regulation

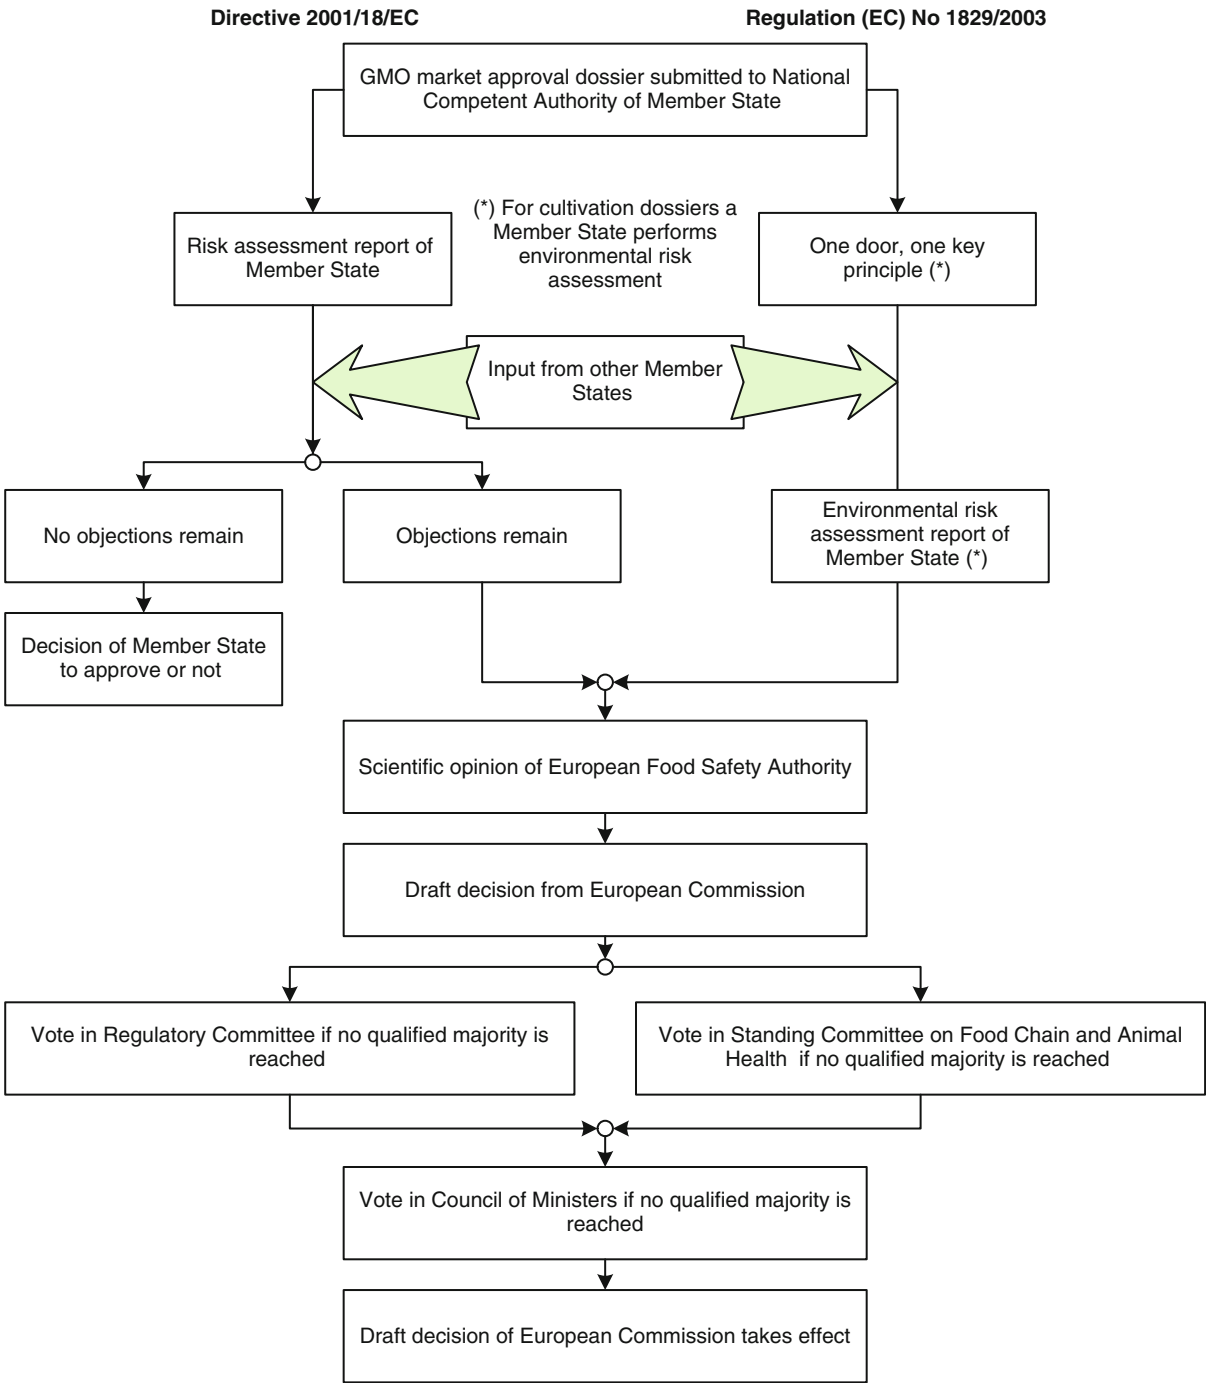
Issued on 18 April 2004, Regulation (EC) No 1829/2003 on GM food and feed covers the commercialization and risk assessment of GM food and feed, such as food/feed containing or consisting of, food/feed produced from, and food/feed containing ingredients produced from GMOs, as well as seed or other plant-propagating material. Prior to this date, approvals for human food use were required under the Novel Food Regulation, whereas feed use was assessed under Directive 2001/18/EC and its predecessor. The amended approval procedure is centralized around EFSA and based on a "*one door – one key*" approach whereby all commercial uses can be covered in the same GM plant market approval dossier. Moreover, it also introduces the need for a GM crop market application to cover both food and feed uses, as it avoids market approval for a single use in case a product is likely to be used for both purposes (e.g., [51]). In response to the heated debates that challenged the "principle of substantial equivalence," the principle was demoted to a "comparative analysis" in the GM Food and Feed Regulation. The safety assessment of GM food and feed remains based on a comparative analysis in which the non-GM counterpart serves as baseline. However, it requires more evidence of safety than before. Since the principle of "substantial equivalence" was intensely criticized by various actors, it was no longer interpreted as the endpoint of risk assessment, but rather as the starting point. Whether GM food is subject to further safety assessment depends on the identified similarities and differences between the GM food and its non-GM counterpart: (1) if substantial equivalence is established, the need for further testing is to be investigated on a case-by-case basis; (2) if substantial equivalence is established, except for a single or few specific traits of GM crops, further tests must be done focusing on these traits in order to assess their potential impact on human and animal health; and (3) if neither partial nor total substantial equivalence is established, the wholesomeness of the food product is to be assessed. In the same line of arguments, the simplified authorization procedure was abandoned under the GM Food and Feed Regulation.

Approval Procedures for placing GM crops on the Market

Procedures for approval of GM crops in the EU follow comitology rules that involve different actors such as the European Commission, EFSA, the Regulatory Committee of Member States representatives under Directive 2001/18/EC, the Standing Committee on the Food Chain and Animal Health (SCFCAH) under Regulation (EC) 1829/2003, and the Councils of Ministers. In principle, the delegation of powers to the European Commission along with the supervision of the European Commission's use of these powers through committees composed of Member States representatives is considered a convenient mechanism. It enables efficient decision making, engenders a close and cooperative working relationship between the European Commission and Member States, and maintains a degree of control over the process by Member States [20]. The voting system is based on the number of votes designated to each of the 27 Member States and is proportional to their percentage of the EU population. A qualified majority should be at least 74% of the total votes (255) *and* 14 Member States *and* 62% of the EU population; a blocking minority is at least 26% of the votes [91] *or* 14 Member States *or* >38% of the EU population [18].

Approved GM products can move freely throughout all EU Member States in conformity with any conditions set out in the approval, and enter into the public register of GM food and feed (Community Register: http://ec.europa.eu/food/dyna/gm_register/index_en.cfm). Authorizations are valid throughout the EU, have a maximum duration of ten years, and can be renewed.

Approval Procedure Under Directive 2001/18/EC
Under Directive 2001/18/EC, the approval procedure for placing a GMO on the market involves all Member States, the European Commission, and possibly EFSA (see Fig. 1). The GM crop market application is first submitted to the National Competent Authority of a Member State. Upon receipt of the application, the National Competent Authority issues a risk



Transgenic Crops, Risk Assessment and Regulatory Framework in the European Union. Figure 1
Approval procedure for placing GM crops on the EU market under Directive 2001/18/EC and Regulation (EC) No 1829/2003 (Figure adapted from EFSA (Parma, Italy) and GHK Consulting Ltd (London, UK))

assessment report that may be favorable or unfavorable regarding market approval of the GMO under consideration. In the event of a favorable opinion, the Member State informs the other Member States via the European Commission. The other Member States and the European Commission examine the risk assessment report and may pose observations and objections.

If there are no objections by other Member States or by the European Commission, the National Competent Authority that carried out the original risk assessment approves the placing on the market of the product, and issues a final approval permitting the marketing of the GMO within the Community.

If objections are raised, the procedure provides for a conciliation phase among the Member States, the European Commission, and the applicant in order to resolve the outstanding questions. In case objections are maintained at the end of the conciliation phase, a Decision is taken at EU level. The European Commission first asks the scientific opinion of the EFSA GMO Panel on the safety of the GMO in question. In the case of EFSA issuing a positive opinion, the European Commission presents a Draft Decision to the Regulatory Committee under Directive 2001/18/EC for an opinion. If the Regulatory Committee gives a favorable opinion by qualified majority, the European Commission adopts the Decision. If not, the Draft Decision is submitted to the Council of Ministers for adoption or rejection by qualified majority. If the Council does not act within three months, the European Commission adopts the draft Decision.

Approval Procedure Under the GM Food and Feed Regulation Under the GM food and feed Regulation, a GM crop market application is submitted to the National Competent Authority of a Member State, which forwards it to EFSA. If the application covers the use of seeds or other plant-propagating material for cultivation, EFSA asks a National Competent Authority under Directive 2001/18/EC to perform the environmental risk assessment that will be considered by EFSA during its final assessment (see e.g., [52]).

From the receipt of a valid GM crop market application, EFSA endeavors to deliver its scientific opinion within a time limit of six months. This time limit can be extended if EFSA or the Commission's Community Reference Laboratory seeks supplementary information from the applicant. Within three months after receiving EFSA's scientific opinion, the European Commission submits a Draft Decision to the SCFCAH. If SCFCAH gives a favorable opinion by qualified majority, the European Commission adopts the Decision. If not, the Draft Decision is submitted to the Council of Ministers for adoption or rejection by qualified majority. If the Council does not act within three months or does not obtain a qualifying majority for adoption or rejection of the Commission Draft Decision, the European Commission adopts the Decision (see Fig. 1).

Labeling and Traceability Regulation

Regulation (EC) No 1830/2003 on the labeling and traceability of GM food and feed complements, clarifies, and makes operational some of the labeling and traceability objectives of previous legislation. This Regulation extended labeling provisions to feed, seed, bulk products, food that are delivered as such to the final consumers or mass caterers, and to products in which GMO-derived DNA or protein (e.g., refined oils) is no longer detectable. These requirements go further than previously, because the use of genetic modification in itself is now sufficient to justify labeling. The label must be shown in a clearly visible, legible, and indelible manner, and must contain the reference "genetically modified," "produced from genetically modified" or "contains genetically modified." When a GM food or feed is different from its conventional counterpart, the label must also provide information about any characteristic or property that renders it different. When there is no conventional counterpart, the label must contain appropriate information about the nature and characteristics of the GM food or feed. Any characteristic or property that gives rise to ethical or even religious concerns also has to be mentioned. Products being produced with the help of GMOs – rather than actually made out of them – do not require labeling. As such, meat, eggs, milk, and dairy products from animals fed GM crops fall outside the remit of labeling provisions. Since substances assisting in food production, carrier substances, or culture media for microorganisms are not considered foods, their labeling is not considered necessary.

Labeling Thresholds

Tolerance thresholds for the unintentional or technically unavoidable presence of approved GM material in non-GM products were established in the EU. A tolerance threshold refers to the maximum admixture level for GMO content under which the comingled product does not have to be labeled as containing a GMO. It is often argued that there is no scientific justification for the established thresholds. Since GM crops and derived food and feed products are declared safe before marketing, thresholds do not relate to safety or health issues. However, thresholds reflect a balance between differently framed societal concerns and requests and technical capabilities. The translation of labeling thresholds in practice still entails enormous technical and scientific challenges.

Regulation (EC) No 49/2000 set the labeling threshold for the adventitious GMO presence in non-GM food at 1% of the food ingredient. The GM Food and Feed Regulation decreased the tolerance threshold to 0.9%, and extended it to feed and products intended for direct processing. There is zero tolerance in the EU concerning unapproved GM plant events, unless they had previously received a favorable scientific risk assessment for marketing from EFSA and a detection method is publicly available. In the latter case, a threshold of 0.5% may be applied transitionally. A threshold has yet to be defined for seeds as discussions have remained at an impasse. Possible thresholds that will be proposed for seeds will be established at levels such that the GMO content of 0.9% can be guaranteed in food, feed, or crops. Proposals made by the Scientific Committee on Plants in 2001 ranged between 0.3% for cross-pollinating crops, and 0.5% for self-pollinating and vegetatively propagated crops [53]. As no such thresholds have been established to date, any seed lot containing authorized GM seed for cultivation in the EU has to be labeled as containing GM material.

Organic growers principally aim at keeping their products free from any GM material. Regulation (EC) No 1804/1999 on organic production of agricultural products states that the use of GMOs is not compatible with the organic production method. The Regulation, however, foresees a *de minimis* tolerance threshold for the unavoidable presence of GM material in organic products. It was thus anticipated that organic producers would opt for a tolerance threshold ranging between the limit of quantification of a DNA analysis (0.1%) and the tolerance threshold for food and feed products (0.9%). In a press release published on 21 December 2005 (IP/05/1679), the European Commission emphasized that an organic product with an adventitious content of GM material below 0.9% could still be labeled as organic. On 12 June 2007, this point of view was confirmed at a meeting of the EU agriculture ministers, where political agreement was reached on a new Regulation on organic production and labeling (IP/07/807). However, in its recent recommendation on guidelines for the development of national coexistence measures to avoid the unintended presence of GMOs in conventional and organic crops [23], the European Commission allows Member States to aim at levels of unintended GMO presence that are *lower* than the 0.9% labeling threshold in certain cases. It stated that

- "The potential loss of income for organic and some conventional producers (e.g., certain food producers) may be due to the presence of GMO traces at levels lower than 0.9%. In those cases, and in the interest of protecting particular types of production, concerned Member States may define measures that aim at reaching levels of presence of GMOs in other crops lower than 0.9%".

In this respect, the European Commission referred to Member States that have developed national standards for different types of "GM-free labeling" [23]. Since the organic sector advocates that GM crops are not compatible with organic farming [54, 55], they will seek to establish the limit of DNA quantification analysis as the basis to determine the tolerance threshold in organic products.

Coexistence

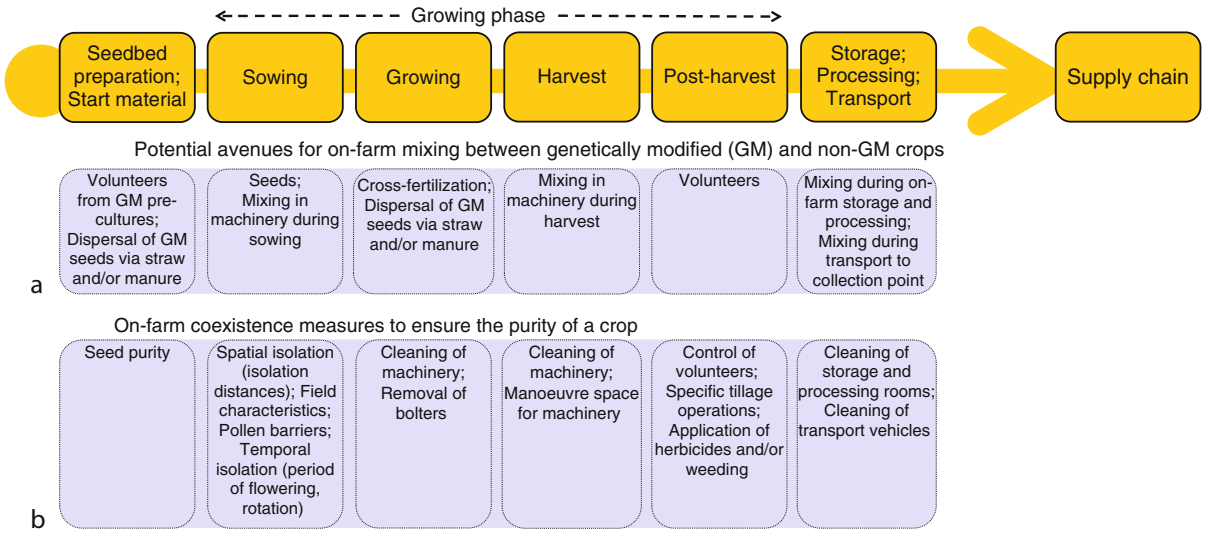
In order to provide a high degree of consumers' choice in the EU, a coexistence policy was adopted to maintain different agricultural production systems. It specifically aimed to enable the side-by-side development of different cropping systems without excluding any agricultural option. In this way, farmers would maintain their ability to make a practical choice between

conventional, organic, and GM crops. Since coexistence only applies to approved GM crops that were judged to be safe before their market entry [56], safety issues fall outside the remit of coexistence [57–59].

The European Commission recognized that completely avoiding the unintentional presence of GM material in non-GM products is difficult in the agricultural context [23, 60]. As agriculture is an open system, a certain amount of adventitious mixing is unavoidable. Various sources have been identified that could contribute to on-farm adventitious mixing between GM and non-GM crops (Fig. 2): (1) the use of impure seed [61, 62]; (2) cross-fertilization due to pollen flow between neighboring fields [63–65]; (3) the occurrence of volunteer plants originating from seeds and/or vegetative plant parts from previous GM crops [66–69]; (4) mixing of plant material in machinery during sowing, harvest, and/or postharvest operations [51]; and – to a lesser extent – (5) cross-fertilization from certain sexually compatible wild relatives and feral plants [70–72]. As completely avoiding admixing is difficult in the agricultural context, tolerance thresholds were established for the unintentional or technically unavoidable presence of approved GM material in non-GM products. If the content of GM material in a non-GM product exceeds the established tolerance threshold of 0.9%, the product has to be labeled as containing GM material, which may affect its market acceptability.

According to Article 43 of the GM Food and Feed Regulation, Member States are empowered to take appropriate measures to avoid the unintentional presence of GM material in other products. There are principally two strategies Member States have established, or are developing, to warrant coexistence of different cropping systems: *ex ante* regulations; and *ex post* liability schemes [23, 73–75]. Regulations are considered *ex ante* if they have to be followed by GM crop adopters while growing GM crops. *Ex ante* regulations prescribe preventive on-farm measures that should ensure that tolerance thresholds are not exceeded in neighboring non-GM agricultural production systems. Contrary to *ex ante* coexistence regulations, *ex post* liability schemes are backward looking: they cover questions of liability and the requirement to redress the incurred economic harm once adventitious mixing in a non-GM product has occurred after the cultivation of GM crops [59].

For decades, seed production regulations have specified statutory segregation measures (so-called identity preservation measures) between seed crops and conventional crop production of the same species to



Transgenic Crops, Risk Assessment and Regulatory Framework in the European Union. Figure 2
(**a**) Potential avenues for on-farm adventitious mixing between GM and non-GM crops and (**b**) on-farm coexistence measures to ensure the purity of a crop during the production process (Figure reprinted from [59])

maximize varietal seed purity. Apart from seed production, experience with identity preservation systems is also available from the cultivation of different crop types grown for different uses [76]. Several of the proposed measures to ensure varietal seed and crop purity can be applied within the context of coexistence to limit the adventitious content of GM material in seeds and plant products. These measures include: (1) the use of certified seed; (2) spatially isolating fields of the same crop; (3) implementing pollen barriers around fields; (4) scheduling different sowing and flowering periods; (5) limiting carryover of GM volunteers into the following crop through the extension of cropping intervals; (6) cleaning agricultural machinery and transport vehicles of seed remnants; (7) controlling volunteers and wild relatives; (8) applying effective postharvest tillage operations; (9) retaining records of field history; and (10) the voluntary clustering of fields (Fig. 2). If Member States can demonstrate that the aforementioned preventive coexistence measures are not sufficient to achieve the desirable levels of purity, the European Commission gives those Member States the possibility "to exclude GMO cultivation from large areas of their territory" [23].

The European Coexistence Bureau (ECoB) recently issued a report on best practices to ensure the coexistence between maize cropping systems. Based on a comprehensive assessment of data generated in field experiments, commercial cultivation of GM maize, as well as modeling exercises under European environmental conditions, the report describes best management practices that can be put in place for each potential source of admixture [77]. It is important to realize that the level of containment needed to ensure coexistence will mainly be driven by the established tolerance thresholds: the lower the tolerance threshold, the stricter the on-farm measures needed to meet labeling requirements. Apart from defining the level of containment needed, tolerance thresholds also determine the level of GM material that initiates the need to redress economic harm due to adventitious mixing. The adventitious presence of GM material above the tolerance threshold set out in EU legislation triggers the need for the product that was intended to be a non-GM product, to be labeled as containing GMOs. In other words, the product has to be labeled as containing GMOs only in cases when the established threshold is exceeded. According to the European Commission,

- "The presence of GM material in food and feed has an economic effect only when it exceeds the 0.9% labelling thresholds", but as mentioned previously, "Member States can aim at levels of unintended GMO presence that are lowerthan the 0.9% labelling threshold in cases where the potential loss of income of organic and some conventional producers may be due to the presence of GMO traces at levels lower than 0.9%" [23].

In its Communication to the Council and the European Parliament from 2003, the European Commission has clearly emphasized that coexistence measures should not go beyond what is necessary to ensure that the unintentional presence of GM material in non-GM products remains below established labeling thresholds, and thus should be proportionate to the objective that is pursued. This point was reiterated in its 2010 coexistence recommendation [23], in which the European Commission stated that

- "Coexistence measures should avoid any necessary burden for farmers, seed producers, cooperatives and other operators associated with any production type". Moreover, it argued that "the choice of measures should take into account the regional and local constraints and characteristics, such as the shape and size of fields in a region, the fragmentation and geographical dispersion of fields belonging to individual farms and regional farm management practices".

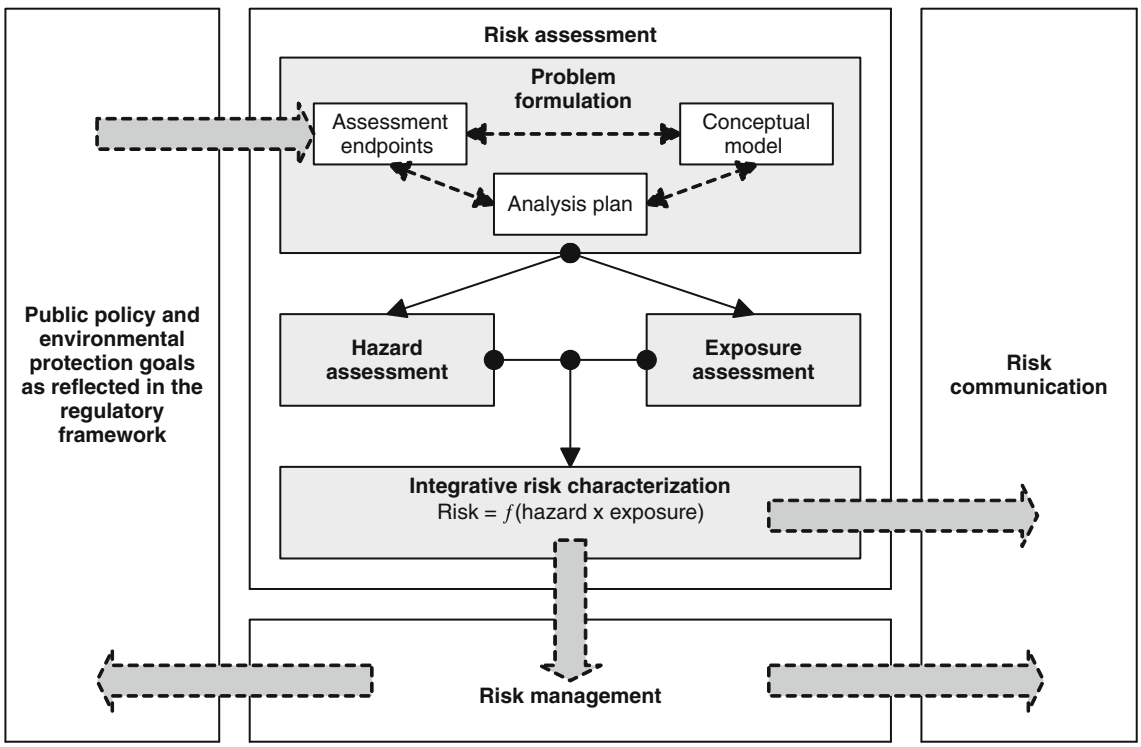
While some Member States have taken this advice into account for most conventional producers, others decided to propose or adopt measures that aim at keeping the amount of GM material present in conventional products as low as possible. In some cases, proposed measures, such as large and fixed isolation distances between fields of GM and conventional crops, appear to entail greater efforts for GM growers than necessary, which raises questions about the proportionality of these measures. Several authors have argued that wide and fixed isolation distances, as currently proposed by several Member States, fail to satisfy several challenges [58, 59, 78–85]. First, they are excessive from a scientific point of view; second, they are difficult to implement in practice; third, they are inconsistent with regional heterogeneity of farming; and fourth, they are not proportional to the economic incentives for coexistence. To enable regionally and

economically proportionate coexistence, policy makers should allow integrating flexibility in *ex ante* coexistence regulations. This might be achieved by allowing plural coexistence measures that are adaptable to local farming and cropping conditions, and that are negotiable amongst farmers. Computer-based decision support tools may thereby play a crucial role in the future case-by-case-based coexistence approach, as they allow the prediction of achievable levels of coexistence between neighboring maize fields under various conditions. One caveat here is that policy makers may be reluctant to adopt such a case-by-case coexistence approach because of the difficulties of implementation.

Risk Assessment Principles

Interplay of Risk Assessment, Risk Management, and Risk Communication

GMOs and their derived food and feed products are generally subject to a risk analysis before they can be commercialized [49, 86]. In the EU, the risk analysis consists of three components: risk assessment, risk management, and risk communication (Fig. 3). In risk assessment, potential adverse impacts associated with a specific activity are scientifically characterized on a case-by-case basis, while in risk management, policy alternatives to accept, minimize, or reduce the characterized risks are weighed and, if needed, appropriate prevention and control options are selected. Because risk managers and regulators rely on risk assessments to make an informed decision on whether or not to approve a certain use of a GM plant, it should explain clearly what assumptions have been made during the risk assessment, and what is the nature and magnitude of uncertainties associated with the characterized risks. The decision whether a certain risk is acceptable and/or tolerable under a particular set of conditions is not part of the risk assessment itself, but part of the wider risk analysis, as this choice is not only based on scientific criteria, but also involves political, social, cultural, and economic



Transgenic Crops, Risk Assessment and Regulatory Framework in the European Union. Figure 3
Risk analysis: The diagram depicts the main components of risk analysis, together with the successive steps comprising the environmental risk assessment of GM plants (Figure reprinted from [50])

considerations. Risk management is also functionally and temporally separate from risk assessment in order to reduce any conflict of interest and to protect the scientific integrity of risk assessment [5]. Risk communication is defined as an interactive exchange of information and opinions on risk throughout risk analysis, between risk assessors, risk managers, and other interested parties. It includes the explanation of risk assessment findings and of the basis upon which risk management decisions are made [87].

Even though there are considerable differences in regulatory requirements for GM crops between countries, environmental priorities (including the preservation of biodiversity) as well as risk terminology, most risk assessments of GM crops follow a science-based assessment process that estimates the level of risk through comparison with a non-GM counterpart [49, 88]. In addition, regulatory requirements involve the consideration of a range of issues relevant to the overall risk assessment in order to determine the impact of the GM crop on human/animal health and the environment relative to the non-GM crop, and thus its relative safety [89, 90]. Some of these elements are discussed in the next sections.

Risk Assessment Methodology and Terminology

Despite the considerable variation among risk assessment frameworks for GM plants, risk assessment generally comprises several sequential steps: (1) problem formulation as a critical first step (including hazard identification); (2) hazard characterization, that examines potential hazards and their magnitude; (3) exposure characterization, that covers levels and likelihood of exposure; and (4) integrative risk characterization, in which the magnitude of consequences and the likelihood of occurrence are integrated (Fig. 3). In the EU, the guidance notes supplementing Annex II of Directive 2001/18/EC on the principles for the environmental risk assessment requires the definition of mitigation measures as a fifth step in the environmental risk assessment in order to manage identified risks. These mitigation measures aim to reduce the identified risks associated with GMO deployment to an acceptable level and should consider defined areas of uncertainty. Accordingly, any proposed mitigation measure is considered for the evaluation of the overall risk of GMO deployment.

Various single risk assessment studies have postulated dire risks when all they have done is characterized either a hazard associated with the use of GM crops, or an exposure to the GM crop without demonstrating whether this exposure is hazardous [5]. These studies confuse hazard or exposure with risk. In this way, they only allow speculative conclusions and contribute to uncertainties in the environmental risk assessment process. Moreover, it is important to distinguish risk from hazard, as the terms have different meanings. The term hazard is associated with the potential of an agent or situation to cause adverse effects or harm. It refers to an inherent property of that agent or situation. Risk is recognized as a function of the probability and severity (magnitude) of an adverse effect occurring to human and animal health or the environment, following exposure to a hazard under defined conditions. Without hazard, there can be no harm and thus no risk.

Problem Formulation (Including Scoping and Planning)

In order to identify the areas of greatest concern or uncertainty related to risks, each risk assessment begins with the identification and formulation of the problem, usually in the context of regulatory decision making [91]. In this respect, the most important questions to be solved and meriting detailed risk characterization are identified [92].

Problem formulation involves: (1) the identification of characteristics of the GM crop capable of causing potential adverse effects to the environment (hazards) together with (2) the identification of pathways of exposure through which the GM crop may adversely affect the environment. This process comprises a qualitative description of the nature of potential adverse effects and its potential triggers, as well as of plausible exposure pathways to the GM crop that might result in environmental harm. Problem formulation also involves: (3) the definition of assessment endpoints, which are explicit and unambiguous targets for protection extracted from legislation and public policy goals; and (4) outlining specific hypotheses to guide the generation and evaluation of data in the subsequent successive risk assessment steps. It involves the development of a methodology – through a conceptual model and analysis plan – that will help

to direct the risk characterization and to produce information that will be relevant for regulatory decision making [92–96]. In this way, problem formulation helps to make the risk assessment process comprehensive and transparent by summarizing existing scientific knowledge and explicitly stating the assumptions and principles underlying the risk assessment. Information considered in problem formulation, comprising existing knowledge of the GM crop and its interactions with the receiving environment, takes many forms. It includes published scientific literature, expert opinions, and research data. Data generated to characterize the GM crop during product development by applicants, and subsequently submitted to regulatory authorities as part of GM crop market application also provide an important source of information considered in the frame of problem formulation. Data to support problem formulation can derive from molecular, compositional, and agronomic/phenotypic analyses performed during GM crop development. Information of this type is frequently available in advance of the environmental risk assessment in order to characterize the GM crop [97–101]. If the level and quality of the available information is high, then the risk assessment can reduce the number of risk hypotheses that need to be tested for risk characterization [94, 95].

Hazard Identification: Characterization of the GM Crop Problem formulation starts with the precise characterization of the GM crop in order to identify potential hazards. This is usually achieved through a comparative safety assessment. A comparison of the characteristics of the GM plant with those of its non-GM counterpart enables the identification of similarities and differences between the two. It enables the characterization of intended differences that were the target of the genetic modification, as well as the identification of unintended differences that may lead to harm [97–101]. The identification of differences in problem formulation is considered of primary importance, because it will direct the subsequent course of actions in the risk assessment [92, 102]. While some differences may be deemed irrelevant to the assessment, others may be meaningful in terms of posing harm to the environment or to human and animal health. Should meaningful differences be identified, the risk that they pose must be evaluated, together with those of the intended modifications, such that an evaluation of their possible biological/ecological relevance can be made (requiring them to be directly linked to those aspects of the environment that are legally protected from harm – see below).

From Protection Goals to Assessment Endpoints A crucial step in problem formulation is to identify aspects of the environment (e.g., valued entity, ecosystem service/function) that need to be protected from harm according to protection goals set out in existing EU legislation, and to translate those into concrete measurable phenomena. Risk assessors need to know *what* to protect, *where* to protect it, and over *what time period*. Usually, aspects of the environment to be protected can be divided into two discrete but interconnected categories: the protection of biodiversity (biodiversity conservation), and the protection of functions/services provided by ecosystems. Ecosystem *services* are distinct from ecosystem *functions* by virtue of the fact that humans, rather than other species, benefit directly from these natural assets and processes. The benefits to humans are many and varied; however, those ecosystem services relevant in an agricultural context include food and feed production, pollination, pest regulation, decomposition of organic matter, soil nutrient cycling, soil structure and formation, water regulation and purification, and cultural services (such as aesthetic value and recreation). The precise relationship between biotic and abiotic processes and the ecosystem functions they drive is an area of considerable scientific debate. Some species contribute to ecosystem functioning in ways that are unique and hence their addition or loss from a community would cause detectable changes in functioning. Most ecosystems, however, exhibit functional redundancy, where several species are able to perform the same critical function. These species are at least partly substitutable and their loss can be compensated for by other species.

The challenge to problem formulation is that, in EU legislation, protection goals are general concepts that are defined in broad terms, which often are too vague to be scientifically useful in the frame of environmental risk assessments of GM crops. Moreover, a broad array and diversity of protection goals are mentioned in EU legislation. The resultant interpretation is that

everything should be protected, everywhere, all of the time. However, to be useful in terms of ecological risks and decision making, it is important that general and broadly defined protection goals are translated into concise and concrete measurable assessment endpoints. If the protection of biodiversity is a public policy goal, then a typical assessment endpoint can be the abundance and species richness of certain groups of organisms at a relevant life stage within a landscape or region over a specific time period [102]. Assessment endpoints represent aspects of the environment to be protected and that can be assessed: they are defined by the valued attribute and/or function (e.g., control of arthropod pest populations) of an ecological entity (e.g., arthropod natural enemies) that could be affected adversely by the GM crop and that requires protection from harm [103]. It is not an abstract goal such as ecosystem health or sustainability, but a real, operationally definable property of an aspect of the environment that reflects management or protection goals laid down in EU legislation. Because arthropod natural enemies fulfill relevant ecological services by contributing to the natural regulation of arthropod pest populations within crop fields, they can be identified as the entity to be preserved; similarly, the biological control functions they perform can be identified as the attribute/function (e.g., [104]). It is important that assessment endpoints are defined as far as possible using measurable criteria relevant to the case under study, such that any change in these endpoints can be readily identified. Moreover, assessment endpoints should ideally be selected based on: relevancy to the protection goal; ecological relevance; susceptibility to the potential stressor; and practicality [105].

Once assessment endpoints have been set, the level of environmental protection to be maintained, or the environmental quality to be preserved, needs to be defined. This process includes establishing the *harmful effect* and both the *spatial* and the *temporal scales* relevant for the ecological entity and its attribute/function to be preserved (Table 1). The harmful effect describes to what extent the environmental quality should be preserved (or above what threshold a difference between the GM crop and its appropriate comparator may lead to harm and would be considered a disturbance in environmental quality). For the conservation of biodiversity, a relevant decrease in abundance of protected or valued species can be seen as a harmful change. Similarly, for ecosystem services, a relevant disturbance in ecological function can be seen as a harmful change [106]. The spatial and temporal scales are the habitats in which, and the period during which, environmental quality should be preserved, respectively [104, 107].

Transgenic Crops, Risk Assessment and Regulatory Framework in the European Union. Table 1 Criteria to operationalise protection goals[a]

Criterion	Measurable variable
Ecological entity	Species of conservation concern; ecosystem service
Attribute	Abundance; ecological function
Unit of protection	Individual; population; community; functional group; assemblage; guild
Harmful effect	Relevant decrease in abundance; relevant disturbance in ecological function
Spatial scale of effect	Field; field margin; other agricultural land; non-agricultural habitats; landscape
Temporal scale of effect	Generations; days; weeks; months; seasons; years

[a]Table adapted from the stakeholders' workshop "Protection goals for environmental risk assessment of pesticides: what and where to protect?" organized by the EFSA Panel on Plant Protection Products and their Residues (PPR) (http://www.efsa.europa.eu/en/scdocs/scdoc/1672.htm); see also [108, 134]

Conceptual Model: Exposure Profiles and Hypotheses The conceptual model describes the consequential exposure scenario of how harm to the assessment endpoint may arise from GM crop deployment and allows for a characterization of risks. Key relationships are described: between the GM crop and the valued entity to be protected from harm; pathways of exposure through which the GM crop may affect the valued entity either directly or indirectly (= exposure profile); and any potential impact of the GM crop to the environment [92, 96]. The conceptual model includes available information on: the nature of the stressor; its intended uses; reasonable exposure profiles; and potential responses of the

assessment endpoint as a result of exposure. It can take an array of forms, from the simplest of statements to complex flowcharts and diagrams.

Environmental pathways and levels of exposure will vary depending upon the intended uses of a GM crop, such as import, processing, food, feed, and/or cultivation. In the case where the use of GM plants does not include cultivation in the EU, problem formulation will consider exposure: (1) via accidental release of propagules, such as seeds of the imported commodity spilled into the environment during transportation and processing, potentially leading to sporadic feral GM plants; (2) indirect exposure through manure and feces from the gastrointestinal tracts of animals mainly fed the GM crop; and/or (3) manure or organic plant matter either imported as a fertilizer or soil amendment or derived from other byproducts of industrial processes. In the case where the GM crop use includes cultivation in the EU, problem formulation will consider exposure resulting from the expected cultivation in the receiving environment.

A well-structured conceptual model in which the components of the system are detailed will allow the identification and formulation of relevant hypotheses that arise from the consideration of potentially significant risks. These hypotheses are necessary to make assumptions and predictions about how a stressor or identified difference in the GM plant could affect and pose harm to an assessment endpoint [94, 95]. Importantly, within the analysis phase, hypotheses amenable to testing and corroboration are defined [92] which further guide the methodological approach taken to evaluate the magnitude of harm [92, 102].

Analysis Plan: Statistical Considerations and Experimental Design The last step of problem formulation comprises an analysis plan in which decisions are made about the most appropriate way to measure the response of each assessment endpoint to GM crop deployment. In this planning phase, approaches are delineated for the generation and evaluation of requisite data, in order to test hypotheses formulated in the conceptual model. Reasonable scenarios are placed in an analysis plan by describing and selecting: (1) the various measures to be used (measurement endpoints) in the assessment and subsequent risk characterization; and (2) the description of methods and criteria for measurement.

The measurement endpoints, derived directly from the assessment endpoints, define the indicator of change that will actually be recorded as part of a comparative risk assessment study [107], and usually constitute estimates of *exposure* or *hazard*. Measures of exposure cover properties of the GM crop and are described in terms of the route, frequency, duration, and intensity of exposure relative to the valued entity [92], while measures of hazard represent the measurable change to the valued entity in response to a changed attribute (e.g., transgenic protein) of the GM crop to which it is exposed [107]. Measures of hazard may be an acute lethal concentration resulting in the death of 50% of the organisms tested (LC_{50}), or a chronic *no observable adverse effect level* (NOAEL) measured for the valued entity [92]. How exposure measurement relates to the hazard measurement is described in the risk formulation.

Once specific measurement endpoints are chosen and given a priority, appropriate methods and criteria of measurement are selected and described in the analysis plan [93]. This includes information on: studies to be conducted; the appropriate tier for analysis; the design of protocols; and statistical power [96, 102, 106, 107, 109, 110]. The selection and prioritizing of measures to be used and testing needed enable the allocation of appropriate human and financial resources [111], so that only essential data for risk characterization are collected [94].

It is important to realize that for practical reasons not all potentially exposed non-target organisms can be tested for regulatory purposes [102]. Therefore, it is necessary to select an appropriate subset of species that can be tested effectively under laboratory conditions [102], or that are available in sufficient numbers in the field to give statistically meaningful results [96, 112–115]. This selection of species is based on several criteria, comprising: ecological relevance of the species; the likely exposure of the species to the GM crop; species susceptibility to known or potential stressors; the anthropocentric value of the species; and species testability [96, 102, 113, 116]. The environmental risk assessment may also consider species with special aesthetic or cultural values, or species of conservation importance and that are classified as threatened or endangered, although these are unlikely to be tested directly but substituted by a surrogate species in tests. The number

and type of species that are to be tested will depend upon the hypotheses generated during the conceptual model.

Once assessment and measurement endpoints have been set and approaches have been delineated for the generation and evaluation of requisite data to test hypotheses formulated during problem formulation, the level of environmental change that constitutes harm is to be set through *limits of concern*. These limits of concern define the minimum relevant ecological effect that is deemed of sufficient magnitude to cause harm, and is therefore biologically significant. Limits of concern are directly related to the type of studies that are to be performed either in the laboratory or in the (semi)-field. For laboratory studies, limits of concern are conservative trigger values which, if exceeded, will indicate potential risks and the need for exposure assessments and determination of field scale effects. For field studies, the lower limit, which corresponds for example to a decrease in the abundance of a particular species in the presence of the GM plant relative to that for its appropriate comparator, will usually be defined by the threshold effect deemed to be of just sufficient magnitude to cause environmental harm [106]. Knowing in advance what effect size is to be determined is crucial, as this information will enable to design the study in a way that it has sufficient statistical power to detect the anticipated effect. Limits of concern are estimated from literature data, modelling, and existing knowledge, and may be based on political, social, cultural and economic considerations. To define the minimum relevant ecological effect that is deemed biologically significant and that is deemed of sufficient magnitude to cause harm, it is important that (sets of) limits of concern for each assessment endpoint are set. Usually, the lower limit, which corresponds for example to a decrease in the abundance of a particular species in the presence of the GM crop relative to that for the non-GM counterpart, will be defined by the threshold effect that was deemed to be of just sufficient magnitude to cause environmental harm [106]. If these limits are exceeded, then detailed quantitative modeling of exposure may be required to scale up effects at the field level, both temporally and spatially. For studies in environment(s) that are controlled, the limits of concern will usually be trigger values which, if exceeded, will either lead to conclusions on risks or the need for further assessment in field [106]. Limits of concern can be defined by, for example, literature data, modeling, existing knowledge and policy goals. Ideally, these limits should be set by risk managers, as they will describe the extent of impact tolerated on a protection goal resulting from GM crop market approvals.

Conclusion Problem formulation is the crucial starting point for risk assessments, as it enables a structured, logical approach to detecting potential risks. Having a properly constructed analysis plan based on a conceptual model that is clearly linked to assessment endpoints helps to guide the collection of data that are relevant to investigating the possible safety of a GM crop. Moreover, it helps the risk assessment process to be comprehensive (by summarizing existing knowledge of the system under study) and transparent (by explicitly stating significant assumptions underlying the risk assessment, and ultimately regulatory decision making). In contrast, poor problem formulation can lead to the collection of data that are either unnecessary, superfluous, or irrelevant, diverting time and efforts from the more serious of the identified risks, thereby slowing down the procedure and increasing associated costs [90, 92, 94, 95, 117].

Risk Assessment Concepts and Approaches

Several concepts and approaches are considered during the risk assessment of GM crops. Risk assessment of GM crops: (1) is science-based, where quantitative information is available, and uses qualitative information in the form of expert judgment; (2) uses a comparative approach; (3) is case specific; (4) is iterative and, in a transparent manner, examines previous conclusions in light of new information; and (5) follows a tiered approach.

Science-Based Assessment

The evaluation of potential adverse effects is based on scientific and technical data, and on common methodology for the identification, gathering, and interpretation of relevant data.

Comparative Safety Assessment and Familiarity Concept

The risk assessment strategy for GM crops seeks to use appropriate methods to compare a GM crop

with its non-GM counterpart. The importance of risks posed by a GM crop is placed in the context of risks posed by its non-GM counterpart. A two-step approach is followed, starting with the identification of possible differences between the GM and non-GM counterpart (= proof of difference); which is then followed by the assessment of the environmental and food/feed consequences of any identified differences (= proof of equivalence) (see [106] for further details). The proof of difference approach verifies whether the GM crop is different from its non-GM counterpart, and may lead to the characterization of a potential risk depending on the type of the identified difference, and the extent and pattern of its exposure. The proof of equivalence approach aims to verify whether the GM crop is equivalent to its non-GM counterpart within bounds defined by so-called limits of concern. The two approaches are complementary: statistically significant differences may point to biological changes caused by the genetic modification, but these may or may not be relevant from the viewpoint of environmental harm [106, 118].

For the *food/feed safety assessment*, the equivalence test involves a comparison of the GM crop with a selection of non-GM counterparts, such as commercial varieties, aiming to identify any values of the GM crop that lie within the range of values from natural variation (i.e., observed among the set of non-GM counterparts included in the trial). The underlying assumption is that traditionally bred plants have a history of safe use for the consumer or animals and the environment, and familiarity for the consumer. For the *environmental risk assessment*, conventional cropping systems are not characterized as having a history of safe use, therefore, a near-isogenic conventional counterpart is used to identify any differences with the GM crop which might result in environmental harm. However, in any agricultural system, environmental impact critically depends upon crop management practices, such as the application of pesticides, environmental stewardship, and any mitigation measures adopted. Hence, the characterization of management regimes is an integral part of the definition of whatever comparator is chosen for the environmental risk assessment of GM crops [106].

The concept of familiarity is based on the fact that most GM crops are developed from more traditionally bred crops, the biology of which is well known. The knowledge about the non-GM crop, gained through experience over time, can therefore be used in a risk assessment to establish differences associated with the genetic modification and the subsequent management of the GM crop. According to the Organisation for Economic Co-operation and Development (OECD), familiarity is derived from the knowledge and experience available from conducting a risk analysis prior to the scale-up of any new crop variety in a particular environment, and from previous GM crop market applications for similar constructs and traits in similar or different crops [119]. However, it is important to bear in mind that familiarity is not an endpoint in risk assessment and does not necessarily equate to safety. If differences between the GM crop and its appropriate comparator have been identified, it needs to be determined whether these differences have any significance for the assessment endpoint under consideration.

The comparative safety assessment is usually based on data from three different sources: molecular, compositional, and agronomic/phenotypic analyses. The molecular characterization includes a precise characterization of the inserted DNA, information on which genes are expressed in the GM crop, and evidence that no detectable unintended effects have occurred because of the insertion [86]. Agronomic, phenotypic, and compositional data collected from field trials carried out in a range of agricultural environments that are typical of the place where the crop is grown will highlight whether the GM crop is equivalent in its functional properties to the non-GM counterpart and, in particular, how stable they are from year to year and across environments.

Molecular Characterization In an environmental risk assessment, molecular characterization data can be used to test the hypothesis that the inserted DNA does not disrupt endogenous plant genes, or trigger the production of new proteins/metabolites (other than the intended ones). If any endogenous plant genes were disrupted, rearranged, or overexpressed, these differences would be considered as unintended effects of the genetic modification, and would be further

assessed to determine the biological significance thereof. A variety of data and information is therefore necessary as no individual test can detect all possible unintended effects or identify, with certainty, those relevant to human health or environmental impact. Specifically, detailed information is usually required on: the source of the donor DNA; the transformation method; the organization of the inserted DNA at the insertion site(s); and on the expression and stability of the insert. Information concerning vector construction and the transformation method employed, as well as on all known gene regulatory elements and coding sequences is also relevant. Many authorities require the modification system to be mapped to a degree consistent with available technology, usually to the level of base sequence. An evaluation of whether the transgenes behave similarly to endogenous plant genes in their stability and inheritance between generations is also carried out. Hence, a risk assessment would have to be conducted to determine whether any detected unintended effects could result in potential adverse effects on human or animal health and the environment [100, 101]. Notably, insertional effects (intended or otherwise) are related to the specific transformation event, and not to the function of the inserted transgene; therefore, as with random mutation, most unintended changes caused by deliberate insertions of genetic material will be, at best, neutral to the plant. It is extremely rare for a significant improvement in ecological fitness or substantial compositional changes to result [120].

Compositional Analysis Compositional analyses enable the determination of any differences in key components as a result of the genetic modification, and to test the hypothesis that no difference in key component concentrations exists between the GM crop and its non-GM counterpart. Compositional data are generated in field trials carried out in several locations throughout the intended area of cultivation of the crop. In these field trials, the GM crop is grown alongside its appropriate comparator, and samples are taken. Parameters are selected that are typical for the crop that is assessed, and that are representative of the main metabolic pathways. Significant changes in these parameters are expected to be indicative of more fundamental changes in the crop that requires further evaluation [121]. The lack of statistically significant differences in the concentration of multiple analytes is a strong indication that the genetic modification has not introduced new constituents, nor harmful unintended changes. However, should statistically significant differences be detected, a harmful change is not necessarily indicated: should the different concentration of a specific analyte in the GM crop be within the range known for the crop, then it can be considered biologically insignificant, otherwise they will constitute "unintended identified" differences that require consideration in the risk assessment [100, 101].

Agronomic and Phenotypic Characterization Information on agronomic and phenotypic characteristics is obtained from multi-location agronomic field trials representative of different environments where the GM crop may be grown. To assess the agronomic performance of the GM crop, a sound understanding of the biology of the crop is required, as well as its relationship with the environment in which it is to be released. A variety of plant characteristics, such as plant vigor, growth habit, yield, crop quality, insect and disease susceptibility, fertility, dispersal mechanisms, and endogenous toxins, are recorded and any differences in the GM crop identified, which could potentially cause it to become a weed of agricultural or natural habitats, or otherwise interact differently than the non-GM counterpart in the environment. If there are no significant differences in characteristics associated with survival, growth, and reproduction, then it is likely that the genetic modification did not alter the persistence, invasiveness or gene flow potential of the GM crop. If significant differences are identified, the values obtained in the GM crop will be assessed for their biological relevance by comparing them with the range of values known for (non-GM) commercial varieties [98–101].

Case-by-Case Principle

No two environmental risk assessments are the same, as each is dependent upon a range of variables found when considering: both the source and target environments; the biological and ecological characteristics of the GM crop; the scale and frequency of the proposed deliberate release; and the interactions

amongst them [97, 122]. It is obvious that each range of variables will also differ between risk assessments, and thus a case-by-case approach is taken. In this way, the required information for the environmental risk assessment may vary depending on: the plant species under consideration; its intended use; and potential receiving environments, taking into account specific cultivation requirements and the presence of GM crops already in the environment.

Iterative and Adaptive

It is recognized that an environmental risk assessment is framed within the scientific knowledge available at the time it is conducted, and that regulatory decisions are made in this context. The environmental risk assessment has to take into account uncertainty at various levels, and which may arise from: limitations in the data (e.g., limited exposure data); gaps in the effect database; the limitation of the test systems and measurement endpoints selected; inadequacy of study designs; and the uncertainties in extrapolating between species. Scientific uncertainty may also arise from differing interpretations of existing data or the lack of some relevant data. Uncertainty may relate to qualitative or quantitative elements of the analysis [106]. Although it may be impossible to identify all the uncertainties present, the assessment should include a description of the types of uncertainties encountered and considered during the different risk assessment steps. Their relative importance and influence on the assessment outcome should also be described. Under current EU legislation, a high precision in environmental risk assessments becomes near impossible to achieve, as the identification of any areas of uncertainty which relate to areas outside current knowledge and the limited scope of the assessment is a mandatory requirement, for example, the impact of large-scale exposure of different environments from GM crop cultivation, the impact of exposure over long periods of time, and any cumulative long-term effects.

PMEM, which became mandatory under current EU legislation, aims to identify possible unanticipated adverse effects on human health or the environment which could arise directly or indirectly from GM crops. It also allows for the collection of additional data during the cultivation phase. The scientific knowledge obtained during the monitoring of GM crops, along with experiences gained from their cultivation and any other new knowledge (generated through biosafety research), provides valuable information to risk assessors to update environmental risk assessments and reduce any remaining uncertainties. In the EU, the objectives of a monitoring plan according to Annex VII of Directive 2001/18/EC are: (1) to confirm that any assumption regarding the occurrence and impact of potential adverse effects of the GMO, or its use, in the environmental risk assessment are correct; and (2) to identify the occurrence of adverse effects of the GMO, or its use, on human or animal health or the environment which were not anticipated in the environmental risk assessment. A PMEM plan of GM crops is mandatory in all market approval dossiers submitted under Directive 2001/18/EC and the GM Food and Feed Regulation.

In the EU, PMEM is composed of *case-specific monitoring* and *general surveillance*. Case-specific monitoring is not obligatory, but may be required to verify risk assessment assumptions and conclusions, whereas a general surveillance plan, as part of a GM crop market application, is a legal obligation. Due to different objectives between case-specific monitoring and general surveillance, their underlying concepts differ [123]. Case-specific monitoring enables the determination of whether, and to what extent, anticipated adverse effects occur during GM crop deployment, and thus to relate observed changes to specific causes. It is mainly triggered by scientific uncertainties that were identified in the environmental risk assessment. Therefore, a hypothesis is established that can be tested on the basis of newly collected monitoring data ("bottom-up approach"). In general surveillance, by contrast, the general status of the environment that is associated with the GM crop deployment is monitored without any preconceived hypothesis in order to detect any possible effects that were not anticipated in the environmental risk assessment, or that are long term and cumulative. Should any such effects be observed, they are studied in more detail to determine whether the effect is adverse and whether it is associated with the use of a GM crop [87]. General surveillance data can originate from various sources: (1) farm questionnaires; (2) existing surveillance networks (such as

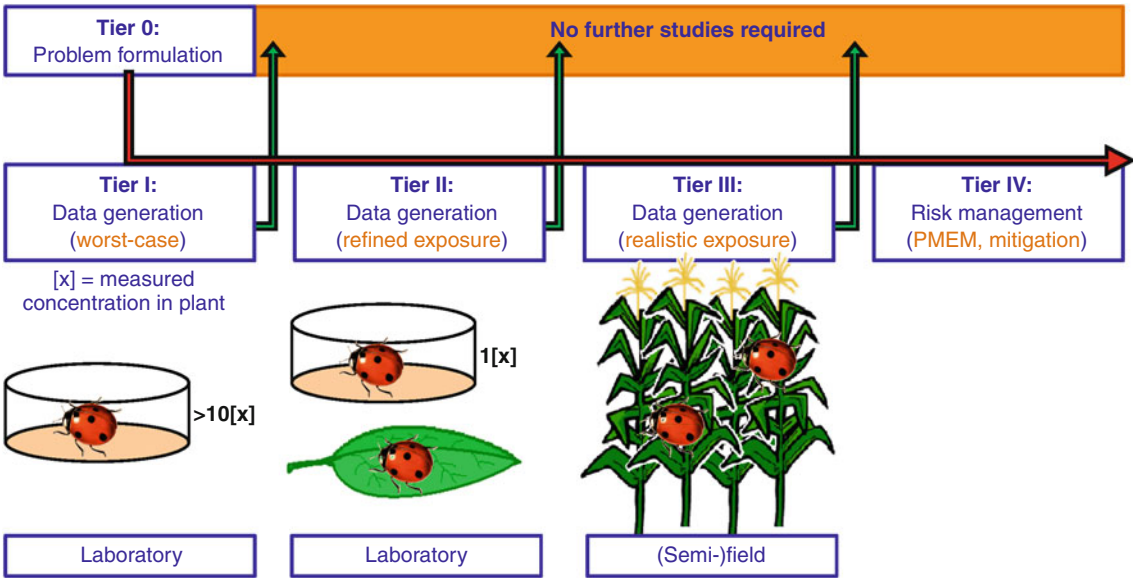
plant health surveys, soil surveys, ecological and environmental observations); (3) scientific literature; (4) industry stewardship programs; and (5) alert issues. Questionnaires for farmers form a useful part of general surveillance, as this tool enables the reporting of any observations of effects linked with GM crop cultivation: farm questionnaires use first-hand observations and rely on farmers' knowledge and experience of their local agricultural environments, comparative crop performance and other factors that may influence events on their land [124]. With this tool, monitoring focuses mainly on the cultivation area of GM crops and its surroundings, which is relevant to protection goals such as sustainable agriculture, soil function, or plant health. Aspects of biodiversity, however, are only addressed indirectly (such as the adoption of conservation/no-till practices, rotation regimes, biological control failures) and may not be sufficiently resolved [125]. Therefore, additional sources of information should be considered in the frame of general surveillance. Moreover, farm questionnaires should include different combinations and mixtures of GM crops that may be grown in sequence or rotation in fields [126]. Directive 2001/18/EC proposes to make use of established routine surveillance networks. EU Member States have various networks in place – some of which have a long history of data collection – that may be helpful in the context of general surveillance of GM crops. The networks involved in routine surveillance offer recognized expertise in a specific domain and have the tools to capture information on important environmental aspects over a large geographical area. However, networks fully meeting all the needs of GM crop monitoring are limited: most do not always provide data of relevance to monitoring the impacts of GM crop cultivation [125, 127]. Concern has been raised, predominantly outside of the EU, however, that in the absence of a valid hypothesis, PMEM for undefined hypothetical adverse effects from a GM crop is not feasible, and adds nothing to the premarket testing results, while potentially undermining confidence in the overall safety assessment process [128].

Risk assessments undertaken in the EU are always iterative, in the sense that regulatory decisions are temporary, reversible, and adaptable in light of new information that becomes available. Under Directive 2001/18/EC, the requirement of reexamination has been strengthened by limiting the duration of any market consent to a maximum period of ten years.

Tiered Approach

An environmental risk assessment is generally conducted in a tiered manner, where information collected in lower tiers directs the extent and nature of any experimentation conducted in higher tiers (Fig. 4). Thereby, hazards are evaluated within different tiers that progress from worst-case scenario conditions, framed in highly controlled laboratory environments, to more realistic conditions in the field [87, 97, 102, 122, 129–131]. Usually, three tiers is the norm, comprising of experimental tests under controlled conditions (tier 1: laboratory tests where test organisms are exposed to a high level of the newly expressed protein as pure protein; tier 2: laboratory tests where test organisms are exposed to refined, more realistic, levels of the newly expressed protein as pure protein or plant material); and (semi-)field tests (tier 3). Within each tier, all relevant data are gathered in order to determine whether there is sufficient information to conclude the risk assessment at that tier. The conclusion can only be made if any residual uncertainty has been defined, otherwise additional investigations to generate further data at a higher tier (s) are designed and undertaken to do so [102]. In the case that no reliable risk conclusions can be drawn, decision making can consider whether risk management measures (tier 4) should be put in place to reduce the overall risk. It is important that throughout the assessment, the problem being addressed (tier 0) remains appropriate and is revised, if necessary.

Lower-tier tests serve to identify and test potential hazards under worst-case scenario conditions and thus involve conservative assumptions, acknowledging that the likelihood of detecting any potential adverse effects of the GM crop or its products on target and nontarget biota increases directly with increasing (usually excessive) levels of exposure. These studies are conducted under controlled laboratory or growth room conditions in order to: quantify effects in relation to known exposure levels; to provide high levels of replication and control; and to increase the statistical power for testing the established hypotheses. Effects of the GM crop on indirectly exposed organisms, that is, those



Transgenic Crops, Risk Assessment and Regulatory Framework in the European Union. Figure 4
Tiered approach to non-target organism testing (Figure adapted from [97])

that are one or two steps removed in the food chain (e.g., predators and parasites of primary phytophagous or plant pathogenic organisms), are generally assessed in the second tier, which is also generally conducted under controlled laboratory, growth room or glasshouse conditions in order to measure effects in relation to known exposure levels [87]. If no hazards are identified and the GM crop is not different from the appropriate comparator, the tested product may be regarded as safe, and no further testing at a higher tier deemed necessary.

However, should potential hazards be detected in early-tier tests or if unacceptable uncertainties concerning possible hazards remain, additional information is required to confirm whether the observed effect might still be detected at more realistic rates and routes of exposure [87, 97, 102, 131]. Progression to larger-scale experiments in higher tiers aims to provide increasingly refined estimates of exposure. Field trials are then established in which the cultivation of the GM crop is conducted with greater environmental realism and thus relevance. As such, actual levels of exposure of different biota can be quantified. In comparison with the appropriate comparator and its management, likely ecological adverse effects due to the GM plant and its management can be determined. While higher-tier studies offer greater environmental relevance, they may have lower statistical power due to the higher variability of environmental conditions (e.g., climate) that can mask effects generated by the GM crop or its product [131]. In exceptional cases, higher-tier studies may be conducted at an initial stage when early-tier tests are not possible or meaningful. As such, many risk assessments are conducted in a tiered manner, meaning that risk assessment studies increase in complexity depending upon the findings at each level of assessment [91]. In cases where uncertainty about the risk remains after higher-tier studies, one can always return to lower tiers to conduct additional studies [102].

The tiered approach is consistent with the iterative or adaptive nature of risk assessment where conclusions are reviewed when new information is obtained. Uncertainty in risk assessment is reduced because each tier is guided by results obtained in the previous tier, and specific, testable, and relevant hypotheses are formulated based on these data [87, 97, 102, 122, 131].

Future Directions

Since one of the main objectives of the EU GMO regulatory framework is to ensure a high level of protection of human and animal health and the

environment, the focus is on the assessment of risks. Whether GM crops fulfill wider socioeconomic and ecological aspirations is not considered explicitly. However, when analyzing potential risks, it is important to bear in mind that the real choice is not between GM crops that are inherently risky and traditionally bred ones that are completely safe. Both existing crops and those with novel traits (including GM crops) will have both positive and negative attributes [56]. To fully acknowledge the overall consequences of adopting specific crops, and to assess and manage more effectively the environmental footprint of agriculture as a whole, it has been suggested that broader and more balanced legislative oversight is needed in the EU [132, 133]. At the EFSA scientific colloquium on challenges and approaches for the environmental risk assessment of GM plants [133], the discussion group on broadening the scope of the environmental risk assessment provided the following recommendations:

- A paradigm shift would be required to change from risk assessment as it is currently practiced, to a more sophisticated assessment which balances risks and benefits: (i) The focus on only GM crops defies scientific evidence. In the longer term, risk assessors could develop an alternative approach on a scientific basis. 'Novelty' is one option. (ii) The status quo, in which risk assessment is interpreted very narrowly in terms of adverse impacts, is not sustainable, and perceptions of the quality of environmental risk assessments suffer as a result. A framework for the future is required. (iii) There is a need to build decision support tools for the risk assessors to better consider impacts of whole farming systems.

The assessment of GM crops has intersected with a wider debate about sustainable agriculture in the EU, blurring any distinctions between environmental, agricultural, and socioeconomic issues. A sustainability assessment may be helpful in recovering public and market confidence, as it integrates larger societal concerns. It enables to define and integrate the underlying values at stake, trade possible risks against benefits, compare technological alternatives, evaluate the usefulness of GM crops, and to assess a whole agricultural system. In this way, it may promote finding a better balance between agricultural production and biodiversity, and evolve toward a socially more robust risk analysis, in which sustainable development is the goal.

While such an integral sustainability assessment certainly will not make things easier and might be an unachievable ideal, it may offer a helpful framing of the debate about multiple controversial aspects. Social, ecological, and economic considerations (such as ensuring social equity and cohesion, a high level of environmental protection, and economic prosperity) that have too often been treated in isolation could then be brought together and explored in a holistic and long-term perspective. Preferences for certain options would no longer be advanced independently of the broader, more complex agricultural and societal context. Likewise, underlying values at stake and normative perspectives fueling the debate might be brought to light.

Transgenic Fishes: Applications, State of the Art, and Risk Concerns

Eric M. Hallerman
Department of Fisheries and Wildlife Sciences, Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

Article Outline

Glossary

Accessible ecosystem The aquatic environment immediately accessible to an organism were it to escape from the research or culture facility, and more distant habitats in the contiguous environment into which the organism or its offspring reasonably may be expected to disperse.

Confinement A system of physical, chemical, biological, and operations management measures used to contain a transgenic fish within an experimental or culture facility or to prevent its establishment in the accessible ecosystem upon escape or release.

Direct effects (or impacts) Effects of a transgenic fish on an (other) organism(s) in the accessible ecosystem, which are effected through mechanisms involving biotic factors. Examples would include but not be limited to reproduction with or predation upon or competition with members of the same or other species.

Environmental effects (or impacts) Consequences of an experiment or of aquaculture that might include, but are not limited to, changes in the structure, function, or resiliency of the accessible ecosystem; changes in the gene pool of populations resident in the accessible ecosystem; or decline in the abundance of a population of threatened, endangered, or special concern species in the accessible ecosystem.

Harm A perturbation resulting in negative impact to a population or species.

Hazard An agent or process that has the potential to produce harm.

Indirect effects (or impacts) Effects of a transgenic fish on (an) other organism(s) in the accessible ecosystem that are effected through mechanisms involving abiotic factors or additional species. Examples would include, but not be limited to, modification of the physical environment, affecting its suitability as habitat for other species and cascading effects of altered trophic function upon the aquatic community.

Introgression The incorporation of genes from one species into the gene pool of another; alternatively, breeding of a transgenic individual with wild-type individuals, leading to introduction and persistence of the transgene in the wild gene pool.

Novel trait Expression of a compound not normally found in the species, e.g., an antifreeze polypeptide in Atlantic salmon; alternatively, expression of a compound normally found in the species, but under novel gene regulation; for example, expression of a growth hormone gene under the transcriptional control of a promoter element not normally associated with the gene.

Risk The likelihood of harm resulting from exposure to a hazard.

Transgene An artificial DNA molecule containing a structural gene whose expression would confer a novel trait upon its host. The transgene would contain a regulatory element to control its expression in the host and an element signaling the point at which transcription would terminate and a poly-A tail added to the messenger RNA transcript.

Definition of the Subject

A transgenic fish or shellfish bears within its chromosomal DNA a gene construct – that is, a transgene, a gene whose expression is under novel regulation – that was introduced by human intervention. A variety

of methods may be utilized to introduce foreign DNA into the genome of fishes [1]. Microinjection of a DNA vector into the cytoplasm of a fertilized egg was the first [2, 3] and remains the most commonly used method for producing founders of a transgenic line. Electroporation, the application of short electrical pulses to make the cell membrane permeable and thereby permit entry of DNA vectors into fertilized fish eggs, has been used to produce transgenic fishes [4, 5]. Electroporation also has been used to introduce DNA vectors into sperm, which in turn was utilized to fertilize eggs to produce transgenic founders [6]. A variation of the "gene gun" method, which involves bombardment of fertilized eggs with DNA-coated microprojectiles, was demonstrated using medaka, or rice fish, a model species [7]. Retroviruses [8] and transposable elements [9] have been modified to carry genes of interest and, using the ability of these elements to insert themselves into the genome of a host, to insert foreign DNA into zebrafish chromosomes.

Because they have large eggs, high fecundity, and external fertilization and development, fishes provide excellent systems for gene transfer. By introducing a major gene whose expression is under novel regulation, biotechnologists can achieve dramatic impacts upon valued phenotypes. Since the mid-1980s when the first transgenic fish were produced [2, 3], gene transfer studies have been conducted using over 35 species [1]. Following the demonstration of the concept [10], a variety of transgenic zebrafish, medaka, and other fishes have been developed as experimental models for biomedical research [11–13]. Many transgenic lines have been developed for potential use in aquaculture (see below), targeting growth rate enhancement and a variety of other production-related traits. Similarly, several sport fishes (e.g., northern pike [14]) have been transformed with growth hormone genes in order to increase growth rate, aggressiveness, or ultimate size. Transgenic zebrafish expressing fluorescent proteins have been marketed as novel aquarium pets [15]. Transgenic lines have been developed for biomonitoring of chemicals in the aquatic environment [16–18].

Because they express novel traits, transgenic fish may prove attractive for aquaculture, fisheries management, or other applications. While production of transgenic fishes may prove profitable, there are broader and longer-term questions regarding whether such use would prove ecologically, economically, and socially sustainable. Because most transgenic fish lines have been produced for purposes of aquaculture, this contribution focuses upon sustainability of transgenic fishes intended for food production.

Introduction

As world population increases, so also does its demand for fisheries products. However, since 1985, the total harvest from capture fisheries has fluctuated at approximately 90 million metric tons (MMT) [19], suggesting that capture fisheries are at or above maximum sustainable yields [20]. Since 1970, the contribution of aquaculture to world supplies of fisheries products has grown from approximately 5 MMT to over 50 MMT annually. Against this background, it is clear that the projected growth in demand for fisheries products can be met only through growth in production from aquaculture. The historical and projected growth in aquaculture raises the question of whether aquaculture is sustainable as currently practiced. First raised by the environmental community [21], the question then was critically examined by the aquaculture community itself [22]. Academic and commercial aquaculturists now are working to define and achieve sustainability [23–25]. Among key innovations so driven are changes in aquaculture feeds to decrease the content of scarce fish meal and oil [26, 27] and selective breeding to develop stocks of fish adapted to utilizing such feeds [28, 29]. There is increasing emphasis among aquaculturists on producing fishes that are herbivores or omnivores rather than carnivores. Within this broader context, whether transgenic fishes would contribute to the sustainability of aquaculture depends upon the host fish, the transgene, the confinement system in which the fish are raised, and any impacts that might follow should transgenic fish escape or be introduced into the accessible environment.

Traits targeted by transgenesis. A number of different traits have been targeted for genetic improvement via transgenesis. Growth hormone (GH) genes have been introduced into over a dozen aquaculture species to increase growth rate. Noteworthy examples where growth was increased several-fold relative to wild-type include Atlantic salmon [30, 31], coho salmon [32, Fig. 1],

Transgenic Fishes: Applications, State of the Art, and Risk Concerns. Figure 1
A coho salmon expressing a salmon growth hormone transgene (*above*) exhibited growth that was dramatically greater than that of a same-aged, non-transgenic full-sibling (*below*) (Courtesy: R.H. Devlin)

Nile tilapia [33], common carp [34], and rohu carp [35]. The most notable example of growth enhancement is that of mud loach, for which up to 35-fold growth rate enhancement was observed [36]. Antifreeze protein genes from Arctic or Antarctic fishes have been transferred to increase the tolerance of species sensitive to freezing in marine waters chilled to below the freezing point of fish flesh (e.g., Atlantic salmon [37]). Genes for bactericidal compounds have been introduced to heighten nonspecific disease resistance of cultured fishes (e.g., cecropin in channel catfish [38] and human lactoferrin in grass carp [39, 40]). The major storage form for phosphorus in grain is phytate, which is largely indigestible and has antinutritional properties; following demonstration that medaka transgenic for a microbial phytase gene exhibited improved phytate utilization [41], phytase also was transferred into tilapia [42]. Transgenic approaches have been proposed for reproductive confinement of fish [43] (see also below), including expression of an antisense DNA complementary to the gonadotropin-releasing hormone transcript [44] and a "sterile-feral" *zBMP2* construct that blocks a critical developmental gene unless a repressor compound is applied to the animal in captivity [45]. When a key biochemical pathway is disrupted by lack of one enzyme, the function of that pathway can be restored by the expression of a transgene; for example, a rat L-gulono-γ-lactone oxidase transgene was introduced into rainbow trout in an attempt to complete the biosynthetic pathway for L-ascorbic acid [46]. While not exhaustive, these examples illustrate the scope of efforts to genetically improve cultured stocks of fishes using gene transfer methodologies.

Most transgenic lines described above have not been subject to the generations of breeding needed to develop a homozygous line stably expressing the transgene. However, development of some GH-transgenic lines is well advanced and efforts to commercialize them are ongoing. A/F protein, producers of GH-transgenic Atlantic salmon, have petitioned the US Food and Drug Administration for approval to market eggs of transgenic Atlantic salmon to commercial aquaculture producers [31]. The Cuban government is considering a request for production of GH-transgenic tilapia [47]. Marketing of a GH-transgenic common carp line is under consideration by the Chinese government [48]. With the prospect of improved production efficiency, it is not surprising that some aquaculturists want to produce GH-transgenic fish commercially. Commercialization of transgenic fishes, however, poses ecological, food safety, regulatory, and animal welfare concerns [49–52].

Confinement systems. Many different fish culture systems are in commercial use. Closed recirculating systems hold fish in indoor tanks and the water is treated in filtration systems; the associated expenses are such that only high-value species can be produced economically. Raceways are long, narrow outdoor tanks, with water from a spring routed through the system once and then discharged; rainbow trout are commonly reared in raceways. Ponds, which may have discharge to a nearby stream or river, are used to produce many species including tilapias and catfishes. Marine netpens, mesh cages suspended in bays or fjords, are used to produce Atlantic salmon, coho salmon, Atlantic cod, and other species. Ocean ranching involves release of juvenile salmon, trout, or charr into the ocean, to be collected later upon their return to spawn as adults. Clearly, these different types of culture systems vary in terms of their production economics and in their ability to reliably confine fishes.

Entry of cultured fish into the accessible ecosystem. Most commercial aquaculture operations have a routine, often significant escape of fish. Escapes can occur through equipment failures, during handling

or transport operations, through predator intrusion into facilities, as a result of storms, or by other mechanisms. In particular, escapes of salmon and trout from marine net-pen facilities are common, ranging from minor incidents where a few fish escape to massive escapes. In the native range of Atlantic salmon, an estimated two million farmed salmon escape each year into the North Atlantic [53]. Outside the native range, millions of Atlantic salmon have escaped on the west coasts of North [54] and South America [55]. Although salmon farm operators are attempting to prevent escapes by upgrading confinement systems, installing predator deterrent devices, and other actions, it still must be assumed that escapes will occur [56].

Escape of cultured fish into the accessible ecosystem and interaction with local intraspecific and interspecific populations is a well-documented environmental concern [57–61]. The potential ecological and genetic interactions between cultured and wild fish have raised concern about the viability of affected wild stocks. Ecological concerns focus upon competition for space and food resources and direct predation [62]. Genetic concerns include the potential breakdown of locally adapted traits through interbreeding and introgression and range up to replacement of native stocks by cultured stocks [63]. Such concerns are posed by the prospect of producing transgenic fish in aquaculture, with the additional unknown posed by possible effects of the transgene. Because of the prospect of escape of cultured transgenic fish, we must consider not only the benefits of transgenic fish to aquaculture, but also any ecological and genetic hazards that they pose. Hazards posed by transgenic fish were first inferred on the basis of ecological principles [64–67], and then supported by empirical studies.

Ecological Risk Assessment for Transgenic Fish in the Accessible Ecosystem

Ecological risk assessment for transgenic organisms should be based upon case-by-case assessment of the host species, transgene construct, transgene integration site within the genome, and receiving ecosystem [49, 64, 68, 69]. Because most fishes do not have a long history of domestication, many cultured stocks retain the ability to survive and reproduce in the accessible ecosystem. Hence, consideration of ecological risk and genetic hazards posed by transgenic fish that might escape from a culture facility is appropriate.

Consideration of harms posed by transgenic fish must be based on an understanding of key concepts underlying the science and practice of risk analysis [49]. In this context, a *harm* is defined as a perturbation resulting in negative impacts to a species. A *hazard* is defined as an *agent or process* that has the potential to produce harm. A *risk* is defined as the *likelihood* of harm resulting from exposure to the hazard. Risk, R, is estimated as the product of the probability of exposure, $P(E)$, and the conditional probability of harm given that exposure has occurred, $P(H|E)$. That is, $R = P(E) \times P(H|E)$. The steps in risk analysis, then, are to: (1) identify potential harms; (2) identify hazards that might lead to harms; (3) define what exposure means for an aquaculture stock and assess the likelihood of exposure, $P(E)$; (4) quantify the likelihood of harm given that exposure has occurred, $P(H|E)$; and (5) multiply the resulting probabilities to yield a quantitative estimate of risk.

Exact probabilities of risk may prove difficult or impossible to determine for all types of possible ecological or genetic harm. Indeed, it is unlikely that all possible harms would be known *a priori*, particularly with respect to any indirect effects. Hence, it may be necessary – based on current knowledge of population genetics, population dynamics, receiving ecological communities, and experience with cultured stocks – to classify levels of concern regarding likely ecological and genetic impacts posed by cultured stocks into *qualitative* categories ranging from low to high.

Potential harms. Harms potentially posed by transgenic fishes would be the outcome of a chain of events occurring after escape or release from a culture system. Examples of harms that potentially might be realized by transgenic fishes entering or becoming established in an accessible ecosystem [49, 64–66] would include decline in abundance of loss of a native species. A locally adapted natural population could be replaced with a transgenic population or experience introgression of the transgene, decreasing the degree of local adaptation. Changes in ecosystem structure or function could result in decreased fisheries production or in ecosystem resiliency in the face of further ecological stressors.

Ecological hazards. Ecological hazards that could lead to harms becoming realized are posed to a range of species with which a transgenic fish might interact in the accessible ecosystem. Ecological hazards include the possibility of heightened predation or competition, as well as alteration of population or community dynamics due to activities of the transgenic fish. Examples from empirical studies illustrate some of these potential ecological hazards.

Several studies have focused on Atlantic salmon expressing a GH transgene. In order to support their rapid growth, these transgenic salmon have significantly faster routine metabolic rates and growth rates than domesticated and wild individuals of equal mass, and therefore require more energy to sustain body function [70, 71]. GH-transgenic salmon must consume food at a more rapid rate than control salmon. Abrahams and Sutterlin [72] observed behavior of size-matched transgenic and control salmon in experiments where fish could feed in safety or in the presence of the predator. Growth-enhanced transgenic fish were significantly more willing to risk exposure to a predator in order to gain access to food, and exhibited increased feeding rate and average speed of movement. However, transgenic fish reduced their exposure to predators in response to increases in the magnitude of risk, suggesting that their more active behavior may not necessarily lead to increased susceptibility to predation.

Devlin et al. [73] compared the intake of contested food pellets by size-matched pairs of one control (1 year older non-transgenic) and one transgenic coho salmon. The transgenic fish consumed 2.5 times more contested pellets than controls. Overall, transgenic fish consumed 2.9 times more pellets than non-transgenic controls, indicating high feeding motivation of transgenics throughout the feeding trials. In subsequent experiments, at low levels of food availability, dominant, generally transgenic individuals dominated acquisition of food resources [74]. Further, when food availability was low, populations containing transgenics crashed, while in contrast, groups containing only non-transgenic salmon exhibited 72% survival and increase of population biomass. Hence, genotype-by-environment interactions affect ecological risk assessment. Sundstrom et al. [75] exposed GH transgenic and wild coho salmon fry to a live predator in a naturalized experimental stream tank under conditions of high and low food abundance. In both cases, mortality rates of transgenic fry were significantly higher than those of wild fry.

Ecological hazards posed by transgenic fish are not limited to salmonid species. Duan et al. [76] observed food consumption, frequency of movement, and feeding hierarchy in transgenic and size-matched control common carp under conditions of limited food supply. Transgenic fish consumed 1.9 times as many pellets, moved 73% more frequently, and exhibited a higher standing in the feeding hierarchy, but did not realize their higher growth potential. The authors concluded that elevated ability to compete for limited food resources could be advantageous to transgenic carp after escape into the accessible ecosystem.

These and other empirical findings to date tend to support the competitive ability of GH-transgenic fishes with conspecifics, and suggest the likelihood that ecological harms could become realized should large numbers of GH transgenics escape from culture or a transgenic population become established. Clearly, not all possible ecological interactions have been considered experimentally. Ecological hazards posed by transgenic fish expressing other sorts of transgenes, for example, a phytase gene that could confer ability to effectively utilize a broader range of foods, have not yet been examined empirically.

Given the range of interacting species and accessible ecosystems, and given the temporal and spatial variation of ecosystems, it is difficult to predict the ecological outcome should transgenic fish escape from aquaculture operations and enter accessible ecosystems. Devlin et al. [77] review methodologies to assess potential ecosystem effects of transgenic fish before they enter unconfined environments, outlining a strategy for identifying the most important data and discussing methods for obtaining them. Key issues include characterization of the accessible ecosystem, phenotypic characterization of the transgenic fish, experimentation appropriate for relating the transgenic phenotype and ecological impacts, and recognizing and accounting for sources of uncertainty.

Genetic hazards. Although reproductive confinement methodologies such as sterilization by triploidy or transgenesis have been proposed to minimize reproductive interaction between transgenic and wild fish

(see below), to date these technologies have not been demonstrated to be completely effective [78]. Should transgenic fish be reproductively fertile, they potentially could interbreed with natural populations. Genetic or evolutionary impacts that could be realized would depend on the fitness of novel genotypes in the wild. There may be cases where fitness relative to the wild type is high, posing introgression of transgenes into natural populations. There may also be cases where maladaptive traits would be introduced into native populations, posing a hazard to the demographic viability of the receiving population. Empirical studies illustrate possible genetic hazards to wild populations of fish.

Considering the possible impact of introgression of transgenes into wild populations, Devlin et al. [79] examined growth enhancement due to expression of a GH transgene in both wild and selectively bred commercial rainbow trout strains and showed that the effect of expression of the transgene varied among the respective strains. Transgenic wild-strain rainbow trout retained the slender body morphology of the wild-type strain, but their final size at maturity was increased by transgenesis. Both domestic and wild-strain trout had reduced viability, and in the case of the domestic strain, all transgenic individuals died before sexual maturation. The greatest response to expression of the transgene was in hybrids of a wild and domesticated strain.

Devlin et al. [80] compared the reproductive performance of transgenic and non-transgenic coho salmon. GH-transgenic fish showed precocious smoltification and onset of sexual maturation but no increase of adult body size, indicating compression of the normal life history. However, strong genotype-by-environment interactions were shown for the effects of transgenesis and culture environment. Bessey et al. [81] found no differences in gamete quality or in vitro offspring production. The transgenic fish were able to breed successfully in the absence of competition, but at a significantly lower level than hatchery fish (i.e., fish reared artificially as young and then released to complete their life history naturally). When in direct competition with hatchery fish, however, the transgenic coho salmon were competitively and reproductively inferior to the point where they had little or no success.

Models have been developed to predict the outcome of introgression of a transgene into a wild population, notably for cases where expression of the transgene differentially affects various components of fitness. Muir and Howard [82] developed a deterministic model that predicted that under certain conditions, a transgene introduced into a natural population by a small number of transgenic fish would spread as a result of enhanced mating advantage enjoyed by larger individuals, but the reduced viability of offspring would cause eventual local extinction of populations. The predicted time to extinction of a wild population would be a function of the mating advantage of transgenic males relative to that of wild-type males and the relative viability of transgenic offspring. Muir and Howard [83] subsequently considered a transgenic organism's fitness components (juvenile viability, adult viability, age at sexual maturity, female fecundity, male fertility, and mating advantage), using various combinations of fitness component values in addition to empirically derived estimates for medaka, a model species, to parameterize and run the model. For a wide range of parameter values, the model predicted that transgenes could spread through populations despite high juvenile viability costs if there were sufficiently high positive effects on other fitness components. Sensitivity analyses showed that transgene effects on age at sexual maturity would have the greatest effect on transgene frequency, followed by juvenile viability, mating advantage, female fecundity, and male fertility, with the least impact due to changes in adult viability. Extinction hazards also could be posed when the transgene: (1) increases male mating success but reduces adult viability; (2) increases adult viability but reduces male fertility; or (3) increases both male mating success and adult viability, but reduces male fertility [84]. Using a different approach, Hedrick [85] developed a deterministic model for invasion of transgenes into natural populations and showed that if a transgene gives rise to a male mating advantage and a general viability disadvantage, then the conditions for its invasion of a natural population are very broad. More specifically, for two-thirds of the possible combinations of mating and viability parameters, the transgene increased in frequency. In addition, the demographic viability of the natural population was reduced, increasing the probability of extinction of the natural population.

Kapuscinski et al. [86] presented a step-by-step method for assessing risk posed by gene flow and possible introgression of a transgene into a wild population (Fig. 2) considering probabilities of escape of a transgenic fish from confinement, encountering wild-type mates, reproducing, and the young surviving to transit the transgene to future generations. Currently, our empirical knowledge of genetic hazards posed by production of transgenic fish and shellfish and their associated risks is limited. Ecological risk assessments are ongoing for GH-transgenic coho and Atlantic salmon, as well as other transgenic fishes, including both model species and aquaculture species. Many critical experiments aimed at estimating fitness parameters [67, 83] have yet to be conducted.

Risk Management

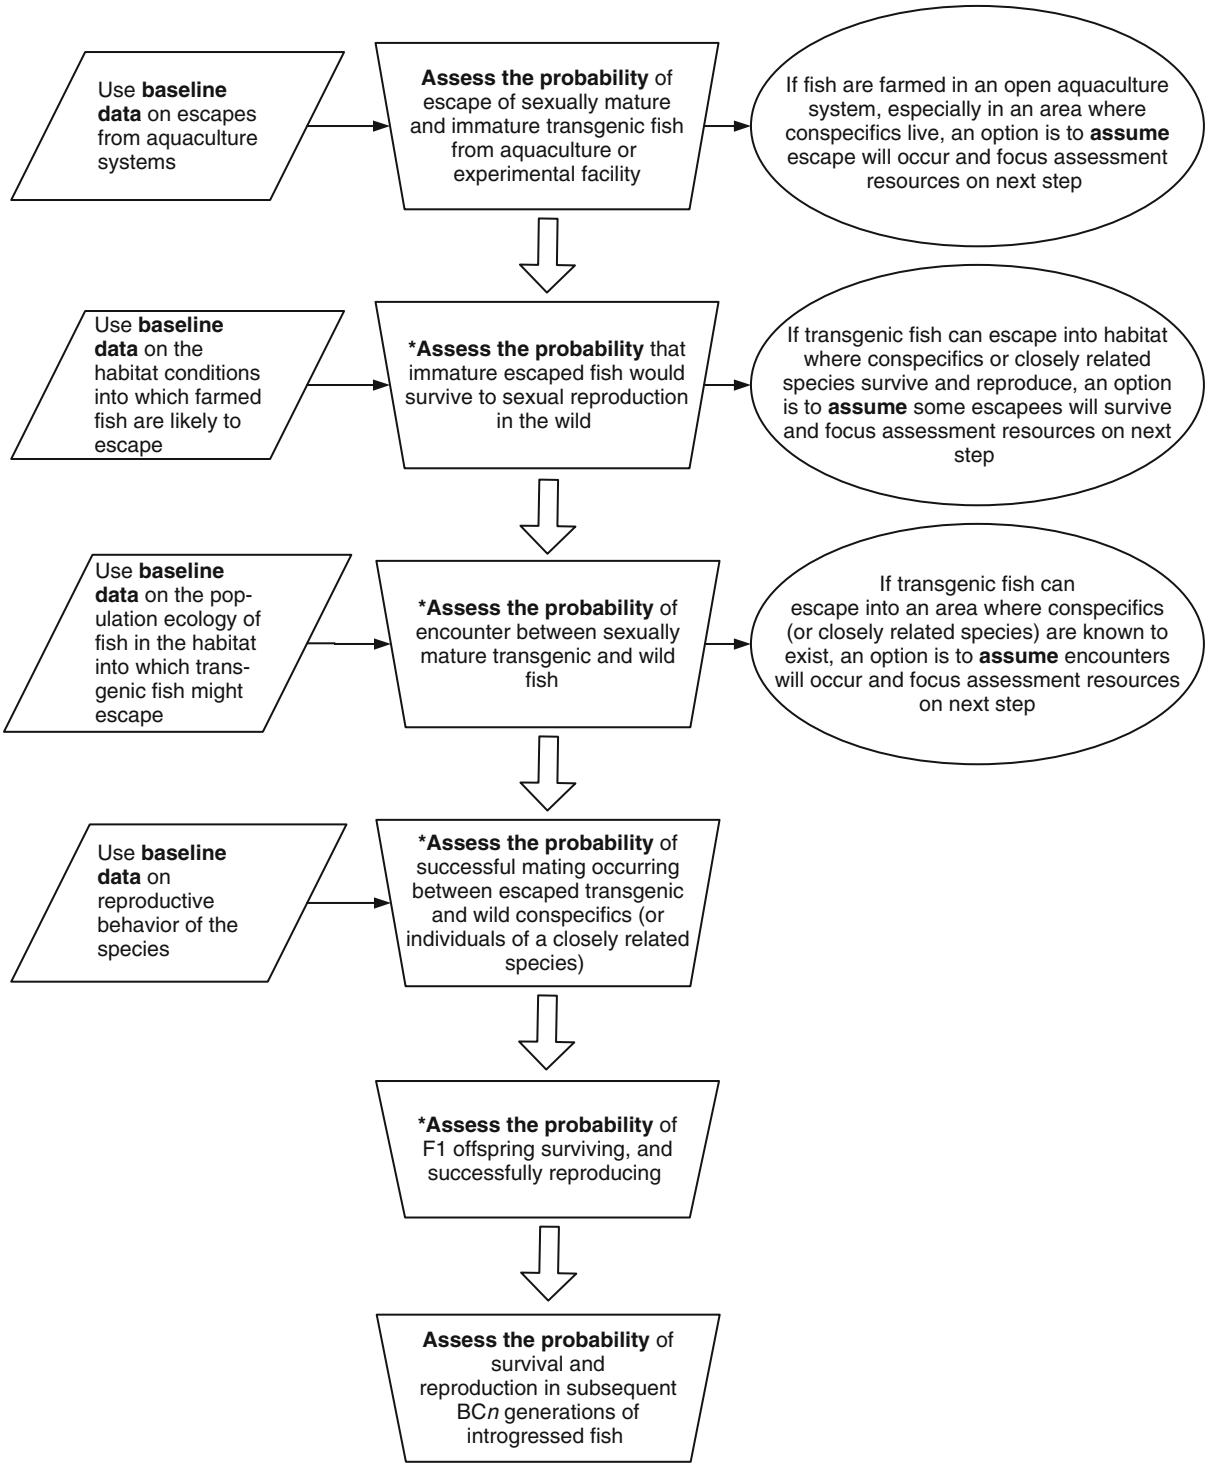
Many key inputs for a quantitative ecological risk assessment currently are unknown. Further, many key aspects of risk assessment are difficult or impossible to address, given the spatial and temporal variability of ecosystems and the adaptive ability of populations. Under at least some circumstances, escaped transgenics could negatively impact accessible ecosystems and populations; hence, should a producer or oversight body determine that production of a transgenic stock poses harm to a population in the accessible ecosystem, the consideration then turns to managing the associated risk. From the viewpoint of ecological sustainability, risk might be managed by producing transgenic fish only under conditions of confinement. In some contexts, production of transgenic fish might go forward only under conditions of strict confinement aimed at ensuring no escape of transgenic fish into the accessible ecosystem.

Risk management is the design, selection, and implementation of a program of actions to minimize risk. In the context of formal risk analysis, it becomes clear that the best approach for minimizing the likelihood of harm being realized is to minimize exposure to the hazard. Three non-mutually exclusive approaches include: (1) physically confining the cultured stock on aquaculture facilities, (2) reproductively confining cultured stocks, and (3) operations management. Management of risks posed by transgenic fishes has been considered for experimental [87] and commercial production systems [88].

Physical confinement. Physical confinement of cultured aquatic organisms will require a combination of measures in order to prove effective [87, 88]. Context is key; the ease or difficulty of managing risk will depend greatly on the geographic location of an aquaculture facility. Sites subject to flooding, violent storms, or wave action are poorly suited for confinement of production stocks. Virtually all physical confinement systems will include barriers to escape of cultured organisms from the culture site, including mechanical or physical/chemical barriers. Mechanical barriers are structures that physically hold back cultured organisms from escaping the project site. Examples include stationary or moving screens, (e.g., floor drains, standpipe screens), tank covers, filters (e.g., gravel traps), grinders or pumps, and French drains. A French drain is a filter for screening effluent from an aquaculture facility that contains gravel and geotextiles through which even small life-stages cannot pass. Physical or chemical barriers use manipulation of physical (e.g., elevation of temperature) or chemical (e.g., administration of chlorine) attributes of effluent water to induce 100% mortality of any escaped organisms before they can reach the accessible ecosystem. The set of barriers must prevent escape of the hardest-to-retain life-stage held at the aquaculture operation, usually the smallest life-stage. Because no barrier is 100% effective at all times, for effective physical confinement, each possible escape path from the aquaculture facility would have redundant barriers to escape of cultured organisms. Barriers also must prevent access of predators that can carry cultured organisms off-site (e.g., avian predators) or damage ponds (e.g., muskrats), allowing escape of cultured organisms.

Reproductive confinement. A key element of many risk management strategies is reproductive confinement, especially for cases where physical confinement alone is unlikely to prove effective. Two approaches, culture of monosex or sterile stocks, might be applied singly or in combination.

Procedures have been developed for producing monosex stocks of fish through direct, hormone-mediated sex reversal and indirectly by sex reversal, followed by progeny testing and selection of broodstock that yield monosex offspring. For example, production of all-female rainbow trout [89] and



Transgenic Fishes: Applications, State of the Art, and Risk Concerns. Figure 2

A pathway for conducting an assessment of the risk of gene flow posed by a transgenic fish (From [86]). *Asterisks* denote assessment steps that require empirical information on traits exhibited by the transgenic fish

all-male Nile tilapia [90] stocks comprise growing segments of the respective aquaculture sectors. Production of monosex stocks may provide an acceptable high level of reproductive confinement in contexts where transgenic escapees have no possibility of encountering prospective mates in the accessible ecosystem. Production of monosex stocks will not provide reliable reproductive confinement if there is a population of the same species or of a closely related species with which escaped transgenics may hybridize in the accessible ecosystem. Further, for monosex production to provide reliable confinement, sex ratios would have to be absolutely monosex, an outcome which has not generally been achieved in commercial production [88].

Reproductive confinement also might be achieved through chromosome set manipulation. Fishes can be produced that have three, instead of the usual two chromosome sets. Such fish are said to be triploid, and are reproductively sterile because they produce gametes with unusual numbers of chromosomes. Should their eggs or sperm give rise to an embryo, the unmatched chromosomes would disrupt normal embryogenesis, leading to death of the embryo. All-triploid stocks can be produced most reliably by the crossing of diploid and tetraploid broodstock, although lack of tetraploid broodstock precludes the approach for many species. Alternatively, triploid stocks can be produced by *de novo* induction. *De novo* triploidy induction is not always 100% effective and, hence, triploid broods will have to be screened to determine whether they are indeed all-triploid [78]. This extra handling and screening add to the cost of seed-stock production.

Other approaches for reproductive confinement may become available in the future, including the possibility of reversible sterility through transgenesis. A transgene that produces antisense gonadotropin-releasing hormone appears to cause sterility in male transgenic rainbow trout [44], but does not seem fully effective in females [91]. Use of a similar approach in tilapia sometimes greatly reduced fertility, but at other times was ineffective in both sexes (N. Maclean, quoted in [45]). Thresher et al. [45] developed a transgene that renders the host sterile, allowing normal development only if a repressor compound is applied during a particular life-history stage. The authors demonstrated its effectiveness in founder-generation transgenic zebrafish, channel catfish, and Pacific oyster. Definitive demonstration of this "sterile-feral" approach would require successful trials in homozygous transgenic lines and demonstration of the effectiveness of the repressor under commercial aquaculture conditions. Wang and Van Eenennaam [43] reviewed developing transgenic approaches to reproductive confinement of transgenic fishes, in addition to the approaches above also considering gonad-specific transgene excision. They suggested that slow progress in development of transgenic reproductive confinement systems is attributable to limited fundamental knowledge of possible gene targets to inactivate in order to induce sterility, preclude gondal development, or disrupt embryogenesis, as well as difficulties in implementing such highly technical approaches in vivo.

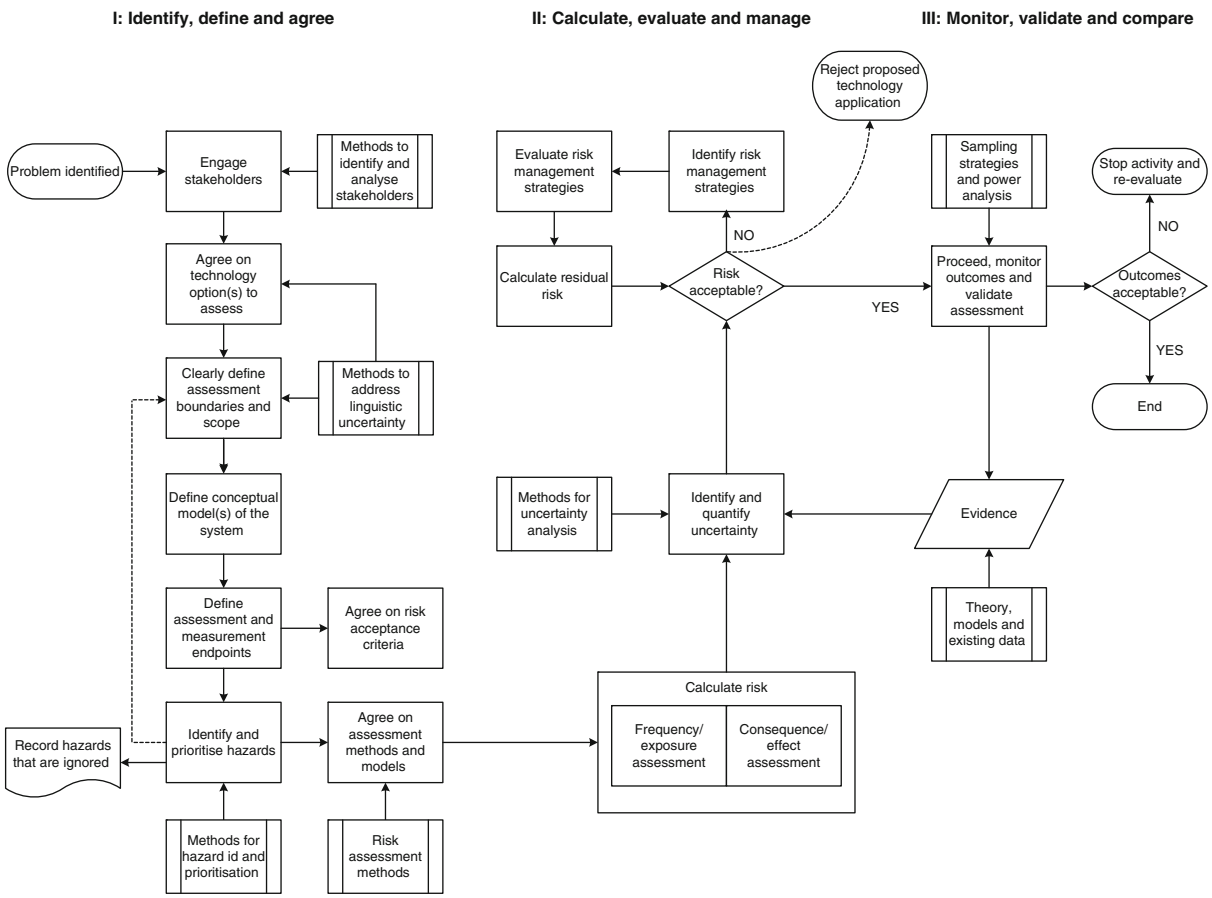
Operations management. Operations management is a key, though often overlooked, aspect of a confinement system [87, 88]. Measures are needed to: (1) ensure that normal activities of workers at the aquaculture operation are consistent with the goal of effective confinement, (2) prevent unauthorized human access to the site, and (3) ensure regular inspection and maintenance of physical confinement systems. Effective supervision of project personnel is critical for operations management.

Operations management also must consider biosecurity after cultured organisms are removed purposefully from the culture site, that is, harvested and transported through the marketing process. For biosecurity purposes, it would be best if only dead fish were sent to market. This is counter to marketing practices in many developing countries, where live sales prevail. Live sale is a known route for introductions of nonindigenous species, and exemplified by recent introduction and establishment of snakeheads in the USA [92].

Effective risk management calls for combinations of confinements. Combinations of risk management measures are advisable so that failure of any one measure will not necessarily lead to escape of confined stocks [87, 88]. It is infeasible to anticipate the best combination of risk management measures for every possible case. Differences in species, production traits, receiving ecosystems, and culture systems will affect the case-by-case determination of appropriate risk management measures.

Future Directions: Transgenic Fish Considered Within the Sustainability Paradigm

Interactive decision-making framework. Recognizing that sustainability has ecological, economic, and social dimensions, what conditions would have to be met for aquaculture production of transgenic fish to prove sustainable? The range of issues posed by a proposed utilization of transgenic fish in aquaculture might best be considered within in a three-stage, interactive framework involving a range of stakeholders [93, 94] (Fig. 3). Involvement of the full range of stakeholders would bring all existing knowledge into the deliberative process, make the process transparent to stakeholders, enhance the understanding and acceptance of the outcome of risk analysis, and promote social acceptance of the technology. Stage I of the process involves identifying the problem at hand, engaging stakeholders, identifying possible technical solutions to the problem at hand, and identifying potential harms, risk pathways, and assessment methods. Stage II of the process is risk



Transgenic Fishes: Applications, State of the Art, and Risk Concerns. Figure 3
Overview of a framework for environmental risk assessment of a transgenic fish embedded within a larger social context (From [94]). The framework has three stages. In the first stage, participants agree of an assessment option, define the scope of the assessment, agree on conceptual models, identify assessment and measurement end points, and agree upon a list of prioritized hazards. In the second stage, the risks and uncertainties associated with these hazards are assessed, risks are compared to predetermined acceptance criteria, and where necessary, risk management strategies are identified and evaluated. In the third stage, predictions of the risk assessment are compared with empirical findings, generating data used to reexamine uncertainty in the risk assessment

assessment, leading to estimating the likelihood that harm will become realized should the proposed production of transgenic fish go forward. Upon estimation of that risk, a decision would be faced as to whether the risk is acceptable. If it proves acceptable, the decision may be made to go forward. If the level of risk proves unacceptably high, risk management measures would be identified and residual risk quantified, and the decision of whether to go forward would again be considered. Should the proposed action be implemented, genetic, ecological, and social outcomes should be monitored. As discussed below, because all potential harms and associated pathways cannot be known and precisely predicted *a priori*, it will be necessary to update the risk analysis as knowledge accumulates using an adaptive management approach [95, 96].

Trade-offs of benefits and risks. The prospect of producing transgenic fishes in aquaculture poses a mix of benefits and risks that would affect the assessment of whether such production would promote ecological, economic, and social sustainability within the decision-making framework. Consideration of several examples will illustrate how trade-offs among benefits and risks will affect the assessment of sustainability.

Benefits and hazards posed by GH transgenics have been considered empirically, and some of the associated risks have been quantified. GH-transgenic fish exhibit rapid growth and perhaps also improved feed conversion ratio, promoting production efficiencies in terms of more efficient utilization of inputs, including facilities, labor, and feedstuffs. However, as noted above, risk assessment research to date suggests a considerable likelihood of ecological or genetic impacts should GH transgenics escape into accessible ecosystems. This risk can be managed by adoption of an appropriate suite of risk management measures (see above). Risk management will have attendant costs, decreasing profitability by some as-yet unquantified amount. Some segments of society are opposed to production of transgenic organisms [97], affecting the social aspect of whether this first wave of transgenic fishes will prove widely marketable and socially sustainable.

Empirical evaluations of both benefits and risks are yet to be conducted for other lines of transgenic fishes that may be considered for commercial production. Trade-offs among benefits and hazards may be anticipated. For example, as noted above, production of fish expressing a phytase transgene would take advantage of their ability to more efficiently utilize seed meals, increasing feed conversion efficiency and reducing the discharge of unutilized phosphorus from feed, decreasing eutrophication of waters in culture facilities and in waters receiving aquaculture discharges [41]. However, ability to efficiently utilize a wider range of natural foods might render escaped transgenic fish more competitive in accessible ecosystems. In particular, phytase-transgenic tilapia [42] might become even more competitive than wild-type tilapia, which are already recognized as invasive in a range of ecosystems in tropical and subtropical regions [98]. While effective confinement might be achievable in well-managed commercial operations, it likely cannot be achieved on subsistence farms, greatly influencing the assessment of whether phytase-transgenic tilapia would promote sustainability in developing countries.

As noted above, several transgenic fish lines have been produced for use as biomonitors [16–18] for detection of waterborne mutagens that would trigger expression of readily detected marker compounds in the fish. Such fishes would be exposed to such compounds by holding them in confinements in the waterbody of interest or by transporting the water to a confined fish-holding system. The benefits of long-term, integrative monitoring of water quality are clear. Any risks that might flow from the possibility of a nonindigenous species being used, escaping, and becoming naturalized in the waterbody at issue could be managed by use of effective confinement or by use of a species that cannot become established in the accessible ecosystem, for example, a tropical species sensitive to winter temperatures in the temperate zone.

These examples indicate how trade-offs of economic benefits and ecological risks, adoption of risk management measures, and ecological and social context interact to affect the sustainability of transgenic fishes for aquaculture and other applications. Explicit consideration of benefit and ecological risk, and hopefully also ecological, economic, and social aspects of sustainability would accompany societal consideration of whether and how to go forward with commercial production of transgenic fishes.

Oversight of production of transgenic fishes. The decision of whether and under what conditions production

of transgenic fish would go forward will largely be made at the national level. As noted above, at least three countries – the USA, Cuba, and the People's Republic of China – are considering applications for commercial production of transgenic fish. The USA, Canada, the European Union, and Norway have regulatory systems in place for oversight of aquaculture biotechnology. Under Article 21 of the United Nations Convention on Environment and Development and the subsequent Cartagena Protocol, signatories commit to developing and implementing policies for oversight of biotechnology. Consequently, many countries – for example, Cuba, Thailand, and the People's Republic of China [99] – are in the process of developing and implementing policy and staffing government offices that would be utilized to consider applications for production of transgenic fish.

Adaptive and proactive management. Many critical unknowns complicate risk assessment and risk management for transgenic aquaculture stocks. The adaptive management approach is based on recognition that knowledge of the environmental and social systems into which the aquaculture stocks would enter is *always* incomplete. Hence, management should evolve as knowledge of these systems increases [96]. Management cannot adapt if realized by a single passage through transgenesis and breeding, decision of whether and how to produce the transgenic stocks, and implementation of the distribution and production process. Instead, adaptive management would include risk assessment for candidate areas for distribution, incorporation of risk management into the production program, and capacity building as appropriate to meet program goals. Once transgenic stocks are distributed, culture operations and receiving ecosystems would be monitored for indicators of ecological and social conditions [96, 100]. Should monitoring indicate that economic and social benefits are being realized without ecological harms occurring, then few if any adjustments to program implementation are required. However, should monitoring indicate that production of cultured stocks is *not* contributing to nutritional and economic well-being or that the stocks are escaping and impacting accessible ecosystems, then it will prove necessary to redefine goals, revise implementation, and continue monitoring.

The issue of whether and under what conditions transgenic fish would promote sustainability of aquaculture has been raised largely after research and development on the first wave of transgenic fish lines was well advanced, after proponents have applied for regulatory approval for commercial production. Kapuscinski et al. [101] proposed a proactive "safety-first" approach in which an early, prospective risk assessment would be conducted in order to guide planning and implementation of measures to prevent or minimize risk as development of a transgenic line progresses. Transgene constructs would be designed for safety. Gene transfer scientists would strive for better control of copy number, genomic insertion site, and control of expression of the trangene, contributing to better-controlled modification of phenotype. Transgenic lines would be evaluated for stability of transgenic expression and transmission. Development of inducible expression of transgenes would reduce risk should transgenic fish escape into the environment. Improvements in confinement also would reduce risk posed by aquaculture production of transgenic fishes.

Applications of transgenic fishes, the science of risk assessment, the practice of risk management, and public policies for oversight of biotechnology are all in development. The degree to which production of transgenic fishes ultimately will prove sustainable will depend upon many societal decisions of whether and under what conditions to utilize transgenic technology in aquaculture.

Transgenic Livestock for Food Production, Introduction

C. Bruce A. Whitelaw
The Roslin Institute and Royal (Dick) School of Veterinary Studies, Division of Developmental Biology, University of Edinburgh, Scotland, UK

Our societies currently face many big challenges: how to feed the increasing world population, how to balance the competing demands for land and water, how to mitigate climate change, and how to maintain healthy lifestyle into old age. Among other technologies, the animal genetic revolution offers several strategies to mitigate these challenges and provide benefit for mankind. While achieving this, we need to maintain and where appropriate increase the welfare and existence of animals we use in agriculture and biomedicine. Transgenic technologies, the ability to add or transfer or change the genetic makeup of an animal, can contribute. In the following ten entries, this premise is presented in detail. Why the entries were selected and how they complement each other while giving an overview of the field of transgenic animal biotechnology is described below.

The cornerstone of biological research is the ability to experimentally alter gene activity. In this way, the functional importance of a gene can be studied. This can be achieved indirectly through altering the environment of cells or organisms, for example, adding specific nutrients to a culture condition or infecting with a pathogen. Alternatively, direct manipulation can be achieved through genetic engineering. This section focuses on the later strategy which includes gene addition, gene removal (or inactivation), or gene alteration. To illustrate this, gene addition might be appropriate where an enhanced functionality is required such as food utilization, while gene inactivation would be appropriate if the aim was to remove a food allergen. Both have been successfully applied to animals and this is likely to be so going forward. In addition, as methodology becomes more sophisticated and the ability to directly alter a given gene sequence, this strategy will see more and more application; for example, where gene diversity is identified that could be applied to engineer altered metabolism or reduce disease susceptibility.

Although initially performed in bacteria, researchers quickly developed the tools to genetically modify animals. First in mice at the end of the 1970s, then livestock in the following decade, in parallel strategies for altering the germ line in fish and birds were developed. Researchers have developed strategies which enable precise spatial and temporal changes to target gene activity. Many consider transgenic or genetic modification (GM) methods (► Transgenics: Alternative Gene Transfer Methods) as part of the technical continuum that is available to animal breeders. As such, GM or transgenic animal technology would simply represent new methodology alongside the more established tools as artificial insemination and embryo transfer. These new animal reproductive tools include somatic cloning and in vitro embryo production, and when combined with the emerging molecular genetic tools provide powerful new opportunities for livestock breeding.

The first transgenic livestock were reported in 1985. Since these early days of this technology, there has been a steady increase in the availability of tools available (► Transgenic Livestock Technologies) for this form of assisted reproduction in animals. Some developments have been heralded as breakthroughs only to quickly drop out of favor while others have received limited use. Recently, reagents based on precisely targeted enzymatic cleavage of the genome that in addition to strategies such as gene knockdown provide the animal geneticist with both efficient and sophisticated methods with which to generate transgenic animals.

Perhaps one of the most consequential scientific advances of recent years was the technical breakthrough that produced "Dolly" the sheep at the Roslin Institute. This animal was produced by nuclear transfer (also termed SCNT, somatic cell nuclear transfer), or as it is commonly referred to as cloning. Animal cloning involves the replacement of the genetic material found in an unfertilized egg with that from a donor cell's genetic material. SCNT reflects considerable scientific thinking and offers the experimental biologist considerable insights into the functional reprogramming of cellular function in addition to details of cellular subcomponent roles in normal cell activity (► Livestock Somatic Cell Nuclear Transfer). In addition to being a valuable aspect of research in its own right, SCNT can be combined with genetic engineering tools to precisely

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

modify the genome of mammals (► Nuclear Transfer to Produce Transgenic Mammals). This combination offers exciting commercial opportunities across the fields of agriculture and animal breeding, to the biomedical arena and novel biotechnological processes.

Transgenic technologies are not restricted to mammals. Due to its use in food production and as an experimental organism in scientific research, the chicken is the most widely used bird species for experimental development of avian transgenic technologies (► Avian Specific Transgenesis). Perhaps the most exiting recent advance is that of precise gene modification in special avian cells called primordial stem cells. These new tools offer strategies for the production of transgenic birds other than the chicken. As such, this is an area currently experiencing rapid development and many expect it will be in birds that GM technologies will be first successfully exploited to produce animals that have enhanced resistance to infectious pathogens.

Although it can be argued that technically transgenic technology is most advanced for mammals, and currently developing quickest for birds, it is considered very likely that the first commercial application of transgenic animals that will enter the food chain will be in fish (► Transgenic Fishes: Applications, State of the Art, and Risk Concerns). Fish that grow faster are providing the first test of the regulatory systems while providing the focus for much debate on broader and longer-term questions regarding whether such use would prove ecologically, economically, and socially sustainable. There is also considerable effort being directed at the development of transgenic strategies to combat disease in fish populations, and the technology can be equally applied to food fish as to sport fish.

As the world population increases there is an increasing demand for food including both plant and animal products. The demand for meat and milk are increasing at a faster rate than for plant products because of increased wealth in developing countries. Animal products represent a concentrated protein and vitamin source which complements cereal and other vegetable proteins. Intensification of livestock production to satisfy the demand is exacerbating the deleterious impact of intensive animal agriculture on the environment and new approaches are needed to reduce the impact. Transgenic animals that have a smaller environmental footprint, increased productivity brought about by enhancing aspects of agriculturally important traits can contribute to this societal challenge. For this potential to be realized an active dialogue between all stakeholders is required to achieve ethically accepted sustainable future animal production.

The animals we all recognize in farms today are the result of many centuries of domestication. The driving force for this has largely come from man's desire for meat. This single process has shaped the rural landscape we all recognize today. It is therefore not surprising that animal breeders look to transgenic strategies to enhance the traditional animal breeding traits including food production (► Transgenic Livestock, Enhanced Nutritional Quality in). The focus now is not on quantity but on quality, while reflecting the rapid industrialization of our world and the associate increase in affluence experienced by many (but not all) of our communities. Food choice is now considered alongside sustainability. Animal welfare is paramount while still recognizing that many of the world population live in poverty with starvation a constant threat. Transgenic technologies offer the potential of quick solutions to the production of food products with enhanced specific nutritional characteristics from animals. The goal is healthier and safer food. However, this potential will only be realized with consumer acceptance in GM technology.

Two specific examples of traditional breeding traits that transgenic technology may provide innovative solutions are worthy of specific attention. The first is that of animal fertility (► Transgenic Technologies and Increased Livestock Fertility). Reproductive efficiency of domestic animals is critical to the sustainability of modern livestock industries. With various indicators of reducing fertility now appearing in our farms it is timely to consider innovative approaches to halt this decline. Aspects under investigation include increasing litter size in livestock or egg-laying capacity in poultry. More radically this technology could be applied to reduce the limitations associated with seasonal breeding.

The second topic that is attracting considerable interest in both the scientific research community and in the animal breeding industry is that of animals that are less susceptible to the ravages and distress of disease (► Disease-Resistant Transgenic Animals). Offering both enhanced animal welfare and economic advantages

this field is both fast moving and innovative, building much on the genomic revolution which is in turn constructed from the strong discipline of genetics. With huge impact on global animal health and the associated impact of zoonotic disease in man, this is an area which offers huge benefit to man and animal alike.

The simultaneous need for more food as the world population expands and that of limiting both short-term and longer-term environmental consequences is a huge challenge for man. Increased animal productivity could directly compromising our environment. Transgenic technology through providing animals that have a smaller environmental footprint (► Transgenic Livestock, Decreasing Environmental Impact of) could form an important part of the compromise that is inevitable if we are to provide sufficient food for our increasing human needs. Under development are projects aiming to reduce manure output and decrease greenhouse gas production. It is argued that the food security agenda being promoted by many governments will lead to greater acceptance of transgenic animals, following the slow but every increasing presence and consumption of transgenic plant products.

Transgenic animals present a dilemma for us. This technology offers rapid change with the promise of economic benefit, enhanced food security and better animal welfare. Yet transgenic technologies directly challenge many ethical aspects of thinking (► Transgenic Livestock, Ethical Concerns and Debate). Central to the process of acceptance is a conscious dialogue between all stakeholders – to build up a generally acceptable stance on what is good with respect to the ethical limits of human use of animals.

At the time of writing, there are no transgenic livestock in production – with faster growing fish being the closest and disease resistant birds being the most exciting. By the time of reading, this may well have changed – or be close to such a scenario. Agricultural advances have been enormously successful in providing an inexpensive supply of high-quality and safe foods. The new advance of transgenesis is likely to continue this trend providing some of the solutions to tomorrow's agricultural challenges. Governmental and industrial financial support – ideally in equal measures – is needed to achieve this. Equally important is the public dialogue to expose the benefits this technology can offer all stakeholders in our diverse world society.

Article Outline

Glossary

Genetic engineering Recombinant DNA technology, gene manipulation including experimental manipulation of genetic material for industrial or medical use.

Germ cells Cells able to give rise to a functional gamete in multicellular animals.

Assisted reproduction The medical and laboratory processes used to reproduce the steps necessary to generate a newborn starting from gametes and or embryos.

IVF In Vitro Fertilization, the laboratory process in which a mammalian egg is fertilized outside the body and then put back inside to grow into a new individual.

ICSI Intra Cytoplasmic Sperm Injection, a procedure by which a spermatozoa is injected directly into the cytoplasm thus overcoming artificially the natural barriers of the oocyte.

SCNT Somatic Cell Nuclear Transfer, a technique that generates genomic copies of any given individual animal by replacing inside an oocyte its genome with the genome taken from somatic cells of a donor animal.

iPS cells Induced Pluripotent Stem cells, somatic cells that have been turned into pluripotent stem cells by the overexpression of pluripotency genes like OCT4, Nanog, Sox3, and Klf4.

Preimplantation embryo Following fertilization, the mammalian one-cell embryo (*zygote*) is still enclosed into the transparent proteic shell of the oocytes (*Zona pellucida*). During the journey along the oviduct it repeatedly cleaves to form an aggregate of smaller cells (*Morula Stage)* and finally develops an inner cavity (*Blastocyst stage*). Once in the uterus, the expanded blastocyst hatches breaking the zona pellucida and begins the implantation on the endometrium.

Chimerism The status of an organism made up by cells of different genotypes (like in the mythological monster *Chimera*). Chimeras derive from the aggregation of two different embryos of the same specie or from two different specie closely related (e.g., sheep and goat).

Mosaicism The cells of the organism own the same background genotype but are diverse in carrying or not a single mutation (or transgene). Such different cells may show a "patchy" distribution within tissues (like in a mosaic).

cDNA (complementary DNA) is a sequence of DNA obtained by reverse transcription of the mRNA (messenger RNA). It retains the whole information for coding the protein, but lacks the introns originally present in the chromosomal gene.

Zinc finger nuclease Recombinant enzyme able to bind a specific sequence of DNA and to "cut" it, generating a Double Strand Break (DSB). It is composed by an artificial DNA binding domain (a polypeptide with a repeat of regions each folded around a zinc ion, to evoke the idea of the fingers) linked to a bacterial nuclease domain, capable to hydrolyze the phosphate bond of the DNA.

Transposon A mobile genetic element able to transpose, that is, to excide itself from one site of the genome and to integrate in a different site. It does not move from one cell to another.

Robert A. Meyers (ed.) Encyclopedia of Sustainability Science and Technology, © 2012, DOI 10.1007/978-1-4419-0851-3

Retroviruses A class of viruses with a RNA genome, able to bind specific receptor on the target cell, to enter across the cell membrane and to transcribe its RNA in a DNA copy by means of its own RNA-dependent DNA polymerase (reverse transcriptase). Specific sequences promote the integration of the viral DNA into the genome of the host.

AAV A defective virus, with a small, single-stranded DNA genome, belonging to the family of Parvoviridae. AAV is able to replicate only in case of concomitant presence of an active adenovirus in the same cell. AAV can often integrate a double-stranded form of its DNA into the genome of the host.

Recombinase A family of enzymes able to exchange stretches of DNA among different molecules. Recombinases like CRE, coded by the genome of bacteriophage P1 (a virus parasiting a bacterium), recognize specific sequences as target of their activity. In the presence of such Recombination Recognition Sites, phagic recombinase is able to insert and excide the viral genome from the bacterial chromosome.

siRNA Silencer RNA or short interfering RNA are small synthetic RNA molecules able to trigger the degradation of a target messenger RNA bearing the same sequence. This results in a posttranscriptional inhibition of gene expression. SiRNA complexes derive from the processing of artificial shRNAs (short hairpin RNA) bearing a secondary double-stranded structure that is subsequently processed by the endogenous cell machinery. RNA-mediated inhibition of gene expression, also known as RNA-interference, is naturally observed in most eukaryotes and relies on a specific pathway involving specific endoribonucleases and endogenous micro-RNA (miRNAs) genes.

Definition of the Subject

Recombinant DNA technology and gene transfer were set about 40 years ago and since then have provided powerful tools for the production of biological molecules, the development of new varieties of crops, and for generating key animal models in biomedical research.

Following the synthesis of recombinant insulin, many other pharmacological proteins have been produced by expressing heterologous genes in microorganisms, plants, and animals.

The application of gene transfer or "transgenesis" to animals has been developed mainly in mouse, while its use for generating transgenic livestock has encountered unanticipated resistances originated by social, economical and technical consideration. Apart from public concern and social consideration about the release of Genetically Engineered (GE) products in the market and GE animals into the environment, which will not be discussed in this chapter, the development of transgenic livestock has been slow due to the technical difficulties faced in transferring this technology from mouse to large domestic animals and by the initial discouraging results, outlining the difficulties in obtaining the expected effect upon a genetic modification.

This review will survey the scientific advancement making the generation of GE swine and ruminants more accessible in the last few years, positively influencing the technical and, as a consequence, the economical issues related to their development.

Introduction

Genetic mutations and equally engineering (GE) of living organisms are part of biological processes that are inherited through reproduction across generations. Such events provide the genetic variability that is at the core of evolution of the species and ensure its survival both in plants and animal kingdoms. The understanding of the biology at the basis of such physiological events, the discovery of the mechanisms and the molecules involved has allowed the investigators to exploit and adapt such tools for the artificial modification of the genome of living organisms from virus and bacteria to mammals including primates. These developments that led to definitions and guidelines of what is now called DNA recombinant technology can be traced back to 1975 to the Asilomar Conference where the scientific community met to discuss potential hazard and regulation. DNA recombinant technology had the potential to be taken from bacteria and viruses to plants and animals with, at the time, unknown biological consequences and biosafety concerns. It was not too long in fact that the first GE mammals were produced [1, 2]. Palmiter's results were dramatic in the sense that the mouse engineered to express the rat growth hormone grew to the size double

that of the normal mice, thus opening the door to the application of such technologies in livestock, as stated in the abstract "This approach has implications for studying the biological effects of growth hormone, as a way to accelerate animal growth, as a model for gigantism, as a means of correcting genetic disease, and as a method of farming valuable gene products".

Since then, GE technology in mammals has been developed mainly in the laboratory mouse to study development and disease processes for research and clinical purposes with the ability to manipulate any given gene of the mouse genome. The developments in livestock immediately followed [3]; however it soon became evident that it was only the beginning and to reach such objective it was a difficult task and more knowledge was required. Beside the know-how required to engineer the genome, to make those modifications into the animals inherited through generations, it is necessary to operate during the early stages of embryonic development or on the germ cells to be able to have all the cells originating from the embryo GE. This is the reason why the developments of assisted reproduction techniques have been crucial for the generation of transgenic animals, especially in livestock where the access in vivo to preimplantation embryos is more complex, expensive, and cumbersome than in the mouse. It can be stated that the developments in transgenic livestock have been set by the development of assisted reproduction techniques like oocyte in vitro maturation and fertilization, intracytoplasmic sperm injection, embryo culture, and somatic cell nuclear transfer (SCNT).

The injection of recombinant DNA into the pronucleus of the zygote has been the first technique used to generate GE livestock. This required a large supply of zygotes that can be easily generated in mice in vivo but are very expensive or sometimes impossible to obtain from the donor females of larger animals because of the costs involved and the low efficiency (only 1–5% of the injected embryos result in transgenic offspring).

Nevertheless, first studies on sheep and pigs involved the use of in vivo produced zygotes, adapting the protocols already set for the mouse [1, 3–5]. On the other hand, the generation of transgenic calves was not practically manageable by this route and could only be achieved [6] using in vitro maturation and fertilization of oocytes collected at the slaughterhouse [7] where large numbers can be generated at a low cost without the use of live animals.

Besides the classical microinjection procedure, alternative approaches have been developed to bring exogenous DNA into the nucleus of the embryo. Embryonic stem cells are largely used in the mouse to generate transgenic animals. They can be replicated in culture for a long period without losing their pluripotency, that is, their ability to take part in the formation of a developing embryo. Thanks to this peculiar behavior, they can be GE to obtain cell clones bearing specific modification of the genome. Such cells can be introduced in the early embryo where they participate in the development of a chimeric organism and eventually integrate into the germ line [8]. This approach has opened the way to the development of the so-called gene targeting, allowing the generation of transgenic mice bearing specific mutations, including disruption of specific genes (knock-out) or insertion of new coding sequences in specific loci (knock-in). ES cells are not yet available in livestock, therefore this route is not yet practicable [9].

An alternative approach has been disclosed by the development of somatic cell nuclear transfer (SCNT) technology, currently the preferred route to make transgenic livestock [10]. Somatic cells may be GE, even by gene targeting, and then used for SCNT. Although SCNT is not very efficient, all the animals obtained carry the selected mutation that has been introduced in the somatic cells subsequently used for nuclear transfer.

In addition, alternative approaches have been developed to generate transgenic animals like the infection with an engineered retrovirus of in vitro cultured preimplantation embryos or the injection of a sperm together with the desired recombinant DNA vector during intracytoplasmic sperm injection (ICSI).

In the following paragraphs, the developments in assisted reproduction technologies that have made GE of livestock possible will be described, then the methods currently used, and finally emerging technologies that promise to make GE simpler, more precise, and reliable.

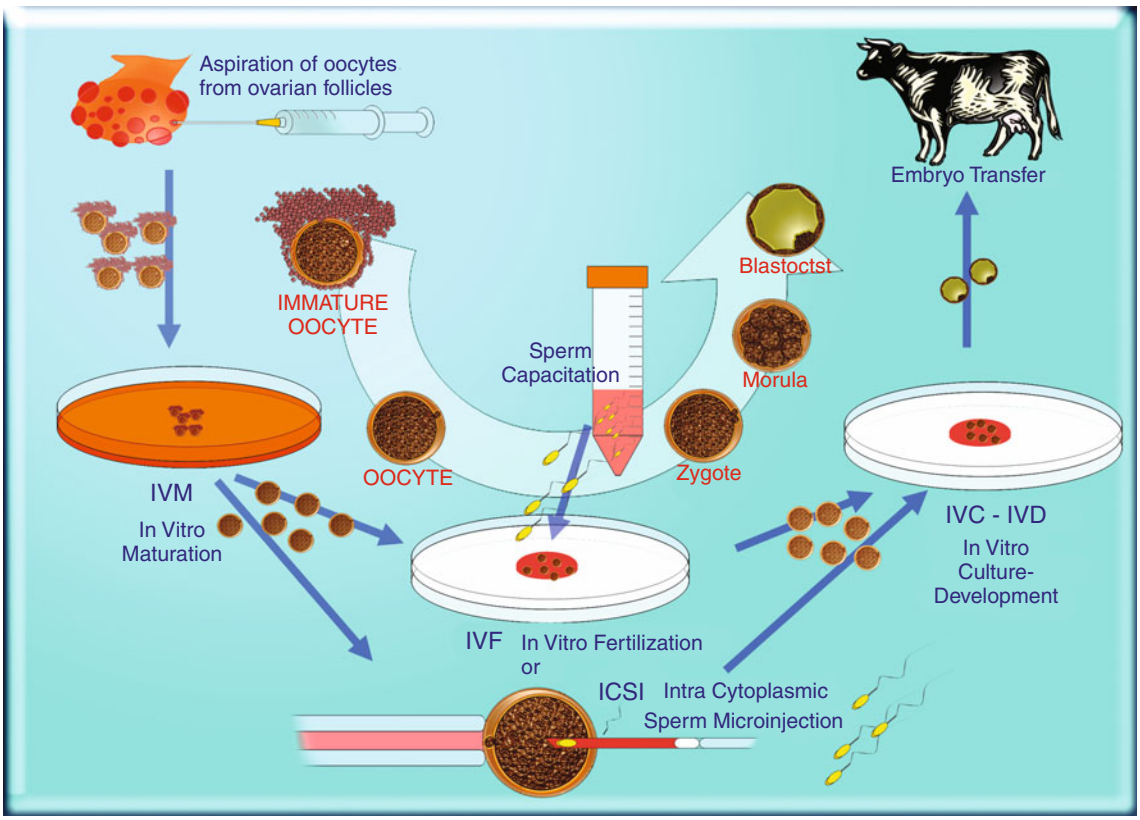
Assisted Reproduction Techniques

Reproduction is the key biological function that is exploited to make a GE animal. Other approaches can

be used, however, if the procedures do not target the germ line or the very early embryo then the genetic modification will not be inherited by the offspring and will be lost in the following generation. This is why the transgene has to be introduced either in the gametes or in an embryo at the very early stage of development, ideally when the embryo it is at the one-cell stage. Therefore, mastering assisted reproduction techniques is the key for the successful generation of GE mammals including livestock (Fig. 1).

Male Germ Line

Male germ cells are located in the testis. In the testis, all stages of development are found from spermatogonial stem cells to mature spermatozoa. Spermatogonia can be collected through a biopsy, cultured in vitro [11] and when are reintroduced in the testis they can give rise to functional spermatozoa [12, 13]. During in vitro culture, spermatogonial stem cells can be GE and later transplanted back to the testis to restore spermatogenesis [14]. More easily from sexually mature animals, spermatozoa are recovered from the ejaculate, extended with appropriate diluents, and stored for fresh insemination or cryopreserved for later use. This is a well-established technique in livestock for use in artificial insemination. Spermatogenesis continues after puberty throughout the life of the animals producing an unlimited amount of spermatozoa. In an alternative route, prior to artificial insemination, spermatozoa can be exposed to the transgene in vitro.



Transgenic Livestock Technologies. Figure 1

Summary of Reproductive Technologies (*in counterclockwise*) Ovarian immature oocytes are recovered from ovaries at slaughterhouse, matured in vitro by culturing in a specific medium, fertilized in vitro by co-incubation with capacitated spermatozoa or microinjected with a spermatozoa with a glass micropipette.The resulting zygotes are cultured in vitro until developed to blastocyst stage and finally transferred to the uterus of a synchronized recipient female by a surgical or a nonsurgical procedure depending on the species

Spermatozoa can bind DNA and then convey it inside the oocyte at the time of fertilization [15]. Although the technique is not always reproducible [16], in this simple way some success in making GE livestock has been reported [94–96].

Female Germ Line and the Embryo

In mammals, primordial follicles, the functional unit that contains the female germ cell, exist on the ovaries but only a tiny proportion of the oocytes are effectively generating a progeny while almost all of the remaining are lost during lifetime through atresia. For many years, several investigators isolated and investigated the biology of intact primordial follicles in rodents [17] and finally grew them successfully in culture [18]. This task proved much more difficult in large animals with bigger ovaries having a lot of connective tissue [19]. Successful development with the birth of live calves, albeit at a low rate, was later obtained by culturing bovine oocytes from more advanced (secondary) follicles [20]. The culture requirements for growing a complex tridimensional structure, such as an ovarian follicle, are so complex that the only progress that has been made is the culture in vivo of thin slices of the ovary following transplantation in humans where this now has a potential application in patients undergoing certain therapies [21].

From the late 1970s, it became clear that also in farm animals it was possible to exploit the oocyte reservoir present in antral follicles from the ovaries of slaughtered animals. Oocytes present in antral follicles have completed the growth phase and they are ready for maturation and fertilization [22, 23]. Initially, successful development was obtained by maturing the oocytes inside the follicles [24]. The subsequent understanding of the crucial role of the surrounding follicular/cumulus cells during the initial phases of maturation [25] lead to the development of a coculture system for in vitro maturation of extrafollicular oocytes obtaining a high proportion of such oocytes developing into live lambs after in vivo transfer [26]. After the successful achievement of in vitro maturation in sheep, the work was expanded investigating in the sheep the effects of gonadotropins [27], and to the cow [28–31] but also to the pig [32] and to the horse [33] and other species as well. Immature oocytes can also be recovered with the ovum pick-up technique in live donor females of different livestock species like cattle [34–36], buffaloes [37], and horses [38]. The development of in vitro maturation is today an irreplaceable, cost-effective and reliable source of mature oocytes for the production of embryos in vitro following in vitro fertilization and the various biotechnological applications connected to it.

Following the seminal work done in laboratory animals [39] in vitro fertilization (IVF) is well developed in farm animal species. Following the birth of the first IVF calf derived from in vivo matured oocytes [40] significant advancements were obtained in IVF when heparin was used as capacitating agent for bull sperm [41]. At about the same time, IVF became a reality in other large species except the horse where the success has been only exceptional and only one foal has been reported as the result of IVF. The horse eventually benefited of the development of intracytoplasmic sperm injection (ICSI) in humans [42]. The use of ICSI has been very efficient as a way to circumvent failure of in vitro fertilization with a high degree of efficiency [23], not matched in other farm animals like cattle [43, 44], sheep [45], or pigs [46] where the efficiency of ICSI for embryo production is lower as compared to IVF and, therefore, this technique is not used for routine practical application. But this is in fact the way to introduce together with the sperm also the DNA vector required to make the genetic modification [47]. In pigs on the other hand, IVF is characterized by a high incidence of polispermy that compromises embryonic development. This problem has been overcome in part by improving the quality of in vitro matured oocytes rather than effectively changing IVF conditions.

The immediate goal of increasing the efficiency of in vitro embryo production (IVP) especially in cattle has been the initial driving force of applied research in this field. However, it became soon obvious that merely counting the number of blastocysts was not an accurate measure of the quality of the overall procedure and of the viability of the embryos [48]. For many years, these constraints on the culture of viable cattle embryos in vitro were overcome by using in vivo culture in the oviduct of sheep [7]. In particular, a major concern after in vitro culture of IVF embryos was caused by the description of the so-called Large Offspring Syndrome (LOS), first in sheep and then in cattle [49]. The use of

serum supplementation and coculture were later recognized as the primary cause of LOS. Later on, an extensive field study [50] demonstrated that the incidence of LOS was greatly reduced using a SOF (Synthetic Oviductal Fluid) [51]-based formulation or similar formulations of the embryo culture media. These findings clearly indicated that in vitro culture can alter development at very early stage and that the Large Offspring Syndrome is correlated to abnormally advanced embryonic growth and gene expression pattern already at very early stages [52]. Nevertheless the in vitro fertilization and preimplantation embryo culture in vitro allow to generate the number of zygotes required either for DNA microinjection or for virus infection, procedures that would otherwise not be possible or be very difficult for livestock using in vivo produced zygotes from superovulated donors as it is done in laboratory mice.

Nuclear Transfer and Cloning

Somatic cell nuclear transfer, better known as cloning, is a technique that allows the generation of individuals with the same genome; thus technically speaking, cloned animals carry the same genome of the donor cell used for the SCNT process, thus they are like twins between themselves and twins of the animal who donated the somatic cell. The genome comes from the nucleus of a cell that can be taken from an embryo, a fetus, or an animal. The nucleus has to be placed into a mature oocyte, as outlined above whose chromosomes are removed before hand. The nuclear transfer step reconstructs an embryo, with its entire genome originating from the cell's nucleus that will subsequently develop like any other embryo conceived by fertilization albeit at a lower efficiency. Cloning by nuclear transfer that brought to the birth of Dolly the sheep [10] is a milestone achievement that has attracted the attention of the general public toward farm animal embryo technologies. This is one of the best examples where the search of new reproductive techniques in farm animals has also provided basic knowledge not previously obtained in laboratory animals. The fundamental work of cloning by nuclear transfer was done in amphybia [53] in the 1960s, however, significant advancements of the technology were achieved with embryo cloning of farm animals [54] when matured oocytes, instead of zygotes, became the recipients of the donor nuclei. Ten years later, it was again farm animals that, with somatic cell nuclear transfer, gave a major contribution to the basic understanding of cell reprogramming and epigenetic control of mammalian development, opening a new era in cell biology. The success with which different mammals were cloned was directly correlated to the availability of good quality mature oocytes and good quality embryos either after in vivo or in vitro culture. Then, it was merely a combination of already available technologies of gamete and embryo manipulation that lead to success and, for example, in the horse it was not until such technologies were developed that cloning was achieved in a consistent and reproducible way [55, 56]. In the last 10 years, the efficiency of somatic cell nuclear transfer as a whole has not improved much and its practical application is limited to the production of animals that have high added value like breeding stock [56–58] or for generating transgenic founder animals when nuclear transfer is combined with genetic engineering of somatic cells [59–62].

Understanding the constraints of nuclear transfer and developing the concept of reprogramming of fully differentiated somatic cells and the derivation of stem cells from cloned embryos [63, 64] for potential biotechnology and therapeutic applications, has fostered the idea of reprogramming differentiated cells in vitro directly without the need of the oocyte. A set of four genes has been demonstrated to be at the core of pluripotency and when transfected to somatic cells gave rise to induced pluripotent stem cells (iPS cells) [65]. These cells, of somatic origin, are extraordinary because they carry most of the properties of embryonic stem cells derived from the early embryo and represent a major breakthrough to overcome the limitation of embryonic stem cells derivation in humans and livestock.

Once the molecular basis of pluripotency will be fully understood, it will be a major step forward that is expected to lead to advances in nuclear transfer technology and cloning of farm animals for agricultural and biomedical applications on a larger, solid basis.

Embryonic Stem Cells

Embryonic stem cells (ES cells) are pluripotent cells that originate from the early embryo either from the inner cell

mass or from the early epiblast. ES cells are cultured and expanded in vitro in undifferentiated conditions, can be GE if necessary, and when reintroduced in the embryos can give rise to any cell type including the germ line, except trophoblast. This is why they are defined as pluripotent and not totipotent cells which is a feature of gametes, zygotes, and early cleavage stages blastomeres only. Today, mouse ES cells technology is the principal route to make GE offspring [8].

The derivation of farm animal ES cells, equivalent to those described for the mouse, has not been reported yet (therefore this route for GE is not available at present in livestock species but it might be so in the near future). However, over the years, from 1981 when mouse ES cells were first discovered [66, 67], many laboratories have attempted ES cell derivation mainly from cattle, pig, and sheep embryos [9, 68]. The original mouse approach has been extensively used and finally proven, with no doubt, unsuccessful although a few reports have been published on the derivation of so-called ES-like cells [69]. However, the stemness (pluripotency) of these cells appeared to be very limited and most likely they represent trophoblastic cells given their epithelial nature, loss of OCT4 expression, and limited differentiation potential [68–70]. The prominent tendency for neural differentiation often observed when attempting ES cell derivation from large animals is another challenge, but it represents an interesting and robust in vitro model for the study of early neurulation events in mammals [64].

In light of all the published reports and observations, it appears that the search for ES cells in farm animals should abandon the original mouse procedure and pay more attention to the recent findings for ES derivation in mouse and humans based on different signaling pathways and/or specific small molecules inhibitors. Advances in mouse and, more recently, in human ES cells culture have demonstrated that a number of different culture conditions can support pluripotency of embryo-derived stem cells. Mouse ES cells can be grown not only in serum-supplemented cultures with LIF and feeders but also in serum-free and feeder-free culture by the addition of BMP molecules. This second method has been developed following the finding that mouse ES cells grown in serum-supplemented medium and LIF can be differentiated in neuroectodermal cells by serum and LIF withdrawal [71]. The role of BMP molecules is to counteract and block the induction of neural differentiation and fix the undifferentiated state in a clever balance between conflicting inductive signaling pathways [71]. Along the same lines, a novel approach for ES derivation in the mouse has been developed on the rationale that the undifferentiated state can be maintained in culture by simply shielding the pluripotent cells of the embryos from endogenous pro-differentiation FGF4 signaling. This method is based on the use of specific inhibitors of the FGF signaling cascade in association with GSK3 inhibitors, the latter acting by improving cell viability. Both mouse and, remarkably for the first time, also rat ES cells have been obtained by inhibition of differentiation signaling introducing the concept that ES cells represent a ground-state pluripotency capable of self-renewing providing that differentiation signals are blocked [72, 73].

Other protocols, based on the stimulation of the nodal-activin signaling pathways, have been shown to maintain the undifferentiated proliferation of human ES cells and mouse epiblast stem cells (EpiSCs). The latter are a type of pluripotent embryo-derived stem cells derived from the egg cylinder as compared to ES cells that derive from inner cell mass or very early epiblast cells. Interestingly, mouse EpiSCs have been shown to be very similar to human ES cells in morphology, growth factors requirement, and gene expression [74, 75] while mouse ES cells differ considerably from human ES in culture requirements for the maintenance of the undifferentiated state, growth rate, and response to inductive signals. Another important difference between mouse ES cells and EpiSCs is the fact that only the former are capable of giving rise to chimeric offspring following blastocyst injection. A recent publication has reported the first success in the derivation of pig EpiSCs [76] and represents a significant step forward toward understanding the requirements for maintaining pluripotency of cultured epiblast cells from farm animal embryos.

In an applied perspective, embryonic stem cells in farm animals are important for several reasons but the most relevant is to provide a method to introduce precise genetic modification into animals by homologous recombination in ES cells [60] followed by blastocyst injection for chimera derivation and breeding, or by somatic cell nuclear transfer. A second important objective is to provide large animal models in which the ES cell technology can be tested for tissue-specific differentiation [77] and cell therapy of various tissues and organs.

Techniques for Genetic Engineering

The meaning commonly given to the term "transgenic" or "GE-" animal, indicate an individual bearing an exogenous fragment of DNA integrated in its genome and transmitting such modification to its descendant through a Mendelian fashion. Therefore, situations like "somatic transgenesis" will not be taken into consideration, where the genetic modification is limited to somatic tissues e.g., in case of gene-therapy protocols applied to adult individuals) or "episomal transgenesis", where the exogenous DNA is present inside the cell nucleus but as an autonomous replicating entity, whose stability and replication are separated from those of host's chromosomes.

The natural processes driving the integration of a transgene into the chomosomes of the host cell are mediated by a set of enzymatic function related to the DNA-repair pathways. The enzymes involved in these pathways are responsible of repairing the host's DNA molecule in case of double strand break (DSB). The resolution of a DSB inside the cell nucleus may follow two alternative pathways, catalyzed by different enzymes. The first and more common process involves the Non-Homologous End Joining (NHEJ) pathway, where the free ends of DNA generated by the DSB are relinked together. The exogenous DNA introduced in the nucleus may be recruited during this process and integrated between the endogenous arms of a broken chromosome. The integration of a transgene through the NHEJ pathway causes its random positioning into the genome of the host and the frequent integration of multiple copies of the transgene in the same locus, end by end. Both the random integration site and the generation of a multiple-copy array can influence the expression of the transgene in an unpredictable way. The alternative enzymatic machinery available in the cell for repairing DSBs is the Homologous Recombination (HR) pathway. It relies on the availability of a full copy of the broken molecule to provide a one-strand template to restore the original DNA sequence. This enzymatic activity is principally evident during gametogenesis (when it is involved in crossing over between sister chromosomes) and maintains higher level during early embryonic development compared to somatic adult cells.

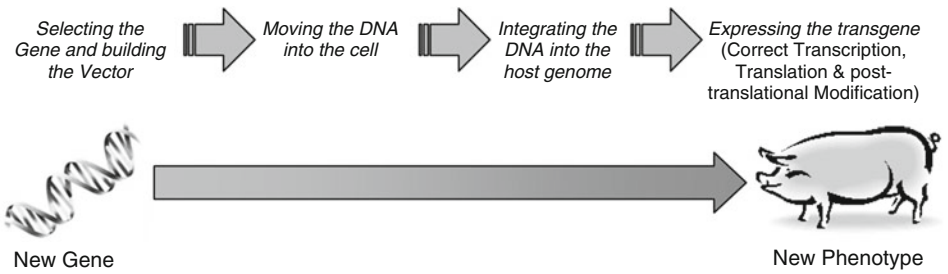
A transgene may be integrated by HR if it carries a region of homology with the target region in the host genome with the advantage of driving the insertion of the transgene in a specific locus and as a single copy. Nevertheless, this event is still rare compared to random integration by NHEJ. Even in ES cells, that retains a significant HR activity, the event of a targeted insertion of a transgene by HR is two to four orders of magnitude less frequent compared to its random integration.

For this reason, the process of gene targeting through natural HR can be performed only on cell cultures, where a large number of integration events can be generated and the cells carrying the desired event can be selected and isolated. The obvious next step to generate a transgenic animal is the capability of turning these cells into new individuals. In mouse, this has be accomplished by performing gene targeting in ES cells, that are able upon being introduced in a host embryo, to take part to the generation of a chimeric animal including part of its germ line and, as a consequence to pass the acquired mutation to its offspring [78]. As functional pluripotent ES cells have never been obtained from species different than the mouse, the possibility of performing gene targeting has been limited to this species until in 1996 Ian Wilmut and colleagues disclosed the way toward mammalian cloning by SCNT [79].

By then, even though somatic cells retain lower HR activity compared to ES cells, the option of performing gene targeting in this cells and to derive a whole animal from their genome has been demonstrated in swine, ovine, and bovine.

Since the generation of the first transgenic large animals by pronuclear microinjection, including transgenic pigs [3], major advances have been made, mainly by use of assisted reproductive technologies [80] as described earlier. Depending on the purpose of the genetic modification, the approach to transgenesis may aim to the random or the targeted integration of the transgene. In both cases, the obvious but sometime underscored consideration is that the final aim of the process is not only to insert a transgene into the genome, but also its proper *expression*. The hard track toward this is the result of intermediate steps, including (Fig. 2):

1. *Accurate design of the transgene*, involving the selection of the desired gene, its regulatory



Transgenic Livestock Technologies. Figure 2

Steps in obtaining a functional transgenic animal. The definition of transgenic is commonly associated with an organism bearing a new piece of DNA, but the true goal of the procedure is obtaining an animal expressing a new gene according to a desired pattern, that is, showing a new phenotype. Anticipating the final expression pattern of a transgene is still the weaker step in this technology (From [141])

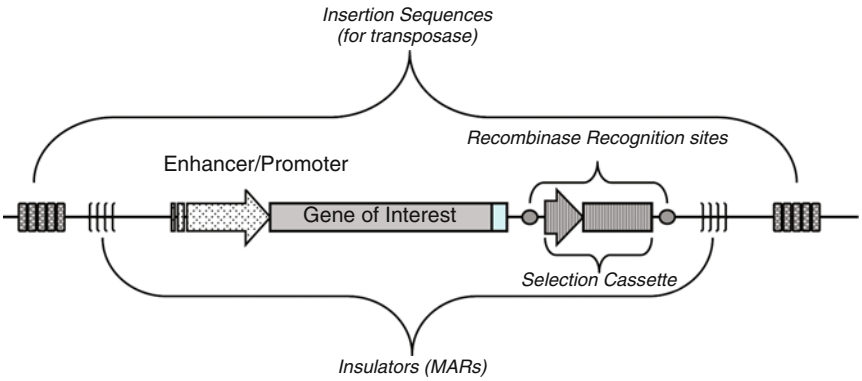
sequences, and all the additional sequences able to drive its integration and the expression of the desired phenotype in the right tissue at the right time

2. *Introduction of the DNA across the cell membrane* of the embryo or of the cell to be used in nuclear transfer
3. *Integration of the new DNA sequence into the genome*. This step may be mediated only by the endogenous NHEJ or HR pathways but, in some cases, a customized integration of the transgene may be artificially induced by the activity of exogenous recombinases or endonucleases specifically introduced into the cell
4. *Correct expression of the transgene* is dependent on the good implementation of all of the previously described phases and on a bit of luck. It is usually necessary to producing a large number of different integration events (i.e., embryos or cell clones) to allow the identification and the selection of the best performing, that will be used to generate and expand the desired transgenic line.

During the last years, the toolbox of the genetic engineer has expanded with new instruments allowing a better control on each of the described steps and an overall improvement on the whole procedure. Moreover, some genetic manipulation procedures initially available only for mice, have become concrete even for livestock.

Choosing the Gene and Assembling the Vector

Once the gene to be transferred has been identified, several alternative options are available to generate a transgenic vector (Fig. 3). The coding sequence of the gene itself may be used as cDNA, as genomic sequence (including introns) or as a minigene (a fusion of cDNA and genomic sequences of the same gene). The presence of one or more introns into the transgene, triggering the splicing process, is a major factor improving the transport of mRNA through the nuclear membrane and the effective expression of the exogenous gene [81, 82]. The regulatory sequences to be included into the transgene are chosen according to the need. The original promoter and enhancers may be conserved to drive the gene according to its original expression pattern, alternatively, heterologous promoters may be used to trigger a different tissue-specific or an ubiquitous expression. In case the gene has to be driven by its original regulatory sequences, the selected genomic fragment should be as large as possible to maximize the chance of a correct expression [83]. Indeed, if a gene has to be transferred from one species to another where the same regulatory signals are recognized, increasing the dimension of the fragment to be transferred allows to including not only the original promoter, but also distal enhancers and chromosomal modifiers [84, 85]. On the other hand, the large size of such DNA molecules influences the choice of the technique required for their introduction into the cell, due to the care required to purify and handle large and fragile DNA molecules. Although microinjection allows the introduction of such big molecules, larger than 100 Kbp, the efficiency of the procedure greatly decreases with the increase of DNA size and a significant part of the resulting transgenic animals



Transgenic Livestock Technologies. Figure 3

Generic structure of a transgenic vector. Beside the expression cassette for the Gene of interest (promoter, CDS and polyA site), additional sequences may be useful to increase the integration frequency of the vector (transposon-derived IS) or to support its regular expression (Insulators). Some features, like drug-resistance genes, are required for isolating cell clones but their persistence in the resulting transgenic organism is undesirable. They can be ablated by means of exogenous recombinases (From [141])

integrates only fragmented transgenes, due to shearing of DNA during injection and/or its enzymatic degradation before going into the chromosome. To improve the transfer of large DNA fragment into the genome, specific procedures have been developed, like the ICSI-mediated Gene Transfer (see below). Besides the selection of the gene and its regulatory sequences, additional features may be inserted into the transgenic vector. In case the transgene has to be introduced in cultured cells, it is often required the insertion of a selection cassette, providing resistance to a specific xenobiotic. As the integration of the vector in the genome of the cell is quite a rare event, the addition of a xenobiotic to the culture medium allows to grow only the transformed cell, that become resistant to it, and to eliminate the rest of the culture.

On the other hand, as the residual presence of this cassette in the transgenic animal may be deleterious or undesired, such cassette may be "floxed" (flanked by lox sites) for a subsequent removal through transient expression of Cre recombinase [86] (see further below).

Random integration of the transgene into the genome is recognized as the main source of variability in the expression of the exogenous genes, due to the influence of flanking genomic regions that may affect the expression pattern of the transgene or "switch it off" by epigenetic silencing. To avoid this behavior, insulator sequences may be inserted to shield the transgene from the influence of the chromosomal location [87–90]. Such insulators, called Matrix Attachment Regions (MARs), bend the transgene in a single transcriptional domain bound by its ends to the nuclear matrix. Additional features of the DNA construct can confer to the vector the behavior of a transposon, being recognized by a transposase that can be cotransferred or transiently co-expressed with the gene during gene transfer. This strategy will be described further below.

Transferring the DNA into the Cell

Pronuclear Microinjection

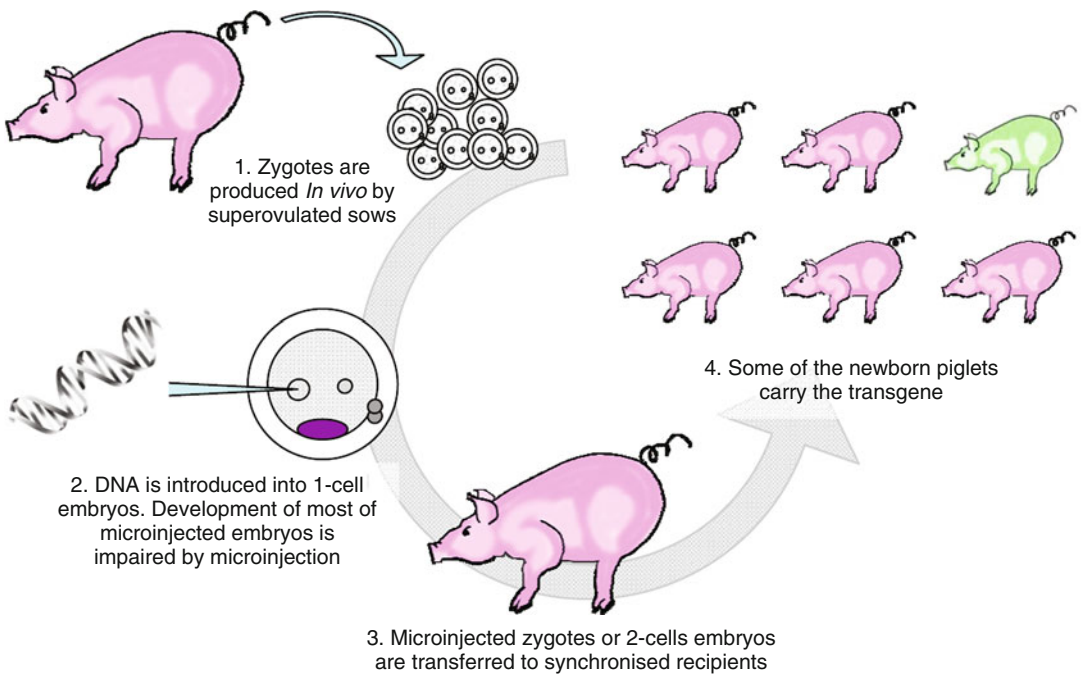
Pronuclear microinjection is now less commonly used in livestock, having been largely replaced by more efficient and less expensive techniques, after the demonstration of the possibility of cloning mammalians by nuclear transfer [10, 91]. Previously, microinjection was considered the most reliable technique to generate transgenic large animals, albeit inefficient and quite expensive in large animals. In vivo production of zygotes provides very viable embryos, but is an expensive approach. The data reported by Krimperfort concerning the generation of the first transgenic calf in 1991, starting from in vitro

produced embryos, evidenced the huge effort made in generating this animal.

Two thousand four hundred and seventy (2,470) oocytes were matured and fertilized in vitro to give 1154 zygotes that underwent microinjection; among them, only 129 developed and were transferred in 99 recipient cows. Twenty one (21) calves were born, only two of which were bearing the transgene. One of them died at birth. The other, a male called Herman, grew to adulthood and was mated, because its transgene, coding for human lactoferrin, was designed to be active into the mammary gland of transgenic cows. Sadly, the expression of this gene in the milk of Herman's daughters was extremely low, making the whole project useless. At the time, the cost of the whole procedure for producing such transgenic bull was estimated around 500,000 dollars.

Different factors may affect the expression of microinjected transgenes, considering that they integrate in random sites of the host genome. The disadvantage compared to what happens for gene transfer in cultured cells, in detecting the transgene integration ahead of embryo transfer, although possible, is not practically convenient following pronuclear microinjection, let alone the assessment of its expression. For this reason, most of the animals resulting from microinjection protocols are non-transgenic (Fig. 4).

Last but not least, obtaining embryos bearing targeted transgene integration, until recently, was considered nearly impossible by this approach. DNA integration upon standard microinjection is achieved mostly via NHEJ, resulting in a random positioning of the transgene into the genome and a consequent



Transgenic Livestock Technologies. Figure 4

Transgenic production by pronuclear microinjection One-cell embryos are recovered from superovulated females. Such zygotes shows high viability but their production in vivo is somewhat expensive. Embryos are centrifuged to reveal pronuclei and DNA is microinjected into one of them. Microinjection of DNA affects embryo viability. Surviving embryos are transferred in synchronized sows. The proportion of transferred microinjected embryos developing to viable offspring is low and variable, moreover only small fraction of them carries the transgene. The pattern of expression is unpredictable. The overall efficiency of this procedure in terms of living transgenic/microinjected embryos usually ranges from 1% to 4% (From [141])

unpredictable effect of the flanking regulatory elements on the expression of the transgene itself. Recent advances in enzymatic engineering has demonstrated the possibility to overcome this limit obtaining the targeted integration of a transgene by means of Zinc Finger Nucleases [92] as discussed below.

Sperm-Mediated Gene Transfer (SMGT)

In 1989, Lavitrano and colleagues reported a new approach to generate transgenic mice based on pre-incubation of spermatozoa with exogenous DNA followed by in vitro fertilization [15]. This unconventional approach was accepted with skepticism by many scientists working in the field of transgenesis [16, 93]. In spite of that, other authors reported success in obtaining transgenic animals by variations of SMGT protocol [94, 95]. After few years, the same technique was adapted to the production of transgenic pigs bearing a hDAF transgene [94–96]. The benefits of this technique, compared to pronuclear microinjection, are low cost and ease of use. Nevertheless, the insertion is still random and the transgene can be rearranged, thus affecting the expression levels. The long-term expression of the transgene remains controversial [97].

ICSI-Mediated Gene Transfer (ICSI-MGT)

ICSI-mediated gene transfer is a technique sharing some analogies with SMGT and microinjection, where both the transgene and the sperm head are introduced with a micropipette into the cytoplasm of the oocyte [47]. In mice, ICSI-MGT is more efficient than standard microinjection and can be particularly effective when a large construct (ranging from 100 kb to more than 0.5–1 Mb, i.e., YAC, BAC, microchromosome) has to be transferred [98]. Together with the use of polyamines to condense DNA, the large size of the micropipette used for injecting the sperm head preserves DNA integrity minimizing mechanical shearing.

Although assisted reproductive technologies (Fig. 1) in pig still suffer some limits, possibly due to specific requirements in embryo culture conditions yet to be defined, some researchers succeeded in producing transgenic pigs by co-incubating sperm with a DNA vector and microinjecting the spermatozoa directly into the ooplasm. After the transfer of 702 embryos into 5 gilts, 2 out of 35 fetuses recovered were transgenic. In vivo production of zygotes provides very viable embryos, but is an expensive approach and requires the use of animals. Nevertheless, this is the preferred source of embryos for this procedure, because microinjection by itself heavily impairs the subsequent embryonic development and decreases the number of newborns following embryo transfer [99].

Viral-Mediated Transgenesis

During their life cycle, retroviruses are able to enter the cytoplasmic membrane of a target cell by binding specific receptor, to reach the nucleus and to retrotranscribe a DNA molecule using their RNA genome as a template. This DNA molecule will often integrate into the host genome.

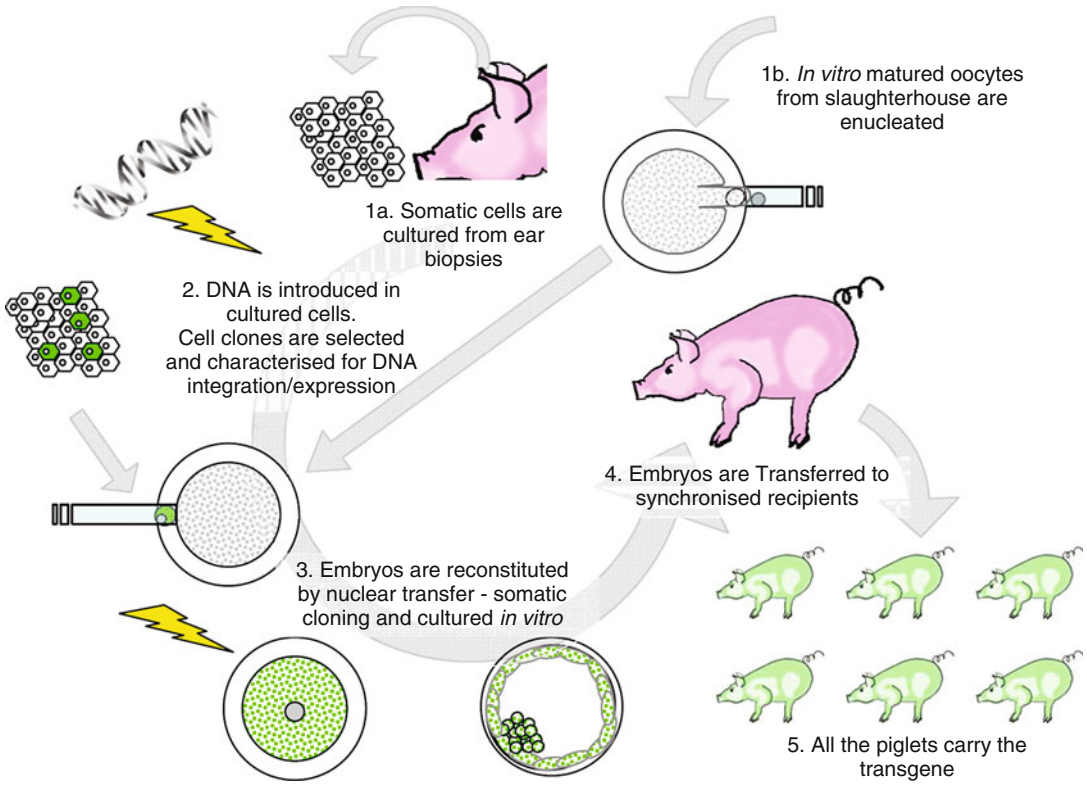
Mimicking such behavior, retroviral-derived vectors have been engineered to carry a specific transgene to be integrated into the target genome, but lack the genes required for completing their replicative cycle. Such retroviral vectors, initially developed to target somatic cells for human gene therapy, can also infect preimplantation embryos, providing that the zona pellucida is removed or at least breached, since it is a barrier to the viruses. The retrovirus integrates its complementary DNA into the genome of the embryo. The cell cycle of the infected cell may be susceptible or not to integration depending on the origin of the selected viral vector. For this reason, early trials with retroviral vectors resulted in mosaic animals, due to the failure of these vectors to enter the genome during one-cell stage but only during subsequent embryo divisions. A more recent generation of viral vectors is based on the structure of lentiviruses like HIV. Lentiviral gene transfer is extremely efficient, with 80–100% of the animals being born transgenic after oocyte or embryo, or somatic cell culture infection@ [100]. Lentiviruses have been used in a variety of experiments to transduce cells with various transgenes. These experiments include siRNA knock-down for stem cells and for somatic cells, and nuclear transfer (see below) for generating desired modifications. Lentiviral transgenesis is one of the main techniques currently proposed for somatic gene therapy. Such approach is associated with known risks and observed limits. During clinical trials, retroviral transgenesis has been associated with oncogene

activation by insertional mutagenesis [101, 102]. To reduce this risk, the interest of the researchers is moving toward replication-deficient vectors [103]. An additional concern about the use of lentiviral vectors is their possible recombination with latent wild retrovirus to generate unpredictable infectious or mobile particles. Among virus-derived vectors, lentiviral (LV) have the property of infecting cells both during replication and in quiescent phase. During lentiviral-mediated transgenesis, the use of some drugs like cytokines or proteasome inhibitors can increase LV gene transfer [60, 104]. Santoni de Sio and colleagues [104] have shown that human hematopoietic stem cells (HSCs) can be transduced to high efficiency by a short exposure to LVs in the presence of SCF, TPO, IL-6, and Flt3L. Moreover, it was shown that the proteasome restricts LV transduction in HSCs and that using the reversible peptide–aldehyde proteasome inhibitor MG132 and the peptide-boronate inhibitor PS-341 during the LV-GFP transduction period, there is a substantial drug-dose-dependent increase in the frequency of transgene expressing cells and in their mean fluorescence intensity [104].

The use of lentiviral vectors for transgenesis results in a significant degree of mosaicism among transgenic newborns, due to the possible multiplicity of integration events during the first cleavages of the embryo [105]. Even though lentiviral vectors enter as a single copy into their insertion site, their integration mechanism is very efficient, frequently resulting in multiple copies integrated in different part of the genome and in a complex pattern of transmission to the offspring [105]. Due to their random positioning into the chromosomes, lentiviral vectors may still undergo epigenetic silencing by methylation [106]. Another class of effective vectors for transgenesis was derived from the adeno-associated virus (AAV). AAV-derived vectors have the advantage to cross the cell membrane delivering single stranded DNA molecules straight to the nucleus. Some adeno-associated viruses are peculiar in their behavior of targeting specific integration site in the host genome [107]. Adenoviral ssDNA shows a high effectiveness in integrating into the host genome through homologous recombination, even in somatic cells [108, 109]. Recently, Rogers et al. produced a CFTR-null pig using AAV-mediated gene targeting and SCNT [110, 111]. These authors generated a pig with both null (knock-out) and ΔF508 (knock-in) modifications. Gene targeting using the AAV approach has resulted in a very efficient strategy for obtaining knock-out of the CFTR gene that is not expressed in fibroblasts.

Somatic Cell Nuclear Transfer

Somatic cell nuclear transfer (SCNT) has become the leading tool for generating animals from GE somatic cells (Fig. 5). SCNT works better in pigs than in other large animals [112, 113]. A recent innovation to make the technique user-friendly is the zona-free system. After zona removal, enucleation can be performed with a micropipette, for subsequent zona-free fusion, activation, and culture [113, 114], or by cutting the cytoplasts for handmade cloning [115, 116]. Major limitations are represented by the lack of embryonic stem cell (ESC) technologies. Somatic cells are currently being used in the procedures, but they have a limited life span, thus restricting the time the cells can be cultured in vitro for genetic engineering. Fibroblasts (both from fetal and adult origin) have a fine life span and can undergo a maximum of 40–50 population doubling in vitro while maintaining a normal kariotype. Such number of population doublings allow only for a round of cell transfection followed by drug selection to identify a clonal cell population with the desired modification. In fact by the time this has been achieved, the cells have spent most of their proliferative capacity and have to be used for SCNT before they reach complete senescence. So, the use of fibroblasts limits this approach to one modification in vitro at the time since they would not survive a second round of transfection. After SCNT, the fibroblasts are rejuvenated and have fully restored their proliferative capacity. At this point, cloned fetuses are recovered to establish a new fibroblast cell line that can be then subjected to a new round of genetic modification. This process can be repeated several times with apparently no adverse effects [59]; however it requires time and animals. Relating to this topic, recent reports describe the derivation of induced pluripotent stem cells (iPSC) from pig fibroblasts [117–119], however the objective is still far since culture conditions to maintain livestock embryonic stem cells are not known (further discussed below). The opportunity of performing the whole genetic engineering on cell cultured in vitro and finally transferring the manipulated genome to the enucleated oocytes allows selection for gene targeting events, both



Transgenic Livestock Technologies. Figure 5

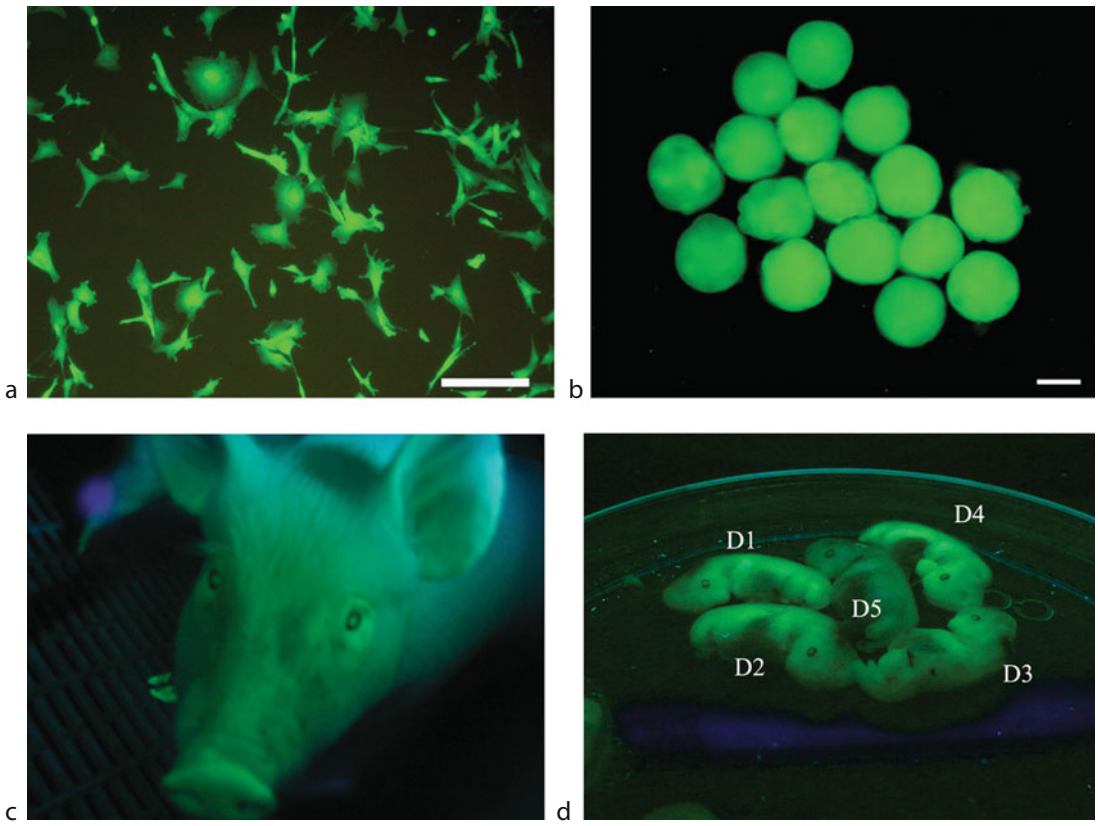
Transgenic production by SCNT. The transgene is transferred into the genome of cultured fibroblasts. Transgenic cell clones are isolated and characterized. This first step is relatively inexpensive. A more accurate prediction of the transgene expression is possible. Next, embryos are reconstituted by SCNT, cultured and transferred in synchronized sows. Although the viability of cloned embryos is variable but usually poor, all of the resulting newborns are transgenic (From [141])

for *knocking out* an unwanted gene or for *knocking in* a transgene in a predetermined reliable position, guaranteeing its best expression.

A similar model, implementing the 1,3 galactosiltransferase knockout in pigs was developed by Takahagi and colleagues that knocked out the first allele of this gene in porcine fetal fibroblast already expressing hDAF and N-AcetylglucosaminylTransferase -III (GNT-III) [120]. In a further step, the authors selected cultures for spontaneous null mutations of the second allele occurring in vitro, and used these cells for nuclear transfer. In this way, the resulting cloned pigs were transgenic for hDAF and GNT-III on a 1,3 galactosiltransferase null background [121].

SCNT technology overcomes many limitations of previous procedures, making possible the gene targeting approach to livestock genome and providing a less expensive way to perform genetic engineering. Indeed, most of the cost and the efforts related to transgenic technology applied to large animal are derived from housing animals, preparation for embryo transfer up to the birth and weaning of the newborn animals.

The opportunity of using cell clones fully characterized in term of transgene integration and expression, guaranteeing 100% of transgenics among born animals, greatly increases the efficiency of the protocol and drops the costs when an ubiquitous or inducible promoter is used and the expression is maintained in subsequent generations through germ line development (Fig. 6) [112]. On the other hand, SCNT is not the final solution for every problem, as most of the matter concerning the proper activity of the transgenes, with regard to its temporal and tissue-specific expression, still needs to be completed on the whole animal.



Transgenic Livestock Technologies. Figure 6

Successful selection of GFP transgenic cells and transmission through the germline of the transgene to the next generation. Clonal fibroblasts selected for high expression of GFP (**a**), GFP expression in embryos after SCNT (**b**) and in the resulting animal (**c**). Fetuses obtained after breeding the GFP boar to a wild type sow (**d**). Fetus D1, D2, D3, D4 are transgenic and express the same high level of GFP of the original boar, D5 is a wild type fetus negative for GFP (From [141])

Possible improvements to overcome these problems are offered by recent advances in genetic engineering.

Emerging Technologies

Several new technologies becoming available may be of great benefit in the future to make GE large animals.

Induced Pluripotent Stem Cells (iPS Cells)

In 2006, a breakthrough study [65] demonstrated that viral transduction of a handful of genes (Oct4, Sox2, Klf4, and c-Myc) can reprogram mouse embryonic fibroblasts into ES cell-like cells which carry all the molecular features of true embryo-derived ES cells including the ability to give rise to germ line chimeras. The following year the generation of human iPS cells was achieved [122, 123] using slightly modified transduction methods and set of genes. Since then, several groups have contributed to the field with new combinations of reprogramming genes, cell types, and viral and nonviral delivery systems. More recently, the addition of small molecules acting on chromatin structure, such as valproic acid, a histone deacetylase inhibitor has allowed further progress by showing that only Oct4 and Sox2 are required for reprogramming of human fibroblasts [124]. Several other small molecules acting on chromatin or on specific signaling pathways have been investigated to improve the efficiency and safety of iPS cells technology (see as review [125]). In large animals, attempts to derive iPS cells have been made resulting in a few reports about induced

reprogramming of pig fibroblasts [117–119]. Although promising data have been presented, the evidence of full reprogramming, measured by sustained activation of endogenous genes and silencing of reprogramming genes, has not been achieved. Most likely, the lack of robust procedures for the establishment embryo-derived ES cells in large animals represents a major limit also for the development of the iPS cells technology. More detailed knowledge on the role of pluripotency genes in the early embryo is needed to advance the field of induced pluripotency not only in the mouse [126] but also in large animal species.

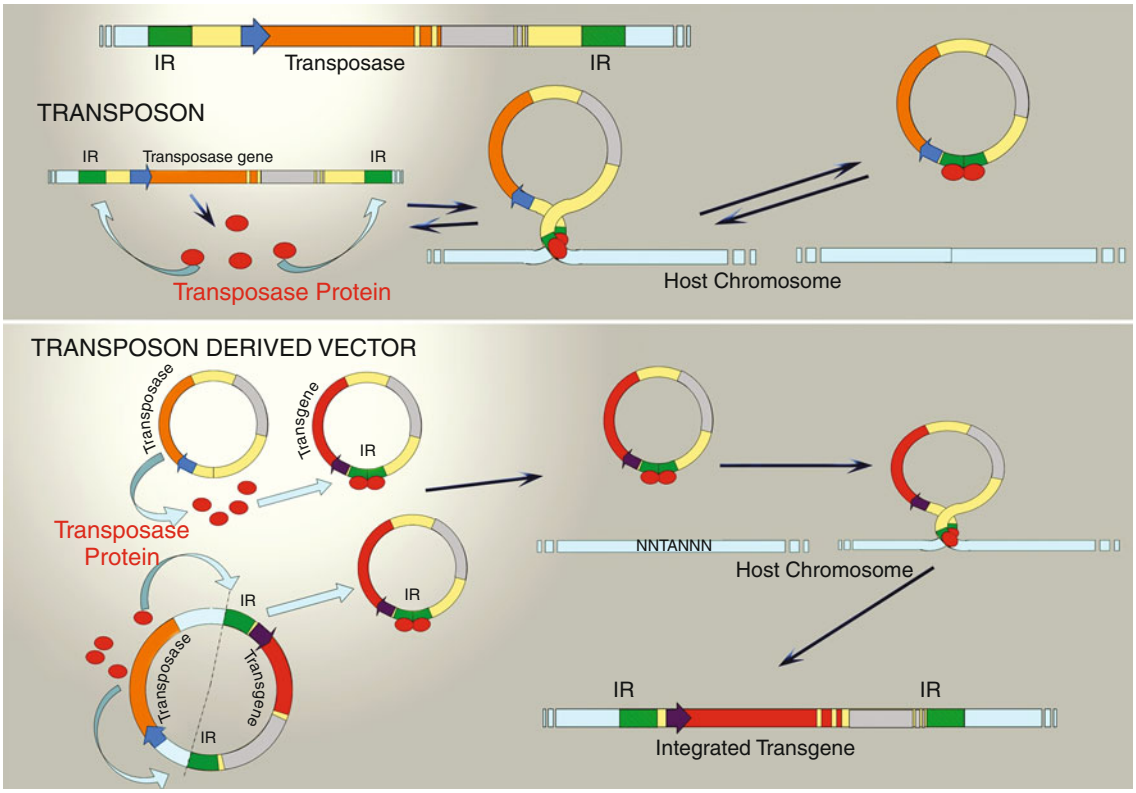
Enzymatic Engineering

Transposons Transposons, called also "jumping genes" are mobile genetic elements; class II transposons are small segments of DNA able to move across the genome of a cell from one region to another, by means of the action of enzymes (transposase) encoded within the transposon itself or supplied in trans by another source (Fig. 7). Transposons have been found in many living organism, from bacteria to plants and animals. The simplest autonomous replicating transposons in vertebrates, like those belonging to TC1/Mariner class, are composed by two inverted terminal repeat flanking a sequence coding for a specific transposase. Although the movement of transposons across different organism does not seem to be a common capability, philogenetic studies strongly suggest that "jumps" of transposons across species have happened during evolution [127]. Modified transposons, like "Sleeping Beauty" and "PiggyBac" have been largely used for precise and efficient delivery of DNA expression cassettes in vertebrate cells. Sleeping Beauty (SB) belongs to the TC1/Mariner class of transposons and these transposases require a TA dinucleotide base pair as integration site, a sequence that is duplicated during the integration process. The SB transposon system consists of two components: (1) a defective transposon, made up by gene of interest flanked by inverted repeats (IRs) but lacking the transposase gene, and (2) a source of transposase. During transposition, the SB transposase recognizes the ends of the IRs and excises the transposon from the delivered plasmid DNA inserting it in to another DNA site.

In a recent study, it was shown that co-transfection of PEGE cells with Sleeping Beauty (SB), Passport (PP) Tol2 and PiggyBac (PB), with their corresponding transposase expression constructs, resulted respectively in 13.5-, 5-, 21-, and 28-fold increases over transfection without transposase [128]. In addition to increasing the efficiency of integration, transposase-mediated transgenesis precisely integrates a single copy of the transposon into one or more locations in the genome, avoiding transgene concatemerization that can cause shutdown of gene expression.

Cre/LoxP Recombinases The integration site of a transgene strongly influences its expression pattern. To overcome the gamble of a random integration, it is possible to target the insertion of the transgene to a transcriptionally active location of the genome, avoiding the risks of both silencing the transgene and disrupting an endogenous gene (insertional mutagenesis).

One possible strategy to obtain this goal is the use of phage recombinases like Cre or FLP that catalyze a conservative DNA recombination event between two short recombinase recognition sites (RRS), loxP and FRT (Fig. 8), respectively. Such enzymes, used by bacteriophages during their infection cycle, allows the excision or inversion of the DNA between two RRSs, depending on their orientation [128]. The artificial modification of the sequences of the parental RRSs has allowed to develop the so-called Recombinase-Mediated Cassette exchange (RMCE), a protocol to modify a specific locus in the genome after an initial "tagging" by the introduction of a pair of incompatible RRSs [129]. In this way, (1) a cell line is modified by inserting a RRS-flanked reporter gene in different random position, (2) the deriving clones are screened to select the one presenting the best integration site, and (3) the gene of interest can be exchanged with the reporter to assure its proper expression. A predictable modification of the genome may be realized by driving the process of DNA repair through homologous recombination (gene targeting). This process, largely used in mouse ES cells, allows the interruption of endogenous sequences (knock-out) or the insertion of new genes (knock-in) in a specific locus [130, 131]. Unfortunately, the HR pathway is much less efficient in somatic cells like

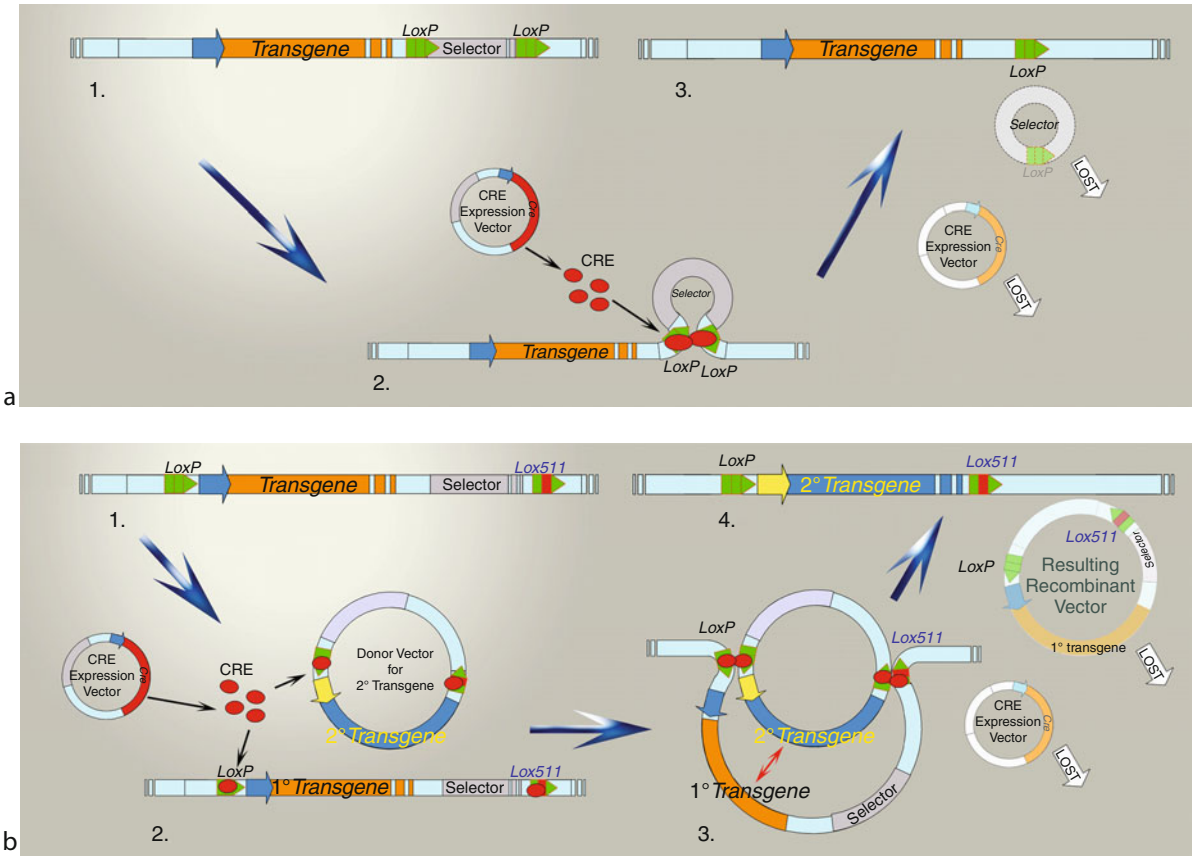


Transgenic Livestock Technologies. Figure 7

Integrative vectors based on Transposon signals *Top*: Natural occurring DNA-transposons consists of a common minimal structure represented by a gene coding for a specific transposase (TP) and two terminal inverted repeats (IRs). Following the expression of the gene, its product is able to bind to the inverted repeats, inducing the circularization and the excision of the complete DNA segment surrounded by IRs. Depending on the type of transposon, excision can leave small footprint in the chromosome or restore the exact original sequence. Following excision, the circular transposon, still bound to transposase, can integrate in a new site of the genome. In presence of transposase, both the excision and the integration of the transposon are catalyzed. Some transposons, like PiggyBac, prefers transcriptionally active genomic region for their integration. *Bottom*: A Transposon-derived vector is represented by a transgene flanked by a pair of IRs, but lacking the transposase CDS between them.The integration of this vector can be obtained with high efficiency by expressing the specific transposase *in trans* – on a different vector (**a**) – or *in cis* – on the same vector but by a cassette located outside the IRs-delimited portion (**b**). The transiently expressed exogenous transposase promotes the integrative cycle of the vector but, due to the absence of a stable source of protein, the integration of the vector is irreversible (From [141])

fibroblasts, making this procedure much harder, in particular for genes that are inactive in the target cell type not allowing the use of gene-trap (promoterless) approaches.

Zinc Finger Nucleases (ZFNs) Zinc finger nucleases (ZFNs) show promise in improving the efficiency of gene targeting by introducing DNA double-strand breaks in target genes, which then stimulate the cell's endogenous HR machinery. Zing finger nucleases are hybrid proteins containing an array of zinc-finger DNA-binding domain and a FokI endonuclease domain (Fig. 9). The DNA zinc-finger domains are designed to recognize a specific sequence, inducing a double stranded break in the target site. Such break promotes a local DNA repair activity that is efficiently accomplished by HR if a template with homologous sequence is provided. Many studies have been



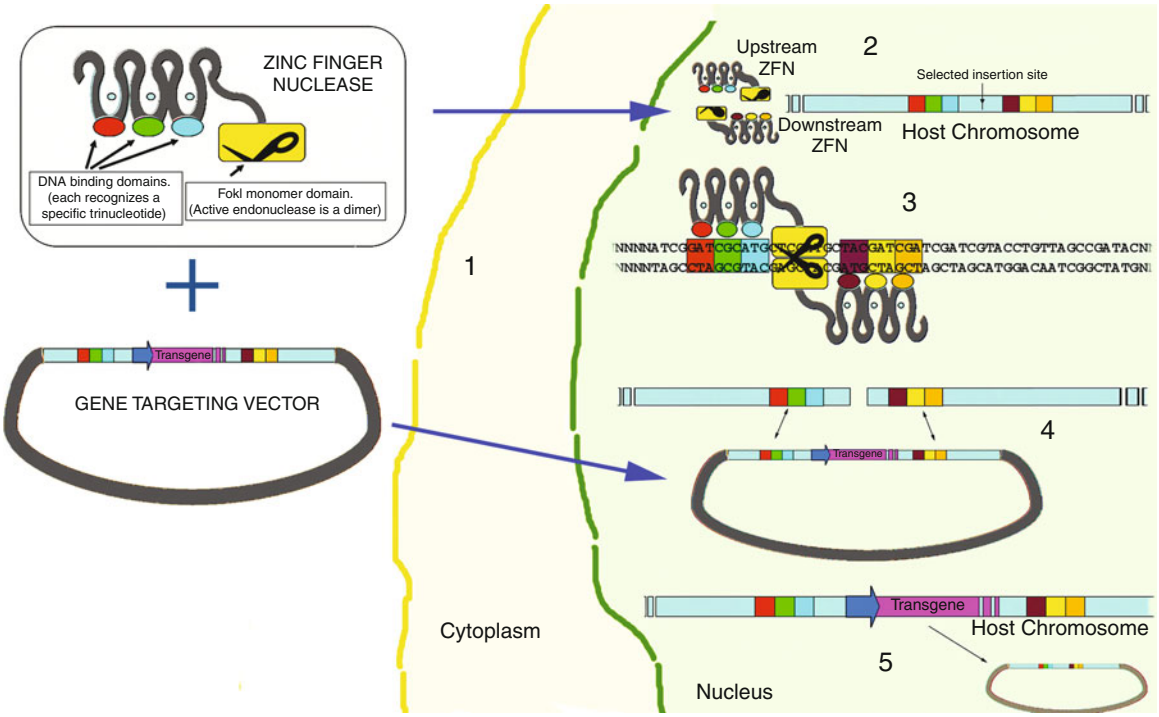
Transgenic Livestock Technologies. Figure 8

Targeted rearrangement of an integrated transgene by Cre recombinase. (**a**) Homologous Lox sites in the same orientation allows the excision of the enclosed region when Cre is expressed (**b**) Heterologous Lox sites do not allow excision but promote RMCE (Recombinase Mediated Cassette Exchange) if a vector bearing a Lox-flanked transgene is introduced together with CRE

developed in human and mouse cells [60, 132]. A recent paper demonstrates the possibility of generating transgenic rats by pronuclear microinjection of specific ZFN expression vectors together with a gene targeting construct [92].

An additional requirement in developing transgenic livestock is the need of expressing multiple transgenes in a coordinate pattern in the same animal. As previously noted, protocol bringing to random integration of multiple transgenes, often result in similarly random level of expression, with some transgenes working and some other not. A strategy to speed multiple transgene integration is represented by recent adaptation of the 2A system from foot and mouth disease virus (FMDV) to mammalian transgenic technology [133, 134]. In this system, the open reading frame (ORF) consists of multiple individual cDNAs separated by sequences encoding 2A and furin cleavage sites. A single complex mRNA is produced and translated into a single polypeptide that is cleaved into individual exogenous proteins at the 2A sites.

siRNA In cells transfected with siRNA vectors, targeted mRNAs are degraded by endonuclease activity and the amount of protein translated may be reduced by over 95%, thus resulting in a significant knockdown and is an alternative approach to achieving more complex and difficult knock-outs (KO). This technique is particularly useful when more than one



Transgenic Livestock Technologies. Figure 9

Homologous Recombination via Zinc Finger Nucleases (ZFNs) 1. A gene targeting DNA vector is prepared, where the transgene is flanked by DNA sequences homologous to the target locus. In different vectors, two ZFNs are designed, each coding for a specific DNA binding region and a FokI endonuclease monomeric domain. The two sequences recognized by the ZFNs are positioned upstream and downstream the selected insertion site in the target locus. The ZFN is introduced into the cell by microinjection, electroporation or transfection of a DNA expression vector or of a mRNA transcript. 2. The mRNAs are translated in two Zinc Finger Proteins. Each "finger" motif of the ZFN recognizes a sequence of three nucleotide (in this example, three "fingers" recognize a 9 bp target). A single ZFN binding to the DNA does not produce any effect. 3. When both the ZFN bind the DNA at the right distance, FokI domains can dimerize and produce a Double Strand Break in the target site. 4. DNA repair on the DSB can proceed through the NHEJ pathway, but, due to the availability of homologous sequences provided by the targeting vector, can also follow the route of Homologous Recombination 5. By Homologous Recombination, the transgene is introduced into the target site. The endogenous allele and the vector backbone sequences are lost (From [141])

copy of the endogenous gene is present and the usual KO approach is not feasible. This is indeed the case of pathogens like porcine endogenous retrovirus (PERV) [135–137]; for example, "knock-down" of PERV expression has been shown in transgenic pigs expressing siRNA corresponding to the viral pol2 sequence [138]. This approach could even be of interest in generating transgenic animals resistant to specific viral pathogens, by steady expression of virus-inhibiting siRNA molecules in their cells.

Future Directions

The GE of livestock is slowly making progress toward possible applications both is science and industry. SCNT has been the major advancement in this field for the last 25 years. Nevertheless, many are the issues that need to be addressed to make GE of livestock robust, reproducible, and affordable. Assisted reproduction techniques are continuously improved and refined, however, the availability of true embryonic stem cells is still the one of the

limiting factors for precise GE and the recent report of alternative sources like iPS cells have yet to prove their value for this purpose and it might take a long time before they become a reality. The designing of more effective DNA delivery vectors relies on the sequence of the genome. In livestock, this is lagging behind that of the human or mouse, therefore, it is not always possible to translate discoveries made in those species to livestock unless genomic information are generated by homology and partial sequencing. The ability to target the insertion of the transgene into a locus on a chromosome to assure its expression also through generations would be a significant advancement since today few of the GE livestock expresses the inserted transgene at the level desired and the expression is often not stable.

The ability to target specific genes either by knockout through HR or knockdown by siRNA, will make it possible to develop functional genomics (i.e., understanding the function of a particular gene) in mammalian species closer to the human other than the mouse and to generate large animal models of human diseases, especially for those diseases that the mouse model has failed to reproduce the human phenotype [110, 139]. Animal models are required both to understand the pathogenesis of a disease, to develop and test possible new therapeutic approaches to it. Biotechnological application of GE animals again for biomedical application include the field of xenotransplantation, i.e., the possibility to transplant tissues and organs from one species (usually the pig) to humans [140, 141]. This requires multiple GE to make pig organs accepted by the human immune system. Another biotech application is the GE of livestock to express antibodies or proteins that have a therapeutic use in human cancer or other diseases [59] in sufficient quantities and affordable costs that would not otherwise be possible by other means.

Although the biomedical field is the more advanced and more receptive for this new technology, there are also potential applications in agriculture for breeding and selection of livestock. Proof of principle have been already obtained for increasing yield in cheese production [62] or better quality pork meat [142] as well as for disease resistance [61, 138].

GE of livestock is an expanding area of research with great potential for applications in the biomedical, biotechnology, and agricultural fields. This technology provides a tremendous potential to select and breed animals with specific genetic makeup much faster than by conventional breeding schemes; however, this will be possible when full understanding of the underlying biological mechanisms will be known.

Article Outline

Glossary

Arabinoxylan A polymeric backbone of β(1,4) linked xylose residues with attached C(O)-2,3-linked arabinose residues that is found mainly in cereal grains. It becomes highly viscous when dissolved in the gastrointestinal tract and is not digested by monogastric animals.

Eutrophication A process where water bodies receive excess nutrients especially as phosphorus or nitrogen that stimulate excessive plant and algal growth resulting in reduced water quality.

β-Glucan A polymer found primarily in cereal grains consisting of β (1,3:1,4) linked glucose residues that becomes viscous on solubilization in the gastrointestinal tract and is not digested by monogastric animals.

Glycanase Any enzyme that catalyzes the hydrolysis of a glycan, which includes glucanases and xylanases of all types.

Phytase Any type of phosphatase enzyme that catalyzes the hydrolysis of phytic acid releasing phosphate molecules.

Phytic Acid Inositol hexakisphosphate (or phytate when in the salt form) is the principle storage form of phosphorus in many plants. It accounts for 50–80% of the total phosphorus present and is poorly digested by monogastric animals.

Definition of the Subject

As the world population increases, there is an increasing demand for food including both plant and animal products. The demand for meat and milk are increasing at a faster rate than for plant products because of increased wealth in developing countries. Intensification of livestock production to satisfy the demand is exacerbating the deleterious impact of intensive animal agriculture on the environment and new approaches are needed to reduce the impact. One approach is through the development of transgenic animals that have a smaller environmental footprint. At present there are no transgenic livestock in production. Transgenic livestock that have reduced environmental impact have been developed, but most proposed strategies are at the early stages of development. Physiological modifications that would reduce the impact of livestock include changes to improve feed utilization, increase growth and increase disease resistance, reduce manure output, and decrease greenhouse gas production. Obviously an essential factor is that the changes in physiology of the transgenic animal must have no deleterious effect on health, welfare, performance, and the environment.

Introduction

Environmental Impact of Livestock

Demand projections point to increases of global meat consumption of 68% and of global milk consumption of 57% of the 2000 base period by 2030 [26, 83]. While agriculture could be considered a "green" industry which uses solar energy to produce food and fiber for human use, it has also become a serious threat to global ecological systems. Currently forest losses in tropical countries is largely due to conversion to agricultural land to increase global grazing and cropland dedicated to the production of feed that already amounts to approximately 70% of all agricultural land [84]. The trends are illustrated by Fig. 1. Livestock production is a major cause of greenhouse gas production, particularly methane production, and as well is a major source of pollution due to the extensive use of pesticides, antibiotics, and nutrients (nitrogen, phosphorus, and minerals) that result in increased

Global expansion of livestock production and supporting land

eutrophication with deterioration in water quality in many countries [87]. The major *challenge for animal agriculture in this century is to sustain and increase meat and milk production without further degrading the environment.*

Production of meat from monogastric animals, mainly swine and poultry, has increased 103% over the period from 1987 to 2007 compared to ruminant meat production that increased by 28% [27]. The shift to monogastric species and continued productivity gains have the potential to reduce environmental impact per unit of animal production in the future, but with overall production increasing, serious pollution concerns remain. The issues and options in addressing the environmental consequences of a growing livestock sector are clearly enunciated in a paper by Gerber et al. [30].

Selective breeding of animals has greatly improved commercial performance of livestock and is especially useful for improvement of *multi-gene traits.* Yet, selective breeding is a slow process, depending on the rate of animal reproduction and can only operate on alleles and genes present in animal population with little control over what to express, where, when, and how much. Continuous selection for a particular trait may result in decreased genetic variability in the locus and decrease ability for further selection. For example, only a few proven bulls produce the majority of offspring in the world Holstein populations and similar reduced breed diversity in US swine and poultry is a cause for concern [56]. It is also difficult to introduce beneficial alleles from rare breeds into existing commercial population because it leads to decreased performance for economically important traits. In contrast, animal genetic engineering allows precise introduction of new alleles from rare breeds, novel genes from evolutionary distant species, or even completely artificial genes with control of the time, place, and amount of gene expression in an animal. Furthermore, a transgenic animal is a self-replicating high-tech animal – it might be expensive to produce but it is cheap to propagate.

Reducing the impact on the environment through animal transgenesis can take many forms (Table 1), for example, improving the overall feed digestion by the animal or reducing the excretion of a specific nutrient such as phosphorus. More subtle means of improving the efficiency of animal production could include enhanced disease resistance or even improving the nutritional quality of the meat since it would increase the product value.

Swine

Growth and Improved Digestion The first transgenic food animal developed that exhibited a trait consistent with a reduced environmental footprint was the transgenic line of pigs developed by Pursel and colleagues [64]. These pigs contained an increased level of bovine growth hormone that gave rise to an 18% increase in feed efficiency and an 11–14% increase in growth rate (Table 1). These improvements obviously decreased manure production per unit of body weight gain. Unfortunately, the pigs exhibited lameness, stress susceptibility, gastric ulcers, and other health problems that negated the unique improvements observed, but the study documented that the problem was due to overproduced growth hormone. In a separate study by Nottle et al. [57], the level of growth hormone was controlled by using an inducible promoter, a modified human metallothionein

Transgenic Livestock, Decreasing Environmental Impact of. Table 1 Genetic modifications in livestock to improve overall performance and reduce environmental impact

Species	Trait	Protein/RNA; Transgene	Reference
Pig	Phosphorus metabolism	Phytase; PSP-APPA	[33]
Pig	Increased growth	Growth hormone; hMTpGH	[57]
Pig	Increased growth	Insulin-like growth factor; (mMT-HIGF-1)	[65]
Pig	Increased lactose in milk	α-lactalbumin; bovine α-lactalbumin	[90]
Pig	Influenza resistance	Mx protein; mMx1-Mx	[53]
Pig, Cattle	Disease resistance	IgA; mouse a and ***x*** chains	[46]
Cattle	Avoids spontaneous prion occurrence	Knockout vectors pBPrP(H)KOneo; pBPrP(H)KOpuro	[73]
Cattle	*Staphylococcus aureus* resistance	Lysostaphin; β-lactoglobulin promoter linked to lysostaphin, neomycin resistance, and GFP	[88]
Cattle	Mastitis resistance	Human lactoferrin in milk	[79]
Goat	Reduced mastitis and healthier kids	Human lysozyme; A_{s1}-casein promoter-hLZcDNA	[38]
Sheep	Visna virus envelope	Visna LTR-env	[14]
Sheep	Ovine prion locus	Homologous recombination	[21]
Sheep	Increased growth	Ovine growth hormone; metallothionein promoter	[1]
Chicken	Influenza virus resistance	Chicken U6 promoter; cRNA binding site influenza virus polymerase	[49]

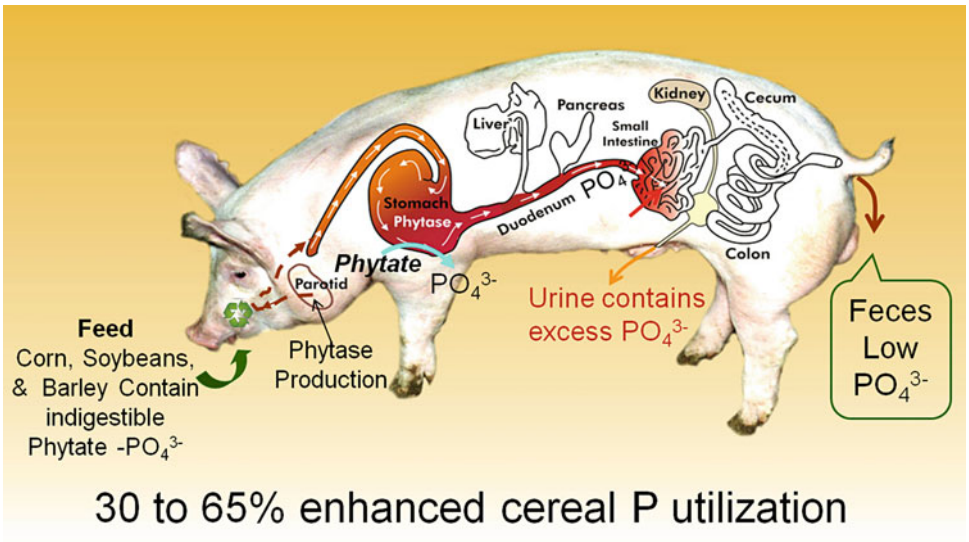
promoter fused to the cDNA sequence for the porcine growth hormone. They documented improved growth of founder animals as compared to non-transgenic littermates, but the study was not carried beyond litter mates. Later, Pursel and colleagues [63] developed transgenic pigs that expressed insulin-like growth factor I (IGF-I) to determine whether directing the expression of IGF-I specifically to striated muscle would enhance lean muscle growth in pigs. However, they observed only a decreased daily rate of fat accretion in the transgenic pigs as compared to the rate in the unmodified pigs. This may be explained by the observation that transgenic modification of a trait that has already undergone intensive selection through traditional breeding and is a metabolic process with multiple effects can have unexpected and in some cases deleterious outcomes [22].

A different approach to enhancing growth rate of pigs was achieved by the introduction of the bovine α-lactalbumin gene into pigs. Sows containing the α-lactalbumin gene produce an increased concentration of lactose in milk during the early lactation that increases the growth rates of piglets [55, 90]. This novel transgenic modification improves efficiency of production by either allowing earlier weaning or more robust piglets at weaning.

Phosphorus is a key nutrient for all living things. At the same time, phosphorus mining damages the environment, and phosphorus-induced eutrophication leads to harmful algal blooms, decreased biodiversity, and changes in species composition. In addition, the global supply of mined phosphorus is running out and some estimate that within 30–40 years there will not be sufficient phosphorus to meet agricultural demand [16, 76]. Manure is a valuable organic fertilizer, but the high phosphorus (P) concentration in relation to the nitrogen (N) content is problematic. A desirable N/P ratio for plant growth is 6.0 for an increment in yield, [42]. This ratio is derived by using the N and P concentrations after losses due to volatilization, which

is primarily an N loss. In contrast, the N/P values for manure from pigs, dairy cattle, and poultry are approximately 0.96, 2.6, and 1.7, respectively. Therefore manures from pigs, dairy cattle, and poultry are 6.3, 2.3, and 3.4-fold enriched in phosphorus in relation to nitrogen utilized by cereal grain crops. This documents the doubly serious impact of excess P relative to N in the manure for land spreading. To decrease phosphorus-induced eutrophication caused by the high phosphorus content of pig manure and to reduce the need for supplemental phosphorus in the diet, Golovan and colleagues [33] developed transgenic pigs expressing an *Escherichia coli* phytase driven by the mouse parotid secretory protein promoter that gave rise to phytase production in the salivary glands (Fig. 2). Phytase, secreted by the parotid gland in the saliva, mixes with the incoming food particles during chewing and hydrolyzes phytate in the acidic environment of the stomach-releasing phosphate that is readily absorbed in the small intestine. Since the dietary phosphorus requirement of the transgenic pigs can be satisfied by the cereal grain diet without inclusion of either supplemental P or supplemental microbial phytase, there is an overall decrease in P excretion in the feces and urine that will enter the environment [33]. A line of these phytase pigs currently in the eighth generation exhibited salivary phytase activities at a levels similar to that of the founding transgenic pig, and excrete 30–65% less phosphorus in the manure depending upon the stage of growth and diet consumed. Trials have documented that the phytase pigs have similar reproductive characteristics, health, and growth rates to that of conventional pigs (Forsberg, unpublished data). The pig parotid secretory protein promoter was also tested [95], but the salivary phytase production in mice was not as efficient as that described by Golovan et al. [32] for the mouse PSP promoter. It would be very instructive to assess the efficacy of the pig PSP promoter driving phytase synthesis in the pig.

Cereal grains and plant protein supplements have an imbalance of amino acids with an excess of nonessential amino acids and lesser amounts of the essential amino acids lysine methionine and threonine [58]. This imbalance results in high excretion of nitrogen from nonessential amino acids, and the swine ammonia emission metric (kg livestock^{-1}) is higher than either beef or dairy cattle [10]. Ammonia emissions are substantially reduced by inclusion in the diet of essential amino acids lysine, methionine, and threonine. Endowing pigs with the selected ability to synthesize essential amino acids in the appropriate proportions would decrease the need for protein



Transgenic Livestock, Decreasing Environmental Impact of. Figure 2
High phytate feed consumption by the Enviropig^{TM}

supplements and would also decrease the excretion of ammonia arising from degradation of nonessential amino acids. To test this thesis, Rees and Hay [71] genetically modified mouse 3T3 cells by the introduction of a chimeric gene containing the coding regions of the *E. coli* gene for aspartokinaseI/homoserine dehydrogenase I and the *Corynebacterium glutamicum* gene for aspartic semialdehyde dehydrogenase subcloned into a Simian virus 40 based mammalian expression vector. These cells produced homoserine. By transfecting these cells with the plasmid pSVthrB/c containing genes coding for homoserine kinase and threonine synthase, the modified cell line expressed the complete pathway for the synthesis of threonine from aspartic acid, and the cell line no longer had a growth requirement for threonine. Therefore, by using the appropriate promoters with these genes it should be possible to produce genetically modified pigs/animals with the innate endogenous capacity to synthesis the essential amino acid threonine. The introduction of genes for the endogenous synthesis of methionine and lysine would be highly beneficial; unfortunately, the development of transgenes appropriately regulated to make each biosynthetic pathway function in tissues will be a daunting task because methionine synthesis requires four additional genes coding for enzymes that convert of homoserine to methionine. Lysine synthesis would require as many as nine genes coding for enzymes in the pathway beginning with aspartic acid (http://www.genome.jp/kegg/pathway/map/map00300). Alternatively, it might be possible to improve utilization of essential amino acids present in feed by increasing ileal digestibility (phytase, cellulase), absorption from gut (amino acid transporters), or even by increasing proportion of gut microorganisms responsible for synthesis of the essential amino acids by developing selective attachment receptors or by suppression of competitors using antimicrobial proteins.

Cereal grains and plant protein supplements contain indigestible structural carbohydrate components including β-glucan and arabinoxylan that are not digested by nonruminant species and are mainly excreted in the manure. It has been shown that supplementation of the diet with exogenous β-glucanase and xylanase improves growth of the piglets [23]. However, supplementation of grower diets with glycanase enzymes has given mixed results. In a study by Nyachoti et al. [59] no beneficial effect was observed by the inclusion of glycanase while Ji et al. [40] observed a distinct beneficial effect on digestion. The beneficial effect of supplemental glucanase was the basis for testing whether this class of enzymes can be expressed in animals to enhance digestion. To test this hypothesis a transgene composed of the mouse pancreas–specific amylase 2.2 promoter and the associated signal sequence was linked to the *Bacillus subtilis* endoglucanase with a 3′polyadenylation sequence. The transgene was introduced into mice by pronuclear microinjection. Offspring containing the transgene expressed the endoglucanase gene in the pancreas and secreted the truncated, but active glucanase into the small intestine [96]. Ohnishi et al. [60] showed that overexpression of the Rab3D upregulated amylase secretion from the pancreatic acini of transgenic mice; therefore it is possible this technique could be used to further enhance glycanase synthesis and secretion from the pancreas into the small intestine. Together with a report by Hall et al. [35] describing the transgenic expression of a *Clostridium thermocellum* thermostable glucanase in the pancreas of the mouse using an elastase promoter/enhancer, these studies show the feasibility of expressing hydrolase genes in the gastrointestinal tracts of livestock.

Health Status Health is a major issue in livestock production documented by the deleterious economic impacts [72] of current and emerging swine zoonoses [82]. Strategies to improve resistance of swine to viral diseases such as foot-and-mouth disease, influenza, and porcine reproductive and respiratory syndrome which depend on host cellular machinery include antisense, decoys, ribozyme, and RNA interference [47, 92]. Recent work on the control of the African swine fever virus through the use of RNA interference may soon show success [41]. To provide resistance against a broad range of bacteria and some viruses, Cheung et al. [11] introduced into mice the porcine protegrin-1 using the cytomegalovirus promoter. Protegrin is an antimicrobial peptide that targets both gram-negative and gram-positive bacteria as well as enveloped viruses. They showed increased resistance to the swine pathogen *Actinobacillus suis*. This protein normally is expressed in neutrophils, and the intent in this study was to assess the effect of more

general expression that would affect the bacteria at an earlier stage in the infection. Introduction of this construct into pigs and subsequent testing will be very informative since subclinical infections in pigs are a major cause of poorer feed efficiency in many environments.

Ruminants

Enhanced Digestion No transgenic ruminants have been reported that have a reduced impact on the environment through enhanced growth characteristics or reduced nutrient excretion. However, it was shown that feeding phytase and cellulases to lactating dairy cows resulted in reduced fecal excretion of dry matter, neutral detergent fiber, and acid detergent fiber, and reduced nitrogen and phosphorus in feces [43]. The beneficial effect of supplemental enzymes was found despite the presence of 101 distinct ruminal microbial phytases [37] and 27,755 putative carbohydrate-active genes, many of which presumably code for ruminal plant cell wall degrading enzymes [36]. Because added phytase enhances phosphorus utilization, transgenic expression of a phytase in the salivary glands of the cow using a promoter such as the indigenous salivary Bsp30a protein promoter [66, 91] would seem to be a possible strategy since Bsp30a is produced at a high concentration in saliva. No information is available on the Bsp30a promoter at this time; therefore background work would be necessary before testing this hypothesis.

Whether there would be interest in exploring the salivary production of glycanases in ruminants is questionable since variable results have been obtained by supplementation of diets with cellulases [5, 6, 62].

Methane from livestock accounts for approximately 37% of the methane produced by human-related activities, and the single largest source being enteric fermentation, mainly in ruminant livestock [30]. To reduce methane production in cattle, one option proposed was to generate transgenic cattle that produce salivary antibodies against rumen methanogens which subsequently bind to and inhibit their action in the rumen [44]. The same authors also identified the prophage φ-mru that is able to lyse methanogen cells. Secretion of anti-methanogenic proteins in the saliva would seem feasible from a physiological perspective as there are several strong salivary promoters [91]. However, before such experiments are undertaken it obviously would be prudent to conduct feeding trials and testing for effects on the methanogenic population and to monitor the effect on the animal.

Health Disease is an ongoing drag on the efficiency in the production of ruminant animals [72]. Mastitis has a serious impact on milk production by ruminants [4]. To eliminate the deleterious effect of mastitis in dairy cows, Wall et al. [88] expressed lysostaphin in the milk. This antimicrobial protein enhanced the resistance to *Staphylococcus aureus* and provisionally could help maintain high milk production as a consequence of reduced mastitis if the genetic modification were accepted for commercial production. In a similar vein Maga et al. [51] demonstrated that human lysozyme expressed in the mammary gland of transgenic dairy goats inhibited the growth of bacteria that cause mastitis and this occurs without an effect on health or performance [38]. In a different approach Simojoki et al. [80] genetically modified dairy cows to secrete human lactoferrin in the milk. Again, it enhanced resistance to mastitis infections. Other avenues to improved performance could be through prion knockouts [73] and developing resistance to viruses (infectious bovine rhinotracheitis, bovine respiratory syncytial viruses, parainfluenza, bovine viral diarrhea, rabies, and foot-and-mouth disease) through the application of an RNA interference-based approach [47].

Poultry

Enhanced Digestion Inclusion of phytase, glucanase, and xylanase in the poultry diet enhances feed digestibility. Phytase was shown to enhance availability of phosphorus and other minerals, and in addition, to enhance amino acid digestibility [18]. The chicken is reported to have a weak endogenous magnesium-stimulated phytase activity associated with the intestinal brush boarder [50], but apparently contributes little to overall phytate digestion. Initial work has been done to develop a secretory competent form of the enzyme with higher activity for expression in poultry [12], although no further work has been reported. Use of the salivary glands of poultry as a site for transgenic

phytase production is a possibility since these glands have been identified [61, 75]. However, based on the low amylase activity of the salivary glands reported for both chickens and turkeys [39], it is questionable whether a suitable promoter is available and a sufficient capacity for synthesis is possible to provide the quantity of enzyme necessary. Another possible site for secretion of hydrolytic enzymes is in the proventriculus using the chitinase promoter [85]; however, this would initially require the cloning and characterization of the promoter. Introduction of any transgene probably would involve use of either a combinatorial cis-regulatory element [77] or a lentiviral vector [49].

Arabinoxylanases alleviate viscosity-induced diffusion constraints associated with diets containing wheat, rye, barley, and triticale. Glucanases have a similar effect digesting β-glucans present and small amounts of amorphous cellulose. These glycanases were shown to enhance the amino acid digestibility [18]. The positive action of these feed enzymes opens the possibility for genetic modification.

Health Subclinical disease in poultry dramatically increases the environmental impact of the birds. For example, subclinical necrotic enteritis in broiler chickens results in a 12% reduction in body weight and an 11% decrease in feed utilization efficiency [81]. Other subclinical diseases undoubtedly have a similar impact; therefore, improving health substantively reduced the environmental footprint of poultry. The application of interference-based gene silencing may be an effective strategy for control of Marek's disease, infectious bursal disease, avian leucosis, Rous sarcoma virus, and avian influenza [47]. The report by Lyall et al. [49] on the production of transgenic chickens resistant to avian influenza viruses is an excellent example of the use of RNA interference to reduce mortalities of producing birds.

Issues with Expression of Novel Hydrolases in the Gastrointestinal Tract

Novel gene products that either have been expressed in the gastrointestinal tract of mammals, or that may be considered for expression are summarized in Table 2. Many phytases have been characterized and considered as potential feed enzymes [67], although only three phytases are illustrated as examples, the *E. coli* phytase expressed in the Enviropig^{TM}, the Avian phytase and the rat phytase, the only phytases so far identified in mammals, but has low activity. A variety of xylanases and glucanases are listed. It includes high-activity glucanases and xylanases, bifunctional xylanase/glucanase enzymes where the same catalytic domain hydrolyzes both substrates and chimeric enzymes. The chimeric enzymes can have any combination of catalytic domains, for example, phytase and endoglucanase, xylanase and glucanase, or other combinations of domains. The bifunctional and chimeric enzymes have the advantage of providing multiple activities in one protein, which has the advantage of using a single promoter.

There are a variety of factors that need to be considered when deciding upon promoter(s) and gene(s) for expression in the alimentary tract of animals. Ideally the introduced transgene should impose the minimal metabolic load with minimal interference of existing physiological and biochemical pathways of the host.

Transgene (protein or RNA):

1. Preferably the transformation of interest should be performed by a single molecule. If more than one protein/RNA is involved it may be possible to design the transgene which express multiple transgenes (see below).
2. The transgene must code for a low molecular mass stable protein with a high specific activity, and targeted to the correct compartment.
3. Cryptic posttranslational modification sites are often present in proteins isolated from non-mammalian species and must be removed if activity/stability is affected (i.e., lysostaphin glycosylation).
4. The pH and temperature optima should correspond closely to that of the site of action which would be pH 2–5 if it should be active in the stomach/proventriculus, or pH 5–8 if secreted into the small intestine where it would be active [13, 20, 34].
5. The enzyme must be resistant to proteases: pepsin if expressed in the stomach, or resistant to tryptic enzymes if expressed and active in the small intestine. If the enzyme were expressed in the salivary

Transgenic Livestock, Decreasing Environmental Impact of. Table 2 Enzymes with some criteria suitable for gastrointestinal expression

Source	Catalytic properties	Mol. Wt.	pH Opt and Min/Max	Temp (°C) Max Act.	Sp.Act. U/mg^{-1} min^{-1}	Protease resistance

glands for activity in the small intestine then it would need to be both pepsin and trypsin resistant, stable at low pH, and highly active at neutral pH.

6. Preferably the enzyme should be isolated from the organism with a Generally Recognized As Safe (GRAS) status and have no significant homology to allergenic, pathogenic, or toxic proteins. It is also preferable that it not exhibit any similarity to known allergens, and it would even be useful to eliminate possible glycosylation sites to avoid the development of an allergenic nature [15].

Regulatory elements:

1. Promoter should be tightly controlled allowing expression of the transgene only in desired tissue at the desired time and at a specific level. Strong ubiquitous promoters commonly used for transgenic work are undesirable as they often result in transgene toxicity and undesirable side effects. An interesting observation in plants was that repetitious use of the same promoter did not lead to transcriptional silencing [54], and this may also apply to mammals.
2. Gene-specific regulatory sequences (5′ and 3′ UTR, polyA, introns, Kozak start sequence, etc.) should be used to optimize the transcription and translation of transgene.
3. The codon usage should be modified to correspond closely to that of highly expressed proteins within the biosynthetic tissue [9, 28].
4. Insulators and locus control regions (LCR), such as the chicken P-globin locus, should be used to isolate transgene from effect of neighboring chromatin and stabilize the expression level across multiple generations [8].

Multi-gene Expression

The obvious path for the development of transgenic animals is the expression of multiple genes to further enhance the value of an animal. Regulatory agencies undoubtedly will have a preference for the expression by multiple novel genes in an animal produced by crosses of "previously approved" animals with a single transgene to avoid confusion that could result from the interaction of transgenic traits. Whether these will require a further regulatory submission remains to be determined. Since it will be desirable to develop lines of transgenic livestock homozygous for multiple novel traits, a new approach will be needed to eliminate numerous crosses and continued testing for the presence of each gene. The approved transgenes could also be introduced into new breeds/species by cotransformation, or sequential transformation of established transgenic lines in the same species. Cotransformation could be done with unlinked constructs using different promoters when different ratios of protein products are required. Multiple transgenes can also be housed on a mammalian artificial chromosome. In cases where the same proportion of the protein product is needed, multicistronic constructs with multiple internal *ribosome* entry site (IRES), or even as a single translation product in which individual proteins are separated by cellular protease sites, *could be used* [52].

A proven strategy for multi-transgenic animal production is to use the recent adaptation of the 2A system from foot-and-mouth disease virus [20, 25]. With this approach the open reading frame consists of multiple individual cDNAs separated by sequences encoding 2A and furin cleavage sites. A single complex mRNA is produced and translated into a single complex polypeptide that is spontaneously cleaved into individual exogenous proteins at the 2A sites in the endoplasmic reticulum. This results in equimolar ratios of each of the individual transgenic proteins emerging from the Golgi. This expression system has been demonstrated to produce transgenic animals with up to four transgenes being expressed from a single transcript [86].

Sequential introduction of transgenes would benefit from establishing transgene locus which allows high and stable expression and into which multiple transgenes can be introduced and removed as necessary using site-specific recombination technologies such as Cre/lox, Flp/frt, φC31 integrase, or Gateway systems [7].

A refinement to further speed up the production of homozygous populations is through the application for flow cytometry [29]. Flow cytometric separation of X and Y chromosome-bearing spermatozoa has been demonstrated to be effective in cattle and pigs and resulted in the birth of healthy offspring of the predetermined gender [68, 69].

Future Directions

Intensive selection by current breeding practices have developed livestock that are growing and producing near their physiological upper limits, and any further improvements may enhance stress leading to disease susceptibility. Reduction in the environmental footprint of livestock will come through: identification and elimination of bottlenecks in metabolic and physiological pathways, introduction of novel traits that enable the digestion of dietary components previously not digested (e.g., phytate, glycans), through the introduction of novel metabolic pathways for synthesis of essential nutrients (e.g., amino acids), and through enhanced disease resistance. These novel transgenic animals will only be accepted by farmers if they are as robust as the currently available conventional livestock. Furthermore, these new genetically engineered animals will only enter the human food chain once consumers are satisfied that the meat products are absolutely safe, since they have the choice between conventional and transgenic products. Therefore, the central issue is the confidence consumers have in the national regulatory system. With the expected increase in human population and increasing environmental constraints, greater acceptance of transgenic animals is anticipated in line with the acceptance of transgenic plant products.

Transgenic Livestock, Enhanced Nutritional Quality in

Götz Laible
AgResearch, Ruakura Research Centre, Hamilton, New Zealand

Article Outline

Glossary

Antimicrobial A substance with the ability to kill microbes.

Bacteriolytic Causing the lysis of bacteria.

Bacteriostatic Term to describe a substance that inhibits bacterial growth.

Casein micelle Protein particle consisting of aggregated casein proteins in colloidal suspension.

Circadian rhythm A daily cycle controlling the biological processes in living organisms.

Dominant-negative molecule A mutant molecule capable of interacting with the wild-type form to produce an inactive complex.

Endogenous Internally derived or synthesized.

Endopeptidase Proteolytic enzyme that can only break peptide bonds within the molecule but not at the termini.

Gastrointestinal Term referring to the digestive tract.

Genome Entirety of an organism's hereditary information.

Glycomacropeptide κ-casein-derived peptide released by rennet during cheese manufacture.

Homologous recombination Exchange of genetic material between two DNA fragments by crossing over in a region with sequence homology.

In vitro Experimental procedure conducted artificially.

Knockdown Attenuation of gene function usually resulting in diminished amount of synthesis of the protein that the gene encodes.

Knockin Integration of a new gene which replaces an endogenous gene.

Knockout Functional disruption of a specific gene of an organism commonly achieved by a partial or complete deletion of the gene sequence.

Pathogen/pathogenic Infectious agent/disease causing.

Phenotype/phenotypic A measurable characteristic of an animal such as hair color growth rate, or degree of carcass marbling. These traits are the product of genetics and the environment.

Phenylketonuria Genetic disorder in which the essential amino acid phenylalanine cannot be metabolized potentially causing mental retardation.

Pleiotropic effects The phenomena of a single gene having influences on multiple traits.

Prion An infectious protein particle.

Promoter A regulatory DNA sequence that controls the transcription of a particular gene.

RNA interference A sequence-specific gene-silencing process in which double-stranded RNAs trigger the destruction of specific RNAs.

Somatic cell count Quantification of somatic cells found in milk as an indicator for the quality of the milk.

Transgene An exogenous gene introduced into the genome of another organism.

Transgenic An animal plant or microbe whose genetic material has been altered using an artificial process.

Unsaturated (saturated) fatty acids Fatty acid molecules with (no) double bonds.

Whey Liquid that remains after separation of the solid fraction when cheese is made.

Definition of the Subject and Its Importance

Since the domestication of animals several millennia ago, which enabled the transition from hunter-gatherer to farming communities, humans have shaped livestock according to specific needs for food, both in quantity and quality. Industrialization and rapid population growths prompted immense changes to

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

farming systems, human lifestyle, and food choices, and is predicted to result in drastic climate changes within a relative short time period. Thus, current food production systems face new challenges in this rapidly changing world, in particular demands for safe and healthier food to address modern health concerns and the desire for longevity. In the past, traditional breeding and selection schemes have been invaluable for the incremental improvement of food animals. However, the process is slow and undirected and is not well suited for enhancing specific nutritional characteristics. The relatively new transgenic technology offers the potential for enhancing existing or introducing entirely novel characteristics at unprecedented rates and magnitudes and could provide substantial benefits for consumers in the form of healthier and safer food. Nevertheless, the complexity of food production traits should not be underestimated. The accurate modification of the appropriate gene(s) to generate desired phenotypes able to deliver enhanced food products remains challenging and requires careful testing and evaluation. Despite the unrivaled opportunities for innovative functional foods and the progress realized with transgenic crops, lack of acceptance due to concerns associated with the technological novelty of transgenic livestock has so far greatly limited even the research-driven evaluation of new concepts aimed at food applications.

Introduction

Livestock animals are farmed for human food production and are a primary source of dietary proteins, lipids, carbohydrates, vitamins, and minerals from milk and meat. The development of efficient farming production systems has played a crucial role to satisfy the elementary requirement for a stable food source to meet the daily nutritional needs of a multibillion human population. While milk and meat represent in general, a high-quality food source for humans, the effects of modernization and associated substantial changes to the farming systems and lifestyle of people create new challenges for providing a healthy diet of high nutritional quality. The increased understanding of how human nutritional requirements relate to health and longevity provides new opportunities to optimize the nutritional quality of food products and thus improve human health and well-being. Animal fat, which is an ingredient of all animal food products, can serve as an example to illustrate this correlation. They are relatively high in saturated fats (which have been strongly associated with cardiovascular and coronary heart disease), but low in beneficial, unsaturated fats. Thus, higher levels of unsaturated fats and lower levels of saturated fats would improve the nutritional quality of animal-derived food products. Efforts to increase the ratio of unsaturated to saturated fat have received considerable attention. However, attempts to alter the composition of milk and meat to improve its nutritional quality by conventional breeding and selection strategies have proved to be difficult. Traditional breeding and marker-assisted selection schemes are limited to the random combination of some but not all superior allelic gene variants existing within the gene pool of the livestock species. In contrast, transgenic animal technology allows for a more targeted approach with the prospect to introduce specific genes which are known to impact on defined phenotypic traits to enhance existing characteristics. Unlike traditional breeding and selection, the genetic improvement of livestock by genetic engineering is not restricted by the species barrier and can utilize the gene pool of other species to introduce entirely novel and unique characteristics. Moreover, transgenic technology is a versatile platform technology that can employ additive strategies to introduce a new gene function (gain of function), delete gene functions (knockout, loss of function), replace an endogenous gene function with a different one (knockin, exchange of function), or precisely control when and where the genetic alteration is applied (inducible gene expression and conditional knockout). Thus, it holds great promise as a new tool that can deliver solutions for many of the problems concerning the efficient production of high-quality foods from animals.

Despite mounting lifestyle-related health problems, food security, and environmental pressures which need to be urgently addressed, negative public perception, ethical concerns, regulatory uncertainties, and an associated reluctance to fund this line of research have been major factors that have so far greatly limited the international research efforts to evaluate the potential of the transgenic technology for enhancing food production of livestock.

While transgenic plants have been commercialized since 1996 [1], transgenic livestock applications for food production have so far been restricted to a few proof-of-concept studies that aim to improve the nutritional quality of milk and meat and will be outlined in detail in the following sections.

Milk with Enhanced Nutritional Qualities

Milk is an important food with high protein content. The protein fraction determines many of the functional properties and provides opportunities for nutritional enhancement through additional health benefits, increased food safety, and improved processing properties for dairy food manufacture.

One approach has been the introduction of new antimicrobial properties into milk, to provide passive immunity to consumers. Lyzozyme (LZ) is a naturally occurring antimicrobial protein, present in milk, saliva, and tears of mammals, where it forms part of the defense system against bacterial infections. However, it is found at three orders of magnitude higher concentration in human milk as compared to dairy milk. The introduction of an expression construct for human LZ resulted in LZ levels in the milk of the transgenic goats equivalent to about 68% of the level found in human milk [2]. The consumption of the human LZ-containing goat milk by pigs exerted beneficial effects and improved their gastrointestinal health [3, 4]. Although the milk has not been tested in humans, the promising results suggest similar gastrointestinal benefits could be possible for humans. In addition, the elevated LZ levels increased general food safety properties of the milk by reducing the bacterial growth that causes cold-spoilage thus prolonging its shelf life. Following a similar strategy, recombinant human lactoferrin (LF) has been overexpressed in the milk of dairy cattle [5]. LF is a minor milk protein with antimicrobial and anti-inflammatory properties, which can support the innate defense mechanisms. Although bovine LF has similar functions, it is present in milk at very low levels. Its human counterpart has been fully adapted to human requirements during evolution and is expected to be better suited for human health applications, in particular, at elevated levels. The transgenic cows were shown to produce milk that contains human LF at concentrations much higher than the natural level of bovine LF. These new characteristics indicate that this functional food might offer new health benefits such as increased protection against infections and healthier intestinal microflora. A conceptually related approach aims to boost the immune system through food-mediated delivery of neutralizing monoclonal antibodies to target specific pathogenic microorganisms of the digestive tract. Thus, consumption of antibody-enriched milk could provide instant protection from infections which severely affect those with increased susceptibility, including the elderly, infants, and patients with illnesses. Proof-of-concept studies in mice successfully demonstrated the potential of this approach. The expression of high antibody levels in milk was able to confer complete protection for the suckling young when challenged with an otherwise lethal dose of virus [6]. Whether the health-enhancing attributes of the functional proteins described above can indeed be realized as food-mediated health benefits in humans is presently unknown and still needs to be assessed.

Although milk from dairy cows is a very common human food, it is known to trigger allergic reactions in some people, a phenomenon that is particularly problematic in infants. Not present in human milk, β-lactoglobulin has been identified as a major whey protein in the milk of dairy species and is thought to be a major allergen in the milk of cows. Reduction of this allergenic protein in dairy milk would make it more amenable for susceptible individuals. This could be achieved by either the disruption of the β-lactoglobulin gene using homologous recombination, often referred to as knockout, or the specific knockdown of its expression by RNA interference (RNAi). However, gene knockouts, a standard approach for the functional characterization of genes in mice, proved to be difficult in farm animals due to low recombination efficiencies in primary livestock cells. Thus RNAi technology might provide a more straightforward approach to unravel the role of β-lactoglobulin and reduce the allergenicity of cow's milk.

Altering the milk composition by altering the levels and ratios of the main endogenous milk proteins has been suggested to enhance the nutritional quality of milk and its processing characteristics, including increased heat stability, calcium content, and cheese manufacture [7, 8]. A drastic change of milk composition has been achieved recently with the introduction of

additional β- and κ-casein genes in transgenic cattle [9]. The milk derived from these cows showed a two- to threefold increase in κ-casein and a minor change for β-casein. These changes affected the physical appearance of the milk, which showed a distinctive color change from ordinary white to yellow for the modified milk [10]. Because κ-casein is located on the surface of the casein micelles, any increase in κ-casein is expected to reduce the size of the casein micelles [11]. The reduced size of the micelles affects the light scattering properties and is thought to be the reason for the observed color change in the high κ-casein milk [10]. Although the effects on the processing characteristics of this novel milk still remain to be determined, trial cheese production resulted in cheese with increased levels of essential amino acids and beneficial minerals and thus improved nutritional quality.

Furthermore, due to the higher κ-casein content, this speciality milk is an improved source of κ-casein-derived bioactive peptides [12] such as glycomacropeptide (GMP) which has been associated with a wide range of health-promoting activities including protection against toxins, bacteria, and viruses, suppression of gastrointestinal inflammation, and modulation of the immune system [13]. GMP is one of the few naturally occurring proteins that lacks the amino acid phenylalanine, which makes it a safe source of dietary protein for people suffering from the genetic disorder phenylketonuria (PKU). They cannot metabolize phenylalanine, and normally need to avoid high-protein foods such as dairy products to prevent the detrimental accumulation of phenylalanine metabolites.

An extension to this, highlighting the unique ability of the transgenic technology to provide novel foods tailored for specific dietary requirements, is the development of transgenic rabbits that produce a milk protein suitable as dietary replacement for PKU sufferers [14].

The carbohydrate component of dairy milk has been another target for modifying milk composition to improve health attributes. The milk sugar lactose causes intestinal disorders in lactose-intolerant people who lack adequate intestinal lactose-hydrolyzing enzyme activity to sufficiently digest lactose after milk consumption [15]. Two strategies to reduce the milk sugar lactose content were evaluated in transgenic mouse models which could provide an elegant alternative to expensive postharvest milk processing. The complete disruption of the expression of α-lactalbumin, an essential component of the lactose synthetase complex, resulted in lactose-free milk [16]. However, because lactose is the main osmotic regulator of milk secretion, it strongly affected production and secretion of the milk, which was highly concentrated and the transgenic mice were unable to sustain lactation. In comparison to the knockout strategy, knockdown of α-lactalbumin expression through RNAi could offer better control, to achieve an acceptable reduction of the lactose and water content of milk, without impacting on its vital attributes. Thus, it might provide an opportunity to reduce the lactose content and at the same time significantly lower transportation costs of liquid milk.

A more successful approach addressing lactose intolerance, which cleverly dissected the issues of osmolarity and lactose levels, targeted the expression of a mammalian lactose hydrolyzing enzyme to the mammary gland [17]. Milk lactose was reduced by 50–85% without affecting osmolarity, due to the conversion of the produced lactose into the osmotically active monosaccharides, glucose, and galactose. Although the transgenic mouse results are promising, and it was speculated that a similar reduction of lactose in bovine milk could ameliorate lactose intolerance, they can only provide an indication due to substantial species-specific differences in milk composition. So far, this approach has not been transferred to livestock and still awaits verification of its merit in dairy cows.

Beside protein and sugar, fat is another important nutritional component of milk which has a significant impact on human health and provides opportunities for the improvement of dairy products. Animal fats are very rich in saturated fatty acids (SFA) which are considered “unhealthy” and have been associated with cardiovascular and coronary heart disease. A major focus is therefore to decrease the unhealthy fats in favor of the healthier unsaturated fats. This would have the added benefit of decreasing the hardness of milk fat resulting in softer butter, with improved spreadability. As the majority of the long-chain fatty acids in milk fat and in particular unsaturated fatty acids (UFAs) originate from food sources, an effective approach to improve milk fat composition might be to tailor the diet of dairy cows through the use of particular forage species or feed additives [18, 19]. Transgenic

technology on the other hand provides the ability of a more directed approach, by modulating endogenous enzymes involved in lipid metabolism. The mammary gland-specific expression in transgenic goats of the rat stearoyl-CoA desaturase (SCD), an enzyme involved in converting SFAs into mono-UFAs, resulted in an increase of mono-UFAs and decreased levels of medium chain SFAs [20]. However, this beneficial change in the milk fat composition was only transient in this particular study. It was most prominent in early lactation which was thought to be a consequence of high instability of the SCD-encoding mRNA and the resulting low expression levels.

Another concept has been to lower the total fat content by disrupting acetyl-coenzyme A carboxylase to prevent de novo fatty acid synthesis in the mammary gland, which accounts for about 50% of the milk fat [7]. While low-fat liquid milk is desirable from a consumer perspective, for the cow it could reduce the feed energy requirements and improve body condition which is likely to translate into lower milk production costs and improved conception rates during early lactation.

A more extreme variation of the concept of adjusting the activity of endogenous enzymes involved in lipid metabolism is the introduction of novel enzymatic activities normally not found in mammals. This can provide livestock animals with the ability to endogenously synthesize essential poly-UFAs (PUFA) and transform their food products into enriched sources. As a result, food products derived from these animals could offer a range of additional PUFA-specific health benefits such as reduced risk for the development of coronary heart disease and a healthy immune system [21]. This strategy was first tested in transgenic mice with the introduction of the fat-1 gene encoding the Caenorhabditis elegans n-3 fatty acid desaturase, an enzyme activity that is absent in vertebrates and renders transgenic animals capable of producing omega-3 FAs through conversion of dietary derived n-6 FAs. Omega-3 is a class of beneficial n-3 PUFAs that is associated with a lower risk of morbidity and mortality from atherosclerosis and coronary heart disease. Milk-specific expression of the desaturase in transgenic mice resulted in elevated levels of long-chain n-3 PUFAs and a concomitant decrease in n-6 PUFAs, although this was most pronounced in phospholipids which are a minor fraction of milk fat, and to a lesser degree in the milk triacylglycerides [22]. Pups consuming the n-3 PUFA enriched milk accumulated the n-3 PUFA docohexaenoic acid in their brains, a compound which has been associated with cognitive performance [23]. The constitutive expression using a humanized fat-1 gene resulted in essentially similar qualitative changes of the n-3 and n-6 PUFAs in milk but at a higher magnitude [24]. So far, the concept has been transferred to pigs but not to any of the dairy species. Unfortunately, changes to the milk fat composition were not investigated in these pigs because the main focus for the study was on the fat content of meat and will be discussed in the next section.

Meat with Enhanced Nutritional Qualities

The introduction of a novel FA desaturase activity to genetically complement mammals with the ability to endogenously synthesize essential PUFA and improve the nutritional characteristics of meat was pioneered in a transgenic mouse model mentioned in the previous section [24]. Mice were engineered by integrating a humanized version of the fat-1 gene into their genomes. Expression of the Caenorhabditis elegans n-3 FA desaturase in these transgenic mice resulted in muscles that were highly enriched in the beneficial omega-3 FAs. While all organs and tissues of the transgenic mice showed a marked reduction of the n-6 to n-3 FA ratio, the effect was greatest for skeletal muscle where the ratio dropped from a value of ~50 for conventional mice to close to 1 for transgenic mice. Considering the health concerns associated with the typically high n-6 to n-3 ratio of Western diets, consumption of food products from omega-3 enriched livestock may provide an opportunity to improve diets. When the approach was recently applied to pigs, the constitutive expression of the fat-1 transgene essentially replicated these results with tail samples from the transgenic pigs found to be highly enriched in omega-3 FAs, in particular for two of the most potent n-3 FAs mainly found in fish [25]. Although, the nutritional consequences still need to be investigated in greater detail, transgenic

food animals enriched in omega-3 FAs may provide a more economical, safe, and sustainable means to fortify meat than the current practice of feeding animals with fish meal and satisfy the growing demand for omega-3 fatty acids in human nutrition [26].

Following a similar concept, pigs were engineered for the endogenous production of the essential PUFA linoleic acid by introducing the FAD2 gene encoding the Δ12 FA desaturase from spinach [27]. Expression of the plant desaturase was selectively targeted to adipocytes and resulted in transgenic pigs showing a 20% increase in linoleic acid content of their white adipose tissue. These results further substantiate the prospect for improving the fatty acid composition of domestic animals through transgenic technology. Meat produced by transgenic pigs could ultimately provide an alternative source for essential FAs, which may ameliorate lifestyle-related health concerns.

Early transgenic livestock studies were mainly focused on modifying body composition for enhanced meat production by stimulating muscle growth via the introduction of genes for growth factors such as growth hormone (GH) or insulin-like growth factor I (IGF-I), a concept that has been highly successful in proof-of-concept studies in transgenic mice [28–31]. Although pigs responded with remarkable growth enhancement following the administration of exogenous GH [32], the initial studies with transgenic GH pigs [33] and sheep [34, 35] were disappointing. The transgenic animals achieved only slightly increased growth rates and were plagued by a range of deleterious side effects due to high systemic GH levels. These were a consequence of poor regulatory control of the transgene activity [33, 36]. Targeting the transgene expression to skeletal muscle [37] or applying conditional expression strategies with the ability to switch it on or off [38] essentially overcame the problem of generating adverse health effects in the transgenic animals and resulted in more desirable effects on growth rate and body composition. Pigs engineered for the tissue-specific expression of human IGF-I in skeletal muscle produced approximately 10% more carcass lean tissue and 20% less total carcass fat. Unexpectedly, the effects showed a strong gender bias with the body composition of transgenic males remaining comparable to conventional boars [37]. Transgenic sheep overexpressing ovine GH, controlled by a zinc-inducible promoter, grew significantly faster, and had a leaner body composition [39]. However, the transgenic sheep had higher parasite fecal egg counts, a potential indication of a compromised immune system.

The modest success of improving growth characteristics in sheep and pigs with growth factor-encoding transgenes is in complete contrast to what has been achieved with GH-enhanced transgenic fish using all piscine DNA constructs [40–43]. In the majority of fish species, the GH transgene resulted in dramatic growth acceleration with up to 35-fold increased growth rates in transgenic loach and salmonids and produced fish that reach double the normal body size in half the normal time [44]. However, some of these growth-enhanced fish showed undesirable pleiotropic effects such as altered skin color, modified skull shape, decreased fertility, and decreased viability. Intriguingly, the astounding growth phenotypes were only achievable in wild fish and could not be replicated in domesticated fish [45]. This may indicate that there is a biological ceiling for further growth enhancement by GH in highly selected domesticated animals, which could explain why the approach achieved only slightly accelerated growth rates in transgenic GH pigs and sheep. Thus, for livestock, the approach, at least in its current form, appears unlikely to deliver on its promise to substantially increase meat production which has to be achieved without adversely impacting on the health of the transgenic animals. The only beneficial outcome realized was some nutritional enhancement through the production of leaner meat, which may provide new leads to further improve the nutritional quality of meat.

A promising alternative strategy to boost growth performance with the prospect of greater control might be the direct manipulation of key regulators of skeletal muscle development. Myostatin is a crucial negative regulator of muscle growth, whose function was revealed with a mouse knockout model which showed two to three times the muscle mass of wild-type mice [46]. These mice closely resembled the double-muscling phenotype of some cattle breeds characterized by a 20% increase in muscle mass associated with a reduction in fat tissue. Analysis of the myostatin gene revealed that these breeds are carriers of natural mutations that result in loss of myostatin function as the underlying cause for

the double-muscle phenotype in cattle [47, 48]. The bulkier conformation of these animals is, however, causing major calving difficulties in these breeds, which are associated with significant welfare concerns. Transgenic technology provides the possibility to avoid these concerns by restricting the effects on the myostatin pathway to only postnatal stages of major muscle growth. The feasibility of such an approach was already demonstrated with a conditional myostatin knockout in mice resulting in postnatal disruption of the myostatin gene and comparable increase in muscle mass to a constitutive knockout [49]. However, additive strategies to interfere with the myostatin pathway including the expression of dominant-negative molecules [50, 51] or RNAi [52, 53] might offer even more flexibility with the ability to control the degree of increased muscle mass. Using site-specific recombination techniques, transgenic mice were generated with a muscle-specific expression cassette for a dominant-negative myostatin pro-domain integrated into the male-specific Y-chromosome [54]. Males of these lines showed a 5–20% increase in skeletal muscle mass; because females do not have a Y-chromosome, all females were non-transgenic and not affected in their growth characteristics. Combined with a postnatal or inducible expression strategy, interference with myostatin function targeted to males only could improve the efficiency of current cattle production systems with the concomitant production of bulls with superior meat production ability and elite dairy cows.

Safer Food from Livestock with Enhanced Health Characteristics

Any improvement to the health status of food animals has an immediate positive effect on food safety, which ultimately will lead to safer food products of superior quality. Moreover, healthier livestock would deliver a whole range of additional beneficial attributes, including improved animal welfare, reduced reliance on animal remedies, reduced risk for disease transmission to humans, and improved reproductive performance and production. While conventional breeding programs with the aim of reducing susceptibility of livestock to pests and diseases have not been very successful, the prospect of complementing traditional disease control measures with transgenic technology is particularly appealing, because it provides new, targeted strategies for improved disease control and animal health [55, 56].

One of the most costly diseases in agriculture is a bacterial infection of the mammary gland known as mastitis. The disease causes a significant reduction of milk yields and renders the milk produced by infected cows unsuitable and unsafe for human consumption. In its nonclinical appearance, the main indicator is a high somatic cell count in milk. Mastitis, however, has the potential to severely affect the health of infected animals and can cause death or require euthanasia on animal welfare grounds. In dairy cattle, about one third of clinical mastitis cases are caused by Staphylococcus aureus infection, a pathogen which, due to its ability of intracellular survival, is particularly difficult to control with conventional antibiotic therapies. Transgenic technology can provide alternative mastitis prevention strategies and in one such approach, the expression of a bacteriolytic enzyme in mammary gland cells, has already been evaluated.

Lysostaphin is a bacterial enzyme with endopeptidase activity that cleaves crucial cell wall components of staphylococci resulting in the lysis of the bacteria. Its potential as an effective antimicrobial agent for the treatment of mastitis was first demonstrated in a mouse model where the mammary-specific expression of lysostaphin conferred a protective effect against Staphylococcus aureus infections [57]. Recently, the concept has been successfully extended to cattle. The transgenic cows, which produced lysostaphin in their milk, recapitulated the mouse results and showed a high degree of protection when challenged with the pathogen [58].

Two other proteins with antimicrobial properties, LF and LZ have long been suggested as strong candidates to confer resistance of mastitis in cattle [59]. Although conceptually similar to the lysostaphin approach, cows overexpressing the antimicrobial protein human LF in their milk appeared to gain no improved protection against mastitis when challenged with an Escherichia coli strain isolated from cows with clinical mastitis [60]. This was rather unexpected, considering that these transgenic cows produced much greater levels of human LF in milk compared to the milk enriched with lysostaphin. Serving as a model for dairy cattle, human LZ has been expressed in the mammary gland of goats [2]. The potent bacteriostatic properties of the milk produced by these goats against two mastitis causing bacteria strongly

suggests that human LZ might be another excellent candidate for conferring resistance to mastitis [61]. Particularly, in light of the human LF results, direct experimental validation of the protective potential will be required to determine the effectiveness of human LZ in preventing mastitis.

A different concept to introduce disease-resistant properties into livestock attempts to strengthen the immune system through the expression of pathogen-specific antibodies and thus providing instant immunity without prior exposure to this particular pathogen. The first studies in livestock involved the expression of mouse monoclonal antibodies in transgenic rabbits, sheep, and pigs but were met with little success because of unexpected problems to express fully functional antibodies [62, 63].

An extension of this approach has been the targeted production of viral-neutralizing monoclonal antibodies in milk, to provide passive immunity and protection from viral infections, which can severely affect suckling neonates. A mouse model expressing a coronavirus specific monoclonal antibody in milk demonstrated that the sustained production of high antibody levels throughout lactation could successfully neutralize the viral infectivity [64]. Moreover, in a similar study, suckling young were challenged with a lethal dose of murine hepatitis virus (MHV). Ingestion of MHV-specific antibody-enriched milk produced by the transgenic mice induced full protection against the viral infection in the pups [6].

The disruption of the virus entry mechanism proved to be an equally potent strategy. Transgenic mice engineered for the expression of a soluble form of a porcine herpes virus receptor, gained effectively full resistance against pseudorabies virus (PRV) infections [65]. Furthermore, the transgenic mice displayed superior protection levels compared to mice vaccinated with an attenuated PRV strain, demonstrating that this transgenic approach may offer superior efficiency for the control of pseudorabies in livestock [66].

The introduction of a specific disease resistance gene MX1 from mouse, known to confer resistance to influenza viruses in mice was another approach evaluated for its potential to protect livestock animals from viral infections. Similar to other pioneering studies prior to the mid-1990s, difficulties to adequately control Mx1 expression in transgenic pigs hampered the approach, which ultimately failed to achieve viral protection in pigs [67]. For now, the real potential of this approach remains unknown but the identification of antiviral Mx alleles from livestock species [68–70] and new tools for the improved control of transgene expression levels, such as the recently developed auto-regulative tetracycline-responsive expression cassette [71], may encourage a reevaluation of MX alleles for their potential to confer disease resistance in domesticated animals.

Rather than attempting to provide additional protective attributes, transgenic technology also enables the direct targeting of endogenous genes implicated in disease pathways. Such a concept has been applied to produce livestock animals which are resistant to the fatal neurodegenerative prion diseases or transmissible spongiform encephalopathies. This family of diseases, which include scrapie and the "mad cow disease" bovine spongiform encephalopathy, or BSE for short, is characterized by an accumulation of a misfolded isoform of the cellular prion protein (PrP) that acts as a novel infectious agent. Proof-of-concept studies in the mouse [72, 73], either introduction of mutated prion protein genes [74], gene knockout [75–77], or RNAi-mediated knockdown of PrP expression [78] demonstrated the possibility to produce animals that are resistant to prion diseases. Resistant livestock, certain to be free of such diseases would eliminate the risk for potential transmission of the disease to humans and provide additional safeguards for the food chain. However, some mouse studies raised concerns that the loss of the normal cellular function of PrP may adversely affect the animals by interfering with the circadian rhythm [79], synaptic functions [80, 81], learning [82], or loss of movement coordination [83]. When these findings were further investigated, the underlying molecular cause was not the loss of PrP function but an interference with the expression pattern of an adjacent gene as a result of only partially deleting the PrP locus [84–86].

Initial studies in sheep [75] and goats [77] indicated that animals heterozygous for the PrP knockout display, at least in young animals, a normal phenotype. These findings could now be confirmed with homozygous knockout cattle with deletions of the entire PrP gene [87]. In vitro assays with brain tissue homogenates derived from these PrP deficient cattle

demonstrated resistance to prion propagation while the cattle were apparently normal in all aspects analyzed.

The recent development of RNAi technology, based on the expression of a short RNA molecule that can interfere with the activity of a specific target gene offers new opportunities to directly attack pathogens by disrupting their lifecycles. It is particularly attractive as an antiviral strategy, where RNAi can be used to target viral transcripts and suppress viral infection [88]. Because RNAi is a sequence-specific process, it will only affect the virus but not the host animal. Validated by the successful application of RNAi to control viral diseases in mouse model systems [89–91], the concept is applicable to a wide range of significant pathogens such as the RNA viruses that constitute over two thirds of the Office International Des Epizooties (OIE) list-A pathogens [88]. Recent outbreaks of viral diseases in farmed animals with immense socioeconomic and animal welfare costs such as foot and mouth disease or with the risk to cross the species barrier into humans such as Severe Acute Respiratory Syndrome (SARS), avian influenza and swine flu highlight the importance for improving current intervention strategies. Several studies are presently undertaken to evaluate the effectiveness of RNAi-mediated viral resistance in domesticated animals including chickens, pigs, cattle, sheep, and horses.

Future Directions

Transgenic livestock technology has made tremendous progress since its humble beginnings in 1985 [92]. Poor control of the transgene activity presented a main problem in early studies. Today, it is possible to integrate a transgene into a specific site of the genome and provide accurate control from the endogenous regulatory sequence elements. In addition, molecular switches have been developed which enable to switch the expression of a transgene on or off and can be combined to form sophisticated gene control networks [93]. In parallel, the understanding of how gene function relates to phenotypes is rapidly growing and has been further accelerated with the sequencing of the genomes of livestock species [94–96]. Thus, the application of transgenic technology to improve food production holds much promise for the future. Yet, transgenic technology should not be seen in isolation and as sole answer to all questions. The greatest benefit will result from combining transgenic strategies with other effective technologies. At present, however, most consumers consider transgenic technology for food applications as risky and unsafe and thus not acceptable [97]. While this may be predominantly driven by a general unease about an unfamiliar new technology, it had profound effects on politicians, regulators, and research investors and has largely prevented its application. With the mounting pressure on food safety and security, food and lifestyle-related health problems in the context of the rapidly increasing population and a changing climate, calls are becoming louder that this promising technology can no longer be ignored [98]. To gain consumer acceptance, it will be crucial to engage into an open dialog with the public that balances perceived against real risks. Only if a robust risk benefit assessment forms the bases for a decision on the acceptability of food-producing transgenic livestock will there be a chance to realize the benefits of the technology.

Article Outline

Glossary

Animal bioreactor Transgenic animal that produces recombinant proteins in its milk, egg white, blood, urine, or seminal plasma.

Antibody Protein produced as part of the immune reaction to render harmless a foreign substance (e.g., bacteria) entering the body of an organism.

Cloning (a) Production of exact copies (clones) of a gene/genes (gene cloning). The DNA strand containing the gene of interest is cut into suitably sized pieces (fragmentation) and the gene of interest is linked to a piece of DNA (cloning vector). This vector is then introduced into cells (transfection) which are cultured in vitro and then screened for the presence of the gene of interest. (b) Production of genetically identical organisms by somatic cell nuclear transfer (SCNT). It involves the introduction of the nucleus of a somatic cell from the organism to be cloned into an enucleated egg cell. The resulting cell divides after activation (application of electric shock) into an embryo which may then be implanted into a surrogate mother (reproductive cloning) or used to establish a tissue culture (therapeutic cloning).

Embryonic germ cell Pluripotent stem cells derived from early germ cells with properties similar to embryonic stem cells.

Embryonic stem cell Cell derived from an early embryo that is not differentiated by itself but may divide either to form (a) other stem cells or (b) cells that differentiate into specialized cell types.

Gene copy number Genes naturally exist in varying number of copies in the genome. In relation to genetic modification, gene copy number refers to the number of copies of a transgene that integrate into the host genome.

Gene expression The assembly of a product (mainly protein) based on the information coded in a gene.

Gene targeting The modification of a certain endogenous gene of an organism based on homologous recombination.

Germ cell Cell that produces gametes (egg cells in females, sperm in males).

Heterozygous Organism/cell in which the two chromosomes in a pair contain different alleles (alternative forms of a gene) at a given locus. The dominant allele will determine the phenotype.

Homologous recombination The exchange of genetic information between two similar or identical strands of DNA (often during meiosis, i.e., the formation of gametes). This process is used for the introduction of DNA sequences into the genome of organisms by gene targeting.

Homozygous Organism/cell in which the two chromosomes in a pair contain identical alleles (alternative forms of a gene) at a given locus. The alleles may either be dominant or recessive.

Hemizygous Organism/cell with only the given allele present at the given locus of only one of the chromosomes in a pair.

Knockout The replacement of a functioning endogenous gene with an inoperable version.

Lentiviruses Viruses that are able to infect both dividing and nondividing cells and are therefore used as tools as vectors for gene delivery.

Marker-assisted selection Method allowing the selection of breeding animals based on their genotype rather than their phenotype. Regions of the genome

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

Originally published in

that control certain production traits are mapped and DNA markers that control production traits are identified. Animals whose genome contains the desired markers are selected for further breeding.

Motivation The internal state of an animal which makes it behave in a certain way; the overall summation of all internal and external factors affecting decision-making.

Pronucleus The nucleus of either a sperm (male p.) or an egg (female p.) cell before their fusion inside the egg cell in the process of fertilization. At pronuclear microinjection, the DNA containing the transgene is injected into one of the pronuclei which fuse. After implantation of the egg into a female, the resulting embryo develops into a hemizygous transgenic animal which must be bred to obtain homozygous transgenic animals.

Recombinant protein Proteins that are expressed based on recombinant DNA (rDNA). rDNA is obtained by genetic engineering techniques, i.e., the ´artificial´ combination of information contained in the transgene and in the host genome.

Somatic nuclear cell transfer See Cloning.

Subjective experience Conscious mental state, an experience that the individual is aware of.

Viral vector Virus-based vehicle to introduce genetic information into cells making use of the capacity of viruses to transfer their genome into the cells they infect. For transgenesis purposes, they are rendered replication-deficient to avoid replication once the transfer of the genetic information of interest into the cell has taken place.

Definition of the Subject

Humans have been able to manipulate the genomes of livestock through selective breeding for centuries; however, direct intervention has become possible only through the development of transgenic technology over the past 3 decades. So far, genetically modified animals have mainly been developed for basic research and biomedicine, but they are slowly beginning to enter the agricultural production system. In this article, livestock is defined to be all species used within the agricultural and aquacultural system. Note that such animals can be genetically modified for use within basic and medical research as well.

Most people would readily agree that there is a difference between what humans *can* do and what they *ought* to do. Equally, most people would happily acknowledge that it is good to do the morally right thing. However, the harmony usually ends there, because although it is easy to agree that a good thing should be promoted, it is often hard to reach consensus on what that good thing is, how it can be promoted, and to what extent the end justifies the means. There may also be disagreement over what counts as a bad outcome or about whether there are acts which are wrong in themselves. As soon as questions as these are discussed whether in private or in public, people are engaging in an ethical discussion – a discussion in which the aim is to reach agreement on what is good and bad and what is right and wrong.

Such ethical discussions have closely shadowed developments within biotechnology over the past 30 years. A range of applications of biotechnology to animals, including reproductive technologies, genetic modification, and cloning, has prompted concern about the ethical limits of human use of animals. It is probably an understatement to say that discussion has so far led to no consensus in the public sphere, but it would also be an overstatement to say that the debate has led to unanimous agreement. What *has* emerged, among other things, is a clearer understanding of the basic ethical assumptions driving the different viewpoints, together with greater attention to the ethical duties of humans toward animals.

The technological challenge of animal biotechnology is: What *can* be done? This question is closely followed by the question: What *ought* to be done? As with any other human activity, this question needs to be answered if decisions on what to do are to be made. That is both the blessing and the curse of being an ethical creature equipped with a conscience. Humans cannot just act and use the possibilities that lie before them; they have to take responsibility for the values that are promoted through their choices. At the same time, there are huge disagreements about what the relationship between *can do* and *ought to do* in the area of transgenic animals is. One of the consequences of this is that ethics cannot be pursued as a mere afterthought to the technology or as something of concern only to opponents of the technology.

The subject of this article is the ethical concerns about transgenic livestock. While the strict scientific definition of "transgenesis" implies that genetic material is transferred between species [1, 2], the term is often used interchangeably with genetic modification to cover a wider range of techniques in which the animal genome is manipulated – e.g., including the inactivation of genes. For livestock applications, transgenesis proper is the predominant kind of genetic modification, and so, in this chapter, "transgenic" is used only to refer to the transfer between species. Examples of genetic modification will be used additionally to clarify important points. The goal is to make the different areas of concern that arise in the ethical debates transparent, and to discuss different ways of approaching a public dialogue on these matters.

Introduction

Gene technology and other forms of modern biotechnology have given rise to ethical controversies since they were first introduced in the early 1980s. This has led to a growing awareness among both scientists and politicians that successful implementation of biotechnology in democratic and pluralistic societies requires ethical concerns to be discussed and taken seriously. Numerous and extensive attempts have thus been made over the past 3 decades to engage stakeholders and the public in general in discussion of the ethical aspects of biotechnology.

Already, the earliest transgenic animals in the 1980s were the subject of controversy [3–6]. However, it was probably with the creation of the cloned sheep Dolly in 1997 that animal biotechnology became widely known to the public in the industrialized world [7]. Looking at both studies of public opinion on the subject and the ethical literature, one can see that the concerns here can be divided into distinct groups. Some relate to possible impacts on humans, either through health-related risks, environmental consequences, or socio-economic changes. Some revolve around the possible conflicts arising from the possibility of patenting living beings. Others revolve around animal welfare, and different concepts of that, while the last group expresses more general concerns about the (un)naturalness of the technologies, and possible violations of the integrity of the animal species. One discussion that arches over all of these issues and has been an important determinant in framing the ethical debate as a whole focuses on how best to regulate the area.

Sociological studies have revealed public skepticism about transgenic animals. Considerations of risk, usefulness, animal welfare, and other moral values play a substantial role in the public evaluation of the technologies. Based to some extent on these studies, many attempts have been made to engage the public and stakeholders such as scientists, politicians, legislators, industry, animal welfare organizations, consumers, and others in society-wide discussions of how the new technologies can be implemented in a way that will be acceptable for a majority of citizens. Whether or not these attempts have been successful obviously depends on the criteria of success applied. What can be said, however, is that they have not led to general agreement about the development and use of transgenic animals.

In this area of ethical thinking and public discourse, it is necessary to be aware of the open-ended nature of the discussion. From a scientific point of view, there is a world of difference between a knockout pig that has had a gene disabled to better serve as a organ donor for humans (xenotransplantation) [8] and a goat that has had a human gene inserted that expresses itself in the mammary glands thus enabling human proteins to be harvested from the milk [9]. But from the point of view of the nonexpert, these differences might seem ethically unimportant if the concern in play is the possible violation of the species' integrity.

There is also a tendency among experts to look primarily at methods, or techniques, when evaluating biotechnology, whereas members of the public often bring in considerations of usefulness as well. Ethical discussions thus differ from technical discussions, and it is necessary to critically evaluate the amount of scientific knowledge and expertise needed within different layers of the ethical discussion. Obviously, science and scientific thinking cannot be left out of ethical discussions of science and its technical applications, but neither should their importance be overstressed [10].

Similarly, it can be problematic if the subject of the ethical discussion becomes too narrow. There is a tendency in the current research environment for ethics to follow natural science into increasingly specialized fields where it becomes difficult to include other areas of science with similar concerns. But at

the level of ethical concerns, it is sometimes helpful to discuss transgenic livestock together with, for example, other issues relating to modern intensive animal production [11]. Thus the concerns that people have about transgenic livestock may to a large extent be about taking an already problematic development even further.

As a prerequisite to any ethical debate about transgenic livestock, it is of course necessary to make it clear what the subject of the discussion is, and what areas of application are involved. This ensures an informed debate in which misunderstandings resulting from unclarity are avoided.

Science and Applications

From Early Research to Maturing Technology

Humans have manipulated the genetic makeup of livestock through the process of domestication for thousands of years. Scientifically based farm animal breeding began in the early twentieth century, and, particularly since the 1950s, it has had a profound effect on most livestock species. Various modern biotechnologies – particularly reproductive technologies – have gradually been adopted since the 1980s.

A comparatively recent technology in this process of development is genetic engineering/modification; this emerged in the 1980s and has evolved considerably since. Genetic modification involves the direct manipulation of the genome of a group of founder animals, unlike traditional breeding, where animals are selected on the basis of their phenotype and then mated in order to approach a certain breeding goal gradually. There is a degree of vagueness in the definition of the techniques used to generate genetically modified organisms. Genetic modification, in the broadest sense, has been defined as an "altering of the genetic material in that [the GM] organism in a way that does not occur naturally by mating or natural recombination or both" [12]; this covers a wide array of technologies.

Genetic modification and transgenesis are sometimes used synonymously, but the term "transgenesis" is often defined more narrowly to apply to just one aspect of genetic modification: transgenic animals carry foreign genetic information (i.e., information from another species) and transmit this information to their progeny, because the transgene is integrated in the germ cells of the animal [1]. Genetic modification may involve further modification of the genome (moving, deleting, multiplying, modifying genes) within an organism – e.g., the creation of knockout animals. Creating a knockout animal involves the targeted inactivation of a gene. In this process, the protein usually produced as a consequence of the genetic information in question is no longer produced. This is achieved by replacing an active gene with an inactive version, thus preventing the gene in question from being expressed [13]. Knockout applications are common in mice used for fundamental and biomedical research; however, in livestock species, transgenesis is the most common form of genetic modification, although even here, knockout applications do exist (e.g., mini-pigs which have had genes knocked out in connection with xenotransplantation research) [14].

The main projected advantages of transgenesis over established breeding techniques include the possibility of introducing genes that do not exist in the genome of the parents (outside the species), and the opportunity to target desirable traits without coselecting genetically coupled undesirable ones. The foreign gene is introduced in early stage embryos (first cell stage) or in cells that participate later in the complete development of the animal [13]. These embryos develop into transgenic founder animals, which can then be used in further breeding. Regardless of the particular method used, the main steps in producing transgenic animals are as follows [15]:

- Identifying the trait of interest and localizing the corresponding gene in the donor species genome
- Multiplying the gene through cloning
- Production of a suitable construct for gene transfer
- Gene transfer
- Proof of integration of the foreign gene
- Proof of expression of the foreign gene in the host animal
- Demonstrating that offspring of founder animals inherit the foreign gene
- Selective breeding to diffuse the foreign gene into the relevant population of animals

Some of the technology to create transgenic livestock is based on methods developed for use in mice: the first transgenic mammals created by pronuclear microinjection in 1980 were mice [16]. This method

was adapted in 1985 to create the first transgenic livestock (rabbits, sheep, pigs) [17].

In further developing the technologies, researchers have tried to address technical limitations, and to develop alternatives to pronuclear injection with improved efficiency (i.e., proportion of newborn animals carrying the transgene), predictability, and control of gene expression. Predictability refers to where in the host genome the transgene is integrated. When technologies in which the integration site is random are used, there may be unexpected expression patterns as a result of interference with the host genome. Technologies allowing targeted integration increase predictability by giving greater control of gene expression. Whether or not the number of copies can be controlled is also relevant, as copy number influences the level and stability of transgene expression [18].

Table 1 provides an overview of the most prominent methods of transgenesis, noting the availability for different species as well as the predictability, efficiency, and feasibility.

There are however several practical obstacles to routine production of transgenic livestock [21]. The efficiency of the methods used was very low in the beginning, and although progress has been made here, transgenesis still cannot compete with other methods used for the genetic improvement of livestock (e.g., selective breeding in combination with artificial insemination and marker-assisted selection) on cost efficiency, practicality, and public/political acceptance. Furthermore, many traits of interest in livestock are controlled by more than one gene and are therefore difficult to improve by transgenesis. The introduction of transgenesis in livestock breeding is further complicated by the fact that, typically at any rate, very few transgenic animals are generated in the first generation. This makes diffusion into a breeding population without corresponding inbreeding depression difficult. It also means that, since the phenotypic uniformity of transgenic offspring is often limited, the evaluation of gene expression in transgenic livestock would require a large number of animals.

Fish have been popular models for research into transgenesis as they are easy to maintain/handle and highly fertile. They have easily manipulable, large eggs, which are fertilized and develop externally; fish species also usually tolerate genetic manipulation well during early development (unlike, say, rats). The most

Transgenic Livestock, Ethical Concerns and Debate. Table 1 Summary of existing transgenic approaches (Adapted from [19, 20])

Transgenic method	Availability	Integration site(s)[a]	Number of copies per site	Efficiency[b]/ technical difficulty	Note
Microinjection	Most mammals[c]	Random	Variable	Low/medium	First method
Somatic cell nuclear transfer	Most mammals	Can be determined	Often single copy	Low/high	>1997
Lentivirus-based	Most mammals	Random and multiple	Single copy	High/low	Late 1990s
Sperm manipulation	Most mammals[c]	Random	Variable	Moderate/low	Successful application in few laboratories so far
ES/EG[d] cells	Mice and rats, not (yet) available in livestock	Predetermined	Often single copy	Low/NA[e]	Recently successful in Chicken (EG [91])

[a]Determination of the site of integration or random integration in the genome

[b]Arbitrary scale: low, <5%; moderate, >5%; high, >80%

[c]All mammals tested so far

[d]Embryonic stem/Embryonic Germ

[e]Not Applicable as not used in livestock (so far)

common technique used for gene transfer is still pronuclear microinjection but, as with other livestock species, research into increased efficiency has led to the development/adaptation of new methods, including electroporation (i.e., improving the permeability of the cell membrane for DNA macromolecules by applying short electric pulses), sperm-mediated gene transfer, direct gene transfer into tissues of adult fish (via intramuscular injection of DNA or "gene gun delivery"), and the use of viral vectors [22–24].

Risks are attached to the technology, naturally, and sometimes these are unpredictable. They include the occurrence of undesirable effects of transgene expression, which should be addressed in food safety assessment schemes (like in other emerging novel foods). In particular, safety assessment should be performed regarding toxic/antinutritional effects, allergenic potential, bioactivity (e.g., hormones active *post* consumption) [25]. For a thorough discussion of different risks associated with transgenic livestock, please see "The Ethical Issuessection ."

Applications of Genetic Modification to Livestock

Several explorations of potential applications of genetic modification to livestock species have been published [1, 20, 26–29], and agricultural purposes have been examined in particular [2, 30]. The authors of these studies usually distinguish between biomedical and agricultural applications. The basis of this distinction seems to be that applications in the agricultural domain facilitate the direct consumption of products from transgenic animals/their offspring by humans, while in the biomedical field, applications target human health via the development of pharmaceuticals, antibodies, transferable organs/tissues, or by studies into basic biological processes and disease mechanisms. There are products for direct consumption, such as functional foods, which however may fall into both categories [31].

The history of R&D here shows that – apart from scientific interest in basic biological questions – transgenic livestock research has undergone changes of focus and has followed funding and fashion. In this process, biomedical applications such as xenotransplantation, animals as "bioreactors" and disease models, and among agricultural applications the "Enviropig®" have emerged.

Initial developments in transgenic farm animals focused on the improvement of one of the classical production-related traits: growth [17]. The animals involved have become popularly known as "Beltsville pigs." Ever since, there have been reports of procedures involving transgenesis for specific problems with, and questions about, livestock production (for a recent review [2]).

There have been attempts to use the technologies to improve animal health and disease resistance. There are various ways of achieving this, including passive immunization of young animals against viruses through antibody expression in milk and improvement of early growth and/or viability in piglets through increased sow milk yield when overexpressing bovine alpha-lactalbumin. Food quality and the improved usability of animal products for human consumption (e.g., the expression of human lactoferrin in milk to obtain positive effects on the immune system, reduction of lactose to circumvent intolerance, carcass and meat composition alteration toward leaner meat, and meat with higher content of omega-3 fatty acids) can also be mentioned in this context. Another production-related application aims at diminishing the "ecological footprint" of industrial pig production: this involves the expression of a bacterial phytase gene in the saliva of pigs which leads to reduced phosphorous excretion.

Moving to the broader and related area of genetic modification, gene knockout has been employed in efforts to induce disease resistance (prion diseases) [1]; it has also been used to create pigs that do not express alpha 1,3 GT in an attempt to overcome organ rejection after xenotransplantation.

Apart from its applications in biomedicine and basic biological research, transgenic technology has been used in fish to improve production parameters such as growth and food conversion, adaptation to cold environments (lowering the freezing point of body fluids through the expression of antifreeze proteins), disease resistance and prevention of the introduction of transgenes into wild populations (sterility). As with land farm animals, in 1985, the very first successful application of transgenic technology reported in fish aimed at increased growth by introducing a gene for human growth hormone (to be expressed, in this case, in goldfish). For an extensive review of applications see [24].

In a relatively recent review paper, tentative projections as to when various applications of transgenic livestock will be applied in the field are made [20]. Most of the biomedical and agricultural applications projected by Niemann and colleagues to be introduced some time beyond 2005 are still at the research stage in 2010; and, of the applications listed, only recombinant pharmaceutical proteins have actually reached the market: in 2006 the European Commission, and in 2009 the FDA in the USA, gave approval for the drug ATryn® (a recombinant form of human antithrombin, an agent that prevents blood-clotting) to be produced in the milk of transgenic goats for pharmaceutical markets. Growth-enhanced transgenic fish are often presented as the most promising candidate for the introduction of transgenic animals for food production [23, 32].

Future Perspectives

The idea of using transgenic animals in food production is controversial not only with the public, but also within the scientific community. The success of transgenic livestock for agricultural purposes has failed to meet initial expectations not least as a result of its practical limitations as compared with other breeding tools [1].

Scientists differ considerably in their assessments of the impact transgenic livestock will have on animal agriculture, and in the time-frame within which this impact will unfold. These attitudes also reflect opinions about the usefulness and feasibility of the technology; in general, biomedical applications usually meet with more optimism than agricultural applications. The following excerpts from relevant publications that can be seen in Table 2 illustrate the range of views:

Animal biotechnology is embedded in a social context and therefore affected by general trends in the societies in which it unfolds. This also means that one should be neither excessively optimistic about altruistic motives behind the technology nor excessively suspicious about possible egoistic and narrow motives. In general, one should bear in mind – when listening to all the problems that the technology might solve and how soon it will revolutionize human lives – that in western capitalist society, the worlds of research and business, science and technology, and knowledge-building and knowledge-using, have converged. Scientists are not necessarily independent and altruistic, but human beings working in a marketplace like everybody else. They are, in other words, stakeholders. A certain amount of sound skepticism in evaluating the claims they make is therefore probably not going to be wasted [33].

It must at the same time be remembered that the potential of the technology is enormous and the range of applications almost endless – in theory, at any rate. But as the last 25–30 years have shown, it is a long way from having an idea to making it work. Sometimes, it seems that the more that is learned through science, the more it is realized how little is known, because the world in general, and molecular biology specifically, turns out to be much more complicated than initially believed [34]. When trying to assess the potential applications of transgenic livestock, there is, therefore, a large and inescapable uncertainty.

Public Perceptions of Transgenic Technologies

This section describes public perceptions of transgenic animals. As a point of departure, it should be noted that while experts, in the nature of their profession, tend to assess transgenic animals as an isolated phenomenon, the public often see these animals within a wider context. Thus most lay persons will see transgenic animals as parts of modern biotechnology. Respecting this, this section first places public perceptions of transgenic animals within a wider context of other applications of biotechnology within the agricultural and medical fields; and, second, present various aspects of the public perceptions of transgenic animals. Another aspect of the contextuality of public perceptions is the fact that perceptions should be interpreted, or understood, in the particular context in which they arise. Perceptions reflect deeper rooted cultural and/or religious values as well as passing material settings – and so they will vary with continents, countries, and religions. The following descriptions examine public attitudes in both Europe and North America, but the main focus is on Europe.

Accounts of public perceptions have two main empirical sources: qualitative interview studies or quantitative surveys. The former, which involve group interviews or individual interviews, are effective at delivering a deeper insight into the arguments and values behind specific views, but as a result of the

Transgenic Livestock, Ethical Concerns and Debate. Table 2 Examples of scientists' views on impact of transgenic livestock and relevant time frame

	Impact	Time frame
Optimistic/clear-cut predictions	"Transgenic technology allows for the stable introduction of exogenous genetic information into livestock genomes. With its ability to enhance existing or introduce entirely novel characteristics at unprecedented magnitude and speed, this emerging technology is expected to have a profound impact on the genetic improvement of livestock in the future." [2] "The overwhelming challenge to agriculture in the next century will be to feed a huge population while creating and maintaining sustainable agricultural systems. Biotechnology, including transgenic livestock, will play a key role in meeting this challenge by allowing greater precision in resource use and product design." [30]	"Sixteen years ago, transgenic animal technology was invented, and, since then, an industry has formed to exploit that technology. In the next 16 years, products created by that technology will likely be in the hands of consumers." [26]
Moderate optimism/"some time in the future"	"New methods for modifying the genome will underpin a resurgence of research using transgenic livestock. This will not only increase our understanding of basic biology in commercial species, but might also lead to the generation of animals that are more resistant to infectious disease." [1]	"We anticipate that in the near future, genetically modified animals will play a significant role in the biomedical field but that agricultural applications will develop more slowly due to the complexity of many economically important traits and to current resistance to the concept of engineered farm animals." [15] "While various transgenic concepts for the genetic improvement of livestock animals for agriculture are being evaluated the integration of this technology into practical farming systems remains some distance in the future." [2]
Critical/uncertain about time-frame	"It is not clear at all that the benefits that genetic engineering has produced hitherto compensate the potential risks of widely using these products in animal production. Putting the question in a crude way: Are we risking our health for a 5% of the benefits in milk production? Should we use transgenic pigs for a 33% less manure spread? In general, every advance of molecular genetics has been received with high expectations in the field of animal production, but the consequent application, if any, has been much more modest." [1]	"Over the past few years several commercial ventures have withdrawn from transgenic biopharming for various, usually financial, reasons. So, even though much of the groundwork has been doneit is unclear what the future holds for this use [agricultural applications] of transgenic livestock. [. . .] It will take both a better understanding of the genomes of livestock, with the anticipated increase in candidate genes to choose from, and a major practical success before transgenic technology seriously challenges genetic improvement of livestock through selection for most conventional traits." [1] "When a procedure is challenged for some present reason, it is not uncommon to argue that in the future all these problems will be solved. [. . .] In the opinion of the author of this paper, the general attitude towards genetic engineering in domestic livestock should be reconsidered." [21]

limited number of participants, the interviews give a poor picture of the representation and structure of perceptions across the public at large. Quantitative surveys, by contrast, often involve 1,000 or more respondents. Their strength, as a tool, lies in the ability to produce a picture of the distribution of perceptions within a population in a country or a region.

One of the most frequently cited sources of information about public perceptions of new biotechnologies is the Eurobarometer surveys. These have been carried out regularly and simultaneously in all EU-member countries, since 1989. Since the Eurobarometers contain a number of core questions which, with small variations, have been included in all surveys, they provide real insight into the longitudinal development of public perceptions of modern biotechnology in Europe. As a supplement – but indeed not as systematically and regularly – interview studies have been carried out. These, however, are often designed to study a specific aspect of modern biotechnology, and this aspect, or topic, is seldom transgenic animals.

Perceptions of Transgenic Animals as an Application of Modern Biotechnology

A number of interesting findings emerge in the Eurobarometer surveys [35–38]. First, the surveys demonstrate that the new biotechnologies are not assessed and rejected, or accepted, en bloc; rather the public makes a balanced judgment about different applications by weighing the relevant pros and cons. One distinct result of the surveys has been the finding that if these pros and cons are categorized as matters of risk, usefulness, and moral concerns, both risks and utilities are important, but moral concerns has a veto-like character [39].

Second, the studies show that perceptions depend on the type of application. Relatively speaking, applications within the medical domain are generally accepted, whereas food-related applications are viewed with considerably more skepticism. Qualitative studies have demonstrated that this differentiation between applications is linked to the kinds of usefulness provided by the different applications [40, 41]. Thus more acceptable applications are seen as useful, in a societal sense, in virtue of their potential contribution to, for example, the alleviation of hunger, human suffering, or environmental problems. The less acceptable applications, by contrast, are generally useful only in an economic way or to the individual.

Within this general picture, it has been found in North America as well as in Europe that applications including transgenic animals tend to be approached with skepticism [41, 42]. In the 1996 and 2002 Eurobarometers, for example, transgenic animals produced for xenotransplantation were, together with GM foods and GM crops, assessed as one of the least acceptable of seven applications [37, 43]. Despite the fact that xenotransplantation belongs to the medical area it is viewed with some skepticism by the public. One explanation of this may be another somewhat consistent finding. This is the existence of an "organism scale" – something not only indicated by the Eurobarometers, but also found in interview studies [41, 42, 44]. On this scale, acceptance is related to the distance (as it were) between the genetically manipulated organism and humans. Apes and some other mammals are located at the top of the scale, and plants and microorganisms are at the bottom. Thus the fact that the use of transgenic animals in xenotransplantation involve organisms (animals) located toward the top of the scale may contribute to the public skepticism.

Perceptions of Transgenic Animals

This section provides more details about the specific concerns present in public perceptions of transgenic animals. The presentation is structured using the now common distinction between risks, usefulness, and ethics/other moral concerns.

Transgenic Animals as a Risk In the sociology of risk, the concept of risk most often refers to any side effect of an action, practice, or technology [45]. Here, however, public perceptions of risks of transgenic animals follow the convention within studies of biotechnology, where risks are solely understood as the (unwanted) consequences for human health and the environment.

The data on transgenic animals as a risk is somewhat limited. Eurobarometer surveys include perceptions of risk related to transgenic animals in 1996 (xenotransplants and research animals) and again in 2002 (xenotransplants). In 1996 as well as in 2002,

almost 60% of the respondents to some extent agreed that the use of transgenic animals in xenotransplantation was risky [43, 46]. It is, however, impossible to determine whether this relatively high perception of risk refers to xenotransplantation as a strategy or to the transgenic animals themselves. The fact that 60% also regarded the less complex question of transgenic research animals as risky in 1996, however, indicates a considerable concern about the risks.

A qualitative study carried out in Denmark in 2002 gives an indication of the worries lying behind this risk perception [44]. First, it was found, during the exploratory interviews, that human health problems arising from the consumption of meat from transgenic or otherwise manipulated animals were not prominent issues. In discussions of GM foods in general, it transpired that there were no particular short-term concerns, mainly because people trusted the authorities and their risk assessments – but also that, by contrast, in the long run, there was some skepticism, partly because participants were not sure if the experts could foresee the long-term risks to human health. Here, references were made to the BSE crisis, which was taken to have demonstrated experts' inability to predict health consequences. In this context, some also raised concerns about the fact that the natural order of things is challenged through the use of modern biotechnologies. This natural, or god-given, order is seen as incorporating an inherent safety mechanism that is bypassed by the use of genetic technology.

Other interview studies have found similarly low levels of concern about the risks associated with the use of transgenic animals in xenotransplantation [47]. The environmental risks also seem to be considered low: essentially, it is believed that it is possible to prevent transgenic animals (unlike microorganisms and plants) from escaping and spreading their genes.

Transgenic Animals and Usefulness As noted above usefulness has several aspects: societal, individual/self-interested, and economic. Within this spectrum, the Eurobarometer surveys aim to determine the level of perceived societal usefulness by asking how useful for society the respondents find different applications. Results show that in both 1996 and 2002, about 60% of the Europeans surveyed judged xenotransplantation useful to society, and in 1996, a somewhat smaller proportion (52%) found transgenic research animals useful. It should be stressed, however, that both applications fall within the medical area, which is known to be generally more acceptable. The interviews in Denmark confirmed this general picture, sometimes pointing to the purpose (e.g., fighting obesity) being noble, but the strategy (e.g., transgenic leaner meat from pigs) wrong, since there are well known and less controversial alternatives (e.g., obesity-curbing diets) that should be pursued first. Interview participants, however, often found themselves trapped in a dilemma between the highly valued principle that transgenic animals must serve a societal purpose, and their own interests; and sometimes this resulted in pragmatic acceptance of applications in their own interest, despite their principled rejection of the same applications.

Transgenic Animals and Other Moral Concerns In most other situations where the human use of animals is on the agenda, animal welfare is a major theme. It is striking that there is little evidence that welfare, conceived of, in the narrow sense, involving a direct effect on the well-being of the animals, is important in public perceptions of transgenic animals. In interview studies this aspect seems to be conspicuous by its absence. Instead, participants raise questions about animal integrity, or about what can be justified with regard to human treatment of animals [39, 44] – a finding that by and large is confirmed by an OECD review from 2008 [48]. In particular, the question of integrity seems to be important in the assessment of transgenic animals, and to contribute to the establishment of the ethical limits to the degree of manipulation that can be exercised over other living beings. Rather than providing final answers to the question of where such limits should be drawn, qualitative studies allow the public to voice questions such as: "Is human life worth more than that of an animal? (. . .) Which is more morally acceptable: waiting for a 17-year-old motorcyclist to die or using a pig as a 'spare parts bin'" [39].

Despite such statements, in which animals are valued as such, a zoo-sociological classification [49] can, it seems, be discerned in the few studies of public perceptions of animal biotechnology. According to this classification of animals, there are different limits to what you can do to different species of animal.

The classification seems to reflect the idea that the closer an animal resembles humans, the better are the reasons (or the greater the usefulness) required to justify manipulating it. Hence, fish are not as important as cows, and cows are less important than primates.

The Ethical Issues

In this section, the ethical concerns typically raised in published discussions of animal biotechnology and in debates in the public sphere will be analyzed. The concerns will be organized into three main categories: risks to humans, risks to animals, and other moral concerns. In this way, the section follows the findings of the sociological studies and can be seen as an attempt to provide an ethical analysis of the values underlying public perceptions of biotechnology at the same time as being an assessment of the kinds of risk the development of transgenic animals present.

It is important to realize that ethical categories do not come out of the blue. The fact that many discussions of transgenic animals center on risks is no coincidence; it reflects the fact that the regulation of biotechnology is cantered on risks, as was mentioned earlier. There are differences in the way biotechnology is regulated in different parts of the world. However, the various regulatory regimes governing transgenic livestock more or less share the following requirements: (1) the livestock must not present a risk to the environment; (2) nor may it present a risk to human health; and (3) nor may it present a risk to animal health. If these three requirements are fulfilled, there is, in most regulatory regimes, no legitimate reason to set up limits to the development and use of transgenic livestock. In light of this regulatory situation, it is no wonder that discussions of transgenic livestock, like discussions regarding other forms of biotechnology, take risk issues as their starting point.

Risks to Humans

The risks to humans are uncontroversial in the sense that everybody involved in the discussion acknowledges that, to the extent that the technology presents serious risks to humans, this is a serious matter. Following the literature on the subject, it can be said that with regard to human health and the environment, transgenic technology so far does not seem to carry significant risks to humans, whereas the socio-economic impact of the technology on such matters as food prices, agricultural production systems, and financial interests are much harder to assess.

Health Risks to humans are most often equated with the risks to human health presented by products from transgenic animals consumed as medicine or food. Only a very limited amount of research has been done in this area, since very few products have been developed. There is, however, a substantial literature on what risks should be taken into consideration when such products are evaluated. In the medical area, it is recommended that the risk assessment should follow the conventional testing of newly developed drugs. In the food area, risks arising from the modification of proteins, allergenicity, toxicology and nutritional value, and so on, will be important parameters [50].

One concern relates to the possibility that the genes transferred might cause allergic reactions in people. If a gene from a plant is transferred into an animal and that gene is responsible for the production of a protein that makes some people allergic to the plant, then that gene could very well make the same people allergic to the meat and/or milk from the animal. There are clearly ways of avoiding the most obvious problems here – by choosing genes that are not known to produce allergenic proteins, or by labeling all products from transgenic animals. But the whole area of food allergy is scientifically complicated, with many unknowns. Basically, it would seem that the risks in this area can be managed, but for each potential product careful consideration will have to be given to the question which genes should be used for modifying which animals [51].

Another issue of importance is whether the physical composition of the food product will change and thus possibly alter the nutritional value of the product. This result could be intentional or unintentional. One might attempt to genetically modify an animal to change the nutritional value of its meat and milk. It could be the amount or composition of fat in pigs, as in the case of the omega-3 pig [52] or the amount of lactoferrin in milk [53]. In such cases, it would be necessary to evaluate how these changes might affect human health in comparison with traditional products. But the changes could be unintended. Thus they might be caused by changes in genes that are not directly linked

to the nutritional value of an animal. Molecular biology is a very complex science that tells that genes are interconnected and seldom work alone. What happens to one gene can have effects elsewhere. Thus changes in genes related, for instance, to the environmental impact of an animal might have unintended side effects in that they also affect its nutritional value. Furthermore, less than perfect methods of gene transfer could also lead to unintended genetic changes. Only through effective testing and control procedures can such problems be countered in a responsible way. As no genetically modified animals have been approved for the agricultural market yet, and since only few have been developed and tested, it is very hard to say precisely how large a risk this is. It should be clear, however, that this issue will need to be addressed on a case-by-case basis. It will depend on the gene inserted and the animal modified, and it will, in all likelihood, be impossible to say anything general about the matter.

One area of biomedicine where it can be foreseen that the technology presents serious risks to humans has attracted attention. This is the xenotransplantation of pig organs. The worry is that dormant viruses in the pig genome could be transferred to humans through the organs and then "awaken" in the new environment in the human host organism, giving rise to a newly emergent disease against which humans have no natural defense. Notorious examples of emergent diseases transferred from animals to humans are the Spanish Flu, AIDS, and Avian Influenza. In the worst-case scenario just one xenotransplantation "gone wrong" could cause a pandemic [54]. The degree of scientific uncertainty here is rather high, as is generally the case in newly emerged fields of research. However, putting problems raised by the transplantation of live tissue from one species to another to one side, at present, the risks to human health presented by transgenic animals seem to be manageable.

The Environment Some of the ethical concerns connected with transgenic livestock relate particularly to the environment. One such concern is that the animals might escape and breed with wild populations, thus spreading their genes in an uncontrollable way. The most cited example here is that of transgenic fish – e.g., salmon with genetic alterations allowing faster growth. The concerns in this area can either be about the indirect consequences this might have for humans (in this case, economic losses to the fishing industry if transgenic fish cause havoc in the wild-living species that are already under pressure from intense fishing), or direct concerns for the animals and the wider ecosystem [51, 55]. With the exception of fish, individual animals produced by biotechnological methods are rather easy to confine, and this makes it less likely that they will be a hazard for the environment. But here, as with most other concerns discussed so far, it will be necessary to evaluate the animals case by case to estimate the risks: in this case, by trying to anticipate how the animals will interact with the environment and whether this will be a threat to human interests.

Other Concerns for Risks to Human Interests Other concerns focus on the socio-economic changes transgenic animals could bring about, especially if they are ever integrated on a large scale into farming and food production. As the technology is not yet developed, let alone introduced, in this area, it is very hard to guess what will happen. But concerns that the technologies will strengthen the movement toward large-scale farming and could deepen the divide between the developed and the developing world are not unrealistic – witness what usually happens when new technology is introduced and what has happened within the sphere of plant biotechnology. For further discussion of these concerns about the impact of biotechnology on agriculture in general [10].

Another kind of concern for humans that is sometimes raised is that the continuing reification or commodification of nature, where nature is seen exclusively as a resource to be used by humans, will harden human ethical sensitivity in general, thus ultimately causing ethical problems between humans as well. This kind of argument has been laid against the unethical use of animals since the dawn of western philosophy – as, for instance, in the work of Thomas Aquinas (*c.* 1225–1274). The key idea is that by being harsh to animals, humans may end up being harsh to their fellow humans. This idea is closely connected to concerns that humans, by turning what is strange and unknown into biological factories, lose an important part of what it is to be a living being that shares the world with other living beings, thus diminishing the human world [56].

In addition to these concerns, it is often suggested that if the applications of biotechnology are accepted on animals, there might be a gradual change of views on these applications and in the end their use on humans would be found acceptable. In this "slippery slope argument" the problem is not the production of transgenic animals in itself (point A), which is seen as ethically acceptable, but the production of transgenic human beings (point B), which is seen as unacceptable and claimed to be at the bottom of an inescapable slide down a moral slope. Thus point A should be avoided, although it is perfectly acceptable in itself, because it automatically leads to point B: a place that it is in no way desirable to be at.

Risks to Animal Welfare

Transgenic technologies used on livestock may cause welfare problems for the animals. As genetic modification means, by definition, the generation of animals of a genotype and phenotype not presently existing, during research and development, it is necessary to make predictions about the health and welfare of these animals, based on what is known about the gene itself and on previous experience with the technology. Genetically modified animals have so far mainly been used in biological research and as disease models. Usually, the goal of modification is to produce animals that either under- or overexpress certain genes, or which express a mutated, disease-causing human gene. In all of these cases, body function in the organism is in some way disrupted. Although the severity varies, welfare problems often accompany these disruptions.

The situation is different with transgenic livestock. Here, there is no *formal* conflict between the objective of the research and the health of the animals: ideally, animals functioning as bioreactors or xenotransplantation donors, as well as transgenic animals in food production, should be healthy. But this is not always the case, and harmful side effects may arise. For example, the "Beltsville pigs" involved in the earliest experiments suffered from extensive health and welfare problems (stress susceptibility, with only marginal improvement of the desired trait, namely growth [57]).

The problems here may arise at different stages in the development of transgenic animals: the in vitro technologies used at the beginning of the process may have a negative impact on early development by disturbing early gene expression. The site of transgene integration is also relevant, as insertional mutations may lead to the loss of host gene function in the "affected" region. This risk is more frequent with those technologies where there is no control over where the transgene integrates. However, it is primarily a problem at the research stage: as such animals are not desirable as so-called "founder animals" for diffusion of the transgene into a wider population, other individuals will be selected for further breeding.

Finally, the level, and the developmental and temporal control of their expression, may mean that proteins, which are the products of transgene expression, cause problems in transgenic animal [58]. Welfare problems deriving from the activity of the transgene itself will affect much larger numbers of animals, because these problems will accompany the gene as it spreads in the population. This could be the case, for example, if animals are engineered to improve production, and if the greater production results in more prevalent production-related diseases.

Systematic welfare assessment schemes in transgenic livestock are still lacking, even though recommendations on this matter were published almost 10 years ago [58] and have been updated more recently [59]. Conclusions about the welfare of transgenic livestock have often been based, not on comprehensive studies, but rather on small-scale, or anecdotal, reports leading scientists to state, for example, that the transgenic animals "have shown no obvious abnormal phenotype" [60], are "apparently normal" [2], or "developed normally" [20].

Welfare Assessment The requirements of welfare assessment schemes in experimental design should reflect the numbers of affected animals at different stages of a transgenic program (first time generation, an increasing number of animals, and establishment of the production herds). In the early stages, with low numbers, predictions of the welfare of the animals will mostly be based on previous experience with the transgene/gene product, if available, in other species (mice); anecdotal information will be essential. As animal numbers increase quantitative research comparing groups of transgenic and control (nontransgenic) animals should be performed. With the establishment of

production herds it will not be possible to monitor the individual animal; therefore, surveillance and sampling of welfare-relevant effects of transgenesis will become more important [59].

Which aspects of the welfare of transgenic animals are assessed will depend to some extent on how animal welfare is defined. Animal welfare scientists typically base their evaluations on the clinical health and subjective experiences of animals [61]. Often, the subjective experience of animals is taken to be expressed in what animals choose. Recently, this approach has been summarized as follows: "Good welfare is defined as animals being healthy and having what they want" [62].

A broader, and complementary, perspective also includes the animal's opportunity to engage in essential species-specific behavior [61, 63, 64]. This broader perspective is related to an even wider set of concerns about animal biotechnology wherein, the anxiety is not that the technology poses risks to animal welfare, but that it violates animal integrity and basic concepts of naturalness. This will be further discussed in section "Naturalness and Integrity".

The Narrow and the Broad Perspective on Animal Welfare From the narrow perspective defined above, a transgenic application is problematic only if it gives rise to health problems or negative subjective experiences. From the broader perspective, the question of animal welfare is also about the extent to which the animal is allowed to fulfill its species-specific potential. The broader perspective thus points to an additional group of considerations that has to be taken into account when reflecting on animal welfare. It should be noted that the two perspectives are not mutually exclusive. Equally, they will often deliver similar recommendations.

Nevertheless, the two kinds of consideration can, on occasion, be difficult to reconcile in practice; and in that eventuality, it becomes important to clarify what kind of perspective is in play. This can be illustrated with two examples.

First, the battery cage in which laying hens are prevented from performing a range of highly motivated behaviors emerged early on as one of the most emblematic issues in the discussion of farm animal welfare. Following many years of intense debate, accompanied by research to develop and evaluate alternative approaches, policy makers have decided to outlaw this housing system, which will be phased out in the EU by the end of 2012. However, if the problem is defined as the frustration of highly motivated behaviors, an alternative (though as yet hypothetical) solution would be to change the birds, so that they become content with the limited life in a battery cage. From a narrow perspective, there is no ethical objection to denying the animal the opportunity to behave as a bird would do in nature (as battery cage egg production does) as long as this does not negatively affect the subjective welfare of the animals, i.e., lead to negative experiences [64]. Therefore, if birds could be caused to lack motivations other than those that could be satisfied in the cage, this would be a good thing to do from the narrow perspective; it would reduce animal suffering in what is, of course, a highly profitable housing system [65, 66].

For the foreseeable future, this seems to be an academic discussion, as the technology is not, as yet, able to produce such animals – if it ever will be. To begin with, the trait to modify would have a complex genetic background, since the objective must be an animal in which one has eradicated all motivations other than those that can be satisfied in a battery cage. Second, it will be a difficult challenge to ensure that one is indeed modifying the animal into one with a restricted set of motivations rather than an animal that reacts passively, or even with apathy, to adverse conditions [67].

From the broader animal welfare perspective, on the other hand, the very idea that hens should be designed to cope well with battery cages raises serious worries and questions about the natural life of chickens, and about the experiences that constitute such a life. Thus even if it is technically possible, this kind of manipulation is highly questionable from the broader perspective.

If the battery cage case was hypothetical, the blind hen case represents a real situation. A Canadian scientist involved in poultry breeding has bred a blind egg-laying hen [68]. The blindness was thus not inflicted on living chickens, but congenital. According to the researchers, blind hens would be at less risk from feather-pecking and cannibalism, these being welfare problems typically found within free-range production systems. Again, from a narrow welfare perspective, this would seem to be a welcome solution to a rather serious welfare problem.

From the broader perspective, both the notion of deliberately breeding chickens that have such limited potential as to be content with life in a battery cage and the aim of breeding blind hens to solve production problems in the agricultural sector are seen as ethically problematic in ways that might outweigh the advantages of these ideas as perceived from the narrow perspective. Something just seems to be amiss when you deliberately create an animal with less potential than normal [69], whether or not the animal has negative experiences as a result. From this perspective, the task is not to change the animals to fit within the limits of the production system, but to adapt the production system to accommodate the needs of the animals. Implicit in this version of the broader perspective is a certain respect for the natural state of the animal.

It should be said, however, that another version of the broader perspective takes a slightly different view. While agreeing that the natural behavior of the animal is to be respected, the advocate of this view does not consider the natural behavior of the animal to be something static. Just as domesticated animals have been bred to be better adapted to housing in confinement in the past, animals today can be bred, either conventionally or through genetic modification, to be better adapted for modern-day production systems. Thus the fact that one can alter the nature of an animal by genetic modification does not constitute an ethical problem as long as one respects the nature that the animal ends up with [65, 66].

Whether animal welfare is seen from the narrow or one of the broader perspectives, the difference between traditional breeding technologies and the new biotechnological tools seems to be more of a quantitative difference in the potential of applications and associated welfare problems than a qualitative difference that creates entirely new welfare issues. The novelty or technological nature of the changes does not in itself introduce new concerns.

Other Ethical Concerns

From the concerns regarding species-specific behavior within the broader perspective, there is a connection to other concerns that are most often treated outside the discussion of animal welfare. These are concerns about the perceived unnaturalness of the technology and possible violations of the integrity of the animals. Rather than being related to the individual animals themselves, these have to do with a more abstract and wider human perception of what an animal is. They can be said to fall within the scope of animal ethics, but outside the scope of animal welfare.

Naturalness and Integrity Technologies involving the genetic modification of animals are often labeled "unnatural" [44, 70]. As discussed previously, there might be differences in the more technical details over how unnatural the animals are in scientific terms. An animal that has had a gene inserted from another species that it would not be able to share genes with is normally seen as more unnatural than an animal which has had an extra gene from its own species inserted. But it is often argued that from a scientific perspective, this is just a matter of degree and not something requiring the label "unnatural" to be placed on products with which it is associated. There seems to be no qualitative differences between what is going on in traditional breeding and modern biotechnologies. The one follows almost logically from the other, and to label one of them "unnatural" would be to label the other likewise [71]. However, not everyone agrees with this conclusion. It has been argued that the fact that traditional breeding methods are already accepted by at least most of the public, does not necessarily mean that the next, much more advanced, step is also acceptable [72]. The growing attention to the welfare of animals produced through transgenic technologies might even serve as reason to look back on already established, and hitherto innocent, methods of animal breeding with critical eyes [34].

Another criticism of the term "unnatural" is that, although it is intuitively compelling, the normative impact of naturalness suffers from three inherent ambiguities when applied to domesticated animals. First of all, it is almost impossible to point to a stage in the development of such animals that would constitute their natural state and thus be the developmental point that should be respected [64]. Second, even without human interference, animals evolve to adapt to changing environments. Claiming that it is unnatural to change the genomes of animals can therefore, from a scientific point of view, be seen as saying that nature is unnatural. Finally, it needs to be explained why it is

assumed that what is natural is also ethically good. Cancer, earthquakes, and influenza are naturally occurring phenomena, but very few would, for that reason, deem them to be ethically good. For reasons such as these, the notion of naturalness is very often rejected as unclear and insignificant to the ethical debate [73].

These criticisms are very relevant. However, they might be seen as utterly failing to address the fundamental issues at stake in ethical debate about unnaturalness. There seem to be two different viewpoints from which the technologies can be discussed. As Anne Chapman has pointed out, the debate around unnaturalness and biotechnology tends to operate with only two very distinct concepts of nature. Nature is seen either as everything there is (leaving nothing to be unnatural) or as everything that is untouched by humans (in which case all things touched by human activity become unnatural). What is lacking is a middle ground that takes into account the fact that, from an everyday perspective, most people experience the naturalness of things as a gradually developing quality: things can be more or less natural [74]. This difference can very well be expressed in terms of the degree of control that humans exercise over natural processes. Here, it becomes obvious that although the genetic inheritance of animals is changed both through conventional breeding and through transgenic technologies, the latter, being more powerful, are more unnatural.

This understanding of the difference between natural and unnatural as being determined basically by the extent of human control can also be used as an interpretative key that helps to clarify the concerns underlying the claim that transgenic technologies violate the *integrity* of animals.

There are several definitions of the concept of animal integrity available, yet it seems that the notion still eludes clear understanding. The word is derived from the Latin "integer" meaning *wholeness, completed, untouched, unharmed.* Rutger and Heeger [75] define animal integrity as the "wholeness and intactness of the animal and its species-specific balance, as well as the capacity to sustain itself in an environment suitable to the species." De Vries [76] interprets this definition as one mainly aiming at physical, biological, or genetic wholeness. To a large extent, violations of animal integrity will therefore also violate the welfare of the animal [77]; and they will do so irrespective of whether animal welfare is understood from the narrow or one of the broad perspectives.

What is of special interest here, however, is whether practices that do not produce ill health, negative mental states in the animal, or prevent the animal from performing its species-specific behavior can also be seen as violation of integrity. An example, already discussed above, would be breeding animals that fits the production systems better rather than developing housing systems that satisfy the existing behavioral needs of the animals [66]. Again, one might consider changes of composition in dairy cow milk to mimic the content of human milk [78].

The debate about what integrity is, and why it is relevant, mimics the debate about naturalness in important ways. The concept of integrity is often (as in the definition proposed by Rutger and Heeger [75]) tied tightly to biological, empirical features such as behavior, the possession of an unaltered genome, and so on. The concept is then often criticized and questioned, since it makes it unclear why the integrity is especially violated through biotechnology [79].

The notion of integrity is perhaps better understood as one expressing the ethical reservations some experience when animals are commodified to an extent where the distinction between unnatural and natural breaks down, or where the power humans exercise on the animal leaves the animal as nothing more than a resource to fulfill human needs. Integrity is thus something that is experienced directly, but something also that shows up when there is a violation of it [80]. It is experienced in a phenomenological understanding of the animal – not reducing it to an object for examination or a resource to be developed, but affirming the notion of it as another "flesh-of-the-world" entity [81] sharing a "more-than-human-lifeworld" [56] with humans and all the other members of the biotic community. The claim is then that the integrity of the animal is present at this level of experience as the "completeness" of the animal before humans show up with their ability to change animals into something that can satisfy human needs. Self-evidently, an animal can be killed, but life cannot be breathen back into it. In essence, integrity is the experience that the animal is whole, complete, full, finished, when humans encounter it. Humans cannot add to it, only take away [82].

When developed along these lines, the concept of integrity loses it biological foundations and thus becomes impossible to assess from a scientific point of view. Some will probably find that the prescientific nature of the concept disqualifies it automatically; others might find that by interpreting integrity as a "zone of untouchableness" given by the sheer existence of the animal, the moral concerns about interfering in the lives of animals can be seen to make sense, even if they go beyond the animal's welfare interests.

Respect for Autonomy As has already been mentioned, current legislation in most countries is set up to permit transgenic livestock only if this does not pose a risk to the environment and to the animals' health; and to ensure that products originating from transgenic livestock will be allowed to enter the food chain only if they pose no risk to human health. As should be clear from the above analysis, a number of reasons why people might be skeptical about transgenic livestock can be described, and some of these will go beyond what is captured by legislation. First, some people will assess risks differently from the experts giving advice to the authorities. Second, some people will have a wider notion of what counts as a risk than that embedded in the legislation. Finally, third, some people may have moral concerns that go beyond the risk paradigm as shown earlier.

In light of this, one can ask to what extent people should have choice when they buy animal-based products. According to current legislation in the US, there is no requirement to label products derived from GM animals, whereas current EU legislation requires such products to be labeled. Here, then there will be room for a genuine ethical disagreement about whether consumers have the right to be told about the origin of animal products – and retain this right whether or not the products pose a risk. Those opposed to mandatory labeling will typically argue that such labeling may cause unfounded fears in consumers, whereas those in favor of it may argue that consumers ought to have the right to choose for themselves in line with what matters to them; and opinion polls seem to show that many consumers want to know whether or not food products are genetically modified [83].

Public Discussions

The advent of modern biotechnologies, and subsequent ethical debate, has been closely followed by a number of stakeholders: researchers, the biotech industry, politicians devising the legislative framework, NGOs within the areas of environmentalism, animal welfare, animal rights, and so forth. From the outset, it has been clear that the technologies raise ethical issues and that it is necessary to debate these. Equally, after the controversies surrounding the introduction of GM crops and products based on these crops in Europe in the 1990s, it became glaringly apparent that there was widespread skepticism about biotechnology, and that it would be necessary to create some kind of dialogue between stakeholders in the public sphere.

In this section, it is discussed how different motivations for entering this dialogue shape the dialogue itself and the subjects that are deemed relevant within it. As should be apparent from the analysis of ethical concerns provided above, it is not a shortage of subjects to talk about that characterizes the area. As in the section on public perceptions of transgenic animals, it has been necessary to widen the scope and look at the issue at a more general level to capture the trends in the discussions. There is, however, little reason to doubt that ethical discussion of the issues raised by transgenic animals will follow the pattern seen so far in adjacent technologies.

Public Participation and Dialogue

Today "dialogue with the public" is almost a mantra within the biotech community – a community that can be said to consist of all stakeholders, from the most jubilant adherents of the technologies to the most fundamentalist skeptics. The idea of public participation in the preparation of policies for emerging technologies such as biotechnology is very widely accepted. But whereas the general idea of public participation and the concept of dialogue are almost universal within the western world, the content of these notions is far from self-evident [84].

Quite what is meant by "public participation" can, generally speaking, be said to be decided by the reasons for supporting such participation in the first place. There seems to be a continuum from, on the one hand, those who support public participation because

it is a way of assuring the public of some sort of democratic or semi-democratic influence, to those who see public participation as a way of merely legitimizing the technologies in the eyes of the public. In the first case, the goal is to live up to democratic ideals of some sort without influencing the result of the participation. In the second, the point is to get the technologies accepted [85].

The influence of the goal of the public participation on the structure of the debate can most easily be seen when the concept of *dialogue* is considered. There seem to be three different understandings of the concept of dialogue in ethical discussions of biotechnology today. One is (1) a specific variety of (so to speak) *monological* dialogue. This assumes that widespread skepticism about biotechnology is based on the public's lack of knowledge and understanding of the technologies. The remedy to this is therefore knowledge transfer from the sphere of science to the public. As soon as public has been educated the skepticism will disappear.

This way of thinking, sometimes labeled "the knowledge deficit model" [86], is very widespread in the scientific community. One noteworthy example of it can be found in the report *Why clone farm animals? Goals, motives, assumptions, values and concerns among European scientists working with cloning of farm animals* [87]. Here, a group of scientists working on cloning are interviewed about the technology and various aspects of it. All say that it is very important to establish a dialogue with the public about the technology, but when directly asked what subjects would be suited for such a dialogue, they invariably answer that the public should be provided with information about the technology.

The largest problem with the knowledge deficit model is that, although it continues to thrive within the scientific community, it has been refuted in sociological studies of the public perceptions of biotechnology. What happens when citizens are provided with information about the science and possible applications is that they form an opinion about it; but there is no evidence to suggest that knowledge in general erases skepticism [44].

(2) A second form of dialogue is as monological as the first, but the exchange moves in the opposite direction – it is the public rather than the scientists now doing all the talking. Here, the task is to examine public attitudes to biotechnological applications and figure out which will be socially acceptable. The goal is thus to ensure that the technologies pursued will not end up in the same situation as the GMOs in Europe in the 1990s. Very often, the two monological kinds of dialogue are combined, so that consumer preferences and consumer education go hand-in-hand in an attempt to produce social acceptance for the development of the technologies [85].

(3) The third concept of dialogue in the current debate sees dialogue as a way of balancing two very important considerations. One consideration is to respect the other person, whether it is a single person, a group of stakeholders, or society at large. The other is to take responsibility for one's own views of the world and attempt to do what one sincerely believes to be in the best interest of the other (whoever that may be). A classic example of this conflict can be found in the relationship between the physician and the patient. The ethical duty for the physician is to avoid taking all responsibility from the patient (paternalism as tyranny) and yet not leave the patient on his own in trying to decide upon different methods of treatment in the mistaken belief that the task of a physician is just to provide neutral information and at all costs respect the patient's right to self-determinacy (autonomy as denial of responsibility).

The concept of dialogue implies that there are two or more opinions about something, and that the people holding these opinions are willing to discuss them, holding a small window open in the back of their minds to the possibility that they may be wrong. A dialogue where it is from the outset decided that only one part of the dialogue (and that is usually the other part) could end up changing their minds is no dialogue, but could better be described as a caricature of energetic and zealous religious proselytizing.

When promoting public participation in the debates about such things as transgenic animals, it is important to realize that this is always done with a specific goal in mind – and that this goal will always influence the way the dialogue is structured. Similarly, the motivation for entering the dialogue in the first place will influence views on what questions are relevant and who should participate. These differences are also visible within different cultures where, for example, the role of the scientists and nonexperts in the

debates are understood very differently, just as the purpose of the whole exercise is understood quite differently [88].

Possible Goals of Ethical Dialogues

Motivation for entering ethical discussion of biotechnology in general and transgenic livestock in particular varies from stakeholder to stakeholder, although it is probably safe to say that all stakeholders enter the discussion because they think that the information they can bring will convince others of their viewpoints [73]. But besides the urge to win the argument, there are other and more realistic goals of ethical dialogue, and these could provide reasons for entering in the first place.

The first reason is enlightenment or clarification. Ethical debates are where humans meet and exchange their views. This gives the involved parties a chance to explain their views and listen to the explanations of others. Thus the areas of disagreement and the values that underlie them can both be clarified. This need not lead to agreement, of course; it will only do so if some of the disagreements turn out to be based on misunderstandings either of the viewpoints of the opponent or the facts of the issue. But it can lead to a better understanding of the opponent's viewpoints; and that is valuable in itself. It is valuable, first and foremost, because understanding is itself valuable, and second, because it is easier to find areas of consensus and compromise if you have an understanding of the viewpoints of others rather than just finding them irrational or blind to the ethical dimensions of the issue. Understanding why someone has certain opinions makes it easier to respect him or her, and it can create an environment around the debate that makes it easier to move on to the next step [89].

The second possible result of ethical debates is that the decisions eventually reached are socially robust. A socially robust decision is here understood as a decision that seeks to include widely held concerns about a technology while at the same time allowing it to progress in areas that are of significant benefit to society. As mentioned earlier in section "Public Perceptions of Transgenic Technologies," it is apparent from sociological studies that, in biotechnology, there are two scales of importance. One is the scale of organism, the other a scale of applications. The simpler the organism, the more acceptable the technologies become; and the more the application of the technology addresses issues like health, the environment, and aid to the developing world, the more acceptable it becomes [44]. Thus using transgenic technologies to produce livestock that will benefit medical research will, in all likelihood, be more socially acceptable than producing livestock that can improve productivity in agriculture.

By targeting on areas of need, developments in transgenic livestock would therefore be less problematic than they would be if the focus was on areas of economic gain. A socially robust development process will mean that certain applications are left aside in order to gain broad societal acceptance of the progress of the technologies [90].

Future Directions

The technology to produce transgenic animals is here to stay. The genie cannot be put back in the bottle. And as the technology is further developed and refined, it will, in all likelihood, become more and more economically feasible and sustainable to produce animals through these technologies. But the ethical problems will not disappear either. The issue of animal welfare as seen from a narrow perspective will continue to play a role, as will the issues around possible negative impacts on human health and the environment. Even when more data on these risks become available, it should be obvious from the discussion of GM crops that the risk evaluation will continue to be an area of controversy for many years to come.

Discussion of the socio-economic impact of the technologies will intensify. If the animals enter the agricultural sector and the food production chain, there is reason to expect that they will only strengthen the current trends within agriculture, where ever larger units with animals dominate production in a highly technological environment. This will inevitably give rise to ethical debate – but probably debate of a sort that is already taking place about how the agricultural production system should function. In the areas of naturalness and integrity, ethical disagreement will continue to flourish, especially if animals are produced for applications that are not generally regarded as important to society.

All in all, then, it is safe to say that ethical debate about transgenic livestock, and about the development of the technology, will continue to play a significant role in the future. As research and technology development becomes more and more reliant on private funding, it will be necessary to show that the development of transgenic animals will pay off investors. Finally, there is no doubt that the area will continue to be a political and ideological battle scene. It will therefore be necessary to apply methods of public participation that include many viewpoints. These methods should help to ensure socially robust development in a technology, for which the potential to create social and ethical conflicts seem as large as the technological potential.

Article Outline

Glossary

Bone morphogenetic proteins (BMPs) Group of molecules belonging to the transforming growth factor family that were initially discovered by their ability to induce the formation of bone and cartilage. BMPs provide pivotal morphogenetic signals orchestrating tissue architecture throughout the body.

Calving The act of delivering a calf at the end of normal bovine pregnancy.

Energy balance In reference to animal physiology, it is the relation between energy intake from nutrient consumption and energy expenditure to maintain body functions.

Estrus The stage of the estrous cycle when a female is sexually receptive and during which ovulation occurs.

Fertility The ability to produce healthy offspring.

First-service conception rate Refers to the percentage of animals in a herd that become pregnant upon insemination on the first estrous cycle after parturition.

Genetic selection/selective breeding The process of breeding animals or plants with the goal of enhancing particular genetic traits.

Heterozygous Refers to an individual having two different alleles for a given trait.

Homozygous Refers to an individual having identical paternally and maternally inherited alleles for a given trait.

Knockin Integration of a new gene which replaces an endogenous gene.

Knockout Functional disruption of a specific gene of an organism, commonly achieved by a partial or complete deletion of the gene sequence.

Livestock Domesticated animals raised to produce commodities such as food, fiber and labor.

Mutation A change in the DNA sequence of a gene which can result in changes in the sequence and function of the encoded protein.

Ovarian follicle The structural and functional unit in the ovary within which an oocyte grows and matures until it is expelled during ovulation.

Ovulation The process by which mature ovarian follicles rupture under the influence of luteinizing hormone to release an oocyte into the oviduct.

Phenotype/phenotypic A measurable characteristic of an animal such as hair color or growth rate, and which is the product of genetics and the environment.

Point mutation A mutation involving a single nucleotide base pair in a DNA sequence.

Production trait A genetically determined characteristic of an individual of a livestock species which relates to its capacity to provide a certain product (milk, meat, fiber, eggs, work) which contributes directly to the value of the animal for the farmer.

Promoter A regulatory DNA sequence that controls the transcription of a particular gene.

Reproductive performance The productivity of an animal or herd in terms of offspring produced.

Reproductive/breeding efficiency Related to the capacity of an individual to successfully carry out all reproductive processes from gamete formation to fertilization, establishment of pregnancy and delivery of healthy offspring.

Originally published in
Robert A. Meyers (ed.) Encyclopedia of Sustainability Science and Technology, © 2012, DOI 10.1007/978-1-4419-0851-3

Seasonal reproduction Refers to the dependence of reproductive activity on seasonal factors, most notably changes in day length, in certain species.

Single nucleotide polymorphism DNA sequence variations involving alteration of a single nucleotide in a genome sequence.

Transgene An exogenous gene introduced into the genome of another organism.

Transgenic An animal, plant or microbe whose genetic material has been altered using an artificial process.

Zinc finger nucleases (ZFNs) Synthetic proteins consisting of an engineered DNA-binding motif characterized by multiple finger-like protrusions (finger domain) and which has been fused to the cleavage domain of the *FokI* restriction endonuclease. ZFNs can be used to induce double-stranded breaks in specific DNA sequences and thereby promote site-specific homologous recombination and targeted manipulation of genomic loci in a variety of different cell types.

Definition of the Subject and Its Importance

The possibility of using transgenic technology to promote desirable traits, including enhanced reproductive efficiency, in livestock species has attracted considerable interest since transgenic animals were first produced. Almost 20 years ago McEvoy and associates [1] proposed that transgenic technologies could be used to increase reproductive output in food producing animals by increasing litter size in livestock or egg-laying capacity in poultry, and by reducing the limitations associated with seasonal breeding. During the intervening 2 decades, the uptake of transgenic technologies in livestock production has been limited because of technical, regulatory and ethical constraints [2]. However, the availability of novel technologies, such as Zinc finger nucleases (ZFNs) [3], which allow for greater precision and control, together with a growing need to increase livestock productivity to meet the requirements of a growing world population will likely help to realize current aspirations on use of transgenesis in animal reproduction. The application of transgenic technologies in laboratory animals has been invaluable in considerably furthering our understanding of numerous reproductive processes including gonad development and function [4–6], oogenesis and early embryogenesis [7, 8], and trophoblast gene function [9, 10], and through this increased understanding will lead to new strategies to improve reproductive efficiency of livestock species.

Introduction

Reproductive efficiency of domestic animals is critical to the sustainability of modern livestock industries. Thousands of years of domestication led to changes in the reproductive physiology of animals, for example, a dramatic reduction in the influence of season on reproduction in cattle and pigs. During modern times, intensification of farming systems coupled with the implementation of programs of genetic improvement aimed at selection for specific (non-reproductive) productivity traits had further effects on reproductive physiology often with negative consequences to breeding efficiency, with ultimately an impact on the overall productivity and sustainability of livestock industries. Meeting the increasing world demands for animal products will require increased production of healthy offspring from livestock while coping with a decrease in the availability of natural resources to maintain these animals. Achieving this within a reasonable time frame will require the use of strategies alternative, or in addition, to traditional breeding and genetic selection. This entry will describe current limitations in reproductive performance of livestock. The potential and limitations of transgenic technologies to address such problems will then be described and specific illustrative examples will be provided.

The Problem of Low Fertility in Modern Livestock

At its 2009 World Food Summit, the United Nations Food and Agricultural Organization recognized that agricultural output will need to increase by 70% by 2050 in order to feed the world's population which is expected to exceed 9 billion in this timeframe (FAO 2009, ftp://ftp.fao.org/docrep/fao/Meeting/018/k6050e.pdf). A significant portion of that output will be derived from the demand for animal protein, especially in developing countries as they become more affluent. Considering increasing production constrains derived from climate change and competing demands on resources, the key target for the future of livestock

production will be to maximize the number of offspring produced by each female animal that are also fit for purpose. This will involve three challenges, namely, to increase the numbers of offspring that a female can produce, to optimize the in utero conditions under which fetuses develop so to maximize development of appropriate phenotypes, and to bias offspring sex to reflect animal usage. Meeting these challenges will require continued advances of traditional methods and approaches, such as husbandry and genetics, as well as the broad uptake of newer and emerging biotechnological solutions such as transgenesis.

An important point to be made is that these challenges will need to be accomplished in the face of a persistent decrease in livestock fertility associated with modern farming systems in western countries, particularly affecting the dairy, pig and chicken meat industries [11–13]. In these animals, specific production traits (milk, meat) have been genetically selected at the expense of a reduction in non-selected traits such as fertility. In many cases an even more important contribution to low fertility in modern livestock herds has resulted from industry consolidation into fewer, larger production units which are managed intensively toward the primary objective of maximal economic gain.

A clear example of this is the dairy cattle industry, where a steady increase in milk productivity over the past few decades has been associated with a progressive decline in fertility to current first-service conception rates below 40%, resulting in extended calving intervals and premature culling [11, 14, 15]. According to the UK's Dairy Science Forum (2008), poor fertility in dairy herds is estimated to cost to the UK industry alone above £300 million a year, in addition to being a major welfare issue. Under current management schemes, to maximize milk production cows need to conceive soon after parturition so that the interval between lactations is minimized and a target of one-calf-a-year can be achieved. This requires timely restoration of gonadotropin secretion and ovarian activity after calving, together with adequate uterine clearance and repair, if successful follicle maturation and ovulation followed by fertilization and establishment of pregnancy is to take place by about 90–100 days [16, 17]. However, dairy cattle have been selected to efficiently partition nutrients toward milk [18] production thus creating a state of negative energy balance after parturition where reinitiation of high milk production will occur preferentially to restoration of reproductive function conducive to establishment of pregnancy [19].

Even more profound effects on reproductive activity in cattle but also in other livestock [20–22] are derived from suboptimal management of animals under intensive farming conditions including under nutrition, stress and general poor health reflected, for example, in a high incidence of lameness and mastitis, two major conditions associated with low reproductive performance of dairy cattle [11, 14]. Repeated calving itself poses an enormous risk to sustained reproductive performance because of the incidence of parturition-related or postpartum complications (e.g., dystocia, retained fetal membranes, endometritis). Poor management, together with suboptimal ovarian function during postpartum, also leads to poor estrus detection in large herds of dairy cows and other livestock leading to a dramatic decrease in the efficiency of artificial insemination-based programs [23]. Finally, several other factors can have a large impact on overall female health including subclinical infections and environmental factors such as heat stress which has direct effects on follicle development, oocyte quality and embryo development [24, 25].

Poor management is a primary cause of low reproductive performance of livestock in developing countries. As an example, the domestic buffalo constitutes an essential farming resource to millions of families in developing countries, particularly Asia. This species has been traditionally regarded as having low reproductive efficiency, including late attainment of puberty, a seasonal pattern of reproduction, poor expression of estrus, low conception rates and long calving intervals. To a large extent, these characteristics can be attributed to environmental and managerial factors including the absence of a year-round nutrient supply, harsh environmental conditions and suboptimal human intervention [26, 27]. Different studies have shown that buffalo fertility can improve considerably by exercising proper management and feeding and that this can be enhanced by genetic selection [27, 28].

In some instances, the problem is not a lack of nutrients but over nutrition. This is the case in the broiler chicken, in which overfeeding of growth-selected animals results in excessive recruitment of ovarian follicles leading to simultaneous ovulation of multiple follicles. This alters the timing of egg laying and results in poor eggshell quality [29]. This problem has been addressed by nutrient restriction of animals which is necessary to achieve reasonable levels of egg production. This is a significant production and welfare issue as nutrient-restricted broiler breeders show clear evidence of physiological stress as well as an increased incidence of abnormal behaviors, among other problems [30].

Limitations on the reproductive performance of livestock can also be imposed by naturally evolved traits. This is the case in sheep, goats and horses, in which ovulatory activity is restricted to certain periods of the year to ensure that offspring are born at a time when food resources are plentiful [31]. Another example is the inability to selectively breed for the desired gender for a given production trait (for example females only for milk and males only for meat production) which within livestock industries leads to considerable waste and welfare concerns due to the need to cull the less useful gender.

The Need and Potential of Transgenic Technologies to Improve Reproductive Performance of Livestock Species

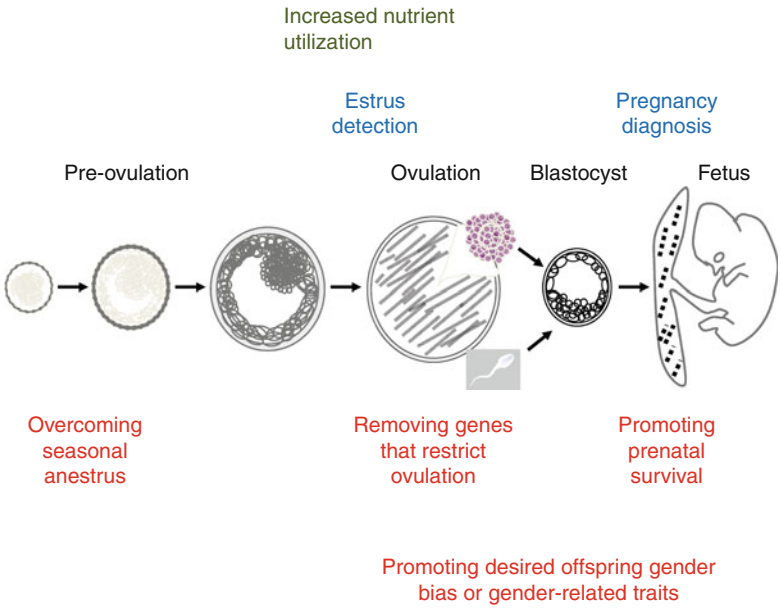
As outlined above, declining fertility trends in livestock can be partially reversed by improved management. This may include pharmacological control of reproductive function which, although effective in the short term, is nonetheless expensive and has limited benefits as not all animals respond adequately to hormone treatments, particularly if these are not associated with improvements in more basic aspects of management [32–34].

Interventions aimed at increasing general herd health and welfare and reducing stress can be very effective in substantially improving fertility, particularly if they include close monitoring of the reproductive status of individual animals. Optimal implementation of such measures, however, can be costly and in some cases may not be feasible and/or economically viable, particularly in developing countries.

Optimum nutrition is also an important aspect of good management, particularly as it relates to prevention of low energy balance during postpartum and other critical reproductive states [15, 19]. It has been shown that the extent to which reproductive performance can be increased through nutrition is limited [35] and that a given diet can have different effects on different aspects of reproduction, as exemplified by the administration of diets which stimulate plasma insulin levels in postpartum cattle [36]. Such diets can effectively stimulate follicle development but at the same time have negative effects on the oocyte, justifying the need for carefully tailoring diet composition to specific reproductive functions if optimum fertility is to be achieved.

Although selection of livestock for certain production traits has been associated with a loss of fertility, studies with dairy cattle have shown that this loss can be reversed, through genome-wide selection on multiple traits, without completely compromising milk production [35]. However, eliminating the fertility problem in livestock through genetics would require that reproductive traits be included as a significant component of selection indexes and the desired outcome may not be achieved in decades. Alternatively, genetic gain could be aimed at reducing the impact of poor fertility on productivity, for example, by selecting for extended lactation periods in dairy cattle [14], although in many instances this may not be economically feasible. In addition, it is unlikely that existing genetic variation in modern livestock lines will continue to generate the rate of gain obtained in the past. On that note, the use of transgenic technology to induce modifications in selected genes followed by conventional breeding and selection would offer an attractive alternative to effectively introduce desirable fertility traits in livestock, particularly in cattle and sheep which have long generation times and small offspring numbers.

Transgenic approaches have been used in livestock for the purposes of increasing productivity, conferring disease resistance and increasing environmental sustainability [2]. Similar approaches could be used to increase fertility (Fig. 1). These could be aimed at improving reproductive function directly (for example,



Transgenic Technologies and Increased Livestock Fertility. Figure 1
Schematic diagram showing stages of the reproductive process where transgenic technologies could impact. The examples presented include strategies to directly improve reproductive function (in *red*), to indirectly favor reproductive success (in *green*), or to facilitate reproductive management (in *blue*)

by removing genes that naturally suppress ovulation) or indirectly (for example, by improving energy utilization by reproductive tissues) or at facilitating reproductive management of livestock (for example, by inserting reporter genes that could facilitate estrus detection or early pregnancy diagnosis). To achieve this, gene knockin or knockout approaches could be used to modify whole genes or large portions of these genes. Alternatively, novel ZFN technology allows for targeted or untargeted gene mutagenesis to be induced to selectively modify gene function in animals [37–39]. This approach would be more likely to be accepted by the public than the insertion of foreign genes into livestock genomes and it could also provide more predictable results, particularly if natural or induced mutations of the gene(s) of interest already existed in the same or a different species.

Successful application of transgenesis in livestock fertility will ultimately require a more thorough understanding of reproductive physiology in these species. Transgenic studies aimed at targeting fertility genes in livestock have not been reported and therefore potential gene targets would have to be obtained from data on naturally occurring mutations or single nucleotide polymorphisms associated with fertility, or from results of experimental gene targeting in rodents, which can already provide a substantial list of candidate genes [40]. It must be stressed that, because of significant species differences, considerable caution should be used when attempting to extrapolate results from genetically modified mice into other species. A clear example of this is the failure of genetic deficiencies in bone morphogenetic protein (BMP) 15 or growth differentiation factor (GDF) 9, which are naturally associated with multiple ovulation in sheep, to increase the ovulatory response in mice [41]. In addition, it is essential to remember that most reproductive traits are controlled by several genes acting in concert and they may not therefore be easily altered by targeting a single gene. Finally, genetic modification in mice can reportedly be associated with a reduction of fertility in vitro [42], an observation that would need to be properly addressed.

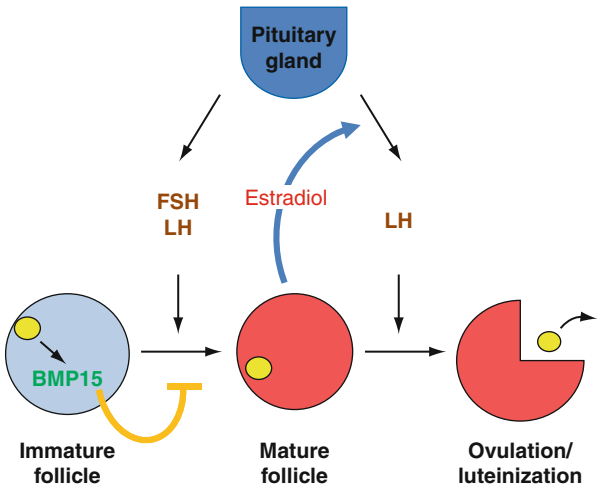
The choice of a particular gene modification aimed at improving livestock fertility would need to be based on different considerations. Optimally, a gene should be

targeted only in a specific cell type or organ of interest. This could be achieved with the use of cell-specific gene promoters to drive the targeting event. Choosing a gene target with naturally restricted expression, if possible restricted to the cell type of interest, would be technically simpler and more efficient. In addition, small-scale mutagenesis rather than whole gene replacement or insertion of a new gene would be preferred to achieve the desired phenotype effects. This is now possible with remarkable efficiency in rodents and pigs by using ZFN technology [37–39]. Lastly, the intended mutation would optimally exist naturally and have been characterized thus allowing more accurate prediction of the phenotype in transgenic offspring.

Potential Targets for Transgenic Improvement of Livestock Fertility

Among the genes that could be targeted to increase fertility in livestock, certain members of the BMP family meet all three criteria described above for an optimum target. In this section, these genes will be first considered in detail followed by brief reference to others that could be targeted to improve different aspects of reproduction.

Natural mutations in the BMP ligands, BMP15 and GDF9, and in the BMP receptor type 1B (BMPR1B) have been described in different breeds of high prolificacy sheep and some of them have been characterized in detail [43, 44]. Five different point mutations were identified in BMP15 (*FecX* locus) and one in each of GDF9 (*FecG*) and BMPR1B (*FecB*). These mutations led in each case to reduced production of biologically active protein and/or altered protein signaling. Homozygosis for either BMP15 or GDF9 mutations is associated with infertility due to disruption of early ovarian follicle development, whereas heterozygous animals show natural higher ovulatory rates than wild types (about 3–4 vs 2 follicles per ovulation). The BMPR1B mutation in sheep is also associated with a higher ovulation rate in heterozygous animals, but in this case homozygous animals not only are fertile but they display an even larger positive effect on ovulation rate ($\geq$5 follicles per ovulation). Expression of BMP15 and GDF9, but not BMR1B, is mostly restricted to the oocyte. For both BMP15 and GDF9 mutations, the different ovarian phenotypes observed in homozygous and heterozygous animals are thought to largely reflect the role of these growth factors in promoting cellular proliferation during early stages of follicular development and in preventing premature maturation of late stage follicles, respectively (Fig. 2) [43, 45]. In heterozygotes for either mutation, reduced growth factor levels reportedly lead to increased responsiveness to the gonadotropin, follicle-stimulating hormone, and premature acquisition of responsiveness to luteinizing hormone, by granulosa cells of developing follicles which facilitates follicle maturation leading to the recruitment of an increased number of ovulatory follicles [43]. This phenomenon could be exploited using transgenesis to increase ovulatory rate not only in other sheep breeds but also in monovular species such as cattle. Evidence from immunization studies indicates that, as in sheep, altering the levels of BMP15 and/or GDF in cattle has clear effects on follicle development and ovulation rate [46]. Based on this and other information on the biological role of BMP15 and GDF9 in the bovine ovary [47], as well as on the phenotype described in mutant sheep, it can be predicted that similar mutations in BMP15 and/or GDF9 in cattle would result in animals with increased follicular sensitivity to gonadotropins and therefore a reduced gonadotropin dependence for follicle maturation. This change would provide a clear physiological advantage during situations, such as the early lactation period, when energy demands for reproduction cannot be fully met resulting in insufficient gonadotropin stimulation that prevents normal follicle maturation and restoration of ovulatory activity [16, 48]. As a result, ovulatory activity would be predictably restored early after parturition providing an opportunity for reduced calving intervals. It is very important to consider, however, that for the increased incidence of ovulation in such transgenic cattle to effectively lead to an increase in reproductive efficiency, it would have to be associated with the implementation of measures to ensure adequate oocyte quality and uterine health, so that pregnancy could be successfully established and maintained. An increased frequency of twining would be likely in the transgenic cattle lines which, although not desirable in certain situations, could still be exploited by the cattle industry to increase productivity. In addition to the natural mutations considered here, there are other high prolificacy



Transgenic Technologies and Increased Livestock Fertility. Figure 2

Schematic of the physiological control of ovarian follicle maturation by pituitary gonadotropins and oocyte-derived BMP ligands. For simplicity, only BMP15 is shown. During normal estrous cycles, systemic gonadotropin levels stimulate follicle maturation leading to the production of estradiol which will eventually trigger a surge in pituitary LH release and ovulation followed by luteinization of follicular cells. Current evidence from ruminants indicates that BMP15 restricts the maturation-promoting effects of gonadotropins thus preventing the development of an excessive number of preovulatory follicles and early ovulation and/or luteinization. It is proposed that transgenically altering the levels of BMP15 in cattle would counteract the relative deficiency in gonadotropin levels during the postpartum period leading to early ovulation. *FSH* Follicle-stimulating hormone, *LH* Luteinizing hormone, *BMP15* Bone morphogenetic protein 15

phenotypes identified in sheep which do not seem to be associated with the BMP system [49]; identification of the specific genes involved will provide additional targets for manipulation of fertility in livestock.

Aside from the BMP system, there is evidence in livestock to indicate that the estrogen receptor (ESR) could be targeted to increase prolificacy. In pigs, there are associations between litter size and several genes including the ESR, prolactin receptor (PPLR), and retinol-binding protein (RBP) genes [50]. Rothschild and associates [51] found a *Pvull* polymorphism in intron 9 of *ESR1* in prolific Chinese Meishan pigs and commercial Large White populations. Among the Pvull genotype sows homozygous for the desired allele had larger litters at birth with more live born piglets. Introduction of a mutated or polymorphic ESR gene could therefore be used to increase litter size in several pig breeds.

The use of transgenesis has also been proposed to address gender inefficiency in livestock industries [2]. More precisely, it was suggested that genes involved in the production of functional sperm [52] or sex determination [6] and that have been successfully targeted in mice and birds could be used as targets for transgenic alteration of sex ratios in livestock. For example, the gene, *DMRT1* (doublesex and mab-3-related transcription factor 1), is implicated in male gonad development in vertebrates and its knockdown using RNA interference in early chicken embryos resulted in gonadal feminization of genetically male embryos leading to partial sex reversal [6]. An alternative approach to address gender inefficiency would be, rather than trying to alter the natural gender ratio, to transgenically enhance specific production traits in a gender-specific manner. As an example, in an attempt to produce transgenic animals with muscular hypertrophy similar to "double-muscling" which results from naturally occurring loss-of-function myostatin *(MSTN)* mutations in cattle [53], Georges and associates [54] targeted trans-inactivators of *Mstn* on the Y chromosome of mice. The resulting transgenic males showed a 5–20% increase in skeletal muscle mass. The authors suggested the use of this approach in dairy cattle to produce breeds with combined beef and dairy abilities [54].

Finally, targeting of a number of other aspects of reproductive physiology through transgenesis may be desirable to address specific causes of reduced fertility. This could be done for example to improve prenatal survival in different species by increasing the expression of known luteotrophic and antiluteolytic conceptus signals which would be expected to reduce embryo mortality and thereby improve pregnancy rate [55], or to reduce seasonal constraints on reproduction by targeting the neuroendocrine pathways involved [56] to generate transgenic small ruminants capable of year-round breeding in temperate latitudes.

Future Directions

Since first reported over 30 years ago [57], the use of transgenic technologies in mice has been extremely useful in unraveling genetic mechanisms, including reproductive processes. Although since then the application of such technologies in other species including livestock has encountered numerous roadblocks, considerable technical improvements have been made which now allow specific and precise gene targeting in vivo [38, 39]. The vast potential of transgenic technologies in livestock has been extensively demonstrated by the successful targeting of many production-related traits in ruminants, cattle and sheep [2]. Although there has been public reluctance toward the use of such technologies in food-producing animals, technical advances allowing the production of safer foods from transgenic animals together with mounting social pressures demanding an increase in the availability of animal products for a growing world population will likely change this, and recent FDA approval of a genetically modified salmon [58] is a good indication of such change already happening. Although attempts at transgenically increasing livestock fertility have not been reported, transgenic technologies hold particular promise in that regard, both in terms of reversing current decreasing fertility trends and alleviating natural fertility constraints of livestock, two aspects that have a profound impact on overall industry productivity and efficiency, and which is set to become increasingly important as demands for higher livestock productivity continue to increase. Studies in livestock species to increase understanding of their reproductive processes and to develop further refined gene targeting technologies will be key in bringing the realization of such promise much closer.

Article Outline

Glossary

Animal cloning Non-sexual reproduction of an animal by transfer of a nucleus from a differentiated cell into the cytoplasm of an enucleated oocyte; SCNT (somatic cell nuclear transfer): cloning using a somatic cell as nuclear donor.

Chimeric animal Animal containing cells from two animals; chimeras are obtained by transferring embryonic cells from an animal into a recipient embryo; the chimera gametes contain the genome from one of the two embryos.

Hybrid Animal resulting from the sexual reproduction of parents from different breeds (intraspecies hybrid) or parents from different species (interspecies hybrid).

Knockdown Inhibition of the expression of a gene at the mRNA level by a siRNA.

Knockin Targeted integration of a gene by homologous recombination.

Knockout Inactivation of a gene by homologous recombination.

Lentiviral vector Gene construction able to integrate a foreign gene into a genome via an infection mechanism.

Meganuclease Endonuclease that is able to cut both strands of DNA and enhance the efficiency of homologous recombination.

Pluripotent cell Cell that is able to participate in the development of all the organs; lines of pluripotent cells can be established from early embryos (ES: embryonic stem cells) or from somatic cells (iPS: induced pluripotent cells) obtained by the transfer of genes responsible for the pluripotency of embryonic cells.

siRNA Small interfering RNA (also known as RNAi) that is able to inactivate specifically an mRNA by its degradation or by the reversible inhibition of its translation; siRNAs are generated by the degradation of long double-stranded RNAs, by the transcription of micro-RNA genes, by the transcription of gene constructions coding for shRNAs (small hairpin RNAs), or by chemical synthesis.

Transgenesis Experimental transfer of an isolated gene (or a DNA fragment of any origin) to animal cells making the transmission of the genetic modification to progeny by sexual reproduction possible. The animals harboring the foreign genes are known as transgenic animals, transgenics, GM animals (genetically modified animals), rDNA animals (recombinant DNA animals), or GE animals (genetically engineered animals).

Zinc finger nuclease (ZFN) Engineered nucleases that are able to cleave both strands of genomic DNA in specific sites. ZFNs as meganucleases are able to induce a DNA repair and a local mutation equivalent to a knockout in the absence of foreign DNA or targeted gene integration at a high efficiency in the presence of a homologous recombination vector.

Definition of the Subject

Various techniques and mainly gene cloning, genome sequencing as well as transcriptomics provide researchers with an increasing number of genes. In order to know the role of the genes and the mechanisms of their regulation, it is mandatory to reintroduce them into their natural complex environment, cells, and animals. Transgenesis has thus become a major tool for biologists, and presently, at least 90% of GM animals are generated for basic studies. Transgenesis is not only a tool for research; it is also more and more extensively used for various biotechnological projects in the traditional fields of biology applications: medicine and agriculture.

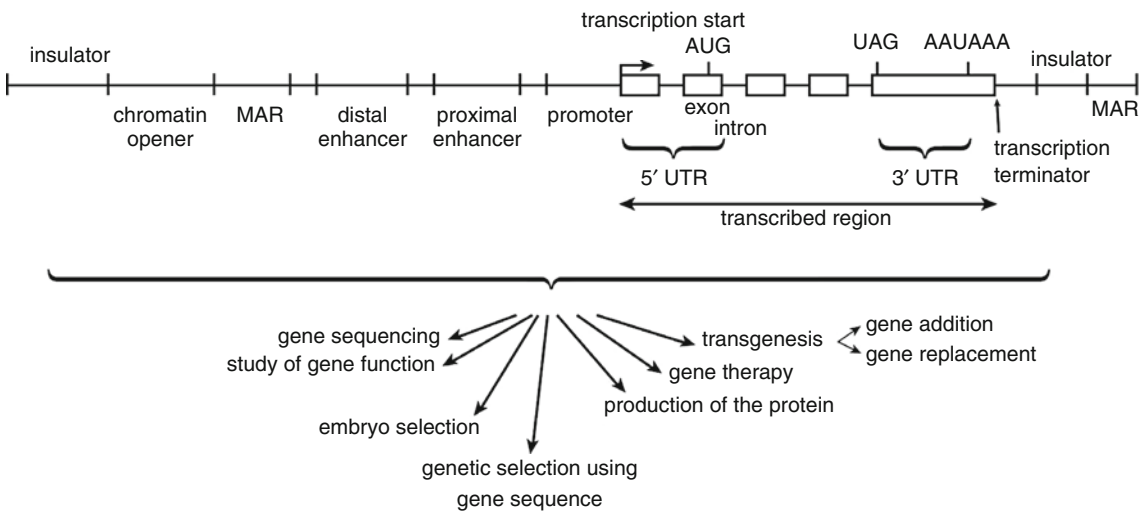
The information provided by the understanding of the biological functions of humans and animals may give clue for the design of new treatments for patients and selection of farm animals, respectively. Transgenesis has thus become a key tool for the creation of animal models for the study of human diseases. These studies may even provide researchers with genetic markers for diagnosis and genetic selection. The newly identified and studied genes may be used to produce small quantity of the corresponding recombinant proteins to establish relations between their structure and their activity. Very large quantity of recombinant proteins of pharmaceutical interest may also be produced in milk or egg white of transgenic animals. Pig cells and organs may in principle be genetically modified to become tolerated by patients. Some newly identified genes may as well be transferred to farm animal to improve production as it is already the case in plants [112](Fig. 1).

The available techniques make it possible the addition of exogenous genes and the elimination of genetic information in various animal genomes. Several more and more sophisticated tools allow also a fine-tuning of transgene expression. Although the generation of transgenic animals is no more a bottleneck for their different use, it remains laborious and costly especially in large animals. Some improvements of the methods are required and in course. The methods of gene transfer are closely linked to the reproduction techniques and to the aim of the projects. These methods, which include the construction of the genes to be transferred and which are adapted to the different animal species are described in the present chapter.

Introduction

By essence, living organisms are in permanent evolution. This phenomenon is relatively slow, and it was probably not perceived by humans until they invented agriculture and breeding. The control of plant and animal reproduction made the empirical genetic selection possible which provided to human communities all their essential food products, pets, and ornamental plants. This led to the generation of profoundly genetically modified organisms. Carrots, tomatoes, silkworm, some dogs, etc. are unable to survive without the assistance of humans.

The discovery of the Mendel laws allowed an improvement of the genetic selection. Yet, this selection remained based on spontaneous, thus random and unknown, mutations. During the first half of the last century, it appeared necessary and possible to increase the number of random mutations to enlarge the choice of the genetically modified organisms corresponding to

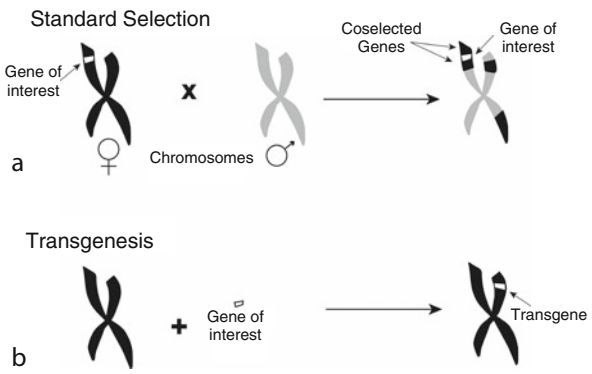


Transgenics: Alternative Gene Transfer Methods. Figure 1

The different uses of isolated genes. Transgenesis, which includes random and targeted gene addition as well as specific gene inactivation and replacement is an essential tool for gene study and for biotechnological applications

the expectations of experimenters, farmers, and breeders. This was achieved by using chemical mutagens and by generating multiple intraspecies and interspecies hybrids. One of the most impressive examples is the creation of a new cereal, triticale, which results from an artificial crossing between wheat and rye. This new plant is currently a source of feed.

All these methods are imprecise as they induce multiple unknown mutations in addition to those which are expected. One of the problems of conventional genetic selection, either to create models or to improve production, is that the selected genes are unknown and that a large number of genes also unknown are co-selected with the genes of interest (Fig. 2). Yet, these approaches were globally highly beneficial for humans. They also show that the plasticity of living organisms is high and that humans have empirically learned to manipulate them successfully with limited undesirable side effects. The discovery of DNA and genes opened wide avenues for research and biotechnological applications. Indeed, the manipulation of isolated and known genes makes it possible more diverse and better controlled genetic modifications (Fig. 2).

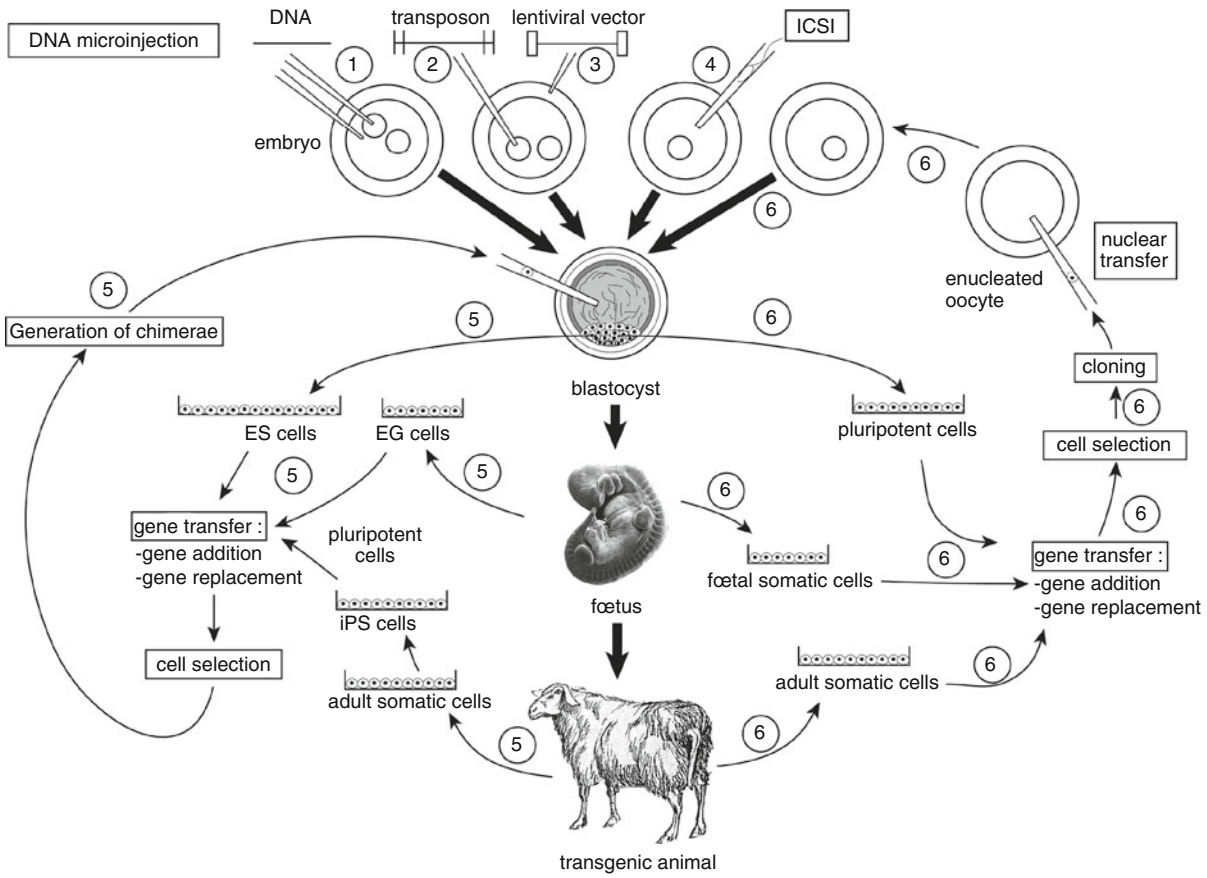


Transgenics: Alternative Gene Transfer Methods.
Figure 2
(**a**) Conventional genetic selection relies on the random chromosome rearrangement during sexual reproduction and, thus, to the random distribution of the different gene versions in offspring. The gene of interest responsible for the expression of a valuable genetic trait, and which is selected, is then unknown and the process implies the co-selection of a number of unknown potentially deleterious genes surrounding the gene of interest. (**b**) Selection by gene transfer offers the possibility to add (or delete) a single gene having a known function into a living organism. This gene may be of various origins and may be optimized before being transferred

The introduction of isolated genes into cells has become a common practise in the 1970s of the last century, soon after the emergence of the genetic engineering techniques. It represented a great progress for the understanding of gene functions and mechanisms of action. This technique is still widely used, and it started being complemented in 1980 and 1983 by gene transfer into animals and plants, respectively, to generate lines of genetically modified organisms, also known as transgenic animals and plants.

The first transgenic animals, mice, were obtained by microinjecting the genes into one of the nuclei (pronuclei) of 1-day embryos [31]. This method could be extrapolated successfully to three other mammals (rabbits, pigs, and sheep) in 1985 [32], but it soon appeared that other methods had to be implemented for some species. Transgenesis is presently carried out essentially for basic research in only a few species: a mammal (mice), an insect (drosophila), fish (medaka and zebra fish), and a worm (*Caenorhabditis elegans*). Some farm animals (rabbits, pigs, chicken, sheep, goat, and cow) are being used for specific studies, which cannot be performed for biological reasons with laboratory animals. Essentially, the products from some farm animals are expected to be improved by transgenesis in addition to classical genetic selection in the coming decades.

Several techniques to generate transgenic animals have made considerable progress in the past decade: (1) direct gene transfer into embryos either by microinjection of DNA, transposons, or lentiviral vectors or via sperm incubated with DNA and transferred to oocytes by ICSI (intracytoplasmic sperm injection), (2) via intermediate cells in which the gene modifications have been achieved and further used to generate animals harboring the foreign DNA sequence; these cells are either pluripotent cells that are able to give birth to chimeric transgenic animals ES (embryonic stem cells) in mice as well as iPS (induced pluripotent cells obtained after dedifferentiation of somatic cells) potentially in most species or somatic cells used for generating transgenic clones (Fig. 3).



Transgenics: Alternative Gene Transfer Methods. Figure 3

Different methods to generate transgenic animals: (1) DNA transfer via direct microinjection into pronucleus or cytoplasm of embryo; (2) DNA transfer via a transposon: The foreign gene is introduced into the transposon, which is injected into a pronucleus; (3) DNA transfer via a lentiviral vector: The gene of interest introduced in a lentiviral vector is injected between the zona pellucida and membrane of the oocyte or the embryo; (4) DNA transfer via sperm: Sperm is incubated with the foreign gene and injected into the oocyte cytoplasm for fertilization by ICSI (intracytoplamic sperm injection); (5) DNA transfer via pluripotent or multipotent cells: The foreign gene is introduced into pluripotent cell lines (ES, embryonic stem cells: lines established from early embryo or iPS: cells obtained after dedifferentiation of somatic cells) or into multipotent cell lines (EG, gonad cells lines established from primordial germ cells of fetal gonads); the pluripotent cells containing the foreign gene are injected into an early embryo to generate chimeric animals harboring the foreign gene DNA; the multipotent EG cells containing the foreign gene are injected into embryos to generate gametes harboring the transgene; in both cases, the transgene is transmitted to progeny; (6) DNA transfer via cloning: The foreign gene is transferred into a somatic cell, the nucleus of which is introduced into the cytoplasm of an enucleated oocyte to generate a transgenic clone. Methods 1, 2, 3, and 4 allow random gene addition whereas methods 5 and 6 allow random gene addition and targeted gene integration via homologous recombination for gene addition or gene replacement including gene knockout and knockin

Another problem emerged rapidly. The very first transgenes were expressed, and they were able, in some cases, to induce some phenotypic modifications in animals. The first example was the giant mice obtained in 1982 [71] by overexpressing growth hormone genes. It also appeared that the expression of the transgenes was often not satisfactory and not easily controlled. This was clearly due to the insufficient knowledge of the

mechanisms controlling gene expression. Thus, for years, only empirical gene constructions having sometimes limited efficiency were used. The strategy of researchers was and often still is to generate several lines of transgenic mice (or other species) and to keep only those in which the transgene is expressed as expected. This strategy appeared insufficient when costly large transgenic animals were to be used and when finely tuned transgene expression was needed. Different methods to express transgenes in a well-controlled manner were found: (1) gene targeting by homologous recombination [8] improved or not by a genomic DNA cleavage locally induced by engineered meganucleases or zinc finger nucleases, leading either to gene knockin or knockout by a gene replacement as well as by NHEJ (non-homologous end joining), (2) conditional knockout using Cre recombinase gene controlled by exogenous inducers such as doxycycline and a engineered Cre recombinase activated by 4-hydroxy tamoxifen, (3) inactivation of mRNA by knockdown with siRNA derived from transgenes coding for shRNA or miRNA, (4) overexpression of negative transdominant proteins inactivating the genes at the protein level.

The failure of transgene expression raised fundamental questions on gene mechanism of action to experimenters. This is particularly the case for the discovery of remote regulatory elements globally known as insulators. Indeed, as opposed to bacteria, yeast, and plants, essential transcription regulators are spread over long genomic DNA regions in animals and, namely, in higher vertebrates [53]. Interestingly, answers were given to some of these questions, thanks to transgenesis and transgenesis efficiency was improved, thanks to these discoveries. Despite very significant improvement of several transgenesis methods, the efficiency of gene transfer and the control of transgene expression remain limiting factors for the optimal use of transgenic animals for research as well as for biotechnological applications. Important improvements of these methods are in course. The more efficient of gene targeting via the action of meganucleases and zinc finger endonucleases is a case in point.

Methods of Gene Transfer

Gene Transfer into Cells

Spontaneous gene transfer into cells occurs only marginally. Different techniques are being used to reach this goal. A group of techniques relies on artificial physicochemical or mechanical processes whereas another group utilizes natural mechanisms of gene transfer, essentially infection. Transfection implies the association of DNA with molecules, which have the capacity to bind cell plasma membrane and to internalize the complex into the cytoplasm. The endocytosis process includes the transfer of the internalized material into lysosomes where it is processed or degraded. A proportion of non-degraded DNA is more or less randomly recombined. A part of the DNA is then transferred to the nucleus, and the genes it contains may be transiently transcribed. When cells do not divide, the DNA may stay several days in the nucleus. During cell division, most part of the foreign DNA is degraded and in a small percentage of cells, the foreign DNA becomes integrated into the host genome either randomly or in a targeted manner according to the sequence of the transferred DNA. A number of molecules are available, and new ones are regularly proposed to enhance the efficiency of cell transfection. These molecules may increase the endocytotic process according to the cell type, diminish the degradation of DNA, favor the transfer of DNA or the nucleus, or be less cytotoxic.

An alternative to transfection is electroporation. The method consists of incubating cells in the presence of DNA and to submit them to pulses of electric field, which generate transient pores in plasma membrane allowing the uptake of DNA. This technique is relatively efficient according to the cell type to obtain stable cells harboring a foreign gene, but many cells do not survive after the electric pulses. The fate of DNA in cells is essentially similar to this following transfection.

It is possible to select the cells in which the foreign DNA is stably integrated into the genome. To reach easily this goal, one popular way consists of co-transfecting a selection gene with the gene of interest. The selection gene may be independent of the gene of interest. Random recombination may then associate the two genes in the same DNA fragment, making the selection of the cells harboring the two co-integrated genes possible. Alternatively, the selection gene may have been associated to the gene of interest in a specific construction. The co-integration of the two genes is then more frequent, and the selection of the cells harboring the gene of interest is easier.

One possible drawback of this protocol is that the selection gene remains present in the cell.

The most efficient classical way to transfer gene into cells is the direct DNA microinjection in the cytoplasm or the nucleus. This method is relatively laborious, requires specific material, and a specific training. Moreover, gene transfer can then be achieved only in a limited number of cells.

Natural mechanisms of gene transfer are being implemented to transfer foreign DNA into cells. Some molecules are naturally able to transfer DNA from the outside of the cells to their nucleus. Lactoferrin was shown to have this property, but this mechanism seems insufficiently efficient to be used. The natural capacity of viruses to transfer their genes into cells by infection mechanisms has been retained to design viral vectors carrying the foreign genes. Such vectors have been studied and used during the last two decades with limited success for gene therapy. A few types of viruses have been retained to be used for gene therapy and those which transfer their genes into the cell genome are being implemented to generate transgenic animals. These vectors rely on the use of retroviral genomes, which must be integrated into the infected cells to be replicated and able to synthesize infectious viral particles.

Gene Transfer into Embryo

To generate transgenic animals, the foreign gene must be present and integrated into the genome of the embryos at the one-cell stage to allow its transmission into all the cells of the animal or at least of their gametes. The simplest theoretical way to reach this goal is to transfer the foreign gene directly into the embryo. In practice, this strategy is not always efficient. Indeed, embryos are rare and costly cells especially in large farm animals. In species in which gametes are very abundant, the direct gene transfer using biolistics has met success in fish and marine invertebrates [63] and insects [18]. In practice, this method consists of incubating DNA with gold or platinum. The DNA-coated particles are then launched through the membrane of the embryos.

Hence, only the highly efficient methods of gene transfer may be successful in these conditions even if only random gene integration is needed. The targeted integration of foreign DNA is a rare event as it is based on a homologous recombination between the host gene and the vector. In these situations, even the most efficient classical techniques of gene transfer are unable to induce a gene targeting at an acceptable rate.

The genetic modifications must then be achieved in cultured cells, which must have the capacity to participate in the development of the embryos and be able to transmit the genetic modification to progeny. Pluripotent cells (ES cells or iPS) may, in the best cases, participate in the generation of chimeric animals in which a significant proportion of the gametes harbor the foreign DNA. Particular multipotent cells, the primordial germ cells (EG cells) in birds can participate in the formation of genetically modified gametes and in the generation of transgenic animals. The animal cloning technique is another possibility. The genetic modification is then performed in somatic cells that are further used to generate transgenic clones by nuclear transfer.

These different methods to generate transgenic animals are schematically represented in Fig. 3.

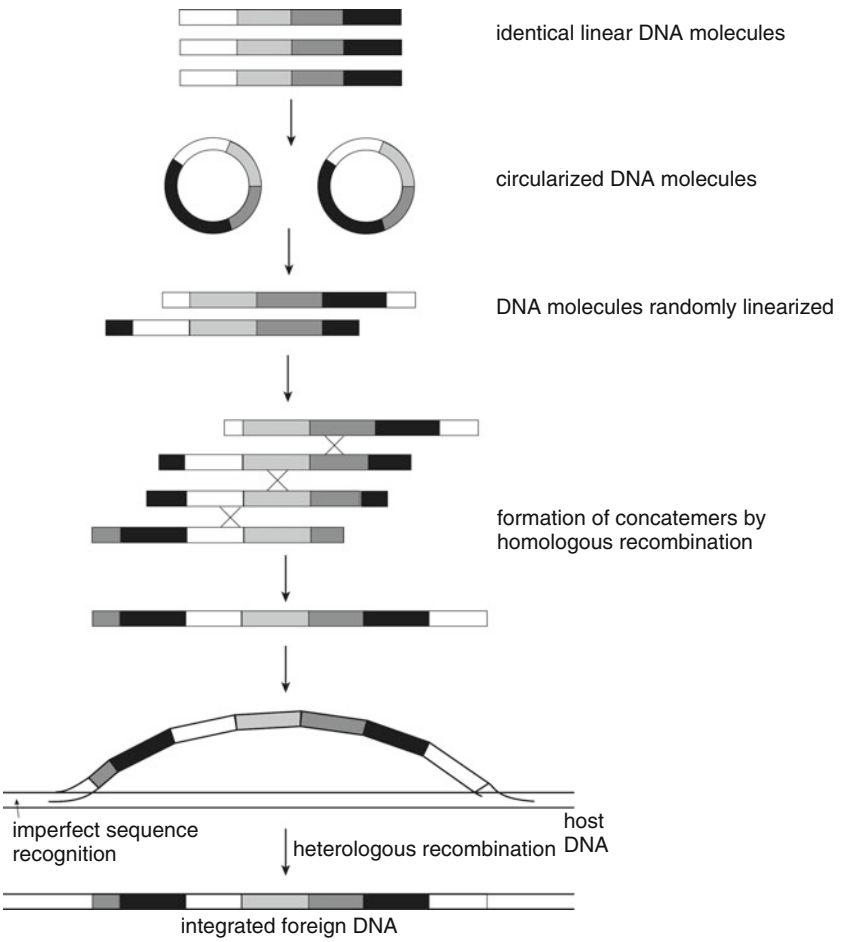
Mechanisms of Gene Integration

Random Integration The foreign DNA introduced into the cytoplasm by any method recombines according to a random process, leading to the formation of multimers known as concatemers including gene rearrangement and mutations. The different copies of the gene are then organized in head to tail or in tandem. When the foreign DNA is introduced directly into the nucleus (essentially by microinjection), a polymerization also occurs but following a process of homologous recombination generating concatemers organized essentially in tandem with limited mutations and rearrangements. The integration of foreign DNA fragment into a genome may occur by two different mechanisms. The most frequent process is considered as leading to a random integration. Targeted integration is much less frequent.

In both cases, the foreign DNA is progressively degraded by the cell. This includes the action of exonucleases, which generate randomly single-stranded sequences in both ends of the foreign DNA. These sequences can recognize complementary regions in the genome, leading to the formation of hybrids. During the cellular DNA replication, these abnormal

structures are corrected by the repair mechanisms of the cell. This leads to the elimination of the foreign DNA or to its integration in the genome [3] (Fig. 4). This process implementing a heterologous recombination is considered as random since the recognition of the host DNA site depends on the action of the exonucleases. The different lines of transgenic animals obtained in this way are thus all different from each other. They contain variable copy number of the transgene integrated each time at a different site. The integration of the foreign gene may damage locally the host DNA. Moreover, the transgene is then frequently submitted to the unpredictable and unknown effects of the transcription regulatory elements located in its vicinity. The regulatory elements of the transgene may also alter the transcription of the host genes in its vicinity.

The integration of the foreign DNA by these methods is thus not controlled but likely not completely random as it occurs more frequently in regions containing genes and thus having an open chromatin structure, favoring the access of the foreign DNA to the host DNA. The integration site may be known by sequencing the flanking regions of the transgene.



Transgenics: Alternative Gene Transfer Methods. Figure 4
Mechanism of random DNA integration. The ends of the foreign DNA are partially digested generating single-stranded sequences, which randomly recognize complementary host DNA sequences and provoke the integration of the foreign DNA

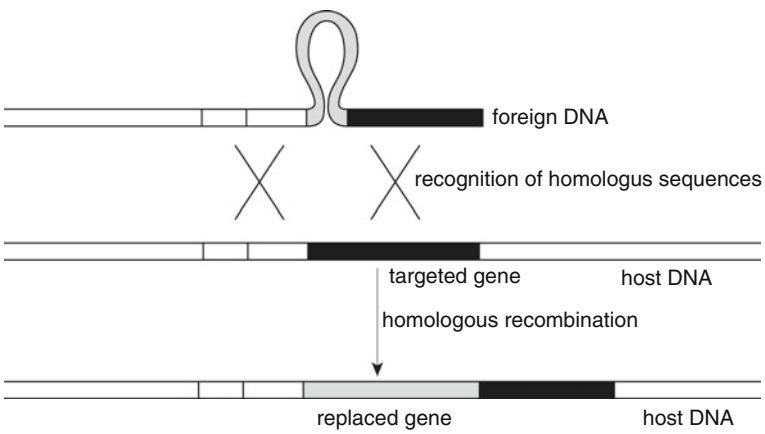
A systematic study revealed that transgenic mice heterozygous for the transgene show rarely abnormalities. On the contrary, the homozygous mice appear altered in a proportion as high as 3–10%, suggesting that the uncontrolled integration of the foreign DNA is often mutagenic [103, 104].

Targeted Integration To avoid the side effects of the random integration, it is possible to target the integration of the foreign gene using homologous recombination. This mechanism is based on the recognition between a genome sequence and the sequence of the exogenous DNA. This recognition leads to the formation of hybrid and finally by the precise replacement of the endogenous gene by the exogenous DNA (Fig. 5). Homologous recombination exists in all living organisms. It is implemented to repair mutated genes using the other allele as a matrix, to redistribute the regions of homologous chromosomes during the formation of gametes, and to generate functional antibody genes from parent genes. Homologous recombination is routinely used to genetically modify bacteria and yeast. Homologous recombination is a rare event corresponding to about 0.1–1% of the heterologous recombination. It is therefore not implemented directly in early embryos but in intermediate cells further used to generate transgenic animals.

Homologous recombination allows in practice the replacement of a given gene by an exogenous DNA fragment. Several applications of this approach are possible: (1) the replacement of a gene by a non-functional DNA sequence, leading to the inactivation of the targeted gene known as gene knockout (Fig. 5), (2) the targeting of a foreign gene into a given region of the genome or the replacement of an allele by another allele known as knockin.

DNA Microinjection

About 1,000 copies of the isolated foreign gene contained in 1–2 pl may be injected into one of the pronuclei of 1-day mammal embryos. This method implies a superovulation of the females followed by a mating with a male to obtain an optimum number of embryos. The resulting one-cell embryos are collected the next day and microinjected with DNA. The embryos are then transferred to hormonally prepared recipient females using surgery operations. The yield of this method in mice is of 1–3 of transgenics for 100 microinjected and transferred embryos. This rate is relatively low, and this is due to a large extent to the fact that only 50% of the embryos survive after the microinjection. This is clearly due to the mutagenic effect of DNA as the survival of



Transgenics: Alternative Gene Transfer Methods. Figure 5
Mechanism of targeted integration. An exogenous DNA having a sequence of several kb similar to that of a host gene may replace the host gene using a homologous recombination process. If a non-homologous sequence is surrounded by two homologous sequences, the two independent homologous recombinations direct the integration of the non-homologous sequence, leading to the knockout of the targeted gene

embryos is high when the buffer without DNA is injected. In fact, 1,000 copies of the gene correspond to a very large excess of DNA in the cell, making the multiple random deleterious integrations and genome rearrangements depicted above possible. Despite its drawback and the fact that it is laborious, this technique is still the most frequently used in mice and rabbits. The efficiency of DNA microinjection is lower in all the other mammalian species and very low in ruminants. This is not due to the difficulty to inject DNA but to the fact that the mechanism of integration is for unknown reasons much less efficient in some species.

The DNA microinjection in pronuclei gives birth to at least 30% of mice mosaic for the transgene. The transgene is then not present in all the cells of the transgenic founder. This is due to the fact that the integration of the foreign DNA occurs sometimes not in the first cell but later at the two- or four-cell stage. The transmission of the transgene from these founders appears not to respect the Mendel law. The transmission rate is due to the fact that the transgene is not present in all the gametes. At the next generation, the proportion of transgenics is Mendelian [24]. About 1% of transgenic founders do not transmit their transgene as the mosaicism is very high and the transgene is rare or non-existent in gametes.

In non-mammalian species, the pronuclei cannot be visualized as the embryo is embedded in an abundant and opaque vitellus. High amounts of DNA (millions of copies in a few nanoliters) must then be injected into the cytoplasm of the one-cell embryos. This relatively simple technique is efficient in several fish species [42, 56] but highly inefficient in chicken, in Xenopus, in some fish, and in insects. For unknown reasons, the integration of the foreign DNA thus does not occur in some species. In lower vertebrates and invertebrates, the embryo DNA and the foreign DNA are replicated very rapidly. The foreign DNA is then highly amplified leading to multiple independent integrations occurring during the first days of embryo development in the same animals. The resulting transgenic animals are often very mosaic making it difficult their use. Several reproduction cycles allow a segregation of the different transgenes until the animals contain a single integration site.

In a *C. elegans*, direct DNA injection into gonad syncytium leads to the generation of transgenics with a good yield [98].

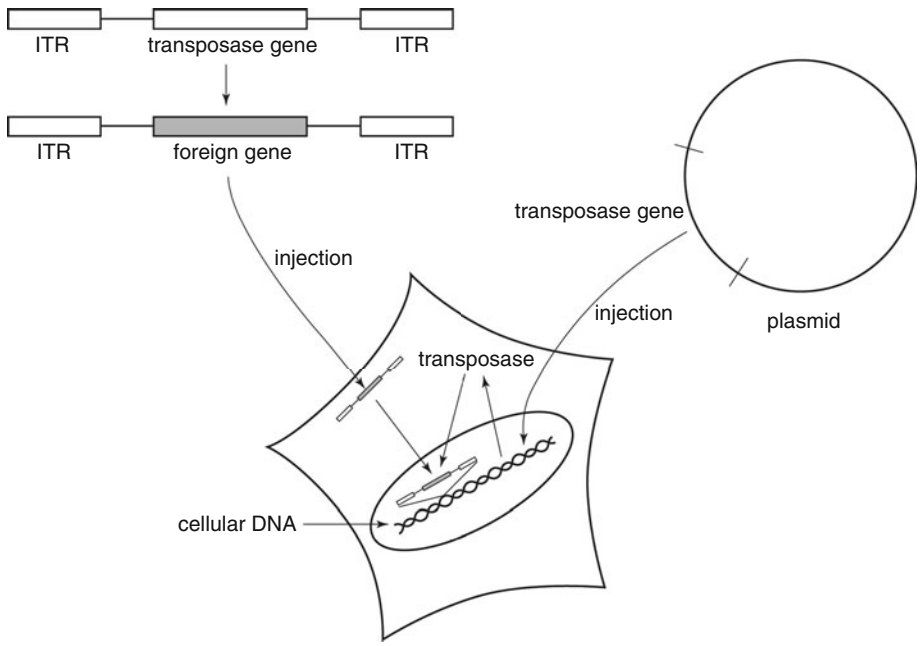
Gene constructs bordered by I-Sce1 sites have been used to generate transgenic fish. The plasmids were previously cut by the I-Sce1, and the fraction was injected without any previous DNA purification. Unexpectedly, this protocol markedly increased the yield of transgenesis. Interestingly, the same observation was made in Xenopus. The mechanism improving transgenesis is not known [97]. The I-Sce1 might protect DNA against degradation, favor DNA transfer to the nucleus, or directly stimulate the integration mechanism.

Microinjection is therefore a good technique but insufficient in some species. Additional methods have been found and are still under study.

Detection of the transgene and examination of its integrity can be achieved using Southern blotting or PCR using multiple primers corresponding to various regions of the transgene. Zygocity of the transgene may be evaluated by quantitative PCR [69] or in situ hybridization.

Use of Transposons

Transposons are short genomic DNA regions, which are replicated and randomly integrated into the same genome. The number of a given transposon is thus increasing until the cell blocks this process to protect itself from the degradation of its genome. Foreign genes can be introduced into transposons in vitro. The recombinant transposons may then be microinjected into 1-day embryos as it is for DNA. A transposon contains a gene coding for an integrase specific of this type of transposon and required for the integration of the transposon. The integrase gene is bordered by two inverted terminal repeat regions (ITR) required for the transposon integration. The addition of the foreign DNA implies the elimination of the integrase gene. This makes space for the foreign DNA, and it also prevents the recombinant transposon to disseminate in the genome. To allow the integration of the recombinant transposon, the integrase protein or a gene construction directing the synthesis of the integrase must be co-injected with the recombinant transposon (Fig. 6).



Transgenics: Alternative Gene Transfer Methods. Figure 6

Gene transfer using a transposon. The integrase gene of a transposon is replaced by the gene of interest between the two ITR (inverted terminal repeats) required with the integrase for an efficient integration. Integrase or a gene coding for this protein must be injected with the transposon to allow its integration

The foreign gene thus becomes integrated into the embryos with a yield of about 1%. Essentially, all the transgenic insects are generated by using transposons as vectors [43, 95]. Transposons also proved efficient to generate transgenic fish, chicken, and mammals [22, 23]. The transposons used for transgenesis are chosen or engineered to be unable to disseminate in the host genome under the action of the integrase of endogenous transposons. Transposons are therefore efficient and safe tools, but they can harbor no more than 2–3 kb of foreign DNA.

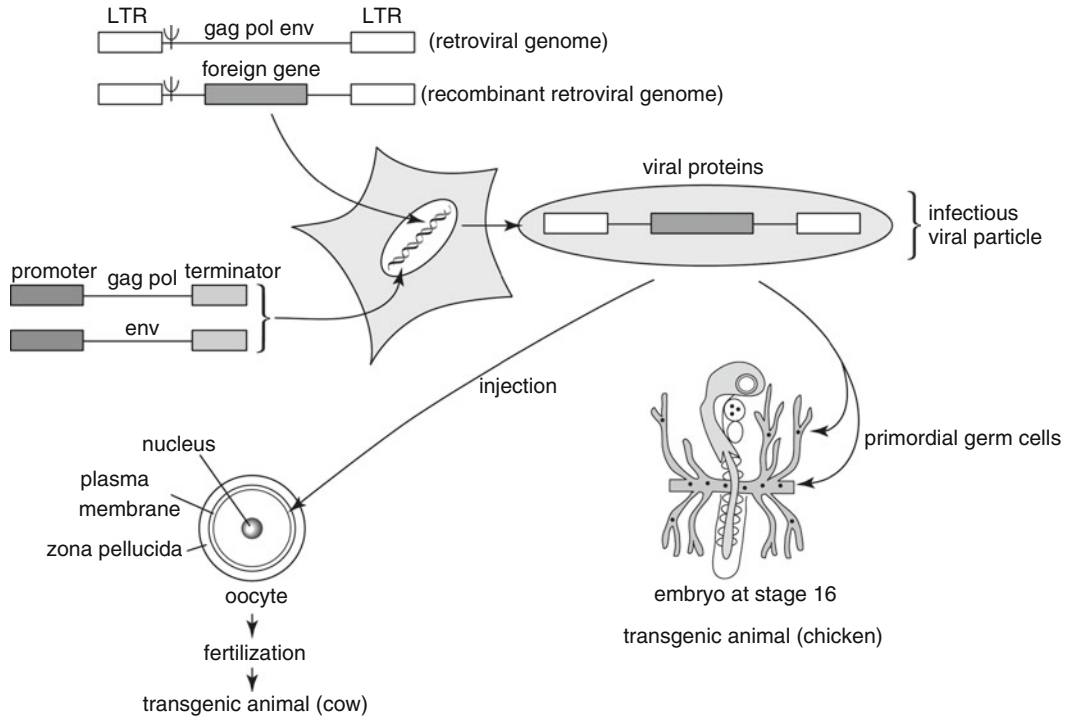
Transposons are being used with ICSI giving a high transgenensis rate [64].

Efficient transposons started being used to disseminate in genomes after the addition of the corresponding integrase into cells. This leads to multiple random integrations of the transposon providing researchers with insertional mutants. A correlation may then be established between a biological alteration of the animals and the nature of the gene inactivated by the presence of the transposon within the gene [22].

Use of Lentiviral Vectors

Retroviruses have not the capacity to autoreplicate, and they must be integrated stably into the genome of the cells they infected to replicate. This explains why up to 1% of animal genomes contain degenerated retroviral genes. This property of retroviruses is implemented to integrate foreign genes in cells, in animals, and in patient's somatic cells. For this purpose, the viral genes are removed from the genome of lentiviruses (a category of retroviruses) and replaced by the genes of interest. Viral particles are then prepared and used to transfer the foreign genes into oocytes or one-cell embryos (Fig. 7). Retroviral vectors have been studied and used during the last two decades for gene therapy. Important improvements of these vectors have markedly enhanced their efficiency. Vectors using ALV (avian leucosis virus) studied two decades ago proved poorly efficient to generate transgenic chicken [4, 83].

The lentiviruses have the advantage over the common retroviruses to be able to infect and transfer their genes in quiescent as well as in multiplying cells. The



Transgenics: Alternative Gene Transfer Methods. Figure 7

Gene transfer using lentiviral vectors. The pathogenic genes are removed from the HIV genome and replaced by the gene of interest. The gene construction is transfected into trans-complementing cells synthesizing the essential HIV proteins required for the formation of infectious recombinant particles. The particles secreted from the cells in the culture medium are injected between the zona pellucida and the membrane of the cell embryos or of oocytes or within the fetal gonad in chicken. The infection is followed by an efficient integration of the gene of interest

majority of the retrovirus genomes need a cell multiplication including a transient degradation of the nuclear membrane to reach chromatin and integrate into the cell genome. On the contrary, lentiviral viruses contain proteins carrying their genome to the nucleus in quiescent as well as in multiplying cells. EIAV (equine infectious anemia virus) proved that it is able to generate transgenic chicken [60]. Presently, the most frequently used lentiviral vector derives from the HIV (human immunodeficiency virus) genome. The natural envelope protein of the HIV, which recognizes specific receptors on the plasma membrane to induce infection has been replaced by the envelope of vesicular somatitis virus, which is not a retrovirus. This envelope recognizes the phospholipids of plasma membrane, making the infection of essentially all cell types possible. The particles containing this envelope are stable, and they can be concentrated and administered at a high concentration into embryos or oocytes. For unknown reasons, lentiviral vectors have to be injected in cow oocytes rather than in one-cell embryos to transfer their genes.

Safe experimental conditions have been defined to use the lentiviral vectors. This method proved very highly efficient in several species including mammals [74, 78] and birds [11, 52, 86]. Up to 90% of transgenic animals may be obtained. This results from the fact that with high viral particle concentration, multiple independent integrations take place in the embryo genome. These integrations may occur later than the first cell stage giving birth to mosaic animals. The selection of lines harboring a single integration is preferable, but it may take a very long time in farm animals. Reducing the concentration of viral particles reduces the yield of transgenics but also the multiple integrations.

Trangenes transferred by lentiviral vectors are reputed not to become silent on the contrary to transgenes transferred by plasmidic constructions. This may be due in part to the fact that one or several integrated copies are active whereas others have been silenced. Lentiviral proved to be efficient tools to express transgenes coding for siRNAs [99]. Interestingly, siRNA could induce specific gene knockdown in rat [19, 35]. This observation is important as the classical tools to induce gene knockout (ES cells and cloning) are not available in this species. Lentiviral harboring foreign genes driven by cell-specific promoters may direct the expression of the transgenes in the targeted cells specifically [86]. The use of lentiviral vectors is limited by the fact that they cannot harbor more than 8 kb of foreign DNA. Special constructions must also sometimes be prepared to reduce the influence of the viral enhancers on the transgene promoter.

In mammals, the lentiviral vectors are injected between the zona pellucida and the cell membrane of one-cell embryos or oocytes. The efficiency of lentiviral vectors may be enhanced by injecting envelope-free constructions into cell cytoplasm [108].

The preparation of lentiviral particles carrying foreign genes is routinely achieved by academic and private structures at a moderate price. This possibility is particularly attractive for laboratories, which do not need a frequent use of this tool.

Use of ICSI

Foreign DNA must not necessarily be introduced into one-cell embryos. In principle, it can be as well injected in gametes before fertilization. DNA microinjection into oocytes proved inefficient, and this approach was soon abandoned. Using sperm is another possibility based on the assumption that foreign DNA cannot integrate into the genome as in this cell DNA is embedded in protamines and not able to replicate. Sperm was rather postulated to bind DNA in its surface and carry it into the oocyte during fertilization.

More than a decade ago, it was shown that sperm incubated in the presence of DNA before being used for fertilization was able to transfer the foreign gene into the oocyte and generate transgenic mice. This approach proved capable of generating transgenic mice, sheep, chicken, fish, and pigs [45, 109]. However, this method appeared difficult to use as DNA was frequently degraded [91]. The seminal plasma contains high DNAse activity, which degrades the gene and only rearranged fragments of the foreign genes were generally found in the transgenic animals. An appropriate sperm washing is required to prevent DNA degradation. For no clear reasons, not all the ejaculates can lead to a success of the method. Transgenic mice and rabbits were obtained by incubating sperm with DNA in the presence of DMSO (dimethylsulfoxide) and by using conventional in vitro fertilization [87].

The method has been greatly improved by using ICSI (intracytoplasmic Sperm Injection). This technique, which consists of injecting sperm into the cytoplasm of oocytes is currently used for in vitro fertilization in humans. To transfer genes, sperms from which plasma membrane has been damaged by freezing and thawing or with a mild treatment by nonpolar detergents were incubated in the presence of the gene of interest and further used for fertilization by ICSI. The ICSI approach started being implemented in Xenopus a decade ago as all the other methods failed [59]. This method proved efficient in mice [65, 88] and pigs [109]. Transposon use and ICSI may be combined to increase the yield of transgenesis [64, 88].

ICSI is therefore an excellent method to generate transgenic animals on condition that ICSI is possible in the considered species. One advantage of ICSI is that both long and short DNA fragments of DNA may be used sucessfully. DNA rearrangements may occur during ICSI especially when long DNA fragments are used. Another advantage is that foreign DNA is integrated mostly at the first cell stage of embryos. This reduces the number of animals being mosaic for the transgene.

Use of Episomal Vectors

The methods described above to transfer foreign genes rely on the integration of the DNA into the host genome. Another theoretical possibility is the use of episomal vectors capable of autoreplicating in host cells independently of the genomic DNA and transferred to daughter cells. Fragments of chromosomes are being used for particular projects, requiring the transfer of very long DNA fragments [44]. These chromosomal vectors are not of an easy use, and they carry a number of genes in addition to the gene of interest.

These extra genes may interfere with the transgene or with the whole organism of the host.

Another possibility consists of using vectors, which derive from viruses having the capacity to replicate in animal cells and to be transferred to daughter cells. Herpes viruses are naturally stably maintained as autonomous circular minichromosome at a low copy number in animal cells. Foreign genes can be introduced into Herpes viral vectors and be maintained during cell division. This kind of vectors is generally species specific. This greatly reduces their potential use as well-known Herpes viruses are not available for all animal species.

Episomal vectors not based on the use of viral elements are available. Such a vector proved highly efficient to transfer foreign genes into pig embryo using ICSI [58]. This vector was maintained without any selection pressure in the cells of the early developing embryos but seemingly not later. These vectors are therefore excellent tools to study transgene effect during early embryo development. Hence, until now, only the integration of foreign DNA into the host genome makes it possible the generation of stable lines of transgenic animals.

A theoretical safety problem raised by the use of episomal vectors is that it could be transmitted to other cells mechanically and thus independently of any infectious process. However, this event is expected to occur very rarely. More likely, non-integrated DNA is more available to recombine with homologous sequences in the host genome, leading to mutations, chromosome rearrangement, or integration.

Use of Intermediate Cells

Use of Pluripotent Cells In some situations, the efficiency of the genetic modification is too low to be achieved by the methods described above. This is particularly the case for gene targeting. One possibility to circumvent this problem is to genetically modify pluripotent cells that are further used to participate in the development of living organisms. Pluripotent cells have the capacity to participate in the development of all the organs including gametes.

Pluripotent cells exist in the early embryos (morula and blastocysts), and they are known as ES cells (embryonic stem cells). The pluripotent cells can be cultured, genetically modified, selected and transferred into morula or blastocysts. These cells participate in the development of the embryo to give birth to chimeric transgenic animals (Fig. 3). This means that the organs of the animals, including sexual cells, derive from the genetically modified cells or from the recipient embryo. A proportion of the offsprings from these chimeric animals harbor the genetic modification if they derive from the transplanted cells.

The first ES cells implemented to genetically modify animals (mice) were used at the end of the 1980s. For unknown reasons, commonly used ES cell lines have been established only in two mouse lines and mainly in the 129/Sv strain. In other lines and species, the ES cells lose their pluripotency. They can give birth to animals, which are still chimeric but have no more the capacity to transmit the genetic modification to their offspring. In practice, this complicates sometimes the use of the knockout mice. Indeed, in a number of cases, the gene knockout should be obtained in a genetic background very different from that of the 129/Sv strain. Successive crossings allow the mutation to be transferred in the strain in which the biological function in question may be optimally studied.

After sustained efforts for two decades, authentic rat ES cell lines have been established [7, 2, 49–51]. This breakthrough relies on the use of small molecules added into the culture medium. These molecules control essential genes required for the maintenance of pluripotency. They replace proteins like LIF, which are commonly used for mouse ES cells but are not successful in other species.

Recent experiments have shown that the transfer of three genes, normally expressed in pluripotent cells, into somatic cells can dedifferentiate these organ cells into pluripotent cells known as iPS (induced pluripotent cells) and almost similar to ES cells [68, 72, 93, 105]. Interestingly, small molecules can mimic and replace Kfl4 gene, which is one of the genes required to transform somatic cells into pluripotent cells [55]. These experiments open avenues for cell therapy and gene therapy [76]. The approach known as therapeutic cloning and based on the capacity of cloning (SCNT) to dedifferentiate somatic cells into totipotent cells further differentiated in vitro into pluripotent cells has become virtually no more strictly necessary. iPS cells can potentially be obtained in different species by this

method. Similarly, iPS cells might be implemented for transgenesis in species in which ES cells are not available (Fig. 3). Cow and pig iPS cells have been obtained and are currently under study.

Use of Primordial Germ Cells and Testis Stem Cells

Experiments carried out a few years ago showed that chicken primordial germ cells (PGC) can be isolated and cultured in conditions maintaining their multipotency giving stable cell lines known as EG cells (embryonic gonad cells). Foreign genes can be transferred into EG cells, which can be implanted into recipient embryos and participate in gonad development. In practice, the EG cells, which contain the gene of interest and a selection gene are cloned, amplified, and injected into an early embryo in which the majority of the cells have been destroyed by irradiation. This gives the best chance to the EG cells to colonize the embryo and to give birth to transgenic showing a high degree of chimerism and thus transmitting their transgene to progeny with a high yield. This approach has greatly simplified the generation of transgenic chicken [33, 101].

Testicular cells, which are sperm precursors can be isolated, cultured, genetically modified, more or less differentiated in vitro, and transplanted into recipient testis to give functional sperms that are able to generate transgenic animals by fertilization. Alternatively, sperm cell precursors may be genetically modified in situ using viral vectors [33, 41, 46, 48, 94]. These methods are still under study, and they are not currently used to generate transgenic animals.

Use of Cloning

The birth of Dolly, the sheep, demonstrated that the genome of somatic cells can be reprogrammed after being introduced into an enucleated oocyte. This generates a pseudo-embryo capable, with a relatively low yield, of giving birth to clones of the cell donor. This technique was initially designed to improve transgenesis efficiency in farm animals. This approach is likely to be used to accelerate genetic selection, but its only real application is presently transgenesis [81, 85]. The principle of this method is described in Fig. 3, and this topic is the matter of another chapter. Genes are transferred into somatic cells, which are then used to generate transgenic clones. This method has become the most frequently used for big farm animals as it simplifies the task of experimenters and enhances the rate of transgenic animals. Recently published important data have shown that the cloning technique does not provoke mutations in the clones [67].

Gene Construction

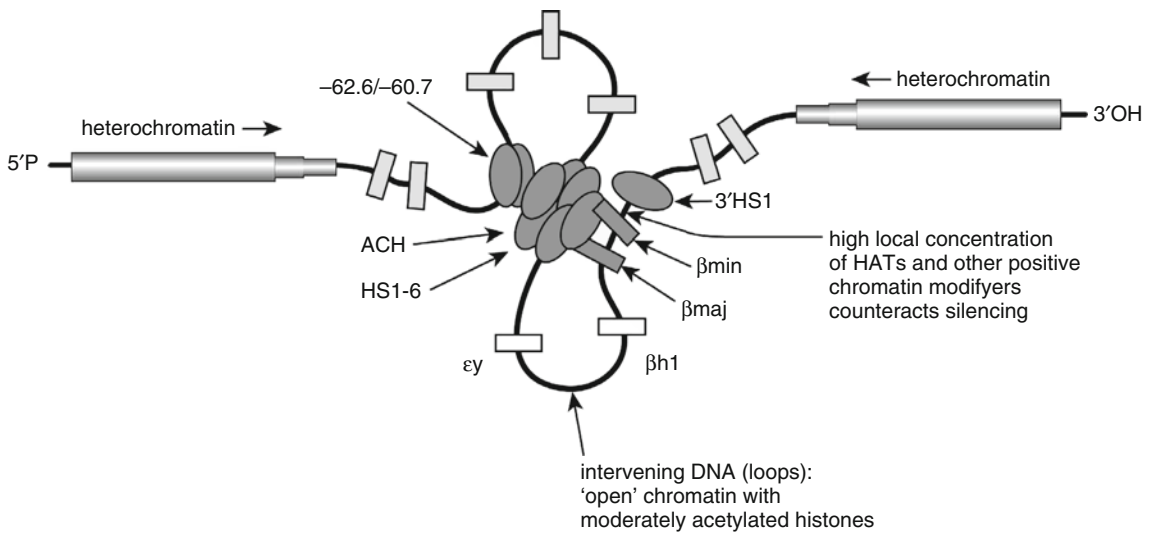
Random Integration A problem, which has not been completely solved is the reliability of transgene expression [36–38]. In the early 1980s, the first experiments to generate transgenic mice revealed that transgenes were often not working as expected. In a number of cases, the expression of the transgenes was very weak and not strictly specific to the promoter associated with the foreign gene. In a few cases, it was demonstrated that the ectopic expression of the transgenes was due to the presence of genomic enhancers in the vicinity of the integrated foreign DNA. The frequent transgene silencing was thought to be induced by the integration of the foreign genes near genomic silencers. These putative silencers were rarely identified suggesting that the ectopic transgene expression and their silencing could be not symmetrical phenomena. It was also proved that the level of transgene expression was generally not a function of the integrated copy number. In a number of cases, the expression level appeared even lower when the number of integrated copies was higher. A striking demonstration was given by the experiment in which the human β-globin gene was bordered by two LoxP sequences and integrated into mouse genome as several copies in tandem. The transgene remained silent in these mice but was reactivated in their offspring in which the copy number was reduced to one by the action of the Cre recombinase [26].

After about one decade, it appeared that this was due to chromatin position effects suggesting that the transgenes were recognized as foreign sequences by some unknown cellular mechanisms. One of the most surprising data was that a genomic DNA sequence containing the whole human β-globin gene including its promoter region allowing the gene to be expressed as expected in cultured red blood cells remained silent in transgenic mice. This discrepancy suggested that the transgene silencing occurred more in vivo than in

cultured cells and that this phenomenon could take place during the early phase of embryo development. A hypothesis was also that the genomic DNA sequence contained the whole β-globin gene and some but not all the transcription regulators. A confrontation of the very low expression level in patients suffering from β-thalassemia and the structure of their DNA in the genomic β-globin gene region revealed that, in some cases, the gene and its promoter were normal but that some remote genome regions were missing. This suggested that these regions could be the putative regulators missing in transgenic mice. An association of these regions with the β-globin gene allowed the later to be highly expressed in transgenic mice. The extensive study of the β-globin gene locus in several species revealed that remote regulatory elements are present on both side of the locus. These elements bind transcription factors specifically present in differentiated red blood cells, and they form a transcription complex known as a hub in the vicinity of the promoter through a looping process (Fig. 8) ([20, 21]). This type of mechanism seems to be common to many if not all genes in vertebrates and similarly also in invertebrates.

These observations may explain at least in part why traditionally constructed transgenes are so often poorly active and they suggest using long genomic DNA fragments contained in BAC (bacterial artificial chromosome) vectors to promote transgene expression [53]. The implementation of the long DNA fragments may be laborious as they are sensitive to mechanical degradation [100, 102]. The long DNA fragments can be transferred using microinjection, ICSI, gene targeting, or via intermediate cells. The failure of transgene activity is likely due to multiple reasons, which still complicate the construction of vectors allowing an efficient and reliable expression of transgenes. The optimized conditions to use long DNA fragments as vectors are described in a recent paper [102].

Nucleotidic Composition of the Vectors Integrated retroviral sequences and transposons are inactivated by a cytosine methylation of the CpG motifs and the local formation of condensed chromatin (heterochromatin) in which histones are deacetylated and methylated in some sites. Transgenes seem to be inactivated by similar mechanisms. Many of the vertebrate genes contain CpG islets in their regulatory regions, which contribute to their expression. Some of the CpG motifs belong to the binding site of the transcription factor Sp1, which is present not only in the promoter region of the gene but also sometimes in the first introns. An exceedingly large number CpG motif in vectors induces transgene



Transgenics: Alternative Gene Transfer Methods. Figure 8
Mechanism of action of remote transcription enhancers. The formation of loops allows the various regulatory factors to be in close vicinity and generate an active transcription complex

silencing. The replacement of some of the GC-rich regions by AT-rich regions improves transgene expression. MARs (matrix-attached region) are frequently found in the vicinity of genes, and they bind DNA to the nuclear matrix locally. MARs are generally AT rich, and they have been added into vectors to tentatively improve transgene expression. This approach met variable success. The *Escherichia coli* β-galactosidase gene is rich in CpG, and it is known to be a potent transgene silencer. This silencing potency proved to be markedly reduced as the number of CpG was diminished [17, 34]. The coding sequences of a transgene may thus be obtained by chemical synthesis to replace a part of the CpG-rich codons by others without modifying the sequence of the corresponding protein.

Use of Insulators In order to improve the expression of transgenes, it is possible to use large genomic DNA fragments (50–250 kb) expected to contain all the regulatory elements of the gene of interest [53]. It implies only the isolation and characterization of BACs (bacterial artificial chromosome) from a bank. Linearized or circular BACs may be used as such if the expression of the gene(s) they contain is wanted [102]. One drawback of using BACs is that they often contain several genes. The BACs thus transfer all these genes potentially generating unknown and unwanted interactions with the animals. If needed, these genes may be inactivated in BACs by performing short deletions, for example, of the cap region, using homologous recombination in bacteria.

An attractive approach consists of using BACs as vectors harboring the foreign genes. The foreign DNA sequence must be introduced into the BAC using homologous recombination in bacteria. It is important to note that the transgenes driven by BACs rarely work in an ideal fashion, if only this concept has a real meaning. Long genomic DNA fragments are expected to suppress the position effects, which is not often fully the case. Indeed, it is clear that the variegated expression, which characterizes the conventional transgenes is less or even much less frequent in animals harboring BAC vectors. A higher proportion of animals expressing the transgenes is generally found with BAC than with plasmid vectors. Yet, the different lines harboring BACs vectors usually do not express the transgenes at an identical level for a given number of integrated copies. Similarly, it has been rarely reported that the expression of the transgenes was strictly a function of the copy number of the integrated BACs. This means that the BACs provide transgenes with essential elements for their expression but they remain often not fully able to suppress the position effects. This disappointing observation may not be surprising from a theoretical point of view. Indeed, a locus has been constructed during evolution to express in an appropriate manner the genes it contains. This implies that these genes are protected against deleterious positions effects in their natural chromatin environment. They have no theoretical reasons to be independent of the position effect in all their integration sites. Some BACs may contain all the elements providing transgenes with a complete independence of the integration site. If not, a BAC vector may still contain enough regulatory elements improving significantly transgene expression to justify its use.

A more sophisticated approach could consist of using as vectors containing not all the DNA sequence of BACs but only the major elements involved in the control of gene and transgene expression. This implies that these regulatory elements have been identified, characterized, and introduced into mini-BACs or even plasmids. An example of this is a major regulatory region of the genes present in mammalian β-globin locus, which is located upstream within the locus of olfactory receptor genes [21]. The study of the remote genomic regulatory elements is still in infancy. Apart from the technical difficulty to study them is the fact that each gene or gene cluster seems to have used available genomic sequences to design specific mechanisms allowing a satisfactory expression. Some of these regulatory elements have an unexpected structure. Examples are SINE B2 and Alu sequences or some active tRNA genes, which are essential regulators for neighbor genes [54].

The notion of boundary elements and insulators is essential to understand how unrelated genes can be expressed in a specific manner without being under the dependency of the neighbor gene regulators. This situation is clearly often not encountered for transgenes suggesting that the constructs commonly used do not contains the natural insulators. Insulator activity has been found in the LCR (locus control region) of the chicken β-globin locus. This activity was identified in

a 300 bp fragment, which proved its ability to block in a specific sense the action of an enhancer when added between this enhancer and a promoter directing the expression of a reporter gene. The enhancer blocker was mediated by the binding of the regulatory protein CTCF to a specific DNA sequence. The CTCF element has now been found in the boundary region of several other genes. This type of elements, known as enhancer-blocking insulators, cannot be assimilated to silencers as the former act only when they are located between an enhancer and a promoter. Moreover, the enhancer-blocking insulators often show unidirectional action.

This 300-bp region of the chicken β-globin locus was found later to contain another sequence known as a chromatin opener. Chromatin openers are regulators capable of maintaining a local euchromatin configuration favoring the expression of the neighbor gene by preventing the local formation of condensed chromatin (heterochromatin) [27]. The elements having this function are known as barrier insulators [27]. The barrier insulators cannot be assimilated to enhancers as their effect does not occur during transient foreign gene expression in transfected cells. The region locus known as 5'HS4 and containing the 300-bp sequence can improve the expression of a number of unrelated transgenes in mammals [29, 92]. However, the potency of the 5'HS4 element remains generally insufficient to express transgenes in a fully satisfactory manner.

In the mean time, the presence of AT-rich MARs within the genomic region required for the expression of a gene suggested that these sequences were essential remote regulators. This hypothesis was not confirmed [90].

Optimization of the Transcribed Region The 5′UTR (untranslated region) must have less GC sequences stabilizing double-stranded hairpin structures, which do not favor ribosome migration to the initiation codon. The AUG initiation codon must preferably be in the Kozak consensus sequence GCCA/GCCAUGG to optimize translation initiation. The natural 5′UTR of the gene of interest may contain sequences regulating translation. It may be then useful not to keep this region and replace it by a short (not less than 80 nucleotides) AT-rich 5′UTR region from gene known to be efficiently translated in many cell types or in the targeted cells of the animals. Some mRNAs encode proteins, which are not naturally secreted. Peptide signals may be added to their cDNA.

A transgene must contain at least one intron, which is required to favor the transfer of the mRNA to the cytoplasm. The first intron of many genes contains sites, which bind transcription factors and they may favor transgene expression. The intron excision is dependent upon several signals comprising consensus sequences in both splicing sites (CAG GUA/GAGUA/UGGG in 5′ and CAG G. . .GAA/G. . .GAA/G. . .in 3′), namely, a CU-rich region immediately upstream of the 3′splicing site and a BPS site (branched point sequence) U/CNCUGAC at about 30 nucleotides upstream of the 3′splicing site and upon splicing enhancers [61]. The second intron of the rabbit β-globin gene is considered as efficient to express transgenes in mammals. The intron(s) must preferably be put before the coding region. If an intron is added after the translated region, the 5′splicing site must be located not more than 50 nucleotides from the termination codon to avoid the activation of the NMD (nonsense-mediated decay), which degrades the mRNA [10].

The cDNA and other regions of the vectors may preferably be chemically synthesized. This allows reducing the number of CpG motifs, to choose the best codons, to eliminate cryptic 3′or 5′splicing sites and sequences known to prevent transcription or translation.

The 3′UTR region of a number of mRNA contains signals for mRNA translation and stability. A number of mRNAs have an AU-rich region with the AUUUA motif in their 3′UTR. These mRNAs have a short half-life controlled by the cell cycle (Beelman and Parker 1995). The fortuitous presence of such sequences must be searched and eliminated to prevent a poor transgene expression. Some mRNAs contain translation regulators acting by the binding of proteins favoring the recycling of ribosomes by binding to the 5′UTR. CU-rich regions in the 3′UTR enhance the stability of the mRNAs, and they may be added in the vectors downstream of the cDNAs. Stabilizing sequence can be taken in the 3′UTR of the human or bovine genes and of the α-globin gene, which also contain efficient transcription terminators [13]. Some proteins are anchored to the plasma membrane by a GPI structure (glycophosphatidylinositol). A protein normally not anchored in this way acquires

this property by adding in the 3′end of the cDNA the peptide, allowing the addition of GPI. Micro-RNAs (miRNA), the role of which was recently discovered, inhibit specifically the translation of an mRNA after forming a hybrid with its 3′UTR. The presence of target sequence for a miRNA may unduly inhibit the expression of a transgene. This target sequence should then be deleted.

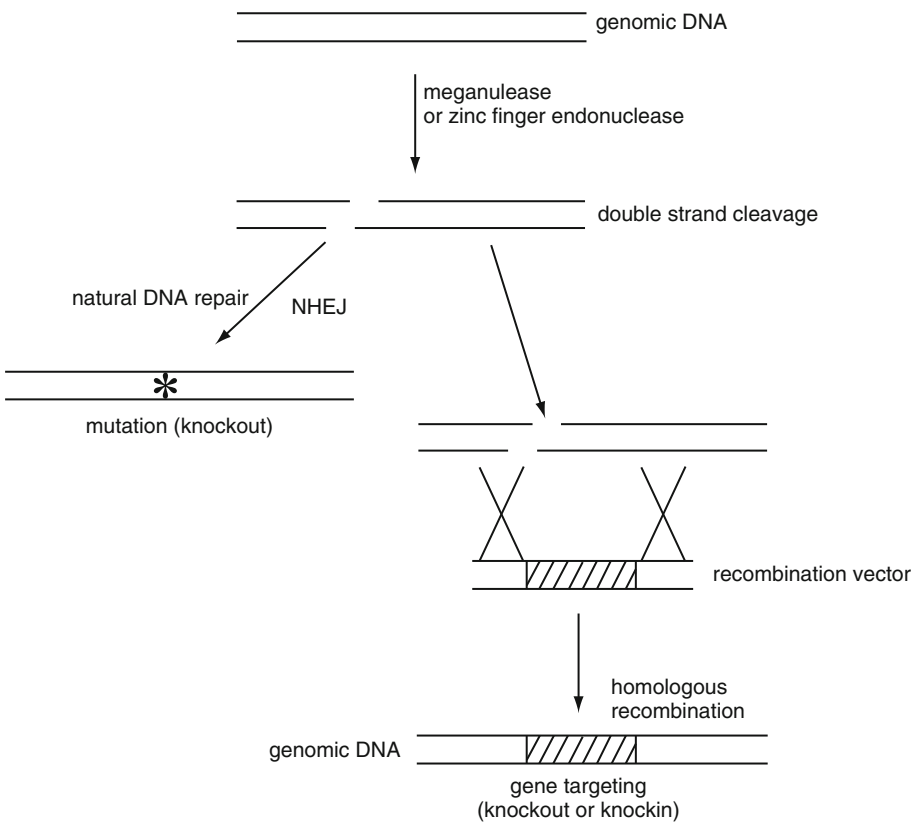
Targeted Integration The techniques described above lead to uncontrolled but not strictly random gene integration. Foreign DNA is preferentially integrated into gene-rich genome regions, and its location can be precisely identified. A foreign DNA fragment can recombine very precisely with a genomic DNA region containing a similar sequence. This natural mechanism known as homologous recombination makes the precise replacement of a gene by another possible. An active gene may thus be replaced by an inactive version, leading precisely to an inactivation of the targeted gene (gene knockout).

The targeted gene may as well be replaced by an active gene (gene knockin). This technique allows therefore a better controlled transgenesis reducing possible damage of the genomic DNA at the integration site and frequent side effects of the genes located in the vicinity of the transgene on the expression of the transgene. Two mouse genomic loci are currently being used as foreign gene knockin. One is the HPRT locus [6] and the other is Rosa 26 locus [110]. The genes of these loci are known to be expressed constitutively, and they were supposed to be bordered by regulators able to drive the expression of transgenes in a reliable manner. In practice, a number of transgenes appeared to be expressed as expected when integrated in these loci. Interestingly, also the expression of the transgenes added in these loci remained specific to the promoter linked to the foreign genes. The two loci thus appear to maintain an open chromatin configuration, favoring the expression of the transgenes irrespective of their composition.

Yet, this approach remains limited by the fact that the homologous recombination required for gene targeting is a rare event. The targeted integrations by homologous recombination of a foreign DNA represent 0.1–1% of the total integrations. The cells in which targeted integration occurred must be selected and used to generate a transgenic animal. The formation of chimeric embryos using pluripotent cells, multipotent cells, or the cloning technique is presently required to obtain a targeted integration.

Meganucleases were discovered in yeast about two decades ago, and it was shown that they participate in intron generation. These enzymes recognize sites as long as 18 nucleotides leaving negligible chance to cleave mammalian genomic DNA. About 80 natural meganucleases have been identified so far. It was observed later than one of these meganucleases I-Sce1 induces chromosome recombination in mammalian cells and this was attributed to the fact that meganucleases cleave both DNA strands [14]. Such breaks stimulate DNA repair mechanism. It was also shown that I-Sce1 amplifies the rate of homologous recombination [15] and consequently gene replacement in mammalian cells [16]. The DNA sequences recognized by natural meganucleases must then be added to the genome of animals either at targeted sites by homologous recombination or at random sites. To circumvent this problem, hundreds of engineered meganucleases each recognizing a specific genomic DNA sites have been obtained making a local cleavage of DNA and gene targeting possible [25].

Multiple engineered zinc finger nucleases (ZFN) have also been obtained. Each of these enzymes has the capacity to cut one DNA strand at a unique genomic DNA site. To mimic natural meganucleases and cut locally both DNA strands, two ZFN each recognizing a DNA strand at neighbor sites are needed [75]. Engineered meganucleases and engineered zinc finger nucleases, thus, make it possible gene targeting at multiple sites of the genome. This method, which is being developed to improve the efficiency and the precision of gene therapy for humans can be applied to target the integration of foreign DNA into experimental animals. Interestingly, when the recombination vector is not added with the meganuclease or the ZFN, the genomic DNA repair takes place spontaneously but often with alteration of the sequence. This process known as NHEJ (non-homologous end joining) corresponds to a knockout (Fig. 9) [84, 106]. This mechanism is efficient, and it allowed a knockout in one cell fish and rat embryos after the injection of engineered meganucleases [28, 107]. This method can be considered as a transgenesis without transgene. This inclines to think that gene targeting might be achieved directly



Transgenics: Alternative Gene Transfer Methods. Figure 9
Engineered meganucleases or ZFN (zinc finger nucleases) induce a targeted local cleavage of both genomic DNA strands. In the absence of recombination vector, the DNA is repaired leading to frequent local mutations and to a knockout. In the presence of a recombination vector, the foreign gene is integrated into the targeted site with a high efficiency

in mammal embryos by injecting an engineered meganuclease or ZFN with or without a homologous recombination vector.

In the same line, the bacterial enzyme phiC31, which is an integrase, recognizes several sites in various animal genomes and allows the efficient integration of foreign genes at the targeted sites. Several other recombination systems rely on the use of integrases such as Cre and Flp, which recognize specific sites of about 30 nucleotides (LoxP and FRT, respectively), which must be added to the animal genome. In practice, deletion of the integrated foreign DNA has more chance to occur than integration. Mutated LoxP and FRT sequences capable of promoting integration but not deletion must be used. This approach is known as RMCE (Recombinase-mediated Cassette Exchange) [1]. These systems are more often used to delete a DNA region previously bordered by the LoxP or the FRT sequences.

The Co-expression of Several Cistrons It is sometimes necessary to express two or even three genes in the same transgenic animals. The co-injection of several independent vectors makes the generation of up to 80% of the animals harboring the two or three genes, which are co-integrated at the same site possible. An alternative consists of using IRES (internal ribosome entry site). Such sequences exist in the 5′UTR of many mRNAs, the translation of which is controlled by these sequences, which bind specific cellular inducible proteins. Such sequences may be added between two cistrons and allow their simultaneous translation from a single vector. The addition of the IRES 80 nucleotides after the termination codon of the first cistron may

contribute to favor the expression of the second cistron [39]. It should be kept in mind that IRES represents a family of sequences acting by different mechanisms, which are only partly known.

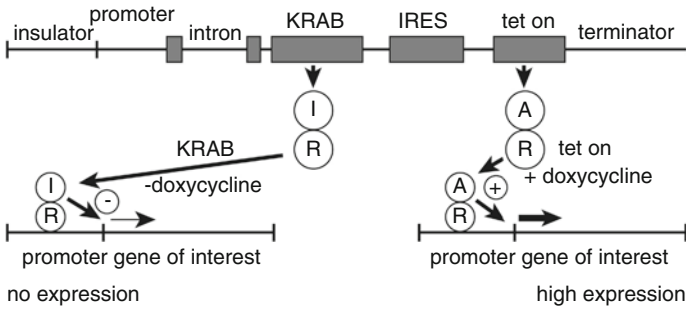
Gene Inactivation (Knockdown) with Interfering RNAs Long double-stranded RNAs are randomly cut into 19–21 nucleotide fragments known as siRNA (small interfering RNA) or RNAi. One of the two strands of the siRNA is kept and targeted to an mRNA having a complementary sequence. This induces the degradation of the mRNA or the reversible inhibition of its translation. In practise, a synthetic gene containing the targeted 19–21 nucleotide sequence followed a short random sequence and by the targeted sequence in the opposite orientation is linked to a promoter acting with RNA polymerase III (usually U6 or H1 gene promoters). The RNAs synthesized by such vectors form a 19–21 nucleotide double-stranded RNA known as shRNAs (short hairpin RNA) and are processed in cells to generate active siRNAs. An appropriate expression of siRNA genes in transgenic animals can be obtained when they are introduced into lentiviral vectors [99].

The recent discovery of the role of micro-RNAs has increased the possibility to use interfering RNAs. Micro-RNAs are encoded by short genes expressed under the control of RNA polymerase II promoters. Their primary products are transformed into siRNAs. Alternatively, the sequence coding for a micro-RNA and even several micro-RNAs in tandem may be inserted into introns without any promoter. The promoter of the gene or transgene thus drives transcription of the micro-RNA genes and the intron degradation releases micro-RNA precursors, which are processed in the nucleus and the cytoplasm, generating active siRNAs (Ripoll et al. unpublished data). The mature miRNAs, which are fully complementary to the targeted mRNA induce degradation of this mRNA. The miRNAs, which are only partially complementary to the targeted mRNA and which recognize a sequence located in the 3′UTR (3′untranslated region) of the mRNA inhibit translation of this mRNA without inducing its degradation. The possibility known as knockdown to generate transgenic animals expressing siRNAs preventing specifically the expression of a gene by degrading the corresponding mRNA or inhibiting its translation has opened avenues for the control of gene expression in vivo. The application of the siRNA approach raises specific problems in animals. Long double-stranded RNAs induce interferons and some unspecific immune reactions [89]. On the other hand, siRNAs are not autoamplified in higher animals and this reduces their potency. Vectors to express miRNA gene are available, but simple shRNA genes are not easily expressed in transgenic animals using conventional vectors. Moreover, siRNAs may off-target mRNAs and generate deleterious side effects.

Several programs based on empirical data indicate the putative optimal shRNA sequences that are able to generate siRNA strands complementary to the mRNAs. A very important point is to choose a target region of the mRNA, which is not in double-stranded structure and thus accessible to the siRNA. Banks of shRNA genes in lentiviral vectors are available for the mRNAs of different species. It remains that most of the siRNAs do not inhibit the targeted gene to more than 70–80%, which may be insufficient to obtain some relevant animal models. It is tempting to use vectors expressing the shRNA genes at a relatively high level. This may not lead to any significant increase of the inhibition and to an off-targeting, which may be detrimental or even lethal for the animals [89]. In fact, it seems that a well-targeted siRNA can be highly active even at a low concentration. It appears, therefore, to be of paramount importance to select the shRNA capable of inhibiting strongly the targeted mRNA even at a low concentration in cell systems before generating transgenic animals [79].

Use of Transdominant Negative Proteins The action of a gene can be blocked at the protein level by expressing specific inhibitors such as antibodies recognizing the protein of interest [66]. Alternatively, transdominant negative proteins acting as decoys may be used. Transgenic mice mimicking type II diabetes were obtained by overexpressing a mutated insulin receptor still capable of binding the hormone but not of transducing its message [9]. Similarly, overexpression of pseudorabies virus receptor in transgenic mice protects these animals against Aujeszky disease [70].

Genetic Ablation Destroying specifically given cell types in animals may reveal their role in organogenesis.

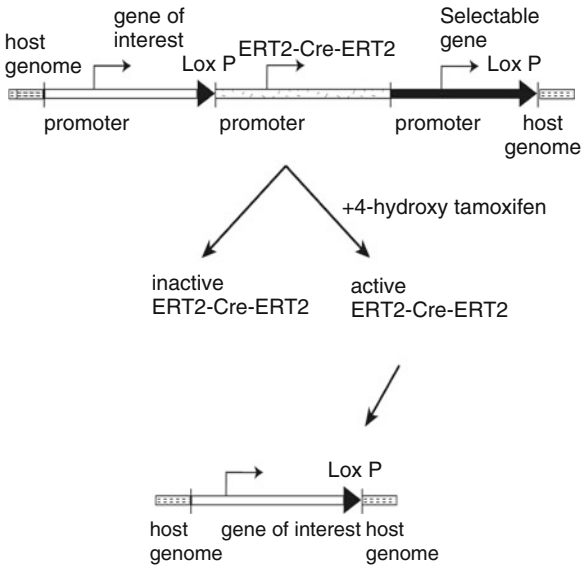


Transgenics: Alternative Gene Transfer Methods. Figure 10
The control of transgene expression may be controlled by an exogenous inducer. In the absence of the inducer (doxycycline), the transcription enhancer (Tet on) is not bound to DNA and it does not stimulate transcription whereas the transcription inhibitor (KRAB) is bound to DNA and reduces the background expression of the gene of interest. In the presence of doxycycline, the reverse is true and the gene of interest is activated

This can be achieved by expressing genes coding for toxins. The challenge is then to express quite specifically the transgenes. Different systems are implemented for this purpose [12, 82]. They rely on two-step mechanisms, which reduce the risk of ectopic expression of the toxin genes.

Control of Transgenes by Exogenous Inducers All the vectors described above and used to express transgenes contain promoters, which are naturally active in the cells of the transgenic animals. This implies that the transgenes are regulated by the natural inducers of the host genes. The induction of a transgene may then coincide with the unwanted stimulation of a number of host genes. Artificial promoters containing regulatory elements from both animal genes and bacterial genes have been designed. The resulting promoters are active in animal cells but controlled by substances active in bacteria but not in animals. The most popular system is based on the use the bacterial tetracycline repressor gene. In practise, the transgene becomes reversibly activated only when tetracycline or doxycycline is administered to the animals. Various mutants are available making it possible either the induction of the transgene or its inhibition by the addition of the exogenous inducer. A number of similar systems are available and currently used in transgenic animals with a good success [30, 57]. In order to reduce the background expression of the transgene in the absence of the exogenous inducers, the alternative expression of a transcription repressor as KRAB and of an inducer as Tet-on system may be implemented (Fig. 10). These tools, which require the transfer of several genes offer virtually the possibility to express a transgene precisely in a given cell type and at a given moment.

Gene Deletion Conventional homologous recombination makes it possible gene deletion known as knockout. Another possibility consists of using the Cre-LoxP or Flp-FRT systems. A LoxP sequence must first be added to both ends of the fragment to delete. The presence of the Cre recombinase will then recombine the two LoxP sites, leading to a deletion of the DNA fragment located between the LoxP regions. This makes it possible the elimination of a selection gene. The same approach allows the specific and controlled deletion of an inhibitory DNA region, leading to the activation of the gene located in its vicinity. The Cre recombinase may be synthesized by the corresponding gene under the direction of a cell-specific promoter including promoters under the control of doxycycline. Another level of control can be obtained by using an engineered Cre recombinase, which becomes reversibly active in the presence of an estrogen analogue, 4-hydroxy tamoxifen (Fig. 11) [62]. This offers the advantage of having the active Cre recombinase for short periods of time. This prevents the non-specific action of the Cre recombinase, which can recognize cryptic sites in the host genome and induce illegitimate recombination damaging the host DNA. This tool is appropriate to delete genes for resistance to antibiotics.



Transgenics: Alternative Gene Transfer Methods. Figure 11

Activation of Cre recombinase and selectable gene elimination by 4-hydroxy tamoxifen. The Cre recombinase gene expression may be under the control of the Tet-on system itself under the control of a cell-specific promoter. The fusion protein Cre recombinase–mutated estrogen receptor is active only in the presence 4-hydroxy tamoxifen. The elimination of the DNA region bordered by LoxP sequences is thus sharply controlled. The selection gene and the Cre recombinase may thus be eliminated from transgenic animals at any stage of their life

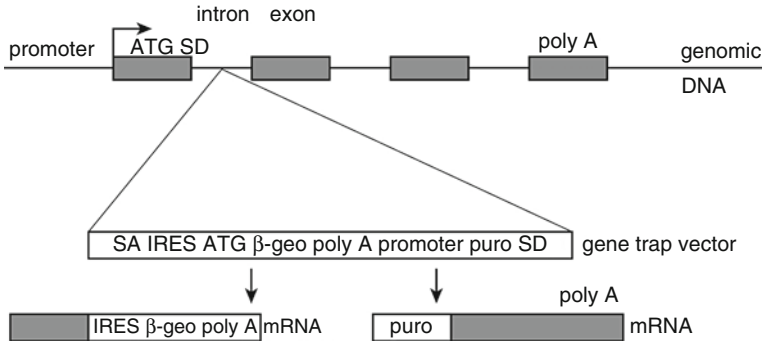
Vectors for Gene Trapping The identification of genes involved in a given biological function is an essential step to understand the role of the genes particularly those responsible for human diseases. One possibility is to use vectors for the trapping of active genes. One such vector is described in Fig. 12. Other vectors are shown in the chapter of a book [36]. New tools make it possible random gene knockout in genomes by inserting foreign DNA sequences using transposons [22] or lentiviral vectors. Banks of siRNA genes in lentiviral vectors can also be used to knockdown genes. The inhibited genes can thus be identified and correlations with altered biological functions in the animals become possible.

Future Directions

During the coming decade, transgenesis in animals is expected to be as intensively or even more used than presently. One of the trends is to refine the different tools for basic research as for the different applications. The time when transgenic mice were prepared in a blind manner by microinjecting simple gene constructions is getting over. The recent and very significant improvement of the gene transfer techniques should make several animal species less marginal in the transgenesis field. The number of transgenic models for basic research is being extended to a larger number of species, namely to rats, chicken, Xenopus, and even cow [47, 80, 96]. The sequencing of an increasing number of genomes, including different mouse strains and even different individuals, will contribute to extend the use of animal transgenesis.

The proportion of transgenic animals used for basic research, including the models for the study of human diseases, is currently very high. This proportion should change but moderately in favor of applications in the food domain and also in the pharmaceutical field including the production of pig cells and organs for patients and the production of recombinant pharmaceutical proteins. Indeed, the production of pig cells and organs is making significant progress but it remains unpredictable when and if the transplantation of pig cells and organs will become a tangible reality as many problems remain to be solved [73].

The production of pharmaceutical proteins in milk and egg white has become a realistic approach as the techniques have reached sufficient maturity even if the production of each protein is a challenge. Yet, this application of transgenesis is coming more slowly than anticipated. For complex reasons not clearly related to the efficiency of the technique or to biosafety guidelines, the pharmaceutical companies remain more or less reluctant to start using animals to obtain pharmaceutical proteins. Companies may consider that their profit is presently higher with the production of recombinant proteins in conventional fermentors harboring animal cell lines, even or because this system generates a shortage of medicaments for patients. A recent multiauthor book is a survey of all the aspects of this technique including the ethical considerations [77].



Transgenics: Alternative Gene Transfer Methods. Figure 12

Schematic representation of a gene trapping vector. The vector is randomly integrated into the genome of cells that are able to generate transgenic animals (Fig. 3). The β-geo gene is a fusion of the β-galactosidase gene, giving a blue color to cells, and neomycin resistance gene, giving a resistance to geneticin. The vector contains also the puromycin resistance gene, splicing acceptor sites, no promoter, and no transcription terminator. The β-geo selection gene is expressed only when it was integrated into a functional gene. The inactivated gene may be identified by sequencing the genomic DNA flanking the integrated vector. A correlation between the inactivated gene and an altered biological function of the animal may be established

Whatever happens, the application of transgenic animals for food production should become a reality in the coming decade. The increasing knowledge of alleles in farm animals and of a variety of other possible transgenes should give more space to the use of transgenesis to improve animal production. The recent achievement of the cow genome sequencing will contribute to using cattle alleles more extensively. It remains that the generation of relevant transgenic founders and their extensive use in breeding will be slower than in plants due to the high cost of transgenesis and the time required for the dissemination of their genomes in herds. The poor acceptability of biotechnology particularly in the EU is another hurdle.

The recent progress of several techniques of gene transfer are becoming more popular in laboratories and companies and therefore should be pursued. DNA microinjection into embryos will still be used in the species in which it is efficient. Lentiviral vectors are more and more frequently used, and this trend should become still stronger as the preparation of efficient and safe lentiviral particles has become a standard technique. Other viral vectors could be implemented in future. One candidate is AAV (adeno-associated virus). This virus is spontaneously integrated into cell genomes as lentiviruses. AAV vectors are used with some success for gene therapy in humans [111]. One of its advantages over lentiviruses is that they can harbor longer DNA fragments. Viral vectors might prove attractive for some applications in breeding. It is indeed conceivable to introduce massively foreign genes only into somatic cells. Examples are fish or more generally the animals, which swim or fly and can disseminate in environment. Growth hormone genes transferred into a sufficient number of salmon somatic cells might have the same biological effect on growth than the corresponding transgene without any risk of its dissemination in oceans.

More and more transposons are found and engineered to be able to generate efficiently and in a safe manner a variety of transgenic animals. One of the challenges of modern biology is to decipher the mechanisms involved between given genetic information and the expression of a physiological function. The systematic random integration of transposons and also of lentiviral vectors into the genome of cells able to participate in the development of transgenic animals is expected to generate banks of cells and animals in which physiological disorders can be connected to the genes interrupted by the vectors. This approach is similar to that of generating banks of animals having

genes inactivated by knockout or knockdown. Several animal and data banks are available: EMMA in EU, Jackson Laboratory in USA, IMSR (International Mouse Strain Resource), ISTT (International Society for Transgenic Technologies) www.transtechsociety.org, [40], private companies (namely Charles River) as well as academic and private structures for the generation of transgenic mice, rats, and rabbits.

Gene transfer using ICSI has met a great success in mice and a few other species. It is simpler and more efficient than conventional DNA injection. A broader implementation of this technique is presently limited by the fact that ICSI independently of transgenesis is still possible in only a small number of species. This situation is essentially due to the fact that researchers have not yet acquired this knowledge. The principle of ICSI is common to all species, but the manipulation of oocytes and sperm needs specific training. ICSI should thus be used more intensively in the near future in mice and extended to other species. The possible combination of ICSI and transposons as well as of envelope-free lentiviral particles might contribute to enhance gene transfer efficiency.

A trend is clearly to perform the genetic modifications not directly in embryos but rather in intermediate cells further used to generate transgenic animals. The long-term success of mouse ES cells to target gene transfer via the generation of chimeric animals is expected to be rapidly extended to the use of rat ES cells and iPS cells in different species, which are able to generate chimeric animals as ES cells. Progress must be made before iPS cells are used for transgenesis. This is being achieved as iPS cells are extensively studied since they are expected to be a major tool for cell therapy and gene therapy in humans. The techniques to generate iPS cells from somatic cells must be adapted to each species. An important recent progress is the possibility of dedifferentiating somatic cells no more by transferring the three identified key genes but by introducing the corresponding mRNAs, which are unstable by essence and thus leave no genetic information in the iPS cells. It is conceivable to transfer the three genes able to generate iPS cells into embryonic cells to obtain more easily ES cells. Indeed, cultured ES cells are known to quickly lose their pluripotency in most mouse lines and essentially in all other species but rats. ES cells from a number of species might become a reality in this way. The preliminary success, which made it possible the use of small molecules in culture medium instead of proteins to generate pluripotent cells from embryos or somatic cells is very encouraging. It suggests that the generation and the use of pluripotent cells in multiple species might become a relatively easy task. This would facilitate markedly the genetic modification of animal genomes. A more speculative reasoning is to postulate that the complete dedifferentiation of somatic cells into totipotent cells will be possible some day by the transfer of genes or chemical inducers, which remain to be found. Cloning and transgenesis as well as their coupling and related ethical problems would be considerably simplified.

Cloning by SCNT proved that it is possible to make the random and targeted gene transfer. The popularization of this technique is likely, but it depends on improvement of the technique. Indeed, clones are often if not always epigenetically modified leading to a limited efficiency, to a reduced welfare of the animals, and potentially to health problems. Significant improvement has been achieved in 10 years, and a better control of cloning should occur in the coming years.

The construction of vectors making it possible a reliable and well-controlled expression of the transgenes will be progressively improved by the empirical use of BAC containing long genomic DNA fragments with the majority of the remote transcription regulators. The use of long genomic DNA fragments as vectors is expected to become more and more frequent but to remain empirical for some time. Most likely, an increasing number of BAC vectors containing regulatory elements for the expression of transgenes in the different cells types will become available. Despite the higher difficulty to manipulate BAC rather than plasmids constructs, researchers will prefer in a number of cases to invest a part of their time in the construction of BAC vectors to tentatively obtain better transgenic models. Rapid progress is being made on the description of chromatin structure and activity. Gene study is more and more performed at the level of a locus and not only of a given gene. This will provide researchers with well-identified chromatin regulators, which will be used to design compact vectors containing these regulators capable of optimizing transgene expression.

Gene targeting is essential to obtain relevant transgenic models. The demonstration that a local cleavage of DNA by natural or engineered meganucleases or by engineered zinc finger nuclease considerably increases the efficiency of homologous recombination is of major importance for basic and applied research particularly for projects involving transgenesis. Gene knockin and knockout are expected to become much more efficient, up to the point perhaps to be possible directly in one-cell embryos and not only via intermediate cells. The demonstration that DNA cleavage by zinc finger nuclease in the absence of recombination vectors is followed by an imperfect DNA repair (NHEJ), which in a significant proportion of cases leads to a mutation, thus to a gene knockout. The fact that gene knockout by NHEJ could be obtained directly in fish embryos opens new avenues as this protocol does not require any more the laborious gene knockout by homologous recombination. Hundreds of engineered zinc fingers have been designed to recognize specific sites in different genomes. This number should increase rapidly in the coming years. A particularly fascinating point is that NHEJ as well as conventional knockout and knockin might be applied not only to genes proper but also to their genomic regulators. This would allow the study of the regulators of various loci without implementing the laborious manipulation of BACs.

The discovery of siRNA has rapidly been followed by the generation of gene knockdown in plants. The same did not occur in animals. The use of long double-stranded RNA induces deleterious side effects in animals. The availability of lentiviral vector banks harboring genes coding for shRNAs makes gene knockdown easier in animals. The efficiency of this approach remains limited by the insufficient knowledge on the mechanisms of RNA interference. Progress has been made to empirically design siRNA having a high and specific inhibitory effect on gene expression. An important parameter is now taken into consideration. It is known that the sequence of the siRNA determines the choice of the strand, which will target the mRNA of interest and its capacity to inactivate this mRNA. It now clear that the local structure of the mRNA is essential to make the access of the siRNA possible. Additional progress is expected in this field, and it should facilitate gene knockdown in transgenic animals.

Using constructs in which the transgene is under the control of exogenous inducers like doxycycline is a reality. Sophisticated systems reducing the background expression of the transgene expression in the absence of the inducers are currently used. The possibility of using these systems to create relevant transgenic models is expected to be more and more frequently used. Improvement of these techniques is likely by finding additional inducers.

It is essential to be able to knock out genes in chosen cells and at defined period of the animal life. This conditional knockout implies the used of the Cre/LoxP or similar systems. The conditional expression of the Cre recombinase and its conditional activation by 4-hydroxy tamoxifen offer a great flexibility. Improvement of these systems is possible. A more extensive use of these systems, which give satisfaction to researchers will be done in the coming years.

Transgenesis techniques are thus making important progress for the generation of transgenic animals as for the fine control of transgene expression. The available tools and those in development are expected to be adapted to the systematic study of multiple genes required for the development of integrative biology.
