The Inter-American Institute for Cooperation in Agriculture (IICA)	As requested by the Ministries of Agriculture in 2002, IICA, in collaboration with the OIRSA and the Tropical Agricultural Research and Higher Education Centre (CATIE), was put in charge of preparing a regional biosafety regulatory framework, in response to the lack of regulations in certain countries that are receiving, or may potentially receive, requests for field trials or trade in LMOs. A group comprising of various agencies was formed, along with a consultative process, which led to the preparation of a Regulatory Framework Draft for Living Modified Organisms for Agricultural and Livestock Use in Central American Countries. This initiative intends to promote a model regulation on agricultural biotechnology that is to be adapted by each country, according to its particular needs and situation. There is hope that this regulation will be enacted in a similar fashion by the various nations, thereby triggering a process of harmonization of regulatory frameworks in the region.
Other relevant agreements and declarations	– CGRFA draft Code of Conduct on Biotechnology [107] – United Nations Model Regulations on the Transport of Dangerous Goods (UN Recommendations) [108] – The Aarhus Convention on Access to Information, Public Participation in Decision-making and Access to Justice in Environmental Matters, which contains specific guidelines on public participation in LMO-related decision-making processes [109]. The Convention entered into force in 2001. Although it was enacted by the United Nations Economic Commission for Europe, the convention is open to other nations. The Convention was amended in 2005 in order to set out more precise provisions on the deliberate release of genetically modified organisms, but the amendment has not yet entered into force. The amendment will enter into force once it has been ratified by at least three-quarters of the Parties. In September 2007, the amendment had only been ratified by four countries. The third meeting of the Parties was held in Riga, Latvia, on 11–13 June 2008. The meeting adopted the Riga Declaration and a strategic plan for the Convention, resolved the issue of how to calculate ratification of amendments, and renewed the mandates of task forces dealing with access to justice, electronic information tools, and public participation in international forums.

their products. To develop such a regulatory system, a government can use existing laws or develop new laws. Any national biosafety regulatory system that is proposed, however, must be functional, protective, and also comply with international trade standards that are evolving in recognition of the growing importance of GE organisms in world affairs.

A national biosafety regulatory system is a regulatory regime responsible for assessing and managing the full range of potential risks that might be posed by a GMO and its products. It addresses potential risks to the environment and biological diversity as well as any food/feed risks or other safety-related issues involving GMOs (e.g., worker health, drug safety, etc.). A protective biosafety regulatory system ensures that any risks from GMOs are managed and allows safe GMOs to be developed, marketed, and utilized for their intended purpose. Such a system, however, must also be functional, which means that it should be understandable, workable, equitable, fair, adaptive, and enforceable [114].

Existing biosafety regulatory systems from around the world reflect, among other things, the type of government in the country, the politics of the country, the country's view on the relative safety of GMOs, and the country's regulation of food, agriculture, and environmental issues. Establishing those systems required balancing numerous goals and trading off different interests. Through an analysis and comparison of

different existing biosafety regulatory systems, however, one can identify key characteristics and components that are generally important to a functional and protective biosafety regulatory system [113]. Incorporating each of those characteristics and components in a functional and protective biosafety regulatory system involves problem solving because there can be tensions between the different characteristics.

Jaffe [113] indicates the following attributes of a system:

- Comprehensive.
- Adequate legal authority to subject each GMO to a food-safety and environmental risk assessment approval.
- A clear safety standard.
- Proportionate risk-based reviews.
- Transparent and understandable.
- Participatory.
- Post-approval oversight. A biosafety regulatory system does not stop its oversight once a GMO has been approved for a confined field trial or for a commercial release.
- Flexible and adaptable.
- Efficient, workable, and fair.

Decision-makers are facing an important challenge because biotechnology and biosafety fields are ever evolving at a dramatic pace. In this context, overly precise and detailed regulatory frameworks can easily become obsolete in a short period of time. In order to avoid forever having to enact new legislation and policies, it is preferable to develop a regulatory framework that takes on the form of a general guide, thus regulating more specific biosafety aspects by way of by-laws and other regulations. In fact, this alternative allows more efficient regulation of future situations but has the effect of conferring the power of regulating specific aspects of biotechnology to the executive branch of government and other administrative institutions, instead of to the Parliament [115].

General Comments on Evolution of Biosafety Regulatory Systems

The nature of GM crop regulations around the world has as much to do with social and political values as with concerns about health and safety. Consumers' growing awareness of their rights and farmers' increasing fear of dependence on multinational companies are symptoms of a deeper concern about values and priorities, the type of environment that people want, the role of biodiversity, their tolerance to risk, and the price that people are prepared to pay for regulation. Therefore, the regulations in the study countries were formed, or amended, during this period of heightened public awareness and are a reflection of how the various governments have attempted, or not, to address these concerns. A comprehensive discussion of regulatory requirements for GM crops at the national and international levels is a broader topic than can be covered here, and previous studies have addressed them in detail [5, 116].

In general terms of regulatory systems, several approaches have been considered worldwide with respect to the safe use of modern biotechnology: (a) certain countries decided to apply preexistent plant or animal health regulations to GMO-related issues or to incorporate biosafety provisions into plant and animal health protection laws; (b) other countries decided to adopt specific biosafety regulations that need to be enacted by the Parliament, the executive power (through agreements or resolutions), or public sector institutions; (c) certain countries decided to mention biosafety in their environmental regulations; (d) some countries decided to apply seeds, pest control, and plant or animal regulations to modern biotechnology, enacting but a few coordination rules and specific provisions associated to biosafety.

The original trend of agricultural biosafety regulations focusing on transgenic plants continues to exist in some countries but is in the process of being replaced by a broader focus that comprises biosafety regulation of animals, microorganisms, fish, and forest species. This progressive expansion of biosafety toward new areas results from the need to regulate research and eventual trade of other types of organisms created through genetic engineering. The CPB, whose scope extends beyond the issue of plants, and the subsequently developed regulatory frameworks implementing its provisions, brought on a gradual increase in the number and variety of organisms and activities being regulated. In addition, health authorities have increased participation in biosafety advisory commissions and committees.

In view of the complexity of biosafety issues, particularly issues of risk assessment and risk management, and several other issues associated to the introduction of GMOs into the environment, almost all of the countries have established a committee or a national commission to assist decision-makers in the development of biosafety regulations. The composition of these committees and commissions varies considerably in the region, mainly with respect to the inclusion of the productive sector, consumers, and non-governmental organizations. However, the trend points toward the inclusion of these organizations, even though such an inclusion can potentially lead to conflicts of interest. Currently, these committees or commissions are for the most part directly connected to the regulatory authorities in place. Nevertheless, independent national commissions (commissions that are not connected to the regulatory authorities) were created in some countries and were assigned political and coordinative functions, leaving the issue of technical recommendations to be dealt with by other sector-based authorities established by each country's competent Ministry or Secretariat.

The entry into force of the CPB had the effect of introducing the Ministries of Environment to the biosafety debate. For the reasons mentioned in the previous paragraph, the Ministries of Agriculture have traditionally been the authorities involved in the decision-making process regarding GMOs. Gradually, environmental authorities started demanding and assuming an active role in the regulation of GMOs in view of their mandate to protect the environment. This trend has been strengthened by the incorporation of biosafety provisions into environmental laws and regulations. In some cases, GMOs are even subject to environmental impact assessments (at least based on a literal interpretation of the pertinent legal provisions).

Comparison of Approval Systems

In Asia, the only major GM crops approved for commercial release are Bt cotton, which is grown commercially in China, India, and Indonesia, and GM corn recently approved in the Philippines. To date, no Asian government has given official permission to plant GM soybeans or rice.

In the context of GM crops, the concept of "biosafety" is, in principle, a broad one, covering three areas: the health safety of humans and livestock, the safety of the environment (i.e., ecology and biodiversity), and socioeconomic safety (i.e., the economic and social impact on farmers, consumers, and different social classes, as well as on trade and economy in general) [44]. While the biosafety regulations in force in industrialized countries (e.g., Canada, the European Union, and the USA) address only the health and environmental risks and exclude socioeconomic considerations, the regulations in developing countries (e.g., India, Argentina, SA, and the Philippines) tend to include all three areas.

Countries have responded differently to the opportunities presented by GM crops and the potential risks associated with them (Table 2). The composition of the "trade off" between potential benefits and risks in each case depends upon whether a government adopts a permissive, precautionary, or prohibitive policy approach to GM crops. Three basic conditions may thus trigger application of protective measures: uncertainty, risk, and lack of proof of direct causal link [5]. As major agricultural exporters, Argentina, Canada, and the USA have each adopted a permissive attitude very early on, widely authorizing most GM products for production and consumption, thereby benefiting from lower production costs and greater export profits. Regulators in India, Europe, and the Philippines, on the other hand, have taken a more cautious approach based on guaranteeing a very low level of risk to human health and the environment. They have therefore imposed strict control measures on approval and marketing of GMOs and GM products [5]. While China had initially moved quickly on the approval of GM crops for environmental and commercial releases, the approval process has slowed considerably since 2000, and strict regulations have been implemented for GMO imports [15].

Further differences are obvious. Process-based regulation is the rule in almost all countries that have developed national biosafety regulatory systems. Even in countries employing a product-focused RA process, the scope of regulatory oversight is defined by the process of genetic modification. Canada is the only country in which regulatory oversight is triggered solely by the novelty of the trait(s) expressed by plants, irrespective of the means by which the novel traits were introduced – an approach that is most consistent with

Commercialisation of GM Crops: Comparison of Regulatory Frameworks. Table 2 Main characteristics of commercialization approval systems in study countries

Element of approval system	Country/region							
	Argentina	Canada	China	Europe	India	Philippines	S. Africa	USA
Biosafety/GMO-specific law/act	X	X	X	✓	X	X	✓	X
Regulatory trigger: process (A) or product (B)	B	B[a]	B	A	A	A	A	B
Responsible ministry or government department: agriculture (A), environment (E), or health (H)	A	A,H	A	A or E[b]	E	A		A, E[c]
ERA committee composition: academia (A), commercial (C), government (G), or public (P) representatives	A,C, G,P	G	A,G	A	G	A,G	A,G	G
Obligatory domestic field testing	✓	X[d]	✓	X[d]	✓	✓[e]		
Obligatory prior approval in export country		X	✓	X		✓	✓	
Compulsory compliance with food-safety requirements	✓	✓	✓	✓	✓	✓	✓	X[f]
Socioeconomic impacts considered	✓	X	X[g]	X	✓		✓	X
Compulsory variety registration	✓	✓	✓		✓			
Mandatory post-market monitoring[h]		X		✓	✓			X
Time- or spatially restricted authorization		✓		✓	✓			X
Public consultation (days)				30	30[i]	60	30	✓

[a]In contrast to all other countries, Canada relies on the concept of novelty to trigger regulatory oversight and has declared that all plants derived through genetic modification are considered novel

[b]The European Commission sends its draft approval to the Council of Ministers (agricultural or environmental ministers), which has three months to reject or adopt it. If they do not act within this time, the Commission may adopt its own decision and authorize the new GM product

[c]For those GM plants producing their own pesticide, the evaluation is coordinated between APHIS and the USEPA

[d]Where data from field studies on other continents are supplied, the applicant should submit a reasoned argument that the data is applicable to domestic conditions

[e]For local applications only, not for applications for import

[f]Developers of GM crops engage in a voluntary, but recommended, consultation process with the USFDA (voluntary pre-market review). This process is currently under review

[g]Taking socioeconomic considerations into account during the risk assessment process is not legally required in China [30]

[h]✓ – Mandatory requirement for approved post-marketing monitoring plans and reporting. X – No specific approval requirement, but the developer is expected to monitor for existing and emerging risks that may be associated with its product and notify the regulatory authorities whenever new information is uncovered

[i]Thirty-day time period is provided for public consultation after the formal approval

the scientific principle that the risks associated with GM crops are not inherently different than those posed by more conventional crops [117, 118]. Indeed, the US National Research Council has explicitly recommended using objective compositional changes, not breeding method, as the basis for regulatory scrutiny and even then, only "when warranted" [119]. India, Argentina, Canada, most EU countries, and South Africa have all used non-statutory guidelines to manage the environmental impact of GM crops before promulgating new acts or regulations. There is no evidence that this approach has ever compromised environmental safety. India is the exception among the study countries in locating its biosafety decision-making authority solely within the ministry responsible for the environment, while the Ministry of Agriculture predominates among the remaining study countries. As a rule, environment ministries have a more precautious or preventative approach to introducing new technologies, as compared to those with the responsibility for agriculture. Different structural approaches are used to secure the necessary scientific advice for the decision-making process. The EU has implemented a system of expert advisory committees, while others, such as India, Canada, and the USA, rely primarily on scientists and professionals working within government departments and agencies. Other countries, e.g., Argentina, China, and South Africa, have a combination of both. Only India and the EU mandate post-market monitoring in attempts to gauge the impacts of the introduction of GM crops over the long-term as well as larger spatial scales. Other countries may address this indirectly by authorizing time-limited or geographically limited introductions (e.g., Canada), whereas the USA does neither.

Conclusion and Future Directions

Governments have an important role in ensuring that novel foods are safe for human consumption and that novel agricultural inputs do not cause major negative impacts on the environment and long-term agricultural production. The adoption of biosafety regulatory frameworks is a challenging task since decision-makers are faced with numerous difficulties, such as ever-evolving technology, which can quickly render specific regulations obsolete. Countries and policy-makers are responding to these various problems with different legislative and policy-based strategies. As seen above, most countries, with the notable exception of the USA, consider GM crops to be novel foods, regardless of the characteristics of their final product. Hence, new laws and institutions to regulate potential biosafety and food-safety issues have and continue to be established, requiring that GM products be approved before they may be grown in, consumed in, or imported into a country. Concurrently, public opinion in many parts of the world still regards the use of GM crops as controversial. Concerns about new risks have led biosafety, food-safety, and labeling regulations to become complex and costly, with no tiered mechanisms in place to regulate the various and different GMOs based upon the level of risk presented and the amount of regulatory experience gained with similar products. As a result, regulation has evolved which implicitly assumes that all GMOs have the ability to present the same (high) risk unless proven otherwise, requiring the over-production of data of questionable value to decision-making. This regulatory position has become a real threat to the future development of GM crops in the non-corporate and public sectors, especially for those subsistence crops involving tolerance to abiotic stress and higher nutrient contents being specifically developed for the benefit of farmers and consumers in the developing world. Should regulatory safety standards be set to an impossibly high threshold (e.g., at zero risk), these GM crops are unlikely to be approved in those countries who stand to gain most from their potential benefits.

The requirements of setting up effective and efficient regulations and legislative systems pertaining to products of rDNA technology inevitably involve additional costs, e.g., the development and maintenance of institutions, procedures, and management tools, costs which many developing countries cannot afford. Even should developing countries decide to form their regulatory frameworks by adapting regulatory guidance already implemented elsewhere, cost sharing still carries a financial burden. Once a system is in place, other relevant costs include the cost of compliance with biosafety regulations and risk management conditions, as well as the economic, environmental, and health costs related to delayed access to new technologies and products and their associated benefits. The variety

and disparity of potential frameworks call for a normalization of information requirements and, wherever synergies and cooperation mechanisms are promoted, a harmonization of the scientific and technical aspects of regulatory oversight at the national and subregional level. As such, an expanded use of internationally accepted consensus can promote the acceptance of regional approaches to regulation. Examples include OECD documents on scientific aspects of risk assessment, as well as guidelines issued by international standard-setting bodies such as the International Plant Protection Convention and the Codex Alimentarius. Programs that create networks on regional and subregional levels may also facilitate the acquisition and dissemination of biosafety expertise at reduced costs. Providing useful, relevant information is a worthwhile task, but it can also prove expensive to provide training on how best to utilize such information in decision-making. It is therefore imperative that external funding streams continue to be directed toward supporting the establishment of effective regulatory systems in developing countries that respond to national needs and policies, until such time that they become self-sustainable.

Article Outline

Glossary

Association mapping Association mapping is a high-resolution method for mapping quantitative trait loci (QTLs) or gene(s) for traits of interest based on linkage disequilibrium (LD) and holds great promise for the dissection of complex genetic traits.

Back cross (BC) Back cross is a cross of the F_1 with either of the parental genotype and the resultant progeny is called BC_1. The progeny of the cross between BC_1 and the recurrent parent is called as BC_2.

Gene pyramiding Gene pyramiding is a process of accumulating the favorable genes/alleles from different genotypes into an elite/commercial cultivar. Gene pyramiding is often performed through marker-assisted selection (MAS).

Genome-wide selection or genomic selection (GS) Genome-wide selection or genomic selection is a concept for accelerating genetic gain especially for complex traits in elite genotypes by utilizing genomic information and estimating their breeding values in breeding strategies. GS is becoming very popular over marker-assisted selection that was focused on few individual genes or few QTLs to improve genotypes, especially when recent advances in genomic technologies have drastically reduced the cost on marker genotyping.

Genomics-assisted breeding (GAB) Genomics-assisted breeding is a holistic approach, where genomics technologies including molecular markers, trasncriptomics, metabolomics, proteomics, bioinformatics, and phenomics are integrated with conventional breeding strategies for breeding crop plants resistant/tolerant to biotic and abiotic stresses or improved for quality and yield.

Haplotype Haplotype is a set of alleles of closely linked loci on a chromosome that tend to be inherited together.

Linkage disequilibrium (LD) Linkage disequilibrium is a nonrandom association of alleles at different loci, describing the condition with non-equal (increased or reduced) frequency of the haplotypes in a population at random combination of alleles at different loci. LD is not the same as linkage, although tight linkage may generate high levels of LD between alleles.

Marker-assisted selection (MAS) Marker-assisted selection is a process of indirect selection for improving the traits of interest by employing morphological, biochemical, or DNA-based markers. DNA-based markers/molecular markers, in the recent past, were proven to be the markers of choice for MAS.

Narrow genetic base Narrow genetic base does frequently exists in modern crop cultivars or breeding lines due to the continuous use of small number of elite genotypes in breeding programs. In fact, it is

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

Originally published in
Robert A. Meyers (ed.) Encyclopedia of Sustainability Science and Technology, © 2012, DOI 10.1007/978-1-4419-0851-3

a serious obstacle to sustain and improve crop productivity due to rapid vulnerability of genetically uniform cultivars to emerging biotic and abiotic stresses.

Next-generation sequencing (NGS) technologies Next-generation sequencing (NGS) technologies include various novel sequencing technologies for example 454/FLX (Roche Inc.), ABI SOLiD (Applied Biosystems), Solexa (Illumina Inc.), etc., that have surpassed traditional Sanger sequencing in through-put and in cost-effectiveness for generating large-scale sequence data.

Polygenes Polygenes are a group of non-allelic genes, each having a small quantitative effect, that together produce a wide range of phenotypic variation.

Quantitative trait loci (QTLs) Quantitative trait loci are the loci or regions in the genome that contribute towards conferring tolerance to abiotic stresses (e.g., drought, salinity) or resistance to biotic stresses (e.g., fungal, bacterial, viral diseases) or improving agronomic traits (e.g., yield, quality) which are generally controlled by polygenes and greatly depend on gene × environmental (G × E) interactions.

Sustainable agriculture Sustainable agriculture refers to efficient agricultural production while maintaining the environment, farm profitability, and prosperity of farming communities.

Sustainable development Sustainable development is defined as balancing the fulfillment of human needs with the protection of the environment so that these needs can be met not only at the present time, but also in the future.

Definition of the Subject

There has been significant improvement in production and productivity of important cereal crops globally as a consequence of the "Green Revolution" and other initiatives [1]. However, today the stage has reached that the available traditional methods of crop improvement are not sufficient to provide enough and staple food grains to the constantly growing world population [2]. This situation is projected to be worse by the year 2050, especially in context of climate change [3]. In other words, the conventional plant breeding practices may not be able to achieve the sustainability in today's agriculture.

It is under such circumstances that advances in plant genomics research are opening up a new era in plant breeding, where the linkage of genes to specific traits will lead to more efficient and predictable breeding programs in future. Several initiatives have been started towards use of genomics technologies in number of crop plants to ensure the sustainable production of healthy and safe crops and the results are encouraging. It is therefore expected that the genomics will be the integral part of the agricultural/plant breeding practices in future for improving crop productivity leading to achieve food security and sustainable production.

Introduction and Importance of Sustainable Agriculture

The goal of agricultural science is to increase crop productivity coupled with the quality of the products, and maintain the environment [1]. Food security is a growing concern worldwide, and more than 1 billion people are estimated to lack sufficient dietary energy availability [2]. The issue of "food security" has become so important that prominent scientific journals, including Science, have also published a special issue on this subject recently (February 12, 2010 issue). With the current rate of growth, the global population is likely to plateau at some 9 billion people by roughly the middle of this century [3]. With this ever-increasing human population and amidst the fear of shrinking resources in terms of cultivable area, irrigation resources, newly emerging insect pests, stagnated yields, etc., it has become difficult to maintain agricultural sustainability. In order to make today's agriculture sustainable, it is necessary that plant breeders adopt innovative technologies that can increase the efficiency of selection with more precision [4]. Under such circumstances, molecular approaches including modern genomics and genetic engineering technologies have emerged as powerful tools to assure rapid and precise selection for the trait(s) of interest. Maintaining effective and environmentally friendly agricultural practices is a necessary prerequisite for maintaining sustainability.

Plant genomics is a rapidly developing field, which is radically improving our understanding of plant biology by making available novel tools for the improvement of plant properties relevant to sustainable agricultural production. Recent advances in high-throughput genomics technologies, including that of next-generation sequencing and high-throughput genotyping, have helped immensely in understanding the functions and regulation of genes in crop plants [5]. The ever-increasing availability of genome sequences in crop plants have facilitated greatly the development of genomic resources that will allow us to address biological functions and a number of basic processes relevant to crop production leading to sustainable agriculture.

One of the myths linked to sustainable agriculture means going back to past techniques/farm practices, which were followed by our ancestors. In fact, sustainable agriculture can be achieved by combining some of the wisdom of past practices with careful use of current technology, including the vast array of information technologies now available. Sustainable agriculture is a key element of sustainable development and is essential to the future well-being of the human race and the planet. A compelling need exists for restorative and sustainable agriculture to help address the pressing trends of population, climate, energy, water, soil, and food. Sustainable agriculture needs to be economically viable, environmentally sound, and socially acceptable. In other words, it is a system of agricultural production that, over the long term, will: (1) satisfy human food, feed, and fiber needs; (2) enhance the environmental quality and the natural resource base upon which the agricultural economy depends; (3) make the most efficient use of available technologies, nonrenewable resources, and on-farm resources, and integrate, where appropriate, natural biological cycles and controls; (4) sustain the economic viability of farm operations; and (5) enhance the quality of life for farmers and society as a whole.

There are various components of sustainable agriculture, which include technological interventions, and environmental and socio-economic factors. As the factors related to socio-economics and environments have been discussed in a number of reviews earlier, in this article, we focus on the interventions of plant genomics technologies in crop breeding.

Contribution of Plant Genomics Technologies to Crop Breeding

Plant genomics technologies have contributed immensely in today's agriculture which has led to better understanding of how plants function, and how they respond to the environment. This has also helped in achieving targeted objectives in breeding programs to improve the performance and productivity of crops. The DNA-based molecular markers have facilitated smarter and knowledge-based breeding, by enabling early-generation selection for key traits, thus reducing the need for extensive field selection. Besides this, the molecular tools can effectively be used for the characterization, conservation, and use of genetic resources.

Recent advances made in the area of molecular biology and bioinformatics offer substantial opportunities for enhancing the effectiveness of classical plant breeding programs. These tools can be integrated into breeding work in order to analyze efficiently high numbers of crosses at the early seedling stage. This approach is known as "genomics-assisted breeding" [6]. Through this approach, both the phenotype and the genotype of new varieties can be analyzed and the performance of new specific introgressed traits can be predicted. The goals of the integration of these technologies in classical breeding are to create genotype-to-phenotype trait knowledge for breeding objectives and to use this knowledge in product development and deployment for the resource poor farmer.

For successful utilization of genomics-assisted breeding approach in a crop, availability of basic molecular tools, such as molecular markers, genetic maps, etc., is a prerequisite. Among molecular markers, though a variety of molecular markers such as restriction fragment length polymorphism (RFLP), randomly amplified polymorphic DNA (RAPD), microsatellite or simple sequence repeat (SSR), amplified fragment length polymorphism (AFLP), and single nucleotide polymorphism (SNP) markers have been developed in a range of crops, SSR and SNP markers have emerged as the markers of choice [7, 8]. Because of advent of NGS technologies [5] and high-throughput genotyping platforms, SNP marker system and array-based genotyping platforms are becoming more

popular [9, 10]. An overview on availability of genomic resources in some selected important crop species is shown in Table 1. It is evident that cereal crops, especially rice, maize, wheat, barley, etc., are on top in terms of availability of genomic resources (see [11]). Genome sequences have already become available for several crop species, including rice (http://rgp.dna.affrc.go.jp/IRGSP/), sorghum [12], and maize (http://gbrowse.maizegdb.org/cgi-bin/gbrowse/maize/). Recent investments coupled with advances in genomics technologies have contributed towards developing a good resource of genomics tools in legumes as well [13, 14].

Some Modern Breeding Approaches

The availability of genomic resources in almost all important crops combined with information on pedigrees as well as optimized methods of precise phenotyping make it possible to undertake genomics-assisted breeding approaches for crop improvement. In fact, some molecular breeding approaches like advanced backcross QTL (AB-QTL) analysis and marker-assisted selection (MAS) have been successfully employed in several crops, leading to improved cultivars, some other approaches such as marker-assisted recurrent selection (MARS) or genomics selection (GS) are being used in several crops [15, 16].

Marker-Assisted Selection (MAS)

There are three major steps involved in MAS: (1) identification of molecular marker(s) associated with trait(s) of interest to breeders, (2) validation of identified marker(s) in the genetic background of the targeted genotypes to be improved, and (3) marker-assisted backcrossing (MABC) to transfer the QTL/gene from the donor genotype into the targeted genotype. In context of marker-trait association, linkage mapping has been extensively used for identifying the markers associated with a trait of interest in a range of crops including cereals, legumes, horticultural crops, etc. These studies have been reviewed in detail in several reviews [14, 17] and books [18]. Although hundreds of studies have been undertaken, only a few studies were taken further to marker validation and MABC. This may be attributed to (1) identification of few markers associated with small-effect QTLs, (2) non-validation of markers in elite genotypes, and (3) slow adoption of markers by breeders in their breeding programs. Recent advances in association genetics, however, offer opportunities to overcome the first two constraints.

Association mapping (AM) is considered an alternative strategy to linkage mapping for identifying marker-trait associations and has been used extensively in human and animal systems. AM has a number of advantages over linkage mapping, including the potential for increased QTL resolution and an increased sampling of molecular variation (for reviews see [19, 20]). AM involves studying a natural population rather than the offspring of crosses, and associations in natural populations are typically on a much finer scale because they reflect historical recombination events. Several examples on marker-trait association using AM are available [21]; however, there is a need for optimization of more advanced analytical tools in the area of association genetics [22]. It is anticipated that because of reduction in costs on marker genotyping [10], AM will be extensively used for trait mapping in the future.

Once the markers associated with a trait of interest are identified through linkage mapping or AM, the next step is to use these markers in the breeding programs. In this context, the selection of one or a few genes (QTLs) through molecular markers using backcrossing is a very efficient technique [23, 24]. Important advantages of MAS are that it can be effectively utilized for traits with low heritability; for gene pyramiding, selection can be made at seedling stage; and, above all, there are no issues involving GE crops [25]. Although use of markers in breeding programs through MABC is a common practice in the private sector [26], MAS is in routine use in wheat and barley breeding programs in Australia [8, 27–29] and USA (www.maswheat.ucdavis.edu; http://barleycap.cfans.umn.edu/). Nevertheless, there are several success stories in many crops including wheat, rice, barley, maize, soybean, etc., where MAS has successfully been utilized to develop superior lines/varieties/hybrids for improving quality, resistance to diseases or tolerance to abiotic stresses. For example, Gupta et al. [17] has recently summarized success stories of molecular breeding in wheat.

A widely discussed success story of molecular breeding is the introgression of the FR13A *Sub1* locus conferring resistance against submergence in an Asian rice cultivar, Swarna [30, 31] that can confer tolerance

up to 2 weeks of complete submergence. This has offered great relief to the large number of Asian farmers whose rice land is located in deltas and low-lying areas that are at risk from flooding during the monsoon season every year. Some selected examples of molecular breeding in rice and wheat (adopted from [17]) are summarized in Table 2.

Advanced Backcross QTL (AB-QTL) Analysis

Although MAS has been quite successful, it has always been a difficult task to tackle linkage drag, especially when a QTL or a gene is to be introgressed from wild/exotic species. Furthermore, in MAS, QTL/gene discovery and variety development are two separate processes. To deal with this problem and to harness the potential of the wild/unadapted germplasm in breeding programs, a new approach referred as advanced backcross QTL (AB-QTL) analysis was proposed by Tanksley and Nelson [32]. AB-QTL aims at simultaneous detection and transfer of useful QTLs from the wild/unadapted relatives to a popular cultivar for improvement of a trait. In this context, a superior cultivar/variety is crossed with a wild species leading to the production of a backcross population (BC_2, BC_3), and molecular markers are used to monitor the transfer of QTLs by conventional backcrossing. The advanced backcross approach has already been successfully utilized in different crops, including tomato [59], rice [60, 61], barley [62], and wheat [63]. It is anticipated that the use of AB-QTL will be accelerated in a range of crops for improving important traits such as disease resistance as well as yield traits.

Marker-Assisted Recurrent Selection (MARS)

In the majority of traits of interest, quantitative variation is controlled by many QTLs, each with minor effect. Moreover, minor QTLs show an inconsistent QTL effect in different environments and over different seasons. Even when the effect of these minor QTLs is consistent, their introgression into the desired genotype through MABC becomes extremely difficult as a larger number of progenies are required to select appropriate lines. In such cases, MARS has been proposed for pyramiding of superior alleles at different loci/QTLs in a single genotype [64, 65].

It was demonstrated in recent studies that the response of MARS is larger when prior knowledge of the QTLs exists and the response decreases as the knowledge of the number of minor QTL associated with the trait decreases [66]. In sweet corn, MARS was employed to fix six marker loci in two different F_2 populations which showed an increase in the frequency of marker allele from 0.50 to 0.80 [64]. Similarly, in a separate study, enrichment of rust resistance gene (*Lr34/Yr18*) with an increase in frequency from 0.25 to 0.60 was reported in wheat BC_1 through MARS [28]. MARS can be utilized effectively for selection of traits associated with multiple QTLs by increasing the frequency of favorable QTLs or marker alleles. Several companies are using MARS in their maize, soybean, etc., breeding programs [66, 67]. Recently, some institutes like International Crops Research Institute for the Semi-Arid Tropics (ICRISAT), the French Centre for International Agricultural Research (CIRAD), and the University of California-Riverside, USA, have also initiated MARS programs in chickpea (PM Gaur, personal communication 2010), sorghum (J-F Rami, personal communication 2010), cowpea (J Ehlers, personal communication 2010), etc., for pyramiding favorable drought-tolerant alleles.

Genome-Wide or Genomic Selection (GS)

Although MAS has been practiced for the improvement of quantitative traits, it has its own limitations. Therefore, in addition to MARS, Genomic Selection can be used to pyramid favorable alleles for minor effect QTLs at the whole genome level [68, 69]. Genomic selection predicts the breeding values of lines in a population by analyzing their phenotypes and high-density marker scores. A key to the success of GS is that, unlike MABC or MARS, it calculates the marker effects across the entire genome that explains the entire phenotypic variation. In simple terms, genome-wide selection refers to marker-based selection without significance testing and without identifying of a subset of markers associated with the trait [68]. The genome-wide marker data (marker loci or haplotypes) available or generated on the progeny lines, therefore, are used to calculate genomic estimated breeding values (GEBV) as the sum of the effects of all QTLs across the genome, thereby potentially exploiting all the genetic variance for a trait [68, 69]. The GEBVs are calculated for every individual

of the progeny based on genotyping data using a model that was "trained" from the individuals of another training populations having both phenotyping and genotyping data. These GEBVs are then used to select the progeny lines for advancement in the breeding cycle. Thus GS provides a strategy for selection of an individual without phenotypic data by using a model to predict the individual's breeding value [69].

Recently, Wong and Bernardo [70] simulated the comparative responses of phenotypic selection (PS), MARS, and GS with small population sizes in oil palm, and assessed the efficiency of each method in terms of years and cost per unit gain (i.e., the time and cost saved by these different methods over each other for making selection). They used markers significantly associated with the trait to calculate the marker scores in MARS, whereas all markers (without significance tests) to calculate the marker scores in GS. Responses to PS and GS were consistently greater than the response to MARS. Furthermore, with population sizes of $N = 50$ or 70, responses to GS were 4–25% larger than the corresponding responses to PS, depending on the heritability and number of QTLs. In terms of economics, cost per unit gain was 26–57% lower with GS than with PS when markers cost US $1.50 per data point, and 35–65% lower when markers cost $0.15 per data point. Reduction in costs in sequencing and high-throughput marker genotyping may enhance uptake of GS for crop improvement in the future.

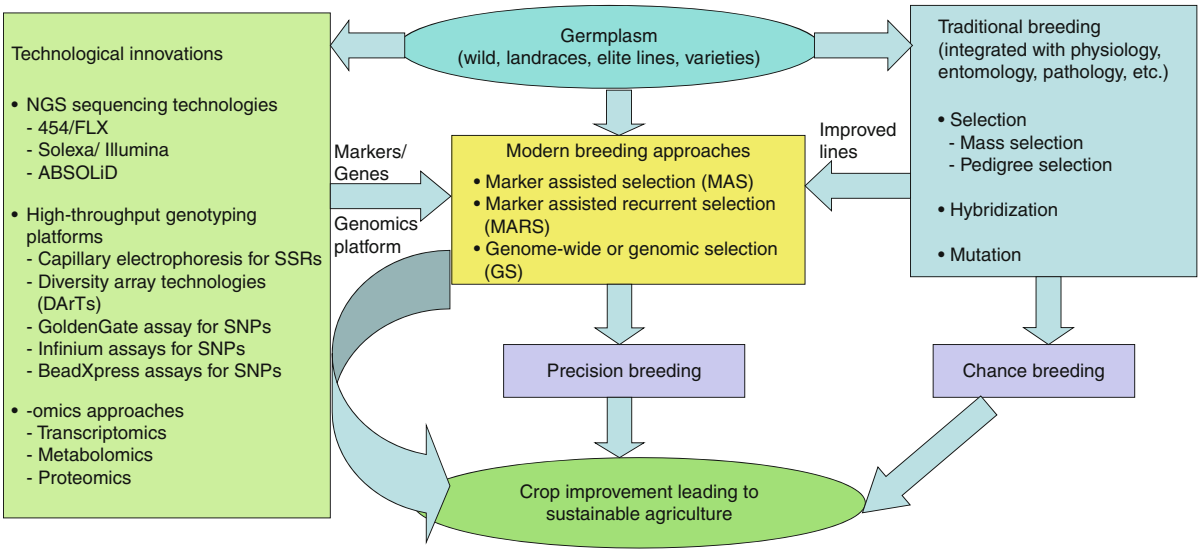
Challenges in Adoption of Genomics Technologies

Developing sustainable approaches to agriculture is one of the most difficult challenges facing growers and scientists today. Agricultural sustainability involves successful management of resources for agriculture to satisfy changing human needs, while maintaining or enhancing the quality of the environment and conserving natural resources [71]. However, sustainable production is hampered by the decline in land and soil productivity as a result of inappropriate soil and water management and other agricultural practices, as well as misguided policies and frequent opposition to technological advances that have the potential to improve the quality of life of billions of people worldwide. This is in addition to the postulated challenges of climate change, the number of hazardous chemicals (pesticides and fungicides) that are constantly being released into the environment and are becoming increasingly toxic to human and animal life [71]. In recent years, the use of promising biotechnology tools like genetic engineering (GE) has offered potential solutions to the above problems. However, the adoption of any new technique, particularly related to genetic engineering, remains a policy matter and as mentioned above faces stiff opposition many a times. In a recent review, Farre et al. [25] addressed several of these issues and advocated to overcome on the major barriers to adoption, which are political rather than technical, for realization of the potential of GE crops in developing countries.

It is thus obvious that the challenges facing agriculture are massive, particularly with the controversies over GE crops world over. It is clear that current methods of food production, in both the developing as well as the developed countries, are neither sufficient nor sustainable [72]. Under these circumstances, genomics interventions have great role to contribute to sustainable agriculture. As mentioned in this article, genomics approaches are very powerful to predict the phenotype, with higher precision and efficiency, based on the genotype. A variety of approaches ranging from MAS to GS are available to become integral part of plant breeding. While in the past, plant breeders were hesitant to use genetic variation existing in wild relatives of crop species in commercial breeding programs due to the long time it takes to recover desired phenotypes because of linkage drag, approaches like AB-QTL, in addition to MAS, can be successfully utilized. Availability of NGS technologies, associated with low costs and high-throughput, offers the opportunity to sequence either entire or major proportion of the germplasm collection for a species present in the gene banks around the word to understand genome variation. In case, the genome variation can be associated with the phenotype, which is not trivial, it will be possible to develop the ideotype, based on haplotype, of the variety to be developed.

Future Directions

While success stories of genomics-assisted breeding are available in several crops, it must also be recognized that much of the genome information generated is not being routinely used by plant breeders, especially in public breeding programs [26]. This may be due to



Crop Breeding for Sustainable Agriculture, Genomics Interventions in. Figure 1
Schematic representation of genomics technologies for crop improvement and sustainable agriculture
In general, traditional crop improvement programs (shown in the box on the right hand side in Fig. 1) employ different breeding strategies integrated with physiology, pathology, entomology, etc., and generate superior lines or improved crop varieties. These approaches, however, take more time, and sometimes such breeding is referred as "chance breeding" due to uncertainty in successes predicted in these approaches. On the other hand, genomics technologies (shown in the box on the left hand side) such as a number of next-generation sequencing (NGS) technologies, availability of high-throughput genotyping such as capillary electrophoresis for large-scale SSR genotyping, microarray-based DArTs, GoldenGate/Infinium/BeadXpress assays for large-scale SNP genotyping, and a range of -omics technologies provide candidate markers, gene(s), and QTLs to be integrated into the breeding programs by using high-throughput genomics platforms. Integrated breeding approaches (shown in the box in the middle) such as marker-assisted selection (MAS), marker-assisted recurrent selection (MARS), and genome-wide selection (GS) offer "precision breeding" with a great potential, versus "chance breeding" to contribute to sustainable crop improvement

shortage of trained personnel, inadequate access to genotyping, inappropriate phenotyping infrastructure, unaffordable bioinformatics systems, and a lack of experience of integrating these new technologies with traditional breeding [4, 26]. However, recently, several international initiatives such as the Integrated Breeding Platform (formerly Molecular Breeding Platform, www.mbp.genertaioncp.org), a joint initiative of The Bill and Melinda Gates Foundation and The Generation Challenge Program, have been started so that plant breeders especially from developing countries can have access to many genotyping, phenotyping, as well as information technologies to integrate their breeding programs with modern genomics approaches.

We believe that integration of modern genomics in combination with other cutting edge technologies in breeding programs is invaluable for crop improvement (Fig. 1) and will lead to sustainable agriculture for food security, especially in developing countries.

A vital task facing the plant breeding community today is to enhance food security in an environmentally friendly and sustainable manner. Though genomics interventions will not solve all the problems associated with agricultural production leading to sustainability, they have the potential, especially when they are used in an integrated manner as described in Fig. 1, to improve the breeding efficiency to address specific problems. These include increasing crop productivity, diversification of crops, enhancing nutritional value of food (biofortification), and reducing environmental impacts of agricultural production. However, only through judicious, rational, and science- and need-based exploitation

of genetic resources through genomic technologies coupled with conventional plant breeding and genetic engineering will lead to sustainable agriculture.

Acknowledgments

We thank the Generation Challenge Program (www.generationcp.org), the Indian Council of Agriculture Research (ICAR) and the Department of Biotechnology (DBT) of Government of India for funding various research projects (RKV) on genomics applications in breeding.

Article Outline

Glossary

Base temperature Lower temperature threshold below which development ceases.

Epigenetics Genetic information other than DNA sequence information.

Phenology Study of the sequence of developmental stages of a plant and how it relates to climate.

Photoperiod sensitivity Requirement for a minimum (or maximum) day length for reproductive phase induction.

Phytomer Fundamental building block of plant canopies. A vegetative phytomer is comprised of leaf, node, internode, and axillary bud.

Phyllochron Rate of appearance of leaves on a shoot.

Shoot apex The tip of the shoot where usually there is meristematic tissue producing new organs.

Thermal time Temperature response curve used to estimate development rate.

Vernalization sensitivity Requirement for a period of low temperatures for reproductive induction.

Definition of the Subject

Plant development, or the progression of plants through their life cycle, has been of great interest in human history because of the need to know and predict when the harvested part of the plant was at the optimum stage. This knowledge was especially important (even vital) in medicinal plants, where the timing of harvesting defines the medicinal value of the product. This interest increased as groups moved from hunting and gathering to agrarian societies.

Crop development can be defined with the number and rate of appearance, growth, and senescence of phytomers. However, that definition lacks information about when the switch of vegetative to reproductive phytomers occurs, which is defined by the phenology of the crop. Crop development is of great importance in agriculture because it is the main mechanism for plants to escape both biotic and abiotic stresses, and adapt to the environment. At a more practical level, it affects the management of the crop because cultural practices are more effective at specific stages of crop development.

Introduction

Major food, feed, and industrial crops were domesticated in a few centers of origin, including the "Fertile Crescent," the Americas, and China. The wild relatives of modern crops were adapted to survival in the environment prevalent in the center of origin. Those original crops were locally grown in the region of origin, but some species showed a significant ability to adapt to new environments and were spread globally with human migrations and trade. For instance, wheat was domesticated in the Middle East (the "Fertile Crescent") [1, 2], around 32°N and is currently cultivated from between 30°N and 60°N and from 27°S to 40°S. However, it can grow beyond those limits, in lower latitudes, in high altitudes, or even in the arctic circle. This range of environments where wheat can grow makes wheat one of the most plastic crops currently grown. It requires a large range of developmental mechanisms to adapt to such different environments, where photoperiods vary from 13–14 h to nearly 20 h. One of the major accomplishments of the "Green Revolution" was the discovery of photoperiod insensitive mutants in wheat that could be grown at lower latitudes.

Plasticity in development is key for the adoption of crops in a wide range of environments. Although growth and development are related, they are different processes. Development is the initiation and

differentiation of organs and the progression of stages through which cells, organs, and plants go during their life cycle, whereas growth is the change in size or weight of the initiated organs. Biotic (e.g., genetics, weeds, and diseases) and abiotic (e.g., temperature, light, water, and nutrients) factors influence the initiation, growth, and senescence of plant organs.

Since the "The Metamorphosis of Plants" by Johann Wolfgang von Goethe, originally published in 1790 [3], there has been extensive research on how plants proceed from germination to maturity in an orderly and predictable manner. This research has led to an extensive conceptual framework of plant development resulting in many tools to predict plant development. Plant shoots develop by forming a series of nearly identical building blocks, called phytomers [4, 5]. The vegetative phytomer is associated to a leaf, and phytomers are produced in an orderly manner on a shoot; for example, the phytomer of leaf 2 is formed after the phytomer of leaf 1.

Phenology is the study of the plant (or animal) life cycle and how it is influenced by seasonal and interannual variations in climate. The phenology of a crop is defined by the sequence of stages, which, in turn, define phases. Identification of certain stages may require examination of the shoot apex. For example, after germination, the apical meristem produces vegetative structures such as leaf primordia. When temperature and photoperiod requirements are met, the shoot apex will start initiating reproductive structures (e.g., spikelet and floret primordia).

The rate of appearance of phytomers and changes at the shoot apex are regulated by the genetics of the plant, the environment, and often an interaction of both. The main environmental drivers of plant development are temperature and photoperiod; their effects on phenology interact with the genetics of the plant responses by photoperiod sensitivity genes, vernalization genes, and earliness *per se*.

This entry covers how plant development is regulated by temperature and photoperiod. Temperate cereals are emphasized because they are adapted to a wide array of environments and show a diverse set of adaptive mechanisms regulating their development. However, defining plant parts and how canopies are built as well as the sequence of events throughout the crop cycle is required before their regulation can be explained. This entry starts by defining the canopy structure and the sequence of events that define the developmental processes of a crop, followed by the current knowledge on how temperature (including vernalization) and photoperiod regulate crop development. This entry finalizes with two important parts: modeling crop development and future directions. Modeling crop development is twofold important; first to understand the physiology and genetic basis of crop development, and second to predict when key developmental events are likely to happen as accurately as possible.

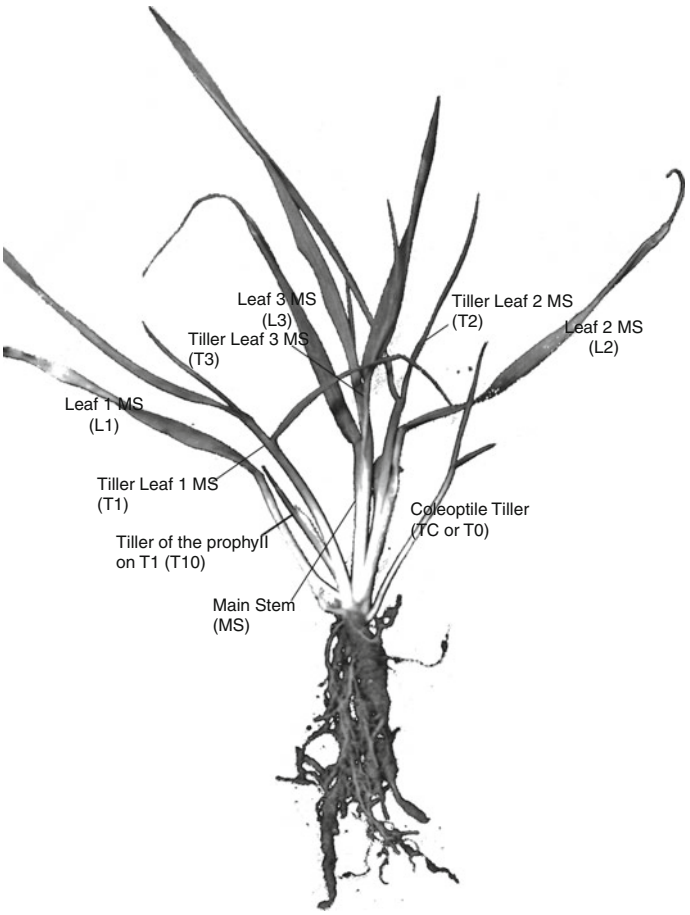
Canopy Structure: Phytomers, Phyllochron, and Plastochron

The phytomer is considered the basic building block of plant canopies and is most commonly defined as the leaf, node, internode above the node, and the axillary bud [6]. Therefore, canopy architecture and development is determined by the dynamic appearance, growth, and abortion/senescence of phytomers (and components of the phytomer). Phytomers originate at the shoot apex with the initiation of a leaf, and the potential for a new shoot is formed with the presence of the axillary bud. The growth and differentiation of each component of a phytomer will lead to their visual appearance. For example, the internode can continue differentiating and growing, resulting in its appearance from the leaf sheath. Tillers may appear when the axillary bud differentiates and grows.

Naming Plant Parts

Because plant development is an orderly process, accurately identifying plant parts aids in describing the process and quantifying the developmental rate.

Several naming systems of plant parts have been proposed, but most are quite similar. For example, true leaves can be numbered acropetally for each shoot with an *L* [7–9] (Fig. 1) beginning with the first foliar leaf, L1 [9]. Similarly, Jewiss [7] proposed a system for naming tillers that has been modified and extended by many, but the modified system proposed by Klepper et al. [8, 9] is increasingly being adopted. This system uses the leaf axil number of the parent shoot to name the tiller. The first shoot to appear from the seed is the main stem (MS).



Crop Development Related to Temperature and Photoperiod. Figure 1
Naming leaves and tillers of a winter wheat plant

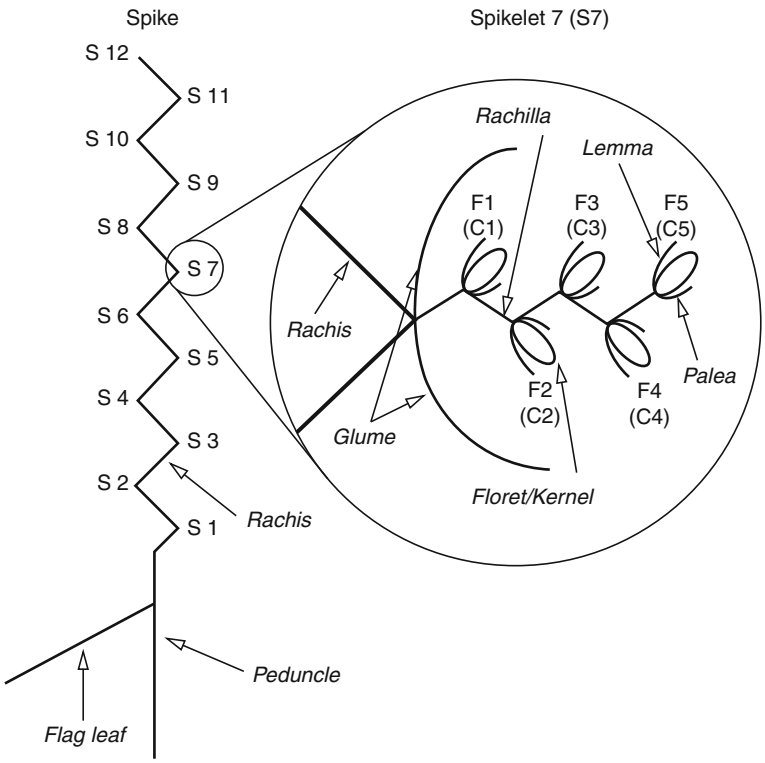
Tillers appearing from the axils of leaves on the main stem are primary tillers and are named with a T and a digit corresponding to the leaf number. For example, the tiller appearing from the first leaf (L1) on the main stem is called T1. This system is however limited by the potential production of tillers from the axil of leaf 10 and above, which rarely happens. Primary tillers can produce tillers that are called secondary tillers. Secondary tillers can arise from the axil of the prophyll of primary tillers and their second digit is a zero (Fig. 1).

Haun [10] proposed a numerical leaf staging system to quantify the number of leaves appearing on the main stem (which can be extended to any shoot):

$$\text{Haunstage} = (n-1) + \frac{L_n}{L_{n-1}}, \left(0 < \frac{L_n}{L_{n-1}} \leq 1\right) \quad (1)$$

where n is the number of leaves that have appeared on a shoot, L_{n-1} is the blade length of the penultimate leaf, and L_n is the blade length of the youngest visible leaf extending from the sheath of the penultimate leaf. Therefore, when a shoot is identified, it can be further characterized using the Haun system. For example, the Haun stage for shoots on the plant shown in Fig. 1 is: MS (5.3), T0 (1.5), T1 (2.4), T2 (1.4), and T3 (0.7). The Haun stage of a tiller with one leaf not fully unfolded is arbitrarily assigned as 0.1 or 0.9 when only the tip of the leaf is visible or most of the leaf blade has appeared, respectively.

Similarly, the leaf and tiller naming scheme has been extended to the wheat inflorescence. Klepper et al. [11] defined a numerical index for the development of the inflorescence and Wilhelm and



Crop Development Related to Temperature and Photoperiod. Figure 2
Naming scheme for reproductive organs of spike inflorescence. Spikelet positions are denoted by the letter S and numbered acropetally along the rachis. Florets/caryopsis positions are denoted by the letters F/C and numbered acropetally along the rachilla (From Wilhelm and McMaster [12])

McMaster [12] extended it to uniquely identify each plant part. Spikelets are named with an S followed by the position from the base of the spike. Then, S1 is the basal spikelet and S2 is the second spikelet from the peduncle (Fig. 2). Florets are designated with an F and numbered acropetally from the base of the rachilla. After fertilization, the letter F designating a floret is changed to a C for caryopsis. This system allows naming reproductive structures in grasses with one spikelet per rachis node such as wheat.

These naming systems of leaves, tillers, spikelets, and florets or caryopsis allow the accurate identification of each plant part. For example, the second caryopsis on the third spikelet on the primary tiller from the axil of the second leaf of a wheat plant would be T2S3C2.

The systems for naming individual plant organs can be easily extended to name vegetative and reproductive wheat phytomers [13]. A phytomer would be denoted with a "P" followed by an "L," if it is a phytomer associated with a leaf or an "S," if it is a reproductive phytomer and the leaf or spikelet number. The name of the shoot can be added to identify the tiller being described. For example, MS PL2 is the second phytomer on the main stem and T1 PS1 is the basal spikelet phytomer in the spike of the first tiller.

Dynamic Appearance of Plant Organs: The Plastochron and Phyllochron

The naming systems of plant parts described earlier are the landmarks to describe the development and structure of a wheat plant. However, plant development is a dynamic process that follows the formation, growth, and senescence of phytomers and their components resulting in a continually changing architecture.

The creation of the vegetative phytomer is dependent on the initiation of the leaf primordium. Therefore, the rate of leaf primordia initiation controls the timing of phytomer formation. The plastochron was first defined as the interval between the formation of two successive internode cells of the green alga *Nitella flexilis* [14], as cited in [15]. Milthorpe [16] and Esau [17] defined the plastochron as the interval between the formations of successive leaf primordia at the shoot apex, which is now commonly accepted. Similarly, the phyllochron was defined as the interval between appearances of consecutive leaves on a shoot [18] as cited in [6]. Wilhelm and McMaster [6] further refine the definition of phyllochron by defining appearance as "visible without magnification, dissection or changing leaf display." The inverse of the phyllochron is termed development rate (DR), which can be generalized as the inverse of the time interval between two developmental events. The relationship between the plastochron and the phyllochron depends on the species. In wheat, leaf primordia are produced more rapidly than they appear, suggesting that different mechanisms are involved in regulating each process. Leaf primordia are initiated at the meristem on the shoot apex, where new cells are produced very quickly. After a leaf primordium is formed, it continues to grow in cell number and cell size, but this growth does not happen at the shoot apex meristem, rather at the intercalary meristem at the base of the leaf. The amount a leaf grows until it appears through the curl of leaves is much larger than the growth involved in forming a leaf primordia, therefore it is more dependent on the available resources (e.g., water, carbohydrates, and nutrients).

Developmental Stages and Phases: Phenology

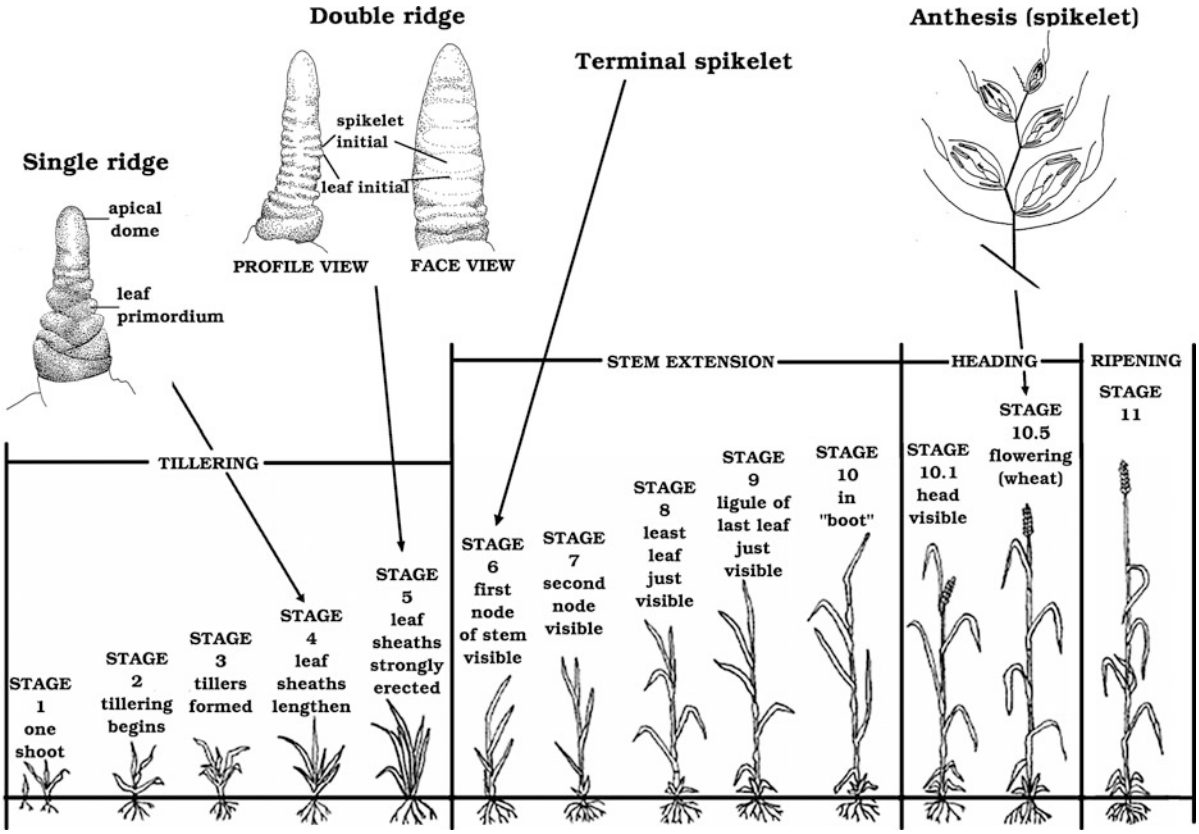
Plants develop by the repetition of elementary building blocks (i.e., phytomers), whose morphological, dimensional, functional, and anatomical features change during ontogeny and according to several processes called heteroblasty, phase change, life stages, maturation, aging, age states, or morphogenetic progression [19]. In this entry, those changes will be referred as *developmental stages* (or simply *stages*) and the time between stages will be referred as *developmental phases* (or *phases*). It is common in the literature referring to these stages as "growth stages." However, there is little growth in some developmental events such as anthesis. The phenology of a crop is the ordered succession of stages and phases that can have different lengths determined by internal factors (e.g., the genetics of a variety or species) or biotic and abiotic external factors (e.g., diseases, temperature, light, and nutrients).

Plant development can broadly be divided into vegetative and reproductive phases that often overlap. The switch from vegetative to reproductive phase happens at the meristem level, which stops producing vegetative phytomers (i.e., leaves, nodes, and internodes) to start producing reproductive phytomers (rachis, spikelets, and florets).

Phenological Scales

Developmental stages occur in a consistent pattern in a crop each year and numerous approaches exist that characterize crop phenology. The most widely used phenological scales for temperate cereals are Feekes [20], Zadoks [21], Haun [10], and BBCH [22]. The Feekes scale is shown in Fig. 3 and described, jointly with the Zadoks' decimal code, in Table 1. The BBCH scale for cereals is mainly based on the Zadoks scale, and the Haun scale primarily describes the development of shoots until the last leaf is fully expanded.

Phenological scales consider basic developmental stages like germination, emergence, tillering, stem elongation, heading, flowering, grain filling, and physiological maturity, with differences among scales primarily in how much detail each stage is characterized. Some developmental stages are not well defined, leading to confusion in measuring and reporting these stages. For example, the beginning of stem elongation is usually recorded as the jointing date or when the first node is visible above ground; however, the first node is formed when the apex is underground and is only visible after the stem has elongated sufficiently to elevate the apex and the node above ground. Likewise, physiological maturity is defined as when the maximum dry weight is reached. In wheat, determining physiological maturity is somewhat difficult because there is not a clear morphological change in the plant morphology as it happens in maize (and sunflower). In maize, a black layer near the base of the kernel appears when the maximum dry weight is reached. The Feekes scale defines harvest maturity as when the grain is



Crop Development Related to Temperature and Photoperiod. Figure 3
Feekes developmental scale with the approximate timing of some shoot apex developmental events (From [13])

difficult to divide along the crease and Zadoks [21] defines the 90% of ripeness of rice (*Oryza sativa* L.) when the kernel cannot be dented with the fingernail. These definitions likely are not precisely correlated with maximum seed biomass. Therefore, it is now commonly accepted practice to assume physiological maturity for temperate cereals occurs when all green color has disappeared from the spike. This definition seems reasonable as leaves and internodes have long since lost all green color so that no photosynthesis occurs, and there is no report showing retranslocation from carbohydrate reserves to the grain at this time.

Regulation of Crop Development

Plant development is highly dependent on temperature, which controls the rate of development and the switch from vegetative to reproductive states. Both high and low temperatures may have a major effect on plant development, especially controlling the switch to the reproductive state. For example, winter wheat requires a period of low temperatures to start producing reproductive structures (vernalization). The length of the cold period varies with genotype.

Besides vernalization, day length (or photoperiod) modifies the temperature-controlled rate of development. Photoperiod refers to the number of daylight hours, which changes through the seasons and with latitude. Photoperiod increases after the winter solstice (December 21 in the northern hemisphere or June 21 in the southern hemisphere) and decreases after the summer solstice. Crops and genotypes vary in their sensitivity to photoperiod and the minimum amount of daylight required to switch from vegetative to reproductive phases.

Developmental Response to Temperature

The relationship between temperature and phenology has been long recognized. Temperature is a better

Crop Development Related to Temperature and Photoperiod. Table 1 Description of the main developmental stages according to Feekes [20] and Zadoks [21], and suggested measurements characteristics (Modified from [23])

Stage or phase	Description		Measurement characteristics
	Feekes	Zadoks	
Germination	No stage	Stages: 00 – dry seed, 01 – beginning of imbibition, 03 – imbibition complete, 05 – radicle emerged from caryopsis, 07 – coleoptile emerged from caryopsis	Beginning of imbibition: Seed begins to swell
Emergence	Stage 1 – main shoot only	Stage 09 – leaf at the tip of the coleoptile	Beginning of emergence: First true leaf emerges through the coleoptile and the tip is visible above the soil surface
Tillering	Stage 2 – beginning of tillering	Stages 21–29 – main stem plus 1 to 9 tillers	Beginning of tillering: The first tiller is visible
Single ridge	No stage	No stage	Shoot apex shape changes from dome to more elongated and leaf primordia begin to form a ridge around the apex
Double ridge	No stage	No stage	Formation of double ridges around the apex. Bottom ridge is leaf primordia and top ridge is spikelet primordia
Terminal spikelet	No stage	No stage	Apical spikelet primordium appears and noted by a 90° rotation from the plane of previous spikelets
Jointing	Stage 6 – first node visible	Implicit in stage 31 – first node detectable and change of plant habit from prostrate to erect	First node visible above the soil surface
Stem elongation	Stages: 4 – change of plant habit from prostrate to erect, 5 – pseudo-stem clearly erect, 6 – first node visible, 7 – second node visible, 8 – last leaf appearance, 9 – last leaf ligule visible, 10 – last leaf sheath swelling	Stages: 30 – pseudo-stem erect, 31 to 36 first to sixth node detectable, 39 – flag leaf ligule visible, 43 to 49 – flag leaf sheath swelling	Beginning when the first node is formed, usually below soil surface, and pushed above the soil surface
Flag leaf	Stage 9 – last leaf ligule visible	Stage 39 – Flag leaf ligule visible	Ligule of last leaf is visible and no new leaf is emerging

Crop Development Related to Temperature and Photoperiod. Table 1 (Continued)

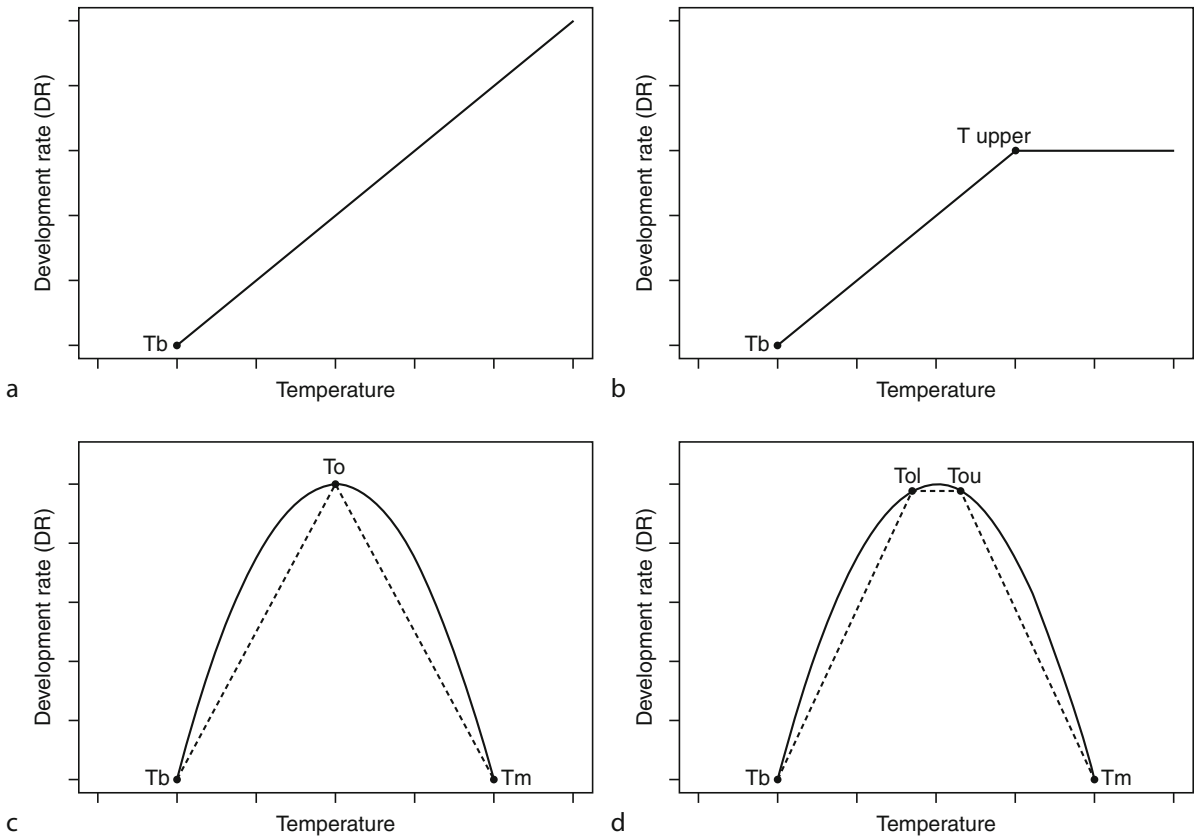
Stage or phase	Description		Measurement characteristics
	Feekes	Zadoks	
Booting	Stage 10 – last leaf sheath visible	Stages 43–49 – flag leaf sheath swelling	Begins at flag leaf and ends at heading
Heading	Stages: 10.1 – first ears just visible, 10.2 – ¼ of heading completed, 10.3 – ½ of heading completed, 10.4 – ¾ of heading completed, 10.5 – all ears out of the sheath	Stages: 51 – first spikelet just visible, 53 – ¼ of the inflorescence visible, 55 – ½ of the inflorescence visible, 57 – ¾ of the inflorescence visible, and 59 – inflorescence completely emerged	Begins when first spikelet is visible and ends when the inflorescence is fully emerged
Anthesis	Stages: 10.5.1 – anthesis starts, 10.5.2 – flowering completed to the top of the ear, 10.5.3 – flowering completed to the bottom of the ear, 10.5.4 – flowering over/kernel watery ripe	Stages: 61 – beginning of anthesis, 65 – mid-anthesis, 69 – anthesis completed	Starts when the first anther is visible on an inflorescence and ends when no more anthers appear on the inflorescence
Grain filling	Stages: 10.5.4, 11.1 – milky ripe, 11.2 – mealy ripe	Stages: 71 to 77 – milk grain, 83–87 – dough grain	Begins at fertilization, usually considered anthesis and ends at physiological maturity
Physiological maturity		No Stage	When all spike components, internodes, and leaves lose green color
Ripening	Stages: 11.3 – kernel hard, 11.4 – ripe for cutting	Stages 91–99	Ripening and dormancy

predictor of many developmental processes than calendar time. Reamur [24] formalized this relationship by creating the concept of heat units, now referred to as thermal time. The relationship between temperature and developmental rate is a curve with a maximum development rate at the optimum temperature (T_o) and developmental rate reaching zero at temperatures below the base temperature (T_b) or above the maximum temperature (T_m; Fig. 4). This nonlinear relationship is shown in several studies [25, 26].

Thermal time has two components: (1) the average temperature (T_a) over some time interval (e.g., hourly, daily), and (2) a temperature response curve describing the effectiveness of T_a on the development rate for the process (e.g., phyllochron, phenology). T_a is the integral of temperature over the time period of interest; however, in practice the average of the maximum and minimum temperatures in the time interval is often used:

$$T_a = \frac{T_{max} + T_{min}}{2} \quad (2)$$

This approximation is fairly accurate, but its error increases with deviations of from 12 h photoperiods and if sudden changes in temperature happen within the time interval. The time interval mostly depends on data availability, but common intervals range from daily to hourly time intervals, with daily the most commonly used. There are many temperature–response curves, which greatly diversifies the



Crop Development Related to Temperature and Photoperiod. Figure 4

Development rate as a function of temperature. Temperature response curves: (**a**) linear response, (**b**) extended linear response with an upper temperature threshold, (**c**) bilinear model with two zero development temperatures (base temperature, T_b, and maximum temperature, T_m) and an optimal temperature (T_o), and (**d**) trilinear model with two zero development temperatures (T_b and T_m) and a range of optimal temperatures defined by optimal lower temperature (T_{ol}) and optimal upper temperature (T_{ou})

calculation of thermal time (Tt). The most simple form is a linear relationship with the temperature at which there is some plant development (Fig. 4a), i.e., the difference between T_a and the temperature at which development is zero or base temperature (T_b):

$$Tt = T_a - T_b, (Tt \geq 0) \quad (3)$$

where thermal time is expressed as growing degree-days (GGD, °C·days). Modifying Eq. 2 to include a maximum development rate (Fig. 4b) is useful if plants are grown at higher temperatures. Given that the relationship between temperature and development rate is not linear [25–27], further refinements to the accumulation of thermal time can include changing the development rate based on certain cardinal temperatures (Fig. 4c, d). These approaches assume development rate increases with temperatures above T_b until an optimum temperature (T_o, or a range of optimal temperatures, T_{ol} to T_{ou}) is reached, and then decreases until development stops at a maximum temperature (T_m). This can be approximated by two- or three-segmented linear models, or curvilinear models such as a quadratic curve [25] or beta distribution [27, 28].

Vernalization

The term vernalization was first used by Lysenko in 1928, but research on the need of a cold period for

winter cereals to flower started as early as 1857 [29]. Vernalization can be viewed as an adaptive mechanism to avoid unfavorable periods for development (e.g., winter) and ensure flower development and subsequent seed growth occurs under favorable conditions (e.g., spring and summer). Hence, vernalization synchronizes plant development with seasonal climate changes.

Commonly, genotypes requiring vernalization are referred to as "winter" wheat (or "winter" barley) and are normally planted late summer or early fall with vernalization occurring during the late fall or early winter. Conversely, "spring" genotypes are commonly viewed as not requiring vernalization, and normally are planted in the spring or in regions where temperatures are often above effective vernalizing temperatures. This well-entrenched distinction between "winter" and "spring" genotypes does not reflect that "spring" genotypes (1) often have at least some vernalization requirements, (2) reach flowering faster if experiencing vernalizing temperatures, and (3) mask the continuum of vernalization requirements present among all wheat genotypes.

Effective vernalizing temperatures range from 0° C to 10° C [30], and a few weeks of cold are usually sufficient to promote the switch from vegetative to reproductive phases and longer periods of cold temperatures can shorten the time to flowering until the vernalization response is saturated [30]. Genotypes vary in the length of the cold period required to saturate the vernalization response. For instance, time to flowering in wheat was reduced in response to longer cold periods [31, 32], and interestingly, genotypes thought to require vernalization to flower eventually flowered without undergoing vernalization treatment [32]. Quantifying responses to varying periods of vernalizing temperatures in calendar time or thermal time does not reflect the biology of the response. A better method to quantify the effects of vernalization would be by counting the number of leaves produced at flowering time [33]. Using this quantification method, vernalization reduces the time to flowering by reducing the number of leaves being produced rather than the phyllochron [31, 33]. That is, the number of leaves produced at flowering increases with shorter vernalization periods, while the phyllochron is not affected by the duration of the vernalization period.

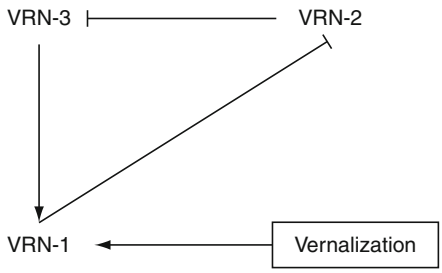
Genetic Regulation of Vernalization Although the mechanisms by which plants sense cold and initiate the cellular signaling to induce flowering are not known, the genetic regulation of vernalization is fairly well known in cereals like wheat and barley, which benefited of the research done on the model plant *Arabidopsis thaliana*. Four major genes are involved in the expression of vernalization sensitivity in wheat and barley, *VRN-1*, *VRN-2*, *VRN-3*, and *VRN-4*. The first three genes have been cloned and identified [34–36]. However, these three genes do not explain the spring habit of all varieties [35], suggesting that other genetic mechanisms may be involved.

The *VRN-1* gene encodes the MADS box transcription factor similar to *APETALA-1*, which is responsible for meristem identity in several plants [34]. This gene is up-regulated by vernalizing temperatures and the degree at which it is up-regulated depends on the length of the vernalization period. However, spring varieties also show an up-regulation of *VRN-1* during the initiation of the reproductive phase and remain high throughout the reproductive phase, suggesting an involvement of *VRN-1* in meristem identity but not limited to vernalization response.

The *VRN-2* gene encodes the *ZCCT1* protein, which shows high similarity to the CCT domain of the *Arabidopsis CONSTANS* and *CONSTANS*-like genes. *VRN-2* represses flowering and is down-regulated by vernalization [35]. The spring allele *vrn-2* in wheat has a point mutation at the CCT domain that replaces an arginine with a tryptophan. It has been suggested that the CCT domain may be involved in protein–protein interactions [37], so a mutation in this domain can alter these interactions.

The *VRN-3* gene is a RAF kinase inhibitor like protein with high homology to the *Arabidopsis FLOWERING LOCUS T* (*FT*) gene [36], which induces flowering when expressed. *FT* is a flowering signal that moves from leaves to stem apices.

VRN-1, *VRN-2*, and *VRN-3* interact with each other regulating flowering under the vernalization pathway (Fig. 5). Before vernalization occurs, *VRN-2* is expressed and represses the expression of *VRN-3*. When plants are vernalized, *VRN-1* is induced and it represses the expression of *VRN-2*, allowing *VRN-3* to express and promote flowering. At the same time, there is a feedback mechanism by which *VRN-3* up-regulates



Crop Development Related to Temperature and Photoperiod. Figure 5
Model of the vernalization pathway in temperate cereals. Arrows mean induction (or up-regulation) of gene expression; for example, vernalization induces the expression of VRN-1. Bar-headed lines mean repression (or down-regulation) of gene expression; for example, VRN-2 represses the expression of VRN-3

VRN-1. It seems that *VRN-1* is the primary target of vernalization and is essential for flowering.

VRN-4 has been recently fine mapped and its cloning is underway [38]. Identifying and including this gene in the vernalization pathway may increase the understanding of vernalization responses in wheat.

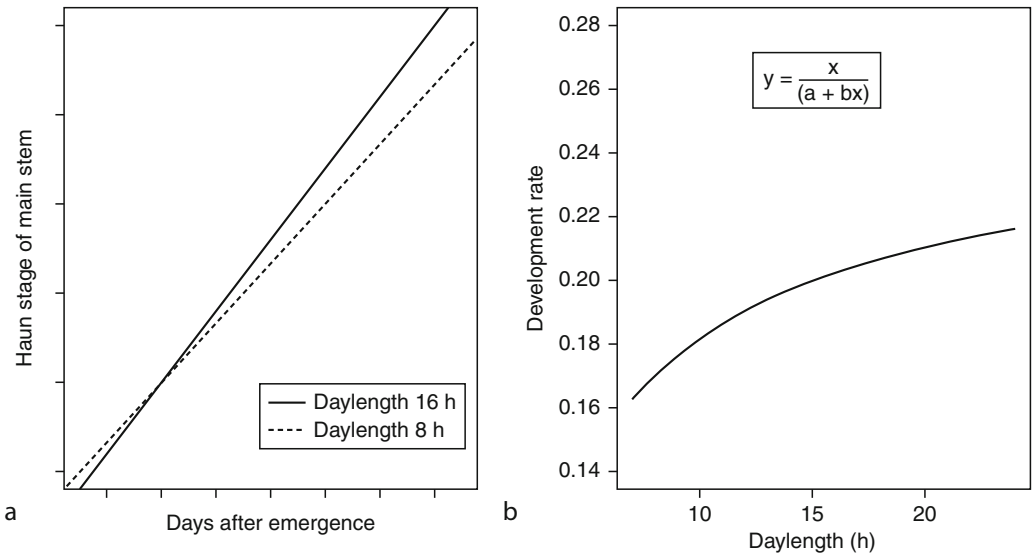
Photoperiod

Photoperiod can be defined as the number of hours of light in a 24-h period, which changes throughout the season depending on the latitude. It has been long recognized that plants, including crops, normally flower only when the length of the day was favorable [39]. Crops sense the amount of light they receive daily and respond to it by accelerating or slowing their development. There is, however, genetic variation of a quantitative nature in the response to photoperiod within a crop, meaning that different varieties respond differently to changes in the photoperiod, and some show no response to photoperiod (or are photoperiod insensitive). Photoperiod sensitivity is thought to be the wild type phenotype because it is wide spread in wild barley (*Hordeum spontaneum* L.) and confers strong adaptive features in the center of origin of barley, where there might be late spring frosts. Photoperiod insensitivity, however, brings wide geographical adaptability because plants do not require long days to flower, and, hence, they are suitable for environments with short seasons or latitudes where long days do not occur. For example, in wheat, day length neutrality, jointly with semi-dwarfism and rust resistance traits, were used to develop the high yielding varieties of the "green revolution" [40]. Photoperiod insensitivity promotes earliness thought to be a desirable adaptive trait for environments closer to the equator where high temperatures and drought can be expected at the end of the season. Therefore, earliness allows wheat and barley varieties to escape this terminal stress.

Although the rate of development mainly responds to temperature, when temperature is fixed, longer photoperiod alters the development rate by shortening the phyllochron [41, 42]. In Fig. 6, the appearance of leaves over time follows a linear model when plants are grown at a constant temperature, and the rate of appearance (slope of the curve) increases with the photoperiod; however, as day length increases, fewer leaves are formed per hour of light, hence there is a reduction in photoperiod efficiency for leaf emergence.

Different crops respond differently to photoperiod; crops can be classified as long day (LD) and short day (SD) depending on which photoperiod accelerates development (promotes flowering). Temperate cereals are long-day crops because flowering is promoted by photoperiod longer than 12–14 h, while maize and rice are short-day crops, meaning that short days induce the switch to reproductive phase. In wheat and barley, increased photoperiod shortens the time to flowering by modifying the length from emergence to terminal spikelet initiation. The effects of photoperiod on the duration from terminal spikelet initiation to flowering depend on what environments they are measured (field versus controlled environments). This reduction of time to flowering is not only due to an accelerated phyllochron, but also by the production of fewer leaves.

Genetic Regulation of Photoperiod Sensitivity In temperate cereals, such as wheat and barley, sensitivity to photoperiod is mainly regulated by *Ppd* genes. Homologous genes have been identified in wheat and barley and have the function of a pseudo response regulator (*PRR*), most similar to the *Arabidopsis PRR7* [43]. The *PPR* proteins are characterized by a pseudo receiver domain near the amino-terminus and a CCT domain near the carboxy-terminus [44], which makes



Crop Development Related to Temperature and Photoperiod. Figure 6
Development rate responses to changes in day length at constant temperature. (**a**) Leaf appearance of plants grown in different day lengths and (**b**) development rate as a function of day length (Based on [41])

them distantly related to other CCT domains important in regulation of flowering such as *CONSTANS* [45] and *VRN-2* [35].

The photoperiod insensitive allele (*ppd-H1*) in barley slightly delays the gene expression of *CONSTANS* (*HvCO1*) that follows a circadian pattern [43] and is a transcriptional regulator of the *FT* gene [46]. In contrast, photoperiod insensitivity in wheat is regulated by a series of three homoeologous genes located in the colinear region on chromosome 2 group, which seem to be upstream of the *CONSTANS* gene in the photoperiod pathway (Fig. 7). The *Ppd-1 Da* allele confers insensitivity to photoperiod in a semidominant fashion, allowing wheat plants to flower regardless of the photoperiod [47]. Sequence analysis of wheat varieties known to have this mutation shows that there is a 2,089 bp deletion upstream of the coding region responsible for the photoperiod insensitivity phenotype. Other sequence variations producing nonfunctional proteins (*null* alleles) at the 2A and 2D genes in wheat have been observed; however their effects on photoperiod sensitivity are difficult to assess because they might be masked by functional proteins from other homoeologous genes. These, and other mutations, however, may have a quantitative effect in photoperiod sensitivity and flowering time [47].

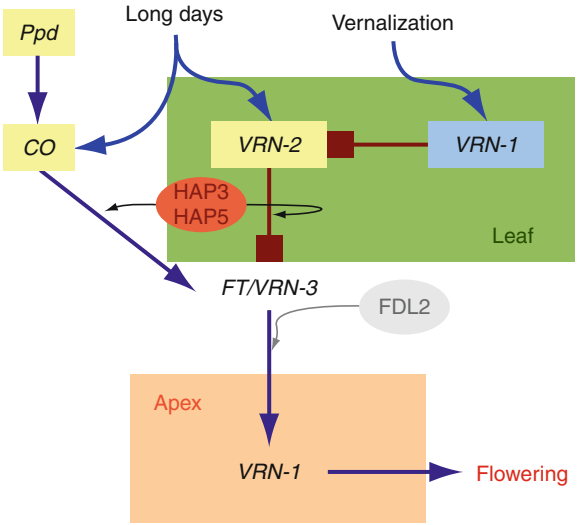
Model of the photoperiod pathway of flowering time. Arrows mean induction (or up-regulation) of gene expression; for example, CONSTANS is induced by the expression of *Ppd* genes

Coordinated Temperature and Photoperiod Regulation of Crop Development

The temperature and photoperiod regulation of crop development has been described in previous parts of this article, but both environmental factors act in coordination. It is clear that the phyllochron varies with planting date in temperate cereals and it has been suggested that the phyllochron is fixed by the rate of change of the photoperiod at crop emergence [48]. However, in general, temperature and photoperiod change together in the field. Results from experiments

in controlled environments show an effect of photoperiod on the temperature–response curve [49, 50]. The term "thermo–photo ratio" (the degree-days divided by day length in hours) has been used to study the coordinated effect of temperature and photoperiod on the phyllochron [49]. A linear relationship was found between the phyllochron and the thermo–photo ratio under both controlled environments and field conditions [49]. Slafer and Rawson [51] partitioned the photoperiod sensitivity of wheat phenophases into different parameters, which were affected by temperature, describing an interaction between genotype, photoperiod, and temperature. The effect of planting date on crop development has been studied extensively, yet it is difficult to draw conclusions of the coordinated effect of photoperiod and temperature on crop development. This is because when planting date is changed, both photoperiod and temperature are changed and their effects are difficult to separate.



Crop Development Related to Temperature and Photoperiod. Figure 8
Model of flowering related to photoperiod and vernalization. *Thick blue arrows* mean induction (or up-regulation) of gene expression or developmental process; for instance, photoperiod induces the expression of *VRN-2*. Square headed lines indicate repression (or down-regulation) of gene expression; for instance, VRN-3 up-regulates *VRN-1* at the apex

Genetic Framework of Flowering Time Several pathways regulate time to flowering in crops, namely, vernalization, photoperiod, autonomous, and gibberellic acid. The vernalization and photoperiod pathways have been described in parts 5.2 and 5.3 and *FT/VRN-3* gene is in both pathways, thus integrating the response to both vernalization and photoperiod factors (Figs. 5, 7, 8).

In the ancestral form of wheat and barley, after germination in the fall *VRN-2* is highly expressed by the long days and represses the expression of *FT/VRN-3*. As winter progresses, the photoperiod decreases and low temperatures induce the expression of *VRN-1* in the leaves, which represses the expression of *VRN-2*, allowing *FT* to be expressed by long days in the spring, a process regulated by photoperiod genes *Ppd* and *CO*. Then, the protein encoded by *FT/VRN-3* is translocated to the shoot apex, where it up-regulates *VRN-1*, which will induce the switch to reproductive phase. The HAP (HEME ACTIVATOR PROTEINS) complexes may mediate the transcriptional regulation of the CCT domain of *CO* and *VRN-2*. In plants, HAP subunits are encoded by multiple genes that, together with CCT domain proteins that can interact with HAP complexes, generate a large number of molecular combinations. These combinations provide a flexible signaling system that can integrate responses to environmental cues as photoperiod, vernalization, or stress (reviewed in [52]).

In environments where temperate cereals usually grow and were domesticated, vernalization requirements are met long before the photoperiod is inductive of the reproduction phase. This requires plants to "remember" they had been vernalized. The mechanism by which temperate crops "remember" vernalization is not known, but it has been studied in the model plant *Arabidopsis*. In addition to the genetic information carried on the DNA sequence (genes and alleles), chromatin structure is recognized as another source of genetic information. The chromatin can be highly condensed (heterochromatin) or more relaxed (euchromatin). The DNA is combined with proteins called histones and specific covalent histone modifications of histones favor the formation of chromatin structure that influences the level of gene expression. Other nongenetic mechanisms of gene expression are related to DNA

methylation. The DNA methylation at the promoter region of genes is generally related to lower levels of gene expression, and even gene silencing. Of the two mechanisms, it seems that histone modifications are involved in regulating the memory of vernalization (reviewed in [53]) in *Arabidopsis*. In *Arabidopsis*, the *FT* gene is repressed by *FLC*, which is down-regulated by vernalization. The stable repression of *FLC* involves de-acetylation of histone 3 (H3) upstream of *FLC*, methylation of H3 Lys9 and Lys27, which allows the binding of HP1 inducing the stable silencing of *FLC*.

Less known is the genetic basis of the quantitative response to temperature (thermal–response curve). The *Earliness* per se *A1* (*Eps^{m}A1*) gene affects time to flowering by reducing the vegetative phase and it has been associated with responses to temperature, probably by modifying the optimum temperature [54]. Two candidate genes for *Eps^{m}A1* are located in the genomic region where this gene has been located, *Mot1* and *FtsH4* [55]. The *Mot1* gene has features of the SNF2 family of transcriptional regulators. Other members of this family have been related to regulation of flowering in *Arabidopsis*, but the gene expression data do not show differences between the two alternative alleles [55]. The *FstH4* is a member of the FstH family of proteases and is homologous to the *Arabidopsis FstH4*, which has been found highly expressed in seed, and mutants in this gene show delayed germination that is carried over the growth cycle [55].

Modeling Approaches

For centuries, people have wanted to understand and predict aspects of crop development, particularly phenology. To do this, different conceptual, statistical, and mathematical models have been developed. Beginning in the 1970s, a variety of digital technologies began to emerge, one of which was crop simulation models for predicting growth, development, and yield. This section presents a broad overview of these crop simulation models, emphasizing wheat.

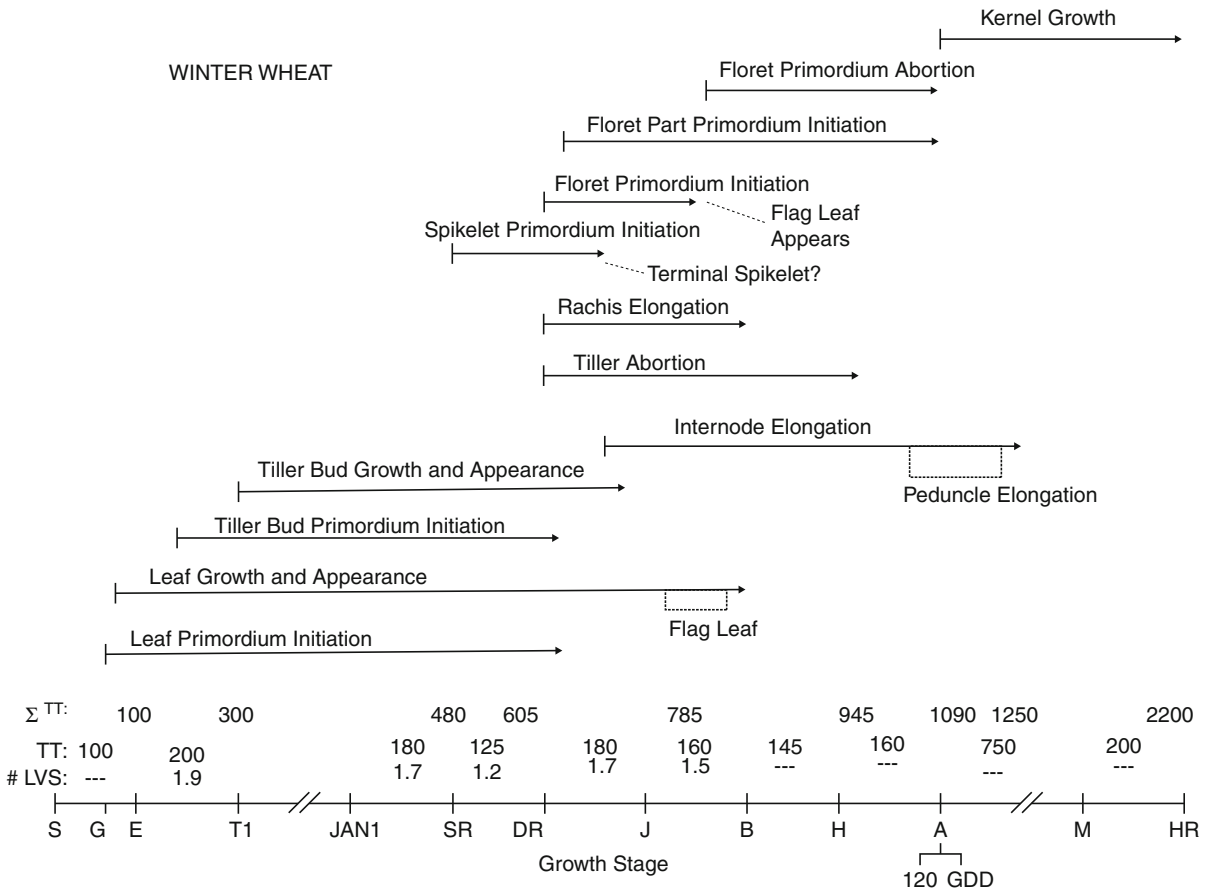
Many crop simulation models exist for simulating growth, development, and yield, and they cover scales from specific processes to the agroecosystem. Crop simulation models are a simplified mathematical representation of the plant. At the most fundamental level [56], crop simulation models generally simulate a trait, for example, yield (Y), as the function of daily growth rate (GR) that is partitioned to the yield component (P) and integrated over a daily time step from emergence (*emerge*) through physiological maturity (*maturity*):

$$Y = \int GR * P \tag{4}$$

Implementing Eq. 3 in a model usually begins assuming non-limiting conditions, thereby allowing for potential production to be estimated. The parameters can either be generic for a crop or adjusted to a specific genotype. By incorporating environmental variables (e.g., temperature, water, light, CO_2, and nutrients), crop simulation models can examine crop or genotype responses across a broad environmental range of limiting conditions, avoiding a common limitation of statistical (or regression) models. Depending on the purposes, including the role of biotic factors or management practices may also be important.

How a model implements Eq. 3 depends on model objectives and interests of the model developers. The earliest crop simulation models tended to focus on the scale of whole-plant growth and development, with little detail on processes at lower scales. These models use an energy- or light-driven approach to determine the growth rate, and this approach remains popular today. The basic approach simulates leaf area index on a daily time step, which is used to capture energy/sunlight and produce biomass that is then distributed to basic plant components of leaves (providing the feedback to the cycle), stems, roots, and seeds. Partitioning coefficients are often used to allocate the biomass produced, and phenology sub-models are essential in accurately predicting the timing when sources and sinks are present, and changing partitioning coefficients based on developmental stage.

As crop simulation modeling progressed, certain trends emerged. First, greater attention focused on representing plant processes below the whole-plant level. In general, energy- or light-driven modeling emphasized functional physiology, particularly for assessing energy balance and leaf functioning at the individual organ level (e.g., [57, 58]). Second, considerable research on crop development during the 1970s



Crop Development Related to Temperature and Photoperiod. Figure 9
Developmental sequence diagram of a generic winter wheat for optimal conditions. Question marks refer to uncertainty, important cultivar variation, or conflicting reports in the literature. Time line legend is TT is the thermal time for the interval; #LVS is number of leaves for the interval; S, sowing date; G, germination; E, seedling emergence; TI, tiller initiation/appearance; SR, single ridge stage; DR, double ridge stage; J, jointing; B, booting; H, heading; A, anthesis; and M, physiological maturity (From [59])

and 1980s undoubtedly spurred interest in including this new knowledge in the models. This led to alternative modeling approaches based on more developmentally driven approaches that recognized that plant development is orderly and predictable based on basic units (i.e., the phytomer) that dynamically appear, grow, and senesce over time as discussed earlier in this entry and shown in Fig. 9.

Early efforts beginning in the mid-1980s focused on developmental concepts such as leaf appearance (the phyllochron) and tillering that led to more accurate representation of canopy architecture. For instance, the AFRCWHEAT1/2 model developed in Europe [60–62] contained detailed tillering and leaf dynamics sub-models (e.g., appearance, growth, and senescence/abortion), and the resulting effect on canopy LAI was simulated and then used to estimate biomass. Simultaneously and independently, another effort was underway in the USA that resulted in the developmentally driven MODWht3 [63] and SHOOTGRO [http://arsagsoftware.ars.usda.gov, [59, 64–67]] models. SHOOTGRO is slightly more developmentally detailed for canopy processes than MODWht3, but less detailed in the root system and simulating biomass production.

SHOOTGRO provides the foundation to simulate the development and growth of individual phytomers (and phytomer components as shown in Fig. 9) on each morphologically identified shoot (main stem and tillers) on the median plant of up to six age classes, or cohorts, based on time of seedling emergence.

The Sirius model has one of the most developed and robust leaf appearance sub-models of any wheat simulation model [68]. As with the MODWht3 and SHOOTGRO models, the assumption used is that the developmental "clock" from emergence to anthesis is best represented by the rate of leaf appearance and final number of leaves, rather than thermal time. Based on vernalization requirement and photoperiod sensitivity of the variety being simulated and leaf ontogeny, the final leaf number is determined [69, 70]. This allows for an elegant quantitative description of both spring and winter wheat leaf appearance and integration with developmental events.

Regardless of modeling approach and goals, the ability to simulate genotype phenology across a broad range of environments for major crops such as wheat has been quite reliable. Many alternative approaches exist for predicting phenology, and approaches differ in input requirements and number of developmental stages simulated. Essentially all models are based on the thermal time approach, reflecting the importance of temperature discussed in Section Developmental Response to Temperature. An alternative to a strict thermal time approach, particularly for small-grain cereals, has been to use leaf numbers to estimate the time interval between developmental stages. In phenology sub-models, temperature effects are well considered, but rarely are the effects of water deficits (or nutrient availability) considered [71]. Exceptions include the SHOOTGRO model and PhenologyMMS (http://arsagsoftware/ars.usda.gov).

Determining plant parameters and how to address the genotype by environment interaction are common concerns for all models. With the explosion of genome mapping and molecular biology research, opportunities for understanding and resolving these issues are emerging [72–74]. For example, the presence or absence of known alleles influencing a trait can be used to determine the parameters used in the algorithm representing the process [75] or the response to environmental factors [76]. Clarification of gene networks controlling processes such as time of flowering has considerably advanced the understanding and simulation of these processes [77].

Crop simulation modeling is increasingly benefiting from the advent of object-oriented design and programming languages such as C++, C#, and Java, both in terms of developing and maintaining models as well as providing greater flexibility in representing plant processes within models. Initial object-oriented designs tended to view the plant as a collection of objects that equate to leaf, stem, root, and seed components. Recent attempts have begun to incorporate the phytomer approach of building plant canopies into the object-oriented design that can also be scaled up, or aggregated, into lower levels of resolution, such as the seed component of earlier designs [78–80].

Future Directions

Crop development is regulated by environmental factors that interact with the genetics of the plant. Many developmental responses related to temperature and photoperiod are well known and it is possible to predict them reasonably well at the crop level. Similarly, rapidly emerging knowledge from genomics research is helping to provide understanding of the genetic basis of certain aspects of crop development. Unfortunately, the quantitative integration of genetic and physiological knowledge is largely unknown, and both genetic and physiological models would benefit from better integration of knowledge. For example, the genetic basis of photoperiod and vernalization pathways is fairly well known and as new genomic studies are carried out, more complex models are being built [81] showing the complexity of flowering time. However, the genetic mechanisms described in this entry interact with responses to other environmental factors defining a network of signaling a highly complex response that is not fully understood.

Knowledge in crop development has greatly benefited from research in model organisms; however there are key differences, like the lack of the vernalization gene *FLC* in temperate cereals. For example, four vernalization genes have been described in wheat, but only three have been cloned and located in the vernalization pathway. Completing this pathway would greatly increase the understanding of how temperate crops respond to nonfreezing cold temperatures.

At the same time, the physiological response to temperature has been extensively studied, and genetic differences are well documented; however, the basis of genetic effects is not known. It is encouraging that new genes (e.g., *Eps-1*) are being identified, but the quantitative variation of crop development, once major processes (photoperiod and vernalization requirements) are solved, requires the identification of new genes, probably of small effect. For example, a recent study in maize found no large effect QTL for flowering time in a nested mapping population [82]. Although no major epistatic or environmental interactions were found, the individual QTL effect varied across founder lines of the population [82]. QTL or gene effects need to be accurately determined to build quantitative genetic models.

Article Outline

Glossary

Biotroph A plant pathogenic microorganism which requires living host tissue in order to complete its life cycle. Rust and powdery mildew fungi are examples of biotrophs, as are viruses.

Oomycetes Also known as water molds, the Oomycetes are a large group of terrestrial and aquatic organisms. They superficially resemble fungi in mycelial growth and mode of nutrition, but molecular studies and distinct morphological characteristics place them in the kingdom Stramenopila (or Chromista) with brown and golden algae and diatoms.

Phytoalexin Antimicrobial substances synthesized de novo by plants and which accumulate rapidly at areas of infection by an incompatible pathogen. Phytoalexins are broad spectrum in action and are chemically diverse with different types characteristic of particular plant species. They can be grouped into several classes including terpenoids, alkaloids, phenolics.

Saprophyte An organism, e.g., a fungus or bacterium, that grows on and derives its nourishment from dead or decaying organic matter.

Virulence Refers to the relative ability of a pathogenic organism to cause disease.

Definition of the Subject

Plant diseases cause substantial crop losses every year and, historically, have led to considerable economic damage and human suffering. Controlling plant diseases is therefore vital to maintaining crop productivity and feeding the ever expanding human population. Crop diseases can be controlled using a variety of methods, notably cultural approaches, the use of resistance in the plant, and the application of chemicals (fungicides). However, the organisms that cause plant disease (plant pathogens) are genetically adaptable and can overcome plant resistance, and the toxic effects of fungicides. Ensuring that crops are adequately protected depends therefore on continually keeping one step ahead of the pathogens by improving existing control measures and developing new approaches. This article provides an overview of the various methods, traditional and novel, used to control crop diseases.

Introduction: The Need for Disease Control in Crops

Plant disease has plagued mankind ever since the beginnings of agriculture. Today, despite the many advances in crop protection technology, crop diseases continue to wreck havoc on crops, because of the genetic adaptability of the pathogens which cause plant disease. Crop losses at farm level can have serious implications for growers, but crop disease can inflict much more serious damage on a larger scale. A good example of just how devastating crop disease can be is the potato blight epidemic of the 1840s in Europe. This disease, caused by the Oomycete pathogen *Phytophthora infestans*, decimated crops across Europe and in Ireland, led to the death of some one million people and the emigration of several million more [1, 2]. Astonishingly, today, more than 170 years later, potato blight still poses a major problem for potato growers across the globe.

Crop losses as a result of disease can be expressed in various ways, such as potential losses and actual losses. Potential loss compares yields in a system without any form of crop protection treatment, with yields from a system with a similar intensity of crop production, but receiving crop protection treatments. Actual losses are those sustained despite the use of crop protection [3]. The efficacy of crop protection can be calculated as the percentage of potential losses prevented. Potential losses range from 8.5% for cotton to 21.2% for

Crop Diseases, Management and Control of. Table 1 Estimated loss potential and actual losses due to pathogens (fungi and bacteria) in six major crops worldwide in 2001–2003 (Adapted from [3])

Crop	Crop losses (%) due to pathogens	
	Potential	Actual
Wheat	15.6 [12–20]	10.2 [5–14]
Rice	13.5 [10–15]	10.8 [7–16]
Maize	9.4 [8–13]	8.5 [4–14]
Potatoes	21.2 [20–23]	14.5 [7–24]
Soybeans	11.0 [7–16]	8.9 [3–16]
Cotton	8.5 [7–10]	7.2 [5–13]

potatoes, while actual losses range from 7.2% for cotton to 14.5% for potatoes, highlighting the importance of crop protection in reducing potential losses in all of these crops (Table 1).

Globally, agricultural production has grown faster than the human population over the past few decades [4]. In most parts of the world, this has been the result, not of increased area of cropped land, but of increased inputs, including pesticides [4]. In the period from 1963 to 2002, cereal yields increased by 114% globally, although the annual rate of growth fell from 3.14% in the period 1963–1976 to 0.84% in the period 1989–2002 [4]. In the period from 1960 to 2004, pesticide sales worldwide increased more than ten-fold to some $30 billion [3]. However, despite this increased pesticide use, crop losses as a result of pests, diseases, and weeds have not fallen significantly in the past 40 years.

Controlling Crop Diseases

Crop disease can be controlled using a variety of approaches. The first line of defense is the exclusion of the pathogen through plant quarantine and, for example, the use of pathogen-free propagating material. The next line of defense is to exclude, eliminate, or reduce pathogen inoculum. This can be achieved in various ways, including cultural control, use of host plant resistance, and chemical control. Finally, several of these approaches might be used together in an integrated program of disease control. In the sections below, these disease control options will be examined in more detail.

Cultural Control

Cultural control aims to prevent contact with the pathogen, to create environmental conditions unfavorable to the pathogen or at least to avoid favorable conditions, or to reduce the amount of pathogen inoculum available to infect crop plants. Methods used include host eradication, crop rotation, sanitation, irrigation, tillage, and improving crop growth conditions, for example, through appropriate fertilizer use. Cultural control provides the foundation for disease control in crops, and yet its important is often overlooked.

Host Eradication Host eradication refers to the removal and disposal of whole infected plants. This method is used routinely in nurseries, greenhouses, and fields to prevent the spread of pathogens, since it eliminates the infected plants that act as a source of inoculum. In potato cultivation, pathogens can overwinter in infected tubers left in the field and give rise to infected plants (known as volunteers) in the spring. These volunteers can acts as sources of inoculum, and their removal from the field and subsequent destruction will reduce levels of pathogen inoculum.

If a pathogen requires two hosts to complete its life cycle, control is possible by eradication of the less important host. The wheat stem rust fungus, *Puccinia graminis* f.sp. *tritici*, is a case in point. It requires two hosts, wheat and barberry, to complete its life cycle and until the 1950s was the most important pathogen of wheat in the United States [5]. Since the 1950s, however, stem rust has declined in importance in the United States, due in part to successful eradication of its alternate host, common barberry [6].

Sanitation Sanitation refers to eliminating or reducing the amount of inoculum present by various means, including removal of infected plant parts and plant debris. Destroying crop residues is an important practice, but how it is performed depends upon the type of crop and the type of pathogen. For example, burying crop debris can destroy certain pathogens, particularly if the residues are plowed in deeply enough, while

burning crop residue is common practice for cereal crops in some parts of the world and will destroy many pathogens. However, burning has some drawbacks, particularly loss of nutrients and increased soil erosion.

Crop Rotation Crop rotation is an ancient cultural practice and its benefits include maintenance of soil structure and organic matter, and a reduction in soil erosion that is often associated with continuous row crops [7]. The main purpose of rotating crops in conventional arable rotations is to reduce the incidence of diseases, pests, or weeds that are difficult to control with pesticides, and for this reason, short rotations of two to three crops are usually employed. In the United States, for example, the majority of the maize crop is grown on a 2–3 year rotation, while in the UK, barley and wheat usually form the main part of the rotation, with breaks of oilseed rape, beans, peas, or potatoes [8].

Continuous cropping with the same susceptible host plant will result in the establishment of a soil population of pathogenic microbes. Crop rotation avoids this and is often associated with a reduction in crop diseases caused by soilborne pathogens [7]. Using nonhost or less susceptible crop plants in the rotation can lead to a decline in specific populations of plant pathogens in the soil and is best suited for biotrophs, since they require the presence of the specific living host for survival, or pathogens with low saprophytic ability [9, 10]. Crop rotation is less suitable for controlling root-inhabiting pathogens that survive saprophytically or can exist for long periods in soil, e.g., pathogens with tough survival structures such as *Rhizoctonia solani*, *Sclerotinia sclerotiorum*, and *Pythium* spp. [11, 12].

Tillage Tillage has indirect effects on pathogen spread and can also be used to reduce pathogen inoculum in the soil. Conventional tillage uses primary and secondary cultivation to prepare a seed-bed for planting and results in considerable soil disturbance, while reduced tillage uses a single cultivation, or even no cultivation (no-tillage, zero tillage, direct drilling), and as a result leads to minimal soil disturbance. Minimum tillage and no-tillage practices can be grouped together under the generic term: conservation tillage [13].

Tillage can bury pathogens deeper in the soil where they are less likely to become a problem. It can alter soil texture, aeration, temperature, moisture, and density, and can also influence nutrient release in the soil, with benefits to the crop [8]. Tillage also leads to clear fluctuations in microbial activity and biomass in the soil [14]. Reduced tillage or no-till is often associated with higher microbial biomass and activity in upper soil layers compared to regular tillage (plowing) [15]. This concentration of crop debris in the top layers of the soil can promote the overwintering and survival of numerous pathogens and has prompted concern that increased disease and decreased yields will be the inevitable result of using conservation tillage practices. Although this has proved to be the case under some conditions, there have also been reports of decreases in the incidence of soilborne diseases. As suggested by Sturz et al. [13], such contradictory reports may reflect differences in root development and soil microbial biomass and activity under the different regimes. Thus, conservation tillage practices can lead to pathogen inoculum concentrations several orders of magnitude greater than those found under conventional tillage [16, 17] and, as a result, plant roots growing in the upper soil layers might be more prone to pathogen infection [13]. In contrast, increased microbial biomass and activity in the top soil layers can give rise to greater root density and root activity [18, 19], which may offset the damaging effects of disease on yield, and might also provide a highly competitive soil environment with resulting disease suppressive effects [20].

Severity of tan spot in wheat was found to increase under no-till conditions, but was reduced following reduced tillage [21]. To control blackleg (*Leptosphaeria maculans*) on canola (oilseed rape), it is recommended that crop debris is buried in the autumn and a nonhost crop be direct seeded the following spring to avoid reexposing the buried residue [22, 23]. Recent research suggests that inoculum production by *L. maculans* decreased with increasing duration of stubble burial in the field over 10 months before stopping completely [24]. This effect may be due to the mycobiota associated with the buried stubble, and these workers suggest that it might be possible to manipulate the population of saprophytic microbiota present on oilseed rape stubble to facilitate the decline of *L. maculans* [24].

Sowing Practices

Time of Sowing Altering the time of sowing to avoid high levels of pathogen inoculum or conditions conducive for development of a particular disease can lead to reduced severity of several crop diseases. For example, in the UK, sowing winter oilseed rape in August rather than September exposes the earlier sown crop to inoculum from stubble of the previous crop, resulting in more severe *Alternaria* infection on pods. In contrast, the risk of infection is reduced in the later sown crop because the stubble is buried by tillage [25]. Late sowing may also be recommended for autumn-sown barley crops, in order to decrease exposure of newly emerging seedlings to inoculum of *Rhynchosporium secalis* produced on previous barley crops in the area [26].

Depth of Sowing Sowing depth can influence the risk of infection, since the preemergence stage of the seedling, which is usually more susceptible to pathogen infection, is longer when seeds are sown deeper. In *Brassica rapa*, for example, rapid emergence of seedlings reduces preemergence damping-off because the period of contact between the emerging seedlings and *R. solani* in the soil is reduced [27]. Thus, significantly higher seedling emergence was reported for several cultivars of *B. rapa* sown at a depth of 1.5 cm compared to 3.0 cm [27].

Crop Density Crop density can exert considerable influence over disease incidence due to the ease with which pathogen inoculum can be transferred between closely spaced plants and alterations in crop microclimate. In densely planted crops, temperatures are more uniform, humidity is increased, and leaves are wet for longer, all of which provides favorable conditions for pathogen infection and subsequent development. Crop density can be manipulated in various ways, e.g., sowing, pruning, and fertilization.

Soil Amendments: Mulching, Fertilizers, and Organic Amendments

Mulches Mulches are used to conserve organic matter and moisture and to reduce soil erosion. A variety of materials can be used as mulches, including straw, manure, plastics, and paper. Mulching can lead to water retention and nutrient enrichment in the soil and can decrease soil temperature, all of which can influence pathogen infection and disease development in plants. Although mulching can reduce the spread of splash dispersed pathogens, by altering the environment, it could lead to increased severity of some diseases. Further, if crop residues are used in mulching, disease incidence could increase since the residues could be used as a food source by a range of pathogens.

Fertilizers Adequate mineral nutrition is central to crop production, and can also exert considerable influence on disease development [28, 29]. Below, the influence of nitrogen, phosphorus, potassium, calcium, and silicon on plant disease will be dealt with briefly.

Nitrogen Using nitrogen fertilizer above recommended rates can lead to increased disease incidence and lesion area. This has been shown for biotrophic fungal pathogens such as powdery mildews and rusts [30, 31] and necrotrophic pathogens such as *Magnaporthe grisea*, the cause of rice blast [32]. It is commonly thought that application of nitrogen fertilizer can increase disease severity via effects on crop canopy development. Thus, large canopies with high shoot densities may be more conducive to spore transfer and pathogen infection than sparse canopies. For example, nitrogen has been shown to increase the severity of *Fusarium* head blight in wheat, and it has been suggested that this might be the result of a nitrogen-induced increase in canopy size, leading to an altered microclimate [33]. In contrast, work on yellow rust on winter wheat suggested that the impact of nitrogen on disease was the result of effects of nitrogenous substances in wheat leaves on pathogen growth, rather than effects on canopy growth and microclimate [34].

But nitrogen is not always associated with increased crop disease. Indeed, various studies have reported no effect of nitrogen on disease severity (e.g., [35, 36]), while Hoffland et al. [31] found that the effect of nitrogen depended on the type of pathogen. Thus, nitrogen increased susceptibility of tomato to the powdery mildew pathogen *Oidium lycopersicum* and the bacterial pathogen *Pseudomonas syringae* pv. *tomato*, while it had no effect on susceptibility to the vascular wilt pathogen *Fusarium oxysporum* f.sp. *lycopersici* [31]. In contrast, tomato plants were more susceptible to *Botrytis cinerea* when grown under low nitrogen conditions [37]. These results do not support the view that

nutrient-limited plants are better defended [38, 39]. It seems that generalizing about the effects of nitrogen on plant disease is unwise, and practically, although manipulation or assessment of crop nitrogen status might be used as part of disease control strategies, the approach adopted will depend on the crop and the pathogens from which it is most at risk [29].

Phosphorus In general, phosphorus fertilization tended to improve plant health, with reductions in disease recorded in 65% of cases studied by Perrenoud [40]. Nevertheless, phosphorus fertilization increased disease and pest problems in 28% of the cases examined [40]. As with nitrogen, the effects of phosphorus on plant disease might be the result of direct effects on the pathogen, host plant metabolism, leading to effects on pathogen food supply, and effects on plant defenses [29]. Indeed, foliar application of phosphate salts has been shown to induce resistance to pathogens in a range of crop plants, including cucumber [41], broad bean [42], grapevine [43], maize [44] and rice [45].

Clearly, an adequate phosphorus supply is important for crop growth and in turn, may well help to reduce disease. However, the regime of phosphorus fertilizer used will depend on a range of factors, including the crop and the pathogens likely to be important. Reuveni and Reuveni [46] suggested that foliar-applied phosphate might be used as part of an integrated disease control program. However, grower adoption of such an approach will depend on the existence of other, effective disease control measures and the economics of disease control in the particular crop.

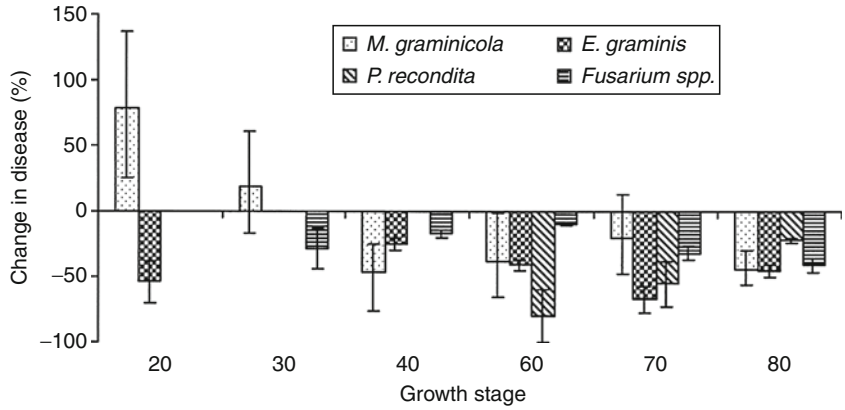
Potassium There are many reports that potassium is associated with disease reductions [47]. However, as these authors point out, inadequate consideration has been given to the effects of associated anions, nutrient balance, and nutrient status, to allow the definitive role of potassium to be determined. Thus, it has been suggested that in some cases, the effects of potassium, applied as potassium chloride fertilizer, might be due to the chloride ion rather than potassium [48]. Further, chloride fertilization has been shown to suppress disease in cereal crops [49].

There has been much interest in the application of fertilizers to crop foliage, including the effects of foliar fertilizer application for crop disease control [46, 50]. Foliar-applied potassium chloride has been shown to control *Blumeria graminis* and *Septoria tritici* on wheat in field studies [51, 52], probably due to osmotic effects on the fungal pathogens, disrupting pathogen development and subsequent infection [52, 53].

Application of potassium to deficient soils usually increases plant resistance to diseases [47]. This might be partly related to the effect of potassium in increasing epidermal cell wall thickness or disease escape as a result of vigorous crop growth [47], although the mechanisms by which potassium affects plant disease are not well understood.

Calcium There are many reports that application of calcium to soils, foliage, and fruit reduces the incidence and severity of a range of diseases of crops, including cereals, vegetable crops, legumes, fruit trees, as well as postharvest diseases of tubers and fruits [54]. For example, calcium has been shown to inhibit anthracnose (caused by *Colletotrichum gloeosporiodes* or *C. acutatum*) in apples [55] and to decrease postharvest disease development on strawberry [56], while treatment of tomato with calcium carbonate reduced fusarium crown rot disease [57]. In contrast, Nam et al. [58] could find no effect of calcium on anthracnose on strawberry. Because calcium increases resistance of plant cell membranes and cell walls to microbial enzymes, increasing calcium concentrations in storage organs could lead to enhanced resistance to pathogens [59, 60]. However, the form in which the calcium is applied can influence the mechanism by which calcium affects disease. For example, the addition of lime can affect disease by altering pH, while calcium salts (e.g., propionate) can be directly inhibitory to pathogens [54]. Making general recommendations for the use of calcium in plant disease control would be unwise, due to the range of crops and pathogens affected by calcium application. Instead, the appropriate amount and form of calcium to apply need to be determined for individual crop–pathogen interactions. The dwindling availability of fungicides, together with increasing public concern for the environment means that the use of calcium to control plant disease, especially postharvest, is attracting increased attention.

Silicon The effects of silicon in reducing disease severity have been known since 1940 [61]. However, it was not until the 1980s that more detailed work was



Crop Diseases, Management and Control of. Figure 1
Changes in disease in plots with incorporated straw. Bars show the difference between straw-treated and control plots as a percentage of the average in the control plots. For *Mycosphaerella graminicola,* the data are for severity on the top three living leaves; for other diseases, they refer to incidence. For *M.graminicola*, errors bars were calculated on the transformed scale and back-transformed; for other diseases, no transformation was needed (From [66])

carried out in this area. Thus, cucumbers grown in nutrient solutions supplemented with silicon were found to have significantly less powdery mildew infection than plants not receiving silicon supplementation [62, 63]. Indeed, silicon has been shown to suppress both foliar and soilborne pathogens in cucurbits [64] and to reduce susceptibility of rice to various pathogens [65]. Wheat grown in soil amended with silicon showed reduced infection by several pathogens, including *B. graminis* f.sp. *tritici, S. tritici,* and *Oculimacula yallundae* (Fig. 1) [66, 67].

It has been suggested that the effects of silicon in providing disease control are due to the creation of a mechanical barrier to penetration [68]. However, this has been disputed by studies which could find no evidence for the creation of a physical barrier following silicon treatment in wheat inoculated with powdery mildew and bitter gourd and tomato inoculated with *Pythium aphanidermatum* [69, 70]. Rather, several studies have suggested that silicon activates defenses in plants. For example, in wheat inoculated with *B. graminis* f.sp. *tritici*, epidermal cells of silicon-treated plants were shown to react to attempted infection with specific defenses, including papilla formation and callose production [71]. In the rice–*M. grisea* pathosystem – silicon-mediated resistance was found to be associated with accumulation of antimicrobial compounds at infection sites, including diterpenoid phytoalexins [72]. In fact, phytoalexin accumulation occurs in silicon-mediated resistance in both dicots and monocots and since phytoalexins are highly specific to plant species, it has been suggested that silicon might be acting on mechanisms shared by all plant species, e.g., those resulting in activation of plant stress genes [73].

Organic amendments Organic amendments include animal manure, solid wastes, and composts. Such amendments are often used to improve soil quality, usually by contributing to general suppressiveness through enhanced microbial biomass and activity [7]. Organic amendments are rich in labile carbon fractions which are an energy source for microorganisms, and moreover, they can themselves contain antagonistic microbes. A substantial body of data indicates that organic materials can reduce incidence of diseases caused by a range of plant pathogens [74, 75].

Irrigation Although an adequate water supply is vital to crop production, irrigation can play a detrimental rather than a beneficial role in managing plant diseases. For example, irrigation water can spread pathogen propagules and under dry conditions, can prevent desiccation of such propagules, thereby effectively increasing the level of inoculum in soil. Watering from overhead prolongs leaf wetness, thereby

providing favorable conditions for germination and infection by fungal spores. Overhead watering also increases the risk of splash-dispersal of spores, thus increasing pathogen spread. However, irrigation can be used to reduce the level of pathogen inoculum. Thus, the activity of microbes that destroy fungal sclerotia can be increased by alternate wetting and drying of the soil. Generally, drip or trickle irrigation, which delivers water directly to the root zone at a rate insufficient to lead to pathogen spread, is least likely to encourage disease development.

Use of Host Resistance

Most plants are resistant to most microbes. Thus, wheat plants are not affected by pathogens of tomato, and vice versa. This is known as nonhost resistance. However, every plant is attacked by its own pathogens, e.g., barley is attacked by the barley powdery mildew fungus, *B. graminis* f.sp. *hordei,* although it might not be able to defend itself equally well against all pathogens that are able to attack it. This ability of plants to resist attack by pathogens is genetically determined, but the diversity of types of genetic control of this resistance, and of conditions required for their expression, has led to a bewildering number of classifications of resistance types in plants. To complicate matters further, in some cases, different terms used by different authors are synonymous, while in other cases, the terms might be based on different criteria.

Types of Resistance

Seedling and Adult Plant Resistance Seedling resistance operates from the onset of plant growth and is effective throughout the life of the plant. It is generally controlled by single genes and is effective in the absence of matching virulence in the pathogen. In contrast, adult plant resistance (APR) covers a broad range of resistance types all of which are not effective at the plant's seedling stage. APR tends to be controlled by a number of genes, which might operate through a wide variety of mechanisms.

Polygenic and Oligogenic Resistance Resistance controlled by one, or at most two or three genes, is known as oligogenic. Here, a single gene can confer complete resistance. A gene conferring such resistance is often referred to as a major gene. Where resistance is controlled by a larger number of genes, it is known as polygenic. Genes conferring polygenic resistance are often referred to as minor genes.

Race-specific and Race-nonspecific Resistance The terms race-specific and race-nonspecific sought to differentiate between resistance that was subject to loss of effectiveness with the appearance of new virulent strains of a pathogen and resistance that was thought would never be lost because the pathogen was not capable of developing virulence to it. A major problem with these terms has been a lack of evidence to suggest that any particular resistance was race-nonspecific. The assumption was generally made that genes of large effect (major or seedling genes) were race-specific and genes of small effect (minor genes or APR) were race-nonspecific. This has subsequently and comprehensively been shown not to be the case in many host–parasite systems.

Vertical and Horizontal Resistance These terms were introduced to convey the difference between race-specific and race-nonspecific resistance [76]. In vertical resistance, there tends to be a high level of resistance by the host to some races of the pathogen and a low level of resistance to others, while in horizontal resistance, resistance tends to be exhibited equally to all races of the pathogen. Vertical resistance has also been denoted as specific resistance and horizontal resistance as general resistance. However, although the specific nature of some types of resistance can usually be established fairly easily, it is much more difficult to prove that resistance is truly general, since there is always the chance of a new pathogen race appearing with the ability to overcome the resistance.

Qualitative and Quantitative Resistance These terms are a rough match for seedling/APR and vertical/horizontal resistance, with qualitative resistance referring to a high level of resistance controlled by a single gene and quantitative resistance being controlled by several genes of smaller effect. The term "quantitative" subsequently came to be used to describe locations on chromosomes where genes of small effect were identified through mapping studies, hence "quantitative trait locus" or QTL. More recently the use of the term QTL has come to be used for major gene loci as well.

Partial Resistance Partial resistance was originally used in studies of the resistance in barley to leaf rust caused by *Puccinia hordei*. It describes resistance that reduced the rate of epidemic development despite having a susceptible reaction type [77]. Resistance to leaf rust was found to be governed by up to 6–7 minor genes with additive effects and was correlated with increased latency period and reduced infection frequency, pustule size, infectious period, and spore production. The term is now used more generally to describe any resistance that is only partially effective in reducing disease expression and is usually synonymous with minor gene resistance.

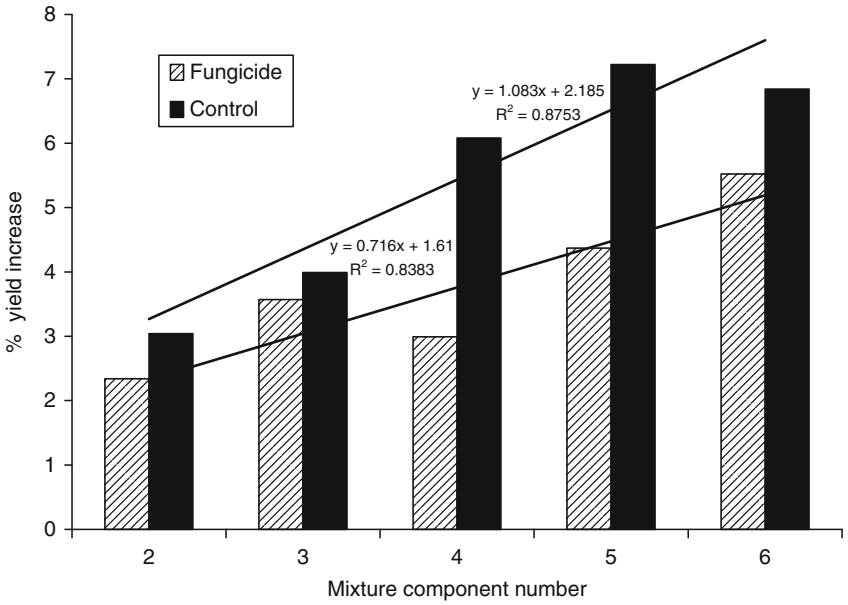
Durable Resistance Durable resistance was suggested for use by Johnson and Law [78] to refer to rust resistance in wheat that in practice had provided stable resistance in varieties that had been grown over a large area for many years. The term specifically avoided identifying the resistance with particular phenotypes or suggesting that the resistance would never be lost to a change in pathogen virulence. Specific well-studied examples are the *Sr2* and *Rpg1* genes for partial stem rust in wheat and barley, respectively, the genes *Lr34* and *Yr18* which provide partial resistance to leaf and stripe rust in wheat and which may in fact be the same gene and the *mlo* locus which provides resistance to powdery mildew in barley.

Genetic Engineering for Disease Resistance Using the techniques of genetic manipulation (GM), it is now possible to sequence and clone resistance genes from distantly related species. These genes could then be transferred into crop species, providing varieties with enhanced disease resistance. For example, the gene for resistance to bacterial blight of rice, *Xa21,* was sequenced, cloned, and transformed into rice, providing resistance against a range of pathogens [79]. This is a good example of how transgenic technologies could be used in a major crop and indeed, transgenic rice lines expressing *Xa21* are currently being tested in the field. The vision is to use GM technology to pyramid several different resistance genes in a rice variety, providing what is hoped will be durable resistance. However, unless there is coordination among plant breeders and the industry to prevent varieties being grown together, thereby allowing the pathogen to mutate one gene at a time, this strategy is unlikely to be successful.

One option for improving resistance to virus infection is to transform the gene that expresses the viral coat protein into the host plant. This approach was used to develop a line of papaya resistant to the very damaging papaya ringspot virus (PRSV). As a result of this work, two papaya varieties, Rainbow and SunUp, were commercialized. Rainbow was widely planted in Hawaii and was important in preventing the complete destruction of the papaya industry by PRSV [80].

Deployment of Resistance in Practice Many new crop varieties have been bred where resistance to a particular pathogen is based on the introduction of one gene. All too often history has shown that the introduction of such varieties is followed, within just a few years, by the appearance of a new race of the pathogen, able to overcome the "new" resistance. Such rapid breakdown of host resistance is favored by modern intensive agriculture, where crops are planted in monoculture covering huge areas. This favors any genetic variants of the pathogen with the ability to infect these new varieties. Breaking this "boom-and-bust" cycle of introducing a new resistant variety, followed by the rapid breakdown of resistance, can be achieved in various ways. One approach is to find durable sources of resistance. Another is to breed for combinations of race-specific genes in one crop variety. This is known as pyramiding and should be quite durable. However, it is controversial, since it might select for complex races of the pathogen possessing several matching virulences. Another approach is to diversify the deployment of resistance genes. This could involve spatial diversity across regions or fields, or the use of multilines or mixtures of cultivars.

A multiline is a series of near-isogenic (genetically identical) plant lines each differing in a single character, e.g., disease resistance. The plant lines can be grown together like a conventional crop, thereby retaining agronomic advantages such as crop uniformity, while confronting the pathogen with the problem of overcoming several different genes for resistance. A number of mechanisms have been proposed to account for disease control in multilines: (1) The high proportion of resistant plants in the multiline grown in the field reduces the amount of pathogen inoculums per unit



Crop Diseases, Management and Control of. Figure 2
Change in *R. secalis* infection of mixtures of winter barley cultivars compared with the mean of their components with different numbers of component cultivars (From [82])

area of crop, thereby reducing the amount of infection in the succeeding generation and the amount of inoculums produced by that generation. (2) Movement of pathogen inoculums between susceptible plants might be hampered by the presence of intervening resistant plants. (3) The average distance which the pathogen inoculums must travel in order to reach another susceptible plant is increased. (4) There might be induction of resistance, i.e., pre-inoculation with a race of the pathogen to which the line is resistant might protect it from a race to which it is normally susceptible [81]. However, the breeding program required for the development of a multiline is extensive. Similar in concept, but easier to put into practice, is the use of variety mixtures. Here, seed of a number of genetically distinct varieties of the crop are mixed and grown together as a single crop. Each variety possesses a different resistance gene(s), again presenting the pathogen with a genetic puzzle. But the use of mixtures requires careful choice of varieties, since they must possess similar characteristics, such as crop height and time to flowering. Nevertheless, mixtures have been shown to develop less disease than would be expected in component varieties grown alone. Mixtures can also provide yield increases, and the magnitude of disease control and effects on yield are dependent on the number of components in the mixture (Fig. 2). The mechanisms proposed to account for reductions in disease in mixtures include less efficient spread between plants and the induction of plant resistance by incompatible strains of the pathogen attempting to infect different hosts in the mixture [82].

Use of Chemicals to Control Crop Disease

Chemicals continue to play an important role in crop disease control. These chemicals act either by inhibiting germination, growth, and multiplication of the pathogen, or by killing the pathogen. Although chemicals can be used to control bacterial pathogens (bactericides) and nematodes (nematicides), this section will concentrate on chemicals with activity against fungal pathogens (fungicides).

Fungicides can be divided into several groups according to their mode of action. Protectant fungicides protect the plant against fungal propagules (e.g., spores) landing on the surface of leaves, stems, or fruit, but tend to be ineffective against established infections, since they do not enter the plant to any extent. To be effective therefore, protectant fungicides need to be

applied before the fungal pathogen enters the plant. In contrast, systemic fungicides enter the plant, and can become generally distributed within its tissues, thereby offering protection against fungal pathogens. Eradicant fungicides can enter plant tissues and can kill established infections. A number of protectant and systemic fungicides possess eradicant properties, while some systemic fungicides also have protectant activity.

Protectant Fungicides Protectant fungicides can be applied to the crop as high-volume or low-volume sprays, or occasionally as dusts. These fungicides tend to be broad spectrum, with activity against a range of different fungal pathogens. As a result, it is unlikely that pathogens would develop resistance to these chemicals. However, because they must be applied before the pathogen attempts to penetrate the plant, there is the need for reliable forecasting of infection risk. Protectant fungicides include the oldest and still widely used inorganic sulfur and copper compounds. Sulfur, applied as a dust, wettable powder, paste, or liquid, is used to control powdery mildews, some rusts, leaf blights, and fruit rots. Bordeaux mixture, made by mixing copper sulfate solution with calcium oxide or calcium hydroxide, consists mainly of colloidal hydrated cupric hydroxide stabilized by calcium sulfate. It has been replaced by copper oxychloride, which can be formulated by the manufacturer and simply diluted by the grower.

Organic sulfur compounds are an important and versatile group of fungicides and include thiram, ferbam, maneb, zineb, and mancozeb. These fungicides are all derivatives of dithiocarbamic acid, and because they are metabolized to isothiocyanate, they inactivate the sulfhydryl groups (-SH) in amino acids and enzymes. Thiram is used mostly for seed and bulb treatment for vegetables, flowers, and grasses, while ferbam is used to control foliage diseases, ornamentals, and fruit on trees. Maneb and mancozeb belong to a group of dithiocarbamic acid derivatives known as the ethylenebisdithiocarbamates. Maneb is a broad-spectrum fungicide for the control of foliage and fruit diseases of vegetables such as tomato, potato, and vine crops, as well as flowers, turf, and some fruit crops. Mancozeb is formed by the addition of zinc ion to maneb and a secondary effect of using mancozeb is the provision of manganese and zinc to plants deficient in these elements.

Various aromatic compounds have been developed as fungicides and include dichloran, used as a foliar or fruit fungicide, or as a postharvest spray for vegetables and flowers, and chlorothalonil, which is a broad-spectrum fungicide used on vegetables, field crops, ornamentals, and turf.

A number of very effective protectant fungicides belong to the rather heterogeneous group of heterocyclic compounds and include captan, iprodione, and vinclozolin. Captan is used for the control of leaf spots, blights, and fruit rots on various crops, as well as a seed treatment. It works by inhibiting thiol-containing enzymes in the fungal cell, and may also react with sulfhydryl groups.

Systemic Fungicides For a systemic fungicide to be effective, it must enter the plant and, to be translocated, it must be reasonably water-soluble. It must also be selective, possessing toxicity against the pathogen but not the host plant. Most systemic fungicides are xylem-mobile and as a result, tend to move from the base to the top of the plant, accumulating in leaves and shoot apices. As a result, such fungicides possess no activity against soilborne pathogens affecting roots. Phosphonate fungicides such as fosetyl-Al are also phloem-mobile and so can move down the plant to the roots, providing protection against, for example, root rots caused by *Phytophthora* species.

A wide range of systemic fungicides are now used to control plant pathogens. Unlike protectant fungicides, most systemic fungicides are site specific, and target only one, or just a few, specific steps in fungal metabolism. Although this was seen initially as a strength of systemic fungicides, it soon proved to be a weakness, since fungal pathogens were able to develop resistance to the chemicals, in some cases with alarming rapidity.

Acylalanine fungicides are effective against Oomycete pathogens such as *Phytophthora* and *Pythium* and include the widely used fungicide, metalaxyl. This is used as a soil or seed treatment and also possesses some curative activity. It moves readily from roots to shoots, although its lateral movement is slight. Some fungal pathogens have developed resistance to metalaxyl, and its use tends to be recommended in conjunction with a broad-spectrum fungicide.

Benzimidazole fungicides include some well-established and important chemicals, including benomyl, carbendazim, and thiabendazole. They are converted to methyl benzimidazole carbamate (MBC, carbendazim), which interferes with cell division. Benzimidazoles are broad spectrum in activity. Thus, benomyl is effective against a wide range of leaf spots, blights, rots, scabs, seedborne, and soilborne diseases. It can be applied to plants as a seed treatment, foliar spray, trunk injection, root dip, or fruit dip.

Oxanthiins, such as carboxin and oxycarboxin, possess the distinction of being the first chemicals with demonstrated systemic activity. They are active against some smut and rust pathogens, and also against *Rhizoctonia*. By inhibiting succinate dehydrogenase in fungal mitochondria, they affect respiration.

Organophosphate fungicides, such as foestyl-Al and phosphorous acid, are effective against Oomycete pathogens on a range of crops. Interestingly, fosetyl-Al has been reported to trigger plant defense mechanisms, e.g., phytoalexin biosynthesis and accumulation.

Other systemic fungicides include the pyrimidines, such as ethirimol and bupirimate, with activity against powdery mildews, and the triazoles, such as triadimefon, propiconazole, cyprodinil, and tebuconazole. The triazoles exhibit long-acting protective and curative activities against a broad spectrum of pathogens.

The most recently developed group of fungicides is the strobilurins. They are based on chemicals extracted from the wood rotting fungus *Strobilurus tenacelus*, and a range of highly effective strobilurins have been developed over the years. They work by blocking electron transfer at the site of quinol oxidation (Qo site, hence their description as QoI fungicides), thereby preventing ATP formation in respiration. These fungicides move trans-laminarly within leaves and some also move systemically through the vascular system. Important strobilurins include azoxystrobin, pyraclostrobin, and kresoxim methyl. They have broad-spectrum activity, and some also possess growth-promoting activity on treated plants, apparently by delaying senescence and altering plant–water relations.

Development of Resistance to Fungicides Until the advent of systemic fungicides, fungicide resistance was rare. The development of resistance in *Pyrenophora* to mercury used as a seed dressing, in the apple scab fungus *Venturia inaequalis* to dodine, and in *Penicillium* species to diphenyl compounds are exceptions. In contrast, the use of systemic fungicides soon led to the appearance of fungicide resistance. Thus, the pyrimidine fungicide dimethirimol was introduced in 1968, and by 1971, strains of the powdery mildew fungus *Sphaerotheca fuligenea* were detected on glasshouse cucumbers in the Netherlands. Similarly, following the introduction of QoI fungicides in the UK in 1996, resistance to powdery mildew in wheat was first recorded in 1998.

It seems that where a single site systemic fungicide is used intensively, there is the risk of fungal pathogens developing resistance to it. With single site fungicides, only a single mutation in the fungus might be required for resistance to develop. Some of the mechanisms by which a fungus might develop resistance following such a mutation include: (1) detoxification of the chemical, (2) decreased permeability of fungal cell membranes to the fungicide, (3) reduced affinity of the fungicide to the reactive site within the fungal cell, and (4) bypassing a blocked reaction via an alteration in fungal metabolism.

Given that fungicide resistance is now an accepted fact of life in crop protection, how can it be managed effectively? The first point to remember is that fungicides to which resistance has developed can still be useful in disease control if deployed sensibly. Strategies to minimize the risk of fungicide resistance developing include:

1. Reducing fungicide use
   - Applying fungicides only when necessary
   - Using fungicides as part of an integrated disease control program, including, for example, appropriate cultural control, and if available, resistant varieties
2. Diversifying fungicide treatments
   - Avoiding the repeated use of fungicides with the same mode of action
   - Instead, use mixtures of fungicides with different modes of action
   - During the growing season, alternating fungicides with different modes of action
   - Including a multisite fungicide in any fungicide mixture or spray program

Pesticides and Nontarget Organisms Pesticide use has greatly increased the quantity and improved the quality of food for the increasing world population. However, as pesticide use increased, so did concern about their adverse effects on nontarget organisms, including humans. Increasing public concern about the accumulation of pesticides in the environment and the impact on nontarget organisms has led to the introduction of rigorous regulatory processes [83, 84]. Nevertheless, there is continued concern over the impacts of pesticides on wildlife, including invertebrate populations, wild plants, and farmland birds [85]. These concerns have led to reviews of active substances used in plant protection, with the resulting withdrawal of an increasing number of crop protection products from the market [86]. This has created problems, and in some situations, effective control measures are no longer available to meet all the challenges posed by pathogens, pests, and weeds [86].

Biological Control of Plant Diseases Using Antagonistic Microorganisms

Biological control can be defined as the control of a plant pathogen using another living organism or organisms. This definition includes direct and indirect effects, as a result of either the introduction of antagonists, or manipulation of existing microbial populations to reduce disease. This section will deal with biological control using antagonistic microorganisms.

Antagonistic microorganisms control plant disease because they weaken or destroy the pathogen. They achieve this by various mechanisms, including: (1) directly parasitizing the pathogen, (2) producing antibiotics or toxins that exert an effect on the pathogen, (3) competing for space and nutrients with the pathogen, and (4) producing hydrolytic enzymes that destroy components of pathogen cells.

To be effective in disease control, a biological control agent (BCA) must be able to colonize a particular habitat or occupy a niche in sufficient numbers to disrupt the growth and survival of the target pathogen. For this reason, the most effective BCAs are likely to be found in the environment in which they are to be used. Thus, if the pathogen to be controlled infects plant roots, the best place to look for a potential BCA would be the rhizosphere. Finding appropriate BCAs is one thing, but using them in practice is quite another. For a start, as a living organism, the BCA must be formulated in such a way as to allow it to remain viable and survive following application [87]. Great advances have been made in the production and formulation of BCAs over the years, but despite the fact that 1,000 of microorganisms have been shown to interfere with growth and survival of plant pathogens under controlled and field conditions, relatively few have been registered and used in commercial practice. Currently, there are more than 50 bacterial products and 50 fungal products available commercially. The majority of both bacterial and fungal products are sold for control of seedborne or soilborne pathogens (Table 2), with fewer for foliar pathogens and timber decay fungi and even fewer for postharvest pathogens. Most contain individual microorganisms although there are some products that contain microorganism mixtures, and some individual microorganism strains are marketed in several different products expanding the potential market of a single active ingredient. Bacterial products are dominated by *Bacillus* species reflecting their ease of growth and production of long-lived spores mentioned earlier. Fungal products are dominated by *Trichoderma* spp. which are also easy to produce, generally have a low toxicity, and can sporulate well.

America's first biological fungicide seed treatment, Kodiak (marketed by Bayer), contains spores of *Bacillus subtilis* GB03 for control of *Alternaria*, *Aspergillus*, *Fusarium*, and *Rhizoctonia* spp. that attack root systems of a number of plants, including seed and pod vegetables, cotton, peanut, soybean, wheat, barley, and maize. The spore concentrate can be applied through standard slurry or mist seed treatment equipment, with fungicides if required, and the bacterium colonizes the root system providing control over the whole growing season.

Numerous products contain strains of *Trichoderma harzianum*, but one isolate, KRL-AG2 (T-22), sold by BioWorks Inc., USA, has been used and developed for several markets in US horticulture and agriculture in a number of different forms. When applied to soil, planting mixes, or turf, this BCA colonizes plant roots and provides protection against root pathogens such as *Cylindrocarpon*, *Fusarium*, *Pythium*, *Rhizoctonia*, and *Thielaviopsis*. RootShield granules are largely targeted at glasshouse and nursery use, and can be incorporated,

Crop Diseases, Management and Control of. Table 2 Examples of bacteria and fungi registered or commercially marketed as biological control agents for control of soilborne and seedborne plant pathogens (from [87])

Antagonist	Target pathogen(s)/ activity	Disease/host	Product name and source
BACTERIA			
Agrobacterium radiobacter	*Agrobacterium tumefaciens* causing root galls	Ornamentals and other plants sensitive to *A. tumefaciens* root galls	Norback 84-C, Galltrol-A, Nogall, Diegall, Dygall (Becker Underwood Pty Ltd, Australia; Bio-Care Technology Pty Ltd. Australia; New BiProducts, Inc. USA; AgBiChem Inc., USA; Agbioresearch Ltd. New Zealand)
Bacillus cereus BP01	Plant growth promotion	Cotton	Mepplus (MicroFlo Co. LLC, USA)
B. pumilus GB34	*Fusarium* spp., *R. solani*	Soybean	YieldShield concentrate; GB34 Biological Fungicide (Gustafson LLC, USA)
Bacillus licheniformis SB3086	Numerous pathogens, especially *Sclerotinia homeocarpa*	Ornamentals, turf	EcoGuard, Green Releaf (Novozymes Biologicals Inc., USA)
B. subtilis	*Pythium* damping-off	Tomato	Cillus, Green-all G (Greenbiotech Co, Korea)
	R. solani, Fusarium spp., *Alternaria* spp., and *Aspergillus* spp. pathogens	Root rots and seedling diseases generally	Kodiak, Epic, Concentrate, Kodiak HB, Quantum 4,000, System 3 (Gustafson LLC, USA)
	Fusarium spp., *Verticillium* spp., *R. solani,* and *Pythium* spp. pathogens	Various vegetable and field crops	PHYTOVIT WG (Prophyta Biologischer Pflanzenschutz GmbH, Germany)
B. subtilis GB03	*Fusarium* spp., *Phytophthora* spp., *Pythium* spp., *R. solani*	Ornamentals, turf, dry and snap bean, cotton, peanut, soybean, wheat, and barley	Companion, Kodiak (Growth Products Ltd, USA; Gustafson LLC, USA; Bayer CropScience LP, USA)
B. subtilis MBI600	*Alternaria* spp., *Aspergillus* spp., *Fusarium* spp., *Pythium* spp., *R. solani*	*Alfalfa*, dry/snap beans, peanut, soybean, field crops, turf, cotton	HiStick N/T, Pro-mix, Subtilex; Subtilex HB (Becker Underwood Inc., USA; Premier Horticulture Inc, Mexico)
B. subtilis subsp. *amyloliquefaciens* FZB24	*Fusarium* spp., *R. solani*	Various vegetables and ornamentals	Taegro, Tae-Technical (Earth Biosciences Inc. USA)
B. subtilis, *Bacillus circulans*, *Bacillus amyloliquefaciens*, *Paenibacillus polymyxa* (Mixture)	Damping-off (bacterial) diseases	All crops	Hydroguard (American Agritech, USA)
Burkholderia cepacia[a]	*Pythium* spp., *Fusarium* spp., *R. solani,* nematodes	*Alfalfa*, beans, clover, cotton, peas, wheat, vegetables, and others	Deny, Blue Circle (Stine Microbial Products, USA)
	Pythium spp., *Fusarium* spp., *R. solani,*	Maize, vegetables, cotton	Intercept (Soil Technologies Corp., USA)

top-dressed, broadcast, or applied in-furrow or to planting holes for use on flowers, bedding plants, ornamentals, vegetables, pome and stone fruit, trees, and tree nuts. For agriculture, T-22 Planter Box is applied as a coating on seeds and seed pieces, an in-furrow spray, and as a transplant starter and T-22 HC as a broadcast or in-furrow treatment, both for use on field and row crops, hay and forage crops, bulbs and vegetables. In Europe, T-22 (Koppert, the Netherlands) is available as TRIANUM-G and TRIANUM-P, wettable granule and wettable powder formulations. Much of the scientific background concerning the use of this isolate has been extensively reviewed [88].

In terms of the future, advances that can improve quantity, quality, and shelf life of inocula would be welcome, particularly for bacteria such as *Pseudomonas* that do not form spores. In recent work, both *Pseudomonas* and *Trichoderma* isolates have been simultaneously applied to seed via drum priming and found to survive and proliferate on roots similarly to when applied individually [89]. This procedure may be a way to apply and maintain multiple BCAs in a commercially relevant process. Further approaches include integration with other control strategies such as cultural methods and chemical treatments [87]. A better understanding of the natural ecology of any potential BCA might facilitate a more rational approach to production and use.

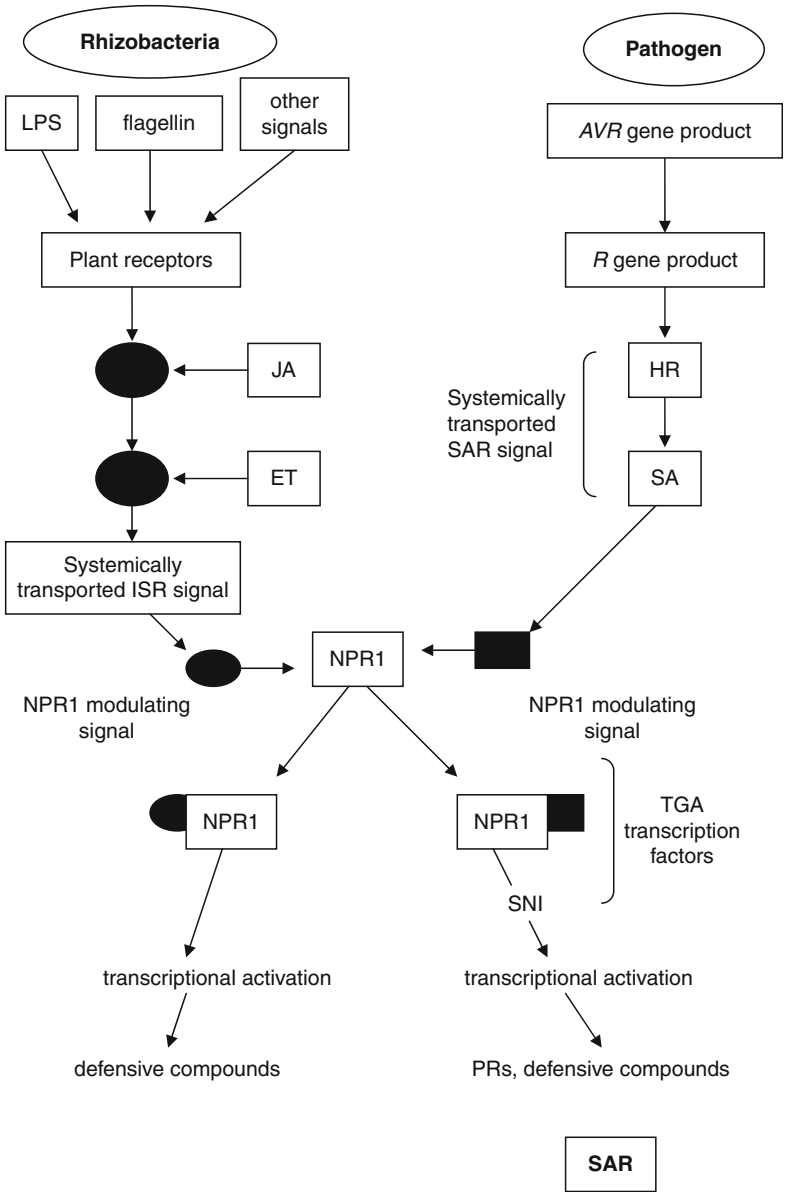
Induced Resistance to Control Crop Diseases

Following infection by a microbial pathogen, susceptible plants can develop an enhanced resistance to further infection [90]. This is known as induced resistance and can be split broadly into two types: systemic acquired resistance (SAR) and induced systemic resistance (ISR).

In SAR plants, develop a broad-spectrum systemic resistance to pathogen infection following a localized infection by a necrotizing pathogen or treatment with various agents, e.g., acibenzolar-S-methyl (ASM) or Probenazole (Oryzemate®). SAR is associated with increased levels of salicylic acid (SA) and with the coordinate expression of a specific set of genes encoding PR proteins ([91]; Fig. 3). Moreover, application of SA or one of its functional analogues, such as ASM, induces SAR and activates the same set of PR genes [92]. Indeed, expression of a set of PR genes, and PR-1 in particular, is used as a marker for SAR induction, although it is important to note that the induction of resistance is not always accompanied by PR-1 expression [93, 94].

In contrast to SAR, ISR develops as a result of colonization of plant roots by certain strains of plant growth–promoting rhizobacteria (PGPR) and is mediated by jasmonic acid– (JA) and ethylene (ET)-sensitive pathways ([91]; Fig. 3). Phenotypically, ISR is similar to SAR in that it acts unspecifically against taxonomically different pathogens [91, 95].

The resistance responses described above can be associated with direct activation of defenses. However, such responses can also be associated with an ability to "recall" previous infection, root colonization, or chemical treatment. This phenomenon is known as priming and results in plants responding more rapidly and



Crop Diseases, Management and Control of. Figure 3
A model for the signal transduction network controlling induced systemic resistance (ISR) mediated by plant growth–promoting rhizobacteria and pathogen-induced systemic acquired resistance (SAR) in *Arabidopsis thaliana*. LPS, lipopolysaccharide; PRs, pathogenesis-related proteins; *AVR*, avirulence gene product; *R*, resistance gene product; HR, hypersensitive response; SA, salicylic acid; JA, jasmonic acid; ET, ethylene; NPR1, a regulatory protein involved in signaling in SAR and ISR in *A. thaliana*; SNI, transcriptional repressor of SAR genes; TGA transcription factors, family of transcription factors interacting with SA-induced NPR1 (From [91])

effectively when exposed to subsequent pathogen attack ([96]; Fig. 3). Usually, no changes in gene expression or in the levels of resistance traits are detectable in response to the priming agent alone, which might be a chemical elicitor such as ASM or a challenging pathogen. Interestingly, priming of resistance is usually caused by agents that fully induce resistance when applied at higher doses [97, 98] and suggests

that direct resistance induction and priming might differ from one another quantitatively rather than qualitatively.

A wide range of microbes and chemicals are known to induce resistance and it seems likely that other forms of induced resistance exist. Thus, it is well known that the nonprotein amino acid, β-aminobutyric acid (BABA), can induce resistance in a variety of crop plants [99]. BABA-induced resistance (BABA-IR) has been used as a model for the study of priming and in *Arabidopsis*, it is based on various mechanisms. Thus, BABA-IR against *P. syringae* and *B. cinerea* functions via priming for SA-inducible defenses, while against a different set of pathogens (*Hyaloperonospora parasitica*, *Plectosphaerella cucumerina* and *Alternaria brassicicola*), it is based on priming for resistance through the formation of callose-rich papillae [100–102].

Since the introduction of the first chemical resistance activator Probenazole (registered in Japan as Oryzemate®, Meiji Seika Kaisha Ltd) in 1975, a number of other chemical and microbial activators have been developed, including ASM, registered as Bion® and Actigard® (Syngenta), Milsana® (*Reynoutria sacalinensis* extract, KHH BioScience Inc. USA), Elexa® (chitosan, SafeScience, USA), and Messenger® (harpin protein, Eden Bioscience, USA). However, although high levels of disease control can be achieved with plant activators in controlled environments, their performance under field conditions has been less impressive. In fact, the moderate levels of disease control and high levels of variability exhibited by plant activators in the field have been instrumental in the very slow uptake of induced resistance in crop production systems. In the following paragraphs, the performance of selected plant activators under field conditions will be discussed.

Probenazole (3-allyloxy-1,2-benziothiazole-1,1-oxide) was first introduced for the control of rice blast disease (*Pyricularia oryzae*) and bacterial blight (*Xanthomonas oryzae*). It is widely used in Asia where it is applied as a granular treatment either to paddy fields or as a seedling box treatment. Following application, the compound is absorbed by the roots, then systemically transferred to the rest of the plant and can control rice blast disease for between 40 and 70 days post application [103]. However, despite continuous use since its introduction, there have been no reports of pathogen insensitivity to probenzole and indeed, it still accounted for 53% of the chemicals used for seedling box treatments on rice in 2005 [103]. It is believed this is because the compound is only weakly toxic to fungi and activates disease defense systems in rice [104, 105].

A large body of data has accumulated on the efficacy of ASM against a range of diseases under field conditions [106, 107]. Most studies report disease control, although the level of control ranges from 4% to 99%. High levels of disease control were achieved on tobacco, where infections by *P. syringae* pv. *tabaci, Cercospora nicotianae,* and *Alternaria alternata* were reduced by 99%, 91%, and 89%, respectively [108, 109]. In wheat, the crop that ASM was originally aimed at, disease control was not so impressive, ranging from 35% for *Puccinia recondita* and *Septoria* spp., to 77% for *B. graminis* f.sp. *hordei* [110, 111]. ASM even increased disease levels in peanut, where infection by *Cercosporidium personatum* was greater than untreated controls by 52% [112]. Working on oilseed rape, Liu et al. [113] found that pretreatment with ASM in October/November decreased the number of leaf lesions caused by the Phoma stem canker pathogen *L. maculans* in the autumn/winter, as well as the severity of stem canker in the subsequent spring/summer. In this work, reductions in numbers of leaves with lesions were between 25% and 55% [113]. More recently, ASM was shown to reduce infection of barley by the leaf scald pathogen *R. secalis* by 45% [114].

Chitosan is a common polymer in shells of crustaceans, exoskeletons of insects, and cell walls of fungi [115]. A commercial formulation, Elexa®, contains 4% chitosan as its active ingredient and has been shown to protect a range of crops against pathogens. For example, when used as a seed treatment, it reduced downy mildew severity on pearl millet by 58%, and when used as a foliar spray, it reduced infection by 75% [116]. When used on grapevines, eight applications of Elexa® applied over the season reduced the incidence of downy mildew by 50% and powdery mildew by 75% compared to untreated controls [117].

A number commercially available products are based on microbial proteins. One such is Messenger®, which is based on the protein harpin obtained from *Erwinia amylovora* [118]. Used as a crop protectant, Messenger® has had mixed success. For example, although it possessed good efficacy against blue mold

in apples [119], its efficacy against gray mold in strawberry [120] and target spot of tomato [121] was poor. In some interesting recent work, Chen et al. [122] generated specific fragments of $HpaG_{Xooc}$, a harpin from *X. oryzae* pv. *oryzicola*, and found that one of these fragments, $HpaG_{10–42}$, stimulated growth of rice plants and provided enhanced resistance to *X. oryzae* pv. *oryzae* and *M. grisea*. $HpaG_{10–42}$ was also shown to control bacterial blight, rice blast, and sheath blight, and to increase grain yields, under field conditions [123]. Here the level of disease control depended on the cultivar, with greater control obtained with *indica* compared to *japonica* cultivars.

ISR was first shown to be effective under field conditions in the mid-1990s, when application of PGPR as a seed treatment followed by soil drench application led to a reduction in severity of bacterial wilt [124], and control of bacterial angular leaf spot and anthracnose [125]. Subsequent research by Raupach and Kloepper [126] showed that treatment of cucumber seed with PGPR led to increased plant growth and control of angular leaf spot and anthracnose. Field experiments in Thailand in 2001 and 2002 studied the effects of PGPR, used alone or as mixtures, on control of southern blight of tomato caused by *Sclerotium rolfsii*, anthracnose of long cayenne pepper caused by *Colletotrichum gloeospoiroides*, and mosaic disease of cucumber caused by cucumber mosaic virus (CMV) [127]. Mixtures of PGPR (all *Bacillus* spp.) were found to suppress disease more consistently than the PGPR strain *Bacillus pumilus* IN937b, used alone.

Induced resistance offers the prospect of durable, broad-spectrum disease control using the plants own resistance. However, it is plagued by inconsistency and relatively poor disease control compared with fungicides. These problems relate to the fact that induced resistance is a host response and as such is greatly influenced by genotype and environment. Unfortunately, the understanding of the impact of these influences on induced resistance is poor, as is the understanding of how best to use induced resistance in crop protection practice. Understanding in these areas needs to improve, and answers to several important, practical questions are required, for example: (1) Should resistance inducing agents be applied early or late in the season? (2) Is induced resistance effective against pathogens with long periods of asymptomatic growth in plant tissue, e.g., *R. secalis* on barley? (3) Can resistance inducers be used as a means of reducing fungicide applications to crops, e.g., can resistance inducers be applied early to reduce pathogen infection and colonization, thereby allowing less fungicide to be used? What is required is research related to specific crops aimed at trying to determine how best to fit induced resistance into disease control programs. Farmers and crop protectionists have grown accustomed to high levels, or even complete, disease control. Ultimately, for induced resistance to gain more widespread acceptance in crop protection, there will need to be a lowering of expectation in terms of levels of disease control.

Other Approaches to Controlling Crop Diseases

Biofumigation Biofumigation involves the suppression of plant pests and diseases by biocidal hydrolysis products, most notably the isothiocyanates released by glucosinolate (GSL)-containing plants in soil. It can involve GSL-containing plants as rotation crops, or intercrops by incorporating fresh plant material as green manure, or by utilizing processed plant products high in GSLs, e.g., seed meals. Strategies for the field implementation of biofumigation are described in detail by Kirkegaard [128].

Soil Solarization Soil solarization, or soil heating, harnesses solar energy in order to increase soil temperature. This is commonly achieved by mulching (covering, tarping) the soil with transparent polyethylene or other transparent plastic sheets. The following are a few of the important principles of soil solarization: (1) It should be carried out during periods of high temperature and intense solar radiation, with low levels, or no precipitation. (2) Soil needs to be moist in order to increase the thermal sensitivity of resting structures and improve heat conduction. (3) The mulching period needs to be sufficiently long (~4 weeks or greater) in order to achieve disease control at all desired depths. The efficacy of soil solarization in controlling crop diseases and the mechanisms involved are discussed in detail by Gamliel and Katan [129].

Integrated Control of Plant Diseases

As pointed out by Agrios [130], plant disease control is most effective when all of the relevant information

regarding the crop, potential pathogens, previous disease history, availability of host resistance, environmental conditions, etc., are taken into account in devising the disease control program. An integrated program of disease control aims to (1) eliminate or reduce the initial pathogen inoculum, (2) reduce the effectiveness of the initial pathogen inoculum, (3) maximize host plant resistance, (4) delay the onset of disease in the plant/crop, and (5) slow down the development and progression of secondary cycles [130].

The precise approach adopted will depend on the crop and its disease spectrum, but would probably include several of the following: (1) appropriate hygiene/sanitation, e.g., using disease-free seed/planting material, (2) using appropriate cultural measures, (3) using resistant plant varieties, (4) using appropriate fungicides, and (5) using biologically based methods, if available and appropriate, e.g., biological control, induced resistance.

Control of late blight (*P. infestans*) on potato provides a good example of an integrated approach to disease control (see www.endure-network.eu). For late blight, the first step in an integrated strategy is reducing primary sources of inoculum, such as avoiding infected seed tubers, using certified potato seed, preventing or reducing oospore production by controlling volunteer potatoes, for example. The next step is variety choice, since use of a variety expressing some resistance to late blight offers the potential to reduce fungicide inputs as part of an integrated strategy. Nevertheless, fungicides play a crucial role in integrated control of late blight. Although control measures are aimed mainly at preventing infection, if late blight appears in a crop, the control strategy switches to stopping or reducing the epidemic. Effective control of late blight depends on access to information such as phase of crop growth, fungicide products available, dose rates, timings, weather conditions, as well as access to tools, such as an appropriate decision support system (DSS). The DSS can integrate all relevant information to generate spray recommendations, thereby increasing the efficacy of the control strategy without increasing risk.

Future Directions

High crop yields are maintained in most developed countries through the use of improved varieties, together with fertilizers and pesticides. In these countries, farmers and growers are accustomed to achieving high levels of disease control with fungicides, although, as discussed above, the development of fungicide resistance can erode fungicide efficacy. Levels of disease control obtained with many biologically based control methods are lower than those achieved using fungicides, and moreover, many biologically based methods tend to provide inconsistent disease control. Thus, although induced resistance can provide high levels of disease control on some crops, with many crops, disease control is less impressive. Expression of induced resistance in crop plants can also be variable, depending, for example, on genotype and environment. Problems also exist with variability and inconsistency of disease control provided by some BCAs. Farmer perceptions of inadequate and inconsistent disease control will not persuade them to adopt biologically based approaches. Minimizing the effects of these problems clearly requires further research.

In spite of the huge effort by researchers to develop novel biologically based solutions for disease control (such as BCAs, plant-derived substances, induced resistance agents), few products have reached the marketplace. The relatively high cost of registration, together with the limited market size for some products, has been identified as a major barrier. However, this problem has been recognized by regulatory authorities, and in the UK, for example, the Chemicals Regulation Directorate (Pesticides) has launched a scheme that encourages applicants to register their products. Under this scheme, the requirements for registration can be tailored to the product type and importantly, the application fee can be reduced [86].

The continued ability of pathogens to overcome host resistance genes and to develop resistance to fungicides seriously erodes the ability to provide effective, lasting disease control on important crops. These problems combined with the withdrawal of active substances from the market and increasing public concern with the effects of pesticides on the environment create a huge challenge for plant pathology in the future. Plant disease control has an important role to play in efforts to feed the world's increasing population. However, providing effective and lasting disease control, without harming the environment, will require not just a sensible approach to the use of host resistance and fungicides, but also a range of innovative approaches. In some situations, innovative

control methods might be used to complement existing approaches. In other cases, for example for those diseases for which no adequate control measures exist, innovative control options might provide the only solution.

Article Outline

Glossary

Acetosyringone A phenolic compound that activates the *Agrobacterium tumefaciens vir* genes and thus initiates DNA transfer.

Agrobacterium-mediated transformation The introduction of DNA into plants by the bacterium *Agrobacterium tumefaciens*.

Bactofection Gene transfer to animal cells mediated by bacteria.

BIBAC A binary vector for plant transformation based on the high-capacity bacterial artificial chromosome (BAC).

Binary vector A plant transformation vector in two parts, one carrying the T-DNA and one carrying the *vir* genes.

Cassette A modular DNA sequence designed for portability between different vectors.

Chimeric (transformed plants) Comprising cells with different genotypes, usually a first-generation transformant (T_0) where some cells are transgenic and others are not.

Concatemer A DNA molecule containing multiple contiguous copies of the same sequence.

Conjugation DNA transfer between cells through a specialized conduit known as a pilus.

Counterselectable marker A selectable marker gene whose absence is required for cells to survive.

Destination vector The vector designated to receive a DNA cassette during LR recombination in the Gateway system.

Direct DNA transfer DNA transfer mediated by physical or chemical means rather than by bacteria or viruses.

Entry clone The vector holding the DNA cassette that needs to be transferred to the Destination vector during LR recombination in the Gateway system.

Episomal A genetic entity that replicates independently of the host chromosome, such as a plasmid or nonintegrating virus.

Explant A piece of plant tissue transferred to culture and propagated independently.

Filler DNA Extra DNA added at junctions during illegitimate recombination, either by synthesis across a template or random addition of nucleotides.

Gateway A proprietary cloning system based on LR recombination, a form of site-specific recombination using the *att*B and *att*P sites of *Escherichia coli* and bacteriophage λ.

Gene targeting Disruption of a preselected gene by homologous recombination with a DNA cassette.

Helper plasmid A plasmid that is not used as a cloning vehicle, but which supplies necessary functions in *trans*.

Homing endonuclease A specialized type of restriction enzyme encoded by introns and inteins with a long asymmetric recognition sequence.

Homologous recombination Recombination requiring long regions of homology but no sequence specificity.

Illegitimate recombination Recombination requiring neither long regions of homology nor specific sequences; it can occur by direct nonhomologous end-joining (all sequences conserved, sometimes with added filler DNA) or at regions of microhomology.

***In planta* transformation** Transformation methods that can be used with intact plants rather than tissue explants, and which therefore require no regeneration.

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

Originally published in
Robert A. Meyers (ed.) Encyclopedia of Sustainability Science and Technology, © 2012, DOI 10.1007/978-1-4419-0851-3

Integration The insertion of one DNA sequence in the midst of another.

Minichromosome A vector comprising the minimal elements that allow it to function as a chromosome.

Minimal cassette The minimal sequences required to achieve transformation and transgene expression, typically a promoter, gene, and terminator.

Multigene transfer The simultaneous transfer of more than one gene into a plant.

Particle bombardment A physical transformation method based on the acceleration of DNA-coated metal particles into intact plant cells.

Promoter The DNA sequence in front of a gene which controls its spatiotemporal expression profiles and whether its expression is sensitive to external stimuli.

Reporter gene A gene whose function is to yield an easily detectable product that can be used to measure or delimit the activity of a regulatory element such as a promoter.

Screenable marker Another name for a reporter gene.

Selectable marker A gene whose function is to confer on transformed cells some property that allows them to be propagated in conditions under which nontransformed cells either die or cannot grow efficiently.

Southern blot (DNA blot) A method for the detection of DNA sequences using specific labeled complementary probes.

Stable transformation Transformation followed by integration of DNA into the host genome such that the transgene becomes a permanent new genomic locus.

Superbinary vector A binary vector in which the *vir* gene functions are enhanced.

Supervirulent An *Agrobacterium tumefaciens* strain with a broader host range or more efficient DNA transfer ability than normal strains.

T-DNA The section of DNA within a binary vector which is transferred to the host plant.

Transactivation domain The part of a transcription factor that activates transcription.

Transient expression The expression of introduced DNA for a short time before the DNA is diluted and degraded.

Transfection (a) In bacteria, the transfer of phage DNA into bacterial cells by chemical or physical means; (b) in animals and plants, the transfer of any DNA into cultured cells by chemical or physical means.

Transformant A plant that has been transformed with exogenous DNA.

Transformation (a) In bacteria, the transfer of plasmid or genomic DNA into bacterial cells by chemical or physical means; (b) in animal cells, the spontaneous or induced change from a normal to an oncogenic phenotype; (c) in plants, any means of DNA transfer that does not involve the use of a virus.

Transgenic Containing integrated exogenous DNA in the nuclear genome.

Transplastomic Containing integrated exogenous DNA in the plastid genome.

Terminator The sequence following the gene that is required to terminate transcription.

***vir* Gene** One of several genes on binary vectors that are required in *trans* to mediate T-DNA transfer.

Zinc finger A zinc-coordinating protein motif usually associated with DNA binding, often found in sequence-specific DNA binding proteins such as transcription factors.

Definition of the Subject and Its Importance

The term **transformation** (or more properly "genetic transformation") was first coined to describe the natural process by which bacteria take up free DNA from their surroundings. The term was required to distinguish this process from two other ubiquitous natural gene transfer mechanisms in bacteria: **conjugation** (direct transfer of DNA from cell to cell through a connecting tube called a pilus) and **transduction** (transfer of DNA between cells carried by the capsid of a virus). All three of these natural processes have been exploited in the laboratory as ways to introduce exogenous DNA into bacterial cells, and in this context the definition of transformation was later refined to take into account the different consequences of gene transfer depending on the origins of the transforming DNA. The meaning of **transformation** was thus restricted to the uptake of naked plasmids or genomic DNA fragments, whereas an alternative term – **transfection** – was coined to describe the uptake of naked phage DNA, the distinction required because only the latter can initiate a phage infection.

Unsurprisingly, the same terms have been adopted to describe analogous processes in other organisms, but the precise definitions vary due to preexisting conventions. Cultured animal cells are said to undergo transformation when they change from the normal phenotype (cessation of growth when confluence is achieved) to an oncogenic phenotype (continued growth, formation of foci) so "transformation" is usually avoided in the context of gene transfer to prevent ambiguity. Therefore, transfection is used to describe the introduction of any naked DNA into animal cells regardless of its origin. The transfer of DNA from bacteria to animal cells (including the use of conjugation-like mechanisms) is unusual and has only recently been adopted as a gene transfer procedure in the laboratory, so a new term has been coined for this process – **bactofection**. The introduction of DNA into animal cells using a virus as a carrier is known as transduction, just as it is in bacteria.

The terminology for plants is a hybrid of the conventions used for bacteria and animal cells. Transformation refers to any gene transfer process where a virus is not used as a carrier (otherwise transduction is the correct term, as in bacteria and animal cells). This means that **plant transformation** includes both the uptake of naked DNA (**direct DNA transfer**) and the transfer of DNA by the conjugation-like method adopted by *Agrobacterium tumefaciens* and *Agrobacterium rhizogenes* (***Agrobacterium*-mediated transformation**). However, due to operational analogies with cultured animal cells, the introduction of DNA into cultured plant protoplasts is also termed transfection, so in this specific context the terms transformation and transfection are synonymous.

The fate of the introduced DNA depends on many factors. If it does not contain an origin of replication that is active in plant cells it is usually maintained in the nucleus for a short period of time (hours to days), eventually being diluted and degraded. If the introduced DNA contains an active expression cassette, then a product may be expressed during this time, a process known as **transient expression**. In a very small number of cells, the DNA integrates into the genome and becomes a permanent new locus. This is known as **stable transformation**. It is a rare event (approximately one in every 10,000 cells that takes up exogenous DNA integrates it into the genome) and selectable marker genes are usually employed to ensure that the small number of transformed cells can grow at the expense of their nontransformed peers, allowing the recovery of transgenic tissues and whole plants. Cells, tissues, and whole plants that are stably transformed with a particular fragment of exogenous DNA are termed **transgenic** if the DNA integrates into the nuclear genome or **transplastomic** if it integrates into the plastid genome. The integrated DNA is known as the **transgene** (depending on context this term can refer to a single gene or to the integrated segment of exogenous DNA which may contain one or more genes).

If the introduced DNA does have an origin of replication that functions in plants, then it may be maintained **episomally** (as an extrachromosomal replicon). This occurs when the introduced genetic material is part of a replication-competent recombinant plant virus, or when it includes the components of a plant centromere, allowing it to function as a minichromosome. Viral vectors are generally short-lived, so they are also used for transient expression. However, the ability of viruses to spread systemically means that the transgene may be expressed at very high levels throughout the plant, and the infection may last days or weeks. Minichromosome vectors are a relatively new development in plants but as with equivalent "artificial chromosome" vectors in yeast and animal cells, the idea is that they should facilitate stable transformation without the need for integration into the genome.

Plant transformation is a fundamental component of both basic and applied plant biology. For basic research, transformation allows scientists to study how genes function and allows the expression of both endogenous genes and transgenes to be controlled. This has increased our understanding of how plants grow, develop, and defend themselves against pests, diseases, and harsh environments, how photosynthesis is controlled, and the basis of primary and secondary metabolism. For applied research, transformation can be used to improve the agronomic performance of crops, making them hardier, more nutritious, more productive, or converting them from conventional crops into green factories producing chemical precursors, novel oils, industrial enzymes, and

pharmaceuticals. Plants provide human beings with all types of useful products: food and animal feed, fibers and structural materials, and small molecules that can be used as dyes, scents, and medicines. Plants have been cultivated for these products since the dawn of history, and for the same length of time people have sought to improve plants by breeding them and selecting the better-performing and most useful varieties. The limitations of this approach, i.e., the fact that breeders are restricted to the existing gene pool in each group of sexually compatible species, and that breeding takes a long time to achieve its goals, can be overcome by plant transformation, thus accelerating the development of plants with novel, beneficial traits.

Introduction

Plant transformation became a routine process in the 1980s but several attempts to transfer DNA into plant tissues were reported in the previous 2 decades, although stable transformation was never confirmed. The first deliberate transformation of plant tissue with laboratory-created recombinant DNA was achieved in 1983 when several researchers reported the introduction of recombinant plasmids, including backbone sequences from cloning vectors and selectable marker genes [1–3]. This marked the first creation of transgenic plant cells in the currently accepted meaning of the word. In the intervening 30 years, heterologous genes have been introduced into well over 100 different plant species either through the use of the soil bacterium *A. tumefaciens* or alternative strategies involving direct DNA transfer to plant cells and tissues. In addition, many plant viruses have been developed as episomal vectors, allowing high-level transient gene expression, although because of their inability to achieve stable transformation they are not considered further in this article.

Principles and Methods of Plant Transformation

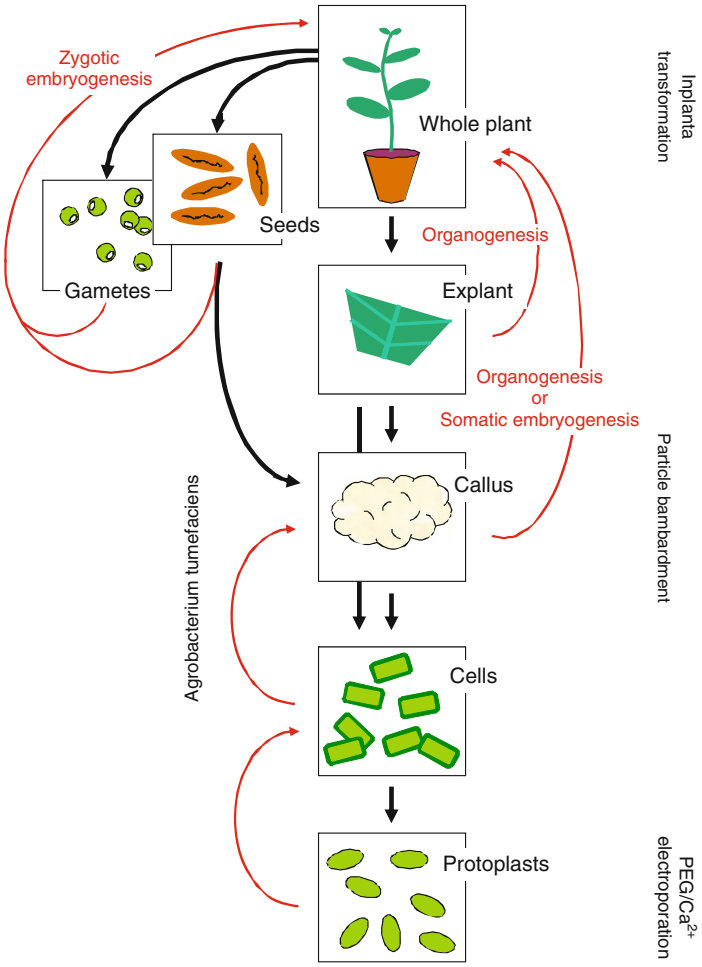
A fundamental difference between animals and plants is that differentiated plant tissue shows a high degree of developmental plasticity. Depending on the species, isolated stem segments, leaf disks, and seed-derived callus tissue may be able to regenerate an entire new plant under appropriate culture conditions. For most plant species, some form of tissue culture step is therefore used for the successful production of transgenic plants after cells or small tissue explants have been subjected to the actual transformation procedure. However, it should be noted that whole-plant (*in planta*) transformation strategies are also available in some species, in which the need for tissue culture is minimized or eliminated.

The ease with which plant material is manipulated and interconverted in culture provides many opportunities for the development of techniques for gene transfer and the recovery of transgenic plants (Fig. 1). DNA can be introduced into most types of plant material – protoplasts, cell suspensions, callus, vegetative tissue explants, gametes, seeds, zygotes, embryos, organs, and whole plants; so, the ability to recover fertile plants from such material is often the limiting step in plant genetic engineering rather than the DNA transfer process itself. It is also possible to maintain transformed plant cell lines or tissues (e.g., root cultures) rather than regenerating whole plants as these can often be sustained indefinitely in culture.

Gene transfer to plants can be achieved through three types of mechanism – viral transduction, bacterial gene delivery, and chemical/physical direct DNA transfer. Bacterial gene delivery using the soil pathogen *A. tumefaciens* is the most widely used method for dicotyledonous plants, but increasingly also for monocots. Physical methods are the next most popular, especially particle bombardment for the transformation of more recalcitrant monocots such as cereals. Chemical transfection methods are little used these days, and are only suitable for protoplasts. Each of the above methods can be used to achieve either transient expression or stable transformation of the nuclear genome, while direct gene transfer can also be used to achieve chloroplast transformation. As stated earlier, viral transduction does not lead to stable transformation and virus vectors are not discussed in this article.

Principles of *Agrobacterium*-Mediated Transformation

Gene transfer from bacteria to plants occurs naturally and is responsible for crown gall disease. This is a plant tumor that can be induced in a wide variety of gymnosperms and dicotyledonous angiosperms by



Crop Plants Transformation Methods. Figure 1

Strategies for the transformation of higher plants [4]. *The boxes* show the various different targets for transformation and how they are obtained from whole plants (*black arrows*). The methods used to transform each of these targets are shown in *black text*. *The red arrows* show the routes used to obtain whole transgenic plants

inoculating wound sites with the Gram-negative soil bacterium *A. tumefaciens*. The tumor produces plant hormones responsible for the proliferation of undifferentiated plant tissue, and specialized amino acid derivatives known as opines that the bacteria use as a carbon source. The entire system has therefore evolved as a way for the bacteria to exploit plants for accommodation and food.

Even so, the continued presence of the bacteria is not required to maintain the tumor, indicating that some "tumor-inducing principle" is transferred from the bacterium to the plant at the wound site. Research in the late 1970s identified the principle as a small segment of DNA that is transferred to the plant genome (hence T-DNA, for transferred DNA). The source of the T-DNA is a large plasmid, the tumor-inducing (Ti) plasmid, resident in the bacterium.

Agrobacterium-mediated transformation was developed as a platform technology following the dissection and functional analysis of two key components of natural Ti-plasmids: the T-DNA, which contains DNA sequences required in *cis* for DNA transfer, and the *vir* (virulence) region, which contains genes whose products are required in *trans* for DNA transfer.

The resulting transformation system is known as a binary vector system because the T-DNA and *vir* genes do not need to be present on the same vector. This means that the T-DNA can be housed on a small shuttle vector suitable for cloning in bacteria, while the *vir* genes are provided on a second "helper" plasmid.

Natural T-DNA carries genes encoding enzymes for plant hormone synthesis and enzymes for opine synthesis, and these are the factors that drive the formation of the crown gall tumor. The hormone genes are often called oncogenes because they lead to tumor formation. However, neither the oncogenes nor the opine genes are necessary for DNA transfer. If these genes are removed, leaving an "empty" T-DNA cassette, the "disarmed" T-DNA can still be transferred to the plant genome, but the transformed cells at the wound site no longer proliferate and form a tumor. All that is required for transfer is the *vir* region, the T-DNA border sequences which are targets for excision from the Ti-plasmid, and a small number of loci on the *A. tumefaciens* genome. The T-DNA border sequences are 25-bp imperfect direct repeats which define the boundaries of the T-DNA. An enhancer, sometimes called the *overdrive* sequence, is located external to the right-hand repeat and is also required for high-efficiency transfer [5, 6]. Disarming the T-DNA does not improve the efficiency of transformation but it does improve the efficiency of regeneration, since the oncogenes produce phytohormones that interfere with normal plant development. At the same time, however, this removes any visual confirmation that transformation has taken place, and selectable or screenable marker genes must be included in the T-DNA to allow the identification of transformants.

The *vir* genes are organized into several operons. Two of these genes, *vir*A and *vir*G, are constitutively expressed at a low level and control the plant-induced activation of the other *vir* genes. The VirA protein is a kinase that spans the inner bacterial membrane, and acts as the receptor for certain phenolic molecules that are released by wounded plant cells. Many such compounds have been characterized, but acetosyringone is the most widely used in the laboratory to induce *vir* gene expression [7]. These phenolic compounds do not actually attract bacteria to wounded plant cells (the bacteria are attracted by simple molecules such as sugars and amino acids) but the *vir* genes are induced after bacterial attachment. Activated VirA transphosphorylates the VirG protein, which is a transcriptional activator of the other *vir* genes. Further genes on the bacterial chromosome also encode transcription factors that regulate *vir* gene expression (reviewed in [8, 9]). The induction of *vir* gene expression results in the synthesis of proteins that form a conjugative pilus through which the T-DNA is transferred to the plant cell. The components of the pilus are encoded by genes in the *vir*B operon (reviewed in [10]). DNA transfer itself is initiated by an endonuclease formed by the products of the *virD1* and *virD2* genes. This introduces either single-strand nicks or a double-strand break at the 25-bp borders of the T-DNA, a process enhanced by the VirC12 and VirC2 proteins, which recognize and bind to the overdrive enhancer element. The VirD2 protein remains covalently attached to the processed T-DNA. Recent studies have suggested that the type of T-DNA intermediate produced (single- or double-stranded) depends on the type of Ti-plasmid, with double-stranded T-DNA favored by nopaline plasmids (where the T-DNA is a single element) and single "T-strands" favored by octopine and succinopine plasmids, where the T-DNA is split into noncontiguous sections. T-strands are coated with VirE2, a single-stranded DNA-binding protein. The whole complex, sometimes dubbed the firecracker complex because of its proposed shape, is then transferred through the pilus and into the plant cell. The VirD2 protein may protect the T-DNA against nucleases, target the DNA to the plant cell nucleus, and help integrate it into the plant genome. The protein has two distinct nuclear localization signals, with the C-terminal signal thought to play the major role in targeting the T-DNA [11]. Once in the nucleus, the T-DNA is thought to integrate through a process of illegitimate recombination, perhaps exploiting naturally occurring chromosome breaks [12–14].

Contemporary binary vectors have all the conveniences of bacterial cloning vectors such as multiple unique restriction sites in the T-DNA region to facilitate subcloning, the *lac*Z gene for blue-white screening and a λ *cos* site for preparing cosmid libraries. A popular binary vector in current use is pGreen, which is <5 kbp in size, has 18 unique restriction sites in the T-DNA, a *lac*Z gene for blue-white screening of recombinants, and a selectable marker that can be used both in bacteria and in transformed plants

[15]. The progressive reduction in size has been made possible by removing essential genes required for replication in *A. tumefaciens* and transferring those genes to the bacterium's genome, or onto a helper plasmid. The pGreen plasmid, for example, contains the Sa origin of replication, which is much smaller than the more traditional Ri and RK2 regions. Furthermore, an essential replicase gene is housed on a second plasmid called pSoup resident within the bacterium. All conjugation functions have also been removed [15].

More recent innovations have also been incorporated into binary vectors, such as the inclusion of Gateway technology, a proprietary technology developed by Invitrogen (now part of Life Sciences, Carlsbad, California, USA) which is based on the *att*B and *att*P site-specific recombination sites and associated enzymes employed by bacteriophage λ to integrate into the *Escherichia coli* chromosome during lysogeny (the process by which the bacteriophage genome integrates into the bacterial chromosome and becomes dormant). Under normal circumstances, the *att*P site in the phage genome and the *E. coli att*B site undergoes site-specific recombination catalyzed by a phage enzyme, resulting in integration and the formation of two hybrid sites flanking the prophage, *att*L, and *att*R. To develop this as a cloning system, sequences are prepared with flanking *att*B sites (typically generated using extended PCR primers) and these undergo recombination with *att*P sites in a Gateway vector to generate an Entry Clone in which the sequence is flanked by *att*L sites. The Entry Clone can then be mixed with a plant-specific Destination Vector, which contains *att*R sites flanking a marker gene, such that the cloned gene is transferred into the destination vector to replace the marker (LR recombination). A large number of Gateway-compatible binary vectors have been developed [16] allowing universal cloning independent of the presence of restriction endonuclease sites and the assembly of multiple genes on one plasmid, a modification known as MultiRound Gateway [17].

Methods of *Agrobacterium*-Mediated Transformation

Many dicotyledonous plants can be transformed using variations of the simple protocol developed by Horsch et al. [18] in which small disks punched from leaves are surface-sterilized and inoculated in a medium containing *A. tumefaciens* harboring the recombinant binary vector. The disks are cultured for 2 days, during which T-DNA transfer takes place, and are then transferred to a medium containing the selection agent and carbenicillin to kill the bacteria. After 2–4 weeks, developing shoots are excised from the callus and transplanted to root-inducing medium, and thereafter into soil.

This leaf disk method is unsuitable for most monocotyledonous plants because they lie outside the *Agrobacterium* host range, and do not respond to wounding in the same way as dicots. In order to transform staple crops such as cereals, modified culture conditions were developed involving explants containing a high proportion of actively dividing cells, such as embryos or apical meristems. In dicots, cell division is often induced by wounding, whereas wound sites in monocots tend to become lignified. This probably explains why traditional procedures such as the leaf disk method are inefficient in monocots. Hiei et al. [19] showed that the cocultivation of *Agrobacterium* and rice embryos in the presence of 100 mM acetosyringone was a critical factor for successful transformation. Efficiency could be improved further by using so-called "supervirulent" strains like AGL-1, which incorporate modifications to boost gene transfer activity, such as overexpressed *vir*G (switching on the expression of the other *vir* genes) and/or *vir*E1, which is a major limiting factor in T-DNA transfer (reviewed in [20]). Komari et al. [21] used a different strategy, in which a portion of the virulence region from the Ti-plasmid of supervirulent strain A281 was transferred to the T-DNA-carrying plasmid to generate a so-called superbinary vector. The advantage of the latter technique is that the superbinary vector can be used in any *Agrobacterium* strain.

Principles of Direct DNA Transfer

Direct DNA transfer, as the name suggests, involves the introduction of DNA directly into the cell without using a biological carrier. This has two important advantages over *Agrobacterium*-mediated transformation. First, there is no dependency on the biological properties of the carrier, so any species and variety is

suitable for transformation. Second, there is no need to use specialized vectors for transformation – indeed transformation is possible without any vectors at all. The principles of direct DNA transfer are therefore much more straightforward than those for *Agrobacterium*-mediated transformation. All that is required is a mechanism for getting DNA into the plant cell, and ensuring it reaches the nucleus. This can be achieved using physical or chemical means.

Chemical Methods for Direct DNA Transfer Historically, the first direct transfer methods were chemical, and were closely related to the (at the time) newly devised methods for gene transfer to animal cells. Animal cells lack a cellulose wall and are protected by a simple plasma membrane. Therefore, the methods devised for animal cells would not work directly on plant cells, but were suitable for protoplasts. Gene transfer across the protoplast membrane is promoted by a number of chemicals, of which polyethylene glycol has become the most widely used due to the availability of simple transformation protocols [22]. Alternatively, DNA uptake may be induced by electroporation [23]. Putative transformants are transferred to selective medium, where surviving protoplasts regenerate their cell walls and commence cell division, producing a callus. Subsequent manipulation of the culture conditions then makes it possible to induce shoot and root development, culminating in the recovery of fertile transgenic plants. The major limitation of protoplast transformation is not the gene transfer process itself, but the ability of the host species to regenerate from protoplasts. Protoplast transformation was also the first method developed for gene transfer to the chloroplast genome of higher plants (see below).

Physical Methods for Direct DNA Transfer There is a great diversity of physical approaches for gene transfer to plants, including electroporation of walled plant cells, perforation of the cell with silicon carbide whiskers, microinjection, and poration with a finely focused laser beam. In most of these cases, only transient expression of the introduced DNA has been achieved, although transgenic corn plants have been recovered following whisker-mediated transformation [24]. Particle bombardment (microprojectile bombardment, biolistics) is a more robust and reliable method for stable transformation which has been successful for the transformation of cereals, soybean, cotton, phaseolus, and other recalcitrant crops. Initially, a modified shotgun was used to accelerate small (1–4 μm) metal particles into plant cells at a velocity sufficient to penetrate the cell wall (∼250 m/s). In the initial test system, intact onion epidermis was bombarded with tungsten particles coated in tobacco mosaic virus (TMV) RNA. Three days after bombardment, approximately 40% of the onion cells that contained particles also showed evidence of TMV replication [25]. A plasmid containing the *cat* (chloramphenicol acetyltransferase) reporter gene driven by the CaMV35S promoter was then tested to determine whether DNA could be delivered by the same method. Analysis of the epidermal tissue 3 days after bombardment revealed high levels of transient CAT activity [26]. The stable transformation of explants from several plant species was achieved soon after these initial experiments. Early reports included the transformation of soybean [27], and corn [28, 29]. The ability to stably transform plant cells by this method offered the exciting possibility of generating transgenic plants representing species that were, at the time, intractable to other transformation procedures. Early successes included soybean, cotton, papaya, and tobacco (reviewed in [30]). Particle bombardment has also been pivotal in the development of chloroplast transformation technology (see below).

There is no intrinsic limitation to the potential of particle bombardment since DNA delivery is governed entirely by physical parameters [31]. Many different types of plant material have been used as transformation targets, including callus, cell suspension cultures, and organized tissues such as immature embryos, meristems, and leaves. The number of species in which transgenic plants can be produced using variants of particle bombardment has therefore increased dramatically over the last 20 years including rice [32], wheat [33], and oat [34], as well as many other crops (reviewed in [30]). The original gunpowder-driven device has been improved and modified resulting in greater control over particle velocity and hence greater reproducibility of transformation conditions. An apparatus based on electric discharge has been used for the development of variety-independent gene transfer methods for the more recalcitrant cereals and

legumes [35], while several instruments have been developed where particle acceleration is controlled by pressurized gas (reviewed in [36]). Physical parameters such as particle size and acceleration (which affect the depth of penetration and the amount of tissue damage) as well as the amount and conformation of the DNA used to coat the particles must be optimized for each species and type of explant [30, 37]. However, the nature of the transformation target is probably the most important single variable in the success of gene transfer.

In Planta Transformation Methods

Most transformation methods for plants require some form of tissue culture step. This is because the fundamental principle of most transformation methods is that plants are regenerated from a small number of transformed cells that can survive under selection. Experiments using the model dicot *Arabidopsis thaliana* have led the way in the development of so-called *in planta* transformation techniques, where the need for tissue culture is minimized or eliminated altogether. Such methods involve the introduction of DNA, either using *A. tumefaciens* or direct transfer, into intact plants [38, 39].

The procedure is carried out at an appropriate time in the plant's life cycle so that the DNA becomes incorporated into cells that will contribute to the germ line, directly into the germ cells themselves (often at around the time of fertilization), or into the very early plant embryo. Generally, *in planta* transformation methods have a very low efficiency, so the small size of Arabidopsis and its ability to produce over 10,000 seeds per plant is advantageous. This limitation has so far prevented *in planta* techniques from being widely adopted for crop species, although radish, pak choi, and *Medicago truncatula* are exceptions [40–42]. The first *in planta* transformation system involved imbibing Arabidopsis seeds overnight in an *A. tumefaciens* culture, followed by germination [43]. A large number of transgenic plants containing T-DNA insertions were recovered but in general this technique has a low reproducibility. A more reliable method has been described by Bechtold et al. [38] in which the bacteria are vacuum infiltrated into Arabidopsis flowers. An even simpler technique called floral dip has become widely used [39]. This involves simply dipping Arabidopsis flowers into a bacterial suspension at the time of fertilization. In both these methods, the transformed plants are chimeric, but give rise to a small number of transgenic progeny. It has been established that T-DNA is transferred into the ovule during the transformation procedure [44].

An alternative to the direct transformation of germ line tissue is the introduction of DNA into meristems *in planta* followed by the growth of transgenic shoots. In Arabidopsis, this has been achieved simply by severing apical shoots at their bases and inoculating the cut tissue with *A. tumefaciens* suspension [45]. Using this procedure, transgenic plants were recovered from the transformed shoots at a frequency of about 5%. In rice, explanted meristem tissue has been transformed using *A. tumefaciens* and particle bombardment, resulting in the proliferation of shoots that can be regenerated into transgenic plants. Such procedures require only a limited amount of tissue culture.

Vectors for Plant Transformation

Components of Plant Transformation Vectors

The vectors used for plant transformation are usually designed with four purposes in mind – the ability to replicate in both *E. coli* and *A. tumefaciens* (i.e., shuttle vector capability), suitability for subcloning (multiple restriction enzyme sites and/or Gateway compatibility), the ability to confer a selectable phenotype on transformed cells (selectable marker genes), and the ability to drive transgene expression (an expression cassette, consisting minimally of a promoter, site for transgene insertion and a terminator/polyadenylation site).

For *Agrobacterium*-mediated transformation, the binary vector system comprises one transformation vector and one helper plasmid containing the *vir* genes (see above). The transformation vector contains the T-DNA, with the selectable marker gene and expression cassette housed within (reviewed in [46]). The replication functions are not required for DNA transfer and are found on the plasmid backbone, but they are required for maintenance in *A. tumefaciens* and cannot be dispensed with entirely, nor moved to the helper plasmid because the replication functions are required in *cis*. The *E. coli* replication functions (generally the ColE1 origin) are not required in

A. tumefaciens but are needed for basic cloning operations prior to transformation (reviewed in [47]) and these are also found on the plasmid backbone.

In contrast to *Agrobacterium*-mediated transformation, direct transfer (e.g., particle bombardment) is an entirely physical process with no dependence on biological functions. Therefore, replication functions on vectors used for direct DNA transfer are solely present to facilitate cloning in *E. coli*. They are entirely dispensable for the transformation process and can indeed be a nuisance if integrated into the plant genome since they encourage recombination and may in some cases promote transgene silencing. Only the expression cassette and selectable marker are required *in planta*, and therefore the plasmid backbones can be removed prior to transformation, leaving the small, linear cassettes as the substrate (reviewed in [31]). Although this is functionally equivalent to the linear T-DNA which is excised from the binary vector during *Agrobacterium*-mediated transformation, it should be noted that the T-DNA excision process is often imprecise, resulting in varying amounts of backbone sequences being cotransferred to the plant genome.

The Development of Binary Vectors

One of the first binary vectors for *Agrobacterium*-mediated transformation was pBIN19 [48] although this has fallen out of favor because of its low copy number in *E. coli*, which makes it difficult to obtain large amounts of DNA for cloning (Table 1). Another disadvantage of pBIN19 is that the selectable marker is next to the right border. Because T-DNA transfer is directional, with the right border being transferred first, it is better to have the marker next to the left border to ensure that resistant plants have received a complete (or nearly complete) copy of the T-DNA. These two disadvantages were addressed in more recent vectors such as pPZP and pBINPLUS, which contained a high-copy-number origin of replication for *E. coli* and a selectable marker gene at the left T-DNA border [49, 50]. Two rare restriction sites were also provided for cloning convenience.

As discussed above, the successful *Agrobacterium*-mediated transformation of monocots rested on the development of superbinary vectors with extra copies of some of the *vir* genes to enhance transformation efficiency. In the first instance, the *vir*B, *vir*C, and *vir*G genes were transferred from Ti-plasmid pTiBo542 [52, 53] carried by supervirulent strains of the bacterium, such as A281 or EHA101. Hiei et al. [19] constructed a new superbinary vector called pTOK233 by adding the *vir*B, *vir*G, and *vir*C genes of pTiBo542 to achieve rice transformation. The T-DNA in this case carried the *npt*II selectable marker under the control of the *nos* promoter, the *hpt* selectable marker driven by the CaMV 35S promoter and an intron-*gusA* fusion gene also driven by the CaMV 35S promoter. A comparison between the binary vector pIG121Hm in the supervirulent strain EHA101 and the superbinary vector pTOK233 in the regular strain LBA4404 showed that pTOK233 was slightly more efficient [19]. Similar combinations have been used to achieve the transformation of many monocot species (reviewed in [54, 55]). In corn and sorghum, efficient transformation systems were established only with superbinary vectors in LBA4404, whereas a standard binary vector in a supervirulent strain was inefficient even with improved co-culture conditions [56].

One disadvantage of the superbinary system is the large size of all the vector components, reducing the convenience of cloning by standard methods. Therefore, the final construction step of a superbinary vector involves the cointegration of an intermediate vector such as pSB11 and an acceptor vector such as pSB1 via homologous recombination between the shared DNA segments [21]. The intermediate vector is a small plasmid containing the T-DNA and ColE1 origin for replication in *E. coli*. The acceptor vector is an IncP plasmid, which can be replicated in *E. coli* and *A. tumefaciens*, and carries the 14.8-kb *KpnI* fragment. If a gene of interest is to be introduced into plants in tandem with a marker gene, the two genes are first inserted into an intermediate vector, which is introduced into a strain of *A. tumefaciens* that carries an acceptor vector so that the cassette is integrated into the acceptor to generate the final superbinary vector. This approach also facilitates the transfer of large segments of DNA with minimal rearrangement and favors a low number of integrated copies [46].

Other improvements have been made to reduce the frequency of vector backbone transfer. For example, Hanson et al. [57] placed the lethal *barnase* gene outside the left T-DNA border so that any transgenic plants

Crop Plants Transformation Methods. Table 1 Development of binary vectors for *Agrobacterium*-mediated transformation

Vector	Category	Details	References
pBIN19	Binary vector	Low copy number in *Escherichia coli,* plant resistance marker is next to the right border	[48]
pPZP	Binary vector	ColE1 origin of replication, plant marker is adjacent to the left border of T-DNA	[49]
pCAMBIA	Binary vector	Modification of pPZP	[49]
pBINPLUS	Binary vector	Selectable marker gene at the left T-DNA border, a higher copy number in *E. coli,* and two rare restriction sites for easier cloning	[50]
pIG121Hm	Binary vector	A derivative of pBIN19	[19]
pTOK233	Superbinary vector	Contains *vir*B, *vir*C, and *vir*G genes from pTiBo542	[19, 51]
pTiBo542	Ti-plasmid	Has *virB, virC,* and *virG*	[52, 53]
pSB11	Intermediate vector of superbinary system	ColE1 origin of replication, multiple cloning sites within T-DNA, replicates only in *E. coli*, has a fragment homologous to the acceptor vector pSB1	[21]
pSB1	Acceptor vector of pSB11 of superbinary system	Replicates in *E. coli* and *Agrobacterium*	[21]

containing sequences beyond the left border were counterselected. Another way to reduce backbone cotransfer is to insert additional left border sequences, increasing the likelihood of recognition by the corresponding Vir proteins and thus suppressing transfer, as has been demonstrated in rice [58] and Arabidopsis [59]. Improvements have also been made to facilitate rapid and efficient subcloning. The zero background TA cloning system [60] was developed for *Agrobacterium*-mediated transformation and uses restriction enzyme *XcmI* to generate 3′-T overhangs in the linearized vector within the counterselectable marker gene *ccd*B, which ensures that self-ligated vectors are not propagated after transformation, but that PCR products with 3′-A overhangs can be inserted without further modification.

Multiple Gene Transfer (MGT)

In the early years of plant biotechnology, most transgenic plants contained two transgenes – one selectable marker under the control of a constitutive promoter to facilitate the selective propagation of transformed cells, and a "primary transgene" or "gene of interest" which could be under the control of any sort of promoter and was intended to alter the plant's phenotype in a specific manner. MGT is now being embraced as an approach to generate plants with more ambitious phenotypes [61]. MGT allows goals that were once impossible to be achieved, e.g., the import of complex metabolic pathways, the expression of entire protein complexes, and the development of transgenic crops simultaneously engineered to produce a spectrum of added-value compounds [61, 62].

Essentially there are two MGT methods known as the linked and unlinked cotransformation strategies. In the linked strategy, all the different genes are linked on the same piece of transforming DNA. This is the normal approach chosen with *Agrobacterium*-mediated transformation where several genes are carried within the same T-DNA borders. However, it is quite possible to transform plants efficiency with (a) an *Agrobacterium* strain carrying a binary vector that has two separate T-DNAs, and (b) different *Agrobacterium* strains carrying different T-DNAs, although this becomes increasingly complex as the number of genes increases. There are several reports of a mixed strategy where two *Agrobacterium* strains carrying different T-DNAs each with multiple genes has been used to achieve MGT (reviewed in [63]).

MGT is more easily achieved by direct gene transfer because there is no need to combine multiple genes on the same length of DNA. When the genes are supplied separately as a mixed preparation of plasmids, there appears to be no bias in the process of integration. Tandem cotransformation can be undertaken, although it becomes more cumbersome as larger numbers of genes are required, but cotransformation with discrete, unlinked genes is just as efficient, and the genes tend to cointegrate at the same locus. As many as 12 transgenes have been integrated using this unlinked cotransformation approach [64].

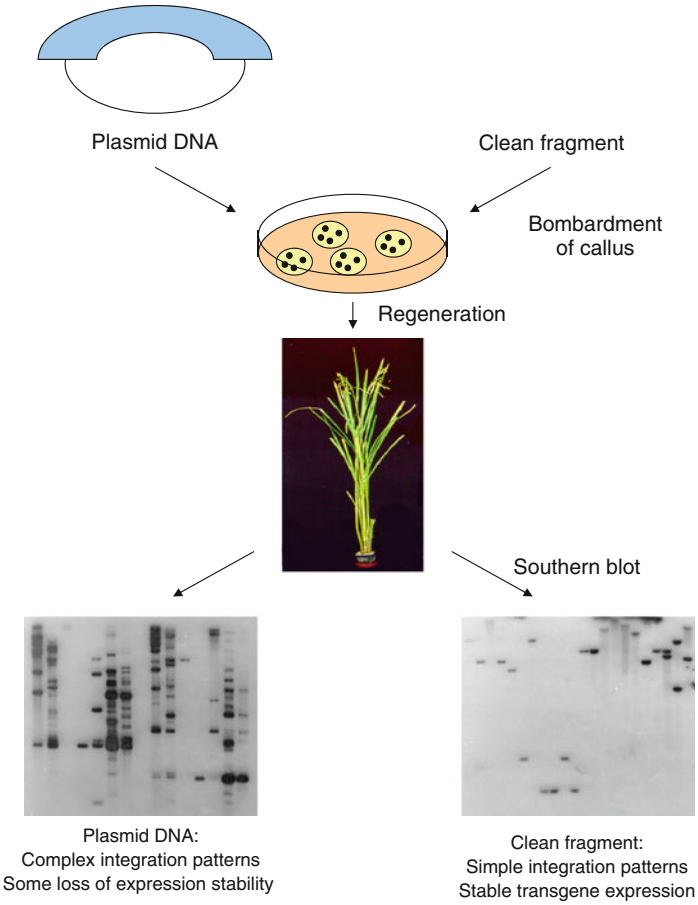
The main issue with linked MGT is the inconvenience of serial cloning. Very rare restriction sites can help to address this challenge, as shown by Goderis et al. [65] who developed a binary vector for MGT incorporating 13 hexanucleotide restriction sites, six octanucleotide restriction sites, and five sites for homing endonucleases, which are extremely rare in natural sequences and allow unidirectional cloning. Six different expression cassettes in auxiliary vectors with different promoter and terminator sequences were cut with the five different homing endonucleases plus an additional octanucleotide restriction endonuclease and transferred into the homing endonuclease sites of the binary vector. Modified auxiliary vectors also facilitate N- or C-terminal fusions to five different autofluorescent tags (EGFP, EYFP, Citrine-YFP, ECFP, and DsRed2) expressed from the tandem CaMV 35S constitutive promoter [66]. Similar systems have been developed by Thomson et al. [67], with the pUGA vectors for direct transfer and the pUGA2 vectors for *Agrobacterium*-mediated transformation. A series of unidirectional shuttle vectors containing various combinations of homing endonuclease sites was constructed and used to create artificial gene clusters in the pUGA or pUGA2 vectors, allowing the simultaneous transfer of up to six genes. Versatile systems now exist that offer a large number of promoters, terminators, and autofluorescent tags (reviewed in [68]).

A further strategy for linked MGT is to use the Cre/*lox*P recombination system together with homing endonucleases. In this method, two donor vectors are needed to introduce the expression cassettes into the acceptor vector using Cre recombinase [69]. After each round of recombination, the unnecessary backbone sequence from the donor vector is cleaved out using the homing endonucleases leaving just one *lox*P site for the next step. In this manner, ten transgenes were inserted in the acceptor vector and introduced into rice by *Agrobacterium*-mediated transformation.

The most recent generation of vectors are modular and multifunctional, such as the pCLEAN-G/pCLEAN-S dual binary vectors for *Agrobacterium*-mediated transformation [70] and the pORE vector system that can be adapted for both *Agrobacterium*-mediated transformation and direct DNA transfer [71]. The pORE vector series consists of "open" vectors for general plant transformation, "reporter" vectors for promoter analysis, and "expression" vectors for transgene expression. The sets comprise various combinations of promoters (PHPL, PENTCUP2, and PTAPADH), selectable markers (*npt*II and *pat*), and reporter genes (*gusA* and *smgfp*), and any element can be modified independently.

Direct DNA Transfer Using Minimal Expression Cassettes

As discussed above, vector backbone sequences are not required for direct DNA transfer and they may also promote recombination within the transgenic locus and/or act as triggers for de novo DNA methylation. To determine whether minimal linear cassettes (promoter, transgene, and terminator) could be used for direct DNA transfer, Fu et al. [72] separated the expression cassettes for the marker genes *gusA* and *hpt* from the parent vector, and used these as substrates for coating the microprojectiles used in particle bombardment, with the intact plasmids as a control. They found not only that the linear cassettes were equally efficient for transformation, but also that the elimination of the plasmid backbone had a remarkable positive effect on the resulting transgenic rice plants (Fig. 2). The cassette transformants generally contained fewer transgene copies than those transformed with intact plasmids, and they showed stronger and more stable expression. Further analysis of the minimal cassette population showed that the transgenes were expressed in most of the transgenic plants and that, for all the transgenes, overall expression levels and coexpression frequencies were higher than previously reported for whole plasmid transformants. These results were confirmed using the *yfp* (yellow



Crop Plants Transformation Methods. Figure 2
The clean DNA transformation system compared to particle bombardment with whole plasmid DNA [4]. The transformation strategy is shown, and two representative DNA blots are compared to demonstrate the simpler integration patterns resulting from transformation with linear minimal cassettes

fluorescent protein) and *hpt* markers, with concatemers forming only rarely in such plants [73].

Promoters Used for Plant Transformation

The promoters used in plant biotechnology are traditionally divided into three categories – constitutive (active continuously in most or all tissues), spatiotemporal (tissue-specific or stage-specific activity), and inducible (regulated by the application of an external chemical or physical signal) [74]. Most basic transformation vectors incorporate strong constitutive promoters because it is assumed that the objective is to express the transgene(s) at the highest possible level. Initially, the *A. tumefaciens nos* (nopaline synthase), *ocs* (octopine synthase), and *mas* (mannopine synthase) promoters were popular because they were already present in the natural T-DNA sequences from which the early binary vectors were developed, and had evolved to be active in many plant species (at least those within the *A. tumefaciens* host range). However, the CaMV 35S promoter was found to be stronger and unaffected by wounding, and its modular nature made it easy to modify [75, 76]. The activity of the CaMV 35S promoter can be increased by duplicating the enhancer up to four times [77] and the enhancer can also increase the activity of heterologous promoters to which it is attached [78].

Although widely used, the CaMV 35S promoter has certain limitations such as its poor performance in monocots, its suppression by feeding nematodes, and

the intellectual property issues affecting its commercial deployment (reviewed in [79]). For this reason, alternative virus promoters with similar or improved properties have been sought. Thus far, however, the only virus promoters that have been developed into established expression vectors are those from *Cestrum yellow leaf curling virus* (CmYLCV) [80], which can be licensed from Syngenta Biotechnology, Inc. for limited research purposes, and from *Subterranean clover stunt virus* (SCSV), which has been used to construct the pPLEX series of expression vectors for use in both dicots and monocots [81, 82].

Constitutive expression in monocots is usually achieved with housekeeping promoters, particularly those from the rice *actin1* and corn *ubiquitin1* genes (reviewed in [83, 84]). In both cases, the presence of the first intron of the gene is required for high-level expression [83, 84], and the addition of this intron to the CaMV 35S promoter also enhances its activity in monocots, e.g., 40-fold in corn [85]. In contrast, the first intron of the recently characterized rice *actin2* gene contains a negative regulatory element whose removal is required for high-level promoter activity [86].

Many different plant promoters have been described that restrict expression to particular cells, tissues, organs, or developmental stages, and seed-specific promoters are probably the most diverse. Seeds are a frequent target for genetic engineering in plants because they can accumulate recombinant proteins to levels that would be lethal in vegetative tissues but can do so without compromising plant growth and development; they are also a harvestable product and thus the target for nutritional improvement. Many promoters have been identified that target gene expression specifically to the seed, or to a particular region of the seed such as the endosperm, embryo, or aleurone [74, 79, 87]. Anther-specific promoters are also very useful because they can be used to control male fertility, an important trait in crop breeding, while fruit- and tuber/root-specific promoters are valuable for the nutritional improvement of fruit and root vegetable crops, pest/disease resistance, and the use of staple crops as factories for the production of novel proteins and metabolites.

Inducible promoters are also highly valued in plants because they allow transgenes to be controlled by internal and external physical or chemical cues. Many different inducible promoters have been identified in plants and these generally fall into three categories – (1) those responsive to endogenous signals (plant hormones); (2) those responsive to external physical stimuli (abiotic and biotic stresses); and (3) those responsive to external chemical stimuli. Such promoters provide immense scope for the precise regulation of transgene expression through external control, ranging from the precise control of transgene activation/inactivation in experimental settings to the ability to activate transgenes on an agricultural scale by the application of chemical sprays. Examples of commonly used promoters include those responsive to phytohormones (particularly auxin, abscisic acid, gibberellin, and ethylene), heat-shock promoters responsive to raised temperatures, light-inducible promoters, promoters induced by wounding or by exposure to elicitors produced by pathogens, and promoters that respond to specific metabolites [74, 79]. Sugar responsive promoters fall into the latter category and the *cis*-acting elements that confer sensitivity to sugar are particularly useful for controlling gene expression in cultured plant cells. For example, elements from sporamin and amylase promoters have been studied in detail and the minimal α-amylase 3 promoter makes the normally constitutive rice *actin1* promoter sensitive to the presence of sugar [88]. Inducible promoters that respond to xenobiotic signals are also valuable because transgenes can be activated without affecting endogenous genes. Martinez et al. [89] developed a hybrid system consisting of the tobacco budworm ecdysone receptor ligand-binding domain fused to the mammalian glucocorticoid receptor DNA-binding domain and the VP16 transactivation domain. The receptor responds to tebufenozide (an insecticide better known by its trade name CONFIRM). Similarly, Padidam et al. [90] have developed a system that is based on the spruce budworm ecdysone receptor ligand-binding domain, and responds to another common insecticide, methoxyfenozide (INTREPID).

Selectable and Screenable Markers

As stated above, selectable marker genes provide a phenotype that allows transformed cells to be propagated under conditions where nontransformed cells cannot survive, such as in the presence of an otherwise

Crop Plants Transformation Methods. Table 2 Selectable markers used for plant transformation (Data compiled and updated from [91–93])

Gene (Product)	Source	Phenotype and other comments
aad (aminoglycoside adenyltransferase)	*Shigella flexneri*	Provides resistance to trimethoprim, streptomycin, spectinomycin, and sulphonamides. Used mainly for chloroplast transformation
bar (phosphinothricin acetyltransferase)	*Streptomyces hygroscopicus*	Resistance to phosphinothricin (PPT), which is a component of the herbicides bialophos, Basta, and glufosinate
ble (glycopeptide-binding protein)	*Streptalloteichus hindustantus*	Resistance to the glycopeptide antibiotics bleomycin and pheomycin (and the derivative Zeocin)
dhfr (dihydrofolate reductase)	Mouse	Resistance to methotrexate
sul1 (dihydropteroate synthase)	*Escherichia coli*	Resistance to sulfonamides (Asulam)
epsps (enolpyruvylshikimate phosphate synthase)	*Petunia hybrida*	Resistance to the herbicide glyphosate
hpt (hygromycin phosphotransferase)	*Klebsiella* spp.	Resistance to the aminoglycoside antibiotic hygromycin B
manA (mannose-6-phosphate isomerase, MIP)	*E. coli*	Ability to grow on mannose as sole carbon source
neo/nptII/aphII (neomycin phosphotransferase)	*E. coli*	Resistance to the aminoglycoside antibiotics neomycin, kanamycin, and geneticin (G148)

toxic or growth-disrupting reagent (positive selection) or in the absence of an otherwise essential nutrient (negative selection). This is necessary to isolate the small number of transformed cells from the overwhelming majority of their nontransformed peers which, without selection, would quickly outcompete them. Although a wide range of selectable markers has been tested in plants, only a few are used routinely (reviewed in [47, 91]). The broadest markers are suitable in most plants and are expressed using the most active constitutive promoters to ensure that all cell types are protected under selection (the CaMV35S promoter in dicots and the actin or ubiquitin promoters in monocots, as discussed earlier). Most selectable markers are described as conditional because an external reagent must be applied to facilitate selection, whereas others are nonconditional, i.e., they work without any external selection reagent. The typical selectable markers used in plant transformation are positive and conditional, and work by conferring resistance to a toxic substance such as an antibiotic or herbicide that has a very specific intracellular target (Table 2).

Marker genes that confer antibiotic resistance originate from bacteria but have been modified to function well in plants. The first marker to be used in plants was neomycin phosphotransferase (*npt*II, *aph*II), which confers resistance to the aminoglycoside antibiotics neomycin, kanamycin, and geneticin (G148) [94]. This is probably still the most widely used marker in the laboratory but some plants are naturally resistant to kanamycin, and the antibiotic can also interfere with normal development in some species. An alternative is hygromycin phosphotransferase (*hph, hpt, aph*IV), providing resistance to the antibiotic hygromycin through the ATP-dependent phosphorylation of a 7-hydroxyl group [95]. Other antibiotic-resistance markers used less frequently include those conferring resistance to bleomycin [96], gentamycin [97], and methotrexate [98].

Marker genes that confer herbicide resistance may originate from bacteria or plants, and those conferring resistance to the broad-spectrum herbicides phosphinothricin (PPT)/glufosinate and glyphosate are used the most widely. PPT/glufosinate is a competitive inhibitor of glutamine synthetase (GS), the only

enzyme that can catalyze the assimilation of ammonia into glutamic acid in plants. Inhibition of GS therefore results in the accumulation of toxic levels of ammonia. The enzyme phosphinothricin *N*-acetyltransferase (PAT) encoded by either the *bar* or *pat* genes (these are genes from different microbial species) can be used to provide PPT/glufosinate resistance in transformed plant cells [99]. Glyphosate, the active ingredient of Roundup, inhibits the enzyme 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS), which is required for the synthesis of aromatic amino acids. Glyphosate resistance can be conferred by markers encoding a modified EPSPS that is not affected by the herbicide, or those encoding a bacterial enzyme that breaks down the herbicide (glyphosate oxidoreductase, GOX) [100]. Markers providing resistance against sulfonamindes such as Asualam [101] and chlorsulfuron [102] are also used occasionally.

Negative selectable markers are useful because they allow transformed cells to be selected based on the absence of something that is necessary for nontransformed cells to grow or regenerate efficiently. The *E. coli manA/pmi* gene confers the ability to use mannose as a sole carbon source so that only transformed cells survive on media containing mannose but lacking sucrose [103]. The gene is a negative conditional marker because mannose itself is not toxic to nontransformed plants, but rather the absence of sucrose (nontransformed plants grow perfectly well in the presence of both sugars). Another example is the *A. tumefaciens ipt* gene, which promotes the synthesis of cytokinins [104]. This is a nonconditional marker because it confers the ability to produce shoots in growth medium lacking exogenous cytokinins, i.e., nothing has to be added to the medium to facilitate selection. Simply, transformed tissues are placed on medium lacking cytokinins and only those tissues that produce shoots are transgenic.

The other major class of marker genes are known as screenable, scorable, or visible markers (or reporter genes) because rather than providing cells with a selective advantage they confer a phenotype that can easily be detected without interfering with other cellular processes, allowing transformed cells to be identified and studied (Table 3). Although screenable markers have been used for the prosaic purpose of identifying transformed cells and manually separating them from nontransformed cells, they tend to be used for more sophisticated purposes, such as reporter assays and tracing experiments. Some screenable marker genes only provide their visual signal when provided with a particular substrate, i.e., they are conditional (e.g., *gusA*, *luc*). Others have an intrinsic ability to yield a visible signal, i.e., they are nonconditional (e.g., *gfp*, *DsRed*), and these are the most useful since they can be used in living organisms.

The *E. coli gusA* (*uid*A) gene encodes the enzyme β-glucuronidase (GUS), the most widely used conditional screenable marker in plants. As well as its endogenous substrates, GUS can process a range of chromogenic and fluorescent derivatives in a range of assays that allow the quantification or in situ localization of reporter gene activity. The most common substrate for GUS histochemical staining is 5-bromo-4-chloro-3-indolyl glucuronide (X-gluc), a clear substrate that yields a blue product. Other common substrates include p-nitrophenyl β-D-glucuronide, which is used for spectrophotometric quantitative assays, and 4-methylumbelliferyl-beta-D-glucuronide (MUG), which produces a quantitative fluorescent signal. GUS is preferred in plants over the very similar reporter GAL (encoded by *lacZ* and widely used in microbes and animals) because of its stability in plants and its lack of toxicity and background activity. The main disadvantage of GUS is that it cannot be conveniently used for in vivo imaging because plant cells must be fixed or destroyed to visualize the reaction. Its stability can also be problematic if the aim of an experiment is to study fluctuations, since the longevity of the protein can mask transient decreases in expression.

Both the disadvantages of GUS are addressed by luciferase (LUC) an enzyme from the firefly (*Photinus pyralis*) which catalyzes the ATP-dependent oxidative decarboxylation of luciferin, producing light in the process. LUC allows nondestructive qualitative and quantitative assays to be carried out both in vitro and in vivo, and because the reaction has a short half-life, it can be used to monitor fluctuating activity. A series of vectors that incorporate the *luc* gene have been developed for plants, including the LucTrap series that allow targeted and random transcriptional and translational fusions of a transgene with a *luc* gene optimized for plant cells [106]. One drawback of *luc* is that it is still

Crop Plants Transformation Methods. Table 3 Screenable markers (reporter genes) used in plants (Data compiled and updated from [83, 105])

Gene (product)	Comments
gusA (β-glucuronidase)	Source: *Escherichia coli gusA/uidA* gene
	Activity: catalyzes the hydrolysis of β-glucuronides
	Assays: nonisotropic; in vitro assays are colorimetric or fluorometric; also histochemical assay format using X-gluc
	Advantages: simple, sensitive, quantitative, many assay formats available, inexpensive
	Disadvantages: assays are destructive; enzyme is stable so unsuitable for studies of downregulation
cat (chloramphenicol acetyltransferase)	Source: *E. coli* Tn*9*
	Activity: catalyzes the transfer of acetyl groups from acetyl coenzyme A to chloramphenicol
	Assays: in vitro assays only, isotropic
	Advantages: simple to perform
	Disadvantages: low sensitivity, expensive, low resolution in vivo, reliance on isotopic assay format
luc (luciferase)	Source: The firefly *Photinus pyralis*
	Activity: light produced in the presence of luciferase, its substrate luciferin, oxygen, Mg^{2+}, and ATP
	Assays: nonisotopic bioluminescent assays in vitro and in vivo
	Advantages: sensitive, rapid turnover, quantitative
	Disadvantages: Expensive detection equipment, limited reproducibility of some assay formats
Anthocyanin regulators	Source: corn (*Zea mays*)
	Activity: induces pigmentation
	Assays: visual screening for pigmented cells in vivo
	Advantages: simple, inexpensive, nondestructive
	Disadvantages: low sensitivity, not quantitative, background expression, adverse effects on transgenic plants
GFP (green fluorescent protein)	Source: the jellyfish *Aequorea victoria*
	Activity: intrinsic fluorescence under blue/UV light
	Assays: nonisotopic, in vivo assays in live plants
	Advantages: intrinsic activity (no substrate requirements), sensitivity, use in live plants; many variants with modified absorption and emission spectra available, and different subcellular targeting signals; several variants can be used simultaneously
	Disadvantages: weak signal in some systems (this is being addressed through the use of modified GFPs with stronger emission and reduced photobleaching); no variants that emit in the orange-red part of the spectrum

Crop Plants Transformation Methods. Table 3 (Continued)

Gene (product)	Comments
DsRed (red fluorescent protein)	Source: coral reef *Discosoma* spp.
	Activity: intrinsic fluorescence under blue/UV light
	Assays: nonisotopic, in vivo assays in live plants
	Advantages: intrinsic activity (no substrate requirements), sensitivity, use in live plants; many variants with modified absorption and emission spectra available, and different subcellular targeting signals; several variants can be used simultaneously
	Disadvantages: weak signal in some systems, no variants that emit in the violet-blue-green part of the spectrum

a conditional reporter, requiring the substrate luciferin and the presence of oxygen, ATP, and magnesium ions. In contrast, the green fluorescent protein (GFP) from the jellyfish *Aequorea victoria* is a nonconditional reporter allowing the direct, noninvasive visualization of fluorescence in vivo in real time merely by exposure to blue/UV light. The original *gfp* gene was nonfunctional in plants because of a cryptic splice site, but this has been corrected and the protein has been widely deployed as a vital marker [107]. One of the major advantages of GFP is that its spectral qualities can be modified by mutation, giving rise to a whole family of derivatives with enhanced brightness, less susceptibility to quenching, and a range of excitation/emission wavelengths allowing different reporters to be used in vivo simultaneously. In combination with variants that allow targeting to different compartments within the plant cell, many sophisticated forms of analysis become straightforward to implement, e.g., allowing the real-time monitoring of protein processing, trafficking and protein–protein interactions [108]. As well as GFP and its derivatives, other bioluminescent proteins have also been identified, including DsRed from *Discosoma* spp. This is similar to GFP but covers a different spectral range (red GFP is not available) but there is little background fluorescence and it can be visible under white light [109].

The useful properties of selectable and screenable markers can also be combined into one protein. For example, Ochiai-Fukuda et al. [110] developed a fusion marker incorporating enhanced green fluorescent protein and blasticidin deaminase, conferring resistance to the aminoacylnucleoside antibiotic blasticidin S. The *gfbsd* marker was introduced into rice callus and allowed the rapid and efficient selection and visual confirmation of transformed cells.

Consequences of Nuclear Transformation

Integration of Nuclear Transgenes

As discussed above, plant transformation is a multistep process, the first step involving the transfer of DNA into the plant cell, which can be achieved either by direct transfer or by *Agrobacterium*-mediated transformation. Once the DNA reaches the nucleus, the next step (transgene integration) is dependent predominantly on that DNA and on factors provided by the plant cell, although in the case of *Agrobacterium*-mediated transformation it is possible that the Vir proteins complexed with the T-strand may facilitate the integration process (see below). A number of groups have investigated the structure of genomic/T-DNA and T-DNA/T-DNA junctions in plants and have concluded that integration occurs by illegitimate recombination (see [111, 112]). A strand invasion mechanism has been proposed (reviewed in [12]), in which the 3′ end of the T-strand initiates the integration process by hybridizing to a short region of homology in the plant genome, the second strand being completed by primer extension of the plant DNA. Other models suggest conversion of the T-strand into a double-stranded intermediate, which integrates at the site of naturally occurring chromosome breaks via double-strand DNA break repair. This is supported by experiments that show transformation efficiency increases following UV irradiation, which generates nicks and breaks in

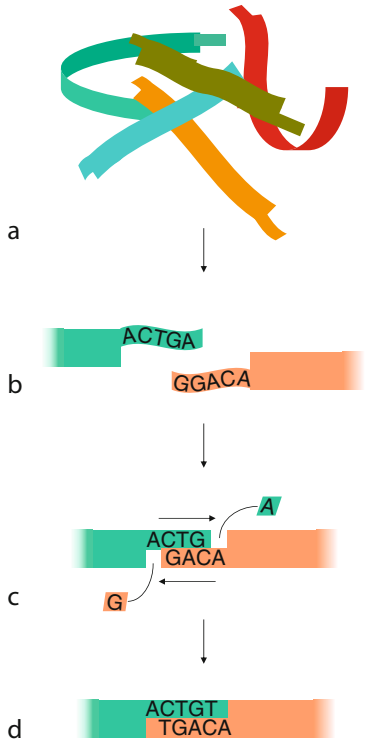
genomic DNA. However, since T-DNA integration still occurs in DNA repair mutants, it is possible both mechanisms occur simultaneously albeit with different efficiencies.

DNA repair models argue that proteins encoded by the host plant have a much more important role in T-DNA integration than *Agrobacterium* proteins, such as VirD2, which are imported into the plant with the T-DNA. However, since the VirD2 protein remains covalently attached to the 5′ end of the T-strand during transfer it is also likely to influence integration [113]. In an in vitro assay, VirD2 can ligate together a cleaved T-DNA border sequence but cannot ligate T-DNA to other genomic targets unless plant cell extracts are also present [114], a phenomenon supported by the identification of Arabidopsis mutants impaired for T-DNA integration [115].

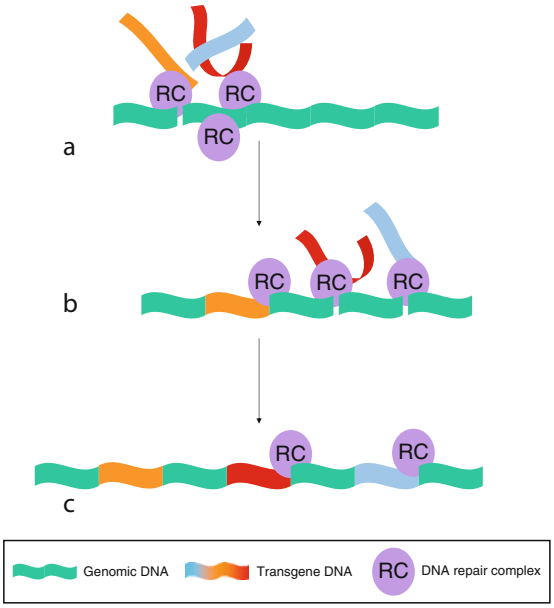
Much can be learned about the T-DNA integration mechanism by the inspection of borders, especially the borders between adjacent T-DNA sequences in multicopy insertions. The formation of heterodimers during cotransformation argues in favor of T-DNA concatemerization prior to integration. Although inverted repeats around the right border are often precise, those around the left border and those separating direct T-DNA repeats are often characterized by the insertion of variable-sized regions of filler DNA, which may be derived from the T-DNA sequence or from plant genomic DNA [116]. This suggests either the simultaneous integration of multiple T-DNAs at a single locus, or a two-phase mechanism, in which a primary T-DNA integration event stimulates further secondary integrations in the same area, similar to those proposed for particle bombardment (see below). Zhu et al. [117] carried out a comprehensive study of T-DNA border characteristics in a population of transgenic rice plants including 156 T-DNA/genomic DNA junctions, 69 T-DNA/T-DNA junctions, and 11 T-DNA/vector backbone junctions, which included 171 left borders and 134 right borders. Conserved cleavage was observed in 6% of left and 43% of right borders, microhomology was observed in 58% of T-DNA/genomic DNA, 43% of T-DNA/T-DNA, and 82% of T-DNA/vector junctions, mostly at left borders, and about one third of the T-DNA/genomic DNA and T-DNA/T-DNA junctions showed evidence of filler DNA (up to 344 bp). This was derived mainly from the T-DNA region adjacent to the breakpoint and/or from the rice genomic DNA flanking the T-DNA integration site, with T-DNA/T-DNA filler DNA showing the greatest complexity. Interestingly, when two T-DNAs were integrated in the inverted repeat configuration, significant truncation was always observed in one of the two T-DNAs whereas with the direct repeat configuration, large truncations were rare. These data suggest that no single integration mechanism can account for all observations but the presence of filler DNA at many of the junctions argues that a template-driven DNA synthesis mechanism must be involved.

The analysis of plasmid/plasmid and plasmid/genomic junctions in transgenic plants generated by particle bombardment reveals features characteristic of illegitimate recombination similar to those seen for T-DNA junctions, suggesting that the same overall integration mechanisms may be involved [118]. For example, such junctions are characterized by regions of microhomology, filler DNA, trimming of the DNA ends so sequences are lost, and AT-rich elements surrounding the junction site, with similarity to topoisomerase I binding/cleavage sites (Fig. 3). In the analysis of multiple plasmid/plasmid junctions in 12 transgenic rice lines, Kohli et al. [120] observed 10 plants with microhomology at the junctions and 2 plants where junctions appeared to be generated by blunt ligation, with no overlap. A similar ratio of conserved end-joining to microhomology-mediated recombination was observed by Gorbunova and Levy [121] and Salomon and Puchta [111]. Topoisomerase I sites were also observed adjacent to 10 out of 12 junctions characterized in transgenic Arabidopsis plants generated by particle bombardment [122] and in four of the six junctions in the commercial SUNUP variety of papaya [123]. Illegitimate recombination therefore appears to be responsible both for the integration of foreign DNA into the plant genome, and the linking of multiple plasmid copies, which is similar to the mechanism proposed for T-DNA integration (see above).

When nuclei from the cells of transgenic cereal plants generated by particle bombardment are analyzed by fluorescence in situ hybridization (FISH) using a transgene-specific probe, a curious phenomenon in often observed in which a single fluorescent spot in the interphase nucleus separates into multiple signals along a metaphase chromosome [124]. Any model for

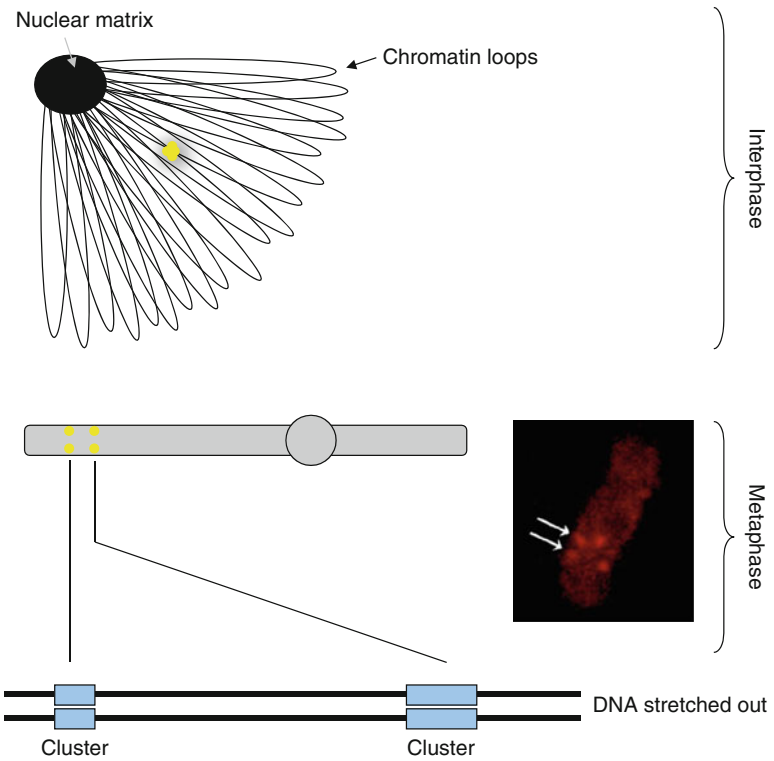


Crop Plants Transformation Methods. Figure 3
Mechanism for transgene integration at regions of microhomology [119]. A mixture of DNA fragments with ragged ends (**a**) interacts with a double-stranded DNA break with partially complementary ragged ends (**b**). Repair synthesis across the gap (**c**) generates a recombination junction (**d**) which may be completely conserved if the homology is precise, or may involve either the loss of terminal sequences or the insertion of filler DNA if the homology is partial



Crop Plants Transformation Methods. Figure 4
Explanation for the formation of transgene arrays and transgene clusters interspersed with genomic DNA [119]. A mixture of DNA fragments interacts with a double-stranded DNA break where a repair complex has already assembled (**a**). The repair complex may stitch together DNA fragments to form concatemers prior to integration, or may integrate single copies. The first integration event stimulates further repair complex activity nearby, resulting in additional nicks and breaks in the genomic DNA that act as further integration sites (**b**). This results in a cluster of transgenes (single copies and concatemers) interspersed with short regions of genomic DNA (**c**)

transgene integration following particle bombardment must take into account some form of three-tier organization, consisting of contiguous transgene arrays, interspersed with short regions of genomic DNA to generate local clusters, and the appearance of widely dispersed signals at metaphase. Two-phase transgene integration mechanisms have been proposed to explain the first two levels of organization, and in such models concatemerization is proposed to occur prior to integration, while interspersion occurs during the integration process [118, 120, 125] (Fig. 4). In each model, penetration of the cell is proposed to elicit a wound response, which would include the induction of DNA repair enzymes, such as nucleases and ligases. The presence of these enzymes and an excess of foreign DNA would result in the linking together of several copies to form concatemers, which would be the substrates for integration. This might be stimulated by homology between individual copies of transforming plasmids, and "backbone" homology might also result in the concatemerization of plasmids carrying different transgenes in cotransformation experiments. However, as stated above, cotransformation and cointegration also occur when two nonhomologous minimal cassettes are used for transformation, so homology might not be as important as the presence of free DNA ends [72]. Kohli et al. [120] suggested that



Crop Plants Transformation Methods. Figure 5

Higher-order transgene locus organization in cereals transformed by particle bombardment [124]. Transformation occurs during interphase, when the chromatin is distributed into specific nuclear zones and territories. If a metal particle causes localized damage, DNA repair complexes will form at these sites and initiate transgene integration (**a**). During metaphase, when FISH analysis is generally carried out, loci that are brought together in interphase may be separated, resulting in multiple signals from the same transformation event (**b**). If the DNA were stretched out, this would reveal large (megabase) interspersed sequences, which have also been observed in fiber-FISH experiments

transgene clusters arise in a second phase where a primary integration event occurring by illegitimate recombination at a chromosome break generates a "hot-spot" for further integration events in the same area. This might be due, for example, to the presence of local repair complexes that can slide along the DNA and introduce nicks which can be exploited by more foreign DNA. Pawlowski and Somers [125] suggested an alternative second phase where a number of discrete transgene concatemers integrate simultaneously at a site containing multiple replication forks. Although there is no direct evidence for either mechanism, it is interesting to note that DNA integration is stimulated in rapidly dividing cells, and is blocked in Arabidopsis mutants lacking essential components of the DNA recombination machinery.

The higher-order organization of transgenic loci observed by FISH is thus far unique to particle bombardment and demands a model which takes into account the three-dimensional structure of the nucleus. It is possible that the transformation event affects a local region of the interphase nucleus, e.g., a metal particle may cause damage to a particular area of chromatin arranged in loops attached to the nuclear matrix, or to a localized transcription factory. If the particle "skims" several loops or several transcription units, there will be regions of DNA damage close together in *trans*, but widely separated in the *cis* configuration were the DNA to be stretched out (Fig. 5). Each of these sites could act as a nucleation point where foreign DNA diffusing from the metal particle is used to patch up double-strand breaks, generating widely separated

arrays and/or clusters [124, 126]. In support of this induced break and repair model, Svitashev et al. [127] have shown that in 6 of 25 transgenic oat plants generated by particle bombardment, transgene integration sites were associated with rearranged chromosomes. This suggests that DNA breaks caused by incoming particles are repaired with foreign DNA and may also result in deletions, inversions, and translocations involving genomic DNA.

Transgene Structure and Integrity

Transgene rearrangements following particle bombardment have been widely reported in the literature and many publications repeat the "lore" that direct DNA transfer is more likely than T-DNA transfer to generate complex rearranged loci. The number of rearrangements that can be detected depends entirely on the resolution of the method being used. Thus, careful analysis of locus structure by Southern blot hybridization, PCR, and DNA sequencing has shown that rearrangements may be more widespread than first envisaged in both transformation methods.

In the case of direct DNA transfer, the analysis of transgenic oat loci by Somers et al. has shown that transgene rearrangements can be extensive and extremely complex, with multiple small insertions, inversions, and deletions within any transgene, plus the presence of filler DNA [127]. In corn, Mehlo et al. [128] noted that every single plant among the population they analyzed showed some form of rearrangement, and they speculated that undetected "minor" rearrangements could be responsible for many instances of transgene silencing otherwise attributed to epigenetic processes. In particular, certain transgene rearrangements were not detectable by Southern blot hybridization because they were too subtle, but they could be picked up by long-range PCR and sequencing. Because Southern blot hybridization is normally the sole method used to determine whether a given locus is intact or rearranged, this suggests caution should be used in relying on such results, since only "major" rearrangements can be detected in this manner.

In the case of *Agrobacterium*-mediated transformation, Afolabi et al. [129] and Zhu et al. [117] found that nonintact T-DNAs were present in >70% of transgenic rice lines, in most cases reflecting loss of the mid to right border portion of the T-DNA. Similarly, Rai et al. [130] found that about 50% of rice plants transformed with a T-DNA containing the phytoene synthase (*psy*) and phytoene desaturase (*crtI*) genes showed evidence of rearrangements, and in the majority of cases the rearrangements occurred in the *crtI* expression cassette, which was adjacent to the right T-DNA border. Rearrangements involving the left border are often characterized by the insertion of variable-size regions of filler DNA, possibly derived from the T-DNA sequence or from plant genomic DNA [116, 131].

Few researchers have characterized transgene rearrangements in detail, but work by Kohli et al. [132] has shown that rearrangements may involve palindromic sequences in the transforming plasmid, which tend to form secondary structures such as hairpins and cruciforms. These investigators characterized 12 transgenic rice lines created by particle bombardment, which had been shown to contain rearranged transgenes. Interestingly, they found that an imperfect palindrome in the CaMV 35S promoter was involved in one third of all rearrangements, i.e., the sequence of this palindrome was adjacent to the rearrangement junction. Similar phenomena have been noted in T-DNA transformants containing the same promoter. This sequence has the ability to adopt a cruciform structure that may stimulate recombination events. Many other promoters contain palindromic sequences of variable length within 100 bp of the transcription start site. The secondary structures formed at these sites enable DNA–protein interactions for transcription under normal circumstances, but may also participate in aberrant recombination events. The fully sequenced papaya genome [123] also revealed a number of previously unidentified transgene rearrangements, i.e., a 1,533-bp fragment comprising a truncated, nonfunctional *tet*A gene and flanking vector backbone sequence, and a 290-bp nonfunctional fragment of the *npt*II gene, in addition to the intact, primary transgene conferring virus resistance.

Transgene Silencing

A common issue raised in association with nuclear transformation in plants is the phenomenon of transgene silencing, where the phenotype corresponding to

the introduced transgene is not expressed. In the absence of a genetic explanation (e.g., an undetected mutation or rearrangement), silencing is an epigenetic phenomenon that can occur at either the transcriptional or posttranscriptional levels. Transcriptional silencing involves the absence of transgene mRNA, and often occurs due to the integration of the transgene at a genomic position that is already repressed (position-dependent silencing). However, transgenes in active regions of the genome may also be silenced if the promoter region is inactivated by hypermethylation, which can occur in response to unusual DNA structures and compositions that attract de novo methylation, or DNA sequences that allow the synthesis of short double-stranded RNA (dsRNA) molecules. In contrast, posttranscriptional silencing actually requires transcription to take place, but the mRNA is rapidly degraded. This is confirmed by nuclear run-on assays, which measure the amount of pre-mRNA in the nucleus. Like transcriptional silencing, posttranscriptional silencing appears to have evolved as a defense against invasive nucleic acids and is also triggered by dsRNA, in this case matching the transcribed region. There is considerable cross talk between the transcriptional and posttranscriptional silencing pathways and if a transgene is homologous to an endogenous gene, the silencing effect can spread to that gene resulting in a phenomenon known as cosuppression.

Transcriptional silencing may be encountered in plants where several copies of the same transgene or part thereof are present in the transgenic locus, or when the same promoter is used to control several transgenes. However, the context is very important. There have been plenty of reports describing transgenic plants carrying multiple transgenes under the control of the same promoter yet showing strong and stable expression. For example, although Zhu et al. [133] used five different endosperm-specific promoters in corn to achieve the high-level expression of carotenogenic genes, Naqvi et al. [134] achieved strong expression of four genes in the same system using the barley D-hordein promoter to control each transgene, with no adverse effects. Transcriptional gene silencing resulting from repetitive promoter regions is correlated with increased promoter methylation [135] and appears to be driven by the production of dsRNA matching the promoter sequence [136]. This has been demonstrated by deliberately expressing dsRNA corresponding to the *nos* promoter in transgenic plants carrying a second transgene driven by the *nos* promoter [137] and by creating transgenic plants with a transgene locus that triggers both transcriptional and posttranscriptional silencing simultaneously, by producing dsRNA corresponding to promoter and transcribed sequences of different target genes [138]. In the absence of deliberately created promoter dsRNA, the transcriptional silencing seen in some transgenic plants carrying multiple copies of the same promoter appears to arise from dsRNA produced either by unfortunate transgene positioning or rearrangements that create hairpin structures, or by transgenes with such high levels of expression that the polyadenylation machinery is saturated. Evidence from many transformation experiments indicates that there is no simple correlation between transgene copy number and expression level, with the exception of certain carefully controlled experiments using boundary elements. In some cases, higher copy numbers have suppressed overall expression levels whereas in others higher copy numbers have enhanced expression. Where suppression effects have occurred, it has been suggested that "runaway expression" resulting in the generation of aberrant RNAs lacking polyadenylate tails has triggered potent silencing through the posttranscriptional silencing pathway [139].

The organization of a transgenic locus is difficult to control, and it is therefore a common occurrence in both *Agrobacterium*-mediated transformation and direct DNA transfer that the juxtaposition of transgenes or fragments thereof can result in the creation of hairpin promoter structures at the DNA level that are transcribed into aberrant dsRNA species. Such arrangements can be obvious and easy to detect, but even where gross rearrangements are absent it is possible that undetected "micro-rearrangements" are present in the transgenic locus, as observed by Mehlo et al. [128] when investigating the structure of a transgenic locus in corn generated by direct DNA transfer. The siRNAs that trigger RNA-dependent DNA methylation are just 24 bp in length, so it is conceivable that inverted repeats of <50 bp could be sufficient for transgene silencing, and such structures would be undetectable using the coarse analysis methods typically employed

to study transgenic plants, such as Southern blot hybridization. The likelihood of dsRNA production depends not only on the presence of damaged or rearranged transgenes, but also on the relative position of intact transgenes, which is itself a reflection of the mechanism of transgene integration. The organization of integrated T-DNA sequences differs among *Agrobacterium* strains, but a common feature of nopaline-type derivatives such as C58 is the preferential integration of T-DNA as dimers with an inverted repeat configuration, linked either at the left or right borders [140]. Where cotransformation is carried out with two T-DNAs containing different genes, the different T-DNAs often integrate as heterodimeric inverted repeats, preferentially around the right border [141]. If the same promoter is used for both genes, this would favor the formation of hairpin structures that could be transcribed from the opposite strand. The structure of loci generated by direct DNA transfer is more variable, but inverted repeat structures involving promoter sequences are not uncommon, allowing the same silencing mechanism to operate [126].

Plastid Transformation Methods

The introduction of DNA directly into the chloroplast genome is considered beneficial for a number of reasons including the high level of gene expression that can be achieved, reflecting the presence of thousands of chloroplasts in photosynthetic cells and the absence of gene silencing. Chloroplast transformation also provides a natural containment method for transgenic plants, since in most crops the transgene cannot be transmitted through pollen (reviewed in [142]).

The first reports of chloroplast transformation were serendipitous, and the integration events were found to be unstable. For example, an early experiment in which tobacco protoplasts were cocultivated with *Agrobacterium* resulted in the recovery of one transgenic plant line in which the transgene was transmitted maternally. Southern blot analysis of chloroplast DNA showed directly that the foreign DNA had become integrated into the chloroplast genome [143]. However, *Agrobacterium* is not an optimal system for chloroplast transformation because the T-DNA complex is targeted to the nucleus. Therefore, direct DNA transfer has been explored as an alternative strategy and efficient chloroplast transformation has been achieved both through particle bombardment and PEG-mediated transformation (reviewed in [144]).

Stable chloroplast transformation was first achieved in the alga *Chlamydomonas reinhardtii*, which has a single large chloroplast occupying most of the volume of the cell [145]. Particle bombardment was used in this experiment and the principles established using this simple organism were extended to tobacco, allowing the recovery of stable transplastomic tobacco plants [146]. These principles included the use of vectors containing chloroplast homology regions, allowing targeted integration into the chloroplast genome, and use of the selectable marker gene *aad*A (encoding aminoglycoside adenyltransferase) which confers resistance to streptomycin and spectinomycin [147]. Basic vectors for plastid transformation include flanking sequences and chloroplast-specific expression cassettes. Species-specific chloroplast flanking sequences are generated by PCR using primers designed from the available chloroplast genomes. The chloroplast expression cassette is composed of a promoter, the selectable marker, and 5′/3′ regulatory sequences to enhance the efficiency of transcription and translation. The most frequently used integration site is the transcriptionally active intergenic region between the *trn*I and *trn*A genes, within the *rrn* operon. The first-generation plastid transformation vectors included the pPRV series and plasmids pRB94/95, in which both the marker gene and the primary transgene have their own 5′ and 3′ regulatory sequences (reviewed in [144]). More recent vectors include modified restriction sites, *lox*P sequences for posttransformation marker excision, and homology regions targeting insertions to the *rbc*L-*acc*D intergenic region [148]. Thus far, chloroplast transformation by particle bombardment has been achieved only in crops that allow direct organogenesis, and this does not include any monocots (reviewed in [142]).

Future Directions

The vast majority of the transgenic plants generated thus far carry a single primary transgene plus a selectable marker. The transgene integrates randomly into the genome, which means it is subject to unpredictable position effects that may result in silencing; the locus structure is also very difficult to control.

In the future, there will be a stronger emphasis on strategies to increase the scope of gene transfer and the predictability and preciseness of DNA integration, and consequently the likelihood of stable and predictable transgene expression.

Transfer of Large DNA Molecules Using Modified Conventional Vectors

A precise upper limit for T-DNA transfer has not been established. It is greater than 50 kbp [2, 3], but using standard vectors it is difficult to transfer inserts larger than 30 kbp routinely due to instability in the bacterial host. However, the analysis of very large genes or the transfer of multiple genes linked in series can now be achieved thanks to the development of high-capacity binary vectors based on the artificial chromosome type vectors used in *E. coli*.

The first to be described was BIBAC2 [149]. This contains an F-plasmid origin of replication and is modeled on the bacterial artificial chromosome. The basic vector transforms tobacco with high efficiency, but the efficiency of transformation drops substantially when large inserts are used. This vector has been used to introduce 150 kbp of human DNA flanked by T-DNA borders into the tobacco genome, although virulence helper plasmids supplying high levels of VirG and VirE in *trans* were critical for successful DNA transfer. An alternative vector carrying a P1 origin of replication and modeled on the P1 artificial chromosome was constructed by Liu et al. [150]. This transformation-competent bacterial artificial chromosome (TAC) vector was used to introduce up to 80 kbp of genomic DNA into Arabidopsis, and while there was some loss of efficiency with the larger inserts, it was still possible to produce many transgenic plants. Both vectors contain a kanamycin resistance marker for selection in bacteria and *hpt* for hygromycin selection in transgenic plants. Both vectors also contain the Ri origin for maintenance in *Agrobacterium*, and within the T-DNA region, the *sac*B marker for negative selection, interrupted by a multiple cloning site for transgene insertion. One of the most attractive uses of high-capacity binary vectors is for the positional cloning of genes identified by mutation. The ability to introduce large segments of DNA into the plant genome effectively bridges the gap between genetic mapping and sequencing, allowing the position of mutant genes to be narrowed down by complementation. Genomic libraries have been established for several plant species in BIBAC2 and TAC vectors [151, 152] and cloning in high-capacity vectors has been simplified by the inclusion of Cre/*lox*P and Gateway site-specific recombination technology [153, 154].

Large (80–150 kbp) DNA molecules have also been transferred to plants by direct DNA transfer [155], and although this is not a routine procedure a novel transformation method has been developed recently, based on bombardment with DNA-coated "bioactive beads" to deliver up to 150 kbp of DNA into rice protoplasts [156].

Plant Minichromosomes

In bacteria, plasmid vectors are maintained as episomal replicons to make cloning and isolating recombinant DNA a simple procedure. When it comes to expressing heterologous genes in eukaryotic cells, episomal vectors are widely used to avoid position effects, hence the development of yeast episomal vectors, yeast artificial chromosomes, mammalian plasmid vectors carrying virus origins of replication (e.g., SV40-based vectors, herpes virus-based vectors), and plant expression vectors based on plant viruses (all of which replicate episomally). The yeast artificial chromosome (YAC) system is the most relevant in this context because it allows genes of any size to be introduced into the yeast genome as an independent replicating unit that is treated by the cell as an additional chromosome. YACs comprise a yeast centromere and telomeres, the origin of replication (autonomous replicating sequence), and selectable markers.

More recently, analogous systems have been developed to maintain genes as episomal minichromosomes in plants. These have many advantages for plant genetic engineering including the ability to express large transgenes or groups of transgenes, and the ability to rapidly introduce new linkage groups into diverse germplasm. Carlson et al. [157] created plant minichromosomes by combining the DsRed and *npt*II marker genes with 7–190 kb of corn genomic DNA fragments containing satellites, retroelements, and other repeat sequences commonly found in centromeres. The circular constructs were introduced into embryogenic corn tissue by particle bombardment

and transformed cells were regenerated and propagated for several generations without selection. The minichromosomes were maintained as extrachromosomal replicons through mitosis and meiosis, and showed roughly Mendelian segregation ratios (93% transmission as a disome with 100% expected, 39% transmission as a monosome crossed to wild type with 50% expected, and 59% transmission in self crosses with 75% expected). The *DsRed* reporter gene was expressed over four generations, and DNA blot analysis indicated the genes were intact.

Gene Targeting (Homologous Recombination)

Gene targeting is the directed modification of an endogenous DNA sequence by homologous recombination, an efficient procedure in bacteria, yeast, certain animal cells, and in the plastid genomes of plants, but typically not in the nuclear genome. Only one plant species has been shown to undergo efficient nuclear homologous recombination and that is the moss *Physcomitrella patens* [158]. Among higher plants, low-level gene targeting has been achieved in certain dicots with frequencies ranging from 10^{-3} to 10^{-6} [159]. However, targeting frequencies of up to 1% have been achieved using a T-DNA-mediated gene targeting strategy involving a long homology region in combination with a strong counterselectable marker in rice [160, 161].

There has also been interest in the use of zinc-finger endonucleases to make targeted double-strand breaks in the plant genome, so that homologous recombination is favored at such sites [162]. The modular nature of zinc-finger transcription factors means that recombinant DNA technology can be used to "mix and match" these DNA-binding domains to create recombinant proteins with unique sequence specificities. Zinc-fingers are motifs approximately 30 amino acids in length which coordinate a Zn^{2+} ion and bind to DNA sequences 3-bp long. Combining different zinc fingers in series allows proteins to be tailor made to bind longer DNA sequences. When a nonspecific DNA endonuclease is incorporated into such a protein, it becomes a targeted DNA cutting tool [163, 164]. The recent achievement of targeted transgene integration and endogenous gene disruption in corn [165] and tobacco [166] using zinc-finger endonucleases provides a tantalizing glimpse of the future of plant biotechnology in which precise changes can be made to the genome of any plant genome that is amenable to DNA transfer.

Site-Specific Recombination

Although site-specific recombination has already been described as a cloning tool, particularly the Cre/*lox*P and Gateway systems for rapid vector assembly, it can also be used in transgenic plants to introduce DNA at a specific, favorable locus, or remove DNA sequences *in vivo*. The Cre/*lox*P system has been most widely used in plants for the controlled excision of selectable marker genes after transformation (e.g., [153]), but also for controlled transgene insertion (e.g., [167]). Controlled integration has been studied in transgenic plants already engineered to contain recipient *lox*P sites [168]. In this study, three different recipient wheat lines were generated by bombarding plants with the *lox*P sequence, and these were subsequently bombarded with a *gusA* construct also containing flanking *lox*P sequences, and a *cre* gene. Following transformation, about 80% of lines contained *gusA* at the recipient site, many with single-copy transgenes and others with concatemers. Both types of locus were stably inherited. There was much less variation in expression among the single-copy lines [168]. Chawla et al. [169] generated 18 different transgenic rice lines containing a precise single copy of *gusA* at a designated site. In seven of these lines, additional copies of the transgene integrated at random sites by illegitimate recombination while 11 showed "clean" integration by site-specific recombination only. The single-copy lines were stable over at least four generations and showed consistent levels of expression, which doubled in homozygous plants. In contrast, the multicopy lines showed variable expression and some fell victim to transgene silencing. Interestingly, where the site-specific and illegitimate integration loci segregated in later generations, transgene expression was reactivated in the plants carrying the site-specific integration site alone, whereas close linkage between the site-specific and random integration prevented segregation in other lines and the silencing persisted.

An exciting recent development is the GENE DELETOR system, which is a hybrid of the Cre-*lox*P

and FLP-*FRT* systems. The GENE DELETOR is based on a fusion recognition site (*lox*P-*FRT*), which is inefficient when both recombinases are expressed but highly efficient when either one of the recombinases is expressed alone, giving up to 100% efficiency in populations of up to 25,000 T1 transgenic tobacco plants [170].

Another use for Cre-*lox*P is the simplification of locus structure by resolving multicopy loci to a single transgene copy [171]. A strategy was developed in which the transformation vector contained a transgene flanked by *lox*P sites in an inverted orientation. Regardless of the number of copies integrated between the outermost transgenes, recombination between the outermost sites resolved the integrated molecules into a single copy. The principle was proven by resolving four multicopy loci successfully into single-copy transgenes.

Article Outline

Glossary

C3 The C3 pathway of photosynthesis, found in most plant species, for example, rice, potato, and wheat.

C4 The C4 pathway of photosynthesis, found in some tropical species, for example, maize, sugarcane, sorghum.

PAR Photosynthetically active radiation. Solar radiation in the wavelength region 400–700 nm.

RUE Radiation use efficiency, the ratio of biomass produced per unit radiation intercepted.

Definition of the Subject and Its Importance

The rate of growth (the rate of the accumulation of dry matter) of all plants is entirely dependent on the interception of energy (electromagnetic radiation) from the sun in the wavelength range 400–700 nm. This energy is utilized by photosynthesis to synthesize carbohydrates and other biological molecules needed for essential plant processes.

The amount of energy intercepted or captured by the whole plant and community system (the canopy) is determined by the organization of leaves into an efficient spatial structure with a large total surface area. The amount of radiation captured will determine the rate of photosynthesis possible and the rate of growth. However, the final growth rate is then determined by *losses* in the system that originate from a number of sources, including the type of photosynthetic mechanism, metabolic and hydraulic constraints, the relationship between photosynthetic source and non-photosynthetic sink organ, variability in environmental conditions, and limitations imposed by management techniques.

The discovery that plant and crop growth is closely linked to the amount of intercepted radiation led to the establishment of methods for measuring radiation use efficiency (RUE). RUE is measured as the amount of dry matter produced per unit intercepted radiation over a given time period and it is often separated into key developmental stages within the life cycle of the crop. It was quickly established that values of RUE tend to be stable for a given species, growth stage, and environment, but there are important differences across crop species and plant types. In the absence of other factors, RUE will set the theoretical limit to biomass production and ultimately crop yield. It is now accepted that RUE is a fundamental measurement which underpins potential crop productivity and yield and it has become embedded into modern methods of crop growth analysis.

In many cases, plants absorb more photosynthetically active radiation (PAR) radiation than they utilize for growth: given the current emphasis on global food security, there is currently much interest in raising the RUE of key crops in important agroecosystems.

Introduction and History

All green plants use sunlight as their sole energy source for assimilation of carbon dioxide into carbohydrates. At its most fundamental level, this process is the formation of energy-rich bonds in a form that is easily stored, transported, and utilized in most essential plant functions. This process is of course photosynthesis and

it is the sole supplier of energy for almost all human nutrition and fuel requirements, via current and prehistoric photosynthesis.

The continuing expansion of the human population and the steady increase in consumption per capita is placing pressure on land availability. A variety of factors including urbanization and the erosion of existing land certainly necessitate production of more food and fuel per hectare with fewer inputs (water, fertilizer) and all of this within the uncertainty of changes in climate and increased pressure to use land which may be currently unsuitable for cultivation. For example, 700 million people depend on rice for calorific intake. Each hectare can currently feed around 27 people; by 2050 this will have to rise to 43 people per hectare [1]. This is compounded by the fact that Asian rice yield potential appears to be stagnating [2]. Wheat is grown on over 200 million hectares of land providing approximately one-fifth of the total calorific input of the world's population, and while there have been steady increases in productivity since the green revolution, global demand for wheat is predicted to increase at a faster rate than the annual genetic gains that are currently being realized [3]. Since the highest yields of major crops are usually only achieved within high input systems, it is not surprising that many suggest a reappraisal of the basis of crop productivity.

It seems clear that an increase in the rate of application of fertilizer or water is neither desirable nor even possible. Nitrogen fertilizer is heavily dependent on the continued availability (physically, financially, and politically) of fossil fuels. Water is increasingly scarce not just in equatorial regions but in temperate regions. One way to improve resource use efficiency is to increase the rate of overall biomass production and this is starting to be associated with yield progress of major crops such as rice and wheat [3, 4]. As shall be described, an increase in biomass production by crops, whilst helping to improve upon current rates of breeding progress in yield potential, would also (1) underpin future genetic improvements in adaptive processes, (2) improve the relative efficiency of resource use in terms of biomass production per unit water, light, and fertilizer, and therefore (3) increase the attractiveness of using waste products of arable crops for secondary uses such as fuel, and (4) if applied universally, reduce the competition for land between biofuel crops and food crops, and (5) increase the feasibility of using marginal land for fuel and food production.

A History of Radiation Use Efficiency

Given that it underlies so much of human activity and endeavor it is perhaps curious that the relationship between radiation and plant growth did not become explicitly defined and quantified until relatively recently. It has been suggested that a tendency to retain methods of classical crop growth analysis during the first half of the twentieth century delayed a mechanistic analysis of the processes of biomass accumulation [5]. In these early studies, growth (crop mass) was described as a function of time possibly because of the ease with which mass could be measured through the growing season. This approach was confounded by its inclusion in measurements of relative growth rate where crop biomass increase is closely related to existing biomass. The central role of light interception in growth was recognized by Watson [6] who suggested a measurement of net assimilation rate which worked in some situations but did not adequately account for the complex relationship between leaf area and variation in assimilation rate (photosynthesis) of individual leaves.

Another advancement in understanding came with the consideration that efficiency of light use declined at high levels (light saturation) [7, 8] and that light levels were lower at the base of the canopy. In fact, as pointed out by Hirose [9], the first mathematical model of canopy photosynthesis was first produced by Monsi and Saeki in 1953 but this was not recognized for more than a decade. This resulted in the first real considerations of growth as a function of the amount of light intercepted by the plant canopy. At this time, it was observed that the amount of light intercepted by the canopy was closely related to dry matter accumulation [5]. Despite this there were many studies in the 1970s which used incident light rather than intercepted radiation to make key studies in agronomy and ecology.

The sole use of incident radiation measurements will lead to errors in the calculation of radiation use efficiency especially before canopy closure when not all radiation is absorbed and when crops possess differing rates of canopy development. Over the whole life cycle of the crop, the proportion of incident radiation that is

intercepted and available for assimilation can be quite small. It was not until the mid 1970s that John Monteith established the relationship between accumulated intercepted radiation and accumulated biomass within canopies [10]. This was accompanied by experimental data demonstrating a level of conservation of radiation use efficiency of crop species when grown under optimal growth conditions with high resource availability and a consideration of the role of leaf photosynthetic capacity in crop canopies. This has since proved to be a robust approach and has remained a central feature of crop growth analysis ever since. Many studies attempted to provide values for RUE across a wide range of species and growth conditions across the world [11, 12]. It was quickly claimed (1) that it was possible to attain consistent values for a given species when growing conditions were good, (2) that suboptimal (e.g., nitrogen or water deficient) or stressful conditions caused RUE to decline, and (3) that there were clear differences between crop species: plants possessing the C4 photosynthetic mechanism had the highest RUE followed by most C3 plant species and finally legumes with the lowest RUE values. Early data suggested that RUE was a conservative or even constant value for a given species. However, data published since has demonstrated significant variation and it has been pointed out that close attention in each case must be paid to the methods of analysis, growth conditions, developmental phase, and genotype.

RUE is commonly used within the crop sciences although it is applicable to growth of any autotrophic organism and most ecosystems. Its calculation requires knowledge of the amount of radiation absorbed in a given time period and measurement of the resulting biomass and energy content. These are easier to measure in a uniform system like a monoculture. The historical development of RUE was no doubt dependent on the advancement in other areas of science such as photosynthetic regulation and the technical development of instruments to accurately measure key attributes, that is, radiation, photon flux density, and the rate of photosynthetic carbon assimilation.

The understanding that RUE is fundamental to crop productivity leads naturally to the question of whether it can be improved. The observation that C4 plants possess a higher RUE leads to the notion that such a change would give a higher biomass productivity which could be exploited to increase yield per hectare. The green revolution provided a step change in agricultural productivity that was able to prevent the tragedy of mass starvation in some regions and also to support population increase. As outlined here, a step change of similar magnitude now would probably require an improvement in RUE.

Determination of Radiation Use Efficiency

RUE is the ratio between accumulated plant biomass and the accumulated radiation intercepted by the crop. A note on terminology: some authors use the terms "radiation conversion factor" [13] and "radiation conversion efficiency." Some authors have pointed out that use of the word "conversion" is inappropriate because energy is not being directly converted to matter but rather converted from one form of energy to another (i.e., solar radiation to higher energy state of chlorophyll molecules) [5]. The term radiation use efficiency (RUE) shall be used.

To calculate RUE, it is necessary to know the amount of radiation arriving at the top of the canopy, the amount of radiation intercepted by the canopy, and the biomass accumulated during a given period. In many studies, the energy content of the dry matter is also required. This section will summarize how RUE is measured in a practical sense and tackle some of the diversity in approaches that have been taken.

Radiation arrives at the edge of the earth's atmosphere at a mean rate of 1.4 kJ m^{-2} s^{-1}, the so-called solar constant. By the time photons reach the earth's surface a number of geometrical and atmospheric factors have reduced this value significantly. Cloud cover notwithstanding the greatest influx occurs in tropical regions at low latitudes. The greatest measured flux at the earth's surface itself occurs in low latitude regions where cloud cover is minimal (20–30°). High latitudes can have extremely low solar radiation levels.

Light is absorbed and scattered by molecules, aerosols, and particles in the atmosphere, reducing flux even further. Gas molecules such as CO_2, H_2O, and CH_4 absorb energy at specific infrared wavelengths whilst gas molecules O_2 and O_3 absorb at lower wavelengths. Photosynthesis is restricted to a range of wavelengths that approximate to those visible to the human

eye: 400–700 nm. Higher wavelengths do not contain sufficient energy to drive photosynthesis. At ground level, this range of wavelengths makes up 49% of total solar energy. In other words, the photosynthetic process does not use over half of the energy available. However, longer wavelengths have an important heating effect which raises plant tissue temperature and accelerates metabolic and developmental processes such as leaf and canopy construction.

Variation from day to day means that it is necessary to integrate measurements of radiation over long time periods. This is often done by positioning devices above the canopy and below the canopy. Most commonly these have been fairly inexpensive tube solarimeters connected to a device that continually stores data produced. Reflection can be measured by inverting the device. Instantaneous measurements (spot measurements) of fractional interception (f) are also used but these can be misleading because they are most reliably taken at midday during the same, usually sunny, conditions and therefore do not account for cloud cover or low solar elevation and give lower values of f.

The proportion of PAR is higher in scattered light than direct beam radiation and so it is useful to distinguish between the two and a few commercially available devices are capable of doing so. This also means that the proportion of PAR changes according to solar elevation, although it is around 0.45 at elevations greater than 30° [5]. Growth in predominantly scattered radiation commonly causes an increase in RUE.

Wavelengths used for growth (400–700) are preferentially absorbed by chlorophyll within the canopy resulting in transmitted light that is depleted in red and blue and enriched in far-red. The formula for fractional interception is presented in its simplest form by Eq. 1.

$$f = 1 - \frac{(I + r)}{Io} \quad (1)$$

where f = fractional interception, Io = incident radiation, r = reflected radiation, I = intercepted radiation.

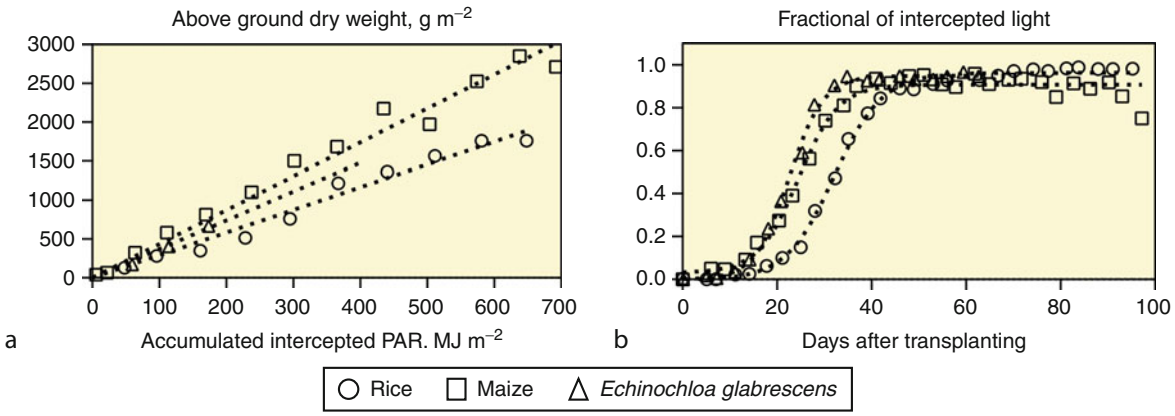
An alternative method for measuring f is spectral reflectance. This compares reflectance from the canopy in the red band and the near IR band to produce a normalized difference vegetation index (NDVI). It has been possible to show the relationship between NDVI and f in many crops [14] and is a technique that is possible to use remotely from satellites and aircraft. Although it is clearly convenient and rapid, one must be aware that it has the drawback of being a spot measurement. Measurements made from satellites suffer from problems of images that deviate from 90° to the earth's surface [15].

Photography is also used to estimate f using a camera fitted with a fish-eye lens positioned below or above the canopy. This has the advantage of encompassing a large area, producing permanent image and being taken rapidly in the field. This method has been shown in many cases to correlate with f measured using solarimeters; however, errors arise due to common bias in positioning the camera. All indirect measurements of f should consider the potential errors that may result.

RUE is usually calculated by measuring the difference in biomass between many consecutive harvests (i.e., accumulated intercepted growth) and plotting this against the measured accumulated intercepted radiation. This is usually a linear relationship and RUE is calculated as the slope of this relationship (Fig. 1). The points at which measurements are made are critical because RUE varies according to developmental state.

Care must be taken when comparing values from different sources [5, 13]. Some of the common sources of variation are as follows:

1. If root mass is not included then RUE values will be lower. However, it is extremely difficult to measure root mass directly and it is often ignored or assumed to be a fixed percentage of total plant mass. Nonuniform growth can therefore be a significant source of error. Energy required to grow and maintain roots is also a function of the biotic and abiotic environment of the soil.
2. Solar radiation flux density is measured using solarimeters, pyranometers, or radiometers which usually cover the wavelengths 300–3,000 nm. The photon flux density is commonly measured using sensors that detect within the photosynthetically active range of 400–700 nm. Therefore the conversion between energy and quanta-based measurements must take into account the energy of each waveband. Data based on different regions of the electromagnetic spectrum can cause inaccuracies, for example, the transmission of shortwave radiation through canopies differs from that of PAR [16].



Crop Radiation Capture and Use Efficiency. Figure 1

An example of the relationship between accumulated intercepted radiation and accumulation of dry matter by three species : the C3 crop rice (*circle*), the C4 crop maize (*square*), and the C4 weed *Echinochloa glabrescens* (*triangle*). Note the higher slope for maize in (**a**), that maize reached full interception before rice in (**b**), and that the weed is the first to form a full canopy but does not achieve the same amount of biomass as the crop species (Redrawn from Sheehy et al. [1])

However, the solar spectrum is fairly constant, and the reliable figure for this is 4.6 µmol quanta. Inaccuracies can arise from badly positioned, poorly leveled or uncalibrated instruments. It is common practice to keep devices free of anything that would attenuate radiation in a way that would bias the results, for example, dead leaves are removed and glass is cleaned.

3. It is important to distinguish *absorbed* from *intercepted radiation*. The latter does not take into account the reflection of PAR from the top surface of the canopy. This is generally assumed to be about 5% of total PAR but variation is likely. Not all of the plant tissues that absorbed energy are necessarily alive or of equal photosynthetic potential.
4. When comparing different species of plant with contrasting harvest organs it is important to consider the *energy content* of the organs involved. Lipid has a higher calorific content than protein, which in turn has a higher calorific content than carbohydrates [17]. The heats of combustion of carbohydrates, proteins, and lipids are 17.3, 22.7, and 37.7 kJ g^{-1}, respectively. Since RUE is comparing the input of energy to the output of dry matter it can vary according to the energy content per unit dry matter and it is essential to adjust RUE accordingly. For example, the RUE of crops that produce particularly oily seeds should decrease during the seed-filling period. However, the nutrient content of plant tissue does not greatly directly influence the measurement of RUE.
5. The stage of growth can have a large influence on the RUE measured (see section Source–Sink Processes and Partitioning of Assimilates). It can be common practice to calculate the RUE over the entire growing season but this does not necessarily represent the maximal RUE value. For example, in many crops RUE appears to be steady during the vegetative period but to decline following the onset of the reproductive phase.

Radiation Capture by Crop Canopies

Canopy structure and therefore the efficiency of light capture was a common feature in the domestication and the later improvement of many crop species. For example, the reduction of branching in maize and sunflower allowed dense planting [18] and there is evidence of further adaptation to higher planting density [19]. The reduction in height of cereals was a key factor in the green revolution, permitting an increase in harvest index and reduction in lodging. Crop canopies

must intercept or capture as much radiation in the 400–700 nm bandwidth as possible. Most of the light interception occurs by leaves; however, stems, petioles, leaf sheaths, and reproductive structures can also absorb significant amounts of radiation. To achieve high interception, they must construct and present a canopy with large leaf area and in many crops the minimum leaf area index (L: the ratio of leaf area per unit ground area) is around three. The L can be expressed by the product of the number of plants per unit ground area, the number of leaves per plant, and the mean area of leaves per plant (plus green stem area). Light can penetrate the canopy and strike the ground below as direct beam radiation (so-called sunflecks), scattered radiation, or radiation that has passed through leaves and other plant organs, that is, transmitted. The amount of penetrated radiation is dependent on the three-dimensional arrangement of leaves in the canopy and for a given L will be a function of a large number of features such as leaf size, leaf density per cubic meter, the angle of individual leaves, heterogeneity of leaves in space (clumping), leaf thickness, and albedo. There is clear variation between species and even between crop varieties in these features. Additionally, it is possible to alter these features through management techniques such as planting density and the application of NPK fertilizer. Therefore there needs to be a way of describing radiation distribution within canopies mathematically and linking this to agronomic characteristics such as leaf area index and nitrogen content.

The relationship between L and fractional interception can be described by Monsi–Saeki equation (Eq. 2), a modification of Beer's law. This assumes that the canopy is a homogeneous medium whose leaves are randomly distributed in space, that is, there is no effect of row structure or clumping and under these conditions Beer's law will apply [9]. The Monsi–Saeki equation can be applied if the canopy is considered to be divided into horizontal layers with each layer possessing a particular L and the irradiance within each layer is measured. The irradiance at each layer will depend on the three-dimensional characteristics of the leaves both within that layer and the layers above. It has been found that this provides an accurate estimate in many crops in which this has been measured: $\ln(I/Io)$ against L provides a linear relationship, the slope of which gives the value k which provides a simple but useful mathematical description of the architecture of the crop canopy in question.

$$I = Io \exp(-kL) \tag{2}$$

I and Io as in Eq. 1, L = leaf area index, and k = extinction coefficient for a given waveband

Crops have been found to vary for the value of k and the major feature is the erectness of leaves. Canopies with erect and narrow leaves such as cereals have a lower value of K than those with flat, broad, and horizontal leaves. This also applies to differences within species, for example, rice varieties vary in erectness [20].

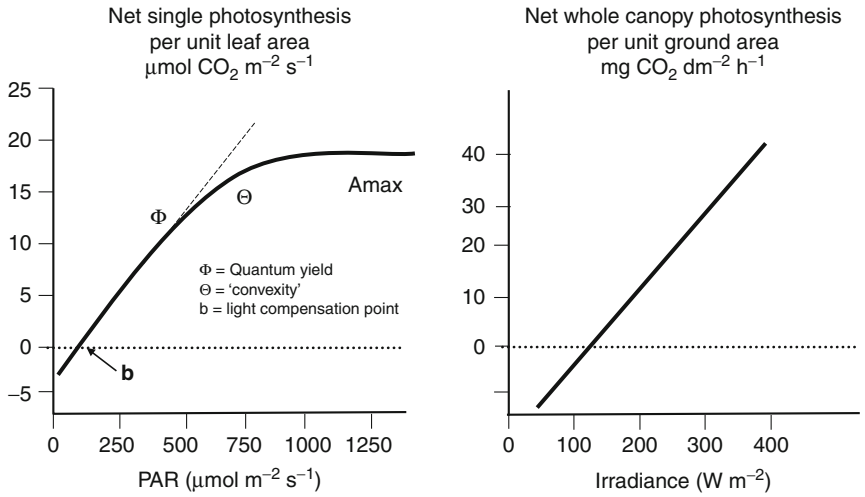
If the Monsi–Saeki equation holds and the k value for a given canopy type is known then it becomes possible to calculate f simply from a knowledge of L (Eq. 3).

$$f = 1 - \exp(-kL) \tag{3}$$

Equation 3, letters as Eqs. 1 and 2

This analysis is useful when canopies are considered to be a three-dimensional "box" of vegetation with radiation penetrating only from above. It can fail where plants are sparsely populated and do not achieve full ground cover or are simply planted in rows with space in between, which is the case for some crops that are tended by hand. The calculation of intercepted radiation in these cases can become quite complex and impractical at high levels of heterogeneity although estimations are often made on the basis of incident radiation and leaf area per plant. Another source of error is angle of solar elevation which can significantly alter the proportion of reflected light and the proportion of scattered light within the canopy. It also does not account for the commonly seen variation in leaf angle that occurs between the top and the bottom of the canopy. Even at a point close to full canopy cover there can be a "bimodal" type of variation in crop canopies. For example, rice plants tend to form "inverted cone" shapes and this causes a complex three-dimensional variation in irradiance distribution especially during canopy development.

The optimal "design" of plant canopies must consider not just maximum interception but also the relationship with photosynthetic rate. In principle, a plant could achieve close to 100% interception with a single, planar chlorophyll-rich leaf and a L of 1.0. However,



Crop Radiation Capture and Use Efficiency. Figure 2
The relationship between photosynthesis and *incident* radiation levels for (**a**) single leaves and (**b**) a full canopy: (**a**) typical features of the leaf response, the linear phase (maximum quantum efficiency), the light compensation point, convexity, and the light saturated rate (Amax, and (**b**) schematic figure: note the linear response of whole canopies in comparison to single leaves

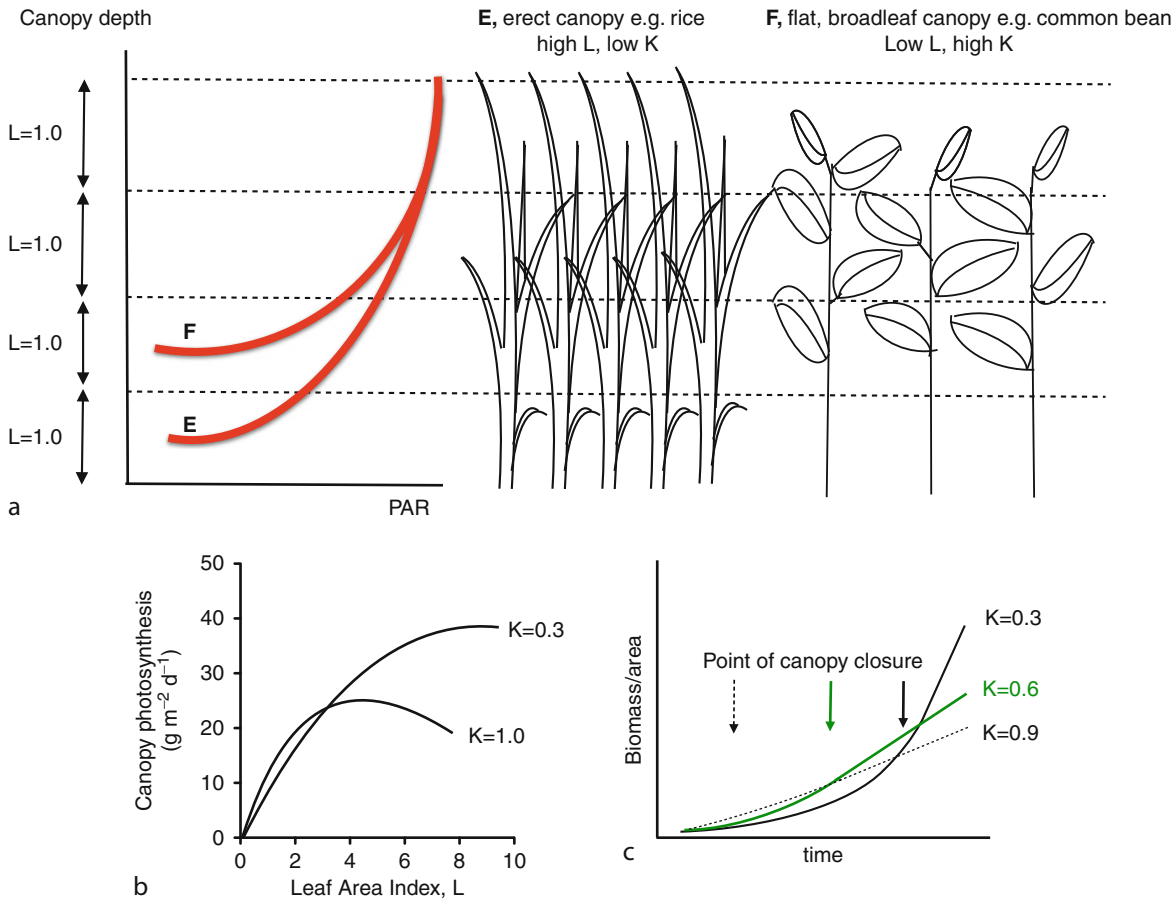
this does not result in optimum productivity largely due to the fact that photosynthesis saturates below full sunlight and this is especially marked in C3 plants. This is a central point: the response of leaf photosynthesis to irradiance is shown in Fig. 2. This is a useful measurement and easy to make with today's equipment. It provides not only a measurement of the maximum rate of photosynthesis (Amax) but also the potential quantum yield of photosynthesis.

A greater canopy carbon gain is achieved by reducing the proportion of leaves in the canopy that exist in the light-saturated state. The leaves lower in the canopy are retained at light limitation while those at the top will be prone to light saturation. If the irradiance increases (e.g., moving from cloud-cover to full sunlight) then those lower in the canopy will be able to respond accordingly. This has lead to the widely observed phenomenon that when irradiance is plotted against carbon-gain (photosynthesis) one commonly observes a linear response for canopies but a saturation in leaves (normally described by a non-rectangular hyperbola) (Fig. 3) [11]. This is important: if canopies demonstrated light saturation then this would severely limit their ability to improve RUE.

Canopy Properties and Photosynthesis

The optimum design for biomass production in terms of carbon gain is predicted to be one that permits a higher proportion of radiation to penetrate to lower layers, whilst also reducing light saturation at the top (Fig. 3). Indeed, this seems to be the trend in species such as rice and wheat although the advantage here is thought to be greatest at lower latitudes where light is overhead for a greater proportion of the year and therefore penetration into the canopy is greater. This also has the advantage that it prevents the unwanted senescence of leaves when light levels drop below or close to the light compensation point [21].

This raises the question of whether there is room for improvement in canopy architecture to improve RUE. Early work found that canopies with a low L benefitted from horizontal posture while those with high L benefitted from upright posture [5, 22]. This work suggested that RUE would not be sensitive to extreme upright posture of leaves. However, it is clear that upright leaves are associated with the highest yielding lines in wheat [23, 24] and it has been suggested that some cereal canopies may benefit from increasing



Crop Radiation Capture and Use Efficiency. Figure 3

Canopy structure and function according to leaf "architecture." (**a**) The schematic figure on the *left* shows canopy depth where the canopy has been divided into layers, each with a leaf area index (*L*) of 1.0. Attenuation of light in the canopy follows the Monsi–Saeki equation. For a broadleaf canopy, the radiation reaches extinction at a higher point and a lower *L* compared to an upright canopy. The canopy extinction coefficient value "*K*" is derived from Eq. 2 and provides a mathematical description of the link between *F* and *L*. (**b**) The calculated relationship between canopy photosynthesis and *L*, measured at irradiance saturating at the top of the canopy for species with two values of *k*. Note the higher maximum value of the species with higher *k* (Redrawn from [9]). (**c**) A highly schematic figure redrawn and adapted from Ong and Monteith [32] and shows the theoretical differences in canopy biomass accumulation over time in species with different values of *k*. Maximum values of carbon gain are achieved after canopy closure which occurs earlier in broadleaf species (high *k*). Species with a lower value of *k* have higher potential rates of total canopy photosynthesis

erectness further [3, 23, 25]. There are relatively few genes controlling erectness and this should be straightforward to test, although work has shown that compensatory effects such as leaf size may be hard to account for.

Modern high-yielding rice lines also have highly erect leaves and it is assumed that this also results in higher potential productivity. In rice, this also permits denser planting which accelerates canopy closure and improves total radiation intercepted over a short tropical growing season.

A further feature is that leaves have different characteristics according to the light intensity to their canopy position. Most notably they have "sun leaf" and

"shade leaf" characteristics, the former having higher light compensation points, higher photosynthetic capacity, and higher nitrogen and enzyme content. This is considered to be an efficient use of resources with nitrogen being located only where it is required for high photosynthetic activity. Additionally, there are a number of acclimation mechanisms to improve light harvesting in shade and diffuse light such as the synthesis of light harvesting complexes enriched in chlorophyll b [20, 26]. The efficiency of use of shade and diffuse light within the canopy is a relatively unexplored area in crops. This raises the question of whether leaf ageing or leaf acclimation gives rise to the nitrogen content of the leaf. There is evidence that both processes are at play: in fact the distribution of nitrogen in plant canopies should be closely related to photosynthesis and irradiance level [27, 28]. There is some indication that this has been achieved although the role of "storage" of assimilated nitrogen in leaves needs further analysis [20, 21].

Canopy development occurs by the successive emergence of leaves from primordia which are localized points of tissue formed around the apical dome of the vegetative shoot. The arrangements of these primordia will largely determine the positions of the leaves in the final canopy. Therefore there is great interest in the genetic manipulation of developmental processes in crops [29, 30]. The thermal time interval between the initiation of successive primordia is critical and determines the time taken for production of successive leaves. The genetic and molecular processes determining leaf development and expansion is an exciting area of research [31].

For annual crops with a limited growing season, it is critical that canopy development is synchronized with periods of high radiation. In temperate regions, low temperatures in Spring can increase the time taken for canopy closure. Since maximum rates of production are not attained until full canopy cover is achieved, this can be deleterious and is referred to as "lost time" [32]. Faster rates of canopy closure can be achieved by different strategies such as the application of nitrogen increasing planting density, irrigation, and the planting of crops in autumn so that the time taken for establishment is reduced. For example, in the UK, maximum radiation receipts occur in June, and for Spring-sown crops such as potato and sugar beet, productivity can depend on the establishment of a high L before this period. In rice, the remarkable erectness of leaves in some modern cultivars has allowed for extremely dense planting and a shift toward a reduction in tillering. This has the advantage that canopy closure can be achieved quickly and the so-called lost time is reduced.

There is no doubt that canopy structure is a central feature of crops with high RUE although the precise three-dimensional characteristics are difficult to quantify by direct measurement and this has meant that the techniques to describe crop canopies mathematically have remained relatively simple and continued to assume that they exist as randomly distributed photosynthetic elements in space. As shall be described in the next section, it will be essential to have a more sophisticated approach which links leaf arrangement and light distribution at higher resolutions and accounts for the dynamics of both light distribution and localized photosynthetic responses. For this various photographic and laser-based methods are available for "digitization" of plant and crop canopies although the high density of many crop canopies makes such measurements difficult in a practical sense. Mathematical modeling of plant canopy structure is progressing rapidly along with increased computing power and more sophisticated programming [33]. It would seem likely that methods that can use empirical measurements to model canopy architecture at high resolution and accurately predict photosynthetic light responses are not far away.

"Conversion" of Captured Radiation: Photosynthetic Mechanisms

The efficiency of radiation use by the whole canopy is the sum of photosynthesis occurring by each leaf and each leaf portion within the canopy. In turn, the photosynthetic rate of each leaf is determined by the sum of photosynthesis in the chlorophyll-containing organelles (chloroplasts). Each leaf and organelle will exist in a dynamic microenvironment and the photosynthetic productivity will depend on the resources available to it at a given moment in time (light, water, nutrients). Due to limitations placed on the photosynthetic process such as light saturation and CO_2 diffusion, the rate of photosynthesis at the leaf level is a strong determinant of canopy carbon gain. This section will describe the photosynthetic process, the different types of photosynthesis, and limitations to leaf level photosynthesis.

The vast majority of chloroplasts are located in leaves and they are numerous, with each mesophyll cell containing between 50 and 200 chloroplasts [34]. Chloroplasts are responsible for absorption of the 400–700 waveband in crop canopies and are the reason that plants appear green. They are sac-like subcellular organelles that contain membranous structures that possess the chlorophyll used for light harvesting. Most of the chlorophyll is contained within pigment protein complexes called "light harvesting complexes" and these are extremely efficient at absorbing visible light, and through a series of resonance transfer mechanisms, they pass the excitation energy to a reaction center where a special pair of chlorophyll molecules use this energy to generate a redox potential capable of oxidizing water via the oxygen evolving complex. The resulting electrons are passed through an electron transport chain and used to generate a proton gradient that synthesizes ATP. Ultimately, the electrons produce a reductant, NADPH. The NAPDPH and ATP are utilized within the Calvin–Benson or photosynthetic carbon reduction cycle to reduce CO_2 to triose phosphates that are used in hexose and starch synthesis or exported from the chloroplast for sucrose synthesis.

How Efficient Is Crop Photosynthesis?

It is useful to consider the amount of light energy arriving at a canopy top or leaf surface and calculate energy losses at each stage based on current knowledge of the photosynthetic process in order to estimate the potential system productivity [35, 36]. As mentioned, only 49% of solar energy is available for photosynthesis. Within the PAR range chlorophyll does not absorb strongly in the green band and the reasons for this adaptation have been well explored [37]. Green photons make up around 10% in the PAR range. Red and blue photons drive photosynthesis with equal efficiency despite the fact that blue light contains more energy per photon than red light. Chlorophyll is excited to higher energy states by blue photons but the extra absorbed energy is not used to drive photochemistry. This extra energy which is calculated to make up 6.6% of incident solar energy is effectively lost [36].

C3 photosynthesis is the dominant form among plant life which uses the enzyme ribulose bis phosphate carboxylase (Rubisco) to fix CO_2 where the initial product of photosynthesis contains three carbon atoms. Rubisco is part of the Calvin–Benson cycle. Examples of C3 crop species are rice, wheat, potato, soybean, cotton, and chickpea. In C3 photosynthesis, three ATP molecules and two NADPH molecules are used to assimilate one molecule of CO_2 and regenerate the acceptor, RuBP. Zhu et al. [36] provide a calculation of the energy required to fix one carbon atom and compare this to the energy contained within that one-sixth of a mole of glucose. A calculation of the quantum requirement of each ATP and NADPH molecule reveals that 8 mol of photons are needed for the fixation of CO_2 molecule and this represents 1,388 kJ of energy [36] whilst the energy content of this carbon atom within the glucose molecule is 477 kJ.

C3 plants operate the process of photorespiration. This is a consequence of the dual reaction of Rubisco: in addition to the fixation of CO_2 into carbohydrates, Rubisco also reacts with O_2 to produce glycolate. This molecule must be metabolized through the photorespiratory pathway, a process that consumes ATP, reducing power and releases CO_2. The product of this is phosphoglycerate which reenters the Calvin–Benson cycle. The losses caused by photorespiration are significant and are greatly dependent on temperature: the specificity of Rubisco for CO_2 and the solubility of CO_2 relative to O_2 in water declines with increasing temperature. In tropical C3 plants the rate of photorespiratory flux can be significant especially when stomata limit the internal leaf CO_2 concentration. In tropical rice in field temperatures of 35°C under otherwise optimal conditions, saturating leaves with CO_2 resulted in an increase in leaf photosynthesis of over 40% [38].

A subset of plants called C4 plants have evolved a fascinating mechanism which minimizes the oxygenase reaction of Rubisco to often insignificant levels. It does this by restricting Rubisco to a bundle sheath cell, which is oxygen free and non-leaky. Initial fixation of CO_2 takes place in mesophyll cells using an alternative enzyme, phosphoenol pyruvate carboxylase which generates C4 acids. These acids are pumped into the bundle sheath cell where they are de-carboxylated, and the CO_2 released is concentrated around Rubisco in the bundle sheath chloroplasts. This effectively reduces the extent of the oxygenase reaction and the photorespiratory pathway to insignificant levels. It is

thought to have evolved in a climate where high temperatures, low CO_2 levels, and low humidity could all have been strong selective pressures. The C4 mechanism is largely found in warm regions. Measurements show that in many plants the advantage of the C4 mechanism over C3 starts to become particularly significant at growth temperatures above 25°C. C4 requires additional ATP synthesis which increases the quantum requirement of the photosynthetic process to 12 photons per CO_2 molecule, in comparison with 8 for C3 photosynthesis. However, this is more than overcome by the elimination of photorespiration and low activity of Rubisco resulting in a greatly enhanced capacity for carbon assimilation at most light intensities in C4 plants. Other advantages become apparent, for example, the higher efficiency of Rubisco means that lower amounts of this protein are needed. Since Rubisco can make up to 35% of total leaf protein in some C3 plants [20], this increases the photosynthetic nitrogen use efficiency of C4 plants. The CO_2 concentrating mechanism of C4 plants means that stomatal conductance does not need to be high and water loss can be reduced.

A substantial "loss" of biomass is mitochondrial respiration which has often been divided into growth respiration and maintenance respiration in accordance with the associated physiological process. Respiration is unsurprisingly difficult to measure and to define in practice [39]. The relative rates can vary substantially according to growth stage. For example, maintenance respiration increases substantially as a proportion of total carbon flux following ear emergence in barley [35]. During vegetative growth, growth respiration is substantially higher than maintenance respiration. Respiration as a whole can vary from 30% to 60% of total carbon exchange and therefore it has a significant impact on RUE. Studies have shown that it undergoes optimization according to the environment and developmental state: for example, it is well known that the relationship between L and respiration is not linear because this would result in a negative net carbon balance in the lower, shaded regions of the canopy. Attempts have been made to optimize respiratory rates to improve crop productivity but this is a difficult task because of the problems with measurement (especially with roots) on different scales from tissue to whole canopy, and of the separation between maintenance and growth respiration. It is often considered that there is greater scope for the improvement of maintenance respiration because this is more sensitive to prevailing conditions. Recent work suggests that the possibilities should be revisited [39, 40].

At any given moment in time photosynthesis can be limited by light level (e.g., under cloud cover or self-shading), stomatal conductance (this becomes severely limiting under conditions of low soil water), and Rubisco (under saturating irradiance and high stomatal conductance Rubisco limits photosynthetic rate in C3 plants). Interactions between growth condition and genotype will determine the final rate of photosynthesis. Growth under optimal conditions is considered: the imposition of resource limitation on RUE will be discussed in the final section.

Taking into account the minimum essential losses that occur, the percentage of "biomass energy" produced per unit solar radiation (total solar spectrum) for C3 and C4 plants is generally agreed to be 4.6% and 6%, respectively (calculated on a kJ/kJ basis) [36]. The highest recorded values are 2.4% and 3.7% [36] with common measured values being much lower than this, for example, [41]. The large difference between measured and attained photosynthetic efficiency of crop canopies is the cause of some debate and some mechanisms focusing on metabolic constraints are discussed here. It is possible that canopy architecture remains a limitation (discussed above). It is however noted that much of the observed reduction in RUE and photosynthetic efficiency in agricultural systems is caused by growth under suboptimal conditions [36].

The above has considered photosynthetic efficiency in the context of a leaf canopy. However there is current interest in exploiting photosynthesis in non-leaf organs such as the green ear in wheat [42, 43] and the spikelets in rice. Despite the relatively small surface area (compared to LAI) it seems clear that the high exposure to radiation and close proximity to the grain sink may mean that their photosynthetic contribution has been underestimated [42]. In the case of oil seed rape, the photosynthesis in seed pods is the dominant supply due to a diminished leaf area [44]. This is a source of photosynthate that deserves closer investigation.

Metabolic and Regulatory Constraints to RUE

Although photosynthesis underpins growth and yield it has often been considered that it is a feature of primary metabolism which has undergone optimization through natural selection and empirical breeding. This view has partly arisen from the conservative nature of the basic mechanism and composition of the photosynthetic apparatus. However, firstly, it is clear that canopy photosynthesis has undergone improvement via total leaf area and nitrogen per unit leaf area (fertilizer) and, secondly, there is considerable genetic variation in leaf photosynthetic capacity and in the response of leaf photosynthesis to environmental factors and abiotic stress. Nevertheless, the role of any improvement in leaf photosynthesis in crop yield progress has been hard to quantify due to the difficulty of routinely measuring net leaf and canopy carbon gain and of eliminating compensating processes, although some success has been achieved [24, 45, 46]. and photosynthesis has been successfully linked to yield progress in some cases, for example, [24]. There is some recent evidence that leaf photosynthesis can exert an effect when biomass production is the dominant limiting factor [47–49]. Nevertheless leaf photosynthesis is considered to be the dominant factor determining RUE [5] and its improvement is increasingly viewed as an important target [49, 50].

Many of the suggested routes to the leaf CO_2 assimilation rate of crops have focused on Rubisco. Increasing the amount of Rubisco in the leaf is problematic: it is already at extremely high levels and to accumulate more would require an increase in nitrogen fertilizer application. There are indications that Rubisco may be accumulated to excess capacity in some leaves [51]. There may be opportunities to improve the properties of the Rubisco enzyme [52] and there is some natural variation among plants and algae in the properties of Rubisco. For example, forms of Rubisco present in the genus *Limonium* have a higher specificity factor than that in all crop species [53]. However, there is a well-cited inverse relationship between specificity for CO_2 and maximum catalytic activity [54]. It has been suggested that different forms of Rubisco could be assigned different roles within the plant according to environmental condition, tailored, for example, to high light or low light conditions. Other enzymes in the Calvin–Benson cycle have been shown to have promise for improvement such as sedoheptulose-1,7-bisphosphatase [55].

Elimination or reduction in photorespiration has been of interest for a long time even though the seemingly wasteful process has been assigned metabolic and photoprotective roles. The increased growth rates, biomass, and yield of plants grown under high CO_2 where photorespiratory flux is reduced indicates that the process is largely wasteful. Methods for blocking the pathway have proved ineffective [56] probably due to the accumulation of intermediates. A recent and novel approach has avoided this problem by using bacterial enzymes to "shortcut" the pathway [57]. In *Arabidopsis thaliana* plants, this has had the effect of improving biomass production and shows great promise although the precise mechanism of improved growth has not been described yet.

The greatest improvements in yield of crops native to warmer climates would come from the introduction of the C4 mechanism into C3 crop species. In the case of rice, for example, it has been calculated that this is the only way to bring about an increase in biomass production sufficient to meet a 50% improvement in yield by 2050 [1, 58]. Early attempts to introduce elements of the C4 pathway into rice by transformation with C4 genes from maize or other C4 species [59] are considered ambiguous or partially successful at best and introduction of the full "Kranz" anatomy seems to be the most likely way to achieve the required goal. Some natural C4 mechanisms exist in a single cell [60] but it is unclear whether this would provide sufficient rates of assimilation.

The evolution of the C4 syndrome independently on more than 60 occasions in angiosperms would suggest there is no intrinsic reason why the C4 pathway could not be introduced into a major crop such as rice or wheat. A combination of advanced molecular techniques, transformation of key genes and smart screening of germplasm may achieve this [61]. Indeed there is now a funded international consortium of scientists formed to address this task in rice (www.irri.org).

Recent modeling work suggests that photosynthesis may not be optimized in many plant species. For example, Zhu et al. [62] used an evolutionary algorithm to partition nitrogen between enzymes associated with different processes within a plant cell. The combination of enzyme amounts and activities that produced

a higher photosynthetic rate was allowed to proceed to the next generation, and after 1,500 generations it was found that photosynthesis was substantially increased. It seems that an over investment in photorespiratory metabolism and an underinvestment in enzymes of the Calvin–Benson cycle may be critical. It is possible that this represents a lack of adaptation to contemporary higher CO_2 levels.

Photosynthesis is a dynamic process and constantly responds to changing environmental conditions. It is still debated as to whether the responses observed in situ are optimized. For example, when light is absorbed in excess of that required for photosynthesis, a series of regulatory mechanisms are activated which dissipate the excess excitation energy within the thylakoid membrane [63, 64]. This is considered a photoprotective process which reduces the likelihood of photooxidative stress. This process often has no impact on the light-saturated rate of CO_2 assimilation but it does reduce the quantum yield at low irradiance levels. Therefore, following a transfer to low light (caused, e.g., by cloud cover or leaf and solar movement), the slow relaxation of photoprotection causes a potential reduction in the rate of CO_2 assimilation. Given the large variation in irradiance in canopies in space and time, this has long been considered a factor in canopy photosynthesis. Indeed the manipulation of photoprotection has been shown to influence fitness in *A. thaliana* [65]. Recently, photoprotection was modeled in a tall three-dimensional canopy using ray tracing algorithms [66]. The reduction in canopy carbon gain was predicted to be as large as 30% under low temperature conditions. This would seem to indicate that there is room for improvement in terms of optimization of photoprotection.

Acclimation of photosynthetic capacity to environmental conditions such as irradiance can occur over longer timescales such as days and weeks. It has been hypothesized that acclimation conferred an advantage in terms of carbon gain [49]. Recent experiments using *A. thaliana* indicate that over long growth periods under naturally variable light levels this is indeed the case [67].

The question of whether plant and crop responses are appropriate for any switch in environmental conditions has been expanded to include those of growth and storage of carbon. For example, there is evidence that transfer of carbon to storage organs can occur at the expense of allocation to new organs [68]. Cross et al. [69] observed that accessions that allocated less carbon to storage at night had a higher growth rate. This concept has yet to be tested in crop species. Genes that are involved in the regulation are being identified, for example, DELLA proteins are negative growth regulators of central importance which are thought to integrate the effects of various growth-promoting hormones such as gibberellins and have been shown to have an effect on rates of tissue growth [70].

Source–Sink Processes and Partitioning of Assimilates

This section discusses the different assimilate sinks that have either direct or indirect effects on light interception (LI) and RUE in crops. As discussed, radiation capture is a highly dynamic process affected not only by sun angle and fluxes in radiation intensity, but also by gross morphological above ground structures that evolve over a plant's life cycle and include leaf area development, stem dynamics, and the emergence of floral structures. Within crop species, there is considerable interest in genetic effects on morpho-physiological traits that affect light interception and distribution. Genetic effects include early vigor; stem density (m^{-2}) and dynamics; leaf anatomy and geometry; the composition, distribution, and duration of light harvesting and photosynthetic proteins in the canopy; the architecture of floral structures; and the continual interaction of these with crop development. Crop management is an additional factor which will affect radiation interception principally through row spacing, N fertilization, and irrigation, and by controlling biotic stresses that may reduce LI.

Direct Effects of Sinks on RI and RUE

It is axiomatic that all photosynthetic structures begin as carbon sinks while at some point becoming net exporters (i.e., assimilate sources). The exact investment strategy in these photosynthetic structures will determine the RUE of the "photosynthetic canopy" as a whole. In this context, leaf area index (L) is a useful parameter to consider. Typically L values above 3 are considered optimal for maximizing RUE in annual crops. However, theoretical considerations suggest

that the relative distribution of leaf area and light harvesting and photosynthetic proteins among different layers of the canopy can also modulate RUE and are currently targets for genetic improvement [25].

In the context of canopy photosynthesis, two other important sinks with direct impact on RUE are the stems and the reproductive structures. Stems, as well as being covered with a green leaf sheath, provide the skeleton for leaf display and, therefore, to a large extent, determine the height and geometry of the leaf canopy. Stems are highly dynamic and may appear and disappear within the main part of the crop cycle. In small grain cereals, full light interception is typically accelerated through tiller development, a strategy which results in the subsequent shedding of nonproductive tillers after optimum *L* is achieved; the investment of assimilates in tillers apparently being offset by the increased *L* [71]. The strategy also has benefit under favorable years when a larger proportion of tillers achieve reproductive success. Reproduction requires a further investment of assimilates in floral structures, which, though often photosynthetic themselves, may also intercept incident light and, therefore, shade other photosynthetic tissue. Reducing panicle height for this reason has proved beneficial in rice [72]. Genetic modification of tiller dynamics and spike photosynthesis are both promising areas in crop breeding; neither has been systematically addressed yet as outlined above, and both traits interact with LI and potentially with RUE. There is considerable genetic diversity for tillering capacity in small grain cereals and a tiller inhibitor gene (*Tin*) has also been identified in wheat [73]. Considerable morphological diversity is also apparent in the reproductive structures of many crop species. However, those which are photosynthetic show a complex physiology, the measurement of LI and RUE is extremely challenging, and studies to establish genetic diversity are scant [43]. Nonetheless, shading studies in wheat have suggested genetic diversity for the contribution of spike photosynthesis to grain filling under drought, and given that reproductive structures intercept a significant proportion of light in many crops, it may be expedient to incorporate them into models of canopy photosynthesis.

Finally, non-photosynthetic sinks such as roots and structural components of the plant (stem wall, rachis, etc.) may impact on LI and RUE by competing with photosynthetic tissue for assimilates, however, these effects are not well documented [74].

Indirect Effects of Sinks on RI and RUE

There are other non-photosynthetic sinks which may also compete directly with photosynthetic tissue for assimilates but whose indirect effects may be much more significant in terms of overall RUE of the crop. These are (1) the accumulation and remobilization of carbohydrates (such as water-soluble carbohydrates in wheat and starch in rice) to and from stems and (2) the partitioning of assimilates to the reproductive spike.

While it seems clear that stem storage carbohydrates accumulate to provide a buffer against post-anthesis stress conditions when current photo-assimilates may be insufficient for grain filling [75–77], it is unclear what trade-offs may be involved in terms of assimilate partitioning. Given that genetic variation for storage carbohydrates is large and may constitute up to 50% of the stem dry weight shortly after anthesis, it could affect not only competition for assimilates from other sinks (e.g., roots, spike) but also RUE if, for example, the demand for stem storage carbohydrates is great enough to solicit feedback responses of the photosynthetic apparatus. While the latter has not been studied, feedback effects that influence RUE have been shown in response to partitioning of assimilates to the reproductive spikes.

A large body of evidence has shown that the number of reproductive sinks that are set in a crop is the main factor determining yield potential [78, 79]. Indeed the post anthesis sink size in wheat has been associated with RUE [80]. Sink strength associated with grain number is the most likely explanation for the relationships demonstrated between yield and photosynthetic rate, for example, in a historic series of wheat cultivars [24]. Furthermore, in other studies in spring wheat it was shown using both genetic and physiological treatments that RUE responded to increased spike fertility, resulting in increased yield and aboveground biomass [3]. It has been suggested that one way to enhance the sink capacity in wheat is to lengthen the stem elongation phase. The stem elongation phase encompasses the spike growth period and this would therefore result in a heavier spike during this period [3]. Another strategy would be to alter the sinks that

compete with spike index, such as roots, stems, leaf sheaths, and infertile shoots. It must be ensured that any reduction in leaf lamina does not have an effect on LI and RUE. Reducing the allocation of biomass to roots may improve RUE by permitting increased partitioning to spikes (discussed in Reynolds et al. [3]). Some caution is urged since future yields may be dependent on increasing the ability to access soil water and nutrients. However, there is a possibility that the efficiency of uptake of water and nutrients could be improved with no change in root mass, for example, partitioning root length density at greater soil depths [81]. Structural stem carbohydrates (not the reserve carbohydrates discussed above) could be reduced by classical methods such as reducing plant height although wheat plant heights of below 70–90 cm are associated with lower biomass [3, 82]. Such approaches must be offset against increased lodging susceptibility. Other possible targets such as infertile tillers and awns are discussed in Reynolds et al. [3].

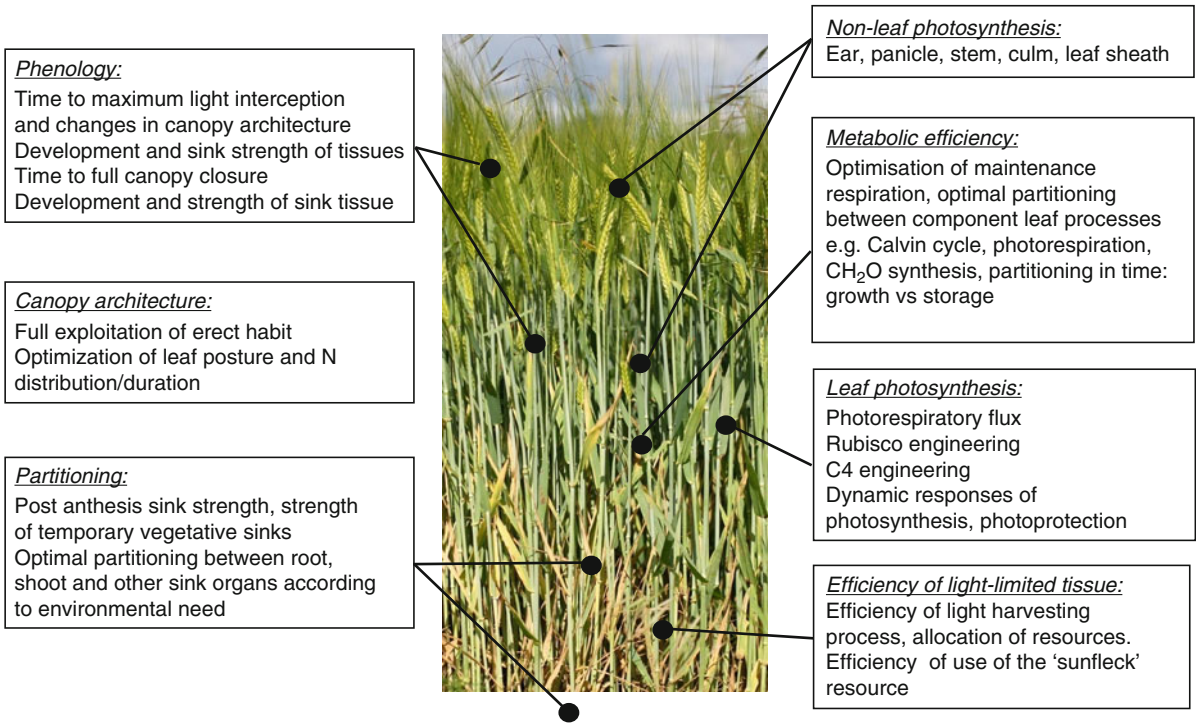
In particular, the maintenance of fertility under unpredictable environments is highlighted: in wheat, kernel set can be very sensitive to a number of environmental conditions such as moisture stress and irradiance. This is part of a set of evidence suggesting that plant signaling is involved in reducing grain number. The signaling (local or long distance within the plant) is a well-established phenomenon: the transport of molecules regulates growth, partitioning, and metabolism and is a fundamental feature of plant biology, likened in some cases to neural networks that sense, quantify, and memorize the environment around them [49, 68, 83]. The most well-known example is that drying soils induce the synthesis of abscisic acid in roots, and transport of this hormone to shoots induces a reduction in stomatal aperture to increase water use efficiency of remaining soil water [84]. It is possible that plant responses to environmental events are preemptive certainly but may also be simply too "conservative" predicting unfavorable conditions and setting seed size accordingly, while a higher yield can be attained by maintaining larger seed number under well-managed conditions. Floral abortion in maize in response to drought appears to be controlled by the up- or downregulation of a few enzymes [85]. In wheat, day length can alter sugar supply to fertile florets leading to cell death [86], and ethylene is a high-temperature signal leading to kernel abortion. Cytokinin appears to regulate the number of spikelets in rice [87]. Therefore, better targeted regulation of grain abortion before the onset of seed filling is a potential target for improvement of RUE and yield potential (Fig. 4).

Theoretical Considerations Related to the Improvement of RUE

The concept of RUE has received some criticism as being one that contains circular reasoning: one cannot have growth without biomass accumulation and vice versa. Additionally it is the product of almost every process in plant canopy growth and development, which makes a mechanistic description quite complex. However, it is established as a unifying concept in crop physiology, for example, [5, 10, 88]. Moreover the understanding of the component parts of the system and their integration is continually improving, and increasingly these parts are not viewed as a "black box," giving more options in the future with regard to RUE improvement.

For a given crop genotype, RUE is largely sensitive to leaf photosynthesis (and therefore nitrogen content) and the proportion of radiation that is diffuse or direct [89]. The latter is a much under-studied area in plant and crop physiology. The stability of RUE has been used to question whether it is possible to improve upon crops with existing C3 or C4 types.

Theoretical figures were outlined above for the maximum efficiency with which photosynthesis can operate and it was concluded that crops operate below this. However, what is the realistic "spare capacity" for RUE improvement in a major crop plant? Reynolds et al. [23] estimate potential productivity for the entire growth cycle of irrigated wheat in a specific and well-characterized location, NW Mexico. Radiation fluxes were measured throughout the season. Due to the time it takes for canopy establishment, large losses can occur before canopy closure, and this was taken into account using a model that used measured intercepted radiation and the time before canopy closure. A value of 1,748 MJ m^{-2} was obtained for radiation absorbed by photosynthetically active tissue. Estimates of field quantum requirement can vary between 10 and 30 mol quanta mol^{-1} CO_2, taking



Crop Radiation Capture and Use Efficiency. Figure 4
Summary of the potential target areas which would result in an improvement of crop radiation use efficiency

into account photorespiration and photochemical inefficiency. For a wheat crop, best estimates would seem to be in the range 15–24 mol quanta mol^{-1} CO_2 [90] which results in a range of RUE between 1.5 and 2.6 g carbohydrate MJ^{-1}. The calculated value of biomass ranges from 2,620 to 4,545 g m^{-2} whilst the measured value for wheat in this environment is up to 2,100 g m^{-2}. This suggests that improvements in field RUE are conceivable.

Sinclair and Horie [88] claimed that the observed stability of RUE arose from consistently high light-saturated leaf photosynthetic capacity (Amax). They plotted the leaf photosynthetic capacity against RUE for C3, C4, and leguminous crops types. The saturation of this response indicated that further modest increase in leaf photosynthetic capacity will only have a limited impact on the RUE, hence the stability of the RUE response [5]. However under conditions of restricted nitrogen, water, or under stress much lower values of photosynthetic capacity caused a larger reduction in RUE. This has been used as an argument that seeking modest improvements in leaf photosynthetic capacity may not be worthwhile. As pointed out here it is possible to trace improvements in biomass production that are linked to Amax. Biomass, yield, and Amax were associated in irrigated wheat cultivars in warm conditions [23] and in temperate conditions [24]. In the latter case, higher Amax may reflect a feedback response caused by greater partitioning to reproductive structures – the differences in Amax were greatest during grain filling and not well associated with above-ground biomass.

There has been a lot of attention paid to the use of Amax in the selection of varieties with a higher photosynthetic potential, largely because it is convenient to measure and shows genetic variability. However, it should be clear from this entry that Amax will mostly be expressed at the top of the canopy (most leaves will not be at light saturation) and may not be a good proxy for canopy photosynthetic rate especially when integrated over long time periods. Care should be taken when extrapolating from spot measurements to whole

canopy photosynthesis. It is not surprising then that attempts to improve yield by simply selecting for Amax have had largely unsuccessful results.

Perhaps more importantly, many of the improvements that show great promise are not solely associated with capacity at light saturation but rather to the dynamic responses of photosynthesis over time and therefore to total canopy carbon gain. These processes are much harder to measure experimentally although advances in techniques such as continual chlorophyll fluorescence monitoring may provide breakthroughs. As the knowledge of photosynthetic regulation improves, these should be installed into agricultural photosynthesis. It would seem necessary to tailor photosynthetic responses to improvements in canopy architecture.

Sources of Variation in Agricultural RUE

In any comparative analysis of RUE, it is necessary to ensure that the methods of analysis are directly comparable and provide an accurate estimate that do not contain any of the potential errors in measurement outlined above. Additionally, consideration must be taken when comparing different environments because varieties may not be well adapted to their locality and therefore able to "express" their maximum RUE. Other reviews, for example, Sinclair and Muchow [5] provide a comprehensive survey of the literature for many key crop species. A summary is provided here of the species and of the environmental factors affecting RUE in agriculture, and available information for a few key species has been provided.

It is in fact not common to find studies that specifically link RUE with yield progress; however, it has been shown, for example, that yield progress in wheat associates with both harvest index and total biomass production [74]. Some evidence also suggests that older wheat cultivars had a lower RUE and this was associated with a lower post-anthesis sink capacity [4, 80].

Species Variation in RUE

As pointed out by many workers, there is no "constant" for RUE and there is considerable variation between species. It is important to pay attention to the developmental stage of each crop in question and maximum attained RUE is referred to here. The highest recorded values for season-long RUE across C4 species are 3.4 g MJ^{-1} and those of C3 species 2.8 g MJ^{-1} [5, 35]. Mitchell et al. [13] reported that average values for RUE in rice, wheat, maize, and soybean in the vegetative stage were 2.2, 2.7, 3.3, and 1.9 g MJ^{-1}, respectively.

Therefore the tendency for a distinction between C3 and C4 crops seems to be consistent. However, care must be taken. For example, sorghum, a C4 species, possesses a relatively low RUE and this has been attributed to low leaf N content. Conversely, sugarcane, also a C4 species, seems to have an exceptionally high RUE. Potato, a C3 species, has shown values for RUE higher than all other C3 crops and even some C4 species (sorghum). It must once again be emphasized that the energy content of dry matter should be taken into account. It has been suggested that the high values for sugarcane and potato reported are due to the exceptionally low energy content of the products (sucrose and starch). It is often claimed that sugarcane has the highest radiation use efficiency among the plant kingdom, although there are relatively few studies.

A few studies have indicated the relatively low RUE of rice among C3 crops [13, 91], although there are surprisingly few studies available for this species and recent suggestions that RUE may not be currently closely linked to high yield potential [92].

Leguminous species such as soya bean have lower RUEs and a high percentage of PAR utilization. This is due to the higher lipid and protein content (see earlier section). However, even when the vegetative stage alone is considered, soybean has shown lower RUE values than wheat, rice, and maize [13, 93]. This has also been observed in other grain legumes [5]. RUE of legumes may be an important future target. For detailed information on RUE values for each species, the reader is referred to detailed reviews such as [5].

In recent years, there has been much interest in "energy crops." These are crops that are grown for the sole purpose of fuel production or combustion for energy generation. This has been stimulated by concerns over emissions of greenhouse gasses and the growth of crops represents a CO_2-neutral strategy. Drawbacks include the clear competition with food supply and the possible threat to natural vegetation. Nevertheless it has been shown that certain species have the potential to be extremely productive in this regard, especially C4 grasses such as *Miscanthus* [94]. *Miscanthus* has the

highest annual primary production of any crop species producing 50% more biomass than corn due to a high leaf area and longer duration, although the energy conversion rate is about the same [95]. Other examples of energy crops under study are willow, poplar, and oil crops such as *Jatropha*, although radiation use efficiency of this category of crop species is not well studied. These crops may find an application on land unsuitable for food crops and low input environments.

Developmental Stage

The stage of crop development has a clear effect on the RUE attained. Firstly the photosynthetic potential may be dependent on growth stage. Secondly the appearance and disappearance of vegetative and reproductive sinks can influence photosynthesis via the presence of feedback signaling mechanisms and carbohydrate accumulation; this has been discussed in detail above. In many species, a lower RUE was observed during earlier crop establishment stages in comparison with later stages and this was attributed to a lowered photosynthetic capacity [5]. The effect of senescence during the post flowering has the effect of reducing photosynthesis, and therefore RUE is usually observed to be higher during the vegetative stages than post flowering. Recent studies have indicated that post-anthesis RUE in wheat is strongly linked to sink size: Older cultivars with smaller sinks had significantly reduced RUE during this phase [4].

There is an indication in some studies that in rice this post-anthesis effect is not as pronounced [13]. In a recent study, Takai et al. [96] suggested that a maintenance of high growth rate and RUE in the late reproductive phase of rice is a key to higher grain yield potential in this species and may be linked to the short tropical life cycle and requirement for rapid photosynthesis during grain filling.

Environmental Factors

There are many practical difficulties involved with linking leaf-level photosynthesis with canopy-level RUE, even though it is technically straightforward to measure leaf photosynthesis. However, increasing the photosynthetic rate per unit leaf area of leaves has direct relationship with increasing RUE. It is frequently observed that the response between light-saturated photosynthetic *capacity* and RUE is curvilinear rather than linear. However, as discussed above it is critical to consider photosynthetic efficiency at all light levels. As a generalization it is fair to say that any factor, biotic or abiotic, that reduces the photosynthetic potential of a canopy is also likely to reduce the RUE. This applies to many of the common factors that reduce growing conditions below optimum such as water availability, nutrients, and extreme temperature.

It is not surprising that nitrogen has a significant impact upon RUE due to the close and well-established relationship with leaf photosynthesis. There is a strong nitrogen-dependent effect on leaf area and consequently light capture in plants, therefore, nitrogen content per unit leaf mass or per unit leaf area is considered. This has been the subject of a number of studies in several species: Usually a curvilinear response with leaf nitrogen is obtained, with RUE increasing up to a saturating value beyond which response is limited such as sunflower (average canopy leaf nitrogen [97]), soybean (specific leaf nitrogen [98]), and maize and sorghum (leaf nitrogen per unit leaf area [99]). However, this relationship is not always observed (see [5]). In examining species differences, the plant matter energy content and the nitrogen–photosynthesis relationship is important. For example, C4 plants have a higher potential photosynthetic nitrogen use efficiency [88]. Naturally site-variation in soil nitrogen is common and potentially a large source of variation in RUE.

Soil water and atmospheric humidity have the potential to reduce photosynthetic rate and therefore RUE. In experiments that imposed soil water deficit, reductions in RUE have been observed in some cases [100] but not others [100]. It has been suggested that the variability in response is a result of variation in the extent of the soil water deficit: When this was measured in a quantitative manner, it could be established that RUE would decline when the level of extractable soil water declined below a certain limit (in this case 30%) [101].

An increase in vapor pressure deficit has been associated with lower RUE in some studies. It is noted that the impact in RUE was greater than that would have been predicted from leaf photosynthesis alone and it was suggested that environmental factors associated with vapor pressure deficit are involved.

Other studies indicated only a small impact of vapor pressure deficit on RUE [5, 102].

Temperature has been associated with RUE when it has an influence on leaf CO_2 assimilation rate and this has also been shown to be related to the physiological effects of nighttime temperature [5].

Future Directions

Due to the effects of climate change caused by anthropogenic emissions, an altered environment for crop growth is likely to be required [103]. Some of these changes can be predicted with a high probability, for example, CO_2 is rising and is likely to continue at a similar rate to the current one with a slowing of rate according to internationally agreed emission cuts. Since 1750, atmospheric CO_2 has risen by around 100 ppm and continues to rise at the rate of around 2 ppm per year. By the end of the twenty-first century, temperature is predicted to rise by between 0.5°C and 4°C in response to levels of the greenhouse gasses CO_2, methane (CH_4), and nitrous oxide (N_2O). Agriculture itself is a major contributor to greenhouses gasses. Studies have already indicated that climate change is having an effect on productivity of crop systems [103–105].

These changes must be considered according to geographical region and in the context of deleterious effects such as a likely reduction in water availability, a rise in pollutants such as ozone, and the increasing frequency of extreme damaging events such as flooding, drought, and storms. They must also be weighed against possible beneficial effects such as higher photosynthetic rates induced by elevated CO_2 and a longer growing season at higher latitudes leading to higher biomass and higher yield. Accordingly, a reduction in yield in the tropics and a rise in temperate regions may be experienced. The effect of most of these factors on RUE has been discussed above and a detailed discussion of the wider impact of climate change on agriculture is beyond the scope of this article. Clearly suboptimal growing conditions will potentially reduce RUE and yield. However, it is important to ensure that the crops are adapted appropriately to future climates.

Experiments using completely enclosed or open topped chambers in the field in which CO_2 levels are elevated above ambient have shown significant increases in growth and yield. The reasons are clear and related to the suppression of photorespiration and consequently an increase in RUE. Additional beneficial effects related to a lowered stomatal conductance [25, 106]. These data have been used in models that predict an increase in future crop production in many northern regions. Experiments with more realistic field conditions (Free Air CO_2 Enrichment, FACE) have also demonstrated an increase crop yields but these were lower than those predicted by chamber experiments. This is lowered further when additional effects such as ozone and disease are accounted for and the net result may be negative [107, 108]. This suggests that the predicted beneficial effects of an increased atmospheric CO_2 on plant growth have been overestimated. However, as pointed out by Long et al. [107] there is still a paucity of data for CO_2 enrichment effects in many agroecosystems so a level of uncertainty remains.

There is also a need for further work into the adaptation of crops to high CO_2 levels: Theoretical work by Zhu et al. [62] using evolutionary algorithms to predict optimal levels of CO_2 for photosynthesis have shown that the relative levels of enzymes involved in primary metabolism are not optimized for carbon assimilation. It is possible that there has been insufficient adaptation during crop improvement since the start of the industrial revolution, raising the intriguing possibility that plants should be bred or engineered for adaptation to higher CO_2 levels of the future in order to maximize yield and RUE. Presumably this also applies to other environmental changes.

Therefore it is clear that there is a demand for greater crop yield per unit area of land with fewer resources available. This step change in yield will arise from an integrated set of targets, most of which have been outlined in this article. Assuming that management of the crop is optimal and improvement of partitioning and sink capacity reach their limits, it will be increasingly necessary to underpin any substantial yield improvements with increased biomass production and this means that RUE will need to increase.

RUE represents a complex system and as pointed out by Reynolds et al. [23], it is a less frequent outcome of the genetic recombination events required for breeding, in comparison to manipulation of sink size. It will be necessary to focus on methods for improving RUE

of crops and to introduce this into breeding techniques. In addition, there have been significant advances in the plant molecular and genomic sciences in the past 2 decades and these should be exploited to raise RUE. The discovery of new genes and combinations of genes requires routine screening of large amounts of leaf material for photosynthetic potential. It is difficult to do this manually using traditional gas exchange techniques; however, there are a number of techniques developing rapidly that could be exploited to act as surrogates or proxies of CO_2 assimilation rate. For example, chlorophyll fluorescence is a rapid method that can be used to image leaf material for photosynthetic efficiency extremely rapidly. It is routine to image chlorophyll fluorescence; however, it is technically difficult to do this on a three-dimensional structure such as a canopy. Another method is canopy temperature depression which measures the difference between leaf and air temperature caused by evaporation. It therefore provides an indication of stomatal conductance and has been correlated with plant performance [109]. Considerable recent interest has been placed on the imaging plant growth leading to the emergence of the field of "plant phenomics." Advances in methods for rapid and high-resolution screening of plant material for photosynthetic performance can be anticipated. Additionally, the complexity of RUE means that a mathematical understanding of the integration and functioning of component processes will be critical. Given the difficulty of direct measurement, modeling of canopy photosynthesis is already used routinely and will be needed for the continued testing of new traits.

The Role in Wheat and Rice Research: Current Research at CIMMYT and IRRI

The challenge of improving photosynthesis and therefore RUE in crops during both optimal and suboptimal conditions has been recognized by the research organizations that were central to the last great agricultural revolution (the green revolution), the International Rice Research Institute (IRRI) in the Philippines and the International Maize and Wheat Improvement Centre (CIMMYT) in Mexico. IRRI has a number of research programs that are centered toward the sustainable improvement of rice yield in changing environments. Perhaps the most relevant here is the C4 rice consortium whose goal is a step change in rice photosynthesis through the introduction of the C4 pathway of photosynthesis (http://beta.irri.org/projects15/en/c4rice). The impact this would have on yield and resource use efficiency of the poorer rice growing regions of the world should not be underestimated.

Given the urgency of the current food crisis coupled with the likely negative impact of climate change on productivity, especially in less developed countries [110], both IRRI and CIMMYT have strategic initiatives to raise the yield potential of rice and wheat, respectively, by around 50%. The IRRI C4 rice initiative is already underway as mentioned. CIMMYT is currently facilitating a Wheat Yield Consortium (WYC) among a group of leading scientists with the view to raising the genetic yield threshold of wheat. A central issue is that the fundamental bottleneck to raising productivity, namely, photosynthetic capacity, has hardly changed since wheat breeding started. Nonetheless, basic research in photosynthesis suggests that substantial improvements in yield are theoretically possible. While increasing photosynthetic potential will require considerable research focused at cellular and subcellular processes (such as the genetic modification of Rubisco and its regulation), intervention at this level must go hand in hand with modification of structural and reproductive aspects of growth, since these will determine the net agronomic benefit of increased RUE .For example, even at current levels of yield potential, a significant portion of yield is lost to lodging damage each year so improved structural integrity will be prerequisite to realizing genetic gains in RUE and biomass. The other major factor determining yield potential is adaptation of the reproductive processes which affect harvest index [3, 111] and whose physiological and genetic basis is relatively poorly understood [112]. The aim of the WYC is to develop or identify sources and genes for the combination of traits necessary to realize improved expression of wheat yield potential and combine them through strategic crossing using the most expedient combination of conventional, physiological, and molecular breeding approaches; the consortium approach is expected to realize impacts in farmers fields in a shorter time frame than if bottlenecks to yield potential are identified successively and investigated in relative isolation.

Article Outline

Glossary

Dehydration avoidance Dehydration avoidance is the strategy of the plants that are able to maintain tissue water potential as long (and as high) as possible under drought conditions.

Dehydration tolerance Dehydration tolerance is the strategy of the plants that are able to cope with severe tissue dehydration.

Harvest index Harvest index is the biomass of the harvested product expressed as a percentage of the total crop biomass.

Photoassimilates Photoassimilates is the energy-storing carbohydrates produced by photosynthesis in the green tissues of the plants.

Water-use efficiency (WUE) Water-use efficiency (WUE) is the carbon gain (or biomass formed) per unit of water transpired or the ratio between photosynthesis (A) and stomatal conductance (g_s), termed as intrinsic WUE.

Definition of the Subject

Sustainable intensification of global agriculture is a major purpose (and challenge) for twenty-first century scientific, social, and political communities, in order to guarantee food security, while preserving natural resources. Fast growing population and climate change could lead to a global crisis if efforts from different disciplines and countries are not congregated. Among limiting factors is water scarcity, which may dramatically decrease crop production worldwide.

Mitigation measures are therefore a major goal for sustaining crop production and they are based either on management practices that will enable water savings or on breeding efforts for more adequate crops. Improved physiological and molecular knowledge on plant's response to water deficits is essential to get improvements in crop yield under adverse environments. Because of the complexity of these responses, it is imperative to integrate disciplines as functional genomics, transcriptomics, proteomics, and metabolomics with plant physiology to improve breeding strategies.

According to the present knowledge, the key factors responsible for high yield under drought in annual plants include an appropriate phenology that will enable escaping drought and getting the timing of flowering right, as well as high water-use efficiency (WUE) and harvest index. On the other hand, the basic knowledge for fruit tree crop breeding under water scarcity is much more fragmented than for annuals because of the highest complexity of fruit trees. Therefore more efforts are needed in this area of research.

Introduction

Scarcity of water resources is an increasingly important issue since it will dictate global production of food and feed for the next generations, as dramatically described by The Economist (May 2010): "Water is the new oil: a resource long squandered; now growing expensive and soon to be overwhelmed by insatiable demand. Aquifers are falling, glaciers vanishing, reservoirs drying up and rivers no longer flowing to the sea. Climate change threatens to make the problems worse. Everyone must use less water if famine, pestilence and mass migration are not to sweep the globe."

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

The International Panel for Climate Change [1] predicts that water scarcity, together with incidence of high temperature, will increase in the near future in many regions of the globe with dramatic effects on agriculture. Of the world's water resources, c. 80% is currently consumed by irrigated agriculture. In this context, the investment in research for improving water use by the crops ("more crop per drop" as in the CGR program Challenge Program on Food and Water) [2], either through improved management technologies [3, 4] or more efficient genotypes [5, 6], is crucial. Increased water use by the crop can be obtained by agronomic practices that decrease water losses by soil evaporation, runoff, through-flow, deep drainage, and competing weeds, thereby making more water available for the crops, and in irrigated agriculture by using deficit irrigation practices.

Crop resistance to drought has been the subject of extensive research in the last decades, ranging from the physiological traits underlying resistance to water deficits [7–12] to breeding efforts [13, 14] including classical and genetic engineering approaches [15–17]. The world's most important crops for human and animal consumption in terms of total production – wheat, maize, rice, soybean, barley, and sorghum – have endured large yield increases during the twentieth century [18–22] and recently became the target of investigation aiming at improved performance under harsh environments, namely water scarcity [5, 6, 15, 23]. To articulate the knowledge obtained in different scientific disciplines (agronomy, breeding, physiology, and molecular biology) still remains a challenge, with the ultimate goal of providing farmers with better performing crops under water scarcity [7, 14]. Designing robust field trials is also essential in order to test improved crops under the multi-stress conditions they generally face under natural conditions. Indeed, there have been several reports of apparently promising biotechnological manipulations that have failed to deliver drought-tolerant crops in yield terms, when the novel material is transferred from the growth room to the field [4].

The key factors responsible for high yield under drought in annual plants are an appropriate phenology that will enable escaping drought and getting the timing of flowering right, high water-use efficiency (WUE) and a high harvest index [14, 24]. To get high WUE would involve the improvement in crop transpiration efficiency but the increased partitioning of biomass into the harvested product will also lead by itself to higher WUE. The relative importance of each of these processes will depend on how water is available during the crop cycle [13]. Indeed, it is noticeable that under most dryland situations where seasonal rainfall is unpredictable, maximizing soil moisture use is a crucial component of drought resistance (avoidance), which is generally expressed in lower WUE [25].

It is also important to recognize that many of the traits that explain plant adaptation to drought (e.g., phenology, the size and depth of the root system, xylem properties or the storage of reserves) are mostly constitutive [21, 26] and therefore can be found within the species population when it exhibits a large intraspecific variability. Moreover, there is the general recognition that the efficacy of high throughput screening of plant genetic material will speed-up crop improvement via breeding programs (see, e.g., [19]).

In fruit crop production, improvement under conditions of water scarcity has been achieved mostly by optimized management technologies such as deficit irrigation [3, 27], with breeding efforts being much more modest. Indeed the basic knowledge for tree crop breeding under water scarcity is much more fragmented than for annuals because of the highest complexity of fruit trees. In tree crops economic return is highly dependent on fruit quality, generally not related with total plant biomass produced and therefore water availability [3]. Moreover, yield-determining processes in fruit trees may not be sensitive to water deprivation at some developmental stages [28] and fruit quality may even beneficiate from a mild to moderate water deficits, as is well documented in grapevines [29]. High-density fruit orchards use composite plants – the scion cultivar grafted into a rootstock. The rootstock can alter the behavior of the scion, including its vegetative growth, flower numbers and flowering time, crop yield [30], and also drought tolerance [31]. The mechanisms underlying the regulation of scion growth and development by the rootstock are not fully understood [32].

Research in the so-called new climate proof crops such as *Chenopodium quinoa* Willd (quinoa) and *Amaranthus* spp is also developing. Quinoa is an

Andean seed crop, very nutritious [33], showing high tolerance to drought, frost, salinity, and biotic factors [34–36]. Quinoa has been selected as one of the crops to secure food production in the twenty-first century [37]. The protein quantity and the quality of quinoa seed is superior to those of cereals, because of the high content of lysine, methionine, and threonine, in addition to a range of vitamins (B2) and minerals (iron, calcium). Although amaranth is less tolerant to a range of stresses as compared to quinoa, it tolerates higher temperatures because it is a C4 plant [38]. The protein content of amaranth grain ranges from 12% to 17%, with a high level of lysine, similar to quinoa [39].

In this review the focus is on the key factors responsible for sustained plant growth and production under water scarcity, referring to both annual and perennial (fruit) crops. During evolution, plants developed different strategies to successfully cope with water stress; they comprised either acclimation to a slowly developing water deficits or the response to a sudden drought. These issues will be discussed in the context of the agriculture needs and related to production (fruit) quality, a major target of modern agriculture nowadays.

Revisiting Plant Strategies to Cope with Water Scarcity: The Crop Perspective

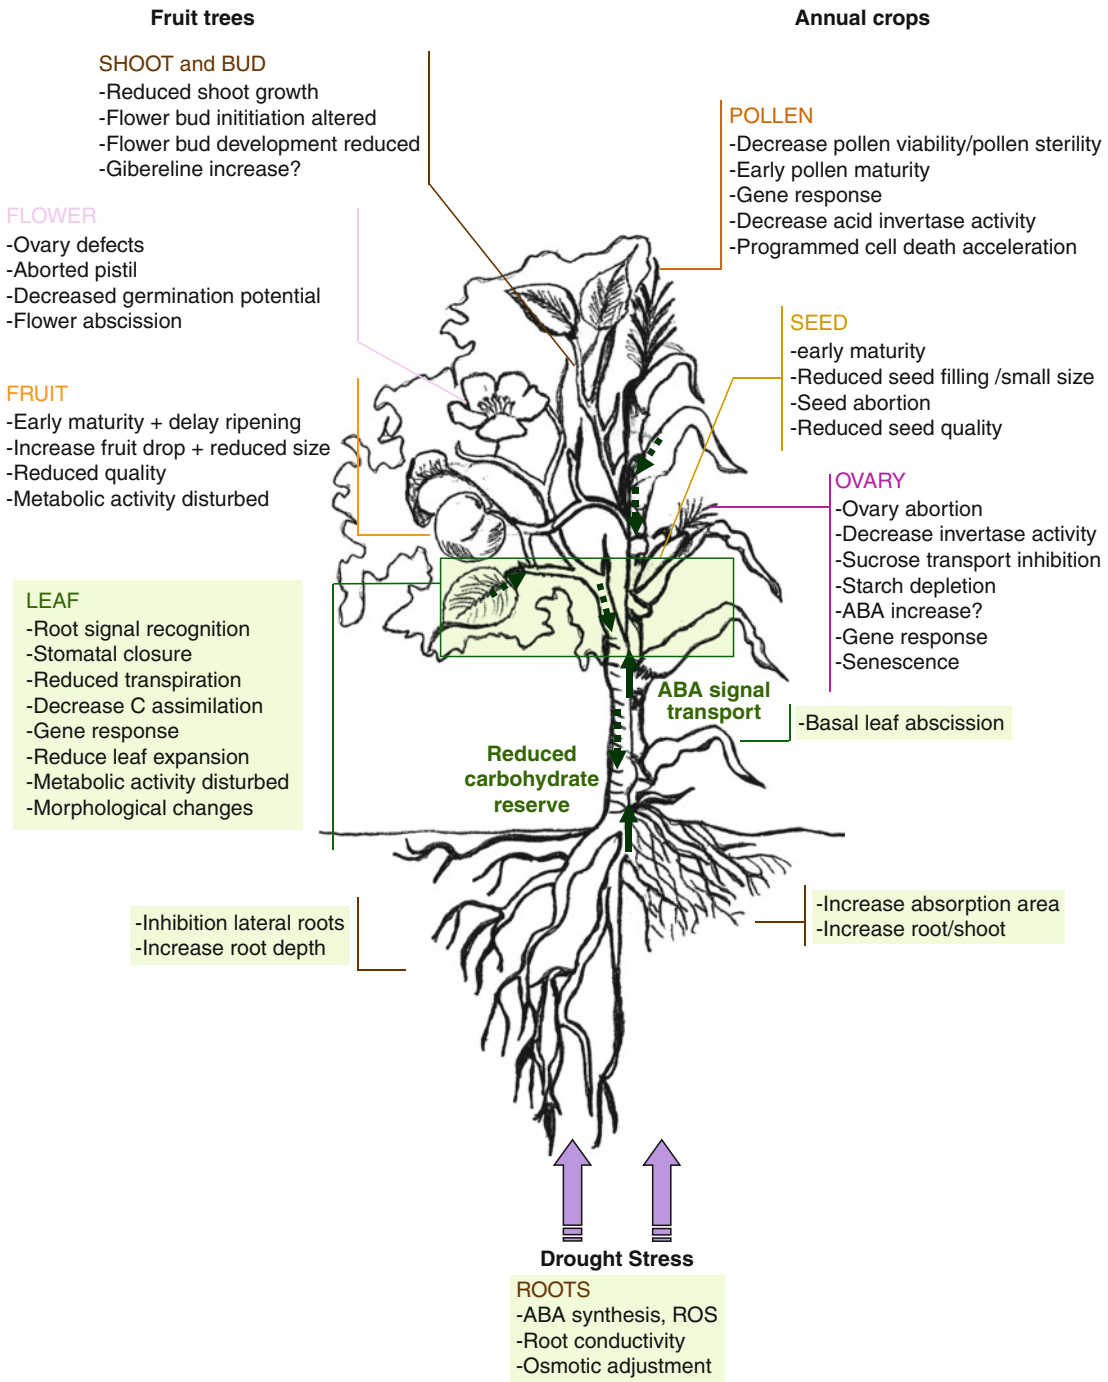
Plants respond and adapt to stress at whole plant, root, reproductive structures, and leaves, by using mechanisms that are being unraveled at the cellular and molecular levels [7, 40].

Classically, plant resistance to drought has been divided into escape, avoidance, and tolerance strategies [7, 41, 42]. However, in practice, most plants combine a range of these different strategies [43].

Plants that escape drought are able to adjust their phenology to the environment, being able to complete their life cycle before drought occurs. Escape strategies rely on successful flowering and therefore reproduction before the onset of severe stress. Plant ability to store reserves in stems and roots and to remobilize them for grain filling under water scarcity is extremely relevant for grain crops under water scarcity [44, 45], as it has been described in cereals such as wheat, maize, and rice [46–48], and legumes [49]. When stem reserve storage/utilization is insufficient to support fruit growth under stress, delayed-senescence genotypes may be desirable in crops where yield is source-limited [50]. High nitrogen availability can further increase the reuse of stored carbohydrates in cereals under moderate soil drying, leading to increased grain yield; under non-limiting water conditions, however, abundant nitrogen was shown to reduce grain yield in stay green genotypes [47].

Dehydration avoidance, which is common to both annuals and perennials, implies the maintenance of tissue water potential as long (and as high) as possible under drought conditions. This can be achieved either by (1) minimizing water loss or by (2) maximizing water uptake. Decreased water loss may derive from stomata closure and/or reduction of absorbed light, including leaf rolling [51], increased reflectance (with, e.g., trichomes), or steep leaf angles [52]. Shedding of older leaves is also relevant to reduce water loss, while allowing the reallocation of nutrients to younger leaves, when water deficit is relieved. Maximizing water uptake may be accomplished by increased investment in the roots at the expense of shoot growth (Fig. 1), which is generally inhibited very early on in response to decreasing water availability [8, 45]. Deep roots have been reported as important drought resistance traits for both annuals and perennials in semi-arid regions [26]. However, in arid environments, where rainfall is sporadic and of short duration, plants may take advantage of shallow roots that proliferate quickly near the soil surface allowing water uptake by the plant before it evaporates [53]. For example, *Zoysia japonica* was reported as having a relatively shallow root system, moderate WUE, while exhibiting a high capacity for osmotic adjustment [53]. High root plasticity is a key factor in this strategy because it will determine how fast roots grow in response to sporadic rain, following a period of drought stress.

Under slowly developing water deficits some plants show osmotic adjustment (OA), a cellular stress adaptive response that may improve tissue resistance to desiccation, by maintaining cell turgor, likely supporting crop yield under stress [25]. Because this mechanism allows plant water uptake at lower soil water potentials it is considered a dehydration avoidance strategy. The alterations observed under OA comprise increases in soluble sugars (like fructans and sucrose) [54], amino acids (e.g., proline, aspartic acid,



Crop Responses to Available Soil Water. Figure 1

Whole plant response to drought stress in fruit trees (*left*) and in annuals crops (*right*). Green boxes and letters correspond to shared responses between the species

and glutamic acid), methylated quartenary ammonium compounds (e.g., glycine betaine and alanine betaine), and some proteins, such as dehydrins [55] and cyclitols (e.g., D-pinitol, mannitol) ([56]; see also review [7]). In addition to the role played via the decrease in osmotic potential, these solutes may protect cell membrane and metabolic machinery under dehydration. According to Bohnert et al. [57] sequestration of H_2O molecules, reducing the solvent-protein interaction, may explain stabilization of protein complexes and membranes.

The positive role of osmotic adjustment on yield has been subject to much discussion since benefits were often not observed (see review by [58, 59]). A possible explanation is that turgor maintenance in cells is often associated with slow growth. It is also likely that osmoprotection mechanisms are not functional until severe dehydration occurs, with the implication that OA may be critical to survival rather than to promote plant growth and crop yield under drought [7].

Mechanisms of protection against oxidative stress are also fundamental to cope with drought and co-occurring stresses under arid semi-arid environments, as it will be discussed below.

Photoassimilates, Water Use, and Crop Yield

As proposed by Monteith [60], yield potential (Yp) of a crop at a given location can be defined as: $Yp = HI.Pn$ with $Pn = \Sigma(PAR^{*}ABSc^{*}\varepsilon c)$ and PAR being the incident solar radiation in the specific location, ABSc the fraction of the radiation intercepted by the crop, εc the efficiency of the conversion of intercepted radiation into biomass and Pn the primary productivity (total biomass produced over the growing season) and HI the harvest index (see also [61]). Under water scarcity a decrease in Yp may occur as a result of less intercepted radiation (due to lower total leaf area and smaller leaf angles) and a lower εc, as a result of a decrease in photosynthesis.

On the other hand, as judiciously proposed by Passioura ([62]; see also [14, 22, 63]), crop yield under water-limited conditions can be estimated by the product of transpiration efficiency (biomass/water transpired) × water transpired (WU) × harvest index (HI). Therefore, optimizing yield under such conditions has to be performed by increasing either water-use (amount and pattern), transpiration efficiency/WUE or partitioning of more biomass to grain. This can be achieved through better water management, the adjustment of crop phenology to the environment, or genetic improvement. The latter implies getting varieties that can give the so-called more crop per drop, either by improved carbon fixation under water deficits or having deeper roots to capture more water or converting more of the biomass into grain (increasing HI). Increasing WUE at the expenses o higher assimilated carbon rather than decreased WU is a desirable way to improve YP under water scarcity, but will generally require biotechnological interventions [17].

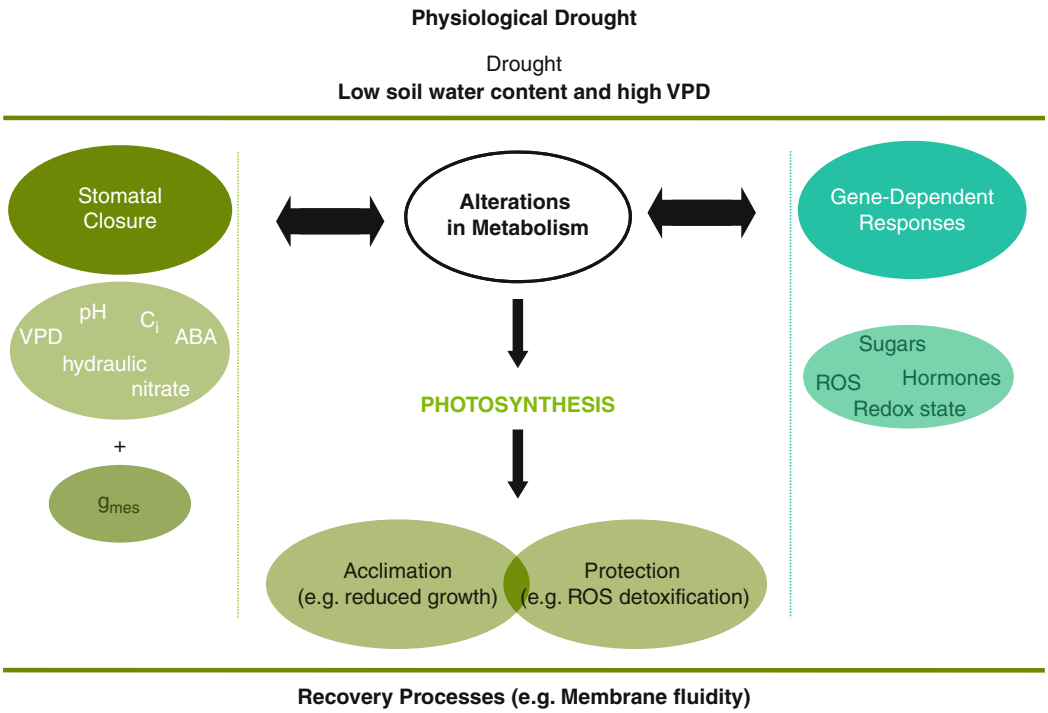
In the last decades, increases in Yp under non-limiting water conditions have been achieved with genotypes of cotton, wheat, and rice that exhibit high stomatal conductance and transpiration. This trait allows a decrease in leaf temperature and a greater CO_2 fixation per unit of leaf and land area [25, 64]. Under water-limited environments crop production has relied mostly in dehydration avoidance traits as described above, which maximize soil moisture use (when it becomes available for example, under sudden rainfall), but is generally associated with lower WUE. On the contrary, drought resistance traits that reduce WU, and are therefore associated with high WUE, will unavoidably reduce YP.

Few successful cases of breeding for water scarcity environments have been reported, one being the dryland wheat grain yield improvement, with selection for high WUE in Australia [65]. This success has been explained by the fact that wheat is grown there mainly on stored soil moisture. Furthermore, as suggested by Blum [2], a major opportunity for yield improvement under water scarcity is the control of WU during the earlier part of the growing season in order to avoid lack of soil moisture later on, during the reproduction phase. An attempt to achieve this was done by Richards and Passioura [66] by selecting for reduced root xylem diameter.

How Metabolic Processes Respond to Drought: Photosynthesis, Respiration, Photorespiration

Photosynthesis

Under water scarcity, restrictions in leaf carbon uptake take place as a result of increased resistance to CO_2 diffusion induced both by decreased stomatal



Crop Responses to Available Soil Water. Figure 2

Direct effects of drought on stomata and mesophyll (g_m) conductance as well as on gene expression, resulting in alterations of photosynthetic metabolism and ultimately on plant acclimation (Adapted from [9])

aperture (Fig. 2) [7, 9] and decreased mesophyll conductance [67]. At the whole plant level, total carbon uptake is further reduced due to the concomitant or even earlier inhibition of shoot growth [8]. Metabolic inhibition of photosynthesis usually occurs under more severe stress conditions or when various stresses co-occur, such as high light and temperature [8, 10], although claims for earlier alterations in photosynthetic metabolism are reported by Lawlor and coworkers ([12]; see a review by [68]). Interestingly, alterations in gene expression are also observed very early on, although these alterations are generally not turned into differential expression of proteins or enzymes in the short term (see revision [9]).

Stomata are able to detect a decrease in water availability either in the soil or in the atmosphere by feedback and feed-forward mechanisms. Feedback mechanisms include the response to dehydration in the leaf itself that is transmitted to the guard cells, either by hydraulic or by chemical signals. Feed-forward responses are generally mediated by hormonal signals and may take place before any alteration in leaf tissue water status occurred. They comprise responses of guard cells to high vapor pressure deficit, whose mechanisms area still not fully resolved [69–71] and to dehydration taking place elsewhere in the plant, namely in the roots [72]. Hormones, with particular relevance to ABA, but also cytokinins and ethylene, have been implicated in the root–shoot signaling, either acting in isolation or concomitantly. This long distance signaling by hormones may be mediated by reactive oxygen species [73].

Primary events of photosynthesis including electron transport capacity are very resilient to moderate drought [74], with the decline in PSII photochemistry being explained by a decrease in substrate availability. In fact, PSII activity often declines concomitantly with carbon uptake under water deficits, suggesting that photosynthetic electron chain is finely tuned by available CO_2 [75]. However, under field conditions, when high light co-occur with water deficits, CO_2 deprivation at the chloroplast (driven by stomatal closure) may

result in the production of excess reducing power and therefore in the decline of the quantum yield of PSII. These stresses also appear to inhibit the repair of PSII through suppression of the synthesis of PSII proteins, in particular, the production of D1 protein [76]. Protection mechanisms against reactive oxygen species (ROS) that are formed under such conditions are an essential component of plant survival [77]. Such protection may be achieved by the regulated thermal dissipation occurring in the light-harvesting complexes, involving the xanthophyll cycle [78, 79] and the lutein cycle [80]. Photoprotective mechanisms compete with photochemistry for the absorbed energy, thus leading to the downregulation of photosynthesis. If the limitation of the rate of CO_2 assimilation is accompanied by an increase in the activity of another sink for the absorbed energy, for example, photorespiration [81] or Mehler-peroxidase reaction [82], the decline in non-cyclic electron transport will be proportionally lower than the decrease observed in the rate of CO_2 assimilation. It was estimated that, in the absence of the repair mechanisms, photodamage would lower the yield of photosynthesis to less than 5% of the yield achieved now [83]. Although these responses have mainly been documented in plants native to semi-arid regions they may also occur in crop plants, even irrigated, when they are subjected to intense heat and irradiance, during the summer period. This is likely to increase its frequency in the near future.

As for Rubisco activity it was shown to be very resistant to water deficits [84, 85], being generally affected only after severe stress [86, 87]. The same authors also found evidence that low CO_2 concentration in the chloroplast (Cc) attained under severe water deficits could induce deactivation of Rubisco sites. It is further suggested that these effects are species-dependent, with species adapted to low Cc being able to maintain active Rubisco longer in response to prolonged drought [87]. These findings are compatible with earlier data suggesting that decreased sink capacity (limited capacity to use photoassimilates), as induced, e.g., by shoot growth inhibition under drought, might feedback to decrease photosynthesis, namely by downregulating the enzymes of the photosynthetic carbon cycle [88].

When studying the effects of drought on photosynthesis it is also important to recognize that crop productivity is dependent on photoassimilates produced at the whole plant level, which partly explains why often there is no correlation between crop yield and leaf photosynthetic rate [61]. Therefore, the impact of drought on shoot and canopy growth may be as important to crop yield as the effects produced at the single leaf level. Indeed, water scarcity by inducing a significant decline in total plant leaf area via the inhibition of new leaf growth or the earlier senescence of older leaves will decrease total carbon uptake by the plant. Moreover, lower leaf angles induced by decreased leaf turgor will reduce total intercepted irradiance, with significant impact on crop yield (Pinheiro and Chaves, unpublished results). However, it must be emphasized that, at least in cereals (wheat, maize and soybean), yield is generally more limited by the sink than by the source [61, 89]. This explains why these crops have the potential to cope with moderate drought and still fill their grains. Of course, this is also possible due to the capacity of remobilizing photoassimilates, previously stored in the shoot, as was discussed above.

Respiration and Photorespiration

The effects of water deficits on *dark respiration* are still unclear, with reports of either decreases, maintenance, or increases in the rates of this process (see the review [90]). Inhibition of respiration under drought has been observed in mature leaves of crops and herbaceous species as well as in roots, and is presumably related with a decreased availability of substrate to mitochondria under conditions of low photosynthesis and growth (e.g., [86, 91, 92]). This may be explained by the need of herbaceous species to quickly respond to water scarcity, thereby lowering their respiration rates in order to optimize their carbon gain over shorter periods of time.

On the contrary, trees and shrubs seem to show slower responses to drought than short-lived species. As suggested by Flexas et al. [86] and Atkin and Macherel [93], a higher demand for respiratory ATP (higher respiration rates) may be required under severe water stress to compensate for the lowered ATP production in the chloroplasts. The increased maintenance respiration will support repair mechanisms needed under acclimation to drought that will ensure a better performance under extended periods of water scarcity.

In general, the changes observed in respiration in response to drought are smaller than those observed in photosynthesis, thereby implying that respiration increases proportionally in relation to photosynthesis, with likely impact on leaf intercellular CO_2 and on plant carbon balance [68].

The role of *photorespiration* during drought stress has been scarcely studied [81, 94], partly due to difficulties in quantifying the rate of photorespiration [95]. Since photorespiration and photosynthetic metabolism are strictly linked and photorespiration depends on the recycling of RuBP in the Benson–Calvin cycle, it may be hypothesized that severe drought stress should result in lower photorespiration. As suggested by Osmond et al. [96], photorespiration and the Mehler-peroxidase pathway could protect the photosynthetic apparatus against photoinhibition in drought-stressed leaves, by sustaining photon utilization in non-assimilatory electron flow, when electron consumption by CO_2 assimilation is reduced due to low internal CO_2 concentrations. However, other studies, such as the one by Brestic et al. [97] concluded that photorespiration was not important for photoprotection in drought-stressed French bean.

In a recent work with glycine decarboxylase-deficient plants, Igamberdiev et al. [98] showed that photorespiration contributes to stomatal regulation. The data obtained with these mutants revealed that the photorespiratory mutants were able to decrease the rate of photorespiration, but only at the expense of increased water loss. Indeed, the necessity to maintain a high CO_2 concentration near the site of carboxylation in the chloroplasts of plants deficient in photorespiratory enzymes required an increased opening of the stomata, with a corresponding increase in water loss and decrease in water-use efficiency.

Yield and Quality Under Water Scarcity

Agriculture depends to a large extent on the success of plant reproduction [99]. Drought affects crop productivity as much as all other environmental factors combined and its impact on crops differs according to the attained developmental stage. The effects of water scarcity are quite different in annuals and perennial species [100]. Reproductive development of cereals, from meiosis to seed set, is highly vulnerable to water deficit [101] and the meiosis stage appears to be the most stress sensitive period of reproduction in all studied species [102]. However, anthesis, pollen fertility, pollination, female fertility, and early zygote development were also reported to be susceptible and finally their failure altered the number and the final quality of grain [102]. Later in the development, water stress tends to reduce grain size [103]. In fruit trees, severe water stress during flowering was reflected in the final fruit number per tree, whereas water stress during the fruit-growth and maturity phases was reflected mainly in fruit size [104]. In addition, the timing and intensity of the drought period dictate the extent of alterations occurring in the final fruit quality [29].

Flower Initiation and Induction

Grain crops are very sensitive to drought during floral initiation and floral pre-meiotic differentiation [105]. Water deficit at this stage causes pollen sterility, but when stress is severe, it usually affects also female fertility. In cereals, water stress during flower induction and inflorescence development leads to a delay in flowering or even to its complete inhibition [105]. The increase of abscisic acid (ABA) in response to water stress has been suggested to play a role in this delay [106].

In woody plants, flower bud initiation is an important feature in fruit tree cultivation. However, the effect of drought on floral meristems is among the least understood aspects of crop reproductive development under water deficit [107]. In species where flowering takes place prior to leaf emergence as *Prunus* trees, flower development occurs in the absence of new photoassimilates and at the expense of pre-stored reserves (starch), either in the flower itself or other plant organs [108]. This explains why in *Prunus* water stress effects are only detected in the subsequent reproduction event and not in the same year. This is the case of peach, apricot, and sweet cherry trees, where drought stress during flower bud initiation markedly slowed the progression of floral differentiation by delaying the differentiation of pistil primordia [109, 110].

In opposition, water stress has been demonstrated experimentally to induce flowering by a direct stimuli

on stem and bud in citrus [111], apple [112], and pear [113]. In these species, water stress showed to stimulate polyamine accumulation, which is linked to floral initiation, thus enhancing the production of floral primordia and re-flowering. However, severe water stress induces little flower production. Indeed, under severe stress during flower bud induction periods, gibberellins level increased, inducing a low level of flower production per shoot [114].

Flowering and Pollen Development

Loss of pollen fertility, spikelet death, and abortion of newly formed seed are associated with a decline in the water status of the reproductive structures and decline of carbohydrate availability [105]. By reducing photosynthesis, drought directly interferes with inflorescence and flower number, flowers life span, flowers opening, and maintenance of floral organs in crops [115] as well as maintenance of nectar production in floral organs [116]. In addition, water stress reduces flower size and sucrose content in nectar [117] leading to an extensive loss in yield [118].

Drought also affects seed yield of plants through an effect on availability and viability of pollen grains [119]. The effect of drought on pollen fertility/availability also depends on the species and it is considered a common symptom in angiosperms [120]. The hypothesis that ABA is a primary controlling agent in water stress induction of pollen viability still remains unanswered [102]. Recently in chickpea [119], water stress was shown to affect pollen growth in the pistil rather than affecting pollen viability. In fact, pistils from well watered plants pollinated with pollen of stressed ones showed fewer germinated pollen grains and fewer pollen tubes that reached the ovary, which suggested that drought has an effect on pollen tube growth, which is inhibited in the pistil [119]. Pollen viability is highly dependent on sugar unloading and pre-anthesis stem reserve accumulation is considered a significant factor affecting flower development in water stressed plants (see Fig. 1) [121]. The decrease of acid invertase activity under low water potential impedes pollen to metabolize incoming sucrose in hexose in the developing pollen, which might lead to pollen sterility [122, 123]. This hypothesis is confirmed by the study of Koonjul et al. [124] who observed a downregulation of the soluble invertase gene *Ivr1* and *Irv5* in wheat microspores, which correlates with accumulation of reducing (fructose and glucose) and non reducing (sucrose) sugars in the ear [125]. Nevertheless, recent studies by Liu and Bennett [126] showed that stress induced sterility in rice is not only caused by disruption in sugar metabolism or by desiccation of reproductive tissue, but also by disturbance of anther pollen development and cell function. In wheat, microspores lost contact with the tapetum at first pollen grain mitosis and the filament degenerated in response to water stress, which resulted in total sterility [127]. The expression of various proteins related to anther wall degradation and cell wall modifications are modified in stressed rice anther [126]. Furthermore, pollen from stressed plants might have a shorter life span and reduced vigor, which explain that pollen tube growth fails to reach the ovule [128]. The depletion of the adenosine triphosphate pool, increased concentration of hydrogen peroxide, and downregulated transcripts in anthers of drought-stressed rice lead to a programmed cell death and may cause pollen sterility [129].

In woody species, as observed in apricot trees, postharvest drought may induce an increase of aborted pistils in the subsequent year, decrease germination potential of pollen (see Fig. 1), and decrease the percentage of fruit set due to an increase of fruit drop [130]. In almond, the number of fruiting positions per tree is negatively associated with water stress [131]. However, drought stress during flower initiation does not influence the percentage of spurs that flowered or set fruit during subsequent years. Although water stress had no apparent effect on spur mortality in the first year, more than a half of spurs died within three subsequent years. In addition, water stress reduces flower bud development in grapevine [132] and peach [133] and increases flower abscission [134] and young fruit drop [135].

Ovary Development

Consequences of inhibited photosynthesis under drought and therefore insufficient assimilates are particularly striking around the time of pollination when reproductive events occur rapidly, namely ovary growth [136, 137]. In maize the pollen does not loose

availability even at severe water stresses (water potential below −12.5 MPa) and low kernel number is explained by a poor receptivity of silks and/or by an ovary abortion. Maize ovaries are normally loaded with glucose and starch on the day of pollination [138, 139]. Under drought, sucrose, the main translocated product from the carbon fixed in photosynthesis, declines (see Fig. 1). The enzymes that convert incoming sucrose to glucose in ovary lose activity and starch starts to be hydrolyzed [137, 138]. Cell wall acid invertase hydrolyses sucrose in the apoplast of the upper pedicel tissues and its activity creates a steep gradient in glucose concentration between the upper pedicel and the nucellus of young ovary. Ovary abortion under drought was attributed to the decrease of glucose and invertase activity in upper pedicel, inhibiting sucrose transport [138]. Sucrose delivery decreased first in ovary and probably triggers an early downregulation of genes coding for sucrose processing enzymes (*INCW2* and *IVR2*). Glucose depletion occurs few days after and triggers an up-regulation of putative senescence genes as *ribosome inactivation protein 2* [139], which suggests the beginning of failed ribosome function and later induces an up-regulation of *phospholipase D1* gene leading to loss of plasma membrane integrity, indicating the onset of senescence [137, 140]. This probably causes the irreversible loss in viability found during abortion [139]. Feeding sucrose during water stress largely prevents these changes, which confirm that senescence genes are "monitoring" the sugar status of the ovary cells and when sugars content decreases these genes turn on in sequence and orchestrate cell death [137].

A transcriptional study of placenta and endosperm of maize under drought showed that both tissues responded differentially to water shortage [141]. While most of the responding genes in placenta involved up-regulation, in endosperm these were downregulated. Downregulated genes relate to cell division and to endosperm growth, which may explain arrested growth and thus decreased demand of photosynthates [141].

These described events are common across crop species [137]. Although wheat requires water potentials to be much lower than maize to lose the same amount of photosynthetic activity [137], starch is also depleted in floral structures after drought (see Fig. 1) [142], inducing an impairment of ovule function [143]. Also in grapevine, drought induces lower availability of sugar due to decreased photosynthesis, which provokes ovary abnormalities and flower abscission [144].

Setter and coauthors [145] suggest an interaction between ABA and sugar that might induce a signal cascade that leads to the abortion process to initiate. The recent finding by Setter and Parra [146] supported the model of the interacting influence of carbohydrates and ABA at least at the pedicel-placenta tissues of basal kernels. Several studies in maize reported that water stress increases ABA in florets, suggesting it might trigger the abortion process [145, 147]. Young and Gallie [148] observed that regulation of programmed cell death during maize endosperm development involves the interaction of ABA and ethylene signaling pathways. However, Boyer and Westgate [99] explained that hormone effects are difficult to interpret because their expression on dry matter or water content basis can cause concentration to increase simply because the ovary dry mass or water content decreased, as it was shown in maize [149].

Yield

All described abnormalities of flowering, fertilization, and zygote development that may occur under drought stress induce yield losses, and the timing of the occurrence of drought stress determines the degree of disturbance. Water stress during ear formation and milk stages in maize was shown to induce early loss of lower leaves and a decrease in plant dry matter and in grain yield, as a result of reduced intercepted radiation [150]. Moreover, all the yield parameters were significantly affected. When water stress occurred at pre-anthesis a reduction in seed numbers was observed due to pollen sterility and ovary abortion. Post-anthesis water stress generally enhances whole-plant senescence and lead to a faster remobilization of carbon from vegetative tissues to seeds, thereby inducing earlier maturity and small seeds [119, 151–155]. This is a typical strategy of Mediterranean annuals, which exhibit a phenological drought-avoidance producing seed before water supplies are exhausted [45]. Remobilization of pre-stored carbon to the seed and acceleration of seed filling rate are associated to an alteration in the hormonal balance of grains, namely

the decrease in gibberellins and the increase in ABA [48, 156]. The reduced duration of grain filling may partly result from reduced number and size of endosperm cells and therefore reduced capacity to accumulate starch following drought stress [157]. Additionally, seed cell expansion is driven by water uptake [158] and when cell expansion in the seed stops, the end of seed growth and seed maturation are predetermined. Indeed, Yang et al. [152] suggested the enhancing of sink strength with water stress is promoted by alterations in sucrose synthase and starch branching enzyme activities taking place in grain during stress. Severe drought stress during seed filling generally resulted in seeds that are shriveled and deformed and with a reduced weight [152, 159]. The shortening in the duration of seed fill limits seed size because grain fill process fails to finish in a short maturation period [155, 160], consequently reducing seed yield [161]. Seed size reduction was highest in late maturing wheat genotypes, suggesting that early maturing genotypes partially escaped late-season water stress [162]. However if water stress occurs after cell division is completed it does not affect yield since sink size per kernel is already predetermined [152]. In sesame, most drought-tolerant cultivars abort a higher proportion of their seeds, and in that case more efficiently shunt available nutrient resources to the healthy growth of remaining seeds [163].

In woody plants and especially in fruit trees, it is generally accepted that post-harvest water stress may negatively influence fruit set and crop load in the next season, as it is the case in peach [164–167], in almond [168] and in sweet cherry [169]. This reduction in fruit set is due to the limitation placed by reduction in the accumulation of carbohydrate reserves. In fact, in cultivated *Prunus* species, floral bud-break and fruit set significantly precede net carbon export from leaves [167]. In citrus, severe water stress taking place during flowering led to decreased fruit number per tree, whereas in water restrictions occurring during the fruit-growth and maturity phases, the effects were reflected mainly in fruit size [104]. Olive tree has a reputation of being a drought resistant crop. However, drought incidence during winter, leading to a low level of soil moisture, may reduce vegetative growth [170] and have an important impact on flowering and fruit set, resulting in a drastic decrease on olive fruit number and size [171, 172]. In fact, severe water stress in phase I of fruit growth was shown to reduce mesocarp cell division and number [170, 173] suggesting a high sensitivity of olive mesocarp cell size to water stress. Grapevines are also well adapted to semi-arid climates, nonetheless severe water stress during the summer largely limit grapevine yield and cluster weight [27, 29]. This reduction is mainly observed in drought-avoiding genotypes, which optimize survival at expense of yield and reduced sugar allocation to reproductive tissues and thereby reducing fertility [174].

The effect of drought in crop plants is enhanced by high temperature and effects are usually difficult to separate [118]. Differences among genotypes are observed; for example barley is much less sensitive to short periods of very high temperature than wheat, and combined drought and high temperatures are more likely than high temperature alone to explain the reductions in grain weight observed in the field [175].

Fruit and Seed Quality

Drought influences end-use quality of major food crops in the world, as it is the case of wheat [176], barley, and maize [177]. Indeed, water stress in wheat changes the patterns of proteins [178]; in barley, grain β-glucan content and malt fine extract decreased with drought stress [179]; in soybean drought during seed development has a large effect on isoflavone concentration in the seeds [180]; in maize, water stress increases flavonoid content in seeds but reduces carotenoids and phenol content inducing a decrease in the antioxidant capacity of kernel oil [181]. In lupin seeds, raffinose quantity and accumulation pattern are reduced by water stress, suggesting an increase in nutritive values of seeds since raffinose is considered to be a major cause of flatulence in animals and humans [161].

Starch granule shape, volume and structure are important factors contributing to starch quality in wheat [182]. Post-anthesis water stress affects the proportions of different types of starch granules and increases the percentage of small granules per seed [183].

Protein content has an important implication in the processing qualities of cereals since it affects the functional properties of processed wheat products [184].

In wheat, grain protein content decreases linearly with the severity of drought stress during grain development [158]. Recently Zhao et al. [184] showed that the intensity of drought dictates the intensity of the effect on protein accumulation and reported a differential accumulation of proteins (especially gliadins and glutenins) in mature grains. The decrease in the accumulation of oil due to water stress was reported in wheat [184], soybean [185, 186], lupin [187] and chickpea [188].

In fruit trees, drought influences fruit development, metabolism, and final composition, and its timing and intensity dictate the extent of alterations occurring in final quality [29]. With regard to the effect of water stress on organoleptic properties, fruit quality is significantly affected by severe water stress during the fruit-growth and maturity periods [104]. Under water restriction, fruit maturity tends to be hastened, supporting the hypothesis that increasing water restriction might encourage early fruit maturity as observed in peach [189, 190]. Post-harvest water deficit was shown to increase fruit soluble solid concentration in the following season in peach [191, 192]. The opposite effect, reducing firmness and soluble solid concentration, was reported in sweet cherry [169].

Water stress was shown to decrease oil content and yield in young olive trees and induce lower level of phenolics in oil [172]. Olive fruits import assimilates from the canopy, but also produce them in situ by photosynthesis in the mesocarp; the fruit is capable of retaining chlorophyll even when its color change [193] and this makes a significant contribution to oil production [194]. This "autonomy" of olive fruits may explain the maintenance of oil quality in trees under water deficits [172]. In fact, although irrigation led to decreased contents of some undesirable sensory qualities as phenols, some favorable intense green notes were also reduced, which suggests complex effects of water stress on olive quality [195]. In grapevine, severe water stress influences final composition of the berries by delaying their ripening but also through an indirect effect on berry size [196, 197] that affects sugar and flavonoids metabolism in the berry (review [29]). However, moderate water deficit was shown to have beneficial effects on grape berries, for example by enhancing photoprotection mechanisms [198] and likely having a positive effect on wine quality [29, 196]. Indeed, moderate water deficit promotes sugar accumulation by inhibition of shoot growth with a subsequent reallocation of carbohydrates to fruits [199] and by the activation of ABA-mediated uptake of hexoses [198]. Under such conditions, sugar accumulation in berries accelerates anthocyanin accumulation or/and biosynthesis [200, 201]. The enhancement of carotenoids content and the up-regulation of genes encoding enzymes involved in biosynthesis of berry aroma were also observed after mild stress imposition [198, 202]. Similar benefits of mild water deficit in fruit quality were also observed in apricot [203], citrus [104] and olive [204].

The Breeding Achievements

Conventional Breeding

To face drought, farm-management practices and plant breeding are used for the improvement of crop yield [18], being the second approach the most promising in the long term [64]. Drought is the most recalcitrant to breeders' efforts due to the complexity of plant drought-tolerance mechanisms [205] and breeders have no reliable method of distinguishing sensitive from tolerant germoplasm other than by measuring yield [19]. Therefore, the main objective of a drought-tolerance breeding program is to select the variety presenting the better yield under stress conditions [206]. However, yield is a trait which is characterized by low heritability, polygenic control, and a high genotype $\times$ environment interaction (G $\times$ E) [21, 207].

During the last 50 years, most of the progress has been derived from empirical (conventional) breeding [208, 209] by selecting desired traits recognized at the phenotypic level. Generally, there is a minimum of 4 years extensive yield testing to further selection at multiple locations before a new variety is released to farmers. Empirical selection for grain yield was effective during the last decades. However, when plants are crossed some undesirable traits may be transferred along with those of interest – including some with negative effects on yield potential. In addition, breeding can only be done between species inter-compatible, which limits the new traits that can be added to those that already exist in a particular species [206]. Furthermore, the variability of rainfall from year to year increases G $\times$ E and reduces heritability for yield,

thereby limiting yield progress [19]. The indirect or analytical approach based on an understanding of the crop physiology, may help to target the key traits that are limiting yield [64]. Such an approach may therefore complement conventional breeding programs and hasten yield improvement [210–212].

A number of physiological studies have identified some traits which presence/expression are associated with plant adaptability to drought prone environment [205] and have been already successfully exploited in crop improvement [213]. Increasing water use by increasing early shoot vigor to escape dryer periods is a common strategy in Mediterranean region [214], but in very dry years this strategy may result in reduced yield. Early maturity by adjusting crop development with seasonal rainfall pattern in environments where they experiment terminal drought, or late flowering with short grain filling period in environments with early season drought, are examples of traits that are being used in breeding. Leaf cuticle waxes appear to play a key role in day and night transpiration and selecting for waxy leaves may reduce water loss and prevent leaf senescence during grain filling [215]. Enhancement of water extraction, by optimizing root architecture that resulted in greater water capture, has also the potential to significantly increase grain yield [63]. In addition, enhancement of root osmolytes accumulation was used in cereals, but a clear evidence of their beneficial role in crop yield was not observed [58].

Carbon isotope discrimination (Δ) is an attractive feature for C_3 plants breeders since it may provide an indirect sensing of transpiration efficiency (TE) [13]. In fact, genotypes showing higher TE (lower Δ) may be more productive under certain environmental conditions [216]. However, in the Mediterranean region the opposite was found and positive correlation between Δ and yield are reported [217], which is probably due to the fact that genotypes with lower TE have maintained a higher CO_2 conductance due to a better water status or by a faster plant development or better access to water [216]. Aerial infrared (IR) methods on vegetative material offer the possibility to detect variation on TE and present the advantage to reduce the cost of measuring carbon isotope discrimination [19, 216].

Fruit tree species propagation is possible only by vegetative methods. However, with the spreading of different species in new areas, the use of rootstock has become the first alternative to adapt scion cultivars to soils or climatic conditions that are otherwise not fully suited to their cultivation. Climatic areas or soils subjected to transient drought conditions require rootstock capable of inducing efficient water use by the scion cultivar. Unfortunately, there is only limited understanding of how rootstock provides tolerance to drought [218] and the majority of rootstock breeding programs addresses fruit quality. Traditionally, rootstocks have been produced using conventional hybridization breeding techniques, which are time and space consuming. Initial selection of main rootstocks is made from open pollinated fruit tree germplasm, generating thereby intra- and interspecific hybrids. The extended use of interspecific hybrids is due to the lower susceptibility of this type of rootstocks to biotic and abiotic stresses and may also overcome soil problems as drought [219], which might derive from heterosis (hybrid vigor) or from the elevation of ploidy levels of these rootstocks [220]. However, the use of known drought-tolerant/resistant rootstocks may not fulfill grower's intents in terms of fruit commercial traits, mainly because they may provide excess vigor. In addition, the problem of graft compatibility of hybrid rootstocks with commercial scion complicated the use of a wide range of cultivars [221, 222].

New Breeding Approaches

Compared to conventional approaches, genomics offer unprecedented opportunities for dissecting quantitative traits into their single genetic determinants, the quantitative trait loci (QTLs), thus paving the way to marker-assisted selection (MAS) and, eventually, cloning of QTLs and their direct manipulation via genetic engineering. Several studies have reported QTLs for roots architecture and investigated their effect on yield under water stress in rice [223] and also in maize, where QTL reported for leaf ABA concentration showed an effect on root size and grain yield [224, 225]. In sorghum QTLs related to 'stay green' trait and yield were identified [226].

Some QTLs of one character were shown to overlap with QTLs of other characters. This is the case in maize, where QTLs of leaf growth sensitivity to water deficit

overlapped with QTLs for leaf responses to evaporative demands, thus suggesting that hydraulic mechanisms are involved in that response [227]. Similarly, overlap between QTLs of leaf growth sensitivity with silk growth was observed [228]. QTLs were also reported for anthesis-silking interval in maize [15], for seed weight and yield under different water conditions in rice [229] and durum wheat [230]. It was also possible to identify WUE QTLs in brassica [231], rice [232], and wheat [233]. However, despite all the recent technological breakthroughs, the overall contribution of genomics-assisted breeding to the release of drought-tolerant cultivars has so far been marginal [234], in part due to the fact that a given QTL can have positive, null or negative additive effects depending on the drought scenario [235]. In addition, cloning QTLs for yield maintenance under drought conditions and drought physiological traits is limited because the unavailable information about the biochemistry of some of these traits [236].

In recent years, proteomic and transcriptomic studies have advanced the basic understanding of protein/gene regulatory networks that are active during the exposure of plants to water stress [237, 238] and there have been several reports of apparently promising biotechnological manipulations emerging from these tools [239]. Remarkable dehydration tolerance has been obtained under laboratory conditions using bacterial RNA chaperones overexpression [16], NFYB2 class transcriptionals regulators [240], as well as modulating the expression of dehydration response element binding (DBF/DREB1) transcription factor [241], using of detoxification of reactive oxygen species that accumulate under stress [242, 243] and of hormone intervening in drought signaling [244]. Introducing RNA silencing in some crops to downregulate poly ADP ribose polymerase and thus inducing tolerance to wide range of stresses [245] and overexpression of cyanobacterial flavodoxin [246] were also reported. However, these reports and others have failed to deliver drought tolerance in yield terms when the novel material is transferred from the growth room to the field [4].

Fruit trees also have benefited from new technologies and it is now possible to reduce the breeding time by MAS. Very recently fruit breeders have begun to examine the possibilities of using such techniques in the production of new rootstocks. The aim is to improve an already good rootstock for yield by modifying its gene expression or introducing new genes to improve resistance to abiotic factors. Unfortunately, the mechanisms by which rootstocks bring about their beneficial effects on the vigor and cropping of scions are still very poorly understood. Until more research is conducted in this field and genes that control such processes are identified, progress in this area may be slow. Recent studies showed that ectopic expression of the transcription factor Osmyb4 gene in transgenic apple trees, improved water stress tolerance and might result in long term ameliorated productivity. Further experiments are required to assess the agronomic value of the plants produced and to verify to what extent the expression of *Osmyb4* may contribute to enhanced drought tolerance under field conditions [247].

Summarizing, to date increased drought resistance of the major crop plants (sustained yield under water scarcity) has been dependent upon the screening of a wide range of germoplasm in order to identify genetic variation in major traits involved in stress resistance [19, 248, 249]. In addition, the effective use by the crop of a limiting water supply has been achieved by adjusting crop phenology to its environment [2, 14] or by using agronomic practices aiming at an improved water use, such as deficit irrigation [4, 29]. A variety of approaches have been successful, particularly in the irrigation of top quality fruit and vineyards [3, 27, 29, 250, 251] but also in annual crops [252–255]. In addition to minimizing changes in shoot water status, deficit irrigation is able to control the balance between fruit and vegetative growth, with likely positive impact on fruit quality [8, 256].

Future Directions

Drought has a great impact on the vegetative and reproductive development of annual and fruit tree crops and thereby impacts on final yield and seed and fruit quality. The key factors responsible for high yield under drought in annual plants are an appropriate phenology that will enable escaping drought and getting the timing of flowering right, high water-use efficiency and a high harvest index. The impact of drought is highly complex and involves diverse processes as photosynthesis, respiration, reserve accumulation, fertilization, gamete and embryo development, and fruit

and seed development. Due to the complexity of crop reproduction and the still incomplete knowledge of mechanisms underlying the response of reproductive events under water stress, it has been until now difficult to construct a model system to guarantee successful reproductive development and high yield under water scarcity. How resource availability (namely carbohydrate reserve) influence the development of reproductive organs under water stress is among the least understood aspects. On fruit trees, it is also urgent to understand (1) how rootstock confers resistance and/or tolerance to drought to the scion cultivar to better adjust breeding strategies; (2) the key events of fruit ripening. In addition, differences between species imply different strategies to improve/maintain yield and quality under such conditions. Spatial strategies also differ: a particular trait may be associated with higher yield in one environment and may have no/or negative effect in other environment [13].

Conventional breeding still appears to be the most effective for a significant drought-tolerance improvement of new cultivars. The application of modern molecular tools to understand responses of crops to water scarcity has only recently begun. In addition, to integrate them in breeding programs it is imperative to incorporate an accurate measurement of the phenotype under water stress. However, the speed of molecular technologies is not matched by the speed on phenotyping, being the latter one of major limitations to improve selection methods for water-limited environments [19]. Moreover, it is imperative to integrate disciplines, as functional genomics, transcriptomics, proteomics and metabolomics with plant physiology to improve breeding strategies. This would allow researchers to address drought tolerance/resistance through an integrated approach based on the knowledge of expression of genes and their products at a particular phenological and developmental stage of the crop.

Article Outline

Glossary

Critical plant N concentration Critical plant N concentration is defined as the minimum plant nitrogen concentration of a crop corresponding to its maximum crop mass.

Critical crop N uptake Critical crop N uptake is defined as the minimum crop nitrogen uptake for achieving maximum crop mass.

Harvest index (HI) Harvest index (HI) is the ratio between harvested biomass Y (grains, tubers) and aboveground crop mass W at crop maturity.

Intercepted photosynthetic active radiation (IPAR) Intercepted Photosynthetic Active Radiation (IPAR) is the proportion of the incident PAR which is intercepted by the crop at a given time. This proportion is related to the size of the canopy, the Leaf Area Index, and depends also on canopy structure: leaf angle and geometry.

Leaf area index (LAI) Leaf area index (LAI) is the total canopy leaf area of a crop per unit of soil area. LAI allows the estimation of the proportion of the incident light which is intercepted by the canopy, and then which can be used for photosynthesis of the whole crop.

Nitrogen absorption efficiency (NAE) Nitrogen absorption efficiency (NAE) is the increase in crop nitrogen uptake per unit of supplemental N supply rate.

Nitrogen conversion efficiency (NCE) Nitrogen conversion efficiency (NCE) is the increase in crop dry mass (dW) or in crop yield (dY) per unit of supplemental crop N uptake corresponding to an increase in nitrogen supply rate.

Nitrogen use efficiency (NUE) Nitrogen use efficiency (NUE) is the increase in crop dry mass (dW) or in crop yield (dY) per unit of supplemental N supply rate. So NUE = NAE × NCE.

N dilution N dilution is the process corresponding to more rapid accumulation of nitrogen-free compounds than nitrogen compounds within plant as plant grows, leading to decline in plant nitrogen concentration with plant mass accumulation.

Nitrogen nutrition index (NNI) Nitrogen nutrition index (NNI) is an index which allows the estimation of the crop nitrogen status. This index is calculated at any moment as the ratio between the actual plant nitrogen concentration of the crop and the critical plant N concentration (see this definition) corresponding to the actual crop mass.

Photosynthetic active radiation (PAR) Photosynthetic active radiation (PAR) is the part of solar radiation spectrum corresponding to wavelengths that are active for photosynthesis.

Radiation use efficiency (RUE) Radiation use efficiency (RUE) is the ratio between the quantity of biomass accumulated within a crop and the quantity of photosynthetic active radiation (PAR) intercepted by this crop during the same period of time.

RuBPc-o Ribulose bisphophate carboxylase/oxygenase, the enzyme located within chloroplasts which allows the carboxylation of CO_2.

Definition

A prerequisite for the analysis of crop responses to nitrogen (N) is the determination of the plant nitrogen content and repartition. How much N is incorporated within plants and crops? Within which plant tissue? For

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

which physiological function? Thus, according to the answers to these questions, it is possible to determine a *critical plant nitrogen status* as the minimum plant N concentration that allows the maximum plant (or crop) growth rate. It has been demonstrated that this critical plant N concentration decreases as plant grows as the result of an ontogenetic plant architecture development leading to a *dilution of N* compounds within increasing proportion of free-N compounds as plant gets bigger. This N dilution process can be formulated through a negative power relationship between plant N concentration and crop mass. This critical N dilution curve allows the discrimination of situations of N deficiency (below the curve) and situations of N luxury consumption (above the curve). So a Nitrogen Nutrition Index (NNI) can be calculated for quantifying the intensity of N deficiency or N luxury of any crop at any stage of its life cycle. This possibility for determination of crop N status and for quantification of N deficiency either in terms of intensity or timing allows the complete inversion of the approach: instead of response of crop to N supply, the problem is to study the response of crop to N deficiency. By this way, the check treatment is the non-limiting N conditions where crop growth potential is limited only by genetics and climate. Then the effect of intensity and timing of N deficiency period on the different plant growth processes and yield component elaboration can be studied with a more generic approach. This new method for analysis of the effect of plant N nutrition on crop yield allows the identification of physiological, agronomical, and genetical ways for improving nitrogen use efficiency of crops.

Introduction

Nitrogen is considered to be the most important limiting factor, after water deficit, for crop production worldwide. Over the last 50 years, the worldwide use of mineral fertilizers is one of the key elements for producing sufficient food to meet the demand of increasing human population [1, 2]. During this period, the use of mineral N fertilizers in agriculture systems increased sevenfold in parallel with the doubling of agricultural food production. This huge amount of mineral N is provided by industrial processes of chemical reduction of atmospheric nitrogen. So even if this resource can be considered as quantitatively non-limited, the energy cost of the Haber–Bosch process necessary to obtain mineral N fertilizers and the large greenhouse gas emission associated with oblige to reconsider the sustainability of the use of mineral N in agriculture. Moreover, the use of large amounts of N in intensive agriculture production systems has led to important environmental problems such as the eutrophication of freshwater [3] and marine ecosystems [4], pollution of ground water, and gaseous emissions of N oxides and ammonia in the atmosphere [5, 6]. In consequence, problems associated with sustainable development, global changes, environment protection, and global food security are now questioning the efficiency of use of N fertilizers in agricultural systems [7].

During the last decades, the relatively high products/fertilizer price ratio, incited farmers to adopt an insurance strategy in fertilizer management: applying excess of N to avoid any restriction in crop N supply and then any penalty in crop yield. These practices, when they were generalized on large agricultural areas led to a progressive increase in soil N surplus accumulation and an elevated risk of N leaching with dramatic consequences on ground water quality [8]. Adoption of a more restricted strategy for supplying and timing of N fertilizers is now a prerequisite for a more sustainable agriculture development. But such a strategy is difficult to be adopted in practice because of the non-predictable variations in weather which determines both soil N mineralization and crop growth potential. In consequence, a reduction in N application rates to avoid surplus of N in soils would increase the probability of temporary crop N nutrition deficiency, and then, as a consequence, an increased risk for a lower crop production and then a deterioration of the economic outputs the farmers are expecting. Therefore, optimizing crop production with the goal of reducing environment hazards requires an improvement in the understanding of the regulatory mechanisms by which crops absorb nitrogen from the soil and use it efficiently for yield component and quality elaboration. But it requires also a better understanding of soil microbial processes and the interaction between C and N cycles in order to optimize crop N residue cycling, soil organic matter dynamics, and to improve the capacity to predict soil N supply.

Fertilization management has to be conceived as a mean to match as closely as possible crop N supply with crop N demand in order to limit accumulation of mineral N within soils, and then emissions to hydrosphere and atmosphere. By this way, matching timing of N supply with timing of crop N demand appears very necessary. It is fundamental to underline here the necessity for a high precision for adjustment of N supply to N demand: for an intensive wheat crop producing about 8 t ha^{-1} of grain, the total N demand is about 240 kgN ha^{-1} and the loss of only 20 kgN ha^{-1} through leaching (i.e., less than 10% of the total N demand) can lead to pass over the admissible limit of nitrate concentration (50 mg l^{-1}) in drainage water! Moreover, the loss of only 2–3 kgN ha^{-1} through emission of N_2O to atmosphere (that corresponds to 1% of the total N demand) is considered as highly detrimental for greenhouse gas effect. So the problem to face now is not to understand how the yield of the different crop species can be improved by addition of N fertilizers, but (i) to determine the dynamics of crop N demands all along the crop development cycle; (ii) to determine the timing of the soil N supply according to soil characteristics, climate, and soil agronomic management; (iii) to determine the crop responses to different intensity and timing of N nutrition deficiency; and then (iv) to manage timing of crop N fertilization using diagnostic and decision tools for optimizing trade-off between minimizing crop yield reduction and minimizing environmental impacts.

N in Plants

For most of the crop species, plant life cycle can be roughly divided into two main phases: (i) the vegetative growth phase, when young developing roots and leaves behave as sink organs that absorb and assimilate inorganic nitrogen for amino acid and protein synthesis, and (ii) the remobilization phase when senescing tissues start to behave as source organs translocating organic molecules to ensure formation of new developing and/or storage organs [9]. The first phase is dominated by the dynamic of leaf area expansion as a mean for light capture, and then the role of nitrogen in both leaf growth and leaf photosynthesis is capital. The second phase is dominated by the development of reproductive organs such as seeds, fruits, tubers, and bulbs, or by storage organs allowing survival for perennial species such as trunks for trees or roots and stubbles for herbaceous species like grasses. As a consequence, the same N absorbed by the plant can be used successively for different functions and then analysis of crop response to N nutrition cannot be simply reduced to an addition of different elementary functions, but as a complex and integrated adaptive system with strong interactions among different processes.

In plants, N is required primarily for the synthesis of proteins, both structural and enzymatic, as the more important components of cells. There is large variation in the composition of the different cell types within a plant according to the different types of tissues. Cells which store carbohydrates or are part of support and transport tissues have relatively lower protein and nucleic acid concentration than metabolically active cells within meristems and photosynthetic parenchyma [10]. The relative numbers of each type of cells determine the organ composition. So organs that have relatively slow metabolism but are specialized in support and transport, such as roots and stems, contain little protein and thus have small N concentration in dry matter. Organs which store starch or other carbohydrate, such as grains, fruits, and tubers, have also low N concentration. On the contrary, leaves having a high metabolic activity through photosynthesis have high N concentrations. So, plants are very heterogeneous systems in terms of N concentration at every level of organization: cells, tissues, and organs. Therefore plant N demand, i.e., the quantity of N required for the plant to achieve its potential growth and development, depends on the morphologic and histologic plant composition.

Leaves are essential organs by which plants capture light and assimilate carbon. Light capture, photosynthesis, and the associated respiratory processes require a large number of different enzymes, pigments, and proteins [11]. About 50% of the soluble protein of the leaf is in RuBPc-o enzyme alone, another 25% is in the light harvesting and electron transport components [11]. Thus the chloroplast, as the location of RuBPc-o and other photosynthetic enzymes, and according to its high protein membrane component, contains the major part of the total leaf N. Composition of leaves and their N concentration varies with age, development

stage, and environment. Leaves of cereals have the greatest concentration of N just after their full expansion that corresponds to their maximum in photosynthetic activity. After a period the N concentration in the leaves decreases in parallel with metabolic activity as senescence progresses [12]. Remobilization of N-components occurs during the senescence process, and then amino acids from proteolysis are transported to younger developing leaves, or reproductive organs. A consequence of this ageing and senescing processes is that older leaves situated in the lower canopy where light intensity is limiting for photosynthesis, provide N for new leaf production at the top of the canopy. This recycling process thus tends to optimize photosynthesis in relation to N supply and light at the level of the canopy [13].

To achieve large rates of photosynthesis in well-illuminated conditions, leaves require a large concentration of RuBPc-o and other N-components and, hence, large N concentration [14]. As N supply rises, the amount of N per unit area in leaves increases, enhancing the rate of CO_2 assimilation [12, 15]. Thus, there is a good correlation between CO_2 assimilation rate and leaf N content. However, with very large N supply, leaf N content may increase without any increase of photosynthetic rate, unless larger CO_2 concentrations are used [16]. Plants with C_3 photosynthetic pathway contain more N per unit leaf area than those with C_4 metabolism. So C_4 crops use N more efficiently than C_3 ones [17]. Ample N increases the number of chloroplast compared with deficient N. Also the density of protein in the stroma is increased by large N supply. All these processes contribute to accumulate N within leaf tissues as plant N supply increases.

Although the primary role of RuBPc-o in plants is to assimilate CO_2, a storage function for N has been mooted for this enzyme [18, 19]. Thus, N of RuBPc-o have two successive functions within plants: CO_2 assimilation and source of N supply for reproductive and storage organs. Storage of N within the plants for further reuse can be considered as an adaptive mechanism for buffering plant N nutrition in highly variable soil N supply conditions. In this way, plants can store N reserves during periods of vegetative growth and large soil N availability, and then to reuse these N compounds at the end of their life cycle when mineral soil N is exhausted. Accumulation of RuBPc-o in excess within leaf tissues is not the only way for plant to store N. Accumulation of vegetative storage proteins (VSP) within different plant tissues or organs is a complementary way for storing N reserves, as demonstrated in alfalfa [20] and in perennial grasses [21]. For perennial plants, the storage of N reserves within perennial organs such as roots, rhizomes, tubers, or trunks is a prerequisite for regrowth after defoliation or after winter.

Due to the importance of light capture and photosynthesis for plant growth, much attention has been paid to allocation of N to leaves within canopies. However, allocation of N to other vegetative tissues is also quantitatively important. Green leaf N content represents only 53% of total shoot N in a lucerne crop [22], and only 30% of shoot N in a wheat crop at the beginning of the grain filling period [23]. Lemaire et al. [24] showed that for a large number of crop species there exists trade-off between accumulation of N in leaves for optimizing crop photosynthesis and accumulation of N within stem tissues for optimizing the plant architecture development and the elaboration of reproductive organs.

N compounds as amino acid and proteins are used within meristematic tissues for initiation and expansion of new organs: leaves, stem internodes, tillers, and branches and roots, and also inflorescences, fruits, and seeds. The use of N for leaf area expansion during vegetative growth period is of first importance because it determines the dynamics of LAI expansion of the crop and then the capacity of the crop to intercept light and to accumulate biomass. The rate at which N is supplied to meristems greatly determines cell production rate while the final cell size is only little affected [25–27]. As cells enlarge in size, their N concentration decreases through a dilution by accumulation of greater quantities of N-free compounds until final size is reached. So any limitation of N supply to meristem tissues leads to a reduction in the cell production rate and in the size of the final organ produced. For reproductive meristems, shortage of N reduces more the number of grains than the grain size [28–30].

When analyzed at the level of a plant population, it has been clearly demonstrated that N is allocated to individual plants according to their own contribution to interception of light [31]. N resources are allocated preferentially to dominant plants and then stressed

plants cannot respond to N supply because of the lack of light. In consequence, competition for light among individual plants within a dense canopy determines greatly competition for N resources.

In conclusion, plants and canopies are very heterogeneous systems in terms of N content, concentration, and repartition. This heterogeneity can be analyzed at different levels of organization: organite, cell, tissue, organ, whole plant, and plant population. N compounds, mainly as proteins are involved in all metabolic processes and then they are used successively for different functions such as cell division, organ growth and development, light capture, photosynthesis and respiration, reserve formation and recycling. Once absorbed by the plant, N is used several times through internal recycling processes and reallocation to the different plant parts. So analysis of plant N nutrition is very complex because it involves several interdependent metabolic functions and due to constant feedback mechanisms, it can be studied only through a dynamic approach.

Crop N Demand

Crop N demand (N expressed in kg ha^{-1}) at any time of the crop cycle can be defined as the result of critical crop mass (Wc) that is the maximum crop mass attainable in a given environment without any limitation of nutrients and its critical plant N concentration %Nc [32]:

$$N = \%Nc\, Wc \quad (1)$$

The critical plant N concentration (%Nc) has been defined as the minimum plant N concentration corresponding to maximum crop mass [33]. This concept can be applied in dynamic terms, such that the daily crop N demand (or critical N uptake rate expressed in kg ha^{-1} day^{-1}) is the quantity of N the crop has to absorb each day to maintain its potential growth rate over a given period of time.

Many studies conducted on a large range of crop species (see [34] for a review) have shown that the critical plant N concentration (%Nc) is regularly decreasing as crop mass accumulates during the crop growth period. Moreover, it has been shown that this dynamic of decline in %Nc could be represented by a unique and constant relationship whatever the conditions and the genotypes for a same species [35]:

$$\%Nc = a(Wc)^{-b} \quad (2)$$

Coefficient a represents the critical plant N concentration for Wc = 1t ha^{-1}. Coefficient b is dimensionless, and it represents the dynamic of the dilution of N within the dry matter.

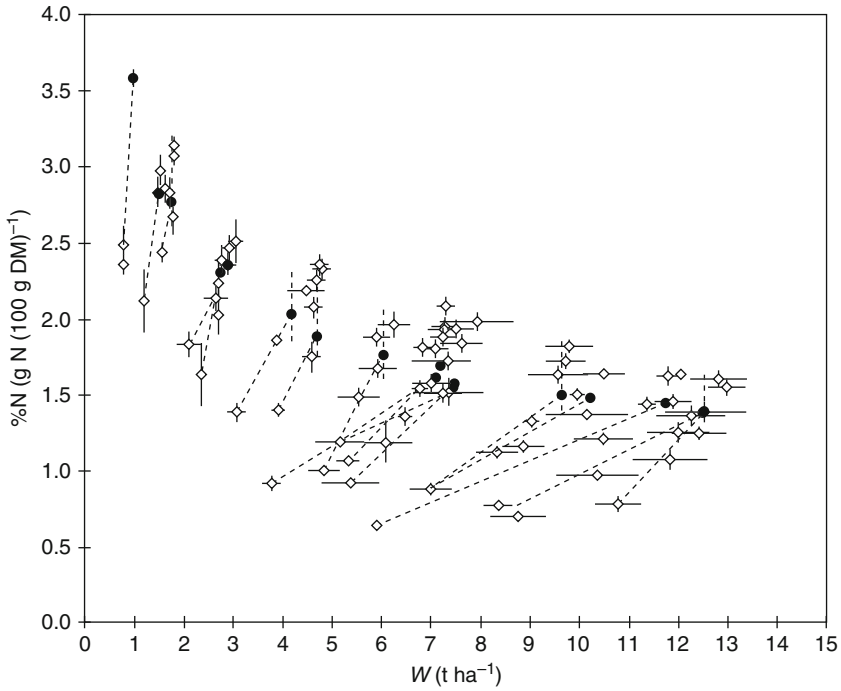
Mixing Eqs. 1 and 2 allows the expression of the dynamics of the critical crop N uptake, i.e., the crop N demand, in relation with the dynamics of potential crop biomass accumulation:

$$Nc = a'(Wc)^{1-b} \quad (3)$$

where coefficient a' is the crop N demand (or the critical N uptake) for a potential crop mass accumulation of 1 t ha^{-1}. Value of a' is equal to $10a$, when a is expressed in % and a' is expressed in kg ha^{-1}.

Values of a (and a') and b have been established for the main cultivated species according to the method developed on wheat by Justes et al. [36]. This method as illustrated on Fig. 1 requires a family of response curves of plant N concentration (%N) vs crop mass (W) across increasing N supply rates. For each response curve, the critical plant N concentration (%Nc) is estimated as the intersection point between the oblique line representing the response of both %N and W to increased rate of N supply, and the vertical line representing the increase in %N with further N supply rates once the maximum crop mass (Wc) is reached that correspond to luxury N accumulation. As the determination of %Nc is done at different stages of growth for a large range of value of W, then it is possible to fit the series of %Nc–Wc data points for getting the critical N dilution curve and to calculate the value of coefficients a and b.

These values are presented in Table 1. For a given species, coefficients a (and a') and b remained constant whatever the climatic conditions (years and locations). Moreover, Lemaire et al. [37] showed that for wheat, maize, canola, sorghum, and sunflower the same value of coefficients holds either in temperate or in subtropical conditions. Comparison among species allows a clear distinction between C_3 and C_4 groups for the value of coefficient a (and a') while coefficient b is unaffected by the type of the metabolic pathway. Within each of the metabolic groups, it is difficult to



Crop Responses to Nitrogen. Figure 1
Determination of the critical plant nitrogen (N) concentration of maize crops as the intersection point between the *oblique line* corresponding to the response of both plant nitrogen concentration (%N) and crop mass (*W*) to increasing nitrogen supply rates, and the *vertical line* corresponding to the increases in plant N concentration without corresponding increase in crop mass that corresponds to luxury nitrogen accumulation [46]

establish clear differences between species because of the high correlation between the coefficient a (or a') and b. Then the fitted curves corresponding to Eq. 2 for the different crop species are relatively close to each other [38].

The derivative of Eq. 3 allows the expression of the crop N demand in dynamic terms:

$$\frac{dN}{dt} = \frac{dN}{dW}\frac{dW}{dt} = a_c(1-b)W^{-b}\left(\frac{dW}{dt}\right) \qquad (4)$$

Equation 4 shows that the daily crop N demand follows the daily crop growth rate, but for a similar daily crop growth rate, the daily crop N demand declines as the crop mass increases.

A theory has been developed for explaining the close relationship between crop N demand and crop biomass accumulation rate [33, 35]. The hypothesis is that plant mass W is composed of two compartments: Wm, the metabolic tissues involved directly in

Crop Responses to Nitrogen. Table 1 Values of coefficient a' and b of Eq. 3, $N = a'(Wc)^{1-b}$, for different crop species

Crop species	a' (kgN ha^{-1})	b (dimensionless)	References
Temperate grasses (C_3)	48	0.32	[39, 40]
Alfalfa (C_3)	48	0.33	[41]
Pea (C_3)	51	0.32	[42]
Wheat (C_3)	53	0.44	[36]
Canola (C_3)	45	0.25	[43]
Rice (C_3)	52	0.52	[44]
Tomato (C_3)	45	0.33	[45]
Maize (C_4)	34	0.37	[46]
Sorghum (C_4)	39	0.39	[47]
Tropical grasses (C_4)	36	0.34	[48]

plant growth processes (photosynthesis and meristem activity) with a high N concentration %Nm; and Ws, the structural tissues involved in plant architecture and transport with a low N concentration %Ns. Then:

$$W = \mathrm{Wm} + \mathrm{Ws} \tag{5}$$

and:

$$\%\mathrm{N} = \frac{1}{\mathrm{W}}(\%\mathrm{NmWm} + \%\mathrm{NsWs}) \tag{6}$$

Supposing that Wm increases allometrically with *W*, then:

$$\mathrm{Wm} = kW^{\alpha} \tag{7}$$

and then:

$$\%\mathrm{N} = k(\%\mathrm{Nm} - \%\mathrm{Ns})\,W^{\alpha-1} + \%\mathrm{Ns} \tag{8}$$

This equation is very close to the empirical Eq. 2. The main difference is the asymptotic value of %Nc which is equal to %Ns and not to zero. But the difference is very little for the range of *W* from 1 to 15 t ha^{-1}[35].

Following Hardwick [49] assumptions, it can be postulated that because Wm is associated mainly with photosynthesis it scales for plant area, and then to crop Leaf Area Index (LAI):

$$\mathrm{Wm} = p(\mathrm{LAI}) \tag{9}$$

and then:

$$\mathrm{LAI} = \frac{k}{p}W^{\alpha} \tag{10}$$

So Eqs 3 and 10 indicate that both N uptake and LAI are allometrically related to crop mass. For a large range of crop species, cultivated either under temperate or sub-tropical climate, the hypothesis for a common value of coefficients *b* and α cannot be rejected, but then a direct relation of proportionality could be established between crop N uptake and crop LAI [37]:

$$\mathrm{N} = \frac{a'p}{k}\mathrm{LAI} \tag{11}$$

So, at crop level, the dynamic of expansion of LAI is driving the crop N demand.

Lemaire et al. [37] showed that the two coefficients *b* and α evolves in parallel during the time course of the crop growth. Just after seedling, and until a crop mass of approximately 1.5 t ha^{-1} is reached the value of *b* and α is high, close to 0.90–0.95 while it decreases rapidly to a value of 0.6–0.7 after this stage when competition for light between individual plants within the canopy is established.

Lemaire et al. [37] tried to determine among the two parameters, crop mass or LAI, who is the fundamental driver of crop N demand. They concluded that Eq. 3 was the more robust across genotypes and environments, but in fact the two Eqs. 3 and 11 each represent an incomplete expression of the feedback regulation by shoot growth of N absorption capacity of the roots and of N partitioning within the canopy as described within the above section. A more complex analysis of N allocation between leaf and stem and of remobilization of N from old leaves would be necessary to better capture genotypic differences in N uptake capacities. Nevertheless, the robustness of the relationship between critical crop N uptake (Nc) or critical crop N concentration (%Nc) with crop mass accumulation (W) across environments and genotypes allows the use of these empirical relationships as a base for the determination of crop N demand and for diagnosis of crop N status.

Regulation of Crop N Uptake

The theory developed above indicates that plant N uptake seems to be regulated by plant growth itself. In steady state N supply conditions, plant N uptake is feedback regulated by shoot signals, with a positive signal from photosynthetic C supply and a negative one from reduced N recirculation to roots [50–52]. So the relationship between N uptake and LAI as attested by Eq. 11 can be explained by the fact that LAI expansion allowing increased light interception provides larger C supply to roots, and also increases N storage capacities within expanding leaves as RuBPc-o that avoids the depletion of N uptake by recirculating reduced N compounds in the phloem. This leads to the proportionality between crop N uptake and LAI for most of the species, but the slope of the relationships, i.e., the N uptake per unit LAI, is variable across species according to their morphology and, more particularly, their leaf/stem ratio. So leaf area expansion is not the only way for plant to store

reduced N. Stem growth and leaf thickness increase are also a possibility for sequestrating N to avoid the repression of N uptake capacity of roots. In consequence, a more general and stable relationship between N uptake and crop mass can be obtained as attested by Eq. 3. Nevertheless, this relationship is not linear because N uptake per unit of crop mass decreases as the LAI per unit of crop mass, i.e., the leaf area ratio (LAR) of the crop, decreases, that determines the N dilution effect.

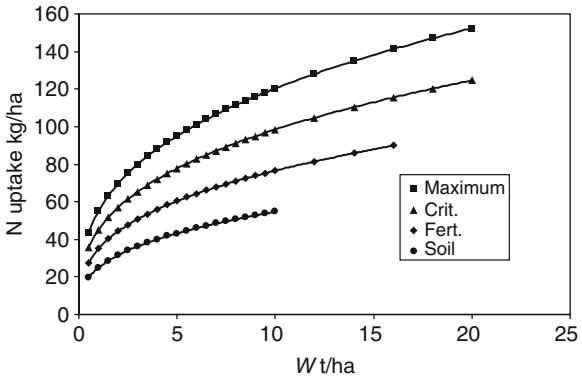
In the field, in a variable N supply condition, plant N uptake is co-regulated by both crop growth rate potential and the soil N availability. Two groups of transport systems, with low and high affinity for nitrate, operate in plants [53]. Devienne-Barret et al. [54] have proposed a model accounting for this co-regulation of plant N uptake by soil nitrate concentration and plant growth:

$$\frac{dN}{dt} = a_c(1-b)\,W^{-b}\left(\frac{dW}{dt}\right)_{max}\left[V_H\frac{C}{K_H+C}+V_L\frac{C}{K_L+C}\right] \quad (12)$$

where V and K are coefficients of the Michaelis–Menten formula and subscripts describe the high (H) and the low (L) affinity transport systems for nitrate; C is the actual concentration of nitrate in soil solution, W is the crop mass in t ha^{-1} and b is the allometric coefficient of Eq. 3.

Figure 2 represents the crop N uptake vs crop mass trajectories for different steady-state N supply conditions, i.e., C = constant. Among these curves, it is then possible to identify the critical N uptake curve as defined above. It is also possible to imagine that the maximum N uptake curve corresponds to the higher quantity of N a crop is able to accumulate at a given crop mass. The difference between this curve and the critical curve correspond to the quantity of luxury N the crop is able to store.

So whatever the cause of the variation in crop mass provided that N supply remains at steady state, any increase in crop mass (ΔW) is accompanied by a corresponding increase in crop N uptake (ΔN). As soil N supply increases, plant N uptake increases as a consequence of both (i) the increase in soil N concentration (C) and (ii) the increase of plant growth rate itself. So, at any moment, crop growth rate is the consequence of crop N uptake and vice versa.

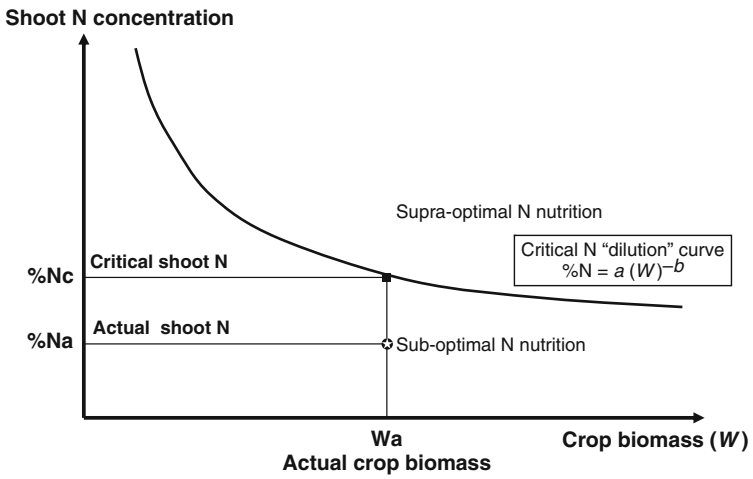


Crop Responses to Nitrogen. Figure 2
Nitrogen (N) Uptake – Crop Mass (W) trajectories for different steady states N supply: critical N uptake (Crit.), maximum N uptake (Maximum), non-fertilized (Soil), and suboptimal N application (Fert.). The two lines represent either (i) two growth stages of the same crop, (ii) two crops having different growth rate, or (iii) an environmental effect. The lines represent the response curves to increased N supply

Diagnosis of Crop N Status: Nitrogen Nutrition Index

The main consequence of the theory developed above is that neither the plant N concentration nor the crop N uptake per se can indicate unequivocally the crop N nutrition status. Eqs. 2 and 3 indicate that these two variables have to be interpreted in relation with crop mass.

As shown in Fig. 2, the critical N uptake curve separate situations where N supply is limiting crop mass accumulation for situations where N is accumulated in excess without any supplemental increase in crop mass. For a given situation and at any time course of the growth period of the crop characterized by an actual crop N uptake (Na) corresponding to an actual crop mass Wa, it is possible to determine a Nitrogen Nutrition Index (NNI) as the ratio between Na and the critical N uptake, Nc, corresponding to the same crop mass provided the critical N uptake of the crop species has been determined. NNI can also be



Crop Responses to Nitrogen. Figure 3
The use of the critical N dilution curve for the determination of the nitrogen nutrition index

determined directly from actual plant N concentration and dilution curves as illustrated in Fig. 3:

$$\mathrm{NNI} = \frac{\%\mathrm{Na}}{\%\mathrm{Nc}} \tag{13}$$

Values of NNI close to 1 indicate that at the date of the determination of Na or %Na the crop were in situation of non-limiting N supply. Values more than 1 indicate a luxury consumption of N. Values less than 1 indicate an N deficiency, the intensity of which can be estimated by the value of the NNI: a value of 0.6 indicating that crop N availability was only 60% of the critical level. Such an index of crop N status has been used as a diagnostic tool for analyzing a posteriori agronomical data from field experiments or farm observations in order to explain variations in yield by differences in crop N status [55].

Nevertheless, this approach does not take into account that the minimum plant N concentration is not 0 but is equal to %Ns (Eq. 8), which is the minimum plant N concentration for the plant to stay alive as postulated by Angus and Moncur [56]. So a more complex nitrogen nutrition index can be calculated:

$$\mathrm{NNI}' = \frac{\%\mathrm{Na} - \%\mathrm{Ns}}{\%\mathrm{Nc} - \%\mathrm{Ns}} \tag{14}$$

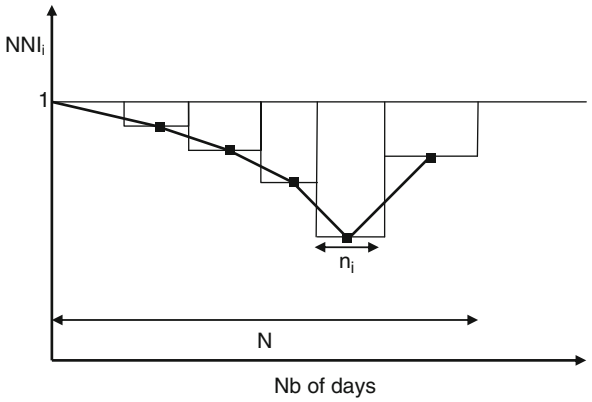
This new index, NNI′, is therefore physiologically more relevant than NNI, but it involves a greater degree of uncertainty related to the value of %Ns which has not been documented for many crop species. Lemaire and Gastal, [35] by using Eq. 8 derived a value of 0.77% and 0.82% for %Ns for wheat and maize, respectively. So variation in %Ns across crop species could be not very important. Therefore, the use of Eq. 2 for determining crop N status can be recommended owing to its simplicity.

NNI estimates the instantaneous crop N status at the period of time when actual plant N concentration %Na and actual crop mass Wa are estimated. But under changing N supply in the field, it is necessary to determine NNI several times during the growth cycle. An integrated value of NNI can be obtained by the weighted mean of NNI during the different growth periods, each time interval representing the duration in days or degree-days. Lemaire and Gastal [35] showed that it was possible to establish a linear relationship between the $\mathrm{NNI}_{\mathrm{int}}$ and the relative biomass accumulation as expressed as the ratio between actual (Wa) and potential (Wm) biomass:

$$\mathrm{Wa}/\mathrm{Wm} = K(\mathrm{NNI}_{\mathrm{int}} - \mathrm{NNI}_0) \tag{15}$$

where K is the response of the crop to increment in its average N nutrition status and NNI_0 is the minimum crop N status to allow plant growth. This minimum theoretically corresponds to %Ns.

Jeuffroy and Bouchard [57] characterizes the N deficiency period of a wheat crop by both its length



Crop Responses to Nitrogen. Figure 4
Estimation of NNIint from a sequential determination of NNI_i : $NNN_{int} = 1/N\ \Sigma NNI_i n_i$ The intensity of N deficiency (ID) is estimated by the lowest value of INN_i, and the duration of the deficiency (DD) is equal to the number of days with $NNI_i < 1$

(deficit N duration, (DD) and its intensity (ID) by means of the 1-NNI minimum observed value, and they calculated an integrated index of crop N status by the mean of the product ID × DD = IDD that represents about twice the area between the curve of NNIi dynamic and the horizontal line NNIi = 1 (Fig. 4). They showed that IDD explained 96% of the variation in grain number of wheat within a large experimental sites x years data set.

So it is clear that NNI is a good basic tool for analyzing actual plant status in crops, and then to interpret agronomical data in field conditions in order to detect if or not plant N deficiency periods occurred, with which intensity and timing and to analyze the consequences on crop growth and the crop yield components. But despite its high informative value as diagnostic tool for crop N status, NNI is difficult to use practically in field conditions and it remains more a research than an agronomical management tool. NNI determination is time consuming because of the necessity to determine crop mass. Then it is necessary to use noninvasive and cost-effective methods for a rapid and operational determination of plant N status, and then to use NNI as a reference for calibration of these indirect methods.

The theory developed above showed that the N dilution effect and then the dependency of plant N concentration from the crop mass is the result of two processes: (i) the decline in plant leaf area ratio (LAR) as crop mass increases, and (ii) the preferential allocation of N to the well-illuminated upper layer of leaves as canopy develops. Therefore, Lemaire et al. [58] suggested that while plant N concentration declines with crop mass accumulation, the N content per unit of leaf area within the upper layer of leaves was more stable and would correlate well with the crop NNI. Then, it would be possible to use the N concentration of the well-illuminated leaf layer as an indicator of crop N status independently of the crop mass. Farrugia et al. (2004), using this correlation, were able to develop a method of diagnostics of grassland N status [59] and of maize crop N status [60]. The leaf N concentration can be measured directly from leaf samplings, but it can also be estimated indirectly by noninvasive methods. The leaf color chart (LCC) is an easy-to-use and inexpensive diagnostic tool for monitoring the relative greenness of a rice leaf as an indicator of the leaf and then of the plant N status [61]. The estimation of chlorophyll content of leaves by portable systems based on leaf transmittance or leaf reflectance in specific wave bands is also well correlated with leaf N content, and can be a method for crop N status diagnosis [62, 63]. But these predictions are in general dependant on cultivars and years [64]. Houlès et al. [65] demonstrated that through remote sensing it was possible to estimate both crop LAI and the quantity of chlorophyll per unit of soil area, and then the quantity of N within the canopy per unit of soil area. Therefore it would be possible to recalculate the NNI of the crop. Such an estimate can be intensively repeated in space and time that allows very precise information on the spatiotemporal dynamics of crop N status that is very useful for precision agriculture.

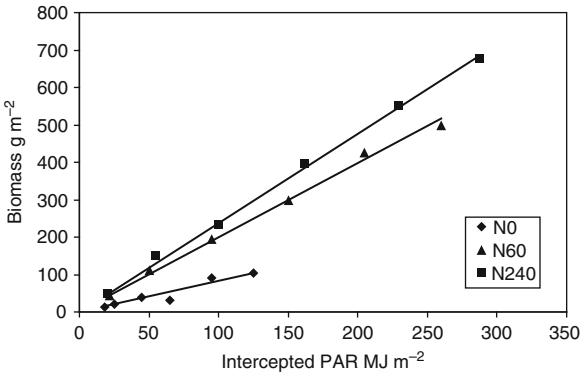
Crop Responses to N Deficiency

The use of the concept of critical crop N concentration and the possibility for diagnosis of the actual crop N status totally reversed the approach of the response of crop to N fertilizers. The response of crop to N was studied by analyzing the response curve of yield to increasing fertilizer rates.

The difficulty for such an approach is that (i) the actual N supply for the crop is not known, because the

quantity of N provided directly by the soil, and then the yield in absence of any fertilization is very variable, and (ii) the potential yield, i.e., the yield achievable in a given climatic condition when N supply can be considered as non-limiting is unknown. So, the crop N demand and the total crop N supply are unknown variables and it is possible to get only the regression between increment in yield and increments in N fertilization rates. This approach led to provide huge families of crop response curves to N fertilizers very variable to each other according to soils, climates, years, species, and cultivars, and the only way was to analyze this variability with statistic approaches with any possibility to identify and to quantify processes in order to develop prediction models.

The possibility for diagnosis crop N status allowed the identification of situations where crop growth and development were not limited by N deficiency, and then to develop crop potential growth models as resulting from climate conditions. Then using the critical N uptake concept, it was possible to derive from these models the dynamics of crop N demand all along the crop cycle. So instead of having the check treatment with no N fertilizer and to analyze response of crop to increments in N supply, the check treatment is now the crop with critical N status, and then the response of the crop to the occurrence of periods of N nutrition deficiency of different timing and intensity all along the crop growth cycle and the consequences on yield components and quality of the yield can be analyzed.



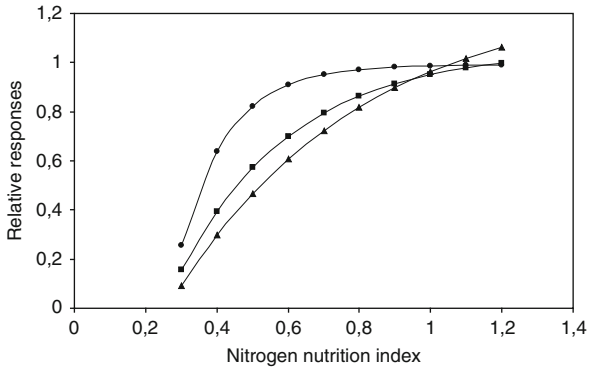
Crop Responses to Nitrogen. Figure 5
Relationships between the quantity of photosynthetic active radiation (*PAR*) intercepted by a tall fescue sward and the accumulation of aboveground biomass for three contrasted N supply rate: N0: no N application; N60: 60 kgN ha^{-1}; N240: 240 kgN ha^{-1}. The slope of the regression represents the radiation use efficiency [67]

N Deficiency Effects on Crop Mass Accumulation

According to Monteith [66], crop mass accumulation is linearly related to the quantity of photosynthetic radiation (PAR) intercepted by a crop during its life cycle. The slope of this regression can be interpreted as the radiation use efficiency (RUE).

As illustrated in Fig. 5, and as shown by Bélanger et al. [67], N deficiency affects both the quantity of PAR intercepted by the crop and the efficiency with which the intercepted radiation is used for biomass elaboration (RUE). These authors, using NNI, have shown that in relative terms, RUE was more affected by moderate N deficiency (NNI = 0.6–0.8) than the quantity of PAR intercepted while for more severe deficiency, the response of the two variables converged. This type of response has been confirmed on sunflower [68] and on sorghum and maize [69]. LAI expansion seems a little bit more responsive to N deficiency than RUE: for an NNI of 0.6, RUE was reduced by 30% while LAI was reduced by 40% (Fig. 6).

RUE is an integrated variable accounting for photosynthesis and respiration, but also the allocation of assimilates to root [70]. These authors showed that, in fact, canopy gross photosynthesis was less affected by N deficiency than the accumulation of total biomass reflecting higher respiration losses in N-deficient crops, and the accumulation of shoot biomass was more affected than the accumulation of total biomass reflecting then an important increase of allocation of biomass to roots in N deficient situations. The lower shoot/root ratio in N deficient crops is widely documented [71, 72]. In fact this increased allocation of assimilate to roots is the consequence of the lower activity of shoot meristems (leaf and stem extension) that allows a greater quantity of carbon to be used for root growth. So the more sensible plant growth process to N deficiency appears to be the leaf area expansion rate, with two major consequences: (i) a reduction



Crop Responses to Nitrogen. Figure 6
Effects of crop N status determined by the nitrogen nutrition index (*NNI*) of tall fescue swards receiving different N application rates and (i) the relative quantity of intercepted PAR, PAR_{act}/PAR_{max} (●), (ii) the relative Radiation Use Efficiency, RUE_{act}/RUE_{max} (■), and the relative LAI, LAI_{act}/LAI_{max} (▲). (Redrawn from [67])

in the dynamic of light interception and then in the canopy photosynthesis and crop C supply and (ii) a preferential allocation of C for root growth that contributes to increase root foraging activity for a further increase in N uptake capacity.

The response of leaf area of plants and canopies to N deficiency is brought about by a decline in the expansion rate and size of individual leaves combined with reduction of branching or tillering. The accumulation of nonstructural carbohydrates in N-deficient leaves indicates that C supply is not the cause of the leaf area expansion under N deficiency [38].

N deficiency decrease the rates of cell division and cell expansion with little effect on final cell length [26], so the reduction of leaf size in N-deficient plants is mainly due to a reduction in cell number. Gastal et al. [73] proposed a quantitative relationship between the leaf elongation rate (LER) of tall fescue and the NNI of the sward:

$$\frac{LER_{actual}}{LER_{critical}} = 1.39 - 1.9e^{-1.49NNI} \qquad (16)$$

Subscript "actual" corresponds to any suboptimal N condition, and subscript "critical" refers to a non-limiting N nutrition. For a severe limitation in N nutrition, NNI = 0.4, LER is then reduced to about 30% of its maximum value in non-limiting conditions. That demonstrates the high responsiveness of leaf expansion to N deficiency.

Lemaire et al. [24] used the relationship between LAI and crop mass (W) of Eq. 10 for studying the different types of response of crop species to N deficiency. This approach allows the separation of the reduction of LAI being directly associated with the reduction in crop mass (i.e., simply a crop size effect) from any specific reduction of LAI at similar crop mass (i.e., a modification of plant architecture through a reduction of leaf area ratio. They demonstrated that under a similar intensity of N deficiency as estimated through NNI, the reduction of LAI of maize is totally allometrically related to its reduction in crop mass (crop size effect), while for wheat N deficiency provokes in supplement a reduction of LAI at same crop mass, i.e., a reduction in LAR. These two types of responses represented two extremes and tall fescue behaves like maize while canola behaves like wheat; sorghum and sunflower having intermediate responses [24]. Hence classification of crops in either metabolic (C_3 vs C_4) or botanical (monocots vs dicots) groups does not correspond to any particular response type. In response to N deficiency, some species such as maize or tall fescue tend to maximize light interception by minimizing the reduction in LAI, at the expanse of N concentration per unit leaf area, and then leaf photosynthesis, while other species such as wheat and canola tend to develop an inverse response. Do these two opposite strategies mean that there exists a trade-off between photosynthesis per unit of LAI and leaf area expansion as already proposed by Sinclair and Horie [74]?

N Deficiency Effects on Leaf and Canopy Photosynthesis

The response of leaf photosynthesis to irradiance largely depends on the leaf N content. Leaf photosynthesis at saturating light intensity (A_{max}) increases asymptotically with leaf N content [75]. This relationship shows a positive intercept on the leaf N content axis, indicating that when leaf photosynthesis rate becomes zero, leaves would still contain significant amount of N, corresponding the structural leaf

N (N_s) of Eq. 8. The variation in the A_{max}/SLN (leaf N content per unit leaf area) relationship seems relatively limited among cultivated species of the same metabolic group [10, 76], despite Sinclair and Horie [74] showed a lower A_{max} at similar SLN for soybean. This variation among species could be due to (i) differences in nitrogen costs of PEP-carboxylase and RuBPc-o and the relative amounts of these two enzymes in leaves, and/or (ii) the possible accumulation of vegetative storage proteins within leaves of legume species such as soybean.

There is a large discussion whether A_{max} has to be related to either leaf N content per unit mass or per unit leaf area [75]. Lemaire and Gastal [32] indicated that none of these two relationships are completely right. The two components of photosynthesis, light harvesting by chlorophyll and CO_2 reduction by RuBPc-o, are affected by leaf N status, and these two processes have to be expressed on a leaf tissue volume basis, and not only on an area basis. Then leaf thickness is an important parameter to take into account. Specific leaf area (SLA) is the parameter allowing correspondence between leaf N content per unit area and per unit dry matter basis. But relationship between leaf thickness and SLA is weak because of the variations of nonstructural carbohydrate content within leaves.

The quantum efficiency that is the response of leaf photosynthesis to light at low irradiance is only little affected by N deficiency [77, 78]. Moreover, the dark respiration of leaves seems to increase with increasing leaf N [78]. Hence, as the leaves are progressively shaded within the canopy the effect of N deficiency on leaf net photosynthesis becomes lower and lower and then negligible.

Gastal and Bélanger [77] showed that canopy gross photosynthesis of a tall fescue sward at high irradiance (CGP_{max}) only responds smoothly to N deficiency: a reduction in NNI from 1 to 0.4 reduced the relative CGP_{max} from 1 to 0.6 only. This low responsiveness of canopy photosynthesis to N deficiency is due to the fact that as canopy develops, a greater number of leaves are shaded and then their photosynthesis does not respond to N shortage. When irradiance becomes more limited, the responsiveness of canopy photosynthesis to N deficiency becomes more limited. So when canopy photosynthesis is integrated over day and for a long period where crop LAI is high, the response of canopy photosynthesis to N deficiency appears relatively limited, which explains the limited influence of N deficiency on RUE.

N deficiency Effects on Harvest Index and Components of Grain Yield

For grain crops, yield is closely related to grain number per unit area of soil. The elaboration of grains depends on flows of C and N compounds to reproductive meristems during a narrow window period around flowering, anthesis, and very initial grain development, and also on environmental conditions (temperature, radiation, and water stress) during this period. This critical period coincides with the maximum rate of crop N uptake [79]. So any limitation of crop growth rate at this period by N deficiency decreases grain number and then grain yield on cereals such as maize [28], wheat [29, 80]. Jeuffroy and Bouchard [57] established for wheat a relationship between grain number and the severity and duration of the N deficiency before anthesis as calculated by NNI method. The effect of N deficiency on grain number is the consequence of two simultaneous effects: (i) a lower crop growth rate at anthesis restricting C supply to spikelets and then a spikelet abortion [81]; and (ii) a decrease in the N content in the spike stems [29] corresponding to a direct effect of N deficiency on floret fertility.

The other grain yield component, grain weight, is generally less affected by N deficiency at anthesis than the grain number [47]. However, it is necessary to take into account the negative correlation between grain weight and grain number: a reduced grain number resulting from pre-anthesis N deficiency can lead to a more favorable source:sink ration during grain filling period and then to an unaffected grain weight. Grain filling in both carbohydrates and proteins depends on (i) the recycling of C and N compounds previously accumulated within vegetative organs during pre-anthesis growth period, and (ii) post-anthesis photosynthesis and N absorption. The relative importance of these two components depends on plant species and their capacities to store C and N compounds in their vegetative organs. So some species such as wheat or rice are able to develop large LAI [7–9] and then to store large quantities of N, then they are able to feed 80–90%

of the N demand for grain development by recycling N stored within vegetative biomass, while other species such as maize, because they develop less LAI [4, 5] with lower N content because they have C_4 metabolism, are obliged to feed 40–60% of their grain N demand through post-anthesis N absorption. As a consequence, crop species like maize are more susceptible to terminal soil N shortage than crop species like wheat or rice.

Delaying leaf senescence for species like maize or sorghum should allow these species to continue to maintain high N absorption rate after anthesis. The supplement of carbohydrates allocated to roots permitted by this delayed leaf senescence allows the maintenance of root absorption capacity [82]. So using stay-green genotypes in low N supply conditions seems to be beneficial for both sorghum [83] and maize [84].

Nitrogen Use Efficiency in Crops

From an agronomic point of view, nitrogen use efficiency (NUE) of a crop represents its capacity to produce a supplement of yield (dY) for each added unit of N fertilizer (dNf) that corresponds to the derivative of the crop yield response curve to the rate of N supply: $Y = f(Nf)$. As this response curve is asymptotic, NUE generally declines with the higher rate of N supply, indicating that the first N unit applied is more efficiently converted into yield than later applications. According to the crop species types, Y can represent either the aboveground biomass, as for forage crops, or the grain part as for cereals, grain legumes, or oil seed crops.

Such a global approach does not allow a clear mechanistic analysis of the physiological traits controlling NUE between different species and cultivars because crops respond to total N supply (Nt) that include fertilizer supply (Nf) and soil N mineralization (Ns). So according to variations in Ns due both to soil and climatic conditions and to previous crop management, different value of Nt can be obtained with the same Nf, leading to large differences in NUE. For this reason, Moll et al. [85] propose to define NUE as the yield produced per unit of N available in the soil, considering two components:

1. The Nitrogen Absorption Efficiency (NAE) which measures the ability of a crop to uptake N from soil
2. The nitrogen conversion efficiency (NCE) which measures the ability of a crop to use absorbed N for dry matter and grain production

$$\mathrm{NUE} = (\mathrm{NAE})(\mathrm{NCE}) \tag{17}$$

Nitrogen Absorption Efficiency

Genotypic differences in N uptake at different levels of N supply have been shown in rice [86], wheat [87], and maize [88]. Modern cultivars have a higher N uptake capacity because they have a higher biomass production. This effect is accounted by Eq. (x) as it shows that the crop N uptake rate increases with crop growth rate. So any factor enhancing the potential crop growth rate, genotype or environment, increase de facto the N uptake capacity of the crop. More interesting from a plant breeding point of view would be to increase the N uptake capacity of crop at similar crop biomass production. Lemaire and Gastal [32] reported data comparing N uptake of tall fescue and cocksfoot swards at similar biomass. These data show that cocksfoot had a higher N uptake capacity than tall fescue under a sub-limiting N supply condition, while the two species had similar N uptake capacity under non-limiting N supply. Similarly, Lemaire et al. [89] showed that grain sorghum had a higher N uptake capacity than maize under limiting N supply, while the two species had similar N uptake under non-limiting N supply.

The fact that N uptake capacity and then nitrogen absorption efficiency (NAE) does not vary too much among crop species is due to the fact that the critical N uptake curve, as described by Eq. 2 is not very different among species of the same metabolic group (C_3 vs C_4). Then differences between crop species in NAE under non-limiting N supply conditions would reflect their differences in their potential biomass accumulation according to their respective metabolic group. Under limiting N supply conditions, clear differences emerge among species. As for cocksfoot vs tall fescue, sorghum appears to have a greater root length density than maize. This would confer these species a better capacity of interception of soil mineral N. Soil N recovery that determines NAE is the result of the nitrogen balance between crop N uptake rate, immobilization by soil microbial communities and losses through leaching, denitrification, and

volatilization [90]. Root architecture and biochemical composition, and perhaps root exudates could play an important role in this balance, and then on NAE. So because of a permanent turnover of N in soil, plants having a dense root system are able to compete more efficiently against microbes for capturing mineral N when the principal source of N is the mineralization of organic matter, i.e., in limiting N supply conditions. In non-limiting N supply conditions, there is ample mineral N in soil, the immobilization capacity of microbial community is saturated and then the differences among species tend to disappear. Only the difference in N uptake capacity linked to difference in crop growth capacity can then be observed.

Some coincidences between quantitative trait loci (QTL) for root architecture and NAE have been detected on wheat [91]. A large genotypic variability has been identified across maize lines for the density and length of lateral roots [92], suggesting that it would be possible to breed this species for improving its NAE under low N supply conditions. Similarly, genetic studies showed that NAE was the most important component of the Nitrogen use Efficiency in rice [93] and wheat [87].

Nitrogen Conversion Efficiency

The efficiency of conversion of absorbed N by crop into yield has to be analyzed at two levels:

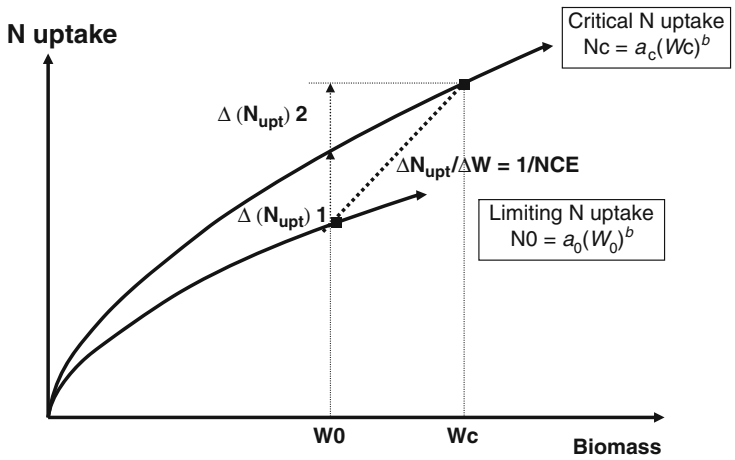
- The efficiency for crop biomass production (W), i.e., the supplement of biomass (dW) associated to the supplement of N uptake (dN) when N supply increases
- The harvest index HI, i.e., the proportion of crop mass allocated to grain

Figure 7 allows a more detailed analysis of the NCE for crop mass production. This figure represents two N uptake vs crop mass (W) trajectories for crops at two level of N supply: a limiting N supply rate and a non-limiting one corresponding to critical N status. At each date the slope of the line joining data points corresponding to the two N supply rates is equal to $\Delta N_{upt}/\Delta W$ which is the reciprocal of NCE. The supplement of nitrogen taken up by the crop, ΔN_{upt}, due to the increase in N supply rate, can be defined as the sum of two components (i) $(\Delta N_{upt})_1$, the quantity of N the limiting N supply treatment should have been absorb in supplement for reaching the corresponding critical level, and (ii) $(\Delta N_{upt})_2$, the supplemental increase in N uptake associated to the accelerated growth rate resulting to the higher N supply level. The NCE of $(\Delta N_{upt})_1$ is 0 as the increment in N uptake is made at a constant crop mass. The NCE of $(\Delta N_{upt})_2$ is not constant and can be approached only for a given crop mass by the derivative of Eq. 3:

$$\frac{dN_{upt}}{dW} = ab(W)^{b-1} \tag{18}$$

This equation indicates that the efficiency of conversion of N absorbed into crop mass dW/dN_{upt} increases as crop mass increases. Such an analysis allows the identification of two different sources of variation for NCE: (i) when W is increased only by other factors than N supply, climate and/or genotype, then NCE increases with crop mass, and (ii) when W is increased by N supply, then NCE is lowered by the cost in N uptake for restoring the plant N status. This approach allows the study of NCE as a dynamic process where the time has to be explicitly taken into account through crop growth rate: the higher crop growth rate, the higher NCE of the crop. Then it allows the identification of the trivial effect of plant mass per se: a small crop, either because genetically small or because of unfavorable environmental conditions will have a lower NCE as compared to a bigger crop. This reason explains why a good correlation is observed between genotypes growing either in high or low N supply conditions [88]. In consequence, breeding for a high NCE must lead to the selection of genotypes to higher growth potential. There is no clear indication until now if NCE variation among genotypes would persist when comparisons are made at same crop mass. Since coefficients a and b of Eq. 2 differ little or not at all between species within C_3 or C_4 groups, the chances to find intraspecific differences in NCE when comparing plants having a similar growth potential remains very limited.

When considering yield (Y) and not only crop biomass (W), NCE can be highly variable among crop species as resulting to large genotypic variations in



Crop Responses to Nitrogen. Figure 7

Schematic representation of the components of the nitrogen conversion efficiency. The first component $\Delta(N_{upt})1$ corresponds to the quantity of N necessary for crop to reach its critical N status, and its NCE is 0. The second component $\Delta(N_{upt})2$ corresponds to the quantity of N necessary for the synthesis the supplement of biomass ΔW and whose the NCE is $dW/dN = 1/ab(W)^{1-b}$ that increases with crop mass

harvest index (HI). For grain crops as cereals, grain legumes, and oil seed species, HI is an important source of variation in grain yield per unit of N uptake. The repartition of N between the harvested and non-harvested plant parts that is the nitrogen harvested index (NHI) is then an important aspect of the grain nutritional quality [95]. Grain produced per unit of N uptake and grain N concentration are in general inversely related [96], and a variable proportion of the variation in yield per unit N uptake is accounted for by grain protein concentration or by NHI, according to crop type.

Grain protein N concentration is the result of two concomitant processes: (i) the rate of accumulation of proteins during grain filling and (ii) the rate of accumulation of free-N compounds (carbohydrates) within grains that lead to a dilution of N as grains develop. So a low grain N concentration can result in both a N deficiency during grain filling period and a large accumulation rate of starch. Thus, late application of N fertilizer to avoid any N shortage during grain filling can lead to an increase of the grain protein concentration. But as the capacity of roots for N absorption at this stage of the crop is largely impaired by the beginning of leaf senescence and the shortage of C allocated to roots, the recovery of this N application is low, and then, large mineral N residues in soil increase the risk for subsequent N leaching.

Conclusion

Since soil N availability, N uptake and distribution within plant and crop and finally crop growth are permanently interrelated during crop development and growth, the traditional view where crop N uptake was totally regulated by soil N supply must be reconsidered and replaced by a more dynamic approach where plant N uptake rate at any moment is co-regulated by both soil N supply and plant growth capacity itself. This co-regulation lead to the concept of critical plant N concentration and N dilution that link plant and crop N status to plant and crop mass. Such an approach allows the determination of the dynamics of plant N demand and plant N status all along their life-cycle. Critical N-curves are now available for most of the crop species growing either in temperate or tropical conditions. This allows the determination of the nitrogen nutrition index of any crop in any condition for diagnosis of its actual N status and estimating the necessity for applying N fertilizers.By this way, it would be possible

now to adjust more precisely the quantity and the timing of N fertilizer supply for matching the crop N demand according to target yields. As a consequence, a reduction of the risk for N losses to atmosphere and hydrosphere should be obtained while the crop productivity would be maintained.

One other perspective is to improve the efficiency of use of N within agro-systems. It appears that improving the ability of crops to absorb and accumulate N efficiently from soil (nitrogen absorption efficiency) is the first objective for high nitrogen use efficiency in cropping systems. This ability of plants and crops to take up mineral N from soil has to be investigated both at high or low N supply conditions. As demonstrated above, in both conditions, N uptake capacity of a crop is directly dependent upon its growth capacity as determined by (i) its own genetic potential, (ii) environmental conditions such as soil and climate, (iii) cropping management techniques, and (iv) interactions between these variables. So any improvement in crop growth capacity by both breeding cultivars and crop management (irrigation, P, K, S fertilization, planting density) will increase NAE of the crop and then will reduce the risk of accumulation of soil N mineral surplus with environmental hazards. But more important would be to improve NAE of crop species at similar crop growth potential. This would allow achieving a given target yield with less N fertilizer. Such an objective requires a more efficient root system to increase the competitive ability of the plant for using soil mineral N against microbial communities. This objective could be reached through a combination of plant breeding strategy and crop management techniques such as soil tillage and soil structure conservation.

Future Directions

The improvement of the ability of plants and crops to absorb and accumulate N efficiently from soil, that is measured by NAE, appears to be the first objective for a plant breeding strategy. As demonstrated above, the N uptake capacity of a crop primarily depends on its growth potential under given climatic conditions. So adaptation of genotypes for fast growth potential is the first way for improving its N uptake capacity. However, it should be also possible to increase the plant N uptake capacity at similar growth potential. By this way, it could be possible to increase the quantity of N a crop is able to uptake from soil in low N supply conditions and then to reduce the quantity of N fertilizers necessary to obtain a given target yield. Under low N supply conditions, root development and architecture as well as the interactions with rhizosphere through root exudates may be of major importance for the determination of the N uptake capacity of crops. Under high N supply conditions, it is the down regulation of root absorption capacities by shoot signals which determine the crop N uptake capacity. So for breeding genotypes with higher N uptake capacities both in low and in high N supply conditions, it is necessary to analyze more deeply all the regulation processes of N absorption at physiological and molecular levels. This kind of approach should be one of the major tasks in the next decade. The development of large-scale genomic, proteomic, and metabolomic studies is necessary for such an objective. However, the difficulty will be to integrate the huge amount of data generated by these studies. All elementary processes studied at cellular or molecular level have to be scaled up to the level of whole plant and crop where they are agronomically relevant. The nitrogen nutrition of crops and its efficiency for yield production is controlled by elementary physiological processes such as nitrate or ammonium transport through cell membranes in roots, nitrate reduction, ammonium assimilation, and protein synthesis. Each of these metabolic processes is regulated at molecular level, and then is susceptible to have more or less genetic variability. But when all processes are scaled up to whole plant or crop level, a large part of this elementary variability is buffered because of existing trade-off among elementary processes and feedback mechanisms. Quantitative genetics using both mutants and genetic engineering appears to be one of the most promising tools to allow the identification of key regulatory genes that are likely to control a variety of physiological and developmental processes involved in the determination of crop nitrogen absorption efficiency. But this approach must be always accompanied by a modeling approach in order to analyze all the feedback and trade-off at whole plant and crop level.

Breeding plants to increase nitrogen conversion efficiency for aboveground dry matter production appears to be more difficult because, apart from the difference between C_4 and C_3 groups, no clear

interspecific differences are observed among cultivated crops. So it seems that intraspecific variability should be very low. However, if the N efficiency for grain yield is considered, it should be possible to detect inter- and intraspecific differences. Detailed analysis of grain development and grain-filling processes should provide information about the genetic variability. The development of models describing both N partitioning and translocation within plant, and dynamics of grain development, taking into account the coupling between N and C fluxes between plant organs are necessary for detecting the key regulation processes for optimizing grain yield and quality. This approach will require a cooperative and integrated effort between plant molecular physiologists, geneticists, crop physiologists, and agronomists and the intensive use of bioinformatics.

Article Outline

Population growth in the coming decades will put severe pressure on human food, animal feed, and fiber production. Bioenergy applications are already exerting increasing pressure on agricultural commodities and land use with severe economic consequences, particularly in the developing world. Any crop productivity increases must come necessarily from enhancing crop performance as further land expansion for agriculture is unlikely to take place. Environmental sustainability and social justice issues are becoming increasingly key elements in debates on how to assure adequate food for the ever-increasing global population. It is likely that the efficiency of increasing productivity would benefit by complementing the conventional empirical approaches with opportunities presented by the development of new knowledge and technologies in the field of Crop Science. Therefore, in this section a number of seminal articles by world experts in the field are featured. Through this collection of articles key advances in the field are highlighted and the reader is pointed to future directions in terms of opportunities and constraints for a more productive and sustainable agriculture. This is not meant to be an exhaustive list of topics; rather the aim is to highlight particular technologies and topics that have a real potential to make a substantial contribution to a more productive and environmentally friendlier agriculture in the short to medium term. This section comprises 45 articles that can be divided into two parts: (a) molecular approaches and (b) crop physiology and agronomy.

Transgenic Crops and Molecular Breeding

World food and feed security are increasingly dependent on continuous crop improvement and in particular the development of crops with increased resistance to abiotic stresses (► Abiotic Stress Tolerant Crops: Genes, Pathways and Bottlenecks). Plants unlike animals are not mobile, consequently they need to develop strategies to combat natural enemies such as herbivores and environmental stresses. Drought, salinity, submergence, and temperature stresses amongst others are all important abiotic constraints which limit crop yields. Significant advances in our understanding of molecular mechanisms underpinning a plant's ability to combat abiotic stresses has resulted in the creation of transgenic plants with improved resistance to such stresses.

Sustainable, renewable resources are those derived from biological sources, primarily plant biomass which can be regenerated with minimal inputs using energy from the sun (► Biomass Crops for Biofuels and Bio-based Products). Biomass for biofuels includes many sources of material derived from agricultural harvests including grains, agricultural residues such as stalks and leaves, perennial crops such as hay and trees, animal manures, building waste wood, municipal solid waste such as paper, and various food industry wastes. Humans currently consume at least 25% more raw materials every year than are replaced through biological growth. In order to sustain quality of life and maintain adequate environmental resources, those resources must be balanced and renewable. Pressure on those resources has never been greater with the world population currently at seven billion people, and estimated to plateau at 10.5 billion by 2050.

Once a gene is introduced into a plant its expression may be controlled by a number of different factors (► Transgene Expression in Plants, Control of). Among these, promoters are most important as they regulate expression temporally and spatially. Transcriptional fusions of genes, with the Cauliflower Mosaic Virus 35S promoter when integrated into the plant genome (mostly dicotyledonous plants), result in

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

transgenic plants with high and constitutive expression of the transgene. However, 35S-driven transgene expression is very variable with ca: 20% of the transformants exhibiting high expression levels, while the majority (ca: 80%) display an intermediate or low and unstable transgene expression. The possible causes of variation in transgene expression in a population of transgenic plants need to be identified and addressed in order to generate useful plants with stable and predictable levels of expression of introduced transgenes.

Plant transformation is a fundamental component of both basic and applied plant biology (► Crop Plants Transformation Methods). For basic research, transformation allows scientists to study how genes function and allows the study of both endogenous genes and transgenes. This has increased our understanding of how plants grow, develop, and defend themselves against pests, diseases, and harsh environments; how photosynthesis is controlled; and the basis of primary and secondary metabolism. For applied research, transformation can be used to improve the agronomic performance of crops, making them hardier, more nutritious, more productive, or converting them from conventional crops into green factories producing chemical precursors, novel oils, industrial enzymes, and pharmaceuticals. Plants have been cultivated for food and animal feed, fibers and structural materials, and small molecules that can be used as dyes, scents, and medicines since the dawn of history, and for the same length of time people have sought to improve plants by breeding them and selecting the better-performing and most useful varieties. The limitations of this approach, that is, the fact that breeders are restricted to the existing gene pool in each group of sexually compatible species, and that breeding takes a long time to achieve its goals, can be overcome by plant transformation, thus accelerating the development of plants with novel, beneficial traits. Plant transformation includes both the uptake of naked DNA (direct DNA transfer) and the transfer of DNA by the conjugation-like method adopted by *Agrobacterium tumefaciens* and *A. rhizogenes* (*Agrobacterium*-mediated transformation).

Genetics, molecular biology, genomics, and other disciplines have now provided us with an insight to the genes that encode important crop traits on which humans now depend. Knowledge of the molecular genetic basis of valuable crop traits will help provide solutions to our requirements for sustainable existence, faced with a growing global population and diminishing natural resources (► Crop Traits: Gene Isolation). Isolated genes encoding useful traits and their use in plant transformation experiments allow the development of an in-depth understanding of the mechanisms that control such important crop traits. Thus, through such investigations that utilize isolated genes, one is able to understand and harness traits involved in plant domestication such as plant architecture, to those offering solutions for high crop production purposes such as growth under unfavorable environments or disease outbreaks. Cloning or identification of the genes involved in crop traits provide an insight into factors which determine gene–trait relationships. Understanding the molecular basis of crop traits provides a route to their controlled modulation ultimately leading to the development and implementation of novel genetic engineering solutions to create plants with superior and sustainable characteristics.

Conventional plant breeding practices alone will not be able to achieve sustainability in today's agriculture. Advances in plant genomics research are opening up a new era in plant breeding where the linkage of genes to specific traits will lead to more efficient and predictable breeding programs (► Crop Breeding for Sustainable Agriculture, Genomics Interventions in). Plant genomics is a rapidly developing field, which is radically improving our understanding of plant biology by making available novel tools for the improvement of plant properties relevant to sustainable agricultural production. Recent advances in high throughput genomics technologies including next generation sequencing and high-throughput genotyping have helped immensely in understanding the functions and regulation of genes in crop plants. The ever-increasing availability of genome sequences in crop plants has facilitated greatly the development of genomic resources that will allow us to address biological functions and a number of basic processes relevant to crop production leading to sustainable agriculture. It is therefore expected that genomics will be an integral part of the agricultural/plant breeding practices of the future for improving crop productivity to achieve food security and sustainable production.

Plants have been used as sources of small molecular weight compounds (secondary metabolites) with applications as medicines, flavors, and fragrances for millennia. However, many plants containing such high-value secondary metabolites are difficult to cultivate or are becoming endangered because of overharvesting. In addition, the chemical synthesis of plant-derived compounds is often uneconomical due to their highly complex structures. The biotechnological production of valuable secondary metabolites is an attractive alternative to the extraction of whole plant material (► Medicinal Plants, Engineering of Secondary Metabolites in Cell Cultures). Functional genomics may open entirely new avenues to screen unexplored medicinal plant species for their pharmacological value.

Molecular breeding (MB) allows the stacking of favorable alleles, or genomic regions, for target traits in a desired genetic background, thanks to the use of polymorphic molecular markers (MM) that monitor differences in genomic composition among cultivars, or genotypes, at specific genomic regions, or genes, involved in the expression of those target traits (► Molecular Breeding Platforms in World Agriculture). The use of MM generally increases the genetic gain per crop cycle compared to selection based on plant phenotyping only, and therefore reduces the number of needed selection cycles, hastening the delivery of improved crop varieties to the farmer. In contrast to the private sector, MB adoption is still limited in the public sector, and is hardly used at all in developing countries. The situation is critical in developing countries due to resource-limited breeding programs. As a result, the developing world has yet to benefit from the MB revolution, and most countries indeed lack the fundamental prerequisites for a move to informatics powered breeding. A sustainable web-based Molecular Breeding Platform (MBP) as a one-stop-shop for information, analytical tools and related services to help design and conduct marker-assisted breeding experiments in the most efficient way will alleviate many of these bottlenecks in the developing world. Such a platform will enable breeding programs in the public and private sectors in developing countries to accelerate variety development using marker technologies for different breeding objectives.

With the advent of molecular techniques, plants have the potential to serve as production vehicles for natural or engineered products that were previously limited to other hosts. Plant molecular pharming of industrial proteins refers to recombinant proteins used in industrial processes and produced in plants (► Plant Molecular Pharming, Industrial Enzymes). Enormous quantities of a variety of enzymes go into making products such as paper, leather, detergents, pharmaceuticals, food, beverages, chemicals, and fabric, to name a few, and economical production of these industrially important enzymes is crucial to commerce. This production must be balanced with the need for sustainability and environmental stewardship. Sustainable production of industrial enzymes requires that resources are not overexploited and wastes are not polluting. The use of plants as "green" factories can meet both criteria. Combined with modern farming and containment methods, transgenic plants have the potential to produce large quantities of target material safely and sustainably.

The demand for recombinant medical proteins has increased in recent years and modern biotechnological methods have, until recently, ensured the production of safe and effective biopharmaceuticals to meet this demand. Various production platforms are currently used in the pharmaceutical industry, most based on the fermentation of engineered pro- and eukaryotic microorganisms, insect cells, or mammalian cells (► Plant Molecular Pharming, Pharmaceuticals for Human Health). The growth of the market for biopharmaceuticals is predicted to outpace production capacity using these platforms in the next decade, so alternatives are necessary. The production of pharmaceutical proteins in plants began with a monoclonal antibody expressed in transgenic tobacco plants more than 20 years ago. Since then many different plant species have been genetically engineered to produce valuable pharmaceutical proteins. Major progress has been achieved in transformation and expression technology, downstream processing of transgenic plant material, and the adaptation of regulatory procedures to encompass the new production platforms, allowing the first plant-made pharmaceuticals to begin clinical trials.

Since the successful expression of complete antibodies in transgenic plants and the first report of plant-based vaccine production in 1992 a large number of different vaccines, antibodies, as well as antibody fragments have been produced in plants for medical

or veterinary purposes (► Plant Molecular Pharming, Veterinary Applications). Novel processing methods have been developed over the past several years to facilitate the development of recombinant proteins for veterinary applications.

Humankind has had an ever-increasing impact on the environment. With the increasing intensification of agriculture, particularly during the twentieth century, this impact has become even more pronounced, often with undesirable or unacceptable consequences, including water pollution, soil erosion, and loss of habitat, often accompanied by a loss of biodiversity (► Transgenic Crops, Environmental Impact). Pests, particularly weedy plants, demonstrate a remarkable ability to adapt to agricultural production systems. The practice of growing monocultures, typically used in intensive agriculture, increases the number of pests; these are currently predominantly controlled through use of pesticides. However, with increasing exposure to pesticides many pest populations are evolving resistance to these compounds. An additional problem encountered with many pesticides, and particularly insecticides, are their nontarget effects on beneficial insects. Transgenic crops expressing genes conferring resistance to insect pests and/or herbicides are becoming increasingly more widely grown and have the potential to eliminate many of the problems in conventional agriculture thus reducing agriculture's negative impact on the environment.

Annual losses worldwide due to plant diseases are estimated to be ~14% of total losses and about $220 billion. In addition, the need for measures to control diseases limits the acreage of land available for cultivation; restricts the crops that can be grown in fields already contaminated with certain pathogens; and necessitates the use of agrochemicals for treating seeds, fumigating soils, spraying plants, and applying postharvest treatments. Such control measures add to the cost of food production and toxic chemicals can be harmful to human health and the environment (► Transgenic Crops Resistant to Fungal, Bacterial and Viral Pathogens). Resistance to pathogens can be achieved by application of disease-suppressing cultural practices, use of plant defense-promoting substances, deployment of biological agents antagonistic to the pathogens that cause disease, agrochemicals, conventional breeding strategies, and genetic engineering. The need for controlling plant diseases effectively is not only a major challenge, but also a necessity to reduce food losses while improving food quality and safeguarding the environment.

Genetic Engineering can increase the nutritional quality of crops by increasing the availability of essential nutrients, which are often limited in human diets and lead to specific deficiency diseases (► Biotechnology and Nutritional Improvement of Crops). Food insecurity is one of the most important social issues faced today, with nearly one billion people enduring chronic hunger and an additional two billion people suffering from nutrient deficiencies, most in the developing world. Strategies to address food insecurity must ultimately address underlying problems such as poverty and poor governance/infrastructure, but the improvement of agricultural productivity in the developing world is an important goal, and biotechnology is one of a raft of measures being considered to achieve it.

The economic impact of transgenic crops has been immense (► Global Economic Impact of Transgenic/Biotech Crops (1996–2008)). This has been a major driver in their rates of adoption amongst farmers in the USA and other industrialized countries but perhaps more importantly by small holders in the developing world. Analysis on farm income effects through extensive analysis of existing farm level impact data for biotech crops confirms this to be a major reason for their broad adoption worldwide.

Biotechnology offers efficient and cost-effective means to produce a diverse array of novel, value-added products and tools. The first generation of commercialized biotechnology products were crops focusing largely on input agronomic traits whose value was often opaque to consumers. The coming generations of crop plants can be grouped into broad areas each presenting what, on the surface, may appear as unique challenges and opportunities (► Transgenic Crops, Next Generation). The present and future focus is on continuing improvement of agronomic traits such as yield and abiotic stress resistance in addition to the biotic stress tolerance of the present generation, crop plants as biomass feedstocks for biofuels and "bio-synthetics," value-added output traits such as improved nutrition and food functionality, and plants as production factories for therapeutics and industrial products. From a consumer perspective,

the focus on value added traits, especially improved nutrition, is undoubtedly one of the areas of greatest interest.

The rapid development and deployment of modern biotechnology in the last decades has made biosafety a major issue. Although modern biotechnology can benefit agricultural productivity in developing countries transgenic crops remain an issue with regard to the conservation and sustainable use of biodiversity, as well as to human health. The perceived risks, which relate to the release of transgenic crops into the environment as well as the placement of genetically engineered crops onto the market, have as much to do with social values as scientific concerns. Regulatory frameworks for transgenic crops and the underpinning legislative frameworks have been or are being developed worldwide (► Commercialisation of GM Crops: Comparison of Regulatory Frameworks). These are viewed as essential components for the prudent deployment of transgenic crops worldwide.

The safety measures associated with transgenic crop deployment are embedded in process- or product-based regulatory approaches. The EU regulatory approach is process-based, precautionary, and includes mandatory labeling and traceability requirements for transgenic crops and their derived food and feed products (► Transgenic Crops, Risk Assessment and Regulatory Framework in the European Union). During its development, the EU regulatory system has become increasingly more stringent and unduly onerous. In the EU, the risk analysis consists of three components: risk assessment, risk management, and risk communication. When analyzing potential risks, it is important to bear in mind that the real choice is not between transgenic crops that are inherently risky and traditionally bred ones that are completely safe. The cultivation of existing crops and those with novel traits (including transgenic crops) will have both positive and negative consequences. To fully acknowledge the overall outcome of adopting specific crops, and to assess and manage more effectively the environmental footprint of agriculture as a whole, broader and more balanced legislative oversight is needed in the EU.

A framework for a better communication about science and regulation and production of GM crops is described in ► GM Crop Risk Debate, Science and Socioeconomics.

While transgenic herbicide resistant crops have been a boon to agriculture, reducing both production costs and ecological impacts of farming, weeds have rapidly evolved resistance to the major herbicide used in transgenic crops (glyphosate), rapidly rendering the technology less sustainable than had been thought (► Sustainable Herbicide-Resistant Crops). While no practice in agriculture has been sustainable forever, the period of sustainability can be extended. Methods to extend both the usefulness to crops where needed as well as the sustainability of transgenic herbicide technologies such as rotations of crops and herbicides, increasing the targets of herbicide action, suppressing herbicide targets in rotation, are needed.

Crop Physiology and Agronomy

Seed dormancy is a means of restricting germination to the season when environmental conditions are suitable for plant establishment. From an agricultural perspective, dormancy is a problem (► Seed Dormancy and Agriculture, Physiology). Many important challenges face agriculture in relation to dormancy and these apply to cultivated crops as well as noxious weeds. The physiological mechanisms responsible for the expression of the character are now better understood and molecular information underpinning the process is gradually being generated and incorporated into strategies to solve dormancy-related problems.

One of the first decisions a farmer needs to make is to choose the particular genotype to be grown in the fields based on anticipated or projected economic returns. This is a critical choice that determines the sustainability of the agricultural system (► Genotype by Environment Interaction and Adaptation). Identifying breeding implications on specific adaptive traits and the different statistical approaches for genotype by environment interaction characterization is important.

Attaining global food security by means of increased crop productivity will require an increase in gains from selection achieved through conventional breeding. The identification of molecular markers associated with loci controlling traits of agronomic interest coupled with the exploitation of marker-assisted breeding (MAB) approaches provides the opportunity to accelerate gain from selection (► Marker-Assisted Breeding in Crops). Genomic selection is already having a positive

impact on the improvement of crop yield, mainly in the private sector where high-throughput infrastructures allow breeders to handle the large number of molecular data points that are needed for deploying genomic selection effectively. Ultimately, an effective exploitation of MAB to enhance crop performance will rely on a closer integration between molecular approaches and conventional breeding.

The next generation of highly productive crops in an increasingly variable and changing climate, will rely on genetic interventions based on process understanding, selection of target traits in managed environments, and high-throughput phenotyping and genotyping (► Plant Breeding Under a Changing Climate). Therefore, it is crucial to understand the recent advances in plant breeding for high yield potential environments and also those where abiotic stress is a major limitation to productivity.

Agronomic systems are defined as site-specific management of soils and crops on the basis of eco-regional and physiographic characteristics, and in the context of socioeconomic and policy environments. These systems are strong determinants of agricultural production, sustainable use of resources, and their environmental impact. Agricultural soils and ecosystems can also be used for sequestration of atmospheric CO_2 by enhancing photosynthesis, increasing net primary productivity (► Agronomic Interactions with CO_2 Sequestration).

Crop management comprises a set of agronomic practices such as tillage systems, methods of fertilization, and crop rotations (► Cropping Systems: Shaping Nature). Cropping system may vary among farms depending on availability of resources and particular constraints. The different cropping systems may determine water and nutrient availabilities, carbon cycle, erosion, and the pathogen inoculum in the soil.

Understanding plant development or the progression of plants through their life cycle is important because of the need to know and predict when harvestable products are at their optimum (► Crop Development Related to Temperature and Photoperiod). Current knowledge on how temperature (including vernalization) and photoperiod regulate crop development is of major interest and determines how crops adapt in a wide range of environments. Thus, it is critical to understand the physiology and genetic basis of crop development, and to predict as accurately as possible the timing of key developmental events.

Reduced crop productivity from the theoretical potential maximum commonly occurs because of high temperatures. In addition, air temperatures are predicted to increase during the twenty-first century. Crop physiological and developmental processes are sensitive to temperature so that high temperatures do frequently affect negatively crop productivity (► Sustainable Productivity, Heat Tolerance for). The effects of high temperature, elevated CO_2 and their interaction on crops, are therefore important to understand and subsequently to mitigate potential negative effects of genes that confer heat tolerance.

Since plants are immobile, their distribution greatly influences the ability of a crop to capture and use environmental resources (radiation, water, and nutrients), which are necessary for growth and yield. The spatial arrangement of plants and the temporal development of their structures (mainly leaves and roots) define the ► Spatial Crop Structure in agricultural systems. Density and spatial arrangement of crops may affect intraspecific competition and resource use efficiency, allowing full or partial use of available resources.

The rate of accumulation of dry plant matter is entirely dependent on the interception of energy from the sun in the wavelength range 400–700 nm. This energy is utilized by photosynthesis to synthesize carbohydrates and other biological molecules needed for essential plant processes (► Crop Radiation Capture and Use Efficiency). Given the current emphasis on global food security, there is currently much interest in raising the radiation use efficiency of key crops in important agro-ecosystems.

Scarcity of water resources is an increasingly important issue since it will dictate global production of food and feed for the next generations (► Crop Responses to Available Soil Water). Key factors responsible for sustained plant growth and production under water scarcity, for annual as well as perennial (fruit) crops are of paramount importance.

Irrigated agriculture is currently responsible for over 40% of total production on 17% of all cultivated land area. It is therefore imperative that irrigated agriculture not only sustains its current rates of productivity but also increases (► Irrigation Management for

Efficient Crop Production). Irrigation expansion is currently under pressure from other sectors to reduce its share of the fresh water resources. Efficient crop production under irrigation in the future would be essential to produce more food with less water. This is an immense challenge, not easy to achieve without novel and innovative approaches in irrigation management and crop productivity.

Sustainability of fertilizer use is very important (► Fertilizer Science and Technology), as fertilizers are indispensable because nutrient supplies from the soil are normally inadequate for high-yielding crops and compensate for nutrient removals by previously cultivated crops. In addition, fertilizer may also improve the quality of human food and animal feed.

Nitrogen is the most important limiting factor, after water deficit, for crop production worldwide (► Crop Responses to Nitrogen). Therefore, understanding how the yield of different crops can be improved by addition of nitrogen (N) fertilizers is critical. There are several important issues regarding the dynamics of crop N demands during the crop development cycle, the timing of the soil N supply according to soil characteristics, climate and soil agronomic management, the crop responses to different intensity and timing of N nutrition deficiency, and the time management of crop N fertilization using diagnostic and decision-making tools to optimize trade-offs between minimizing crop yield reduction and minimizing environmental impacts.

A substantial increase in the effectiveness with which available water and nutrients are used is required to ensure food security and environmental protection. An essential component of crop improvement is breeding for deeper or denser root systems. These characteristics promote soil moisture and nutrient capture and high dry matter production in cultivars subjected to water and/or nutrient stresses (► Roots and Uptake of Water and Nutrients). The current understanding of the structure and functions of crop root systems and the avenues for the optimization of root anatomy and morphology traits that could be applied to the genetic and agronomic improvement of crop root systems for more effective below-ground resource capture are thus very important.

Lodging is the process by which the shoots of small grained cereals are permanently displaced from their vertical stance (► Lodging Resistance in Cereals). The reduced lodging risk of shorter varieties enabled them to respond to greater amounts of fertilizers and this was a significant reason for the steady improvement in global cereal grain yields starting in the late 1960s. However, lodging is still a major problem in many countries and there is an urgent need to improve lodging resistance to further increase the yield of cereal species.

Plant growth and yield are severely affected by saline soils. High concentrations of salt in the soil make it difficult for plants to take up water, whilst the accumulated salts in cells, particularly sodium and chloride ions, are toxic to plant metabolism (► Increasing Salinity Tolerance of Crops). These two factors result in a reduction in plant growth, an increase in the rate of leaf senescence, and a loss in crop yield. Crop salinity tolerance can be improved, but a more in-depth understanding of osmotic and ionic stresses is needed.

Agroecology provides the basic ecological principles needed for studying, designing, and managing agroecosystems that are productive, sustainable, and economically viable (► Agroecological Basis for Managing Biotic Constraints). Rather than focusing on one particular component of the agroecosystem, agroecology emphasizes the interrelatedness of all of its components and the complex dynamics of ecological processes including all environmental and human elements. From a management perspective, the agroecological objective is to provide balanced environments, sustained yields, biologically mediated soil fertility, and natural pest regulation through the design of diversified agroecosystems and the use of low-input technologies.

Plant diseases cause substantial crop losses every year (► Crop Diseases, Management and Control of). Controlling plant diseases is therefore vital to maintaining crop productivity. Crop diseases can be controlled using a variety of methods; however, plant pathogens are genetically adaptable and can overcome plant resistance, and the toxic effects of pesticides. Ensuring that crops are adequately protected from diseases depends therefore on being a step ahead of the pathogens by improving existing control measures and developing new approaches.

Increase of crop yields may be achieved by maximizing the proportion of sunlight energy that is fixed

by the crop or by reducing the amount of energy that is lost by insect pests, diseases, and weeds. More than 50% of the potential yield of agricultural crops is lost by the three constraints. ►Integrated Pest Management (IPM) aims to diminish losses caused by insect pests in agriculture, in an economically, ecologically, and sociologically acceptable manner. A major challenge for ecology is the development of a scientific approach to better understand processes in agroecosystems in order to implement more rapidly sustainable IPM systems.

Yield increases will continue to play a dominant role in world food security (►Crop Yields Around the World: Closing the Gap and Raising the Potential). Understanding the gaps between potential and actual yield is of paramount importance in order to increase actual yields. These include several aspects with respect to the natural resource base of the plot (climate, soil type, topography) and long-term management investments.

Grain quality of field crops is related to seed structure and composition. Grain composition is the major reason why only a limited number of plant species are used for food and fiber (►Grain Quality in Oil and Cereal Crops). It is impossible to put forward a unique grain quality definition for any species because this depends on the specific product end use. Therefore, understanding the physiological bases of seed composition and structure is essential to produce grains with a particular quality specification.

Agricultural production takes place under erratic and unpredictable conditions, particularly the availability and timing of radiation and rainfall patterns which are extremely difficult to predict. Their effects are compensated to some extend by the qualities of the land and the interventions of the farmer. Any methodology that would improve the predictability of the availability of resources and their impact on the performance of the production system could in principle improve performance and reduce the level of uncertainty (►Simulation Models as Tools for Crop Management). Crop growth simulation models are viewed as excellent tools for the reduction of this uncertainty. Advantages and limitations of such models need to be understood in the context of past experiences and the current state of the art in order to ascertain their best possible uses.

Crop Traits: Gene Isolation

[2]University of Arkansas, Fayetteville, AR, USA

Article Outline

Glossary

Backcross To cross the progeny of a hybrid to one of its parents, which when repeated for many generations would yield advanced backcross progeny.

cDNA Complementary DNA (cDNA) refers to the DNA copy of RNA transcripts, which can be cloned into vectors to generate a library (collection) of different cDNAs.

Chromosomal recombination Breakage and rejoining of parental homologous chromosomes during meiosis, resulting in the exchange of chromosomal segments.

Cloning vector DNA molecule into which another DNA fragment can be integrated and replicated to produce large quantities of the cloned DNA. Examples are plasmids, lambda phage, cosmids, yeast artificial chromosomes (YACs), and bacterial artificial chromosomes (BACs).

Complementation A method of validating a gene cloning by using wild-type allele to rescue the function of mutant allele through genetic transformation.

Crop trait Any morphological, physiological, or other biological feature measurable at the plant level, present in different forms in different individuals that enable genetic analysis.

Domestication An artificial selection process conducted by humans to produce plants that have more desirable traits than wild plants.

EST Expressed sequence tag is a short subsequence from a transcribed cDNA sequence.

Forward genetics A strategy to identify or clone genes that are responsible for a phenotype of interest.

Gene A gene is an ordered sequence of nucleotides that encodes a specific functional product (i.e., a protein or RNA molecule).

Marker Molecular or genetic marker is a DNA sequence at a known location on a chromosome.

Mutation Changes in a genomic sequence, occurring naturally or artificially, that can either have no effect, alter the product of a gene, or prevent the gene from functioning properly or completely.

NIL Near-isogenic lines (NILs) refers to genotypes or lines that are genetically almost identical except for a small chromosome fragment or DNA sequence by which they differ.

ORF Open reading frame (ORF) refers to a DNA sequence that does not encode a stopcodon and predicted to encode a protein.

PCR Polymerase chain reaction, a method in which DNA is amplified or increased in number of copies, using oligonucleotide primers flanking the DNA sequence and an enzyme that carries out the reaction.

Polyploid Organism that has more than two paired sets of chromosomes that is present in a diploid.

Positional cloning A method of cloning genes based on their position in the genome, using molecular markers in a genetic map located close to the gene and then identifying cloned DNA fragments containing the gene of interest.

Quantitative trait locus A region on the genome associated with a particular phenotype showing continuous and measurable variation such as height or weight.

Reverse genetics A strategy to identify the function of genes revealed by DNA sequencing, by analyzing the phenotypic effects of the gene sequences by mutations or changes in expression.

RFLP Restriction fragment length polymorphism (RFLP) is a molecular marker revealed by differences in restriction fragments between homologous (similar) fragments of DNA.

STS marker A sequence-tagged site (STS) marker is a short DNA sequence at known location in the genome, with nucleotide differences/polymorphisms that make it a useful marker for mapping.

Originally published in
Robert A. Meyers (ed.) Encyclopedia of Sustainability Science and Technology, © 2012, DOI 10.1007/978-1-4419-0851-3

Transposon A piece of DNA that can move within the genome of an organism, and when inserted in genes can cause a mutation.

Definition of the Subject and Its Importance

Crop plants have been selected from their wild ancestors by humans for food, fiber, health, recreation, industry, and other special purposes. Crop breeding has then added on desired traits for convenience in crop production. Genetics, molecular biology, genomics, and other disciplines have now provided us an insight to the genes that encode these very important crop traits on which the human race now depends. Knowledge of the molecular genetic basis of valuable crop traits will help provide solutions to our requirements for sustainable existence, faced with the threats of growing population needs, climate change, and dwindling natural resources. This entry describes the historical and conceptual discoveries underlying the basis of important crop traits, leading from plant domestication such as in plant architecture to those offering solutions for high crop production purposes such as growth under unfavorable environments or disease outbreaks. Detailed descriptions are provided on the cloning or identification of the plant genes involved in crop traits that give an insight on the evidence required for establishing the relationship. In addition, the molecular basis of the crop trait provides an understanding of the biological processes involved, the interaction to other traits, and a framework that can be built on to engineer novel solutions to the future needs from crop plants.

Introduction

The domestication of the major crop plants from around 10,000 to 4,000 years ago resulted in the selection of crops on which humans are now dependent [1]. The crop traits involved in domestication, transformed the wild species to a crop species catered to the needs of this paradigm shift of human civilization to an agricultural lifestyle. These early crop traits that made agriculture possible were selections from wild species that allowed humans to collect grain from the sown crop involving non-shattering, larger grain and fruit, determinate growth with more synchronous harvest, easier accessibility to the grain from protective hard outer coat, and an overall increase in edibility along with a plethora of many specialized traits. The genetic analysis and molecular isolation of key domestication traits is now uncovering the gene, the regulatory processes, and the selective sweeps from the nearest wild ancestors that accompanied the domestication process [2].

Gene cloning and DNA sequencing from the simple bacterial organisms to that of the complex polyploids such as wheat, has enabled researchers to examine gene sequences one at a time and make conclusions on similarity between close and distantly related species, propose functions based on molecular and biological properties. In fact the generation of gene sequences of a multitude of organisms is the fastest growing dataset, which promises to reveal the identity and function of all living forms. Genome sequencing started with model and standard genomes. The model plant *Arabidopsis thaliana*, a common weed, was selected for genome sequencing and molecular genetics analysis [3], with the DNA sequence of a specific ecotype Columbia [4]. Now, the 1001 genomes project intends to finish off high-quality resequencing of Arabidopsis [5] that will provide sequences of genes from the ecotypes adapted to diverse environments, which might reveal the effect of natural selection and adaptation of this very effective weed species. This also opens up a new era of going beyond a "reference" genome sequence of an organism toward sequence-based maps of closely related genotypes, which can provide a more accurate landscape of differences between genes and genomes and the relationships to expressed traits. The power of this technology was demonstrated by revealing the low level of mutations that occur between plants following a few generations of self-fertilization [6].

Gene isolation and cloning in higher plants has now come a long way since the early days of struggling with genome size and complexity. Isolation of mRNA and characterization of translated proteins was one of the primary methods to demonstrate the function of specific nucleic acids as shown for soybean leghemoglobin mRNA [7], which was then proven to be transcribed from the soybean genome [8]. One of the first approaches in plants to characterize the different components of a plant cell in terms of the complexity of nuclear and polysomal RNA, was using tobacco an

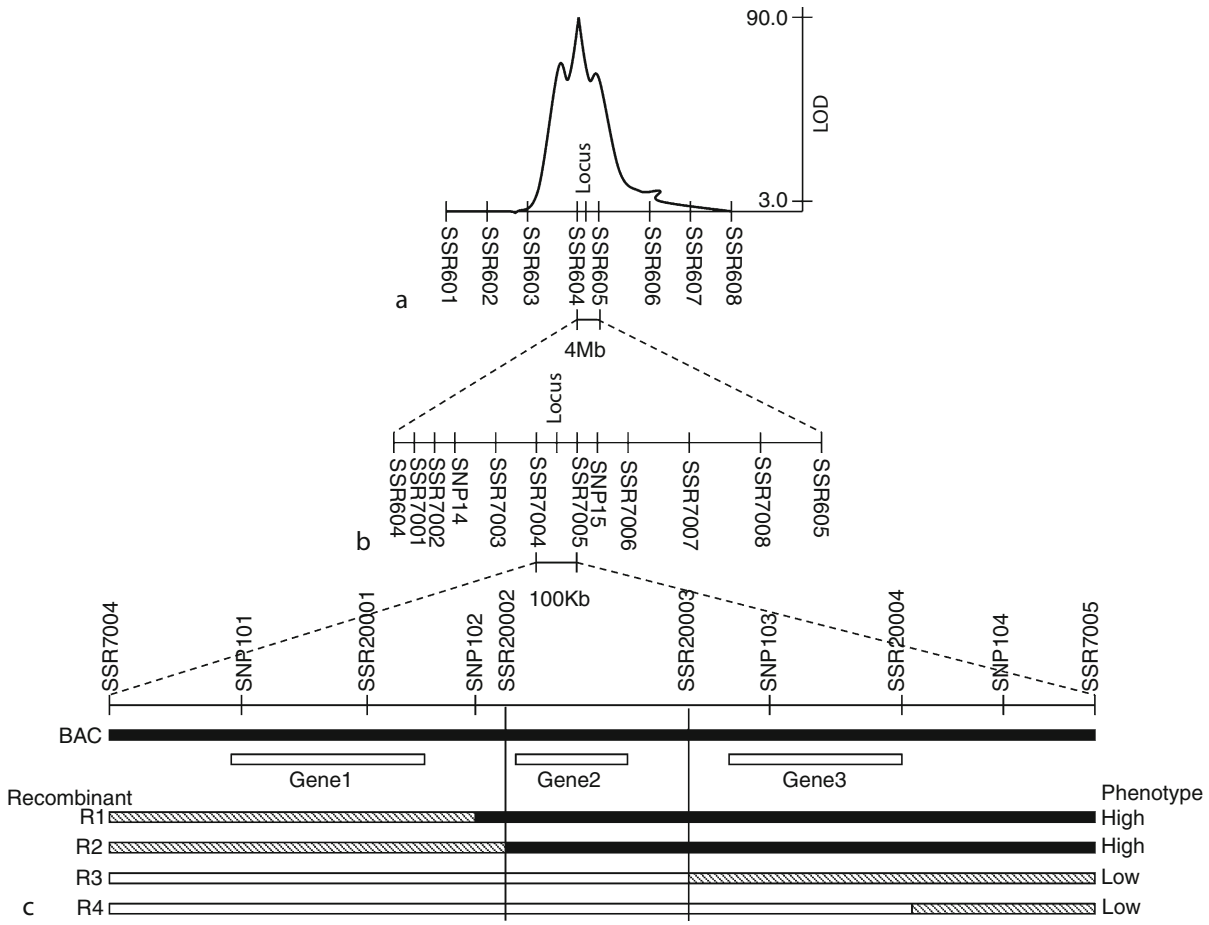
early amenable model for biological studies [9], and then analysis of the proportion of the genome and the genes that were transcribed [10]. One of the first plant genes cloned from genomic DNA was a soybean ribosomal DNA (rDNA) gene from a lambda genomic DNA library [11]. Soybean continued to be a species of interest, resulting in the generation of a complementary DNA (cDNA) library for the analysis of auxin response [12]. In maize, differential expression of the gene for the chloroplast encoded large subunit of ribulose bisphosphate carboxylase was shown in bundle sheath cells and absent in mesophyll cells [13], describing the regulation of enzymes distinguishing C4 plant cell types. These early studies showed the potential to address different plant traits by the analysis of cloned or isolated characterized genes, and the novel insights they provided.

In the course of improvement in techniques for the isolation of plant genes, methods were developed to make a correlation or causative association between specific functions and gene sequences. These functions could be defined on the basis of specific proteins with a biological function or genes determining a phenotype as revealed by isolated mutants or naturally occurring variants.

One of the important technologies that helped bridge the gap between genes and functions was the development of transformation technologies that allowed the expression of isolated genes in plants and the monitoring of the resultant phenotype. Following early demonstrations of the transfer and expression of the *Agrobacterium tumefaciens* Ti-plasmid into plant cells [14], these Ti-plasmids were engineered to transfer DNA (T-DNA) and express genes in transformed plant cells, demonstrated by a number of research groups around the same time in 1983 [15–19]. In addition to *Agrobacterium*-mediated transformation systems, other methods were developed such as direct DNA transfer to plant protoplasts [20], electroporation [21], and particle bombardment [22].

Cloning of plant genes can presently be accomplished by a variety of high-throughput ways. The cloning of expressed genes in the form of cDNA libraries has been done in plasmids, lambda vectors, and other expression systems that allow the selection of specific genes based on hybridization, DNA sequencing, or functional expression assays. The plant genome can be fractionated into representative fragments and cloned in a variety of sizes in appropriate cloning vectors. Genome fragments, in progressively increasing sizes from a few kilobases (Kb) to megabases (Mb), can be cloned in vectors such as plasmids, lambda phage, cosmids, bacterial artificial chromosomes (BACs), yeast artificial chromosomes (YACs), and modifications to these. While the smaller clones are useful for characterizing single genes or fragments thereof, the larger clones are used in positional cloning methods to identify genes using molecular markers located close to the gene of interest.

To enable the isolation of plant genes that are associated with plant biological functions/processes or crop traits, a causal relationship has to be made between DNA sequence and observed phenotype. Genetic analysis of mutants or other genetic variants that are localized on the chromosome can be used to clone the corresponding genes by methods such as map-based cloning (Fig. 1) and transposon tagging (Fig. 2), which are the two most commonly used methods for cloning genes by a forward genetics strategy centered around the phenotype of interest. In positional or map-based cloning, with a general strategy described in Fig. 1, the mapped position of a gene on the chromosome/genome, which specifies a specific trait or phenotype is the starting point to identify molecular/genetic markers close to the gene and then using integrated physical and genetic maps "walk" or "land" closer to the gene. The proof of isolating the gene is by recombination analysis, complementation by transformation, analysis of genetic variants by sequencing, or mutational analysis of the candidate genes. In transposon tagging, described in a scheme in Fig. 2, an insertion sequence from a native or heterologous transposon is used to generate mutants of a specific phenotype or genetic locus, and analysis of the transposon/insertion-tagged mutant by co-segregation analysis to a transposon probe, transposon revertant analysis or complementation of the mutant by transformation, and among the many ways evidence can be obtained to prove the identity of the tagged gene. With the availability of genome sequences of many plant species, these quite anonymous sequences need to be assigned a function, generally through a reverse genetics strategy. In reverse genetics strategies many tools are available, in most models and important crops, to



Crop Traits: Gene Isolation. Figure 1

Example of map-based cloning of a gene. (**a**) Locus mapped to a chromosome region between markers SSR604 and SSR605 via rough-scale mapping, with LOD (log of odds) score indicating linkage. (**b**) The gene further delimited to a 100-kb genomic region between markers SSR7004 and SSR7005 via fine mapping and physical mapping. (**c**) Precision mapping identified break points flanking a region containing a single gene. *Black bars* represent DNA from parent 1 (phenotype: high), *white bars* represent DNA from parent 2 (phenotype: low), and *patterned bars* represent DNA of heterozygote. The *vertical lines* show where recombination break points are positioned along the chromosome

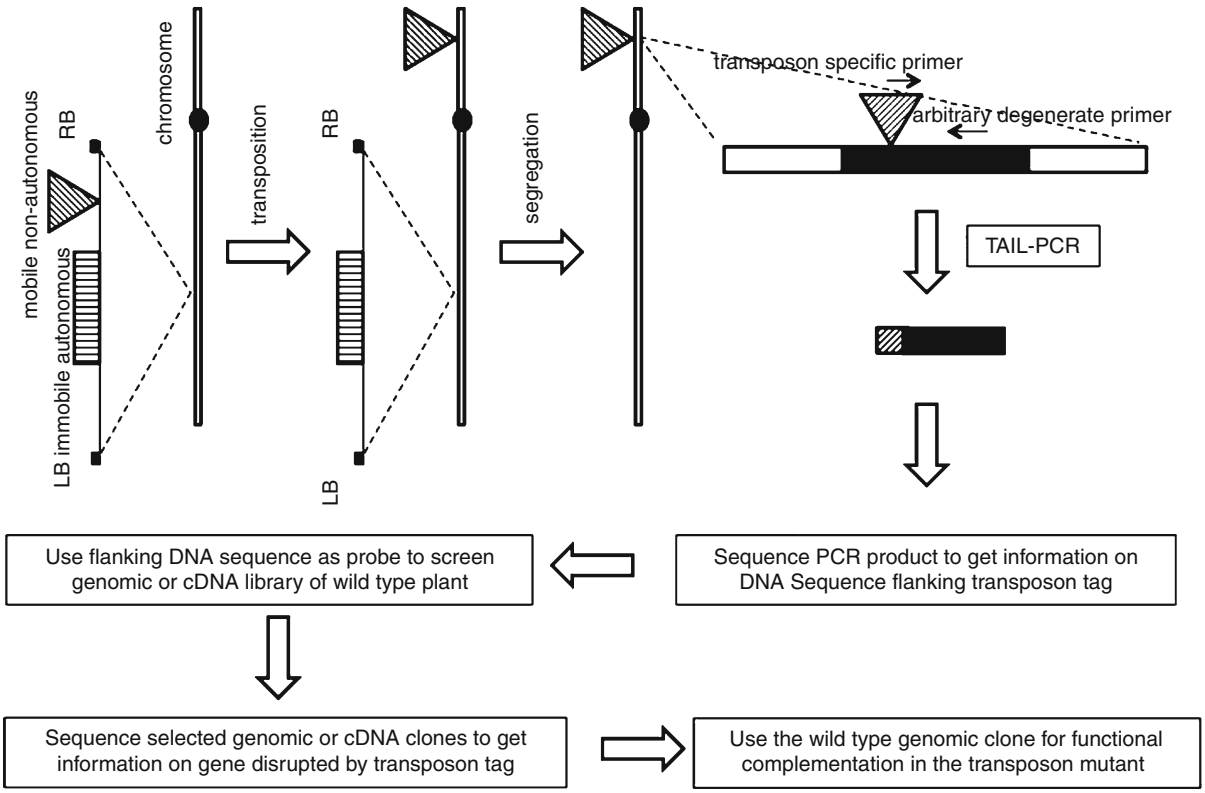
generate or select mutations in specific genes and thus attribute functions by the analysis of the mutant phenotypes.

This entry describes the specific methods that have been used in the isolation and characterization of genes that determine important crop traits that agriculture is based on. The crop traits identified in many plants have homologues in the model plant Arabidopsis that can provide clues to the function. The examples described are described in some detail and others summarized in a table (Table 1) for the reader to refer to.

Crop Traits: Gene Isolation

Dwarfing Genes in Cereals

The biggest increase in agricultural production in the modern era, around the middle of the last century, is attributed to the "Green Revolution" where grain yields of the major world cereals, wheat and rice were improved along with complementary crop production practices [23, 24]. The spectacular increases in wheat and rice yields during the Green Revolution were enabled by the introduction of dwarfing traits



Crop Traits: Gene Isolation. Figure 2

Example of gene tagging using heterologous transposons. An "in cis two-component transposon construct" integrated into plant chromosome via *Agrobacterium*-mediated transformation. The construct contains a mobile nonautonomous transposon and an immobile transposase source. The transposase mediates transposition of the mobile nonautonomous transposon into new chromosomal positions. Segregation in the next generation creates stable mutants containing the transposon inserted in a gene with no transposase source. These stable mutants can be used in forward or reverse genetics. Identification of integration position is typically done by sequencing of DNA flanking the transposon isolated using techniques, for example, TAIL-PCR, Inverse PCR, or plasmid rescue. The flanking sequence is used as a probe to screen genomic and cDNA clones. Functional complementation is done by transforming wild-type genomic clone containing the tagged gene into the insertional mutant line

into the crop varieties. The founder of this Green Revolution, Norman Borlaug received the Nobel Peace prize in 1970 in recognition for his efforts in bringing food security to major parts of the developing world [25]. Identification of the genes responsible for these traits showed that they interfere with the action or production of the gibberellin (GA) plant hormones [26].

The dwarfing gene of wheat, *Reduced Height-1* (*Rht-1*), was isolated based on sequence similarity to the previously isolated Arabidopsis *GIBBERELLIN INSENSITIVE* (*GAI*) gene [27]. GAI is a member of the DELLA proteins and a repressor of GA responses [28]. The wheat *Rht-B1b* and *Rht-D1b* dwarfing mutants had similar characteristics to the Arabidopsis *gai* mutant, including reduced plant height, reduced responses to gibberellin, and increased *in planta* gibberellin levels. Compared to the wild-type *Rht-1* allele, the *Rht-B1b* and *Rht-D1b* dwarfing alleles each contained a nucleotide substitution that created a stop codon near the N-terminus of the protein [27]. It was proposed that translational reinitiation after these introduced stop codons might result in an N-terminally truncated product that confers the mutant phenotype.

Crop Traits: Gene Isolation. Table 1 Some isolated genes in crops

Gene (s)	Crop	Molecular and phenotypic function	Cloning method[a]	Validation method[b]	Causative change[c]	Reference (s)
1. Dwarfing gene						
Rht-1	Wheat	Transcriptional regulator (SH2); plant height	SS	Mut, HE	EStp	[27]
sd1	Rice	GA20 oxidase; plant height	SS, MBC	Var	Coding	[30–32]
d	Tomato	Cytochrome P450 enzyme; plant height	TT	FC		[141]
2. Flowering/heading date						
Hd6	Rice	Protein kinase; flowering time	MBC	FC	EStp	[33]
Hd1	Rice	Transcriptional regulator (zinc finger); flowering time	MBC	FC	Coding	[34]
Hd3a	Rice	Phosphatidylethanolamine-binding protein; flowering time	MBC	OE, Sil	-	[37]
Ehd1	Rice	B-type response regulator; flowering time	MBC	FC	AC	[142]
Vgt1	Maize	Transcriptional regulator (AP2); flowering time	MBC, AM	OE, Sil	Reg	[143]
E3	Soybean	Phytochrome A; flowering time	MBC	Mut	AC?	[144]
Vrn1	Wheat	Transcriptional regulator (MADS); vernalization	MBC	Var	Reg	[145]
Vrn2	Wheat	Transcriptional regulator (ZCCT); vernalization	MBC	Sil	AC	[146]
3. Fruit ripening, shape, and weight						
Rin	Tomato	Transcriptional regulator (MADS-box); fruit ripening	MBC	FC, Sil	Coding	[147]
Ovate	Tomato	Regulatory protein (OVATE); fruit shape	MBC	FC	EStp	[148]
fw2.2	Tomato	Cell signaling; fruit weight	MBC	FC	Reg	[40]
4. Grain yield

[1] with modification)

The rice *sd-1* dwarfing allele, with origin from cultivar Dee-Geo-Woo-Gen and used in the Green Revolution dwarf variety IR8, was mapped to the long arm of chromosome 1 [29]. Characterization and isolation of this gene was reported in 2002 by three different groups [30–32]. Biochemical analysis of the *sd-1* mutant showed that the activity of GA20 oxidase (GA20ox), a key enzyme in the biosynthesis of gibberellin, did not function effectively in the mutant. A wild-type *GA20ox* gene (*GA20ox-2*) was amplified by PCR using primers based on the conserved domain of *GA20ox* genes. Linkage mapping showed that this gene mapped to the long arm of chromosome 1, tightly linked to the *sd1* locus. Compared to the wild-type *Sd-1* allele, the *sd-1* dwarfing allele (in Dee-Geo-Woo-Gen and IR8) contained a 383-base-pair deletion which produces a frame shift that creates a stop codon [30]. Another study showed RFLP markers flanking the *sd-1* locus were positioned on a physical segment of chromosome 1 covered by contiguous BAC clones by using the physical map of the reference genome available in the database. A candidate gene search identified the *GA20ox-2* gene in this region. This gene was amplified in the wild type and mutant, and sequence comparison revealed a 280-bp deletion in the coding region of this gene in the mutant allele [31]. A third independent analysis of 3,477 segregants using several PCR-based markers localized the *sd-1* locus in a 6-kb candidate interval on chromosome 1, containing only one predictable ORF, that of *GA20ox-2*. The 3,477 segregants were derived from selfing of a backcross inbred line (BIL) having close chromosomal similarity to Sasanishiki (normal-type parent) over the whole genome length with the only heterozygous sequences located on *sd-1* locus. Sequence comparison showed that Habataki (semidwarf parent) has a 383-bp deletion from the middle of exon 1 to upstream of exon 2, including a 105-bp intron, resulting in a frame shift that produces a termination codon in exon 3 [32]. These evidence clearly defined the identity of the *Sd-1* dwarfing gene and the mutant *sd-1* alleles.

Flowering or Heading Date

Heading date or flowering time is an important trait for the adaptation of crops to different cultivation areas. In rice, heading date is determined mainly by two factors: duration of the basic vegetative growth and photoperiod sensitivity (PS) [33]. Genetic analysis of heading date in rice cultivars Kasalath and Nipponbare showed that a number of quantitative trait loci, termed Hd (heading date) determine the genetic variation for flowering time [34]. Day-length treatment sensitivity tests with an NIL of *Hd6* [NIL(*Hd6*)] revealed the *Hd6* PS phenotype, with the Kasalath allele increasing days-to-heading under natural and long-day conditions but not under short-day conditions. Linkage analysis of an advanced backcross progeny mapped *Hd6* on the long

arm of chromosome 3 as a single Mendelian factor [35]. High-resolution mapping using 2,807 segregating plants derived from an advanced backcross progeny, in which the region around *Hd6* was heterozygous and almost all other regions were homozygous for Nipponbare, delimited *Hd6* to a 26.4-kb genomic region. The sequence analysis of this region identified one gene with deduced amino acid sequence having high homology (>90%) to the α subunit of protein kinase CK2 (CK2α) in maize and Arabidopsis. Sequence comparison showed a single-nucleotide substitution within the coding region, which changed the lysine codon (AAG) in Kasalath to a premature stop codon (TAG) in Nipponbare. Functional complementation was performed by introducing the Kasalath genomic fragment carrying the CK2α gene into Nipponbare and the transgenic plants scored under natural day-length condition showed late heading, indicating that the Kasalath allele of CK2α increases days-to-heading [33].

Another heading date locus *Hd1* was characterized by high-resolution mapping using 1,505 early heading BC3F3 segregants derived from a cross between Nipponbare and Kasalath, which resolved the locus to a genomic region of 12 kb. Sequence analysis of the region identified one putative gene with considerable similarity to the *CONSTANS* (*CO*) gene, known to be involved in photoperiod response in Arabidopsis. Sequence comparison showed a 2-bp deletion in the second putative exon of the Kasalath allele resulting in a premature stop codon and a predicted shorter protein than the wild-type Nipponbare protein. Functional complementation was performed by transferring the candidate *Hd1* region from Nipponbare into a NIL of Nipponbare carrying an introgression of Kasalath nonfunctional *Hd1* allele. Transgenic plants showed earlier heading under short-day conditions than the NIL control and null-segregants. These results provide clear evidence that the *Hd1* sequence in the candidate genomic region retains the function of photoperiod response [34].

The *Hd3a* locus was roughly mapped on chromosome 6. NIL(*Hd3a*), an NIL homozygous for the Kasalath allele at the *Hd3a* locus in the genetic background of Nipponbare, headed earlier than Nipponbare under SD conditions and headed at almost the same date as Nipponbare under LD and natural field conditions [36]. High-resolution mapping using 2,207 segregants delimited *Hd3a* to a 20-kb genomic region, whose sequence revealed one putative gene with high similarity to the *FLOWERING LOCUS T* (*FT*) gene, which promotes flowering in Arabidopsis. In this study, the nucleotide polymorphism that caused the allelic difference between Kasalath and Nipponbare *Hd3a* could not be clarified [37].

Fruit Weight and Grain Yield

The domestication and improvement of crops has been accompanied by increase in size and yield of harvestable products. Cultivated tomatoes (*Solanum lycopersicum*) have hence undergone more than a 100-fold increase in mass over their wild relatives. A major quantitative trail locus (QTL) for fruit weight, *fw2.2*, was mapped to the same position on chromosome 2 in an introgression line F2 derived from *S. lycopersicum* x *Lycopersicon pennellii* and a backcross 1 (BC1) population derived from *S. lycopersicum* x. *Lycopersicon pimpinellifolium*. The *fw2.2* locus accounts for 30% and 47% of the total phenotypic variance in the *L. pimpinellifolium* and *L. pennellii* populations, respectively, indicating that this is a major QTL controlling fruit weight in both species. The small-fruit *L. pennellii* allele for *fw2.2* is semidominant to the large-fruit *S. lycopersicum* allele [38]. High-resolution mapping using 3,472 F2 plants derived from a cross between *S. lycopersicum* and a NIL containing a small introgression from *L. pennellii* narrowed down *fw2.2* to a less than 150-kb region [39]. A yeast artificial chromosome (YAC) containing *fw2.2* was used to screen a cDNA library constructed from the small-fruit *L. pennellii*. Four unique transcripts were identified and used to screen a *L. pennellii* cosmid library, identifying four positive, nonoverlapping cosmids (cos50, cos62, cos69, and cos84), one corresponding to each unique transcript. These four cosmid clones were transformed into two tomato cultivars carrying the partially recessive large-fruit allele of *fw2.2*. R1 progeny of primary transformants carrying cos50, but not other cosmids, showed a statistically significant reduction in fruit weight compared to null-segregants, indicated that *fw2.2* is contained within cos50. Sequence analysis of cos50 revealed two open reading frames (ORFs): one

corresponding to cDNA44, which was used to isolate cos50, and another 663-nucleotide (nt) gene, *ORFX*, for which no corresponding transcript was detected in the initial cDNA library screen. Analysis on a single recombination event used in the previous mapping showed that *ORFX* is the likely cause of the *fw2.2* QTL phenotype. Semiquantitative reverse transcriptase-polymerase chain reaction (RT-PCR) analysis showed that the relative level of the *ORFX* transcript in the carpels of the small-fruited NIL was significantly higher than in the large-fruited NIL. Analysis of the predicted amino acid sequence of *ORFX* indicated that it is a soluble protein with alpha/beta-type secondary structure, and has a structural similarity to the human oncogene c-H-ras p21. Sequence comparison of *L. pennellii* and *S. lycopersicum ORFX* regions indicated that the *fw2.2* phenotype is probably not caused by differences within the coding region of *ORFX*, but by one or more changes upstream in the promoter region of *ORFX* [40].

Grain yield is a complex crop trait determined mainly by the three component traits, number of panicles, number of grains per panicle, and grain weight; all of which are typical quantitative traits. In rice, the developments in genome mapping, sequencing, and functional genomic research have provided the necessary tools for dissecting the genetic and molecular bases of these quantitative traits [41].

The rice grain number gene *Gn1* was first roughly mapped on the short arm of chromosome 1 using 96 F2 individuals derived from heterozygote (*Gn1*/*gn1*) plants of NIL-*Gn1* carrying the *Gn1* region from cultivar Habataki in the Koshihikari background. Habataki plants have been known to produce more grains in their main panicle than Koshihikari plants. It was found that *Gn1* consisted of two loci, *QTL-Gn1a* and *QTL-Gn1b*. High-resolution mapping using 13,000 F2 plants derived from heterozygotes (*Gn1a*/*gn1a*) of NIL-*Gn1a* narrowed down the *Gn1a* region into a 6.3-kb interval containing one reading frame with high similarity to cytokinin oxidase/dehydrogenase (CKX), named *OsCKX2*. Sequence comparison between Habataki and Koshihikari revealed several nucleotide changes, including a 16-bp deletion in the 5′-untranslated region, a 6-bp deletion in the first exon, and three nucleotide changes resulting in amino acid variation in the first and fourth exons of the Habataki allele. However, protein expression study in *Saccharomyces cerevisiae* showed both Habataki and Koshihikari alleles of *OsCKX2* encode functional enzymes. Sequence analysis of 5150, a rice variety from China producing higher grain number, detected 11-bp deletion in the coding region of this gene creating a premature stop codon. The coincidence of the *OsCKX2* null allele and a higher grain number suggested that a reduction or loss of function of *OsCKX2* enhanced grain production. Confirmation was done by introducing antisense strands of *OsCKX2* into an easily transformable cultivar Taichung 65 (TC65), which possesses the Koshihikari allele of *OsCKX2*. Transgenic plants with reduced levels of expression developed higher grain numbers. Reverse Transcription (RT)-Southern blotting showed that the highest levels of *OsCKX2* expression in inflorescence meristems were found in Koshihikari, but were less abundant in Habataki and NIL-*Gn1a* and extremely low in 5150. These results suggested that the phenotypic differences observed might have been caused by differential transcription of *OsCKX2* [42].

The rice *GS3* grain weight gene was mapped to the pericentromeric region of chromosome 3 [43]. Near-isogenic lines (NILs) of *GS3* were developed by successive crossing and backcrossing Minghui 63 (large grain) with Chuan 7 (small grain), using Minghui 63 as the recurrent parent. High-resolution mapping using 1,384 BC3F2 individuals with the recessive phenotype (large grain) derived from one BC3F1 plant heterozygous for the *GS3* region and containing the least genetic background from Chuan 7 delimited the *GS3* region to 7.9 kb. A full-length cDNA was identified that matched well with the region, and sequence analysis of the predicted GS3 protein revealed the presence of a combination of multiple domains. Comparative sequencing analysis using six cultivars including three with long grains and three with short to medium grains indicated that all the large-grain varieties tested share the same nonsense mutation in the second exon of the *GS3* gene that causes a 178-aa truncation in the C-terminus of the predicted protein. These findings suggest that *GS3* may function as a negative regulator to prevent the growth and size of the grain [44].

Two QTLs for grain width were mapped to the short arm of chromosome 2 [45, 46). Subsequently, a major QTL for grain width GW2, was mapped to the same

region using an F2 population derived from a cross between WY3 (1,000-grain weight, 41.9 ± 1.3 g) and Fengaizhan-1 (FAZ1) (1,000-grain weight, 17.9 ± 0.7 g). High-resolution mapping using 6,013 BC3F2 plants narrowed the GW2 locus to an 8.2-kb region. Only one predicted ORF was considered a viable candidate for GW2 in this region [47]. Homology search in databases showed that GW2 encodes a previously unknown RING-type protein with E3 ubiquitin ligase activity, which is known to function in the degradation by the ubiquitin–proteasome pathway. Comparison of the nucleotide sequences of the FAZ1 and WY3 alleles of GW2 uncovered a 1-bp deletion resulting in a premature stop codon in exon 4 of the WY3 allele. The premature stop codon led to truncation of 310 amino acid residues; the remaining portion of the protein consisted of a 115-residue polypeptide of ~13 kDa. Sequence analysis of GW2 from Oochikara, another rice variety that has a wider grain width, similar to WY3, showed a nucleotide sequence identical to the WY3 allele. These data indicate that reduction or loss of function of GW2 results in increased grain width. Rice transformation was used to produce transgenic plants expressing different levels of GW2. The transgenic plants with antisense strands of GW2 and with reduced levels of endogenous expression had a significantly wider grain width than plants containing the vector control. Transgenic plants overexpressing GW2 cDNA under the control of the 35S promoter, which produced high levels of expression, showed reduced grain width [47].

Disease Resistance

Disease resistance loci (R genes) conferring resistance to specific races of the pathogen, carrying corresponding avirulence (Avr) genes, have been studied in light of the gene-for-gene hypothesis proposed by Flor [48]. Plants that contain such race-specific R-genes with resistance to specific pathogen races, offer an interesting system to study plant pathogen interactions, although the genes are very rarely useful in the crop as they are quickly overcome by the pathogen gaining virulence.

In addition, there are non-race-specific disease resistance loci which provide plant resistance to a wider range or races of the pathogens. The first plant resistance gene cloned was *Hm1* from maize, which belonged to this class of resistance genes, was isolated by transposon tagging [49]. Two RFLP probes were mapped to 5 centimorgan (cM) proximal and distal to the *Hm1* locus, respectively, using progeny from the cross K61/Pr1 × K61 [50]. These two probes were used to classify segregating progeny of transposon insertion *hm1* mutants to determine which *HM1* alleles they had inherited. A transposable element probe was then used to identify a restriction fragment that cosegregated with *hm1* mutant allele. This fragment was isolated and sequenced, and the DNA flanking the transposon insertion was used as probe in northern blot analysis. A 1.3-kb RNA band was detected in polyadenylated [poly(A)$^+$] RNA from the resistant inbred strain Pr1 (*Hm1-Pr1*), while the susceptible strain, K61 (*hm1-2*), and the mutants either had no detectable hybridizing mRNA, or an mRNA of aberrant size. Difference at the transcriptional level between resistant and susceptible genotypes makes it unlikely that susceptible genotypes possess an alternative form of HM1 with specificity for a substrate other than HC toxin. A 1.6-kb cDNA clone was isolated by homology with the probe and sequenced. DNA sequence databases revealed homology between the *HM1* cDNA and the NADPH-dependent dihydroflavonol-4-reductase (DFR) genes of maize, petunia, and snapdragon. This homology supports the prediction that *HM1* encodes HC toxin reductase (HCTR) [49].

Among the race-specific R-genes, the tomato-leaf mold interaction has been well studied and yielded the first examples of cloned R-genes. The avirulence gene *Avr9* in the leaf mold fungus *Cladosporium fulvum* was shown to specify a 28-amino acid secreted peptide that elicits a necrotic response when injected into tomato plants carrying the *Cf-9* resistance gene [51]. The *Cf-9* gene was introgressed into cultivated tomato from wild species *L. pimpinellifolium* accession PI126915 [52]. The *Cf*-9 locus was mapped to the short arm of chromosome 1 [53], and a targeted transposon tagging strategy was employed to isolate the *Cf-9* gene [54]. A tomato line homozygous for *Cf*-9 was crossed to a transgenic tomato line carrying a *Ds* element located 3 cM from the *Cf*-9 locus, and additionally to a transgenic tomato plant containing a stabilized *Ac* (s*Ac*) element. The F1 plants were crossed and the progenies selected to produce tagging parents heterozygous for *Ds* and s*Ac* and homozygous for *Cf-9*. To tag *Cf*-9 the

tagging lines were crossed as female parents to a tomato line homozygous for the *Avr9* transgene and lacking *Cf*-9. The progeny of this cross, which were heterozygous for *Cf*-9 and *Avr9*, became necrotic and died shortly after seed germination, but the mutants for *Cf*-9 survived. Approximately 160,000 progeny were germinated and 118 survivors were recovered. A total of at least 37 independent *Ds* insertions into *Cf-9* were identified. Specific *Cf-9* primers were used in conjunction with *Ds* primers to map the *Ds* insertions on the basis of PCR product size. Twenty-eight *Ds* insertions were mapped to the same 3-kb region of the tomato genome. All stable mutants tested were susceptible to race 5 of *Cladosporium fulvum*, which indicates concordance between the loss of response to the *Avr9* transgene and loss of resistance to a race of the fungus carrying *Avr9*. Isolation via plasmid rescue and sequencing of the flanking genomic sequence showed that *Cf-9* encodes a putative membrane-anchored extracytoplasmic glycoprotein with homology to the leucine-rich repeat family of proteins [54].

Late blight caused by the oomycete pathogen *Phytophthora infestans*, and responsible for the Irish Potato Famine of the mid-nineteenth century that induced vast migration, is still one of the most devastating of plant diseases causing more than $3 billion loss annually [55]. The *P. infestans* pathogen easily overcomes the R-genes crossed in from various wild relatives of potato. Diploid *Solanum bulbocastanum* from Mexico, which was not easily crossable to potato (*Solanum tuberosum*) cultivars, had been characterized to have high resistance to *P. infestans* and was used to characterize the resistance gene loci. The *RB* (for "Resistance from *S. bulbocastanum*") locus was mapped to chromosome 8 of *S. bulbocastanum* [56]. BAC walking by the reiterative screening of a BAC library using probes derived from the ends of previously identified BAC clones, was initiated using linked RFLP markers and the contig subsequently used to develop PCR-based markers to enhance map resolution in the *RB* region. High-resolution mapping using 542 BC2, 1,060 BC3, and 206 BC4 genotypes delimited the *RB* region to approximately 55 kb [57]. This region contained one truncated and four complete CC–NBS–LRR (coiled coil–nucleotide binding site–Leu-rich repeat)-class R-gene analogs (RGAs). Each of the four complete RGAs was amplified from *S. bulbocastanum* using Long Range-PCR and cloned into a binary vector for complementation studies. Katahdin, a late blight susceptible potato variety was transformed with the four complete R-gene analogs. Only the transgenic plants containing *RGA2*-PCR construct displayed resistance to all six isolates of *P. infestans*, including 126C18, a "super race" that overcomes all 11 major R genes identified in *Solanum demissum*, the complementation demonstrating that *RGA2* represents the functional *RB* gene [58].

In a simultaneous effort to the analysis of the RB locus, the *Rpi-blb1* resistance locus was characterized in intraspecific crosses between *S. bulbocastanum* accessions segregating for resistance, and mapped closely to marker CT88 on chromosome 8 [59]. A BAC contig was isolated across the *Rpi-blb1* locus, and sequence analysis revealed 4 RGAs of the CC–NBS–LRR class. One of the genes termed *Rpi-blb1* complemented potato and tomato cultivars to confer resistance to complex races of the *P. infestans* pathogen. In subsequent analysis of resistant complex interspecific hybrids designated ABPT derived from *S. bulbocastanum*, the *Rpi-blb2* locus was identified and mapped to a position on chromosome 6 at a similar position as the tomato *Mi* locus (see below) conferring resistance to nematode, aphids, and white flies. The *Rpi-blb2* locus harbored 15 Mi-1 gene homologues, one of which conferred *P. infestans* resistance in tomato and potato. The Rpi-blb2 protein shares 82% sequence identity to the tomato Mi-1 protein and exemplifies the evolution of a resistance gene cluster to confer diverse resistance specificity to a wide range of organisms such as nematodes, insects, and oomycetes [60].

The barley recessive *mlo* locus conferring resistance against the fungal pathogen *Blumeria graminis* f. sp. *hordei* (Bgh) has been mapped on chromosome 4 [61]. High-resolution mapping using 2,022 F2 segregants identified a DNA marker cosegregating with *mlo* and two flanking markers at a distance of 0.24 and 0.4 cM, respectively. Screening of a large insert yeast artificial chromosome (YAC) library identified three YAC clones containing the cosegregating marker and two flanking markers. Subcloning experiments of one YAC clone into bacterial artificial chromosome (BAC) vector and further mapping and sequencing delimited the *mlo* region to 30 kb. Sequence analysis identified one sequence contig of 5.8 kb, including the cosegregating

marker, revealing an extensive region of high coding probability. Reverse transcriptase-PCR using a series of primers deduced from this region and sequencing revealed a single extensive open reading frame (ORF) of 1,599 bp. The deduced 60 kDa protein was predicted to be membrane-anchored by at least six membrane-spanning helices. Genomic PCR-based sequencing of 11 mutagen-induced *mlo* resistance alleles and their corresponding wild-type DNAs identified nucleotide alterations (point mutations or deletions) in all tested mutant alleles that at the amino acid level result either in single amino acid substitutions or truncated versions of the predicted wild-type protein. A comparison among the wild-type gene sequences of seven tested barley cultivars indicated not a single amino acid difference. Inter-mutant crosses were performed using lines containing different mutant alleles. F2 seedlings were screened for rare disease–susceptible individuals after inoculation with an isolate of powdery mildew which is virulent on each of the parental *Mlo* wild-type cultivars. Homozygous susceptible F3 progeny were isolated and used for molecular analysis using RFLP markers tightly linked (<4 cM) on each side of the *Mlo* locus. Seven susceptible individuals exhibited flanking molecular marker exchange, indicating reciprocal crossover (CO) events. Genomic PCR-based sequencing demonstrated that all seven CO type recombinants restored wild-type sequences [62].

Root-knot nematodes (*Meloidogyne* spp.) are endoparasites of thousands of crop species and are important pests of tomato worldwide [63]. The root-knot nematode resistance gene (*Mi*) was introduced into cultivated tomato, *S. lycopersicum*, from its wild relative *Lycopersicon peruvianum* in the early 1940s [64], and today it provides the only form of genetic resistance against this pathogen. The *Mi* locus was localized to the short arm of chromosome 6 [65] and multiple markers linked to Mi were identified [66–69]. In these studies, it was found that the nematode-resistant tomato line Motelle, and related lines, retained only a small introgressed region (650 kb) from *L. peruvianum*. Efforts to localize the *Mi* gene were hampered for many years because of the severe repression of recombination near this gene in *Lycopersicon esculentum* lines carrying the introgressed *L. peruvianum* DNA [67, 68, 70]. This handicap was circumvented by screening large populations of tomato for recombinants and by identifying recombinants within *L. peruvianum* populations [71]. After data from *S. lycopersicum* and *L. peruvianum* recombinant analyses were combined, *Mi* could be localized to a genomic region of <65 kb. Subcloning experiments of one YAC clone containing the *Mi* locus identified four overlapping BACs hybridizing to the *Mi*-flanking DNA probes. Large-scale sequencing of two BACs identified six open reading frames; three of these are homologous to each other and to previously identified R genes of the nucleotide binding–LRR class. Two of them, *Mi-1.1* and *Mi-1.2*, appear to be intact genes; the third is a pseudogene predicted to not encode a functional product. Complementation studies were performed by transforming a nematode-susceptible tomato line using constructs containing the *Mi-1.1* and *Mi-1.2* genes. Eighty-seven percent of transformants carrying *Mi-1.2* were resistant to the root-knot nematode, whereas all transformants carrying *Mi-1.1* were completely susceptible, confirming *Mi-1.2* as the functional *Mi-1* gene [72].

In cultivated tomato, tomato mosaic virus (ToMV) infections are controlled by the introgressed *Tm-1*, *Tm-2*, and *Tm-2*^{2} resistance (*R*) genes [73, 74]. Among these resistances the *Tm-2*^{2} resistance was shown to be remarkably durable and, therefore, of ongoing practical importance. The *Tm-2*^{2} locus has been localized to tomato chromosome 9, but map-based cloning of this gene has been shown to be difficult, especially due to the lack of recombination in the centromeric region [75]. The two-component Ac/Ds transposon system was utilized to isolate the tomato *Tm-2*^{2} gene. A tomato line (homozygous *Tm-2*^{2}) was crossed with another line (homozygous for *sAc*). One F2 plant from this cross (homozygous for both *sAc* and *Tm-2*^{2}) was subsequently used in a cross with a tomato line having *Ds* transposon on chromosome 9 with distance 2 cM from the resistance gene. About 100 independent plants with the genotype *Ds*/–; *sAc*/–; *Tm-2*^{2}/*Tm-2*^{2} were selected and used as males and females in a cross with a transgenic tomato line which is homozygous for the ToMV *MP* (Movement Protein) gene for a large-scale tagging experiment. Previous observation had shown a lethal combination of the *Tm-2*^{2} gene and the *ToMV MP* transgene in the seedling stage of tomato plants. From about 30,000 seeds obtained from these crosses, five putative mutants were obtained. All contained the *Ds* element and the *MP* gene and only

one mutant plant still contained *sAc*. To test whether these five putative mutants were really mutants in the *Tm-2²* gene, cuttings of these plants were inoculated with ToMV. All the five putative mutants were susceptible to ToMV infection. Plasmid rescue was used to obtain transposon-flanking plant DNA from the mutant plants. Sequencing of 9.8 kb of rescued plant DNA identified an open reading frame (ORF) of 2,586 bp, which corresponds to a polypeptide of 861 amino acids. *In silico* analysis of the ORF did not predict the presence of introns. The polypeptide encoded by the 2,586-bp ORF shows the characteristics of the CC–NBS–LRR class of R proteins, and the 5′- and 3′-RACE experiments confirmed the prediction of the gene structure. Functional complementation was performed by introducing either *Tm-2²* gene under the control of its own promoter and polyadenylation signal or *Tm-2²* gene under the control of the CaMV 35S promoter and the NOS polyadenylation signal into a susceptible tomato line. The transgenic plants of the two constructs were resistant to ToMV [76].

Plant and Inflorescence Architecture

Maize Domestication Traits Most crop plants differ considerably from their wild ancestors in major morphological phenotypes that have probably resulted from visual selection of desired plant type. This is most dramatic in maize, where the major difference between maize and its probable wild ancestor teosinte is that teosinte typically has long branches with tassels at their tips whereas maize possesses short branches tipped by ears [77]. Most of the variation for the dramatic differences in inflorescence morphology between maize and teosinte is explained by five quantitative trait loci (QTLs) [78]. Complementation tests indicated that one of these QTLs, which is on chromosome arm 1L, is the locus for the maize mutant *teosinte branched l* (*tbl*) [79]. To isolate the *tb1* gene, homozygous *tb1-ref* (a spontaneous mutant in a maize population) plants were crossed to an active *Mu* transposon line, and 26,000 F1 plants were grown. Among these, three new *tb1* mutants (*tb1-mum1*, *tb1-mum2*, *tb1-mum3*) were observed. Each new mutant was crossed to maize inbred A532, and 14 progeny from each of these crosses were used for Southern blot analysis with marker loci that closely flank *tb1* to discriminate progeny that possessed the *tb1-ref* versus the new *Mu* alleles. The progeny were also screened by Southern blot analysis with *Mu* element probes, and a *Mu3* element that cosegregated with *tb1-mum*1 was identified. Overlapping genomic restriction fragments carrying the cosegregating *Mu3* element were cloned into λ vectors. Subclones of these were used for Southern blot analyses of the 20 progeny of each of the three mutant plants, showing that each of these mutants has an insertion into this region of the genome that did not exist in their sibs and the progenitor stocks. These observations provided the crucial evidence that the *tb1* has been newly tagged. Portions of the λ clones were sequenced and oligonucleotide primers were designed to be used in conjunction with a *Mu*-specific primer to amplify the insertion fragments for each of the three *Mu* alleles. DNA sequence analysis of these fragments identified the *Mu* insertion point of each allele. A 0.8-kb restriction fragment flanking the *Mu* element was used to screen a cDNA library derived from immature ear. A single clone with a 1,360-bp insert, excluding the poly(A)tail was obtained. The cDNA sequence is fully collinear with the genomic sequence of maize inbred A619, without any evidence for introns. BLAST analysis with the sequence showed that tb1 shares two short regions of homology with the snapdragon *cycloidea* gene. The pattern of *tb1* expression and the morphology of *tb1* mutant plants suggest that *tb1* acts both to repress the growth of axillary organs and to enable the formation of female inflorescence. The maize allele of *tb1* is expressed at twice the level of the teosinte allele, suggesting that gene regulatory changes underlie the evolutionary divergence of maize from teosinte [80]. Analysis of nucleotide polymorphism in *tb1* gene of maize and teosinte populations showed that during maize domestication the effects of selection were limited to the gene's regulatory region and could not be detected in the protein-coding region [81]. Fine mapping showed that the intergenic sequences approximately 58–69 kb 5′ to the *tb1* cDNA confer pleiotropic effects on *Zea mays* morphology. Moreover, an allele-specific expression assay showed that sequences >41 kb upstream of *tb1* act in *cis* to alter *tb1* transcription [82].

The most critical step in maize (*Zea mays* ssp. *mays*) domestication was the liberation of the kernel from the hardened, protective casing that envelops the kernel in

the maize progenitor, teosinte [83]. This evolutionary step exposed the kernel on the surface of the ear, such that it could readily be used by humans as a food source. A large effect QTL for glume induration (husk hardening) was mapped to chromosome 4 using two F2 populations derived from crosses between maize race Reventador (Nay 15) and Balsas teosinte, *Z. mays* ssp. *parviglumis* or between maize race Chapalote and *Z. mays* ssp. *mexicana* [84]. This large-effect QTL segregates as a single Mendelian locus in an isogenic background, and has been designated *tga1* [83]. Maize Mo17 bacterial artificial chromosome (BAC) libraries were screened using a marker on maize chromosome 4, which is tightly linked to *tga1* and a BAC contig near *tga1* was identified. The BAC end and other sequences from this contig were used to BLAST search the rice genome sequence, and a region on rice chromosome 8 that is collinear with the region near *tga1* on maize chromosome 4 was identified. Subsequent BLAST searches using the collinear rice sequence identified a second maize Mo17 contig near *tga1*. Marker analysis showed that these 2 contigs flank *tga1*. Maize B73 contigs that correspond to the two Mo17 contigs were subsequently identified. DNA sequence analysis revealed that the two B73 contigs overlap, and could be merged to a single supercontig of ~1.5 megabases. Fine mapping using 3,106 F2 plants delimited *tga1* to a 6-kb region. Further BLAST searches using the 6-kb region at *tga1* revealed that it has homology to SBP (squamosa-promoter binding protein) transcriptional regulators. DNA sequence analysis of the SPB gene for the *tga1-ems1* stock, another *tga1* allele generated by ethyl methanesulfonate mutagenesis of maize line W22 that matched the phenotype of the teosinte allele in homozygous state, revealed that it differs from its parental (W22) allele by a nonconservative amino acid substitution of a phenylalanine for a leucine at position 5. This mutation in the *tga1-ems1* allele confirmed the conclusion from positional cloning that *tga1* is the SBP gene, and demonstrated that a single amino acid substitution was sufficient to confer the difference between the maize and teosinte phenotypes. Northern blots, real-time PCR, and *in situ* hybridization did not show any quantitative or qualitative differences in *tga1* expression between the isogenic lines (W22 and W22: *tga1*) or between the maize inbred W22 and teosinte itself, suggesting that differences between the maize and teosinte proteins may be critical to phenotype. Further mapping using seven additional recombination events within the 6-kb region narrowed the location of the causative site for the functional difference between maize and teosinte phenotypes to a 1,042-bp segment. DNA sequence analysis of this 1,042-bp segment using 16 diverse maize and 12 teosinte individuals identified seven fixed differences between maize and teosinte. Six of these seven are single base-pair polymorphisms that lie just 5′ of the coding sequence and potentially affect *tga1* expression. The seventh difference encodes an amino acid substitution of lysine (K) in teosinte to asparagine (N) in maize at position 6. Western blot analysis showed that *tga1* protein encoded by the teosinte allele is more abundant than the one encoded by the maize allele over a range of developmental stages that might underlie the phenotypic differences. The K → N substitution might alter protein stability, or it might affect translation efficiency or protein function [85].

Wheat Inflorescence In wheat, the *Q* allele confers the square-headed phenotype and free-threshing character, and is possessed by most of the cultivated wheats, but most wild wheats have the *q* allele and, therefore, speltoid spikes that are not free threshing [86]. Early experiments involving the cytogenetic analysis of aneuploid (abnormal chromosome number) plants located the *Q* gene on the long arm of chromosome 5A [87, 88]. Using chromosome deletion lines, Endo and Gill (1996) physically mapped the *Q* gene to a submicroscopic deletion interval on the long arm of chromosome 5A [89]. Comparative mapping of anonymous RFLP clones, AFLP (amplified fragment length polymorphism) markers, and mRNA differential display analysis of lines which have deletion break points that flank the *Q* locus identified 18 markers within the *Q* gene deletion interval. These markers were used to construct a genetic linkage map of the region in F2 populations derived from chromosome 5A disomic (homologous chromosome pair) substitution lines. The genetic map corresponding to the deletion segment was 20-cM long, and markers as close as 0.7 cM to the *Q* gene were identified [90]. The closest marker to the *Q* gene was used to screen four high-density *Triticum monococcum* BAC filters resulting in

the identification of one BAC clone. Chromosome walking involved the reiterative screening of the BAC library using probes derived from the ends of previously identified BAC clones. A BAC contig was then constructed that spans a physical distance of 300 kb corresponding to a genetic distance of 0.9 cM. The physical map of *T. monococcum* had perfect colinearity with the genetic map of wheat chromosome arm 5AL. Analysis of fast neutron *q* mutants using markers derived from the BAC contig at the *Q* locus confirmed that the *T. monococcum* BAC contig spanned the *Q* locus and narrowed the region for prospective *Q* gene candidates to a 100-kb segment, which contains an APETALA2 (AP2)-like gene that cosegregates with *Q* [91]. Sequence analysis showed that this AP2 gene consists of ten exons and nine introns. The M2 generation of a population of *Triticum aestivum* cv.Chinese Spring (CS) EMS mutants was screened for the speltoid phenotype to identify putative knockouts. Three speltoid mutants harboring point mutations within the AP2 gene were identified. One mutant had a single base substitution in an AP2 DNA binding domain (exon 5) that resulted in the change of a cysteine to a tyrosine. Two other mutants had point mutations in the donor site of intron 2 and the acceptor site of intron 7, respectively, resulting in alternate splicing in these mutants. The sequence analysis of the mutants validated that the AP2 gene is the *Q* locus. Comparison of the genomic sequences of the AP2 gene revealed six conserved differences between *Q*- and *q*-containing genotypes. Four of these differences, including a variable microsatellite (DNA sequence repeat), were present in introns and one was in the 3′ UTR. One conserved nucleotide difference changed a predicted amino acid where, at position 329, all *Q*-containing genotypes possessed an isoleucine while all *q*-containing genotypes possessed a valine. Yeast two-hybrid analysis showed that the full-length Q protein has the ability to form a homodimer, whereas the point mutation of q greatly reduced homodimer formation of the full-length q protein. Rachis fragility, glume shape, and glume tenacity mimicked the q phenotype in transgenic plants exhibiting posttranscriptional silencing of the transgene and the endogenous *Q* gene. Variation in spike compactness and plant height were associated with the level of transgene transcription due to the dosage effects of *Q* [92].

Barley Inflorescence Barley spikes have a unique structure consisting of three one-flowered spikelets at each spike node. Cultivated barley, *Hordeum vulgare* subsp. *vulgare*, can be divided into two forms according to the morphology of the spikelets: two-rowed and six-rowed. The two-rowed condition is believed to be primitive, because wild barley, *Hordeum vulgare* subsp. *spontaneum*, is two-rowed. Row type is controlled by multiple alleles at the *vrs1* locus (formerly *v* for *vulgare*) on chromosome 2H [93, 94]. A recessive mutation from *Vrs1* to *vrs1* changes two-rowed barley to six-rowed barley. High-resolution mapping using 373 BC7F1 plants and 278 BC6F2 plants identified four RFLP-derived STS markers closely linked to the *vrs1* locus [95]. The orders of four marker loci and *vrs1* locus were the same in six different mapping populations developed from nine different barley cultivars (*H. vulgare* subsp. *vulgare*) or mutant and wild barley (*H. vulgare* subsp. *spontaneum*) [96]. Five AFLP markers within the 0.9-cM region associated with the *vrs1* locus were subsequently developed using well-characterized near-isogenic lines as plant materials [97]. Recombinants within the 0.9-cM region were analyzed further using STS markers generated from ESTs (expressed sequence tags) and BAC DNA sequences. PCR screening of BAC clones of cv. Morex using an STS marker located 0.01 cM proximal to the *vrs1* locus isolated one BAC clone. Chromosome walking identified six bacterial artificial chromosome (BAC) clones covering completely the candidate genomic region. The contig containing *vrs1* is composed of 518,343 bp. Annotation showed three predicted genes: *HvHox1* and *HvEP2* appeared to be intact genes, whereas *HvEP1* is highly degenerated and interrupted by several insertions of transposable elements. *HvHox1* is the only gene that lies between two markers that define the break points and is thus a likely candidate for *Vrs1*. The ORF of two-rowed barley encoded a polypeptide composed of 222 amino acid residues, including a homeodomain-leucine zipper (HD-ZIP) motif. Expression of *Vrs1* was strictly localized in the lateral-spikelet primordia of immature spikes, suggesting that the VRS1 protein suppresses development of the lateral rows. Loss of function of *Vrs1* resulted in complete conversion of the rudimentary lateral spikelets in two-rowed barley into fully developed fertile spikelets in the six-rowed phenotype [98].

The wild progenitor of barley, *H. vulgare* subsp. *spontaneum*, has covered (hulled) caryopses in which the hull (outer lemma and inner palea) is firmly adherent to the pericarp epidermis at maturity. In cultivated barley, the hulled or naked caryopsis is one of the most important agronomic traits because of the direct link to its use. Most cultivars have the hulled caryopsis and are mainly used for animal feed and brewing malts. In contrast, naked barley has a caryopsis with easily separable husks upon threshing and is suitable for edible purposes. The naked caryopsis is considered a key domestication character in barley because extensive pearling to remove the hull is unnecessary [99]. The covered/naked caryopsis in barley is controlled by a single locus (*nud*, for nudum) located on chromosome arm 7HL [100]; the covered caryopsis allele (*Nud*) is dominant over the naked one (*nud*). Bulked segregant analysis on an F2 population derived from a cross between Kobinkatagi (naked type) and Triumph (hulled type) was performed using 1,894 primer combinations, and 12 AFLP markers were selected. Among them, five closely linked and two cosegregating AFLP markers were mapped around the *nud* locus using 151 F2 individuals [101]. High-resolution mapping using 2,380 segregants derived from five cross-combinations identified AFLP-derived markers flanking the *nud* locus at the 0.6-cM proximal and the 0.06-cM distal side, respectively [102]. Further mapping using 2,828 progeny segregating for the trait from two cross-combinations delimited the *nud* locus to a 0.64 cM interval. Integration of the flanking markers into a high-density barley expressed sequence tag (EST) map selected two barley ESTs flanking the *nud* locus. BLASTN analysis identified their respective homologous rice ESTs 370 kb apart on rice chromosome arm 6L. Two rice genes within the collinear region were used as vehicles to develop closer barley markers. A BAC library of the covered barley cultivar Haruna Nijo was screened using the closest marker to the *nud* locus. Seven rounds of chromosome walks selected 20 BAC clones and a 500 kb-contig spanning the *nud* locus was constructed. In the physical map, the *nud* locus was covered completely with four overlapping BAC clones. An ethylene response factor (ERF) family transcription factor was the only gene that lies in the region delimited by the genetic and physical mapping and, therefore, is considered as a *Nud* candidate gene [103]. Sequencing of the *nud* region obtained from two naked lines [Kobinkatagi (a Japanese landrace) and *nud*-Bowman (an isogenic line carrying the *nud* allele in the genetic background of the covered cultivar Bowman)] revealed a deletion of 16,680 bp relative to the corresponding region of the Haruna Nijo BAC contig sequence. The 16,680-bp deletion included the entire ERF gene. Thus, the gene structure analysis of naked cultivars supports the candidacy of the ERF gene. Sequence analysis of the candidate gene in two X-ray-induced naked mutants showed that each of the two mutants carried a different single base mutation in the putative functional motif of the ERF gene, but their wild-type varieties (Haisa's and Ackermann's Donaria, respectively) had a nucleotide sequence that is identical to that of Haruna Nijo. RNA in situ hybridization using the antisense probe revealed that, in Bowman, *Nud* was expressed strictly in the testa where adherence occurs, while no signal above background was detected in *nud*-Bowman. The *Nud* gene has homology to the Arabidopsis *WIN1*/*SHN1* transcription factor gene, whose deduced function is control of cuticular wax and cutin-related lipid biosynthesis pathways [104–106]. Staining with a lipophilic dye (Sudan black B) detected a lipid layer on the pericarp epidermis only in covered barley [103].

Rice Plant Architecture Tillering in rice (*Oryza sativa* L.) is an important agronomic trait for grain production. Screening of a collection derived from spontaneous mutations identified *monoculm 1* (*moc1*) mutant. The *moc1* plants nearly completely lose their tillering ability, producing only one main culm, in contrast to the multiple tillers in wild-type plants. Genetic analysis with reciprocal crosses between *moc1* and wild-type plants revealed that *moc1* is a single locus mutation. The *MOC1* locus was mapped to the long arm of chromosome 6 of *O. sativa* using 280 F2 mutant plants generated from the crosses between *moc1* and Minghui 63. Fine mapping using 2,010 F2 mutant plants and newly developed molecular markers delimited the *MOC1* locus to a 20-kb region. Annotation of the 20-kb sequence identified an ORF that encodes a protein highly homologous (44% identity) to the tomato *LATERAL SUPPRESSOR* (*LS*). The corresponding ORF from *moc1* and wild-type plants

were amplified by PCR and sequenced. DNA sequence comparison revealed a 1.9-kb retrotransposon inserted in this ORF in the *moc1* mutant. Transformation of a binary plasmid carrying a 3.2-kb wild-type genomic fragment containing the entire ORF plus a 1.5-kb upstream sequence and the 316-bp downstream sequence, but not the one carrying a 3′ truncated *MOC1* gene, was able to rescue the monoculm phenotype of the *moc1* mutant [107].

Typical common wild rice (*Oryza rufipogon*) tends to have a prostrate growth habit during the vegetative phase and develop erect panicle-bearing stalks during the reproductive phase. Cultivated rice has an erect-growth habit throughout the entire growth phase, which may increase plant density, enhance photosynthesis efficiency, and improve grain yield. A set of introgression lines was constructed using an accession of Yuanjiang common wild rice (YJCWR, *Oryza rufipogon*) with prostrate growth habit as a donor, and an elite indica cultivar Teqing (*O. sativa*) with erect-growth habit as a recipient [108]. One introgression line (YIL18) displaying prostrate growth was obtained, which harbored two YJCWR chromosomal segments on the long arm of chromosome 3 and the short arm of chromosome 7. The tiller angle of YIL18 was larger than that of Teqing. The grain number on the main panicle (GNP) in YIL18 was only 57.6% of that in the recipient Teqing, a result of the lesser number of primary branches and secondary branches on the main panicle. Genetic linkage analysis within 246 F2 individuals derived from the cross between YIL18 and Teqing showed that prostrate growth was completely associated with a marked decrease of GNP and controlled by a single semidominant gene, *PROG1* (*PROSTATE GROWTH 1*), located on short arm of chromosome 7. High-resolution mapping using 3,600 recessive homozygote plants with erect growth from the F2 population delimited *prog1* within an 8.8-kb region. Only one ORF was identified within this region that encodes a putative single Cys2-His2 zinc-finger protein. Transformation of a binary plasmid carrying the entire *O. rufipogon PROG1* with 596-bp or 2,914-bp 5′-flanking regions, but not the one carrying only the 2,914-bp 5′-flanking region, showed complementation of the prostrate growth phenotype. Comparison of the coding sequences of *PROG1* in YJCWR and *prog1* in Teqing showed 15 SNPs and 6 insertion/deletions (indels) that encoded 23 amino acid changes between *PROG1* and *prog1*. Sequencing of the *prog1* coding regions of 182 erect-growth varieties of cultivated rice, including 87 indica and 95 japonica cultivars from 17 countries showed that all the cultivars contained identical mutations as *prog1* in Teqing, including 15 SNPs and 6 indels [109].

Cereal Seed Quality and Color

Cereal grain is the staple food of most of the world, representing the major carbohydrate energy source in the diet. One of the most important crop traits is grain quality, which determines the price and variety of food that can be prepared from the cereal crop. Thus the major cereal crops such as rice, wheat, maize, barley, and oats have undergone selection from the onset of the crop domestication process. In comparison to other crop traits, seed quality and color are primarily biochemical traits and have been studied at the protein, gene, and metabolite or grain component level.

Maize Lysine Content The protein nutritional quality of maize is improved by increase in the essential amino acid lysine in the *opaque-2* (*o2*) mutant locus, which was localized on the short arm of chromosome 7 [110]. To isolate the gene by transposon tagging, normal maize strains (*O2*/*O2*) carrying a mutable allele of *C1* containing an autonomous *Spm* (*c1-m5*) or a mutable allele of *Wx* containing a nonautonomous, defective derivative of *Spm* (*dSpm*) (*wx-m8*) were used as pollen donors for opaque plants (*o2*/*o2*). Three opaque-mutable *o2*/*o2-m* kernels were selected from approximately 530,000 F1 seeds. These kernels were grown to maturity and self-pollinated. DNAs prepared from leaf samples of F2 individual plants were used for Southern blot analysis using a *Spm*-specific probe. The opaque-mutable plants contained a novel 8.4-kb band absent in both parents and missing from at least some of the individuals that had been classified as opaque. Those kernels that had been classified as opaque but possessed the fragment were evidently not mutable because of failure of the *Spm* to transpose, or else transposition occurred so late in endosperm development that revertant sectors were undetectable, giving the kernels an opaque rather than an obvious opaque-mutable phenotype. The fragment was cloned and

restriction enzyme mapping of the clone revealed the presence of a full-length, autonomous 8.3 kb *Spm* and an adjacent sequence of about 150 bp. This non-*Spm* region was sequenced and used as a probe on Southern blot using a BC1 population derived from a cross between opaque (*o2*/*o2*) and normal (*O2*/*O2*) plants. All the plants derived from opaque (*o2*/*o2*) seeds showed a single 6.5-kb fragment, whereas plants from seeds with a normal phenotype (*o2*/*O2*) had a 10-kb fragment in addition to the 6.5-kb fragment. This demonstrates that the 150-bp *Spm*-fanking sequence derived from the opaque-mutable plant represents a single-copy sequence that cosegregates with alleles of the *o2* locus. This fragment was subsequently used as a probe to clone a 17-kb *Hin*dIII fragment of the wild-type *O2* allele from the *c1-m5* parent [111]. A cDNA library prepared from wild-type endosperms was screened with probes derived from the *O2* genomic clone. Analysis of *O2* cDNA sequence showed that the deduced *02* protein sequence contains a "leucine-zipper" domain characteristic of some mammalian and fungal transcription activation factors. DNA binding assays demonstrated that the O2 protein or only a fragment specifying the leucine-zipper domain bound to two specific regions on the 5′ side of the coding sequence in a zein genomic clone [112].

Cereal Amylose Content The maize *Waxy* locus determines starch quality by the level of amylose and amylopectin. Isolation of the gene was carried out by a combination of identification of the protein and the gene associated with the kernel mutant phenotype. The mutant *wx-m6* and *wx-m9* alleles have *Ds* transposon inserts at the *Wx* locus, while the *wx-m8* allele is attributable to insertion of a defective transposon of the *Spm* transposon family. Starch granules from immature endosperm tissue of kernels carrying the *wx-m6*, *wx-m9*, and *wx-m8* alleles were isolated and the starch granule-bound proteins were analyzed on SDS-polyacrylamide gels [113]. When the kernels did not contain an autonomous controlling element (either *Ac* or *Spm*) and showed no somatic reversion of the *wx-m6*, *wx-m9*, or *wx-m8* mutations, the 58 kd protein was either not detectable or present at a very low level. When the *Spm* element was present with the *wx-m8* allele, sectors of endosperm tissue showed the *Wx* phenotype and a 58 kd protein was present in isolated starch granules. By contrast, when *Ac* was present together with the *wx-m6* allele, endosperm tissue showed sectors that were intermediate between the *Wx* and the *wx* phenotypes and a novel 60 kd protein was detectable on starch granules. Hence, reversion of the *wx-m6* mutation gives a protein that is structurally abnormal and appears to have an altered enzymatic activity. Only the 58 kd protein is present in starch granules from kernels that are heterozygous for the *wx-m6* and *wx-m8* alleles, but contain only the *Spm* element. Therefore, the structurally altered protein detected upon reversion of the *wx-m6* allele in the presence of *Ac* is not detected in the presence of *Spm*. Were the *Wx* locus a regulatory locus, both the 58 kd and the 60 kd proteins would be present in a kernel that is heterozygous for the *wx-m6* and *wx-m8* mutations and contains the *Spm* element. It was concluded that the *Wx* locus is the structural locus for the 58 kd protein [113].

Poly(A)$^+$ RNA purified from *Wx* and *wx* endosperms was translated in a rabbit reticulocyte in vitro translation system, and an antigenically related polypeptide was identified using antiserum raised against the *Wx* protein. No major 58 kd polypeptide was evident among the translation products, but a major 65 kd polypeptide was translated from *Wx*, and not from wx poly(A)$^+$ RNA. The 65 kd in vitro translation product may be a precursor that is synthesized, but not processed in the rabbit reticulocyte extract. Poly(A)$^+$ mRNA fractions substantially enriched for *Wx* mRNA were used to construct cDNA clones. Screening of cDNA clones was performed by selective hybridization to the mRNA sequence encoding the immunoprecipitable 65 kd *Wx* polypeptide. Further testing showed that the *Wx* cDNA hybridized to an abundant 2.3-kb poly(A) + RNA present in immature endosperm of plants homozygous for the *Wx* allele, but absent from immature endosperm tissue of a plant homozygous for a stable recessive *wx* allele. Finally, the *Wx* cDNA was shown to hybridize to a unique sequence in maize genomic DNA. That the unique sequence corresponds to the *Wx* locus was deduced from the results of hybridization analyses of DNA isolated from maize strains with and without a *Ds* insertion mutation at the *Wx* locus. The presence of the insertion at the *Wx* locus was correlated with the presence of a 2.4-kb insertion in the sequence homologous to the cloned *Wx* cDNA,

unequivocally establishing the homology of the cDNA to the *Wx* locus [113]. Sequence analysis of genomic and cDNA clones of the wild-type *Wx* gene showed that the coding region comprises 3,718 bp and is composed of 14 exons and 13 small introns. N-terminal sequencing of the mature Wx protein led to the identification of a maize amyloplast-specific transit peptide of 72 amino acid residues [114].

The *Wx* gene homologues were isolated from a number of species by isolating homologous clones or identification of DNA/protein sequences homologous to the maize *Wx* gene/protein. A rice genomic library was constructed in λEMBL-3 vector and screened using the maize *Waxy* gene DNA as probe. Two overlapping genomic clones containing the *Wx* gene sequence were identified. Sequencing and alignment with *Wx* gene of maize and barley revealed that the *Wx* gene in rice contains 13 introns and 14 exons. The full-length of rice *waxy* preprotein is 609 amino acid residues [115]. An analysis of Wx transcripts, Wx protein, and amylose content of 31 rice cultivars revealed that endosperm amylose and Wx protein contents are correlated with the ability of the cultivar to excise intron I from the leader sequence of the Wx transcript [116]. Sticky or glutinous rice quality is related to the low amount of amylose due to the mutant wx allele.

Sweet Corn The maize *sh2* mutant used in "supersweet" corn has negligible starch. The *Sh2* gene was predicted to be involved in carbohydrate metabolism, since the mutant *sh2* endosperm contains reduced starch. Candidate *Sh2* clones were identified from a cDNA library prepared from endosperm by differential screening with labeled cDNA of near-isogenic W64 *Sh2* and W64 *sh2* mRNA. The 1.3-kb cDNA clone pES6-66 hybridized to wild-type cDNA and not *sh2* cDNA. Clone pES6-66 was subsequently shown to hybridize to a restriction fragment length polymorphism (RFLP) associated with normal *Sh2* function in F2 segregants of *Sh2* × *sh2* crosses in three backgrounds [117]. To determine whether this clone was indeed *Sh2* or simply a closely linked gene, a series of maize stocks that differed only at the *Sh2* locus were used, including a wild-type *Sh2* allele (progenitor), *sh2-m1* (mutable) allele containing *Ds* at the *sh2* locus, and *Sh2* revertants [118]. Southern blot analysis using 500-bp fragment derived from pES6-66 as probe showed that *sh2-m1* yielded a fragment that is approximately 1,600 bp larger than that seen in the progenitor or revertant. The data are compatible with *sh2-m1* containing a 1,600-bp insertion. RNA gel blot analysis indicated that the size of the wild-type transcript is approximately 2.0–2.2 kb. A cDNA library constructed from poly A^+ RNA of *shrunken-1*, *bronze-mutable4* (*sh1 bz-m4*) was screened using probes derived from pES6-66. Eight of the 14 clones isolated had the 1.95-kb insert and were almost full length. The 900-bp and 1,050-bp *Eco*RI fragments from one of these clones were subcloned and sequenced. Examination of the 1.95-kb cDNA sequence identified only one open reading frame (ORF) coding for 542 amino acids and making up a polypeptide of 59,845 Da. Homology search identified the *Escherichia coli* glucose-l-phosphate adenyltransferase (ADP-glucose pyrophosphorylase or ADP-glucose synthetase, EC 2.7.7.27) was the only protein having significant similarity to the amino acid sequence of the *Sh2* cDNA [118].

The maize *sugary1* (*su1*) mutant accumulates twice as much sugar as sweet corn, having reduced starch. Mutations at the *su1* locus were generated by crossing active *Mutator* (*Mu*) plants with standard lines. Mutant alleles were identified following the self-pollinations of the F1 plants. Normal and sugary sibling kernels from a population segregating 1:1 for the nonmutant allele *Su1* and *su1-R4582*::*Mul* were germinated, and genomic DNA used for Southern blot analysis using the *Mu1* fragment as probe. A 4.0-kb *Eco*RI fragment containing sequences homologous to the transposon *Mu1* that cosegregated with *su1-R4582*::*Mu1* was identified. This 4.0-kb *Eco*RI fragment was subsequently cloned by screening a BAC library, based on hybridization to a probe internal to *Mu1*, and the genomic DNA insert was subcloned as part of plasmid pMJ60. The nucleotide sequence of both termini of the transposon were determined and found to match the known sequence of *Mul*. A 1.0-kb *Bam*HI-*Eco*RI genomic fragment flanking *Mu1* in the cloned DNA was purified and used as a hybridization probe (termed BE1000). This genomic probe detected a 4.0-kb *Eco*RI fragment that was present in all *su1-R4582*::*Mu1/su1-Ref* plants but was missing from all *Su1/su1-Ref* plants. Thus, the cloned *Mu* transposon is the same element that is within or tightly linked to the *su1* gene locus. Probe

BE1000 identified a second *Eco*RI fragment of 2.6 kb that was present in all plants examined, and representative of the nonmutant progenitor allele. Presumably, insertion of the 1.4-kb transposon *Mul* within this 2.6-kb region resulted in the 4.0-kb *Eco*RI fragment that cosegregated with *su1-R4582::Mu1*. Mutations of the *su1* gene locus other than *su1-R4582::Mu1* were analyzed to determine whether they also cosegregated with physical alterations in the cloned region of the genome. Populations segregating for the nonmutant allele *Su1* and either *su1-R2412*, *su1-R7110*, or *su1-R3162* was digested with *Eco*RI and probed in DNA gel blot analysis with genomic fragment BE1000. In the *su1-R7110* and *su1-R3162* families, the 4.0-kb *Eco*RI fragment was present in all the seedlings grown from sugary kernels but was not observed in any seedlings grown from nonmutant sibling kernels. A different *Eco*RI fragment, 4.6 kb in length, was found to cosegregate with *su1-R2412*. The mutation *su1-R2412* is likely to have occurred via insertion of a 2.0-kb element into this same region. Approximately 200,000 lambda clones from a maize endosperm cDNA library were screened with genomic probe BE1000. DNA from eight different hybridizing clones was digested with EcoRI; the largest cDNA insert was 2.4 kb in length. Rapid amplification of cDNA ends (RACE) protocol was used to obtain the 5′ end of the *sul* cDNA. Sequencing of *su1* cDNA and BLAST search of the deducted amino acid sequence showed that *su1* cDNA specified a polypeptide of at least 742 amino acids, which is highly similar in amino acid sequence to bacterial enzymes that hydrolyze α-(1 → 6) glucosyl linkages of starch [119].

Rice Seed Color Red pericarp is ubiquitous among the wild ancestors of cultivated rice (*Oryza rufipogon*), in which it is closely associated with seed shattering and dormancy. On the other hand, most rice (*Oryza sativa*) that is grown and consumed throughout the world has white pericarp, showing that white pericarp is associated with domestication and remains under strong selection in most rice breeding programs today. A QTL associated with red pericarp, *rg7.1*, was mapped on chromosome 7 using two independent BC2 populations derived from crosses between an accession of *O. rufipogon* (IRGC-105,491) from Malaysia and, in one case, a US tropical japonica cultivar, Jefferson, and in the other case, a widely planted tropical indica cultivar, IR64. The log of the odds scores associated with the *rg7.1* QTL peaks in these two populations were 99 and 33, respectively [120, 121]. The peak of both QTLs corresponded to the previously mapped position of the mutant locus, brown pericarp, *Rc* [122]. Fine mapping using 1,410 BC2F3 plants and high-resolution mapping using 4,000 BC2F6 plants narrowed the rg7.1 QTL to an 18.5-kb region. Two genes encoding CACTA type, *En/Spm* subclass, transposon proteins, and one gene encoding bHLH protein were detected within the 18.5-kb target region. Sequence comparison of bHLH locus between cv Jefferson and H75, an *Rc* mutant stock belonging to the japonica subspecies, carrying a functional allele, but much more closely related to cv Jefferson than to *O. rufipogon*, showed that the coding sequence of the bHLH allele in H75 was identical to the cv Jefferson sequence except for a 14-bp indel in exon 6. This 14-bp sequence was present in the H75 stock as well as in *O. rufipogon*, but was deleted in cv Jefferson and cv Nipponbare. The deletion induces a frame shift in the sequence, resulting in two premature stop codons before the end of exon 6. The stop codons truncate the protein before the bHLH domain. Sequence analysis of bHLH of Surjamkuhi, an indica line that carries a third allele, *Rc-s*, conditioning light red seed pigmentation, showed that the sequence of this line differed from the *O. rufipogon* allele at only four sites (positions 96, 660, 1353, and 1833–1844). The first two changes proved to be synonymous substitutions. The change at position 1353 consisted of a C-to-A change in exon 6. This single-nucleotide polymorphism (SNP) was independent of any change seen in previous comparisons and represented a premature stop codon before the bHLH domain, truncating the protein and rendering the effect of the remaining indel immaterial. Conventional reverse transcriptase-PCR showed no expression of *Rc* in leaf tissue; however, expression was seen in panicles before fertilization, pericarp from grains in the milk or dough stage of filling, and pericarp from mature seeds. Similar expression levels of Rc were detected in cv Jefferson and *O. rufipogon* [121].

Seed Shattering

Wild plant species shatter their seed from the mature infloresence and thus disperse seed for the next

generation to be seeded, while during domestication humans have selected for non-shattering plant types from which the seed can be harvested or gathered from the crop. Study of shattering has been very fruitful in Arabidopsis, setting up the genetic models for shattering phenotypes [123] that have been also revealed in other crops like the cereals.

In rice, a major QTL for seed shattering, *sh4*, has been mapped on chromosome 4 using segregating populations derived from crosses between *O. sativa* ssp. indica and the wild perennial species *O. rufipogon* [124, 125], between *O. sativa* ssp. japonica and *O. rufipogon* and two other closely related wild species *O. glumaepetula* and *O. meridionalis* [126, 127], and between *O. sativa* ssp. indica and the wild annual species *Oryza nivara* [128]. High-resolution mapping using 12,000 F2 (*O. sativa* ssp. indica x *O. nivara*) delimited *sh4* to a 1.7-kb region of a gene with a previously unknown function. The comparison of the 1.7-kb sequences between the mapping parents revealed seven mutations located in the intron, exon, or 5′ upstream of the start codon. Sequencing of this 1.7-kb region from an additional 14 rice cultivars of *O. sativa*, 21 accessions of *O. nivara*, 6 accessions of *O. rufipogon*, and 1 accession of each of the four remaining wild A-genome species and their association with shattering phenotypes showed that a nucleotide substitution of G for T or an amino acid substitution of asparagine for lysine in the first exon was selected for the development of non-shattering cultivars during rice domestication. Annotation of the sh4 protein identified a Myb3 DNA binding domain and a nuclear localization signal, suggesting that *sh4* is a transcription factor. Transformation of a binary plasmid carrying *sh4-GFP* fusion under the control of *Ubi* promoter into rice cv. Taipei 309 determined the nuclear localization of GFP-tagged *sh4*. Transformation into rice cv. Taipei 309 of a binary plasmid carrying *O. nivara* sequence from the 3′ nontranslated region to the inclusion of the G-T mutation site and *O. sativa* sequence for the rest sequence until the 5′ regulatory region, but not the one carrying a shorter *O. nivara* sequence excluding the G-T mutation site, showed significantly reduced strength of grain attachment to pedicel [128].

A major QTL for seed shattering, *qSH1*, was first mapped on chromosome 1 using 182 F2 plants of a cross between Kasalath (a shattering-type *indica* cultivar) and Nipponbare (a non-shattering-type *japonica* cultivar). A near-isogenic line (NIL) was developed that contained a short chromosomal segment from Kasalath at the *qSH1* region in a Nipponbare genetic background. The NIL had a stronger seed-shattering phenotype than either Kasalath or Nipponbare. High-resolution mapping using 10,388 plants from the BC4F2 and BC3F2 populations segregating at the *qSH1* region succeeded in mapping the functional natural variation in 612 bp and only one single-nucleotide polymorphism (SNP) was found within this region. No distinct open reading frame (ORF) was identified in the SNP region based on gene prediction for the *qSH1* region in both Nipponbare and Kasalath genome sequences. However, one ORF for a rice ortholog of the Arabidopsis *REPLUMLESS* (*RPL*) gene was found 12 kb away from the SNP. The *RPL* gene encodes a BEL1-type homeobox and is involved in the formation of a dehiscence zone (or abscission layer) alongside the valve in the *Arabidopsis* fruit (silique). Transformation of 26-kb Kasalath genomic fragments scanning the predicted ORF and the SNP regions into the non-shattering Nipponbare cultivar showed complementation of the complete seed-shattering phenotype. The other fragments were not able to complement the phenotype, even if they contained the entire ORF region or the SNP region. These results indicated that both the ORF and the SNP regions were required for full shattering function. *In situ* hybridization analysis revealed that in the NIL the ORF was expressed at the inflorescence meristem in the stage of rachis meristem establishment [inflorescence stage 1 (In1)]. It was also expressed at both the anther region and the provisional abscission layer at the base of the spikelet in the stage of floral organ differentiation (In7) and in the stage of rapid elongation of the rachis and branches (In8). On the other hand, in Nipponbare, the ORF was expressed in the same way as in the NIL, except that it was not expressed at the provisional abscission layer in either In7 or In8. These results, together with the complementation results, indicated that this *RPL* ortholog was the *qSH1* gene and that the identified SNP affected only the spatial mRNA expression pattern of *qSH1* at the abscission layer [129].

A shattering mutant line of rice, Hsh, was derived from a non-shattering japonica variety, Hwacheong, by

N-methyl-N-nitrosourea (MNU) treatment. Optical microscopy revealed that Hsh had a well-developed abscission layer similar to the wild rice *Oryza nivara*, while Hwacheong did not produce an abscission layer. Genetic analysis showed that the easy shattering of Hsh was controlled by the single recessive gene *sh-h*. Using an F2 population consisting of 240 individuals derived from the Hsh/Blue&Gundil cross the *sh-h* was mapped on chromosome 7 [130]. Fine mapping using six newly developed SSR markers delimited the *sh-h* locus to a 150-kb region. Further mapping using three newly developed SNP markers on five F3 recombinant lines derived from F2 heterozygous plants narrowed the *sh-h* locus to a 34-kb region. Analysis of genomic sequences from Hwacheong, Hsh, and Blue&Gundil lines identified eight genes in this region. Among these, a gene which encodes a protein containing a conserved carboxy-terminal domain (CTD) phosphatase domain was considered to be a strong candidate for the *sh-h* locus because of the presence of a point mutation at the 3′ end splice site of its seventh intron. Sequencing of the RT-PCR products of Hwacheong and Hsh revealed that, compared with Hwacheong, a 15-bp deletion was induced by altered splicing in the mRNA isolated from Hsh. Because the consensus sequence for splicing at this "AG" site was changed to "TG," the next "AG" sequence, 15-bp downstream, was used as a new splice site. The 15-bp deletion in the Hsh mRNA resulted in the deletion of five amino acids in the C-terminal region of the CTD-like phosphatase domain (CPDc), which are situated within the phosphatase active site. Two transferred DNA (T-DNA) insertion mutants and one point mutant exhibited the enhanced shattering phenotype, confirming that this CTD phosphatase-like gene is indeed the *sh-h* gene. RNA interference (RNAi) transgenic lines with suppressed expression of this gene exhibited greater shattering [131].

Tolerance to Abiotic Stresses

Wild species are adapted to the environment where they are found; survive over long periods of time by creating diversity where environmental selection pressures allow the fit to reproduce and survive. The environmental stresses include abiotic stresses such as heat, cold, drought, salt, light, radiation, heavy metals, soil pH, and others. Plant response to these stresses has been studied and shows common and unique responses [132].

Salinity Stress Tolerance Salinity tolerance has been amenable to study for phenotypic variation and the genetic dissection into quantitative traits. In rice, a major QTL for shoot K + content under salt stress, *SKC1*, was mapped to chromosome 1 using 133 lines of an F2 and an equivalent F3 population derived from a cross between a salt-tolerant indica variety Nona Bokra, and a susceptible elite japonica variety Koshihikari [133]. Fine mapping was performed using 192 BC2F2 plants, and a high-resolution map was subsequently generated with 2,973 BC3F2 plants using markers newly developed on the basis of the PAC clone sequences. Progeny testing of fixed recombinant plants (BC3F4) delimited the *SKC1* locus to a 7.4-kb region, and only one predicted open reading frame (ORF) was identified in the region. The *SKC1* promoter region (2,554-bp upstream of the initial codon) and the coding region of the cDNA clone (1,665 bp) were ligated and subcloned into a plant binary vector. This construct was transferred into the japonica variety Zhonghua 11, which contained the same *SKC1* allele as Koshihikari and is salt susceptible. Shoot K + concentrations were substantially higher in all six T1 progeny containing the Nona Bokra *SKC1* transgene compared with plants containing the vector control under salt stress but not under normal condition. Database searches showed substantial similarity between SKC1 and the HKT-type transporters found in plants, bacteria, and fungi. Comparison of nucleotide sequences between Nona Bokra and Koshihikari alleles showed six nucleotide substitutions in the coding region that lead to four amino acid changes, which may be responsible for the functional difference between the two alleles. RT-PCR analysis in both Koshihikari and NIL (*SKC1*) showed that *SKC1* transcript levels were upregulated by salt stress in the root but not in the shoot. Under normal condition, K^+ and Na^+ contents in NIL (*SKC1*) shoots were not substantially different from those in Koshihikari. But under salt stress, NIL (*SKC1*) shoots had a higher K^+ content and lower Na^+ content than Koshihikari shoots. No substantial differences in K^+ and Na^+ contents were observed in the roots under either normal or stress condition. Consistent with the results of shoot analysis, K^+ and Na^+ contents in xylem sap were not different between NIL (*SKC1*) and Koshihikari; under salt stress, however, the xylem sap of NIL (*SKC1*) contained more

K^+ and less Na^+ than that of Koshihikari. These results indicated that *SKC1* is involved in regulating K^+/Na^+ homeostasis in the shoots [134].

Submergence Tolerance A major QTL for submergence tolerance, *Sub1*, was mapped to chromosome 9 using 169 F2 plants and the resulting F3 families of a cross between a tolerant indica rice line, IR40931-26 (a descendant of FR13A), and a susceptible japonica line, PI543851 [135]. High-resolution mapping using 2,950 F2 individuals and the resulting F3 families of a cross between DX18-121 (a tolerant F3 plant from the first population) and M-202 (a submergence-susceptible japonica cultivar that is widely used in California) identified 2 AFLP markers localized within 0.2 cM of *Sub1* [136]. The *Sub1* locus was delimited to an interval of 0.06 centimorgan using 4,022 F2 individuals from the cross between DX18-121 and M-202. Physical mapping with five overlapping bacterial artificial chromosome (BAC) clones derived from submergence-intolerant indica rice varieties and a nearly complete contig of 13 binary clones from IR40931-26 showed that *Sub1* region physically spans over 182 kilobases (kb). This interval encodes three genes containing ethylene response factor (ERF) domains and designated *Sub1A*, *Sub1B*, and *Sub1C*, ten non-ERF genes including four transcribed and six hypothetical protein-coding genes, and >50% retrotransposon-related sequences. The corresponding region of the japonica genome represented by the sequenced variety Nipponbare spans 142 kb and is considerably rearranged. Notably, *Sub1A* is absent from the rice reference Nipponbare genome. Accumulation of *Sub1A* and *Sub1C* messenger RNAs was strongly but transiently promoted by submergence in seedling leaves of tolerant FR13A, while *Sub1B* transcripts increased only slightly during submergence. The ten non-ERF genes in the indica *Sub1* region showed no evidence of expression in seedling leaves before or during submergence in IR40931-26 or the intolerant variety M-202. A survey of the *Sub1* locus haplotypes in 17 indica and 4 japonica varieties identified 2 *Sub1A*, 9 *Sub1B*, and 7*Sub1C* alleles on the basis of variation in amino acid sequence. The *Sub1A-1* and *Sub1C-1* alleles are limited to all six submergence-tolerant accessions. There was no *Sub1B* allele identified as being specific to submergence tolerance. In the tolerant *Sub1A-1* allele, a single-nucleotide polymorphism at position 556 is responsible for a Pro 186 (intolerant) to Ser 186 (tolerant) substitution in a MAPK site. Conversely, the *Sub1C-1* allele of tolerant lines lacks a MAPK phosphorylation site present in the alleles of the intolerant accessions. A *Sub1A-1* full-length cDNA under the control of the maize Ubiquitin1 promoter was transformed into an intolerant japonica variety Liaogeng. A screen of seedlings after 11 days of submergence identified four T1 families, derived from independent T0 Ubi:Sub1A + lines, with submergence-tolerant transgenic individuals, and progeny from two families were examined in detail. T1 families one and three showed a correlation between high expression of the *Sub1A-1* transgene and submergence tolerance. As observed in the FR13A descendant IR40931-26, tolerant Sub1A-1+ plants showed a significant impairment of shoot elongation under submergence compared with the intolerant parent Liaogeng and non-transgenic siblings [137].

Aluminum Tolerance In wheat (*Triticum aestivum* L.) mechanisms that minimize the harmful effects of Al ions have been investigated using near-isogenic lines [ET8 (Al-tolerant) and ES8 (Al-sensitive)] that differ in Al tolerance at a single dominant locus designated as *Alt1*. The *Alt1* locus cosegregates with an Al-activated malate efflux from root apices [138, 139]. One cDNA clone more highly expressed in the root apices of ET8 compared to that of ES8 was isolated by subtractive hybridization. The full-length cDNA was obtained by rapid amplification of cDNA ends (RACE)-PCR. The predicted protein is hydrophobic having six to eight putative transmembrane regions. Heterologous expression of this gene in *Xenopus oocytes* indicated that this gene encodes an Al-activated transporter that facilitates the efflux of malate but not citrate. Based on this result, the gene was named *ALMT1* (aluminum-activated malate transporter). Sequencing the *ALMT1* cDNAs derived from ET8 and ES8 showed that the sequences differed at six nucleotides that resulted in the deduced proteins differing at two amino acid residues. Sequence of the *ALMT1* coding region in Atlas66 (Al-tolerant cultivar) was identical to that of the ET8 allele, while the sequence in Scout66 (Al-sensitive cultivar) was identical to that of ES8. As found for the ET8 and ES8 lines, the expression of *ALMT1* in the root apices was

greater in Atlas66 compared to Scout66. Expression analysis of *ALMT1* in the 57 F2 individuals derived from a cross between ET7 and ES5, the near-isogenic progenitor lines of ET8 and ES8, showed that all the Al-sensitive seedlings expressed the ES8 allele only, whereas Al-tolerant seedlings expressed either ET8 allele only or both ET8 and ES8 alleles. Thus, the ET8 allele was expressed only in the Al-tolerant seedlings, indicating that, in this population, the Al-tolerant phenotype was correlated with the higher expression of this allele. Evaluation of Al tolerance and genotype analyses using an RFLP marker and a PCR-based assay on 204 F3 families derived from a cross between ET8 and ES8 showed that the ET8 allele of *ALMT1* completely cosegregated with the Al-tolerant phenotypes and the Al-tolerance locus, *Alt1*. Heterologous expression of *ALMT1* in cultured tobacco cells increased the tolerance of tobacco cells to Al treatment [140].

Future Directions

The present era of plant sciences is distinguished by an integration of multiple disciplines toward a transdisciplinary/interdisciplinary approach of doing science, utilizing the technology and knowledge from computer science and bioinformatics, genomics, dedicated instrumentation for high-throughput automation of laboratory and field tasks, which can all together provide integrated models and technologies for the improvement of crop traits. The paradigm shift in genetics, due to the reduced cost in genome sequencing, is to be able to generate the genome sequence of any plant genotype of interest that will totally revolutionize the approach to use this information. With a few genetic crosses followed by whole genome sequencing of all genotypes, it would be possible to identify genes and useful alleles that can be incorporated into plant improvement programs. This would make the traditional ways of isolating or identifying gene sequences for crop traits obsolete. The lag will be in phenotyping individual genotypes, which will remain the challenge for the biologist. The association of genes to a trait will still require that traits be characterized, dissected into components and parameters that can be measured, and the candidate gene(s) validated by some reverse genetics strategies using methods such as mutant analysis, transformation, and complementation, at least till the function of every gene/allele is known and how these genes and their alleles interact together to determine the phenotype of a crop trait.

Article Outline

Glossary

Allocative efficiency Efficiency with which given variable input(s) is used.

Attainable yield Yield reached by farmers with economically optimum management and reasonable risk aversion.

Ecotilling Seeking related alleles across germplasm collections based on DNA homology.

Farm yield Average grain yield across farms in a region.

Harvest index Ratio of grain dry weight to total above-ground dry weight at maturity.

Molecular markers Short sequences of DNA that are homologous with sequences close to or within important genes.

Potential yield Grain yield in the absence of manageable abiotic and biotic stresses.

Potential yield water limited Grain yield in the absence of manageable abiotic and biotic stresses apart from that imposed by water supply through inadequate rainfall.

Radiation use efficiency Above ground biomass produced per unit of total solar radiation intercepted by green crop tissue.

Technical efficiency Practices, timing, and technical skills adopted by farmer in using inputs.

Yield gap Difference between farm yield and potential yield.

Definition of Subject

The entry assumes that yield increase will continue to play a dominant role in world food security, as it has over the last 60 years. It is restricted to annual grain crops, since these dominate the world's arable landscape (>70%) and humankind's food supply (>70%), including grain used as livestock feed. Crop yield is the weight of grain, at some agreed standard moisture content, harvested per unit of land area per crop (note, there can be two or even three annual crops per year in some favored environments, meaning a cropping intensity of 200% or 300%, respectively). The starting point for yield is usually the field, district, regional, or national average yield in kg or t per hectare, as reported in surveys or local or national statistics. Here this is referred to as farm yield (FY, t/ha). This and many related cropping statistics are collated annually for all countries by FAO (http://faostat.fao.org/site/567/default.aspx#ancor). FY is usually expressed relative to harvested land area (note: this can fall well below planted area in some situations). Although FY is quoted and used widely, it may not be as accurate as it appears due to uncertain grain admixtures and/or poor collection of the statistics. With survey data sampling error can also arise.

At the highest end of the yield scale it is useful to define *potential yield* (PY), which is the yield to be expected with the best adapted cultivar, the best management of agronomic inputs, and in the absence of manageable abiotic and biotic stresses [1]. Many complications are hidden within this apparently simple definition. PY is usually determined in plots, with of course sampling error. In order to be relevant to the surrounding district, the natural resource base of the plot (climate, soil type, topography) needs to be comparable, including any long-term management investments to improve this aspect of the site (e.g., liming, tile drainage). Water supply must be adequate for PY determination as defined, and this can come from well-distributed rainfall close or equal to crop potential evapotranspiration (crop water use from sowing to harvest without water limitation) or from full or supplemental irrigation; in addition, pests, weeds, and diseases must be held at negligible levels through the use of biocides if necessary. Finally, crops experiencing

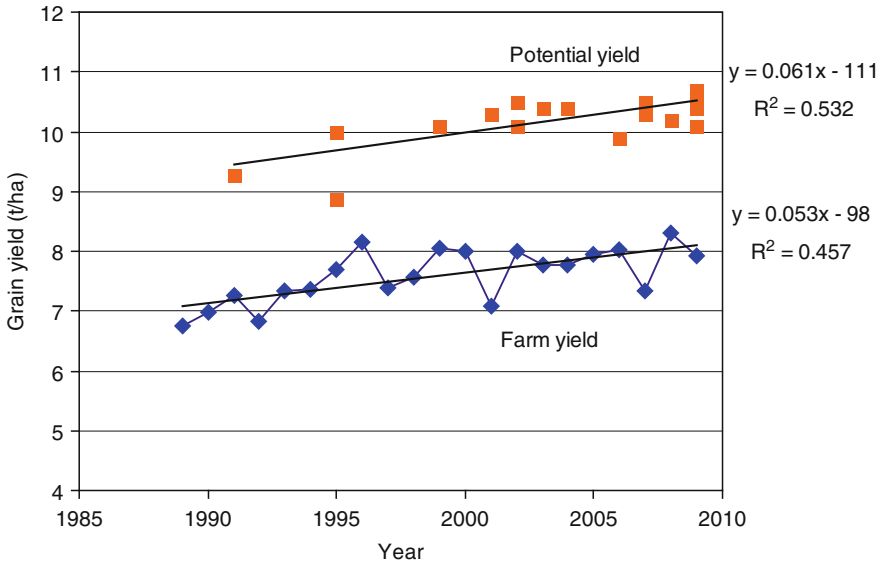
relatively rare weather damage such as crop lodging or unseasonal frosting are excluded from PY measurement. Taken overall, it would seem PY might be impossibly difficult to measure, but it is reported often in the crop science literature, although not always with proper attention to the above caveats.

Since PY is usually measured in plots, edge effects arising from extra solar radiation or soil moisture or nutrients reaching outside plants must be avoided by discarding the plot edges. Two types of PY plots are commonest. Often they are well-managed yield trials to compare new varieties or advanced lines against older ones, or even historic ones, to give measures of breeding progress by plotting variety yield against year of release. The most useful such trials, for example those for wheat conducted by the UK Home Grown Cereals Authority (HGCA http://www.hgca.com/content.template/0/0/Home/Home/Home.mspx), measure yields with and without fungicide protection. Only the former yields are a measure of true PY, but fungicide protection is still not very common in such yield trials around the world, although visible disease levels are usually reported and can be negligible. The second source of PY data comes from experiments conducted by crop physiologists to calibrate and/or validate crop simulation models: the models, driven largely by various aspects of solar radiation and temperature, can then be used to predict PY in other environments (e.g., sowing dates, years, locations). For such purposes modeling accuracy has steadily improved, but models need to be updated with the latest varieties every few years, since breeders are steadily altering varieties (e.g., phasic development, improving PY). Sometimes, crop contest yields or crop record yields are considered to be synonymous with PY. But they need to be treated with caution, because they usually exceed PY measured as defined here, probably because they refer to very favorable circumstances (e.g., soils, weather, management), relative to the district average; nevertheless, we can learn from such yields if all site and management variables are quantified. For example, properly verified world record yields, invariably higher than PY values, not only extend our simulation models but also reveal that there is no anatomical limitation to very high yields, the main limitation evident with such yields being the stem strength needed to support them.

Since much of the world's grain crops are grown in rainfed situations where water supply from precipitation plus starting soil storage falls well below the potential evapotranspiration, it is also useful to define a *water-limited potential yield* (PYw, t/ha): it is the yield obtained with no other manageable limitation to the crop apart from the water supply. Obviously, it will depend on the amount of water, so PYw is usually plotted relative to water supply (or use), the slope being the crop water use efficiency or water productivity, commonly reported in kilograms per hectare per millimeter. Complications can arise due to variation in rainfall distribution with respect to crop development stages, but PYw, defined as a linear function of the water supply, is a very useful simple benchmark, as argued in a recent in-depth review by Passioura and Angus [2], while simulation modeling has been especially useful in dealing with expected deviations due to variation in the distribution of water supply.

In any given region, between FY and PY (or PYw), there is another useful yield notion, namely *attainable yield* (AY, t/ha), which is defined here as the yield attained by a farmer with average natural resources adopting economically optimal practices and levels of inputs. Since risk of financial loss is almost always part of a farmer's decision to invest in increased inputs, the AY definition must temper "optimum level" with "prudent attention to risk"; as an example this could mean input investments must be expected to return at least 50% in net profit at the margin. Of course, AY will reflect the economic circumstances of the crop and region, in particular grain prices relative to input ones, all measured at the farm gate. Thus, it is not easy to know AY, but general experience suggests that it lies around 20–30% below PY in situations where world prices and reasonable transport costs operate. FY for wheat in the UK probably meets these conditions (Fig. 1). Where this does not occur, for example, in much of sub-Saharan Africa where infrastructure and institutions are weak, the AY as defined above may be much lower; alternatively where inputs and grain prices are heavily subsidized, AY could approach closer to PY. Because of these uncertainties, it is easier to talk of the *yield gap* in terms of the FY to PY gap, bearing in mind that even in the most advanced cropping situations in developed economies, operating at close to world prices, FY will remain significantly below PY. Since it



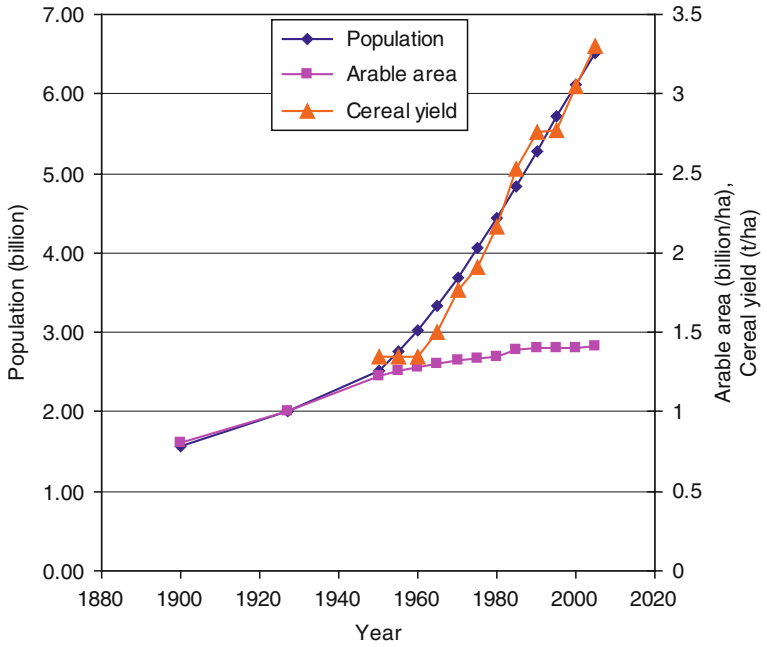
Crop Yields Around the World: Closing the Gap and Raising the Potential. Figure 1
Change in farm yield (FY) and potential yield (PY) with time for wheat in the UK. Source: FAOStat and HGCA. Note that in this and other figures (except Fig. 4), PY is plotted against year of variety release, for varieties are compared side by side in recent yield trials under modern management

is more appropriate to express this gap as a percentage of FY, it can be assumed from the literature that this minimal gap is reached when the PY–FY gap is about 30% (of FY). Any larger gap that this, which is usually the case, is often defined as an "economically exploitable yield gap," but bearing in mind that the expected exploitation can be as much a task for national and local government and agribusiness, as for the farmers.

Introduction

Crop yield has been the subject of attention since the days of Malthus and earlier. More recently, many have pointed out that the improved supply of food calories per capita globally, and reduced real costs of grain, over the last 60 years has been due almost entirely to global crop yields growing faster than the burgeoning world population (e.g., [4]), for there have been only small increases in cropped area (Fig. 2). The world population will grow to over nine billion by 2050, and grain demand is projected to increase around 60–70% (compared to 2000) [5], with others projecting even greater increases, and certainly more rapid increase coming early in this period. Seventy percent over 50 years amounts to an exponential increase of 1.1%; output growth must match this or real prices will increase (see also later). There is some potential new arable land of reasonable quality in South America and sub-Saharan Africa (and in northern latitudes of Russia), but increase in arable area demands heavy capital investment and brings negative environmental consequences; indeed, maintenance of arable area could be a challenge in densely populated fast-urbanizing regions like South and East Asia, and where there is continuing arable land degradation. Crop area can also increase through intensification of annual cropping but that usually depends on expansion in irrigation, which has in fact slowed markedly, especially in Asia where water availability for agriculture is now constrained. As a consequence, most argue that the projected increase in grain demand must continue to be met by yield increase.

Many grain crops have exceeded 1% exponential yield growth in the early decades of the modernization of agriculture last century, including the Green Revolution period for rice and wheat in Asia, but global yield growth trends for most crops over the last 20 years have slowed and have become linear, with current

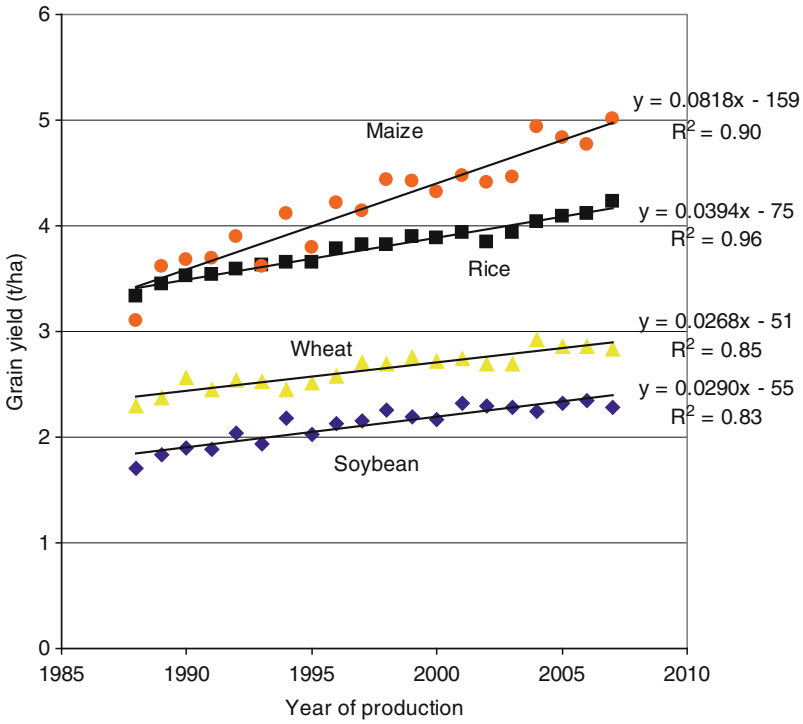


Crop Yields Around the World: Closing the Gap and Raising the Potential. Figure 2
Change in world population, global arable area, and cereal yield. Adapted with permission for Evans (1998)

growth rates at or below 1%; maize at 1.6% and soybeans at 1.1% are the only major crops exceptions to this (Fig. 3; note growth rate is expressed here by calculating the linear slope as a percentage of current predicted yield for each crop). Increasing the proportion of a crop which is irrigated can increase yield growth, as happened with wheat in Asia in the 1960s, but further increases in irrigation area are unlikely, due to cost and/or lack of water, except possibly in sub-Saharan Africa. This leaves the maintenance, or preferably boosting, of rates of yield increase in existing cropped situations as the major route for meeting growing demand for grain, and the major challenge facing agricultural science. And despite some media sentiment to the contrary, agricultural scientists are fully aware that this goal has to be met while sustaining, or better still, improving the natural resource base of cropping, and while confronting the uncertain and predominantly negative projected impacts of climate change.

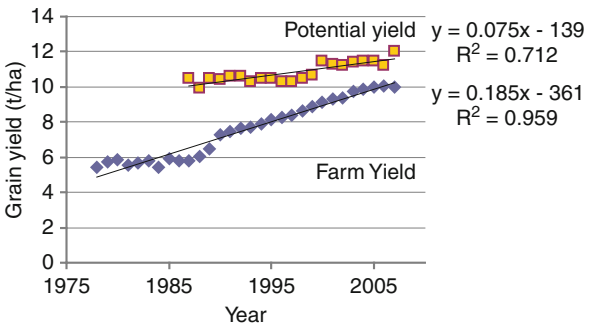
From the definition of the subject, it can be seen that there are two sources of yield increase: raising PY and closing the PY to FY gap (see also Figs. 1, 4 and 5). In most situations, both processes contribute simultaneously to FY increase, with farmers adopting new technologies (varieties, management techniques, input levels) that have been developed years or decades earlier by researchers at which time the associated rise in PY occurred. Recently, two trends in this process are becoming evident. Firstly, management or agronomic innovations for increasing PY, including their positive interactions with new varieties (e.g., the universal nitrogen by variety interaction in wheat and rice, or the plant density by hybrid variety interaction in maize), are becoming fewer, leaving a greater proportion of PY progress to breeding advances. This is a somewhat controversial observation but is clearly supported by analysis of the winter wheat yield changes in the UK [6]. Secondly, in some special situations, as mentioned earlier, the yield gap is approaching the minimal 30% or so dictated by current economics; examples include winter wheat in the UK (Fig. 1) and probably all of Western Europe), rice in Egypt (Fig. 4), and maize in the US corn belt (e.g., Iowa, see Fig. 6).

While it is not always easy to separate PY advance from gap closing, since this volume has given more



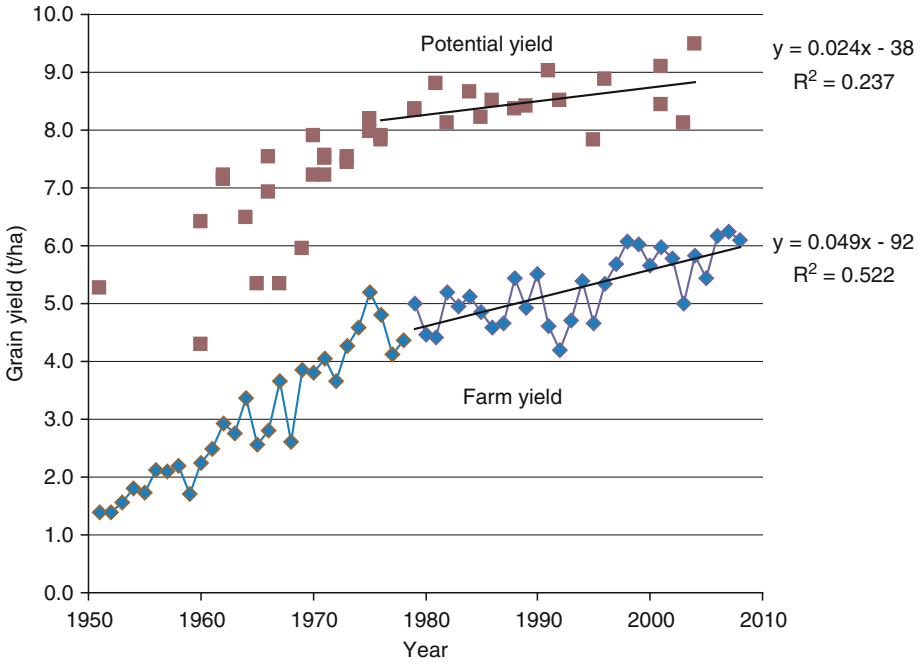
Crop Yields Around the World: Closing the Gap and Raising the Potential. Figure 3
World average yield versus time for wheat, rice, maize, and soybeans over last 20 years. Source: FAOStat

attention to the former, in particular the possibilities arising with new molecular biological techniques becoming available to plant breeders, this entry will give more attention to closing the yield gap than to raising PY. Both issues have been more fully discussed in Fischer et al. [5]. Another reason for concentrating here on closing the yield gap is that, notwithstanding the evidence of small yield gaps in some situations, it is likely that yield gap closing offers better prospects globally for quickly lifting FY progress, as is needed, than does boosting PY progress. The entry continues by looking at the size of the yield gap in various key situations around the world. Passing then to gap closure, traditionally this is considered to arise from farmer adoption of yield-enhancing technologies, the area of agricultural extension or technology transfer. While there is a lively body of socioeconomic research on this process, which will be considered briefly, the way the yield gap is defined here, it is hard to see the new products of breeding and agronomic research reducing the yield gap. This is because their initial

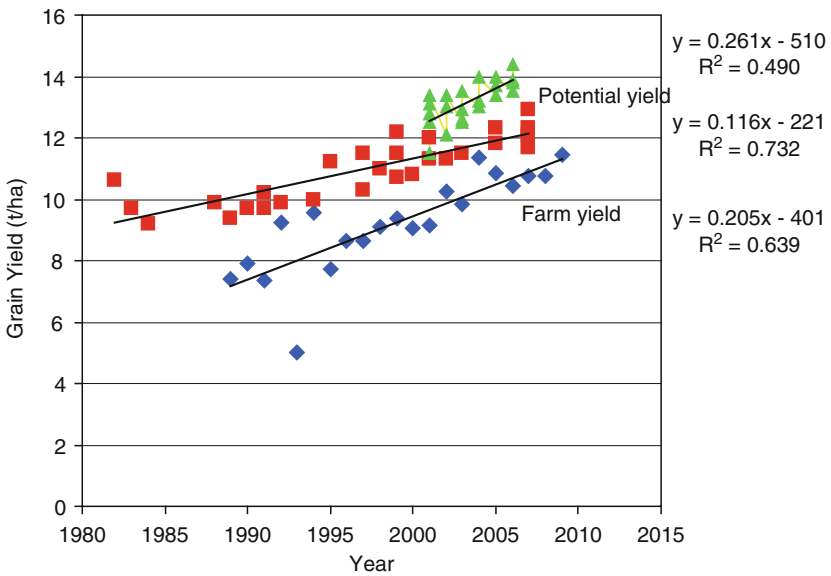


Crop Yields Around the World: Closing the Gap and Raising the Potential. Figure 4
Change in PY and in FY for rice in Egypt. Source: Badawi [3]; A. E. Draz, 2009, personal communication

impact should be on PY as defined, actually increasing the gap, followed by their gradual adoption which, if complete, might be expected to reduce the gap to the same relative value as before, other things being equal.



Crop Yields Around the World: Closing the Gap and Raising the Potential. Figure 5
Wheat PY and FY changes with time, Yaqui Valley, Mexico. Source: [5]



Crop Yields Around the World: Closing the Gap and Raising the Potential. Figure 6
Change in maize FY in Iowa compared to that in PY as estimated by Pioneer (Hammer et al. ([7], *red squares*) and de Kalb (Edgerton [8], *green triangles*) hybrid yields plotted against year of hybrid release

Needless to say the real situation is more complex and examples will be given of how such research, including progress in molecular biology, can help directly reduce the gap (e.g., more adoptable technologies, less costly ones, and better biotic stress resistance). The entry finishes by discussing briefly the current situation with progress in PY and PYw themselves. What will not be discussed further is the likelihood that atmospheric CO_2 increase will continue to improve all grain yields, other things remaining equal, but the rate of increase is currently around only 0.2% in a C3 crop like wheat [9], and less for C4 crops.

Estimates of Yield Gaps

Fischer et al. [5] attempted to estimate yield gaps and their rate of change for a number of key representative cereal-producing regions in the world. The most reliable estimates are summarized in Table 1, supplemented with a few new crops and numbers.

The yield gap estimates for wheat are remarkably consistent at around 50% except for the UK, where as mentioned before the 25% gap probably implies that FY is approaching AY, an AY largely determined by ruling world prices in the UK. Figure 5 illustrates the Yaqui Valley data, where there was substantial yield gap closing as the modern semidwarf varieties took over in the 1960s; lately, however, the yield gap has remained fairly steady at 50%. Lobell et al. [12] recently presented 12 published estimations of the yield gap for wheat in developing countries, the gap ranged from 5% to 150% but the average was close to that in Table 1, namely 55%.

For rice, Table 1 shows gap values around 100% or more for most developing country situations except for Central Luzon in the wet season (65%), and a remarkably low 15% for Egypt (see also Fig. 4). The value of 55% for Japan reflects the heavy emphasis on producing high-quality grain, acting as brake on FY progress, because food-quality rice varieties and agronomy deliver lower yields. From the 41 rice estimates from developing countries in [12], the average gap was 65%, with modeling evidence that the gap was 120% in northwest India (cf. 110% in the Indian Punjab in Table 1).

Table 1 has only two cases for maize: Iowa at 25% contrasts with Kenya at 200+%; sub-Saharan Africa as a whole is similar to Kenya. Tittonell et al. [13] in a detailed survey of farm yields in three districts in the favored Kenyan Highlands confirms the figure shown in Table 1, recording a mean FY of 1.5 t/ha when PY was 6–7 t/ha. Lobell et al. [12] give nine examples of rainfed maize in tropical and subtropical developing countries (average gap 200%) and examples of irrigated and rainfed maize in Nebraska based on simulation of PY and PYw which suggest gaps of 35% and 55%, respectively, both larger than that for rainfed maize in the adjacent wetter state of Iowa (Table 1). While there is no doubt about the huge yield gap with maize in Africa, some uncertainty exists in these critical estimates from the USA, where maize is probably the most intensively researched and promoted crop in the world. No doubt the gap is quite small in Iowa and Nebraska, where it has been closing lately, and FY may be close to AY (Fig. 6), although more PY progress data is needed for a clearer conclusion.

The soybean examples in Table 1 also show a large difference in the yield gap between a developed and developing country, but do not show developing countries Argentina and Brazil, where FY across more than 35 M ha with favorable rainfall is as high as the USA, and PY is unlikely to be any higher. Finally, millet, grown in India under very harsh conditions, shows a gap no worse that of soybeans in adjacent more favorable areas of India.

Closing Yield Gaps

Yield gaps are reduced by farmers adopting new technologies or practices (new at least for them) or adopting higher rates of inputs (e.g., many farmers in western Kenya use added nutrients, either fertilizer or organic ones, but the rate of nutrients applied may be very low relative to the need/optimum (e.g., [13])). Some of this is usefully illustrated in Fig. 7 derived from Byerlee [14].

FY under traditional practices with low inputs is shown by point A on curve 1. Adopting new technologies such as an improved new variety and practices (e.g., line sowing and fertilizer) lifts technical efficiency and brings curve 2 into play. The farmer may move from point A to point B, as in the first years of the Green Revolution. Allocative efficiency could then rise further as fertilizer levels increase, following curve 2 to

Crop Yields Around the World: Closing the Gap and Raising the Potential. Table 1 Estimates of current yield gaps for key crops and regions (compiled from [5] and elsewhere as noted)

Region	Environment	Crop area (M ha)	Yield (t/ha)[a] and gap(%), 2007 or 2008		
			FY	PY	Gap
Wheat					
Yaqui V, Mexico	Irrigated, low latitude	0.16	6	9	50

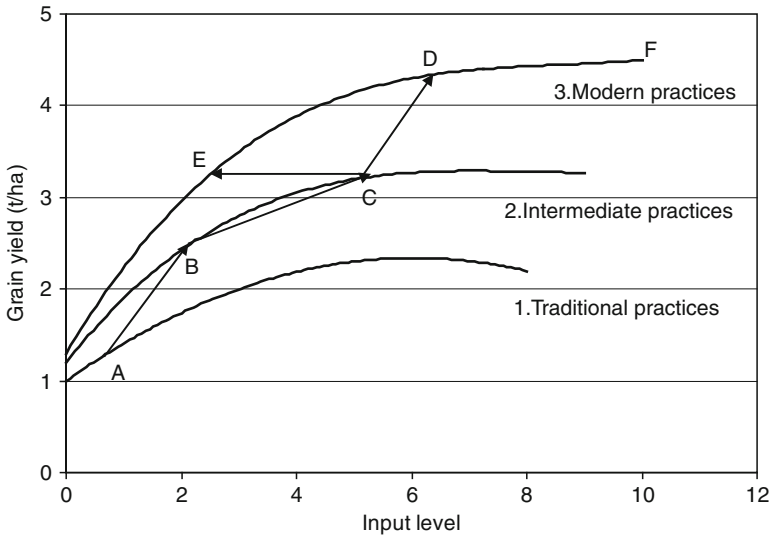
point C, approaching some economic optimum. An even newer variety and the best available practices (e.g., herbicides, conservation tillage) which together define current PY (point F) could lift the technical frontier further (the uppermost curve 3). Farmers might choose to further increase technical efficiency by moving to the uppermost curve, maximizing allocative efficiency at around point D, or sacrificing allocative efficiency, but not yield, by reducing inputs (point E). Of course, curve 3 is not static: for any given



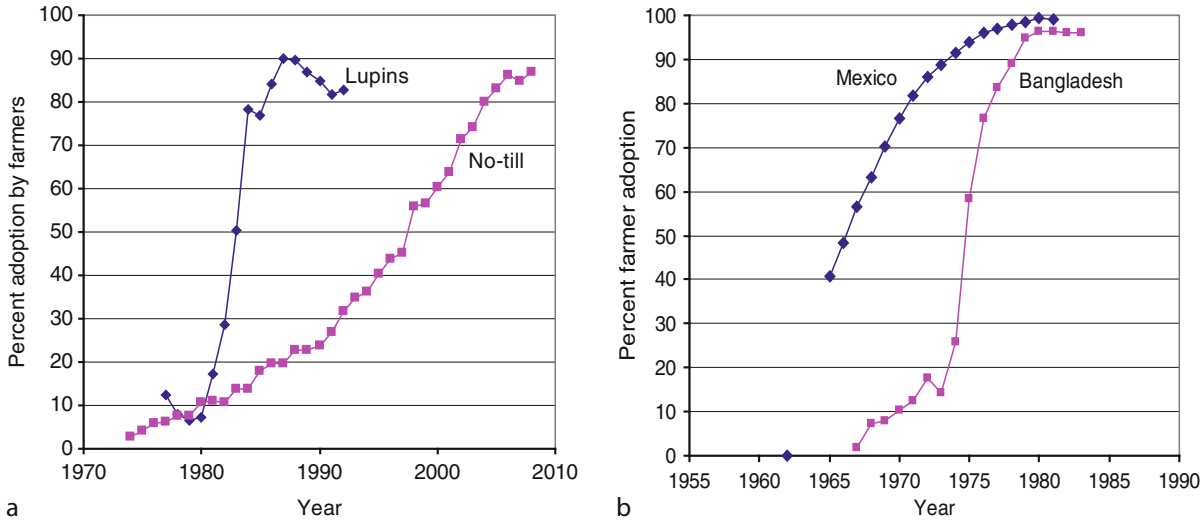
Crop Yields Around the World: Closing the Gap and Raising the Potential. Figure 7
Illustration of pathways from low FY to close the gap with PY; modified from Byerlee [14]

environment it may be moved further upward with new technologies, and it may also shift downward due to problems of resource degradation. This figure also serves to illustrate that the yield gap is not the same as an efficiency gap, gaps between curves are technical efficiency ones, gaps along curves are allocative ones, both combine to make up the FY to AY gap.

Adoption of New Technology

There is a rich agricultural economic literature on the adoption of new technologies by farmers. Examples for the adoption of two new technologies in the rainfed cropping in Australia are shown in Fig. 8a (a new crop, lupins, and a new practice, no till). The new crop was adopted faster than the new agronomic technique. Developing countries have proved equally fast in adopting new varieties (Fig. 8b) when the conditions are favorable. The well-recognized patterns of lag, rate of adoption, and ceiling adoption level clearly differ between technologies and farmers (regions); in addition, the infrastructural and institutional context is important. For the technology itself, key elements are its perceived relative advantage (return over cost, risk of loss, convenience, etc.) over that which it replaces, and its trialability, meaning the ease with which a new technology can be tested on a small scale. Farmer characteristics influencing adoption are very diverse and can also interact with the nature of the innovation: education, age, health, exposure to extension and related media and demonstrations, group pressure, and support can be important. But there is little doubt that farmers around the world, large and especially the small, women and men, aspire to increase monetary return and given the means to do so, will adopt more profitable practices.

It is in the area of rural infrastructure and institutions that developed and developing country farmer circumstances differ most. One obvious example is the effect of poor roads on increasing input costs and reducing prices for surplus farm output. For example, the price ratio of N fertilizer to grain is on average double that in other regions of the world and higher still in inland landlocked regions of sub-Saharan Africa [18]. The high cost of credit, uncertainties surrounding contracts (including land tenure), the risk of poor-quality inputs, theft or unrest, and the prevalence of unfavorable and uncertain tax and pricing policies, all make adoption less attractive in many developing situations. Sometimes, price subsidy on inputs and outputs can compensate for these brakes on adoption, such as in the recent situation where a well-crafted fertilizer supply



Crop Yields Around the World: Closing the Gap and Raising the Potential. Figure 8
Adoption of new technologies by (**a**) farmers in regions of Australia (lupins in Wongan Hills district [15] and no till in Loddon district [16]), and (**b**) semidwarf wheat varieties in Mexico and in Bangladesh [17]

and subsidy policy permitted Malawi, a nation of small holders, to produce an unprecedented surplus of maize and to do so without a maize price collapse. But in general and especially in sub-Saharan Africa the lack of public investment in infrastructure, institutions and agricultural extension, and the lack of sound policy are the major contributors to the yield gap.

Looking at farm-level technical constraints that contribute to the yield gap, in any situation there are usually multiple constraints, and the challenge is to determine which constrains should take priority, while recognizing that interventions often interact positively and are thus more effective when adopted together [19, 20]. This can only be answered by on-farm survey and experimentation. Such work started many years ago with farming system research, farm management clubs, and rapid rural appraisal. It continues in many guises in the developed world, especially influenced by the privatization of agricultural extension, the use of remote sensing and ICT advances, and the entry of input suppliers, in particular seed companies, into agricultural extension.

In the developing world the more traditional approaches remain, although with growing emphasis on farmer participation [21]. Lobell et al. [12] recount how IRRI conducted on-farm rice experiments in Asia in the 1970s to test high inputs, learning that farmer yields varied greatly between fields, as did responses to inputs especially fertilizer and insecticide, which were often uneconomic. This pointed to the importance of field-to-field variability, and the need to adjust inputs accordingly and as the season unfolds, whether by site-specific nutrient management, which reached maturity some 20 years later [22], or via field-level pest monitoring as part of IPM packages. Titonell et al. [13] recount a similar picture of substantial variability in soil fertility, resource use intensity, and yields among small farmer maize fields in western Kenya. Another lesson is surely that this is scientist-intensive expensive research, usually taken over by the farmer and his advisers in the industrial world, and explaining why large yield gaps often persist in the developing one, where circumstances demand innovative approaches in order to reach the billion small farmers (e.g., [21]).

Very recently IRRI again looked at rice yield gaps, this time using expert knowledge to assess constraints and possibilities for irrigated rice in South Asia [23]. For this crop, FY is currently 5.1 t/ha over 34.3 M ha; it was estimated that on average yield was constrained 1.9 t/ha (37%) by yield-limiting factors, which included individual constraints from nutrient insufficiency (10%), diseases (7%), weeds (7%),

water shortage (5%), and rats (4%). The exercise was repeated for the 28.5 M ha of rainfed lowland and upland rice in South Asia with a current FY of 1.8 t/ha: yield-limiting factors amounted to 68% of FY, including nutrients (23%), disease (15%), and weeds (12%). The IRRI paper predicted that with a substantial research, development and extension effort, the adoption of existing technology and ongoing breeding over the next 15 years could reduce these losses by one third (irrigated rice) or one quarter (rainfed rice) adding about 1% to FY growth rate.

With wheat in the Yaqui Valley we have a recent concerted effort to understand the yield gap, PY–FY (currently 50%, Fig. 5, Table 1), this time using the latest high-resolution satellite imagery to estimate field-level yields for all fields in the Valley [24] and supplement a long history of farm surveys. Despite the moderate size and wealth of farms relative to India or Kenya, again field-to-field variability in yield was substantial. It was estimated from images over several years that wheat yields were constrained by late planting, delays in the first post-plant irrigation, and summer fallow weeds [25]. Improved institutions and farm management decisions could largely eliminate these constraints, which averaged over years totaled about 10–15% of FY, and would bridge about half of the gap to estimated *AY* in the Valley. These authors [26] used inter alia classification and regression trees to relate yield to constraints in their complex data sets. The same technique was used by Tittonell et al. [13] to explore management and soil constraints to 150 field-level maize yields in highland Kenya: the rate of added nutrients was the strongest explanatory variable, followed by date of planting and plant density, as yield ranged from 1.2 (low nutrients, late plant) to 4.2 t/ha (high nutrients, normal plant, high density).

Two recent studies illustrate for rainfed cropping the power of simulation modeling and water productivity boundary functions in understanding yield gaps in surveyed farmer fields and in particular removing that part of the apparent gap which is actually due to non-manageable weather (mostly rainfall distribution). Grassini et al. [27] found these distribution effects quite important for sunflower yield variation among fields in the western pampas of central Argentina. Hochman et al. [28] looking at farm wheat yields across Australia, found less influence of rainfall distribution, and more scope for farmers to lift water productivity via improved management (e.g., earlier planting, higher seeding density, higher N input). A weakness of both these studies is that they refer to better farmers rather than to a random sample of fields, for which the opportunities of gap-closing interventions are likely to be greater.

The persistence of large yield gaps in the developing world especially draws attention to situations where these gaps have been closed. Rice in Egyptian is an obvious example where strong R, D, and E engaged a small geographically focused industry of small holders under a sound price policy (Fig. 4). A second example of dramatic technology adoption, albeit with lesser immediate implications for FY than for sustainability of the whole cropping system, relates to the uptake of conservation tillage for wheat, maize, and soybeans in southern South America (Argentina, Brazil, and Paraguay), rising from nothing in 1970 to 24 M ha in 2000. This was very much driven by farmer groups and the farmers themselves faced with the threat of serious soil degradation and by the opportunity provided by knock-down herbicides and knowledge spillover from the North (e.g., [29]). This revolution has yet to reach other developing continents (but is beginning in northwest South Asia). A third success story among small poor farmers has recently appeared with the introduction and expansion of winter maize in northeastern India and Bangladesh.

Despite individual success stories like rice in Egypt, yield gaps in general appear to be quite persistent and close only slowly; this happens even when gaps are well above that to be expected from economics and risk aversion and even when PY progress has slowed such that catch-up through eliminating excessive lags in varietal adoption is not a big issue. The problem is that gap closing on the large scale needed requires massive investments in rural infrastructure and institutions as well as technology transfer, and these are not forthcoming, as maize in sub-Saharan Africa exemplifies. Elsewhere public sector agencies, in particular reaching the billion small farmers in Asia [21], aided by the private sector, in particular in Latin America, have made some inroads on the yield gap; they should continue to do so largely in proportion to the investments made, but there is also scope for innovation, for example, based on modern ICT technologies.

The employment of agronomists by private seed companies is a pattern that is bound to be followed in the developing world as its seed industry grows in strength and competitiveness. With gap closing, there are no spill-ins as there are in the case of PY advance through R and D, innovations need to be adapted locally, but it can be argued that the Internet and mobile phones are relevant spill-in technologies for delivering information to farmers small and large, a role which could greatly expand.

Innovative Adoption-Friendly Crop Management and New Varieties

Research can facilitate the adoption of technologies to lessen those constraints which contribute to the FY to PY gaps. Table 2 lists common constraints, separating research targeting agronomic solutions from that involving breeding, while institutional and infrastructural solutions already mentioned are shown in the last column. Some agronomic technologies are still under development (e.g., improved seasonal weather forecasts), but much of the necessary agronomic research is adaptive, generally fitting technologies from more advanced farming systems. For example, the widespread adoption of direct seeding of wheat after rice in northwest India, which by saving on land preparation time has meant that sowing dates are less likely to be late and yield expectations are hence improved, required research and development on appropriate small-scale drills for this direct seeding operation. Sometimes, the agronomic technology comes from a "less-advanced" field cropping situations or from farmers themselves: for example, the use of plastic film mulches, quite common in northern China with wheat, maize, and oilseeds. Such mulches give substantial yield benefit through retaining soil moisture and aiding soil warming in the spring, and challenge agronomic researchers to adapt them in a sustainable fashion elsewhere, including developed countries.

It is with breeding that there are greater gap-closing opportunities. Considering that actual losses from diseases and insects globally exceed 20% of yield with wheat, rice, and maize [30], any improvement in genetic resistance has an immediate benefit for FY when the improved varieties are adopted. Conventional host plant resistance breeding continues to make progress on this front, while genetic engineering has brought exciting new opportunities. Although engineered resistance does not lift PY, it lifts FY wherever farmers cannot control pests and diseases with traditional means. The experience with Bt cotton in India shows how important this can be: small holder yields are at least 30% better simply because before the advent of Bt cotton they were unable to eliminate damage no matter how much insecticide was used [31]. It is likely that the advent of GM corn resistant to root worm is boosting farm yields in the USA because root worm damage went unnoticed beforehand (and is very difficult to treat with chemicals). Fungal diseases have yet to succumb to genetically engineered host plant resistance, but it is reasonable to expect varietal releases in this area in the next decade; engineered viral resistance has already been deployed in some crops [31]. Actual yield losses due to weeds are estimated globally at about 10% by Oerke [30], to which should be added the costs of current control measures. More competitive cultivars can help, but again genetic engineering has brought revolutionary advances in ease, cost, and effectiveness of weed control. Of course, with any chemical-based susceptibility of biotic stress agents, there will be the risk of resistance evolving in the target organism, but integrated management, albeit requiring greater farmer skills, can prevent that. Given proper R, D, and extension, the potential impact of herbicide-tolerant cultivars on FY in labor-limited African cropping is likely substantial. Of course, all breeding solutions to aid gap closing presuppose an effective seed production and distribution system. Systems are gradually improving in developing countries and most commercial farmers grow improved varieties although the rate of turnover of varieties is often too slow. There is little doubt that wherever plant breeding is privatized, competition drives quicker variety turnover; in advanced systems, it also drives significant agronomic extension by the breeding firms keen to maximize variety by management interactions and to retain clients.

Lifting Potential Yield

Although separated by a yield gap and a time lag, many situations show a close relationship between progress in PY and that in FY, as new technologies eventually

Crop Yields Around the World: Closing the Gap and Raising the Potential. Table 2 Constraining factors contributing to the farm yield–potential yield gap and their alleviation so that farm yield can approach the attainable yield corresponding to the current potential yield with realistic economics

Constraint	Resolution		
	Research		
	Agronomic	Breeding	Institutional/infrastructural
General farmer constraints			
Lack of farmer awareness or conviction or skill	On-farm demonstration	On-farm testing and selection	Education, media campaigns, extension
Risk aversion by farmer	Forecasts, tactical decision making (e.g., for N top dress)	Tolerance of extreme weather events, like drought, flooding, hail, frost, wind	Insurance schemes, favorable credit terms, price stability
Inadequate labor supply	Mechanization, reduced tillage, herbicides	Select for uniform maturity to favor mechanical harvesting	Facilitate labor migration; credit for mechanization
Technical constraints			
Lacking major long-term soil amelioration	Drainage, land leveling, liming, deep tillage, gypsum	Waterlogging, acidity, and salt tolerance	Long-term credit for major soil amelioration, secure tenure
Excess tillage and loss of moisture, soil compaction	Conservation tillage options and suitable machinery, controlled traffic	Suitable varieties: disease and herbicide tolerance	Credit for new machinery
Manageable topsoil soil toxicities	Ameliorate (e.g., lime for acidity)	Acidity, aluminum tolerance	Input suppliers, credit for lime
Suboptimal nutrient supply	Diagnostics, application of nutrients, slow release forms, tactics to match supply with need	Some scope for improved N, P, and Zn uptake and utilization efficiency	Infrastructure, input suppliers, credit, quality control
Soil variation within and between adjacent fields	Diagnostics to aid adjustment of application rates	Greater tolerance of soil stresses	
Growing old varieties, or use of poor seed	Better on-farm seed management and storage	F1 hybrids, licensed traits, royalties to encourage strong seed industry	Strong seed industry and proper regulation, credit
Incorrect time of sowing	Mechanize, reduced tillage to speed sowing; treatments to warm soil for spring sowing	Make available varieties with range of maturities; herbicide and cold tolerant varieties	Policy to favor mechanization, contract seeding
Poor plant population	Better drilling procedures and machines, quality seed storage	More robust varieties (e.g., long coleoptile in wheat, more tillering)	Seed testing and regulations
Diseases and pests, above and below ground	Biocides, sanitation, crop rotation, IPM	Host plant resistance	Input suppliers, pesticide quality control

Crop Yields Around the World: Closing the Gap and Raising the Potential. Table 2 (Continued)

Constraint	Resolution		
	Research		
	Agronomic	Breeding	Institutional/infrastructural
Weeds	Herbicides, cultivation, sanitation, crop rotation	Enhance crop plant competitiveness, herbicide tolerance	Herbicide quality control, release regulation
Poor water management in irrigated systems	Improve water application techniques and skills, land levelling	Greater tolerance water shortage and excess	Efficient supply systems to farm
Long-term soil degradation	Crop rotation, fertilizer, green manuring, farm yard manure, conservation tillage, amelioration	Varieties adapted to biotic and abiotic stresses of high plant residue levels, and with good residue production	Tenure regulations ensuring land ownership by farmer

find their way to farmers. Often the process is facilitated by new varieties linked to agronomic advances, for new varieties are fairly quickly adopted in most commercial farming. Sometimes, the PY advances owe more to innovative farmers than to researchers, as for example, when farmers moved to earlier planting permitted by direct seeding in southern Australia. In all cases, increase in PY is an important component driving increased FY, inevitably so where the yield gap is approaching the economic minimum (e.g., wheat in the UK), but less so where it is large (e.g., paddy or rainfed rice in India), and even less when the gap is huge (e.g., maize in sub-Saharan Africa).

Current rates of PY progress were summarized for the key cereals in [5]. These numbers come from breeders' and researchers' trials containing varieties of different vintage grown under modern agronomic management with little or no biotic stress; thus, the rates capture as well the positive interactions between new varieties and modern management. Linear regression is used to calculate the absolute rate of progress which is then expressed as a percentage of most recent predicted PY in the series, hopefully a recently released variety (>2006) but such data is not always available. For wheat, progress ranged from 0.3% to 1% p.a. with an average of 0.6% (n = 6) and with little difference between water-unlimited and water-limited PY progress (see also Figs. 1 and 5). For rice, the range was 0.2–0.7% (average of 0.4%, n = 4). Progress in PY at the International Rice Research Institute (IRRI) is disappointing, at close to zero; however, there is a one-off yield jump of 10–15% through the recent exploitation of F1 hybrids feeding into the tropical rice regions, and following upon on a similar gain in China over the last 20 years as hybrids moved to >50% of their acreage. For maize, there is only one estimate in [5], coming from Iowa and showing 1%. Data of Luque et al. [32] in a somewhat similar environment in Argentina give a rather similar number for hybrids released up to 1997 (1.3%), but since then PY progress may have slowed (M. Otegui, 2009, personal communication). A subsequent report from Iowa with hybrids of a rival company showed progress at 1.7% but the breeding period sampled was only 2001–2006 [8]. In an irrigated favorable Mediterranean environment, data presented by Campos et al. [33] indicate PY progress in the Iowa Pioneer hybrids of 1% (but interestingly progress in PYw of 1.5% under artificial severe mid-season water stress). PY progress in cereals is discussed in more detail in [9]. Potential yield for soybeans in the USA appears to be progressing at 0.7% p.a. (R. A. Fischer, 2010, unpublished).

From the above, it is apparent that even in advanced situations with substantial breeding investment, potential yield progress from this source is currently at or well below 1%, with maize showing more progress than other major crops. Such PY progress is unlikely alone to drive FY progress at the rates needed. Prospects of lifting this rate of PY progress were now discussed briefly.

New Yield-Positive Agronomic Techniques

Improved agronomy has played a large if not dominant role in past yield increase (e.g., increased fertilizer use, better weed control, better seeding techniques for earlier seeding and more reliable crop stands, and water conserving reduced tillage), and most improvements have interacted positively with variety improvement (e.g., [20]). While many authors have consistently failed to anticipate agronomic advances in the past [34], currently it is hard to see any new ones raising PY or PYw (as distinct from advances specifically targeting improved input efficiency). One example might be improved seasonal forecasts which would permit the farmer to better tailor management and variety to expected weather, something currently limited by the low skill of forecasts. Another, which would clearly lift PYw, would be the reduction of soil evaporation with inexpensive plastic films (e.g., spray-applied nanofilms), copying a common practice seen in northwest China field crops, but designed so as not to contaminate the environment. Also it is possible advances can still come from better management of soil–root–microbe interactions, a complex and neglected area of research: poorly explained observations of "yield decline" and "break crop effects" point in this direction, as do reports of positive effects of increased soil organic matter (independent of nutrition), controlled traffic and reduced soil compaction.

Greater Investment in Current Conventional Breeding Efforts for Yield

Yield improvement through plant breeding is generally regarded as delivering benefits far in excess of the costs [35, 36]. Nevertheless, it has been suggested that returns from the investment in breeding personnel are diminishing, for example in maize, and that yield gains are getting harder to achieve [37]. This is occurring despite greater efficiency through computerization, advanced biometrics, mechanization, robotics, and techniques for rapid generation advance, all part of any conventional breeding today. What is quite unclear however is the marginal return on investment in conventional breeding; for example, what would happen if the number of breeders, and of crosses, selections, and yield trials, were increased say 50% in any currently substantial program? In crops where breeders are devoting many resources to maintaining disease resistance (e.g., wheat) or eating quality (e.g., wheat, rice), and thus unable to give full attention to yield, PY progress is likely to increase, although probably less proportionally that the proportional investment increase. A related question is whether any extra funds would be better spent on new breeding tools.

New Tools to Increase Progress in Conventional Breeding

Genetic variation is the basis of yield progress. It is unlikely that all or even the major part of the existing genetic variation has been utilized in any crop. Sampling germplasm collections is a formidable task, but new tools are becoming available for seeking out new and useful variation, such as the Focused Identification of Germplasm Strategy (FIGS, [39]) and Ecotilling [38]. Because of the low chance of success, this work tends to be in the area of publically funded prebreeding, with only medium to long-term impacts on breeding, but it is worth noting that the steady reduction in genome sequencing costs is also opening up new ways of allele searching [40].

Both parental and especially early generation selection can benefit from the use of low cost performance-related markers. For the last 50 years or so, physiologists have attempted to identify such markers or traits, physiological or morphological, or even whole ideotypes, which would lead to greater yield. There have been some successes, for example, the first high-yielding semidwarf tropical rice variety, IR8, resulted from the pursuit of a specific ideotype [41], and breeding for resistance to some toxicities is usually based on early generation physiological screening (e.g., aluminum tolerance). However, indirect selection for both PYw and especially for PY has proved challenging, and much physiology has been restricted to the retrospective identification and understanding of traits which have changed as direct selection has increased yield. A good example are the many traits that have been found to change as maize yields increased in North America under direct selection for yield, lodging resistance, dry down, and disease resistance alone [37, 42]. As understanding of yield determination improves, including the recognition that seemingly useful traits can carry trade-offs, and as measurements of many

traits become cheaper, especially through the use of remote sensing in the field, the possibilities for physiological traits have improved. At CIMMYT, maize breeding for drought (PYw) has definitely benefitted from the inclusion of physiological traits such as anthesis to silking interval in managed drought environments [43]. More recently, with wheat there has been testing of canopy temperature as an early generation selection criterion, a surrogate for stomatal conductance and possibly photosynthetic rate under irrigation, or possibly for rooting depth under drought; it shows promise under both conditions [44], as does multispectral canopy reflectance under irrigation [45]. In CSIRO, Australia, ideotrait selection for greater PYw has been under way for several decades, with focus on traits such as water use efficiency via carbon isotope discrimination, coleoptiles length, low tillering, and high stem carbohydrate content at flowering, with moderate success [46]. Very recent research points to genetic differences in wheat for grain set under drought and ways for screening this trait which is likely to be a significant bottleneck in PYw determination [47].

While physiology may be beginning to look more useful in early generation yield selection, it is now being challenged by the rapidly growing use of molecular markers for traits, initially qualitative ones but lately also quantitative traits, including yield itself. The huge decline in cost of detecting molecular markers, and their increasing density across crop genomes is driving this. Heffner et al. [48] review the possibilities of such marker-based genome selection in crops. Earthington et al. [49] describe in some detail the extent to which molecular markers are being incorporated into the Monsanto crop breeding programs: rates of progress in multiple trait indices (e.g., including yield, grain moisture, standability, and test weight for maize) can be doubled; indeed, for these authors marker-aided selection is the "new" conventional breeding. These approaches presume accurate phenotyping of genotypes for yield and its interactions with target environments, a challenge in all breeding. However, it is interesting that physiology hardly features in this new scenario, although other groups are busily mapping putatively useful physiological traits at the molecular level (e.g., [50, 51]). It remains to be seen whether physiological traits, either observed directly or identified by accurate markers, will have a place in marker-aided yield breeding, but it is possible some combination of markers and early generation trait phenotyping using smart remote sensing will prove an even more efficient strategy for PY advance. In addition physiology, just like plant pathology, will continue to identify individual traits whose incorporation into leading varieties may lift PY or PYw, a process which could benefit from the use of molecular trait markers, just as is becoming the case with new hard-to-screen host plant disease resistance genes.

Multilocation multiple-year yield testing remains the essential final step in all plant breeding for yield; testing under different management regimes (plant density, planting date, soil stored water) is also recognized as increasingly important. Crop simulation models are now good enough to help breeders understand the environmental and sometimes the genetic bases of the interactions encountered, and thus deploy the testing more efficiently, and more efficiently indentify the genotypes best suited to major environment × management combinations. An excellent example is the analyses of multiple environment rainfed trials of sorghum in Queeensland [52].

Genetic Engineering for Yield

There are many claims of engineered traits that may increase crop yield, but very few of these have been backed up by yield measurements in the field. Crop physiologists have regularly pointed out how different is the performance of a genotype growing in a pot in the glass house from that of one at normal plant density in the field environment [53, 54]. For this reason, they remain skeptical of the value of these claims and await with much interest the results of field tests, for, to date, it appears that only a handful of papers describe performance in proper field tests. In an excellent example, wheat transformed with a more active ADP glucose pyrophosphorylase in the grain to increase grain sink strength and grain size, was thoroughly field tested, but there was no yield benefit [55]. More recently, Monsanto has reported increased PYw in field plots with maize transformed with two separate events [56, 57]; results in the latter case point to modest PYw increases and no change in PY, but the nature of the drought and of the crop physiological responses are not well described. More experimental data is needed before much confidence can be placed in this event,

or in engineering for yield in general, for both genetic and physiological understanding of yield determination indicates that many processes are involved, and that the impact of any single transformation is likely to be small even if key regulatory genes or bottleneck processes are targeted. Indeed, it is now being recognized that if functional genomics is to have a significant impact on yield through engineering yield processes, it must pay more attention to the relevant plant and crop physiology connecting gene action to field performance [58]; even the current fashion for automated phenotyping in controlled facilities must be balanced by substantial investment in phenotyping in field plots in managed environments.

Some Tentative Conclusions on Future Potential Yield Progress

As PY increases, relative rates of PY progress are decreasing; this is probably more than the consequence of a linear rate of progress relative to a rising denominator, and may, in situations where the breeding investment is large (e.g., maize in North America, wheat in the UK and the rest of Western Europe), also reflect diminishing returns as biological limits are approached. Theoretical limits to harvest index are already being reached, but those to radiation use efficiency appear well above current measured values [59]. There have been a couple of attempts to project PY into the future. For example, Sylvester-Bradley et al. [60] propose that a longer period of light capture and a higher radiation use efficiency could lift PY of winter wheat in the UK to 17.4 t/ha by 2050, a linear rate of progress of 167 kg/ha/year, or two and half times the current rate of progress seen in Fig. 1. Taking a different tack, Monsanto has predicted a doubling of US maize yield between 2000 and 2030, based on equal contributions from conventional breeding, marker-aided selection, and genetic engineering, and amounting to a linear annual rate of progress which is 3.3% of today's yields. Physiological theory and commercial optimism both, however, have their limitations. Looking more cautiously at the ways of impacting PY progress outlined above, it is concluded that breeding progress will dominate in the future, that conventional breeding, including the exploitation of heterosis, will continue to deliver small but declining gains, while new approaches may boost gains enough to maintain current rates of linear PY progress at between 0.5% and 1%, other things such as climate remaining equal (note that given the way PY is defined here, this progress is independent of any direct effect of atmospheric CO_2 increase). Observers expect the investment in the relevant R and D to remain large, as the private sector involvement increases to balance a declining public sector, and many argue that it should grow further, although the marginal rate of return is not well known.

Future Directions and Synthesis

The key issue for future food security is the real grain price needed to balance burgeoning demand against increasing supply. World food production demand and supply to 2050 have recently been projected by Hubert et al. [61] with the IFPRI Impact model, and by Tweetin and Thompson [62]. Thus, the baseline case of the former paper projects a 56% increase in cereal production over 2000, accompanied by substantial real price increases over the 2000 base, with negative effects on malnutrition. Demand growth is greater for maize and least for rice, such that the projected real price increases over 2000 are maize (97%), wheat (90%), and rice (60%). Clearly, a 56% increase in production is not enough. For Tweetin and Thompson [62], cereal supply rises somewhat more, by around 75% in 2050, but real prices still increase (on average 44%). The IFPRI projections allow for biofuel demand (peaking in the late 2020s at 16% of total maize consumption, after which second-generation biomass biofuel takes over), rising energy costs and likely restrictions on irrigation water supply. They also point to a much greater increase in grain demand in the first 25 years (1.4% pa) than in the second 25 years (0.4%), clearly placing more pressure on short- to medium-term yield progress. The IFPRI model contains crop area as a variable but, given the cost of developing new lands and its scarcity, this only increases significantly if prices more than double under a very low yield progress scenario.

In the IFPRI baseline projection, yield grows to meet demand at around 1% exponential projected over the whole period. In [62], it is expected to grow linearly at a rate equivalent to 1.4% of current yields. These rates compare to the current rates of world yield

growth, which are wheat and rice (0.9%), maize (1.6%), and soybeans (1.1%), but it must be recalled that the actual rates all appear to be linear, not exponential, and that the projected rates in neither of the models are enough to hold real prices steady at 2000 levels. In addition, the elasticity of demand is such that a supply shortfall due to below baseline yield growth would be disastrous (as we saw 2 years ago although some other factors added to the sharp doubling of prices then): the projections in [61] suggest a 40% fall in yield growth below baseline (to 0.6% exponential) would lift 2050 real cereal prices to more than 200% above 2000 real prices!! Alternatively, 1.4% yield growth would mean continuing declines in real grain prices.

These numbers highlight the importance of yield growth that has been the subject of this entry and reveal that current FY growth rates are inadequate to hold real prices down. Since PY growth can contribute to FY growth everywhere, and is the only source of growth in advanced agricultural systems where FY is approaching PY, it assumes great underlying importance, even as current rates of growth, except possibly for maize, seem to be well below 1% and gradually falling as a percentage of yield. Unfortunately, the brief examination here suggests that the prospects of boosting PY growth, largely now relying on plant breeding, are small, or at least rather uncertain, especially in the short to medium term when yield increases are most critical. Much will depend on whether the molecular marker-aided yield selection can boost rates, for example, double them, as claimed by some; genetic engineering seems unlikely to lift PY in the short to medium term, although the prospects to lift PYw may be somewhat better if water stress-related yield bottlenecks can be relieved. And none of these projections have factored in the possible negative effects of climate change.

As a consequence of the above, yield gap closing assumes great importance for future world food security, especially as there still appear to be large exploitable gaps (>50%) in many situations, and as the way forward is clearer. There are few uncertainties regarding what needs to change at the farm level, but less optimism regarding how to achieve this quickly enough and from where the necessary resources will come. The biggest gaps are associated with small farmers in the developing world, and there is little doubt that strategies to help these farmers will have the greatest benefits for alleviating poverty and food insecurity. And note that the association between large yield gaps and small farmers is not an inevitable association, as can be seen among small holders in Egypt or parts of eastern China. This entry has emphasized that improvements in rural infrastructure and institutions are critical, but that breeding and agronomic research also has a role to play in gap closing, as is illustrated by the impact of simple direct seeding machinery and earlier sowing on wheat yields in the Indo-Gangetic Plains or of Bt cotton with Indian small holders. It is a great pity, however, that the types of on-farm adaptive research and development needed for gap closing in such situations are often thwarted by policy inertia toward agriculture in general, and poor rewards by science funders in particular, although the situation may be gradually improving. In developed countries, new paradigms seem to be emerging in which private sector companies, especially breeding and seed companies, invest not only in developing better varieties but also in applied agronomic research linked to variety development and promotion, and this may account for some of the gap closing in the USA and Western Europe. In addition, and especially in Australia and the southern cone of South America, privately hired agronomists are assuming a critical role in yield gap closing and are rewarded accordingly. Taken overall such changes auger well for ongoing yield gap closing, even in the short to medium term, in the developed world, but their impact at the farm level in developing countries, and that of more traditional approaches, will remain limited by infrastructure and institutional constraints in the near to medium-term future. The cautious optimism expressed a decade ago by leading agricultural scientist Evans [4] regarding world food security may well be overly optimistic.

Article Outline

Glossary

Agriculture Agriculture and farming are often considered to be the same concept. However, both concepts can vary in their territorial scope of application. Agriculture is the production of food and goods through farming and forestry. Agriculture encompasses a wide variety of specialties and techniques. For this reason, its definition has developed to become: The science, art, and business of cultivating soil, producing crops, and raising livestock. The major agricultural products can be broadly grouped into foods, fibers, and raw materials. As of late, agriculture also uses plants to produce biofuels, biopharmaceuticals, and bioplastics.

Agricultural practices Agricultural practices are a set of techniques applied to on-farm production and postproduction processes, resulting in food and nonfood agricultural products.

Agronomic crops Agronomic crops typically involve a crop that is grown for grain, feed, or for processing into oil, starch, protein, or flour. Major agronomic crops include corn (grown for feed, ethanol, or processing), soybeans, wheat, hay (alfalfa and legume and grass mixtures), rice, peanuts, and cotton. Hay is also considered forage [1].

Agroecosystem An agricultural system or agricultural ecosystem is the basic unit of study for an agroecologist. This term is somewhat arbitrarily defined as a spatially and functionally coherent unit of agricultural activity, and includes the living and nonliving components involved in the unit as well as their interactions. An agroecosystem can be viewed as a subset of a conventional ecosystem. As the name implies, at the core of an agroecosystem lies the human activity of agriculture. However, an agroecosystem is not restricted to the immediate site of agricultural activity (e.g., the farm), but rather includes the region that is impacted by this activity, usually by changes to the complexity of species assemblages and energy flows, as well as to the net nutrient balance.

Agronomy The science which establishes the theory and practice of crop production and soil management [1].

Ecosystem A functioning community of nature that includes fauna and flora together with the chemical and physical environment with which they interact. Ecosystems vary greatly in size and characteristics, and can be a mud puddle, a field, or orchard, or a forest. An ecosystem provides a unit of biological study and can be a unit of management [2].

Environment The totality of the surrounding external conditions (biological, chemical, and physical) within which an organism, community, or object exists. The environment can be defined at any scale. The term is not exclusive in that organisms can be and usually are part of another organism's environment. Thus, one can speak of the environment as that within which humankind lives (i.e., separate and external) or, of humankind as a component of the environment [2].

Definition of the Subject

Cropping system (CS) is a general term that describes how a producer or farmer might grow a crop [2]. Pragmatically, CSs effectively address the *what to grow*, *when to grow it*, and *how to grow it* considerations of crop production in the context of optimizing multiple goals [3]. A CS must bring together the biological, technical, economic, and sociological aspects of

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

Robert A. Meyers (ed.) Encyclopedia of Sustainability Science and Technology, © 2012, DOI 10.1007/978-1-4419-0851-3

the land area farmed [4]. Therefore, a CS is a set of agronomic or agricultural practices used in a crop under specific conditions. The CS generates an agroecosystem, agri-environment, or agricultural system. Common synonyms of CS include crop management system, crop production system, farming system, crop production practices, etc. For example, a farming system is defined as a population of individual farm systems that have broadly similar resource bases, enterprise patterns, household livelihoods, and constraints, and for which similar development strategies and interventions would be appropriate [5].

The classification of CSs has been based on the following criteria: available natural resource base, including water, land, grazing areas, and forest; climate, of which altitude is one important determinant; landscape, including slope; farm size, tenure and organization; dominant pattern of farm activities and household livelihoods, including field crops, livestock, trees, aquaculture, hunting and gathering, processing and off-farm activities; and taking into account the main technologies used, which determine the intensity of production and integration of crops, livestock, and other activities [5]. Multiple cropping, in which several crops are grown sequentially in 1 year, and intercropping, when several crops are grown at the same time, are other kinds of annual CSs known as polycultures [6].

In general, each and every agronomic practice used in a CS affects different aspects of the system, i.e., the tillage system prepares the seedbed but affects the availability of water and nutrients, carbon cycle, erosion, diseases, etc. The use of the term CS is often applied to a rotation (wheat-fallow CS), tillage system (no-tillage CS), method of fertilization (organic CS), or agroecosystem (semiarid CSs) to simplify the designation of the CSs. However, it is important to note that a CS involves much more than a rotation, tillage system, fertilization method, or climatic conditions.

Introduction

Since the dawn of settled agriculture about 10 millennia ago, human beings have integrated different agronomic practices for application to selected plants (crops), and as a result generated CSs that transformed the natural ecosystem into agroecosystems. Agricultural practices such as genotype selection, crop rotation, natural fertilizers, irrigation, etc., were developed long ago, but have made great strides in the past century. The history of agriculture has played a major role in human history as agricultural progress has been a crucial factor in worldwide socioeconomic change. When human beings began to produce food beyond their needs, others activities began to take place. It is this agricultural surplus that made the development of civilization possible. A crucial time in the history of agricultural began with the discovery of America. A global exchange of previously local crops and livestock breeds occurred. Key crops involved in this exchange from the New World to the Old included the tomato, maize, potato, manioc, cocoa bean, and tobacco, with several varieties of wheat, spices, coffee, and sugar cane going from the Old World to the New. With the rapid rise of mechanization in the early twentieth century, particularly in the form of the tractor, farming tasks could be accomplished with a speed and on a scale previously impossible. Also during this period, the Haber–Bosch method for synthesizing ammonium nitrate represented a major breakthrough. Synthetic nitrogen, along with mined rock phosphate, pesticides, and mechanization, allowed crop yields to overcome previous constraints. Furthermore, global yield increases were experienced later in the twentieth century when high yield varieties of wheat, corn, and rice were introduced as a part of the Green Revolution. The Green Revolution exported technologies (including pesticides and synthetic nitrogen) from the developed world to the developing world. However, concerns have been raised over the sustainability of intensive agriculture. Intensive agriculture has become associated with decreased soil quality, and there has been increased concern over the effects of fertilizers and pesticides on the environment, particularly as the population increases and food demand expands.

As a result, in the past few decades, a move toward sustainability in agriculture has also developed, integrating ideas of socioeconomic justice and conservation of resources and the environment within an agricultural system [7, 8]. Sustainable agriculture is defined as practices that meet current and future societal needs for food and fiber, for ecosystem services, and for healthy lives, and that do so by maximizing the

net benefit to society when all costs and benefits of the practices are considered. If society is to maximize the net benefits of agriculture, there must be a fuller accounting of both the costs and the benefits of alternative agricultural practices, and such an accounting must become the basis of policy, ethics, and action. Additionally, the development of sustainable agriculture must accompany advances in the sustainability of energy use, manufacturing, transportation, and other economic sectors that also have significant environmental impacts [9]. Sustainable agriculture has renewed research in alternative technologies such as no-tillage, integrated pest management, etc. Recent mainstream technological developments include genetically modified (GM) crops. Also, agriculture has needed – and still needs – subsidies from many governments to ensure an adequate food supply and its competitivity in global markets. However, at times, these subsidies, especially when instituted by developed countries, have been noted as protectionist, inefficient, and environmentally damaging [10].

This chapter is not an overview of a subject as complex and broad as worldwide CSs, where oversights are inevitable. It must first be pointed out that about 85% of the Earth's cultivated land is planted with annual crops [11], and thus the principle CSs are used in herbaceous plants. Of these, wheat, rice, and maize provide more than 60% of human dietary calories, either as cereals for direct human consumption or embodied in livestock products produced from animals fed with feed grains and their by-products [9, 12]. Moreover, it is likely that these same cereal crops will continue to account for the bulk of future human food supply because they produce greater yields of human-edible food, are easily grown, stored, and transported, and require less fuel and labor for processing and cooking than other food crops [12]. Given their importance, this chapter focuses primarily on these crops, but also provides a general view that can be applied to any CS. The chapter starts off with a brief description of CS components and factors that must be taken into consideration during their design (*Components and Design*). To provide a new focus on defining CSs, and as a result agroecosystems, an anthropological view of a CS is then provided (*Anthropological View*). Following, the most important effects of these "human ecosystems" on the environment are reviewed (*Agricultural Practices' Footprint*). At this point, the chapter goes on to analyze the achievements of agricultural research and their importance to man (*Praise of Agricultural Science*). From here, agricultural practices that were unsuccessful in CSs and which must be urgently eliminated are studied (*Eradication of Fallow, Tillage, and Monoculture*). Afterward, the basic principles on which current and future CSs should be inspired are discussed. In fact, the application of these principles to a certain degree involves returning to techniques from the past, based on monitoring technologies of the future (*Biological Synergism and Technical Synchronization*). The application of these principles logically leads to what are called *Dynamic Cropping Systems*, which shift away from the application of a series of rigid agricultural practices to the agroecosystem at each growth stage. Finally, the chapter tackles the *Future Challenges* for CSs in the twenty-first century.

Components and Design

All agroecosystems generated by a CS break away from "natural" ecosystems, and the main effects are the loss of biodiversity and the export of resources. This causes environmental imbalance which means more or less of a struggle, depending on the intensity of the CS, to stabilize it. The more distant it is from a "natural" stable ecosystem, the more inputs are required by the CS as the result of a greater imbalance. In fact, one of the greatest concerns caused by agriculture, which has been a problem from the beginning due to the selection of few species, is the lack of biodiversity in many CSs. Advocates of diversification argue that it provides greater income stability [2].

Many CSs throughout the world are characterized by variable climate and soils, resulting in a high-risk condition for agricultural producers due to extreme variability in precipitation and seasonal temperatures [13]. In other words, crop production occurs in an environment that is always changing. With every growing season, producers must attend to numerous factors that influence their management decisions. Cropping systems vary among farms depending on the available resources and constraints; geography and climate of the farm; government policy; economic, social, and political pressures; and the philosophy and culture of the

farmer [5, 6]. This is a daunting challenge, especially when one considers that producers' decisions are carried out in a financial environment of diminishing economic returns, where one wrong decision could mean financial hardship and potentially the end to a way of life [14].

A CS involves numerous interactive factors that may limit or facilitate crop production. The factors can be divided into the following groups [14]: (1) biophysical environment: weather/climate and soil; (2) socioeconomic externalities: market conditions and government programs; and (3) available technology. These three factors affect or guide the agricultural practices of the CS (crop election, rotation, tillage system, planting date, fertilization, crop protection, etc.), and are conceived on the basis of productive and economic objectives, as well as the social and environmental objectives that must be imposed by sociopolitical externalities.

Most developed countries' agriculture operates in a market-driven economy, although government policies can have an influence on what farmers produce and how they produce it. As with other businesses, agricultural producers respond to economic incentives and disincentives, and make decisions to maximize their welfare; usually measured as net income. Specifically, the farmer must consider the influence of technological advancements, income supports embodied in farm legislation, and changes in market structure and consumer demand. Many of the technological advancements have required large-scale production units to justify the investment. The influence of commodity support programs has been ambiguous. As farm legislation has evolved to decouple production decisions from program benefits, the incentives to specialize in program crops (crops that receive price and/or income benefits under governmental legislation) have diminished. However, wealth and risk effects, albeit small, may have promoted or inhibited the adoption of a more sustainable system. Changes in market structure, channels, and consumer demand in the past five decades have been dramatic with consolidation and specialization in both production and marketing sectors. However, the diversity of consumer demand has also created opportunities for more integrated farm operations. There is an increasing number of consumers who have become concerned about how and where their food has been produced (food security). While price and income supports may have been biased toward specialization (as these programs were targeted to specific commodities), the reduction in risk associated with the programs has enabled producers to expand the number and diversity of their production enterprises [15].

The rapid change in the agricultural industry driven by continuously arising challenges (climate change, market globalization, environmental concerns) requires the development of new methods of production in order to guarantee sustainable agriculture [16]. The design of a CS undergoes a study of the biophysical environment and socioeconomic externalities, and an inventory of available technologies. The first step in developing a CS is the definition of goals and constraints for the new CS. Constraints may result from soil and climate but also from environmental or economic concerns [17]. Afterward, a crop portfolio must be established, usually based on climate, and containing a diverse array of adaptable crop species, economic potential, crop production practices, and soil and water management considerations. The crop portfolio is used to screen adaptable crops for a region and includes the best management practices for the production of each adaptable crop [14]. In others words, it is the selection of crops compatible with the set of constraints. Next is the comparison and choice of the most satisfying crop and management options [16]. Designing new CSs is a long process and occurs in a rapidly changing environment. This is exemplified by climate but also by the economy (prices and policies) and the changing demands and functions that society assigns to agricultural systems. The design process must therefore integrate objectives of the resilience and flexibility of CSs in an unpredictable environment [18]. Obviously, the use of models for the design of CSs can be an important tool for the farmer, although there are some drawbacks [16]. Geographic information systems, qualitative decision-matrix analyses, a simple rule-based model using multi-criteria evaluations, and a machine learning-based land-transformation model can be used harmoniously to study complex socio-ecological systems. Models evaluate how each technique performs in the study of complex socio-ecological systems using a multi-tier framework, detailing how each method analyzes the resource system,

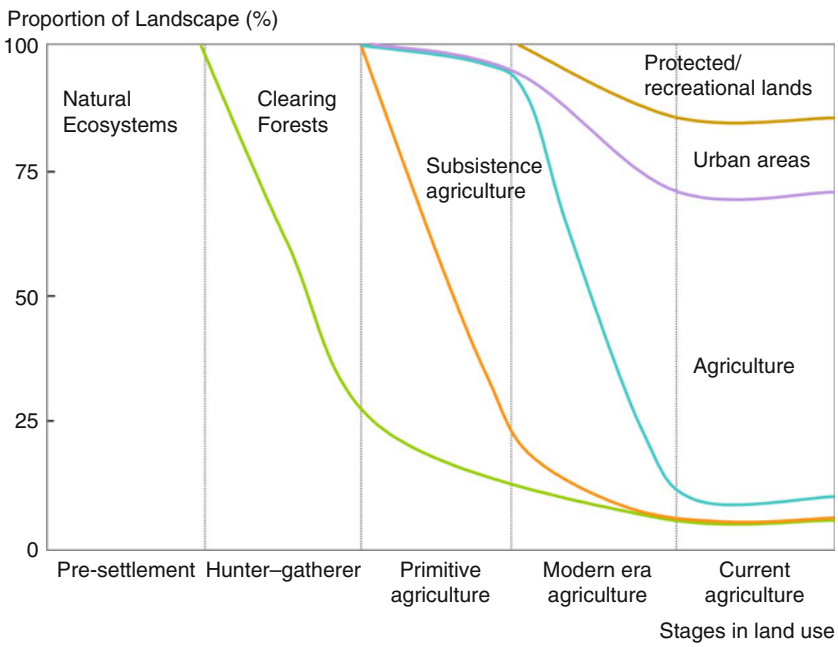
resource units, governance system, users and interactions, and outcomes in the system. Model use enhances our understanding of the land-use decision-making process [19].

Anthropological View

Beginning around 8,500 BC, the transition from the hunter–gatherer lifestyle to food production enabled people to settle down next to their permanent agricultural lands, instead of migrating to follow seasonal shifts in wild food supplies. Food production was accompanied by a human population explosion that has continued unabated to this day, resulting from two separate factors. First, the sedentary lifestyle permitted shorter birth intervals. Nomadic hunter–gatherers had previously spaced out birth intervals at 4 years or more because a mother shifting camp can carry only one infant or slow toddler. Second, plant and animal species that are edible to humans can be cultivated in much higher density in our agricultural land than in wild habitats [20].

Agriculture also led to an explosion of technology because sedentary living permitted the accumulation of heavy technology such as forges that nomadic hunter–gatherers could not carry and because the storable food surpluses resulting from agriculture could be used to feed full-time craftspeople and inventors. By also feeding full-time kings, bureaucrats, nobles, and soldiers, those food surpluses led to social stratification, political centralization, and standing armies. All of these overwhelming advantages are what enabled farmers to eventually displace hunter–gatherers [21].

Like all species, humans have exercised their impulse to perpetuate and propagate themselves. In doing so, humankind has "domesticated" ecosystems in ways that enhance its food supplies, reduce exposure to predators and natural dangers, and promote commerce. On average, the net benefits to humankind of "domesticated" nature have been positive. We have, of course, made mistakes, causing unforeseen changes in ecosystem attributes, while leaving few, if any, truly wild places on Earth [22]. Domestication of plants and animals may be the single most important feature of the human domination of our planet (Fig. 1). Domestication involves the selection of traits that fundamentally alter wild species to become more useful to us. Conservation has often been framed as the science



Cropping Systems: Shaping Nature. Figure 1

Stages in "domestication" of nature by human being in relation with the area occupied (Adapted from [23])

aimed at protecting nature, and especially protecting nature from people. However, there really is no such thing as nature untainted by people [24]. Facing this reality should change the scientific focus of environmental science. Instead of recounting doom-and-gloom statistics, it would be more fruitful to consider the domestication of nature as the selection of certain desirable ecosystem attributes, such as increased food production, with consequent alteration to other ecosystem attributes that may not be desirable. Under this paradigm, our challenge is to understand and thoughtfully manage the trade-offs among ecosystem services that result from the inescapable domestication of nature [22].

It is clear that cities are the main consumers of most ecosystem services. This is important because the desire and value for these services determines the traits that humans select for preservation or elimination. For example, if humans want to maximize food production, landscapes will be domesticated to accommodate a few high productivity species, plus the human-associated species able to survive in these modified landscapes. If people want more wildlife for recreational hunting, populations of predators of game species will be reduced, and the edge habitat that a few game species prefer will be increased. The choices and actions of urban dwellers influence nature far removed from cities, yet urban dwellers are increasingly unaware of these impacts [22].

Agricultural Practices' Footprint

The huge magnitude of human impacts in the environment is recent, but the presence of impacts such as purposeful wildfires goes back thousands of years. The reality of the human footprint renders discussions about what areas of the world to set aside as wild and protected areas as somewhat irrelevant; more germane is a discussion of what trade-offs we are willing to accept as a result of the domestication of nature [22].

The main environmental impacts attributed to agriculture come from the conversion of "natural" ecosystems to agroecosystems by CSs [9]. Clearing land for agriculture, humans target wild species for harvest or elimination. Humans have so tamed nature that few locations in the world remain without human influence [22] (Fig. 1). The whole notion of a "virgin rainforest" may be erroneous, with extensive prehistoric human activity evident in what were once thought to be untouched forests in the Amazon and Congo [25]. Global maps of human impact indicate that, as of 1995, only 17% of the world's land area had escaped direct influence by humans [22]. Between 1700 and 1980, the total area of cultivated land worldwide increased 466%, and yields increased dramatically, particularly because of selectively bred, high-yielding varieties, fertilizers, pesticides, irrigation, and machinery. For example, irrigation increased corn yields in eastern Colorado by 400–500% from 1940 to 1997 [9]. Roughly 50% of the world's surface area has been converted to grazed land or cultivated crops [26]. Cropping systems (areas where at least 30% of the landscape is in croplands, confined livestock production, or freshwater aquaculture) now cover a quarter of the Earth's surface, partly by conversion of temperate grasslands, Mediterranean climate forests, and many tropical ecosystem types. More than half of the world's forests have been lost in this land conversion [26]. Forests have essentially disappeared from 25 countries, with 9.4 million hectares lost annually from the Earth's surface [27]. Species and populations of species are being lost at unprecedented rates, while at the same time, the global biota is becoming homogenized, owing to the introductions of alien species to new regions. These examples represent major losses of pieces of the biosphere machinery, which have a serious impact on the delivery of ecosystem-regulating services – impacts such as greater prevalence of infectious diseases in disrupted ecosystems, adverse effects on local climates by ecosystem modification, and the loss of flood protection [27].

Environmental damages have come from agricultural nutrients that pollute aquatic and terrestrial habitats and groundwater, and from pesticides, especially bioaccumulating or persistent organic agricultural pollutants. Agricultural nutrients enter other ecosystems through leaching, volatilization, and the waste streams of livestock and humans. Pesticides can also harm human health, as can pathogens, including antibiotic-resistant pathogens associated with certain animal production practices [9]. Many CSs have degraded soil quality and necessitated the expense of increased fertilization, irrigation, and energy to maintain productivity [28]. Today, only 30–50% of applied nitrogen

fertilizer [29] and ~45% of phosphorus fertilizer [30] is taken up by crops. A significant amount of the applied nitrogen and a smaller portion of the applied phosphorus are lost from agricultural fields. Nitrogen fertilization can increase the emission of gases that have critical roles in tropospheric and stratospheric chemistry and air pollution. Nitrogen oxides (NO_x) emitted from agricultural soils and through combustion increase tropospheric ozone, a component of smog that impacts human health, agricultural crops, and natural ecosystems. NO_x from agroecosystems can be transported atmospherically over long distances and deposited in terrestrial and aquatic ecosystems. Finally, nitrogen inputs to agricultural systems contribute to emissions of the greenhouse-gas nitrous oxide. Rice paddy agriculture and livestock production are the most important anthropogenic sources of the greenhouse-gas methane [31]. Much of agriculture in the developed world had for a time embraced potentially non-sustainable systems for economic reasons, over-utilizing monocropping, specialization and mechanization, which was damaging to soils and the environment [32]. Modern agroecosystems are also depleted in biodiversity and habitat heterogeneity, often with a reduction in resilience as a result of their biological monotony [22].

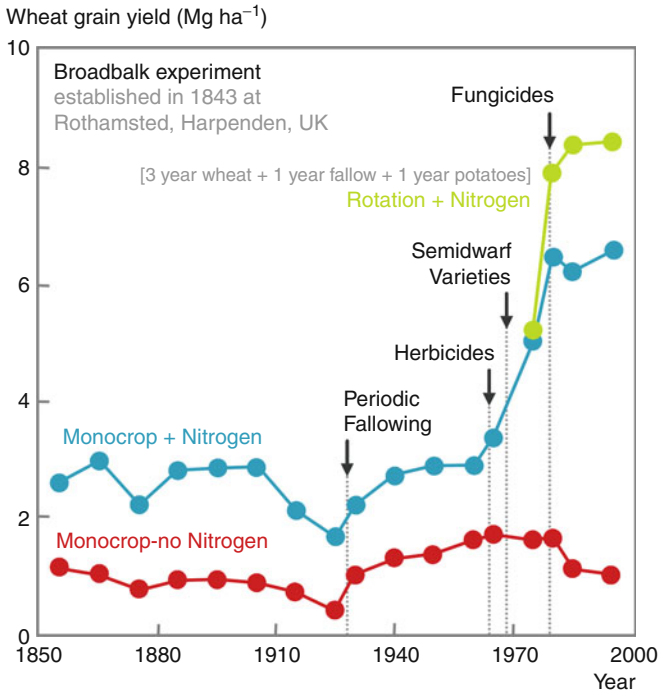
Cities are a good place to start when considering the broader implications of agroecosystems. The cumulative resource demands of cities are often expressed as the total land area required to supply those resources, called the "ecological footprint" [33]. Every city imports resources and exports waste into a region that is spatially much larger than the city's area. However, there is substantial variation in per capita ecological footprints between rich and poor regions, with the average resident of the United States using 6 times the area of the average sub-Saharan African [34].

Praise of Agricultural Science

To a conservationist interested mainly in biodiversity, we have degraded nature, but to an agronomist, we have shaped the nature to make it better serve humans [22]. It is paradoxical that current urban dwellers look down upon and lack an appreciation of agriculture when it is the key to our existence and to obtaining the energy needed for their daily activities. There is no question that humans have been successful in their efforts to produce food, thereby enhancing their well-being [22]. Contrary to Malthus's predictions, food production has kept up with, and even outpaced, human population growth [35]. Malthus did not take into account that "there is no gene for the human spirit" [36]. The massive increase in food supply has been achieved by focusing efforts on planting and consuming a small variety of plants [22]. As of 1999, barley, maize, rice, and wheat occupied almost 40% of global cropland [37].

Nowadays, few scientists think of agriculture as the chief, or model science. Many, indeed, do not consider it a science at all. Yet it was the first science – the mother of all sciences; it remains the science that makes human life possible; and it may well be that, before the century is over, the success or failure of Science as a whole will be judged by the success or failure of agriculture [38]. For too many years, the agricultural sciences have been disparaged in the science and education communities, perhaps because agronomy, soil science, plant pathology, and animal science use a problem-solving approach rather than simply seeking knowledge [39]. But as we move into a new era of shared accountability and responsibility, let's keep in mind that agricultural sciences affect us all, and when agricultural science is thriving, our communities likely are thriving too [39]. Agriculture is not seen as a source of solutions to many of the world's most pressing challenges. When science research funds are handed out, agriculture often gets left off the list. It is possible to suspect this because policy-makers and some scientists see "agriculture" as synonymous with "agribusiness" rather than as a purely scientific discipline, and they assume private funding will take care of agriculture-related research needs [39].

The benefits of agriculture have been immense. Before the dawn of agriculture, the hunter–gatherer lifestyle supported about four million people globally [40]. Modern agriculture now feeds 6,000 million people. Global cereal production has doubled in the past 40 years, mainly from the increased yields resulting from greater inputs of fertilizer, water and pesticides, new crop strains, and other technologies of the "Green Revolution" [41] (Fig. 2). This has increased the global per capita food supply, reducing hunger, improving nutrition (and thus the ability of people to



Cropping Systems: Shaping Nature. Figure 2

better reach their mental and physical potential), and sparing natural ecosystems from conversion to agriculture [43].

Agriculture is the science that has had and continues to have the greatest impact on humanity. The advancements are the result of countless researchers unknown to the general public and who deserve proper tribute and acknowledgement. We should be eternally grateful to people, many of whom are consigned to oblivion, such as Justus von Liebig, (1803–1873), who is known as the "father of the fertilizer industry," for his discovery of nitrogen as an essential plant nutrient and his formulation of the Law of the Minimum which described the effect of individual nutrients on crops; Sir John Bennet Lawes, (1814–1900) who experimented with crops and manures at his farm at Harpenden, nowadays known as Rothamsted, and established the first long-term field experiment in the world, the Broadbalk (1843); Daniel Albone, who invented, in 1902, the world's first successful light farm tractor; Fritz Haber and Carl Bosch, whose work led to the synthesis of the first N fertilizer in 1913, seeing that without the use of synthetic fertilizers, world food production could not have increased at the rate it did and more natural ecosystems would have been converted to agriculture [9]; Sir Ronald Aylmer Fisher, who, working in the long-term experiments at Rothamsted in 1925, established the basis of the modern statistics that so greatly benefited agricultural research and all other sciences; Erling Johnson, who in 1927 developed an industrial method for producing nitrophosphate; Paul Hermann Müller, who discovered that DDT was a very effective insecticide in 1939, in spite of the fact that it was later discovered to be hazardous for many living beings, the good it accomplished for humanity is immeasurable as it controlled mosquitoes spreading malaria and lice transmitting typhus; Judah Hirsch Quastel, who working at Rothamsted, developed the first herbicide (2,4-D) in 1946; Norman Ernest Borlaug, father of the "green

revolution," led the introduction of high-yielding varieties, doubling wheat grain yield in many countries during the 1960s (Fig. 2); John E. Franz, who discovered Glyphosate in 1970, a broad-spectrum systemic herbicide; Marc Van Montagu and Jeff Schell discovered the gene transfer mechanism, developing the first transgenic plant in the 1980s; in addition to a long list of anonymous researchers who contributed their part to providing humanity with the food needed through techniques which have become increasingly more respectful of the environment and safer for consumption.

Eradication of Fallow, Tillage, and Monoculture

There are three agricultural practices that must tend to disappear from present and future CSs because it has been proven, in general, that they are more harmful than beneficial. Two of these, tillage and fallow, have been used since the beginning of agriculture, while the third, monoculture, emerged during the last century as a consequence of the incorporation of other techniques that made it apparently viable in the context of a great demand for food. These practices must be considered errors of the past that the present has allowed us to discover.

Soil is not naturally intended to be in a state of bare fallow. CSs must be inspired by or consider nature in their design. Soil is meant to be covered by vegetation as can be observed in most terrestrial ecosystems; therefore, when man included bare fallow in its group of agricultural practices, he committed a big mistake. Even in the conditions employed to allow low-fertility soils to rest, the most ideal option would be a change in crop, or if necessary, another option would be to not remove the crop. Although it was already known at the end of the last century that bare fallow was not useful, there have been policies, as is the case of the EU, which encouraged this practice as a result of market forces. Efforts to stabilize production of cereal crops led to the adoption of wheat–fallow CSs. This system, while popular with producers because it required limited equipment and managerial skills, has proven to be agronomically inefficient and environmentally unsustainable as shown through poor precipitation-use efficiency and decreased soil quality [44, 45]. In fact, at least 60% of the precipitation received during fallow is lost to evaporation [46]. Recognition of the drawbacks of wheat–fallow as well as advances in weed and residue management technology led to a reduction in the frequency of fallow [13]. Fallow time must be limited to those periods in which no water is available. Leaving a soil without residue shifts away from natural processes since in naturally dry ecosystems, the dry pasture leaves its residue protecting the soil against aggressive climatic events. All of the suggestions for intensifying cropping under dry-land conditions are contingent on maximum water capture and minimum losses to weeds, runoff, and evaporation. Ideally, crops should be synchronized so that there is always one crop in the field available to intercept possible rainfall [44]. Increased emphasis on crop diversity within annual CSs has allowed producers to take advantage of positive agronomic benefits derived from crop rotations [14]. Realizing these benefits requires knowledge of soil-water depletion and recharge characteristics for individual crops. Such knowledge is especially critical for areas where soil-water status can vary greatly between growing seasons [47].

Tillage, as is, is also not observed in nature. It was man, with the purpose of domesticating nature, who introduced it. No-tillage was used since ancient times by indigenous cultures. This was because tillage to any depth required more energy and power than was generally possible with hand labor. The ancient Egyptians and the Incas in the Andes of South America used a stick to make a hole in the ground and put seeds by hand into unprepared soil [48]. For thousands of years, agriculture and tillage were considered synonymous. It was simply not thought possible to grow crops without first tilling the soil before planting and for weed control [49]. Intensive tillage and use of heavy machinery have accelerated soil erosion, soil-C loss and nutrient depletion, soil compaction, acidification, pollution, and salinization [50]. The advent of modern herbicides permitted no-tillage to be developed and practiced on actual working family farms. No-tillage is generally defined as planting crops in unprepared soil with at least 30% mulch cover [49]. Adoption of no-tillage after its successful demonstration in the 1950s was slow. Today, approximately 23% of the total cropland in the United States is planted using no-tillage [49]. No-tillage has revolutionized agricultural systems because it allows individual producers to manage greater amounts of land with reduced energy, labor,

and machinery inputs. Maintenance of surface residue cover is essential to optimize CS performance as residue coverage minimizes erosion, enhances retention of limited precipitation, and improves soil quality [51]. Moreover, no-tillage substantially improves soil carbon, an area that is currently of great importance [45]. Crop residues, including the presence of crop stubble, can alter the soil environment in a number of ways by acting as a physical barrier, exudate of chemical suppressants (allelochemicals) from the residue, or enhancer of biological activity, and by providing a habitat for weed seed predators. These factors, as well as the buffering effect of crop residues on soil moisture and soil temperature and impacts on light availability, have a significant impact on weed-seed germination and emergence [52]. Lastly, the adoption of no-tillage has an economic benefit for farmers, reducing crop costs [53].

Monoculture, the lack of biodiversity, was a contributing factor to several agricultural disasters in history. Monoculture causes a loss of biodiversity in the "ecosystem" soil as a result of the monotony, leading to a yield loss with respect to a crop in rotation [54]. Practices that change species' composition or reduce biodiversity in agricultural systems may also diminish goods and services because the ability of ecosystems to provide some services depends both on the number and type of species in an ecosystem [9]. The supply of agricultural products and ecosystem services are both essential to human existence and quality of life. However, recent agricultural practices that have greatly increased global food supply have had inadvertent, detrimental impacts on the environment and on ecosystem services, highlighting the need for more sustainable agricultural methods [9]. Wheat, rice, and maize crops have become the three most abundant plants on Earth. A central conclusion of epidemiology is that both the number of diseases and disease incidence should increase proportionally to host abundance, and this disconcerting possibility illustrates the potential instability of a global strategy of food production in which just three crops account for so high a proportion of production [9]. The relative scarcity of outbreaks of diseases on these crops is a testament to plant breeding and cultivation practices. For all three cereals, breeders have been successful at improving resistances to abiotic stresses, pathogens, and diseases, and at deploying these defenses in space and time so as to maintain yield stability despite low crop diversity in continuous cereal systems [9]. However, it is unclear if such conventional breeding approaches can work indefinitely. Both integrated pest management and biotechnology that identifies durable resistance through multiple gene sources should play increasingly important roles [55]. Nonetheless, the evolutionary interactions among crops and their pathogens mean that any improvement in crop resistance to a pathogen is likely to be transitory [9]. Although the "Green Revolution" significantly increased rice yields in Asia, yield increases have not occurred in the past 15–20 years. The genetic "yield potential" has increased for wheat, but the yield potential for rice has not increased since 1966, and the yield potential for maize has "barely increased in 35 years." It takes a decade or two for herbicide-resistant weeds to emerge, and insects become resistant to insecticides within about a decade. Within about one or two decades of the introduction of each of seven major herbicides, herbicide-resistant weeds were observed. Crop rotation helps to prevent resistances [9].

Biological Synergism and Technical Synchronization

Agriculture should fulfill the economic, environmental, and social objectives of sustainable development. It is thus necessary to tailor current CSs to meet these needs as they are often too intensive and dependent on external inputs [56]. It is clear that the more we imitate nature or encourage natural processes, the greater the benefits for the CSs and fewer inputs that will be required. Two basic concepts should illustrate the design and management of CSs of the future: biological synergism and technical synchronization.

Biological Synergism

Biological synergic CSs should synchronize edaphoclimatic resources with the natural rhythms of crops, this being a question of common sense that has not always been applied, and clearly speaks of the diversity which has been lost with intensive systems. Therefore, the increase in biodiversity in CSs is a clear consequence of the search for biological synergism in addition to the promotion of natural processes. Biodiversity is essential to ecosystem processes in ways that

are not yet fully understood [57], and it is considered worth protecting in its own right. Crop diversification by itself, however, is of limited use without knowledge of how individual crops affect each other in a sequence. Consequently, a thorough understanding of crop sequencing effects – both positive and negative – on agronomic parameters is necessary to optimize CS performance [13, 46]. One problem associated with synergic CSs is how to choose and sequence crops to develop the inherent internal resources of the system while taking advantage of external resources such as weather, markets, government programs, and new technology [14]. Present CSs rely on extensive use of fertilizer and pesticides and the low cost of fossil fuel energy [46]. Future challenges for CSs will exploit synergism through crop sequencing to improve crop yields without additional inputs and to reduce deterioration of the environment [58].

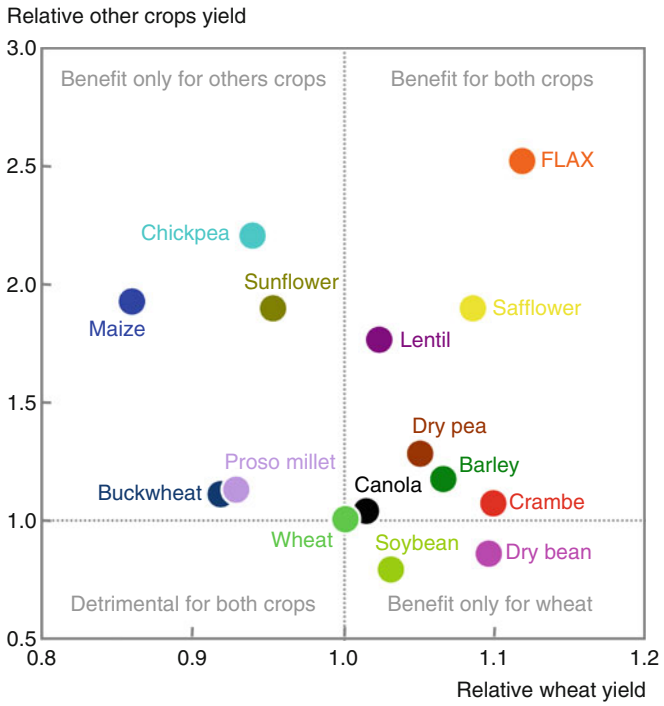
Diversification of farming systems cannot be managed on a farm or field scale alone but also requires management on a regional scale. To improve biodiversity, the interaction with other stakeholders in the region is necessary as part of regional planning processes. This has consequences for agronomic research which thus far has had only limited attention for the regional scale. Spatial planning aimed at multifunctional agriculture can be seen as a negotiation process on environmental, social, and economic aspects of land use. Complexity arises due to the high number of stakeholders and due to limited knowledge, which is often organized along disciplinary divides [59].

Crop rotation is defined as the growing of different crops (spatial and temporal), in recurring succession, on the same land in contrast to monoculture cropping. Rotation usually is done to replenish soil fertility, create a diverse soil organism, and reduce pest populations in order to increase the potential for high levels of production in future years [2, 46]. Each crop or a closely related crop species should not be grown more than every 4 years because of increased pest problems [60, 61]. One of the most effective and inexpensive methods to control plant diseases in CSs is through crop rotation. Through the use of this practice, the need to breed for new disease resistance and to discover new pesticides can be reduced. Recently, an important and costly pathogen of rice was controlled in a large region of China by planting alternating rows of two rice varieties [62]. This tactic increased profitability and reduced the use of a potent pesticide. Specific crop-rotation effects on plant diseases, however, are poorly understood and contradictory results have been reported [13].

Changes in the weed flora of agroecosystems can occur as long-term changes or temporary fluctuations in species composition [52]. Agricultural weeds are a unique group of plant species because of their ability to infest and thrive in intensively disturbed habitats despite extensive efforts to eliminate them. Weed floras differ between fields, farms, regions, climatic zones, and CSs. Weeds are successful because they are generally plastic plants that adapt to and survive changes in the environment. In continuous CSs, changes in the environment may be as a result of differences in crop species, tillage, fertilizers, herbicides, and other weed-control tactics. Long-term population shifts are usually observed after repeated use of a control measure, which exerts a high selection pressure on a population, for example, the increased incidence of some annual grass weed species due to the intensification of cereal production and selective herbicides [52]. Studies have shown that the more diverse the CS, the more diverse the weed community, with less dominant and troublesome species as would occur in a simple rotation.

With diversified continuous cropping, there is greater opportunity to utilize crops that vary in N requirements [63]. Rotations with legumes are of great interest for strengthening the synergism of a CS. Legume crops are often planted to enhance nutrient cycling and availability to other crops in the rotation. Crops with high N demands are usually grown after legume crops. Grain legumes conserve soil N by fixing atmospheric N, thereby leaving residual N in place for the next crop. Wheat yields are often higher following legumes than following other cereals [54] and the N use efficiency of a wheat crop is greater following legumes than others crops [64]. The inclusion of a legume crop decreases its reliance on external fertilizer, supplying a significant proportion of the N for the next crop and may moderate nitrate levels in the soil to avoid the potential for nitrate leaching [65] (Fig. 3).

Alternatives such as plurispecific CSs are of considerable interest for biological synergism because plant associations can provide environmental benefits in terms of better use of resources and provision of



Cropping Systems: Shaping Nature. Figure 3
Effect of 14 previous crops on relative wheat yield and the effect of wheat, as a previous crop, on those crops in the Great Plains (Adapted from [46, 66])

ecological services [67]. Yet they should also be able to maintain a level of productivity and production stability that fits with farmers' objectives. Intercrops (grass cover in the inter-rows) are now being introduced to an increasing extent due to the potential positive impacts on perennial crop and their environment: increased infiltration rate and decreased runoff due to modified soil surface characteristics [68], mitigation of soil erosion [69], limitation of herbicide use and weed control, better water-resource utilization by roots [70], and limitation of risks of diseases by reducing vegetative development [71]. However, intercropping also induces competition for soil resources, and vegetative development and yield can consequently be limited [56]. These different functions should be promoted through simultaneous adapted management of the two crops of the system.

Finally, an important link of biological synergism is the return provided by livestock to the CSs. There was always a crop–livestock pairing in ancient agriculture, but specialization caused this very important aspect of biodiversity and synergism to disappear. Research is needed to better understand interactions between crops and livestock with the intention of identifying management practices that maximize agroecosystem productivity and operational efficiency. This would save having to remove residues, part of which would be used directly by the livestock, partially allowing the recycling of nutrients. Inclusion of livestock in a CS complements both crops and livestock by adding value to grain, improving nutrient-use efficiency, and providing alternative uses for forages and crop residues [72]. It may create synergisms between the two enterprises, resulting in far greater productivity than either enterprise could attain alone [13, 73]. The inclusion of livestock in CSs would also help alleviate the problems generated by livestock: high-density animal production operations can increase livestock disease incidence, the emergence of new, often antibiotic-resistant diseases, and air, groundwater, and surface water pollution associated with animal wastes. Current livestock operations are vulnerable to catastrophic loss

of animals to disease. The handling and disposal of animal wastes are significant problems of high-density animal confinement facilities. Manure lagoons can release high levels of hydrogen sulfide and other toxic gases, volatilize ammonium that greatly increases regional nitrogen deposition, and contaminate surface and ground waters with nutrients, toxins, and pathogens. These animal wastes pose health and environmental risks similar to those of human wastes and should be treated accordingly. For example, animal wastes could be treated by composting to create a crop fertilizer that no longer harbors pathogens, and that is applied at appropriate rates and times and with methods that minimize nutrient leaching. This closing of the nutrient cycle decreases dependence on synthetic fertilizer production, and is more efficient when animal and crop production are combined locally [9].

Technical Synchronization

Technical synchronization must be defined as the concept on which precision agriculture is based, i.e., the temporal and spatial synchronization of agricultural techniques. All agricultural practices must be synchronized in time with the rhythms of the agroecosystem (time-specific management). This synchronization must take into account the growth stage of the crop, different soil characteristics (nutrients and water), weather forecasts, etc. On the other hand, there is the spatial synchronization that divides the land into homogeneous units for management (site-specific management) [63]. A basic principal of technical synchronization is the energetic efficiency when making decisions in relation to the agricultural practices to be carried out.

The key to the application of technical synchronization in a CS is the acquisition of data in order to make management decisions in time and space. There are an increasing number of data acquisition devices available to assist with decision making: global positioning (GPS), satellites or aerial images, information management tools (GIS), weather stations, soil sensors (water content, temperature, etc.), optical sensors (e.g., chlorophyll meters), and remote sensors (visible and near infrared spectral), etc. These tools allow the farmer to have a better understanding of the interaction of climate and management that causes tremendous year-to-year variation in on-farm yields and crop requirements.

Nonetheless, technical synchronization poses a problem when applied by the farmer. There is a large body of published research on technologies for increasing the technical synchronization of agricultural practices, but relatively few have been adopted by farmers because they are not cost-effective or practical. Adoption of improved technologies typically requires additional skills and labor or investments in new equipment. Information on expected costs and economic returns from such investments is required to convince farmers of the benefits from adoption [12]. A possible solution is cooperativism for the acquisition and sharing of these new technologies.

Dynamic Cropping Systems

It could be said that, until now, CSs have been static, i.e., year after year the same group of agricultural practices have been repeated, causing soil monotony in the agroecosystem. A dynamic CS must be flexible and go against repeated management practices, and the decisions must be made based on measured parameters and their determining factors. A dynamic CS is only the consequence of the application of the two previously stated principles: biological synergism and technical synchronization. Cropping systems need to be inherently flexible to take advantage of economic opportunities and/or adapt to environmental realities [13, 18]. The implementation of a management strategy requires knowing, understanding, planning, measuring, monitoring, and record keeping at each step of the production process. Dynamic CSs require the development and implementation of agricultural production systems that are highly productive, energy efficient, and environmentally non-degrading [12].

Dynamic CSs are a form of agricultural production that relies on an annual or pluri-annual strategy to optimize the outcome of (1) production, (2) economic, and (3) resource-conservation goals using ecologically based management principles [74]. Implicit to this strategy is the need for producers to possess information necessary to respond to continual change. The key factors associated with dynamic CSs are diversity, adaptability, reduced input cost, multiple enterprise

systems, and awareness of environment and information [14]. Greater crop diversity and sequencing flexibility within dynamic CSs may result in reduced weed, pest and disease infestations, greater nutrient- and precipitation-use efficiency, decreased requirements of exogenous inputs, and lower production risk [74]. To remain competitive in agricultural markets, increased diversity of systems will be required to minimize inputs and improve economic margins.

To increase responsiveness to externalities, opportunity/flex CS [75] or dynamic CS [14] concepts have been developed. These systems allow producers to adjust CS intensity and/or diversity based on externalities as well as management goals, such as soil-water status at planting, soil residual nitrogen, market demands, etc. This approach to crop sequencing possesses an inherent flexibility to adapt to high-risk conditions, and therefore may be more economically and environmentally sustainable than other approaches to crop sequencing [13]. However, the authors who established the principles of dynamic CSs have focused solely on rotation selection, which is erroneous, since a CS is more than its rotation selection, although the crop selection is without a doubt the most important decision made in a CS. Perhaps the concepts should be called dynamic or flexible crop election system. However, a dynamic CS makes more sense if each year all of the crop techniques used are reconsidered, i.e., crop selection, tillage, residue management, nitrogenous fertilization, etc. in such a way that there are dynamics in the selection of each and every one of the agricultural practices that depend on externalities.

Future Challenges

Agricultural science is ripe for a renaissance [39] as a consequence of the future challenges it must confront. The widespread adoption of CSs that are sustainable and environmentally benign is essential for the long-term survival of civilization [32]. Furthermore, through the use of strategic alliances, cooperation among producers on a regional basis may eventually lead to greater integration and diversification than could be achieved for the individual farm operation [15]. The primary challenges facing CSs in this century are: covering the demands of an increasing world population; water shortage; the inclusion and management of GM crops; harmonization of the production of biofuels and food production; and climate change, and the focus it brings to agricultural research. Obviously, there are many other challenges which have not been presented here, but which are intimately related to those mentioned such as: the biodiversity of CSs – as already previously mentioned – which should redound to a reduction of inputs and, therefore, a reduction of the negative effects on the environment, strategies to manage anthropogenic carbon emissions from terrestrial systems as well as fossil fuel and industrial sources, etc.

Nevertheless, together with these future challenges are a series of forces that may contribute or hinder their fulfillment: research policies, transference, and financing. In view of these challenges, governmental policies play an important role that may help or hurt the achieving of these objectives. For this reason, policymakers have a great responsibility, and their decisions should be guided by agricultural science professionals. Political intervention has an economic facet that arises as the result of the following question: How can society accomplish the dual objectives of improving food production and stability and of preserving the quality and quantity of ecosystem services provided by the Earth's land and water resources? Clearly, appropriate incentives are needed [9]. What incentives and policies could lead to the adoption of sustainable agricultural practices? Several policy initiatives have tried to level the playing field between agricultural production and the production of ecosystem services.

Another problem in the attempt to fulfill these objectives is the transference and application of new technologies in CSs. The earlier paradigm of science being developed at the international or perhaps national level and then disseminated to farmers should be replaced by an active exchange of information among scientists and farmers. Scientists in developing countries who understand the ecosystems, human culture, and demands on local agricultural systems must be actively trained, promoted, and brought into the international scientific community [9].

The economic investment in agricultural research is the third problem. Organized public and private investment in agricultural R&D was a primary driver of the comparatively rapid growth in agricultural

productivity experienced in the latter half of the twentieth century [76]. Substantially greater public and private investments in technology and human resources are needed internationally, especially in low-income nations, to make agricultural systems more sustainable. Global research expenditures are less than 2% of agricultural gross domestic product worldwide [77], being roughly 5.5% of agricultural GDP in developed countries, but less than 1% in developing countries (where most of the increased food demand will occur during the next 50 years). At present, there are few incentives for the private sector to increase investments in lower-income developing countries [78]. Moreover, funds have been redirected away from farm productivity toward other concerns, such as the environmental effects of agriculture; food safety and other aspects of food quality; and the medical, energy, and industrial uses of agricultural commodities. Without adequate investments, yield gains and environmental protection may be insufficient for a transition to sustainable agriculture [9].

Feeding the World: Priority Aim

In a recent update of earlier estimates, the Food and Agriculture Organization [79] of the United Nations reported that more than one billion people now suffer malnutrition [80]. By 2050, global population is projected to be 50% larger than at present and global grain demand is projected to double [28, 82], especially the economic growth of the fast-growing economies of Asia [81]. This doubling will result from a projected 2.4-fold increase in per capita real income and from dietary shifts toward a higher proportion of meat (much of it grain fed) associated with higher income. Further increases in agricultural output are essential for global political and social stability and equity. Doubling food production again and sustaining food production at this level are major challenges [82]. Doing so in ways that do not compromise environmental integrity and public health is a greater challenge still [9]. Agricultural productivity growth will be a pivotal determinant of long-term growth in the supply, availability, and price of food over the coming decades [81]. However, a slowdown in growth of agricultural productivity and grain yields has been documented. If this slowdown in productivity persists, it could have profound implications for food-price trends in the future [81].

A key trade-off in cultivated systems is between increasing the amount of cropland needed to meet growing food needs versus increasing the productivity of each hectare of cropland. The "land-sparing" impact of modern farming practices has mainly been achieved by yield increases from the use of crop monocultures with improved crop varieties, fertilizer inputs, and irrigation. For example, if yields of the six major crop groups that are cultivated on 80% of the total cultivated land area had remained at 1961 yield levels, it would require an additional 1.4 billion hectares of land in 2004 – more than double the amount currently used. This represents 34% of the total land area suitable for crop cultivation and would have required conversion of large areas of uncultivated land that support rain forests, grassland savannahs, and wetlands. In Asia alone, it would require an additional 600 million hectares, which represent 25% more land area than is suitable for cultivation on this continent. Asia would now be heavily dependent on food imports if crop yields had remained at 1961 yield levels. Although this increase in productivity has saved some land from conversion, it has resulted in greater impact on other services through water withdrawals, excessive nutrient loads and pesticide use. The key ecological question is, therefore, whether environmental services – other than food production at regional and global scales – would be enhanced by focusing food production on less land under intensive management with high yields, versus expanding cultivated area in lower-yielding systems using farming practices that preserve environmental services at the field and local levels. Few studies have addressed this issue using sound, ecological, analytical methods [27].

Water: Colorless Gold

Water is the principal factor limiting crop yield and is considered a luxury in many agroecosystems. In many developing countries, water is a major factor constraining agricultural output, and income of the world's rural poor [83]. Forty percent of crop production comes from the 16% of agricultural land that is irrigated [84]. Irrigated lands account for a substantial portion of increased yields obtained during the Green

Revolution [9]. Unless water-use efficiency is increased, greater agricultural production will require increased irrigation. However, the global rate of increase in irrigated area is declining, per capita irrigated area has declined by 5% since 1978, and new dam construction may allow only a 10% increase in water for irrigation over the next 30 years [84]. Irrigation return-flows typically carry more salt, nutrients, minerals, and pesticides into surface and ground waters than in source water, impacting downstream agricultural, natural systems, and drinking water. Technologies such as drip and pivot irrigation can improve water-use efficiency and decrease salinization while maintaining or increasing yields. They have been used in industrialized nations on high-value horticultural crops, but their expanded use currently is not economically viable for staple food crops. In developing countries, 15 million hectares have experienced reduced yields owing to salt accumulation and waterlogging [85]. The water-holding capacity of soil can be increased by adding manure or reducing tillage and by other approaches that maintain or increase soil organic matter. Cultivation of crops with high water-use efficiency and the development – through the use of biotechnology or conventional breeding – of crops with greater drought tolerance can also contribute to yield increases in water-limited production environments. Investment in such water-efficient technologies, however, is best facilitated when water is valued and priced appropriately [9].

However, most of the world's agricultural area corresponds to dry-land areas and therefore the challenge is to increase the efficiency of water use in these areas. Efficient use of limited water supplies in dry-land CSs is critical to system success. In the future, increases to semiarid dry-land system water-use efficiency and precipitation-use efficiency may come from continued improvement in managing residues (especially no-tillage), cropping sequences that minimize fallow periods, herbicides, and crop choice. However, continuous cropping under dry-land conditions remains risky due to the limited precipitation (erratic in distribution and frequency) and high-potential evaporation. In the future, the following are potentially fruitful areas of research that may improve system water-use efficiency [86]: (1) Increasing the amount and persistence of crop residues. (2) Implementation of flexible rotations (i.e., opportunity cropping). The occurrence of precipitation and, hence, the availability of adequate stored soil water for a crop is highly variable, especially in semiarid regions. Sometimes stored soil water at normal planting times for a crop in a given CS is limited; at other times, adequate water for a crop is available when the planting of a crop had not been planned. By practicing opportunity cropping, some crop generally could be planted when water becomes available. The goal should be to grow a crop whenever conditions are or become favorable and not according to some predetermined schedule [87]. (3) Matching of crop cultivar selection to prevailing weather conditions. Genetic yield potential is linked positively with maturity, so cultivar evaluation trials conducted under conditions of adequate soil water often favor longer-maturity cultivars and influence farmer choice. (4) Improvement of the timeliness of cultural operations, including early seeding of crops and optimum timing of weed control, and time operations to coincide with favorable conditions as predicted by short-term (48–72 h) weather forecasts.

Genetic Modified Crops: Essential

Genetically modified crops are a very important part of the "second Green Revolution," which may help to break the tendency toward the stabilization of work agricultural production. Genetically modified crops may offer the best hope for producing crops that can withstand drought, impoverished soils, and disease. Future GM products are likely to carry traits that will improve nutrition and health, help guard against drought, heat and cold, and allow plants to access and more efficiently utilize plant nutrients. All of these technologies have more benefits to offer society, and especially, poor farmers and consumers even more than rich ones [88].

Therefore, GM crops are an essential tool in feeding the growing world population and reducing the negative effects on the environment from the use of pesticides. Nevertheless, this technology must be used properly by growers. Growers who adopt herbicide or pest tolerant crops in all cycles of the crop rotation will be at greater risk than those who choose to rotate crops

and/or use other management strategies [89]. However, farmers must be proactive in protecting the longevity of the technology by reducing the likelihood of resistance occurring and providing alternative selection pressures on weeds and pests [52]. We must not forget that life always finds a way through barriers [90].

Biofuel Crops: A Controversial Birth

Recent analyses of the energy and greenhouse-gas performance of alternative biofuels have ignited a controversy that may be best resolved by applying two simple principles. In a world seeking solutions to its energy, environmental, and food challenges, society cannot afford to miss out on the global greenhouse-gas emission reductions and the local environmental and societal benefits when biofuels are done right. However, society also cannot accept the undesirable impacts of biofuels done wrong [91]. Biofuels done right can be produced in substantial quantities with little or no competition with food production.

The biofuel industry could have many positive social and environmental attributes, but it could also suffer from many of the sustainability issues if not implemented the right way. Putting biofuel crops on marginal lands, rather than on our most productive croplands, could mean preventing competition with food production and concomitant effects on commodity prices, as well as minimizing or even avoiding the carbon debt associated with land clearing. However, marginal lands can also be rich in biodiversity, may require sizable inputs of nutrients and water to make production economically viable, and may carry the opportunity cost of forgone future carbon sequestration [92].

Globally, the production of an important amount of energy with biofuels will require a large amount of land – perhaps as much as is in row crop agriculture today. This will change the landscape of Earth in a significant way. The identification of unintended consequences early in the development of alternative fuel strategies will help to avoid costly mistakes and regrets about the effects on the environment. Policies that support long-term sustainability of both our landscapes and our atmosphere are essential if we are to chart a low-carbon economy that is substantially better than business as usual. Sustainable biofuel production systems could play a highly positive role in mitigating climate change, enhancing environmental quality, and strengthening the global economy. But it will take sound, science-based policy and additional research effort to make this so [93].

Until now, the most convincing option for the production of biofuel has been the use of perennial plants as they require fewer inputs and can be grown on degraded lands abandoned from agricultural use [91]. Use of such lands minimizes competition with food crops. This also minimizes the potential for direct and indirect land-clearing associated with biofuel expansion, as well as the resultant creation of long-term carbon debt and biodiversity loss. Some initial analyses on the global potential of degraded lands suggest that they could meet meaningful amounts of current global demand for liquid transportation fuels [92, 94, 95]. The option of using crop residues from food crops, such as corn stover and straw from rice and wheat is a more controversial matter. Recent research suggests that it is to the benefit of farmers to leave substantial quantities of crop residues on the land [96], but that, nonetheless, even conservative removal rates can provide a sustainable biomass resource about as large as that from dedicated perennial crops grown on degraded lands.

Good public policy will ensure that biofuel production optimizes a bundle of benefits, including real energy gains, greenhouse-gas reductions, preservation of biodiversity, and maintenance of food security. Performance-based policies that provide incentives proportional to the benefits delivered are needed. This is a complex question that cannot be addressed with simplistic solutions and sound bites. It needs a new collaboration between environmentalists, economists, technologists, the agricultural community, engaged citizens, and governments around the world [91].

Climate Change: Technical Plasticity

The scenario produced, if indeed climate change becomes a greater reality, is unclear. There is a “climate of suspicion” as published in the journal Nature at the beginning of January 2010. Climate

researchers must emphasize that – although many holes remain to be filled – there is little uncertainty about the overall conclusions: greenhouse-gas emissions are rising sharply, they are very likely to be the cause of recent global warming and precipitation changes, and the world is on a trajectory that will shoot far past 2°C of warming unless emissions are cut substantially [97]. It is evident that CSs must have the ability to adapt to a more unpredictable amount of rainfall and high temperatures. According to the IPCC definition, the extent to which CSs are vulnerable to climate change depends on the actual exposure to climate change, their sensitivity, and adaptive capacity [98]. The adaptive capacity refers to the ability to cope with climate change, including climate variability and extremes, in order to (1) moderate potential damages, (2) take advantage of emerging opportunities, and/or (3) cope with its consequences [99].

Nonetheless, in spite of the uncertainty regarding climate change, primarily as a consequence of the increase in atmospheric CO_2 levels, there are some positive effects. When you step into a commercial greenhouse, the chances are you are stepping into the future. To plants, CO_2 is food, and greenhouse operators, knowing this, use it to fatten them up. While today's atmosphere contains about 380 parts per million of CO_2, commercial greenhouses often contain CO_2 concentrations of twice that or more – the sort of concentration that we might expect in the open air at the end of the century [100]. Many crop scientists believe that this carbon dioxide fertilization effect will go at least some way toward offsetting the losses in yield to be expected as a result of the higher temperatures, flooding, drought, and rising sea levels that the CO_2 greenhouse effect will bring. But some are not so sure. These researchers point to the known negative effects that increased CO_2 concentrations have on the protein content of crops. When Bruce Kimball started out in the 1970s, available technology for high-CO_2 research was limited. Based on current knowledge, he says, the net effect of increasing CO_2 is a good one: "As far as crops go, I think higher CO_2 is a definite benefit. Yes, a little less nutrition than before, but we get more food" [100]. But while Kimball thinks that, in general, the gains in yield are the most important thing, he is not blind to the drop in protein levels.

Agricultural Research: Return to the Field

In recent years, an important movement in agricultural research has emerged on an economic as well as human resource level, toward molecular aspects of plant growth and development. Progress in understanding plant molecular biology has been impressive, and useful applications are evident [101]. However, agronomy has been marginalized, with its field laboratories which require much more time to produce results. This migration could have something to do with the scientific productivity stimulated by the present scientific system since many agricultural research areas that do not conduct field work require less than a year from the start of experimental design until the results are published. On the contrary, field research requires at least 2 years before the results can be accepted by the scientific community. Most records used to assess ecosystem changes are based on short-term data or satellite imagery spanning only a few decades. In many instances, it is impossible to disentangle natural variability from other, potentially significant trends in these records partly because of their short time scale [102]. It is evident that the improvement of CSs requires research in CSs, and specially long-term experiments. Unless a return is made to the roots of research under field conditions, many of the challenges faced will not be overcome. The return to field research will contribute to the global public good by restoring and sustaining productivity growth over the long run, which in turn will mitigate hunger and poverty and, at the same time, reduce pressure on the natural resource base [81].

Nevertheless, in recent years, some agronomists have begun to once again stress the importance of this marginalized dimension of agricultural research, which is time, in relation to the consequences that CSs have on productivity and the environment. Within this framework, long-term experiments acquire a noteworthy relevance. The aim is to compare the biological and economic productivity of different CSs. The high annual fluctuations in rainfall, and resulting crop yields, may make several crop cycles necessary in order to detect significant differences. Likewise, the differences between soils, water–soil relationship, and variability of pathogens and plagues could provide information that explains the differences in yield

among CSs and suggest strategies in which crop sequences and management practices can be selected to increase efficiency in the use of water and nutrients, and control the populations of weed, plagues, and diseases. In this respect, long-term studies act as "laboratories" in which specific problems or mechanisms can be studied in continuous field conditions, where the crop and "input/output" history is well known, and also where tendencies of the quality of resources over time and crop yields can be examined [103]. The most convincing evidence regarding the sustainability of an agroecosystem comes from long-term experiments with positive results.

Article Outline

Glossary

Allele A variant form of a gene. Differences between alleles of a gene are a result of alternate DNA sequences.

Breeding value The sum of the independent allele effects on the trait of interest (i.e., the additive genetic worth).

Generation interval The average age of the parent when he/she is replaced by their offspring.

Genome-wide selection Selection of animals based on the value of their genomic profile. Animals are genotyped for several (thousands) of markers spanning the entire genome. These markers are so close together that they are thought to be linked with all genes in the genome.

Heritability A population measure depicting the strength of the relationship between performance and breeding value.

Indicator trait A trait genetically correlated with the trait of interest, but is easier, cheaper, or more convenient to measure and select in hopes of indirectly affecting the trait of interest in the population.

Mendelian sampling Describes the genetic variation of progeny of the same parents. More specifically, full-sibs are not expected to be genetically identical because of random segregation and recombination of genes from the sire and dam.

Reliability Regarding estimated breeding values, reliability, or accuracy of the estimated breeding value reflects the strength of the relationship between the estimated breeding value and the true breeding value.

Definition of the Subject

Dairy cattle breeding is the process of selecting and mating individuals in accordance with breeding goals, with the aim of changing genetic merit of future generations and bringing about an improvement in economic efficiency. For instance, a breeding goal may be designed to improve milk production, health, and fertility. Selection would then be for individuals who will produce offspring that genetically will earn greater profit through improved production at a lower cost (due to improved health and fertility).

Many factors have contributed to the vast improvement in dairy cattle production over the last century. One of the most important factors is the regular recording of phenotypic records. It is from these phenotypic records that the industry has estimated genetic worth. Improvement in methods for genetically evaluating dairy cattle is a large contributor to the substantial genetic improvement seen in this species. Such methods include the use of BLUP (Best Linear Unbiased Prediction), a method first proposed by C.R. Henderson in 1949 [1]. Another important milestone in the improvement of dairy cattle breeding was the development of techniques to freeze and store bovine semen in the early 1950s [2]. Because of this, semen can be stored for longer, shipped further, and therefore shared internationally. A large contributor to the success of dairy cattle breeding has been the implementation of progeny testing programs in the 1950s, which allowed for reliable genetic evaluations for bulls, especially for traits only expressed in daughters (such as

milk production) [2]. To aid in the trade and use of dairy cattle genetics on an international basis, Schaeffer in 1994 developed MACE (multiple-trait across-country evaluation) [3]. This methodology allowed genetic evaluations to be converted to different countries' scales. In 2006, Shook [4] described the remarkable increase in yield traits from 1980 to 2000, revealing an increase of 3,500 kg of milk, 130 kg of fat, and 100 kg of protein per cow per lactation. While this increase is due to improvements of many factors, including genetics, nutrition, and management, Shook [4] determined that 55% of the gains in yield traits were due to genetics and that genetic change (versus altering environmental conditions) is permanent and cumulative.

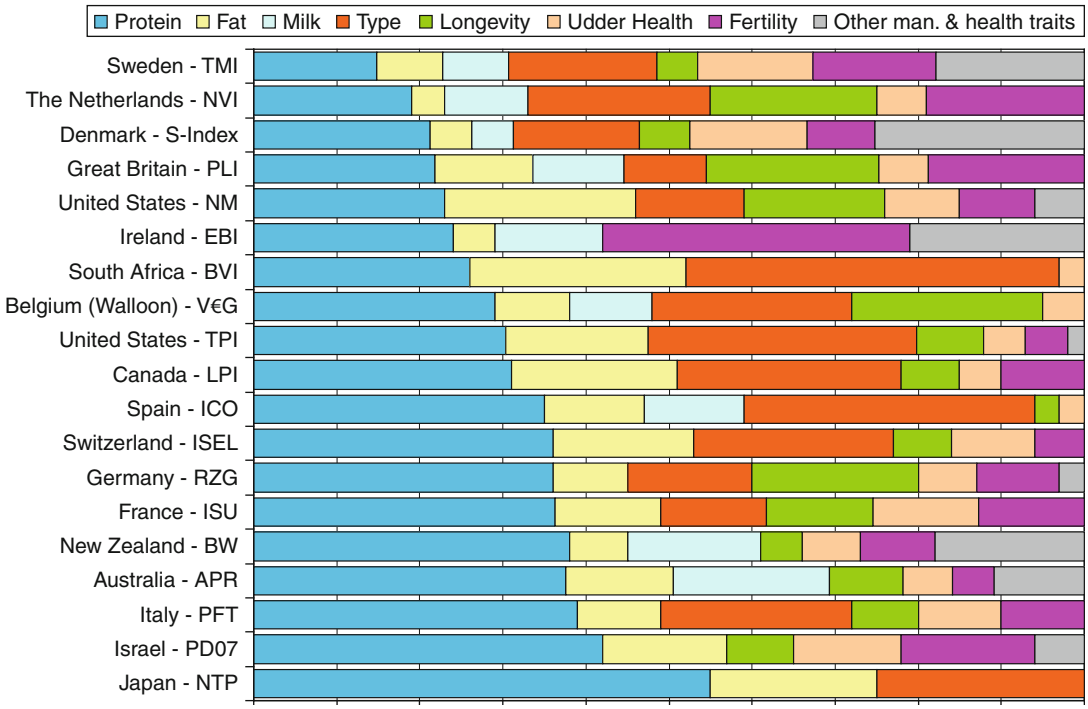
Introduction

As seen in previous entries, genetic improvement in any livestock species requires: (a) identification of breeding goals; (b) accurate data collection, animal identification, and pedigree registration; (c) breeding scheme; and (d) genetic evaluation of measured traits. In dairy cattle breeding, artificial insemination is highly used and traits of interest are usually only expressed in females. Both points determine that males are very important in breeding scheme and genetic progress, but generation interval will be longer than in other species, given that males need to be proven based on progeny performance instead of their own. Another important aspect of dairy cattle breeding is an open international market for dairy genetics, where the male side is controlled through semen sales by a large number of AI organizations, some national and some multinational based. The female side, by contrast, is controlled by the dairy producers. Being an international market with high exchange of semen, and somewhat lower but still common exchange of embryos and live animals, a constant need is to obtain genetic values of foreign animals on local scales, a service provided via international genetic evaluations by the Interbull Centre in Sweden. Finally, in the last 2 years, the full sequence of the bovine genome has opened the way for genome-wide selection. The advent of genomic selection has provided new opportunities and challenges in the global dairy semen market. The market has already seen a partial shift from progeny tested sires to young genotyped bulls. After this transition time, provided one can confirm over the next few months that the genetic level and accuracy of evaluation of these young bulls are as high as expected, genomic selection will revolutionize dairy cattle breeding, and will decrease the importance of progeny testing for some bulls. This chapter will present all the characteristics of traditional dairy cattle breeding, the international aspects of this species breeding as well as the current application of genomic selection and its consequences.

Breeding Goals

Generally, the breeding goal of a dairy producer is to maximize the profitability of his/her dairy farm. The main return in a dairy farm derives from sales of milk production. Cost of milk varies across and within countries based on supply and demand and whether a quota system is present. Additionally, premiums are paid for high-quality milk, and higher percentages of fat and protein. Furthermore, penalization will apply for milk with somatic cell count (SCC) higher than a given threshold. The second return in a dairy farm originates from the sale of breeding stock, primarily young or pregnant heifers. This type of return is less common, being present only in dairy farms with high-genetic-value cows. The same type of farm will generate return from embryo sales by multiple flushings of their top cows. A more common but low return derives from the sale of male calves and cull cows. The most important variable cost in dairy farms is represented by feed costs, followed by veterinary and breeding costs.

For many years, most selection programs worldwide focused on increasing milk production. National selection indices were based on improving milk yield and gradually shifted toward improving protein yield and, outside North America, toward increasing fat and especially protein content. This was true for most countries with the exception of the Scandinavian countries, whose selection indices also included health and reproduction; and North American countries, whose selection indices included conformation together with production. In the last 10 years, a growing interest has broadened selection indices to include functional traits such as reproduction and health. Main reasons for this shift were quota-based milk marketing systems, price constraints, or both, together with increasing producer and consumer concerns associated with the observed



Dairy Cattle Breeding. Figure 1
Relative emphasis of traits for various national selection indexes around the world

deterioration of the health and reproduction of dairy cows. Labor costs have increased relatively more than milk price in some countries. Several studies have shown that selection for production alone causes negative effects on udder health [5] and reproductive performance [6–8].

Figure 1 shows the relative emphasis on traits in national selection indices in October 2009. The main difference between selection indices in various countries was the relative emphasis on production. However, every country has now broadened their index by adding longevity, health, and reproduction to the usual production and conformation traits [9]. The search for the ideal balance between all of these important traits continues.

Data Collection, Identification, and Pedigree Registration

Proper identification, pedigree recording, and performance recording are crucial for genetic improvement of dairy cattle. Without them, accurate genetic evaluations would not be possible. In the past, animal identification was more important within the herd for management purposes [10]. However, it is now important to have proper animal identification for genetic evaluation purposes, which means that an animal's ID should be unique outside its herd. In some countries, a unique animal ID is mandatory. In the Canadian dairy cattle industry, a herd's lactation records only qualify for official publication if 80% of its first lactation animals are registered in a breed association herd book with a unique animal identification. Unique animal identification is not without error, however. Larger ID numbers associated with unique national or international identifications are at risk of recording errors, and ID tags can become worn-out or lost. Identification errors can also lead to inaccurate pedigree recording, though pedigree errors can occur for various reasons. Banos et al. [11] and Israel and Weller [12] showed that pedigree errors resulted in biased estimated breeding values and reduced genetic gain. Also, faulty equipment and human error can lead to inaccurate data recording. Fortunately, several

techniques correct or accommodate erroneous outliers in the data (e.g., robust procedures described by Jamrozik et al. [13]).

In summary, numerous errors can occur when recording performance and pedigree information. Therefore, to ensure better quality data, it is mandatory in most countries to follow the rules and standards established by the International Committee for Animal Recording before records can be used for genetic evaluation. Several traits are of economic importance in the dairy industry, but the relative importance of each depends on the country (Fig. 1).

Test-day models are used for the genetic evaluation of dairy cattle for milk production traits in many countries. These models necessitate the regular recording of milk production traits. A good recording scheme can therefore require records for 24-h milk, fat, protein, and somatic cell count (SCC) to be taken once monthly. These are called test-day records. Generally, production traits such as milk, fat, and protein yield are moderately heritable.

While milk production traits are important, many other traits are of economic importance in dairy cattle breeding, including conformation, longevity, reproduction, health, and workability traits. Conformation (or "type") traits describe the physical attributes of the cow that are generally associated with survival, health, and reproduction. Many traits (e.g., body condition score) require visual appraisal by the recorder, and are considered to be more subjective. In these cases, it is vital that assessors are highly trained to ensure repeatable and accurate recording. Many "type" traits are moderately heritable.

Because of the negative genetic correlations between milk production and fertility or health traits, long-term selection for improved milk production has led to reduced fertility and health in dairy cattle. As a result, routine genetic evaluations of reproductive and health traits are becoming more common, despite low heritabilities. A major challenge is that direct health data has not been recorded for very long and can be difficult to measure. In many cases, countries use indicator traits instead of measuring the health trait directly. An example of this is using somatic cell count as an indicator of mastitis.

Longevity (or survival) describes the length of a cow's survival in the herd, and has a low heritability as this trait can be greatly affected by herd management and other nongenetic factors. Workability includes traits such as milking speed and temperament during milking. Milking temperament has a low heritability, while milking speed has a moderate heritability.

Breeding Scheme

In general, a breeding scheme is the amalgamation of the processes involved in the selection and mating of livestock for the purpose of genetic improvement. Because of artificial insemination in the dairy cattle industry, semen from a single male can be used widely throughout the population. Therefore, genetic improvement is achieved largely through intense selection of males. However, most of the economically important traits in the industry (such as milk production traits) are expressed in the female. As a result, dairy cattle breeding relies on progeny testing schemes for genetic improvement. Data on various milk production and performance traits from daughters are collected and used to calculate estimated breeding values for bulls. The more daughters and daughter records are available for a bull, the greater the accuracy of the estimated breeding values. "Proven bulls" are bulls with very reliable estimated breeding values because they have many daughters with performance records. Estimated breeding values for bulls without progeny records are less reliable because they are calculated using the average of the estimated breeding values of the parents.

The major factors influencing rate of genetic progress for a given trait are the components of "the key equation" of animal breeding:

$$\frac{\Delta BV}{t} = \frac{r_{BV,\,\widehat{BV}}\, i \sigma_{BV}}{L} \tag{1}$$

where BV is true breeding value, t is time, $\widehat{\mathrm{BV}}$= estimated breeding value, $r_{\mathrm{BV},\,\widehat{\mathrm{BV}}}$= accuracy of the estimated breeding value relative to the true breeding value (also the correlation between the estimated and true breeding values), i = selection intensity (a function of the proportion of the population chosen to be parents of the next generation), σ_{BV} is additive genetic standard deviation, and L is generation interval. The aim is to choose animals with superior genetics to be parents of the next generation to improve the genetics of the population. Increasing the reliability (accuracy)

of prediction, selecting only the best animals as parents (increasing selection intensity), and decreasing the generation interval are important factors for increasing genetic improvement per unit time.

A major challenge in dairy cattle breeding is developing an optimum breeding program that maximizes genetic progress while minimizing cost. AI organizations are generally responsible for breeding schemes [14], and a typical AI organization can spend millions of dollars per year progeny testing bulls to find the best bull to market to the world [15]. However, dairy breeding is entering a new era in which genomic selection is possible. With genomic selection, bulls can be genotyped and selected at a young age. This improves the industry's traditional breeding scheme by reducing reliance on progeny testing (a lengthy and costly process), and will theoretically increase response to selection via a reduced generation interval [15]. Also, genomic values will increase the accuracy of genetic evaluations, especially for young sires for which traditional estimated breeding values are derived from parent averages [16].

Purebred and Crossbred Cows

The group of animals selected as parents of the next generation are expected to possess alleles that the industry considers favorable. Therefore, through selection, the frequency of favorable alleles in the population should increase with each generation while that of unfavorable alleles should decrease. The result is an increase in average breeding value, and improved performance of the dairy cattle population. The change in average breeding value over time defines the genetic trend.

As mentioned previously, artificial insemination has allowed for intense selection of sires for increased genetic improvement over time. This means that a few top bulls, with the best collection of favorable alleles, can be mated widely throughout the population. While this is a good way to progress more quickly toward fixing favorable alleles in the population, it reduces the effective population size of the breed which could raise inbreeding and reduce performance from the associated inbreeding depression. The dairy industry needs to find a compromise between selection of the best sires for use in artificial insemination, and minimization of inbreeding depression. This is, of course, less of a problem initially with crossbreeding, as sire and dam are unrelated. However, while several benefits exist with crossbreeding in general, heterosis obtained is too low to lead to more profitable animals than purebred Holsteins (the most widely used dairy breed) [17, 18]. Therefore, in the dairy industry, selection tends to occur within breeds.

Again, a large degree of dairy cattle genetic progress is achieved through the selection and use of semen of a few top bulls. However, it is important to understand that selection and consequent genetic progress within a breed is achieved via four selection pathways, all of which center around the progeny testing scheme.

Progeny testing is required so that the genetic merit of bulls can be calculated reliably via analysis of many performance records on many daughters. Every year, genetically superior bulls and cows are mated using artificial insemination to produce young bulls with high predicted genetic merit. On average, young bulls resulting from these matings will have high true genetic merit, but because of Mendelian sampling, it is not certain that these young bulls will be genetically superior. The young bulls therefore need to be proven via progeny testing. If a young bull is in fact of high genetic merit, he will yield daughters that perform well for traits of interest. The more daughters he produces with superior performance, the more certain it is that he is a genetically superior bull.

So far, two selection pathways have been discussed: selection of sires of young bulls, and of dams of young bulls. The sires of young bulls are proven and their semen can be used widely, so they can be selected very intensely, and their estimated breeding values are very reliable. Referring to Eq. 1, increased selection pressure and reliability will lead to increased genetic progress per unit time. Dams of young bulls can be selected intensely because not many young bulls need to be produced for progeny testing (only about 400 a year in Canada and about 6,000 Holsteins worldwide). However, the reliability of estimated breeding values for dams of young bulls is not as high as that of the sires because the dams have fewer close relatives with records.

In a dairy herd, replacement heifers are required. Therefore, further potential for increasing genetic progress of the population is through two more selection pathways: selection of sires of cows and dams of

cows. It takes several years for young bulls to be fully proven. However, when these bulls have a genomic evaluation or some daughter records (but not yet enough to achieve the reliability of a proven bull), they can be selected to produce replacement heifers with a reasonably high selection intensity. Dams of these future cows, however, cannot be selected so intensely for several reasons. Many replacement heifers are required, and because a female cannot breed as many times as a male, most cows will be selected for breeding. Also, female fertility in the dairy cattle population is typically low, so the industry cannot afford to be very selective with this pathway.

Genetic Evaluation

For progress in the dairy industry, it is important to accurately select genetically superior animals as parents of the next generation. Traditionally, genetic worth could only be estimated by evaluation of phenotypic records, which are a result of a combination of genetic and environmental factors (and sometimes an interaction of the two). Again, genomics is revolutionizing the way the industry evaluates dairy cattle, making it possible to genotype animals instead of waiting for phenotypic records. However, genomics is just one part of the process, and the collection of phenotypic records will still be important for some time.

The additive genetic value of an animal for a particular trait is the sum of the independent effects of that individual's alleles on that trait. On average, half of an animal's additive genetic worth is passed on to its offspring. The greater the animal's genetic worth, the more genetically superior its offspring are expected to be. The additive genetic value is therefore appropriately termed "breeding value." Breeding values of animals can be estimated from many different sources of information, including observations on the animal itself and observations from a variety of relatives. This reiterates the importance of quality phenotypic and pedigree data. True breeding value can never be known, only estimated from a very large (effectively infinite) number of genes with alleles each of which has a small effect on the trait of interest. Breeding values are estimated from limited phenotypic data using models that are not perfect. The accuracy of estimated breeding values (EBV) depends on a variety of factors, including the degree of relationship between the animals providing the phenotypic information and the animal being evaluated, the number of records available, and the heritability of the trait of interest. Of course, through genomics, perhaps one day the effect that each allele in the genome has on each trait could be quantified, bringing the industry closer to an animal's true breeding value for each trait.

Several traits of economic importance to the dairy industry were already discussed. So, a dairy bull or cow has several estimated breeding values, one for each trait. This makes selection complicated. For example, perhaps a potential sire has excellent estimated breeding values for milk production traits, but terrible values for health and fertility traits. Therefore, countries devise a national economic selection index, which incorporates estimated breeding values for traits of interest and their respective monetary worth into an equation that gives a single score for profitability ("aggregate breeding value") of each animal [19]. This makes selection much easier, as animals with the most favorable combination of estimated breeding values (e.g., high milk production and good health and fertility) are the most profitable.

Traditionally, selection index methods were used to combine weighting factors with adjusted phenotypic records from various sources (i.e., own records and records from various relatives) to derive estimated breeding values for traits. The phenotypic records were first adjusted for a variety of environmental influences including, for example, age of animal and effect of contemporary group. These methods of adjustment were not always effective for disentangling genetic effects from environmental influences. To improve the application of selection index methods, the dairy breeding industry began to use the statistical method known as best linear unbiased prediction, or BLUP, in the 1970s. This method was first proposed by C.R. Henderson in 1949 [1]. Without going into too much detail, BLUP is able to simultaneously estimate environmental effects and predict breeding values while taking into account pedigree relationships.

Both the traits and the methodologies involved in national genetic evaluations vary substantially among countries [20]. Therefore, EBVs for one trait in one country may not be representative of EBVs for the same trait in another country. This makes comparing

animals from different countries difficult. Dairy cattle genetics are shared internationally, especially sire genetics via artificial insemination. Therefore, the Interbull Centre was created to provide international evaluations. Specifically, the procedure carried out is called the multiple-trait across-country evaluation, or MACE [3]. This procedure allows Interbull to provide a separate list of International Genetic Evaluations to each participating country, expressed on that country's scale.

Future Directions

As previously mentioned, genome-wide selection is revolutionizing dairy cattle breeding. Young bulls benefit the most with a large increase in reliability of estimated breeding values at an earlier time in their lives, reducing the generation interval of these animals and hence increasing the speed of genetic improvement. It is fairly certain that future dairy cattle genetics research will focus on the improvement of genomic techniques.

Over the years, as quantitative geneticists improve upon techniques surrounding genome-wide selection for animal breeding, it is important to keep in mind the application of such techniques to human health. In 2008, Mardis [21] predicted that sequencing the entire human genome for $1,000 will be feasible in the near future. While animal breeders are currently using genomics to predict the genetic value of animals for complex traits, it may one day be possible to utilize genomics to predict human individuals' genetic risk for complex, multifactorial diseases, such as Crohn's disease [22]. Research in genomics in animal breeding will certainly pave the way for research and development of genomics applied to human health.

Disease-Resistant Transgenic Animals

Caroline Lassnig, Mathias Müller
Institute of Animal Breeding and Genetics & Biomodels Austria, University of Veterinary Medicine Vienna, Vienna, Austria

Article Outline

Glossary

Disease resistance/susceptibility The interplay of the genetically determined ability of an individual to prevent the reproduction of a pathogen or to reduce pathogen growth, host–pathogen interactions, and changing environmental conditions/factors decides on resistance/susceptibility.

Gene targeting Integration of exogenous DNA into the genome of an organism at specific sites as a result of homologous recombination. It can be used to disrupt or delete a gene, to remove or add sequences as well as to introduce point mutations at a given locus. Gene targeting can be permanent, i.e., ubiquitous with respect to tissue and developmental stage, or conditional, i.e., restricted to a specific time during development/life or limited to a specific tissue.

Genetic engineering Technological process resulting in a directed alteration of the genotype of a cell or organism. It combines recombinant nucleic acid technologies, in vitro culture technologies for gametes, embryos, tissues, or organisms, methods for the delivery of nucleic acids to the host genomes (gene transfer), and if needed, reproductive technologies to produce transgenic embryos and transfer them to foster organisms. With respect to inheritance ('transmission') to offspring, germline and somatic gene transfer methods are distinguished.

Knockdown Downregulation of expression of a specific gene by RNAi-based technologies.

Knockout/knockin Incorporation of a sequence into a specific site by homologous recombination (gene targeting) that results in disruption of gene function/altered gene function.

Quantitative trait loci (QTL) Genetic loci or chromosomal regions that contribute to variability in complex traits, as identified by statistical analysis. The genetic basis of these traits generally involves the effects of multiple genes and gene–environment interactions.

RNA interference (RNAi) The silencing of gene expression by the introduction of dsRNA that triggers the specific degradation of a homologous target mRNA, often accompanied by an attendant decrease in the production of the encoded protein.

Single nucleotide polymorphism (SNP) A variation in DNA sequence in which one nucleotide position is substituted for another by either nucleotide exchange, or deletion, or insertion. SNPs are the most frequent type of polymorphism in the genome.

Somatic cell nuclear transfer (SCNT) The nonsexual generation of nuclear genome-identical offspring ("cloned animals") by reconstitution of an enucleated oocyte with the diploid nucleus of a somatic cell to a zygote, which under appropriate culture conditions leads to reprogramming of the genome, enabling embryonic and fetal development.

Zoonotic infection The ability of a given pathogen to cross the host species barrier, from its current or long-term evolutionary host to animals and humans and thereby causing disease.

Definition of the Subject and Its Importance

Infectious diseases of livestock are a major risk to global animal health and welfare. In addition, human health is influenced due to the zoonotic potential of some of these infections.

Moreover, livestock diseases significantly impair food production and safety and cause enormous economic losses worldwide.

Transgenic technology was first developed as a research tool for studying gene function in mice in

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

Robert A. Meyers (ed.) Encyclopedia of Sustainability Science and Technology, © 2012, DOI 10.1007/978-1-4419-0851-3

the early 1980s. The technique was extended and applied to other mammals in 1985. An interesting and challenging focus of agricultural transgenesis was the potential to increase disease resistance and/or reduce disease susceptibility by introducing new genes and/or deleting deleterious genes. The laborious improvements to original and recently developed transgene technologies lead to the generation of transgenic farm animals with improved resistance to infectious diseases, demonstrating the proof of principle that genetic engineering may potentially improve animal health and aid infectious disease control in livestock.

Introduction

Phenotype-driven traditional animal breeding and marker-assisted selection based on quantitative trait loci (QTLs) have been successfully used for the genetic improvement of many agricultural production traits such as body weight, carcass composition, or milk yield. However, these genetic selection strategies have not yet resulted in a significant increase in the resistance of farm animals to disease.

Currently, genomic sequences are available for several livestock species [1] and as a by-product of the sequencing, a huge number of single nucleotide polymorphisms (SNPs) were discovered. The large panels of available SNPs were used in genome-wide association (GWA) studies for mapping and identifying genes [2]. GWA studies have already been successful in identifying causal genes and mutations for monogenic traits [3], but not for complex or quantitative traits such as resistance or susceptibility to disease.

Furthermore, traditional strategies in combating devastating infectious diseases of livestock, such as vaccination, antibiotic treatment, or even culling, have, to date, been unsuccessful (Fig. 1). Parasites evolved to resist chemical or vaccine control measures and bacteria developed resistance to many antibiotics. So far, a single infectious viral disease in livestock, rinderpest (cattle plague) could be eliminated through large-scale vaccination.

As an alternative to the traditional approaches, genetic engineering of livestock species may assist in the fight against infectious diseases.

The oldest and probably the most robust technique to produce transgenic farm animals is the injection of DNA sequences into the pronucleus of recently fertilized zygotes [4–6]. Pronuclear microinjection was successfully used to generate the most important livestock species, mainly for production of highly valuable human therapeutics. A more recent method for generating transgenic animals is the nuclear transfer technology, that is, 'cloning' [7, 8], which, together with a gene-targeting strategy allows the generation of specific gene-targeted animals [9, 10]. Recently, lentiviral vector-based strategies have been established which results in highly efficient production of transgenic livestock [11, 12]. This method in combination with the RNAi-technology may lead to the generation of disease-resistant transgenic livestock in the near future [13].

In the following section, the authors present an overview of the various transgenic methods used for the genetic enhancement of animal resistance to infectious diseases. Many studies were initially done using transgenic mouse models as this model often provides useful preliminary results prior to initiation of livestock studies.

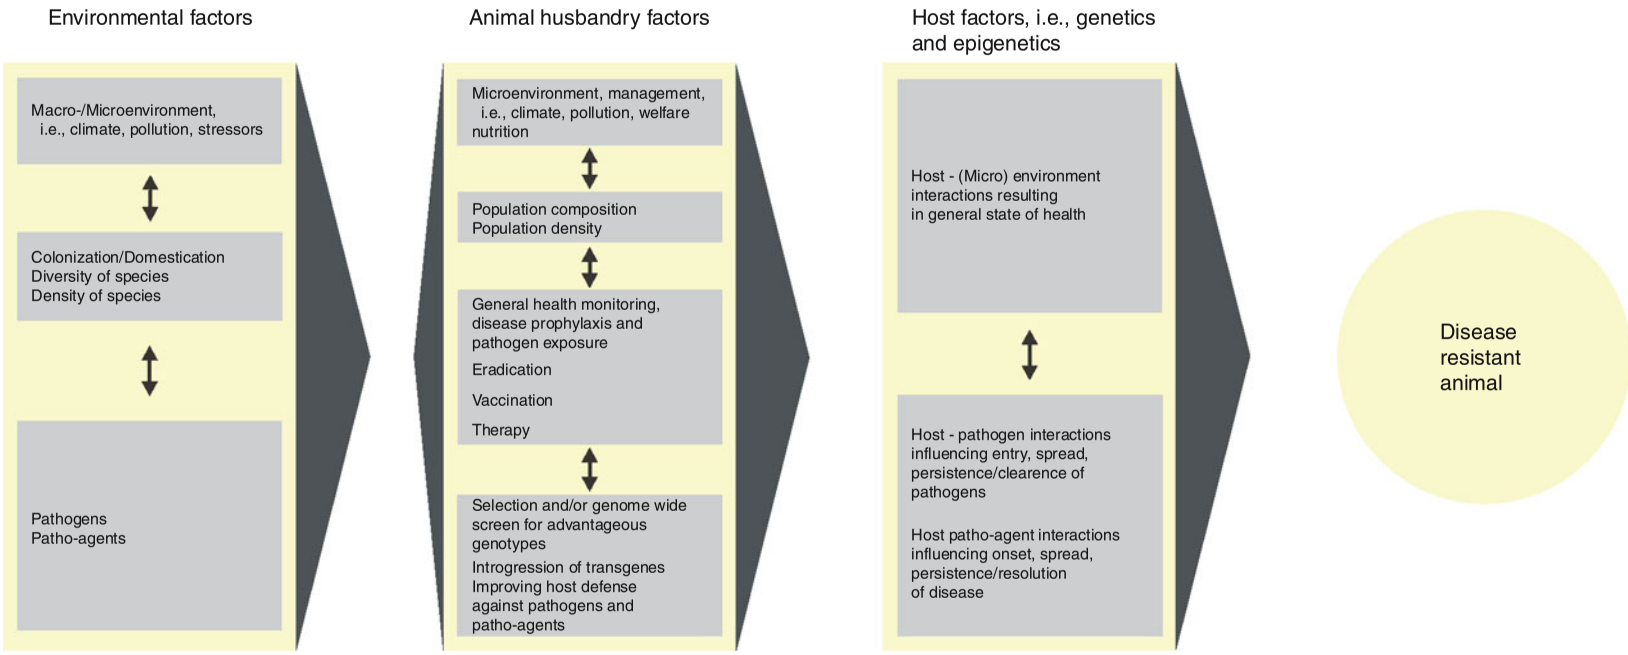
Disease-Resistant Transgenic Animals

Reducing farm animal susceptibilty to infectious diseases via genetic engineering has been an ambitious goal since the first transgenic livestock was generated more than 20 years ago. Various transgenic strategies for improving animal health are described elsewhere [14–17].

In general, disease-resistant transgenic farm animals can be generated by two approaches: (1) introduction of resistance genes into the genome of the host (gain-of-function strategy) and (2) specific targeting of endogenous or exogenous susceptibility genes (loss or exchange-of-function strategy).

Improving Animal Health through Gain-of-Function Gene Transfer

In most cases, susceptibility to pathogens originates from the interplay of numerous genes, meaning susceptibility to pathogens is polygenic in nature. The murine *Mx* gene is one of the few examples of a single genetic (monogenic) locus encoding a disease-resistance trait. Mice and mouse fibroblast cell lines carrying the autosomal dominant *Mx1* allele are



Disease-Resistant Transgenic Animals. Figure 1

Horizontal and vertical interrelations influencing the animal's health status, diseased versus nondiseased. The most specific measures to disrupt the pathogen/patho-agent flow toward the animal and/or improve the animal's disease defense mechanisms are highlighted

resistant to influenza virus infection [18, 19]. The transfer of the *Mx1* gene was able to restore virus resistance in mice lacking the *Mx1* allele [20] and inhibited influenza virus replication in avian cells [21]. However, the introduction of the murine *Mx1* gene into swine via pronuclear microinjection failed to produce influenza-resistant pigs [22]. The constitutive *Mx1* expression seemed to be detrimental to the pigs, whereas the expression from an inducible promoter was too low to produce detectable levels of *Mx1* protein. In the meantime, *Mx* genes of different farm animals have been identified, but their importance for disease susceptibility is not yet clear [23–25]. However, the ongoing detailed deciphering of the genomes of different farm animals, the improved techniques in generating transgenic animals [26–28], and the new tools for controlling transgene expression levels [29, 30] might allow the idea of generating influenza-resistant livestock by transferring a disease resistance gene to be addressed once more.

Antimicrobial peptides (AMPs) are an important component of the innate defense of most living organisms and there is a growing body of evidence to show that their role in defense against microbes is as important to the host as antibodies and innate and adaptive immune cells [31, 32]. AMPs are usually composed of 12–50 amino acids and synthesized by microorganisms as well as multicellular organisms, including plants and animals. They can have broad-spectrum antibacterial, antifungal, antiviral, antiprotozoan, and antisepsis properties. In addition to the wide range of these naturally occurring AMPs, many new ones have also been synthesized [33, 34]. Based on three-dimensional structural studies, the peptides are broadly classified into five major groups namely: (1) peptides that form alpha-helical structures; (2) peptides that form beta-sheets; (3) peptides rich in cysteine residues; (4) peptides rich in regular amino acids namely histatin, arginine, and proline; and (5) peptides composed of rare and modified amino acids [35, 36]. They can induce complete lysis of the organism by disrupting the membrane or by perturbing the membrane lipid bilayer, which allows for leakage of specific cellular components as well as dissipating the electrical potential of the membrane.

In initial engineering studies, the endogenous production of antimicrobial compounds in transgenic animals was shown to enhance disease resistance. Recombinant bovine tracheal antimicrobial peptide (bTAP) isolated from milk from transgenic mice, showed antimicrobial activity against *Escherichia coli*, without any deleterious side effects in suckling pups [37]. The antimicrobial activity of the synthetic alpha-helical peptide *Shiva 1a* was confirmed in transgenic mice, challenged with *Brucella abortus* [38]. The expression of the recombinant peptide significantly reduced both the bacterial colonization and the associated pathological changes in the genetically engineered mice.

Mastitis which is caused by bacterial infection of the mammary gland is reported to be the most costly disease in animal agriculture. It seriously affects animal well-being and is the most common reason for antibiotic use in diary cattle and the most frequent cause of antibiotic residues in milk [39]. The major contagious mastitis pathogen, *Staphylococcus aureus* is sensitive to lysostaphin, an antibacterial peptide naturally produced by a related bacterium, *Staphylococcus simulans* [40]. Kerr and colleagues showed that mammary gland expression of a bioactive variant of lysostaphin conferred protection against *S.aureus* infection in mice [41]. The staphylolytic activity in the milk of transgenic mice appeared to be 5–10 fold less active than bacterially derived lysostaphin, but was sufficient to confer substantial resistance to staphylococcal mastitis. Transgene production appeared to have no apparent effect on the physiology of the animal, the integrity of the mammary gland, or the milk it produces. Using nuclear transfer techniques, this approach was successfully extended to cattle, recently [42]. Transgenic dairy cows secreting lysostaphin constitutively in their milk were more resistant to *S. aureus* infections than nontransgenic animals. Lysostaphin concentrations in the milk of transgenic animals remained fairly constant during lactation. The recombinant lysostaphin was approximately 15% as active as bacterially derived protein. Challenge studies with *S. aureus* clearly demonstrated a direct correlation between the extent of protection against *S. aureus* infection with lysostaphin levels in the milk. Transgenic cows have been previously generated, primarily as bioreactors for large-scale production of pharmaceuticals and nutraceuticals. Thus, lysostaphin-transgenic cattle are the first example for enhancing disease resistance and animal welfare in

livestock, and may allow substantial reductions in antibiotic use. This in turn will help to control the spread of antibiotic-resistant bacteria and to reduce bacterial and antibiotic contamination of milk and milk products.

The antibacterial effect of lysostaphin is restricted to *S. aureus* only and transgenic cows are not protected against other mastitis-causing pathogens. The additional expression of secondary antibacterial compounds in the milk might be necessary for further enhancing mastitis resistance.

Human lysozyme (hLZ), a bacteriostatic milk protein that is known to attack the peptidoglycan component of bacterial cell walls, was expressed in the mammary gland of transgenic mice [43] and transgenic dairy goats [44]. Milk from the transgenic animals showed significant bacteriostatic activity and slowed the growth of several bacteria responsible for causing mastitis and the cold-spoilage of milk. The somatic cell count (SCC) is applied as a measure for udder health and milk quality and a high SCC in milk is directly correlated with mastitis and an impairment of milk quality [45]. Analyzing the SCC in milk samples of transgenic diary goats revealed a significant lower SCC compared to milk samples from control animals suggesting an improved udder health in the transgenic animals [46]. Lysozyme plays a role in the defense against gastrointestinal pathogens and reduces gastrointestinal illness in breastfed infants [47]. Feeding trials were conducted in pigs to evaluate putative health-promoting functions of hLZ-transgenic milk. Pigs are monogastric animals with a digestive system similar to humans and therefore are commonly used to study human health. Brundige and colleagues demonstrated that the consumption of pasteurized milk from hLZ-transgenic goats improved the gastrointestinal health of young piglets and was beneficial against a gastrointestinal infection with enteropathogenic *E. coli* [48].

A Chinese group enabled synthesis and secretion of bioactive bovine lactoferrin and bovine tracheal antibacterial peptides in goat mammary cells by use of plasmid-mediated gene transfer techniques [49], and the milk samples collected from these animals exhibited bacteriostatic effects against different mastitis-causing pathogens.

The authors summarize that genetic engineering for secretion of a broad range of AMPs in the mammary gland of dairy goats and cows reduces susceptibility to various microbial pathogens and is therefore a realistic approach to combat mastitis. Enhanced mastitis resistance will not only improve animal health and well-being, but also reduces bacterial contamination of milk and milk products in addition to reducing the costs incurred during disease prevention and cure.

Transgenic mice, expressing and processing a human enteric alpha-defensin peptide exclusively in specialized epithelia of the small intestinal crypt were generated, and were immune to an oral challenge with virulent *Salmonella typhimurium* [50].

Protegin-1 (PG-1) that is normally expressed in porcine myeloid cells and resides in secretory granules of neutrophils is another potent antimicrobial peptide targeting both gram-negative and gram-positive bacteria [51]. The ectopic expression of PG-1 in transgenic mice conferred enhanced respiratory resistance to an intranasal challenge with *Actinobacillus suis* [52], an opportunistic pathogen that may cause pneumonia, abortion, and fatal septicemia in pigs of all ages [53, 54]. Extending this concept to pigs and other somatic tissues beyond neutrophils will be another step toward the development of disease-resistant livestock.

The overexpression of dominant-negative mutants of viral proteins or pathogen receptors is another potent strategy to enhance animal disease resistance. The major focus has been to block viral attachment and penetration into a host cell by (1) producing viral proteins that block cellular receptors (antireceptor) or (2) altering known host molecular components, such as replacing host receptor genes with a modified version which is able to perform the receptor's physiological function but prevents attachment of the virus [55]. The first successful introduction of pathogen-mediated disease resistance in animals was reported 20 years ago. Transgenic chickens expressing the viral envelope of a recombinant avian leukosis retroviral genome were resistant to the corresponding subgroup of avian leukosis virus due to blockage of the virus receptors by the viral envelope proteins [56]. Using the same strategy, Clements et al. generated transgenic sheep expressing the maedi-visna virus envelope (E) gene, which is responsible for virus attachment to the host cells [57]. Maedi-visna virus is a prototype of ovine lentiviruses that cause encephalitis, pneumonia, and arthritis in sheep. Transgenic lambs expressing the

viral E glycoprotein in monocytes/macrophages, the target cells for virus replication, were healthy and neither deleterious effects nor clinical abnormalities from the transgene was observed. However, up to date, challenge studies to determine the susceptibility of these animals to ovine lentiviruses have not been reported.

Transgenic mice expressing a soluble form of porcine nectin-1, the cellular receptor for α-herpesviruses were generated. These mice displayed high resistance to pseudorabies virus (PRV) infections [58]. In pigs, PRV causes lethal encephalitis, acute respiratory syndrome, abortion and infertility, and latent infections [59]. Analysis of transgenic mouse lines, ubiquitously expressing different soluble forms of the cellular receptor for the viral glycoprotein D revealed that the transgene encoding the soluble form of the entire ectodomain of porcine nectin-1 fused to the human IgG1 conferred highest resistance to intranasal and intraperitonal PRV infections without any side effects [60]. Surprisingly, the expression of a fusion protein consisting of the first Ig-like domain of nectin-1 and the Fc portion of porcine IgG1 not only resulted in reduced virus resistance but also caused microphthalmia and the lack of vitreous bodies [61, 62]. Before implementing this promising approach to the generation of α-herpesviruses-resistant swine, further investigations examining the interactions of different soluble forms of nectin-1, endogenous nectins, and viral glycoprotein D and analysis of the influence of Fc domains of different species are required.

An alternative transgenic approach to protect livestock against infectious diseases is the expression of genes directing the synthesis of defined antibodies which target specific pathogens and thus induce immediate immunity without prior exposure to that pathogen.

Initial studies to express gene constructs encoding monoclonal antibodies in transgenic livestock were conducted nearly 20 years ago [63, 64]. However, the recombinant antibodies expressed in transgenic rabbits, sheep, and pigs showed aberrant sizes and only low antigen binding affinity. Nevertheless, following this idea, transgenic mice expressing coronavirus-neutralizing antibodies in the mammary gland were generated [65, 66]. High antibody expression titres throughout the lactation period provided complete protection against the enteric infection of newborns with transmissible gastroenteritis virus (TGEV), a pathogen which produces high mortality in suckling piglets, and also against a murine hepatitis virus (MHV)-induced encephalitis. Following this strategy, manipulating the lactogenic immunity in farm animals could improve the protection of suckling newborns through colostrium-delivered antibodies [67].

Enhancing Disease Resistance by Targeting Endogenous Susceptibility Genes

Transmissible spongiform encephalopathies (TSE) are fatal neurodegenerative disorders of the central nervous system which are termed scrapie in goat and sheep and bovine spongiform encephalopathy (BSE) in cattle. According to current knowledge, the causative agent of the brain pathology in diseased animals is the prion. Prion diseases are characterized by the accumulation of the abnormally folded and protease-resistant isoform (PrP^{Sc}) of the cellular prion protein (PrP^{C}) of the host [68, 69]. The generation of prion-free livestock resistant to TSE has been an ambitious goal since the BSE epidemic in cattle in the UK and the appearance of a new and highly lethal variant of Creutzfeldt-Jakob disease (vCJD) in humans. Early studies in mice revealed that reduction or loss of PrP^{C} expression did not affect normal development of the mice, but conferred protection against scrapie disease after inoculation with PrP^{Sc} prions [70–73]. With the development of nuclear transfer cloning techniques using genetically modified embryonic or somatic cell donors [7–10], the possible 'knock out' of the prion gene in transgenic sheep, goats, and cattle has opened new perspectives for the generation of disease-resistant livestock. A decade ago, Denning and colleagues generated the first PrP^{C}-targeted lambs. However, none of the cloned sheep survived more than 12 days [74]. Analyses of the targeted fetuses and lambs revealed defects that have been described in other nuclear transfer experiments with nontransfected cells and therefore, the authors expected that the early death of the lambs was not a consequence of the PrP^{C} disruption per se, but was probably due to the nuclear transfer procedures and/or the prolonged culture and drug selection of the primary fibroblasts used for nuclear transfer.

The functional disruption of the caprine PrP^{C} gene in cloned goats was first described by Yu et al. [75] and resulted in two goats lacking the prion protein [76].

The scientists confirmed the complete PrP^C ablation at mRNA and protein levels, and at 2 months age, the PrP^C null goats were healthy and showed no developmental or behavioral defects. The scientific community is awaiting the final proof of the concept – scrapie resistance of PrP^C-deficient goats after infection with PrP^{Sc} prions.

Richt and colleagues described the generation of the first PrP^C-deficient cattle [77]. They used a sequential gene targeting strategy which was demonstrated for the first time by the group of Kuroiwa et al. [78]. Male Holstein primary fibroblasts were transfected with two knockout vectors to sequentially disrupt the two alleles of the PrP^C gene. PrP^C-deficient fetal cell lines were established at 40–75 days of gestation and recloned for the generation of calves. The impact of PrP^C deficiency on calf development, on the immune system, on growth, and general health of the cattle for at least 20 months was analyzed in detail, and no negative influence of PrP^C ablation on animal health and well-being was detected. Importantly, brain homogenates from 10-month-old PrP^C-deficient cattle prevented PrP^{Sc} propagation in vitro, whereas in brain homogenates from wild-type cattle PrP^{Sc} proliferated. The researchers concluded that the presence of the endogenous bovine PrP^C is essential for PrP^{Sc} propagation and that there are no other host-derived cellular factors that can support the in vitro PrP^{Sc} propagation in the absence of the endogenous bovine PrP^C. In vivo tests of resistance to prion propagation in PrP^C-deficient cattle are under way, but still will require some years to complete. Analyses of several PrP^C-targeted mouse lines indicated that the loss of the normal cellular function of PrP^C may adversely affect the animals. For example, PrP^C-deficient mice developed ataxia and cerebellar neurodegeneration [79, 80], slight alterations in sleep–wake circadian rhythm [81], and altered synaptic functions [82]. To date, none of the above-described alterations in PrP^C null mice could be observed in PrP^C-deficient cattle and goats, respectively, but further investigations on aged transgenic animals will be necessary to exclude these altered phenotypes.

Small interfering RNAs (siRNAs) can silence/shut down specific targeted genes by interfering with the RNA transcripts they produce [83, 84]. For a transient gene 'knock down,' synthetic siRNAs can be directly transfected into cells or early embryos. However, for stable gene expression and germline transmission, the siRNA sequences are incorporated into gene constructs which express short hairpin (sh)RNAs that are processed to siRNAs within the cell. Through stably integrated shRNA expression vectors, additional genetic information is introduced into an organism (gain-of-functions strategy), which then produces a 'knock down' phenotype that is functionally similar to a 'knock out' (loss of function). Thus, RNAi-transgenics is an interesting alternative to the homologous gene targeting strategies which are traditionally used for the generation of 'knock out' livestock.

One of the most interesting susceptibility genes in livestock is the PrP^C gene and in a preliminary in vitro experiment, it was demonstrated that siRNA suppression of the PrP^C gene abrogates the PrP^C synthesis and inhibits the formation of PrP^{SC} protein in chronically scrapie-infected murine neuroblastoma cells [85]. Shortly after, Golding and colleagues combined this RNAi-based technique with lentiviral transgenesis for targeting the PrP^C gene in an adult goat fibroblast cell line, which was then used for somatic cell nuclear transfer to produce a cloned goat fetus [13]. Protein analyses of brain tissues demonstrated that PrP^C expression was reduced >90% in the cloned transgenic fetus when compared with a control. In a further experiment, they injected the recombinant lentivirus directly into the perivitelline space of bovine ova. Development of more than 30% of injected ova to blastocysts and expression of the shRNA targeting the PrP^C gene in more than 70% provides strong evidence that this RNAi approach may be useful in creating genetically engineered farm animals with natural resistance to prion diseases.

In two further approaches, lentiviral-mediated delivery of shRNA expression vectors into the brain of scrapie-infected mice resulted in a clear reduction of the PrP^C protein level and a prolonged survival of infected mice [86, 87], inferring that RNAi-technology may also be used for therapeutic applications.

Enhancing Disease Resistance by Targeting Exogenous Susceptibility/Viral Genes

Another application of the RNAi-technology is the silencing of exogenous viral genes through the

introduction of specific dsRNA molecules into cells, where they are targeted to essential genes or directly to the viral genome, thus inhibiting viral replication [88, 89]. Currently, the use of RNAi-based strategies for generation of viral disease-resistant livestock focuses on three pathogens: food and mouth disease virus (FMDV), bovine viral diarrhea virus (BVDV), and influenza A viruses.

FMDV is an extremely contagious pathogen that affects cattle, swine, and other livestock worldwide [90]. FMD is difficult to control by vaccination and impossible to eliminate by conservative natural breeding. Initial studies tested specific FMDV-siRNAs for their ability to inhibit virus replication in BHK-21 cells [91]. Transfection of BHK-21 cells with a mixture of siRNAs targeting highly conserved sequences of the 3B region and the 3D polymerase gene in all FMDV serotypes resulted in nearly 100% suppression of virus growth.

In another approach, siRNAs were designed to specifically target the viral VP1 gene, which plays a key role in virus attachment. This resulted in a nearly 90% reduction in FMDV VP1 expression and conferred resistance to FMDV challenge in cultured cells which are susceptible to this virus [92]. Encouragingly, pretreatment with siRNAs before infection made suckling mice significantly less susceptible to FMDV, and expression of siRNAs directed against the viral nonstructural protein 2B clearly inhibited virus replication in infected porcine cells [93].

Another RNAi target of agricultural interest is the bovine viral diarrhea virus (BVDV), an ubiquitously occurring pathogen that affects cattle herds worldwide resulting in respiratory disorders and increased susceptibility to other pathogens [94]. Lambeth and his group demonstrated that BVDV replication in bovine cells can be efficiently suppressed by RNAi [95]. They transfected shRNA expression vectors and siRNAs targeting the 5′ nontranslated region (NTR) and the region encoding the C protein of the viral genome into MDBK cells. After challenging with BVDV, they detected reduced virus titres by both siRNA and shRNA-mediated RNAi.

Farm animals, in particular swine and poultry, serve as key links between the natural reservoir of influenza A viruses and epidemics and pandemics in human populations. Due to repeated reassortment or mixing of RNA segments between influenza viruses from different species, virulent strains emerge periodically and often lead to devastating human catastrophes [96]. However, the emergence of the RNAi technology has opened many new options for preventing influenza virus infections in animals.

In initial studies, a set of siRNAs specific for conserved regions of the influenza virus genome could potently inhibit virus production in MDCK cells and embryonated chicken eggs [97]. In subsequent approaches, this strategy was extended to an established animal model of influenza infections by two independent groups. Tompkins and colleagues used siRNAs for targeting highly conserved regions of the viral nucleoprotein (NP) and acidic polymerase (PA). After administration of influenza virus-specific siRNAs via hydrodynamic i.v. injection [98], BALB/c mice were infected intranasally with influenza A/H1N1. Virus titre in lung homogenates were significantly reduced in siRNAs-treated mice when compared to control mice 48 h p.i [99]. In addition, they demonstrated that influenza-specific siRNA treatment can protect mice from otherwise lethal virus challenges.

Ge and coworkers administered influenza virus-specific siRNAs intravenously along with lentiviral shRNA expression vectors into C57BL/6 mice. They demonstrated that siRNAs as well as shRNAs can reduce influenza virus production in the lung when given either before or after virus infection and that the simultaneous use of two or more siRNAs specific for different virus genes resulted in a more severe reduction of virus titres [100].

A promising approach for the generation of influenza-resistant livestock was published by Wise and colleagues [101]. They used shRNA expression vectors, targeting the viral NP and PA gene for lentiviral-mediated generation of transgenic mice. Expression of the siRNAs was confirmed by an RNAse protection assay, and thus far, stable transmission of the transgene was observed up to the third generation. Currently, transgenic mice are mated to generate homozygous lines for delivering the final proof for influenza virus resistance in vivo.

Recently the generation of transgenic chicken expressing a shRNA molecule able to inhibit influenza virus polymerase activity [115] was reported. Although

the transgenic chicken did not exhibit a higher resistance to high challenge doses of H5N1, a highly pathogenic avian influenza virus, they showed strongly reduced transmission of the infection to transgenic and even non-transgenic birds housed in direct contact with them, demonstrating that this strategy may be used to prevent transmission and propagation of an infection at the flock level.

Future Directions

The past decade was dominated by large-scale and high throughput nucleic acid analyses allowing comparative genome sequencing and expression profiling projects. The comprehensive and ongoing analysis of the huge data sets led to the need for an updated definition of the term 'gene' and the introduction of the term 'epigenetics.' Taking into account that Mendel's and Morgan's elements of heredity include multifunctional protein coding, structural, regulatory, and RNAs of unknown functions and gene regulation is more complex than previously assumed, the 'gene' is suggested to be 'a union of genomic sequences encoding a coherent set of potentially overlapping functional products' [102] and 'epigenetics' is defined to describe 'stably inheritable phenotypes resulting from changes in a chromosome without alterations of the DNA-sequence' [103]. The future challenge of the postgenomic era is subsumed as integrative, quantitative, and/or systems biology. 'Systems biology is the comprehensive and quantitative analysis of the interactions between all of the components of biological systems over time' [104]. 'Systems biology involves an iterative cycle, in which emerging biological problems drive the development of new technologies and computational tools' [104]. The further understanding of disease mechanisms also depends on these emerging disciplines.

The ongoing genome sequencing programs for various animal species and the increasing densities of SNP arrays will lead to the discovery of new QTLs underlying economically important traits such as disease resistance and susceptibility. In addition, complete genome sequences of many disease-causing pathogens are becoming available. Hence, genome data on host intrinsic factors and host–pathogen interactions causing disease can be used to increase the health of individuals or populations. Conventional breeding and genomic selection will increasingly benefit from the natural variations identified among the populations. This can be supplemented with gene transfer technologies allowing a more targeted approach toward desired animal breeding without the limitation of species barriers.

The future of transgene technologies is dependent on the simplification of the gene delivery systems along with targeted manipulation of animal genomes. The former aim is achieved by using lentiviral vectors which are highly efficient for domesticated animals including poultry [105, 106] and pets [107]. Gene targeting in species other than mice is limited as embryonic stem (ES) cells of farm or pet animals are unavailable and gene targeting via homologous recombination of embryonic and somatic cells and subsequent nuclear transfer is highly inefficient. However, the advent of the RNAi-technology offers new possibilities for specific gene targeting in animal species and will have a huge impact on transgenesis in the near future. Furthermore, the zinc finger nuclease (ZNF) technology has shown to be an attractive alternative to ES cell targeting and nuclear transfer technology [108] and was already applied successfully for targeted gene disruption in rats [109].

For further reading concerning the use of ZFN-technology in farm animals we refer to Kues and Niemann [116]. In addition, site-directed mutagenesis of genomes can be achieved by TALENs (transcription activator-like effector nucleases) which were originally identified in plant pathogens and recently were successfully used to generate knockout rats [117]. These site-specific nucleases may complement/enlarge the well established ZFN-technology for efficient gene targeting in livestock [118].

Last but not least, the cross-species generation of pluripotent/embryonic cell lines has gained new impetus through the induced pluripotent stem cell (iPS) technology, i.e., the reprogramming of somatic cells making them capable of embryogenesis (reviewed in [110]) and the recent isolation of authentic embryonic stem cells from rat blastocysts by novel culture conditions [111, 112]. In the future, animal transgenetics and animal disease resistance will be important in basic research and in the understanding of disease mechanisms. Bridging the gap between model and man by

generating transgenic animals is fundamental to the development of novel therapeutics and disease prevention strategies.

Increased availability of genomic information of livestock species along with more sophisticated transgenic tools offers the potential to generate animal models to combat livestock diseases to a larger extent than ever before. However, animal geneticists/scientists must consider several important aspects. (1) The dissemination of the trait of interest such as disease resistance, introduced by a transgene will neither be simple nor fast, therefore cost–benefit calculations will probably decide on implementation of transgenic animals. For example, transgenic BSE-resistant cattle [77] will probably never gain importance in agriculture where culling is considered to meet demands with respect to cost efficiency and biosafety. However, BSE-resistant cattle may be engineered for the production of pharmaceuticals and therefore will have an enormous impact on providing safer drugs. (2) There is general public opposition to the use of transgenic livestock. However, if animals were resistant to zoonotic diseases, therefore resulting in reduced frequency of pandemics and epidemics such as those caused by influenza virus, attitudes of human societies might change [113]. In this context, recently, a trypansome lytic factor (TLF) from baboons that protected mice both from animal and human-infective *Trypanosoma* subspecies was identified and suggested to be transferred to livestock [114]. Animal trypanosomiasis is one of the major parasitic diseases of livestock flocks and livestock are the major reservoir for human-pathogenic trypanosomes. (3) Scientists and society should clearly keep in mind that pathogens readily change their antigenic determinants and create novel subtypes to escape the 'resistant' host's immune system. Attempts to introduce resistance traits into animal populations either by conventional breeding or transgenesis should be subjected to thorough cost/detriment–benefit analyses.

Environmental Impacts of an Open Ocean Mariculture Operation in Kona, Hawaii

Neil Anthony Sims
Kona Blue Water Farms, Inc, Kailua-Kona, HI, USA

Article Outline

Glossary

Sustainability The use of resources in such a manner as not to impinge upon the ability of future generations to enjoy similar use.

Open-ocean mariculture The culture of marine fish, invertebrates, or algae in exposed ocean locations.

Definition of the Subject

Open-ocean mariculture is the culture of marine fish, invertebrates, or algae in exposed ocean locations. The criteria for demarcation of open-ocean sites from inshore or nearshore aquaculture sites is often the subject of debate, with various schemes using some integration of distance from shore, depth of water, or exposure to open water and high sea conditions. A more meaningful definition is perhaps, simply, that an open-ocean mariculture site is a site where any of these conditions or criteria combine to disconnect the culture system from the surrounding substrates that might otherwise be subject to some significant environmental impact, or might become reservoirs for some ecological feedback with the culture system. Alternatively, rather than using a geographical or operational distinction, open-ocean mariculture might simply be described as culture of marine animals or plants at sites that are further offshore, or in deeper water. This definition reflects the evolving, aspirational, and incremental improvement in culture systems, rather than thinking of the open ocean as a final destination.

Whatever the definition, open-ocean mariculture offers the potential for a scalable production system for valuable, healthful seafood, with negligible environmental impacts.

Introduction

The Seafood Crisis

The oceans are in deep trouble. Even though the demand for seafood has increased, capture fisheries around the world are collapsing from overfishing, or are static. Wild stock fisheries cannot sustain any greater pressures, and clearly cannot scale to meet the growing needs of increasing population size, increasing affluence, and wider recognition of the health benefits of seafood.

The USA is both symptomatic of the seafood crisis and significantly contributive to the problem. In the USA, closures or buyback schemes to reduce effort have effectively shut down once-productive fisheries for Atlantic tunas and swordfish, the groundfish of Georges Bank and other Northeast fisheries, Pacific Coast sardines, albacore, and more recently, rockfish. Other environmental concerns for endangered species or marine mammals have seen closures or limitations placed on fisheries for shrimp in the Gulf of Mexico, purse seining for tuna in the Pacific, and long-lining for tuna and swordfish in Hawaii and the US Pacific. Currently, over 80% of the seafood consumed in the USA is imported, and more than half of those imports are from farmed sources.

Hawaii Fisheries Status The Hawaiian Islands represent a microcosm of the global fishing crisis. Increased fishing power – in terms of both the number of boats and available technologies – has seen the valuable deep bottom fish catches decline precipitously over the last few decades. GPS units allow deep bottom fishermen to return repeatedly and precisely to a "hot spot" until the fish are gone. Electric reels reduce the labor of hauling up from 60 fathoms to simply flicking

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

a switch. Powerful echo sounders allow tuna fishermen to identify the location of individual fish tens of fathoms beneath their boat. At the same time, catches of sashimi-grade tuna have plummeted due to competing gear-types (seiners, long-liners, pole-and-line) and conflicting national interests throughout the range of these highly migratory species. Some 20 years ago, over 25 commercial fishing boats worked out of the local Honokohau Harbor in Kona, Hawaii, targeting deep-water snappers and big-eye tuna in the "ika-shibi" fishery. Today, there is only one commercial fishing vessel based there, and even that is only part-time.

The decreasing catch volume and decreasing average size of fish caught in the bottom fish fishery in Hawaii is causing increasing concern. By 1996, only 20% of the onaga (*Etelis coruscans*) catch in the main Hawaiian Islands (MHI) had previously spawned; similar declines were evident among other species stocks. These species' biological characteristics make them vulnerable to recruitment overfishing; NOAA Fisheries staff estimate that an onaga attains maturity at about 4.1 years of age, at a size of 66 cm. With Federal and State data indicating significant overfishing of these stocks, increased regulation became imperative. In June 1998, new legislation went into effect, establishing limits on fishing gear, bag limits, registration of bottom fishing craft, and restricted fishing areas (up to 20% of the bottom fish ground was placed off limits) for the commercial and recreational fishery industry.

Further restrictions are still needed. Over the last two summers, the State declared all bottom fishing closed for the summer period from May 1st to September 30th, throughout the island range. State authorities have indicated that this seasonal closure may need to be repeated for coming years, as well, before there is any measurable improvement in stocks. The majority of high-value species consumed in Hawaii already are imported from other areas, such as the South Pacific and South East Asia.

Aquaculture as Part of the Solution Aquaculture offers the only viable solution to the growing demand for sustainable, healthy sources of seafood protein for human consumption. Fish farming reduces exploitative pressure on already depleted wild stocks, supports the growth of coastal and rural industries, and yields a product that is low in saturated fat and high in protein. The annual contribution of aquaculture to global aquatic production is now almost equal to that of wild catch (47% versus 53% [1]). In 1985, aquaculture represented only 5% of US fish consumption, yet today that figure stands at around 40%. Aquaculture growth is rapid, and is projected to increase in pace. The US Department of Commerce has set a goal of a fivefold increase in domestic aquaculture production value, to $5 billion, by 2025.

Domestic aquaculture production using existing methods or species cannot keep pace. Almost all US production is from freshwater species; the only marine species cultured in any quantity are salmon and striped bass, both of which are anadromous (freshwater spawning). It is almost impossible to obtain permits for nearshore farm sites; there is intense competition among different user groups for nearshore waters, and aquaculture has been besmirched in the conventional wisdom as environmentally destructive and unsustainable.

The Open-Ocean Potential Open-ocean mariculture technology has recently moved from the realm of science fiction [2, 3] to commercial reality. In the last few years, there have been dramatic advances in the legal and engineering fields, which have opened up the new fish farming frontier of offshore areas. New submersible net pen systems have been pioneered by OceanSpar, LLC, of Washington State ("Sea Station™" net pens), and Ocean Farm Technologies, Inc., of Maine ("Aquapod™" net pens). These new technologies have dramatically increased the workable extent of ocean farming, by providing seaworthy platforms for grow-out of fish in exposed offshore environments. These farms are therefore able to be located further offshore, in sites where currents, prevailing sea conditions or seasonal storm events may make surface pens inadvisable. These operations are also usually portrayed as having less environmental impact than nearshore fish farms. The rationale is that there is a cleaner and clearer disconnect between the farm and the underlying benthic substrate or the adjacent shoreline so that there is both minimal environmental impact and negligible potential for negative accumulative feedback from the environment to the culture system.

But how have these first open-ocean mariculture operations actually performed? Is there any basis in fact to these claims of environmentally sound mariculture in offshore locations? What are the opportunities for expansion of this industry, and what are the risks and precautions – both environmental, biological and economic – that should accompany such scaling?

This entry reviews some of the recent progress toward realizing this potential, as exemplified by one farm operation, in Kona, Hawaii. The environmental performance over the past 5 years of operation at Kona Blue Water Farms' site is instructive. It may demonstrate how open-ocean mariculture may represent a partial solution to the seafood crisis: a scalable, environmentally sound production system for high-value seafood. The environmental impacts of this one open-ocean mariculture site are reviewed here, in the context of both local ecosystem effects and global marine resource use efficiency: the "footprint" on the oceans.

Overview of the Kona Blue Water Farms Operation

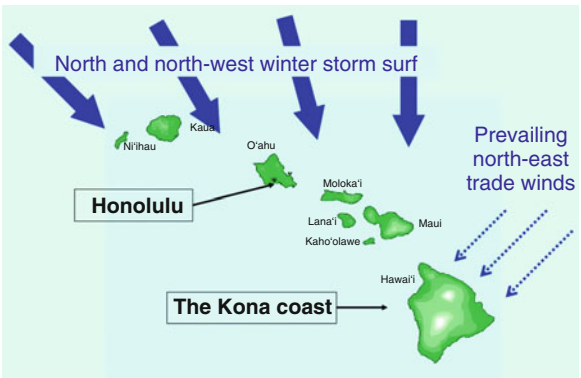
Prior to 1998, Hawaii's ocean-leasing legislation limited any potential project to a maximum of 4 acres, which had to be used for either educational or research purposes, and not for commercial gain. Through several years of work by industry aspirants, and strong leadership by the State Aquaculture Development Program, legislation was passed that allowed commercial offshore fish farms or energy projects.

The Kona Blue Water Farms principals had been involved through the legislative review, and with the passage of the bill, began research into developing hatchery culture techniques for high-value marine fish, simultaneously surveying the Kona Coastline for prospective offshore farm sites. After an extensive 3-year process of consultation and consensus-building with the community, Kona Blue was granted the requisite State and Federal permits for the original offshore farm site in March, 2004. The operation began deployment in February 2005 and first fish were harvested offshore in September, 2005. Since then, production has grown to the extent that Kona Blue has been harvesting up to 25,000 lb of sashimi-grade Kona Kampachi® per week, and up to 500 T per year. Kona Kampachi® (*Seriola rivoliana*) is also known as kahala, Long-fin Amberjack or Almaco Jack. It is related to the Japanese hamachi (*S. quinqueradiata*), but is native to Hawaii, and is distributed throughout the warm waters of the world.

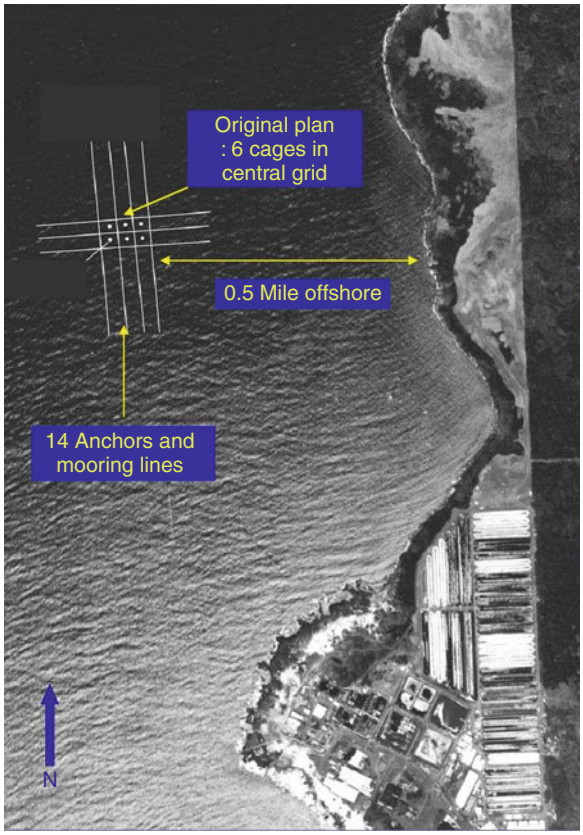
The Offshore Farm Site and Farm Operations

The Lease Area Site selection is a critical component for any mariculture operation, but is particularly so for an innovative offshore farm that is pioneering both a new permitting process and a new net pen system. The original farm lease site was selected on the basis of the following criteria:

1. The selected site was in a deep-water area, over 200 ft deep, with brisk currents.
2. There was little or no public use of this area. The farm site lay between the limits of normal recreational scuba diving (around 120 ft) and the normal depths for offshore trolling for ono (wahoo, *Acanthocybium solandri*).
3. The site afforded some protection from both Kona storms and the strong trade winds (Figs. 1 and 2). The proximity to shore also allows for future telemetry links to shore for farm control and security.
4. There was ready access from Honokohau Harbor, 5 miles to the south, which provides support facilities such as slips, fueling, and land for staging of equipment and feed.



Environmental Impacts of an Open Ocean Mariculture Operation in Kona, Hawaii. Figure 1
Location of the Kona Coast on the western side of the Big Island of Hawaii affords moderate protection from trade winds and winter swells



Environmental Impacts of an Open Ocean Mariculture Operation in Kona, Hawaii. Figure 2
Kona blue water farms' site located in waters over 200 ft deep over a sand bottom, a 1/2-mile offshore from a pristine coral fringing reef abutting lava cliffs. The site is a mile north of Keahole Point and west of the Kona International Airport

5. The site was directly offshore from the Kona International Airport and NELHA (Fig. 2), and, as such, its use was consistent with the adjacent land uses, and it represented no significant impact on the viewplane.

The farm site's topography and oceanography are distinguished by the depth of water, the bare sand substrate, the strong currents through the area, the exposure to high winter surf and strong trade winds, and the adjacent shoreline of a narrow coral bench reef with a steep basalt (lava) cliff. A few black sand beaches also lie along the coastline, to the north of the site, but these are little used, except by recreational fishermen. The preexisting uses of the farm lease area itself were negligible, because of its depth, the paucity of fish, and the barren benthos.

The net pens are all concentrated toward the center of the lease area (see Figs. 2 and 3), within two mooring arrays: one containing six net pens, and the other containing two net pens and the feed barge. The closest distance from the edge of the central grid array to shore is approximately 2,600 ft, or almost half a mile to the northeast, to Unualoha Point.

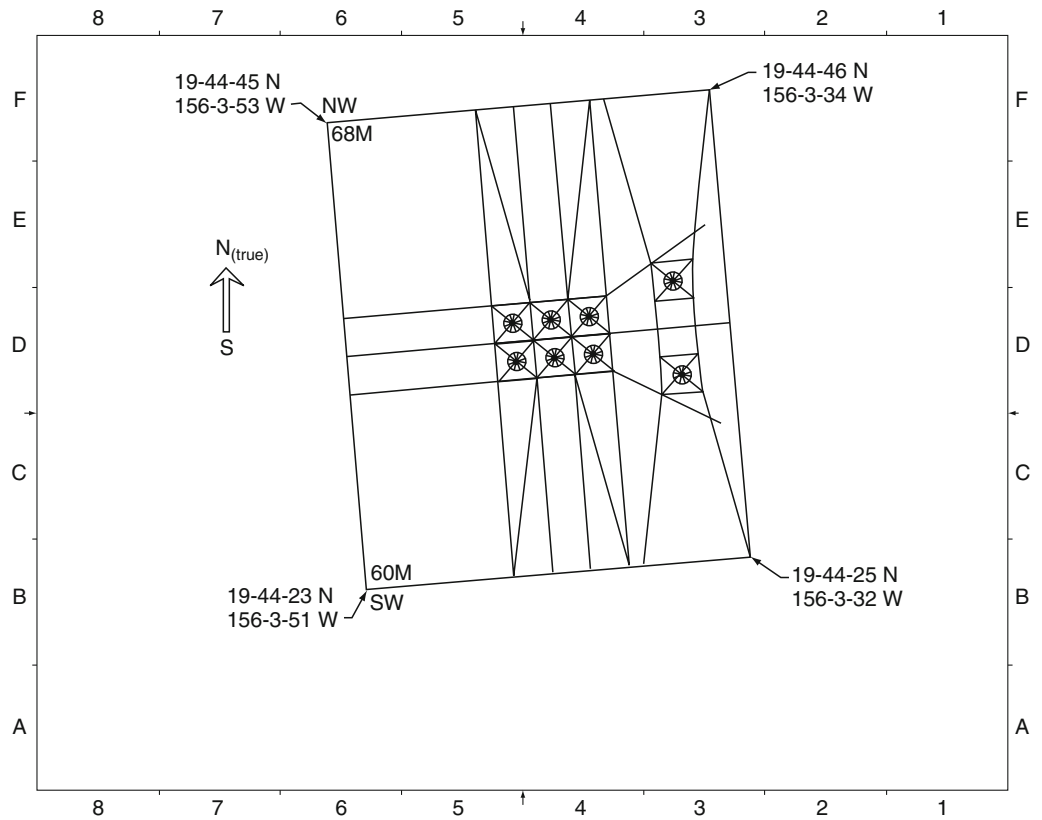
The farm site lease provides "negotiated exclusivity": Transit, trolling, hoop-net fishing and hook-and-line fishing are permitted throughout the lease area, but for liability, insurance, and safety reasons, there is no authorized anchoring, scuba diving, or swimming permitted.

The 90 acre lease area initially accommodated eight submersible Sea Station net pens, each of around 3,000 m^3 capacity (Fig. 4). The outermost area of the lease is used almost solely for mooring lines, which require a 5:1 scope. The net pens were originally tied into submerged grids that were anchored into the soft substrate using steel embedment anchors and chains. A series of buoys and weights ensure that the anchor lines are perpetually taut, to eliminate any risk of entanglement by marine mammals. Bridles from the mooring grid corners attach to the net pen rims, to hold the net pens in place in each grid square.

Farm Operations

The daily activities on the farm primarily consist of feeding the fish in the pens. Underwater video cameras inside the net pens are used to relay visual images to the operators on the feed barge. This enables the feed operators to regulate feed to ensure that no feed is wasted, and that excess feed does not fall below the net pen. Any fish carcasses are regularly removed by divers. Carcasses are disposed of as solid wastes in the county landfill.

Harvests usually occur twice each week. Fish are harvested into an ice-brine slurry, to quickly and humanely kill the animals with a minimum of damage. Fish are all transported whole, in ice-brine, to a single land-based processing facility, for packing and shipping. No fish processing occurs at sea during the harvests. Disposal of processing wastes is the responsibility



Environmental Impacts of an Open Ocean Mariculture Operation in Kona, Hawaii. Figure 3
Modified mooring array and grid dimensions – plan view. The number of net pens is presently being reduced from current eight smaller pens to five larger pens, with the same overall culture capacity (24,000 m^3). The submerged central grid remains at around 30 ft (9 m) beneath the surface

of the wholesalers or other purchasers of the fish, but, at present, most trimmings from fillets go into the landfill.

Support activities for the existing operation are based out of Honokohau Harbor, where a half acre of land rented from the State accommodates containers for feed storage, gear storage areas, a closed workshop area, restroom, and office.

The farm is also serviced by a semipermanent feed barge/security platform vessel, which has been deployed on-site since October, 2007. A separate harvest boat – the 74 ft F.V. Kona Kampachi – transports the harvested product back from the farm site to the harbor. Several other smaller work boats are also used to support net pen and grid maintenance and cleaning, and other tasks.

Localized Environmental Concerns and Actual Impacts

The Presumed Problems

Aquaculture – or indeed, development of any food production system – brings with it attendant environmental concerns. Fish farms are widely accused of environmental degradation. The concerns that are often voiced include the following local-affect possibilities:

- Detrimental impacts on water quality
- Nutrient enrichment of the substrate beneath the farm
- Antifoulant paints from net pens to contaminate the substrate
- Therapeutant or antibiotic misuse to harm the surrounding biota

(**b**) Sea Station SS3000 raised to rim-level on the Kona Blue farm site. (**c**) A submerged Sea Station SS3000 and diver on Kona Blue site

- Escapes to outcompete wild fish for spawning grounds or feed
- Escapes to dilute the wild fish gene pool
- Proliferation of pests, parasites, and diseases inside the net pens, which can then be transferred to wild fish
- Entanglement of whales, dolphins, and other marine mammals
- Disruption of marine mammal or other species' migratory paths
- Harmful deterrents or fatal control measures against predators

- Excessive use of fish meal and fish oil, leading to overharvesting of the smaller pelagic species targeted by industrial reduction fisheries
- Exclusion of other user groups from traditional, cultural, or recreational uses of the farm area
- Visual impact of the net pens on the viewplane

With almost 5 years' experience at the Kona Blue farm site, then, it is appropriate to evaluate the actual data and observations recorded at the Kona operation, and to compare this experience with the concerns that had been, and continue to be, voiced. Each of these issues is examined in detail, below, beginning with an evaluation of the de novo environmental status of the Kona Blue farm site, and then detailing the impacts that have occurred, their context, and their significance.

The Actual Observed Impacts: Locally

Water Quality and Effluent Impacts The water quality at the farm site is close to oceanic, with strong currents and low turbidity. Underwater visibility usually exceeds 100 ft or more.

General water movement patterns at the farm site are governed by the longshore currents past Keahole Point (the western-most point of the Big Island of Hawaii), 1 mile to the South. An S4 current meter deployed at the farm site over several periods since 2004 showed regular peak current speeds of over 50 cm/s (about 1 kt, at a depth of around 40 ft). Current headings were longshore: generally to the North (predominantly), but also to the South. The two points of first impact downstream from the farm site are therefore either Keahole Point, around 1 mile to the south of the site, or the Mahai'ula-Makalawena shelf area, around 3 miles to the north.

Because of the community concerns about potential impacts from the farm operation on water quality, the company had made commitments during the original permit process to a policy of ongoing transparency and objectivity in monitoring. These commitments included:

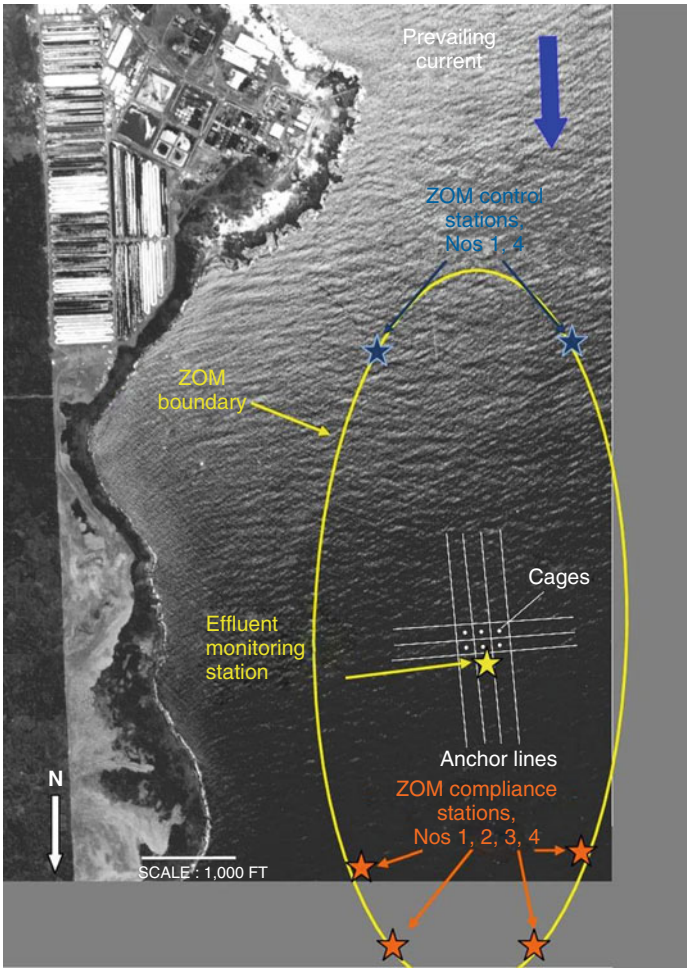
- Use of objective, third party experts to collect the water quality samples.
- Use of local water quality laboratories – such as NELHA Water Quality Lab, or local private laboratories – for conducting the sample analysis.
- Placement of copies of all monthly water quality monitoring reports at local repositories, such as the State Aquatic Resources office at Honokohau, or the NELHA library, so that local residents can review this data.
- Provision of reasonable access to Federal, State, and County officials for monitoring and oversight purposes.

Monthly measurements have been taken of ammonia and turbidity (the two most relevant water quality parameters for fish farming) at three depths (surface, mid-water – 50 ft deep, level with the submerged net pens, and at the bottom) and at a total of seven stations (two control stations upcurrent, one effluent station immediately downcurrent of the net pen with the greatest biomass, and four "zone of mixing" stations 4,000 ft downcurrent: Fig. 5). Quarterly measurements are also taken for a range of other parameters.

Detailed water quality data are available on the company's web site [4]. Figure 6 shows the mean for each sample site for turbidity for September, 2008, when the farm was at peak production of around 500 T annually. Turbidity is probably the best metric for fish feces and other particulates in the water, and so is most likely to reflect any impact from the farm's presence. These data are definitively clear – there is no discernible difference between water quality parameters at the upcurrent control sites, and the effluent site (1 m downcurrent of the net pen with the highest biomass) or the "zone of mixing" sites downcurrent. These results confirm that *there is no measureable impact* on water quality from the existing farm operations.

Benthic Impacts The substrate beneath the farm is over 200 ft deep, and almost exclusively comprises bare, coarse sand. Located along the shoreline, some 2,000 ft to the East (directly across the longshore currents) is a diverse coral reef community.

Impacts on Substrate Beneath and Around the Farm Site Prior to farm installation, a preliminary survey of the site was undertaken by repeated bounce dives, using scuba, to depths of 220 ft. Because the depth of the farm site is beyond the limits of normal safe diving, and the strength and unpredictability of the currents precluded ready use of grab samples or drop video



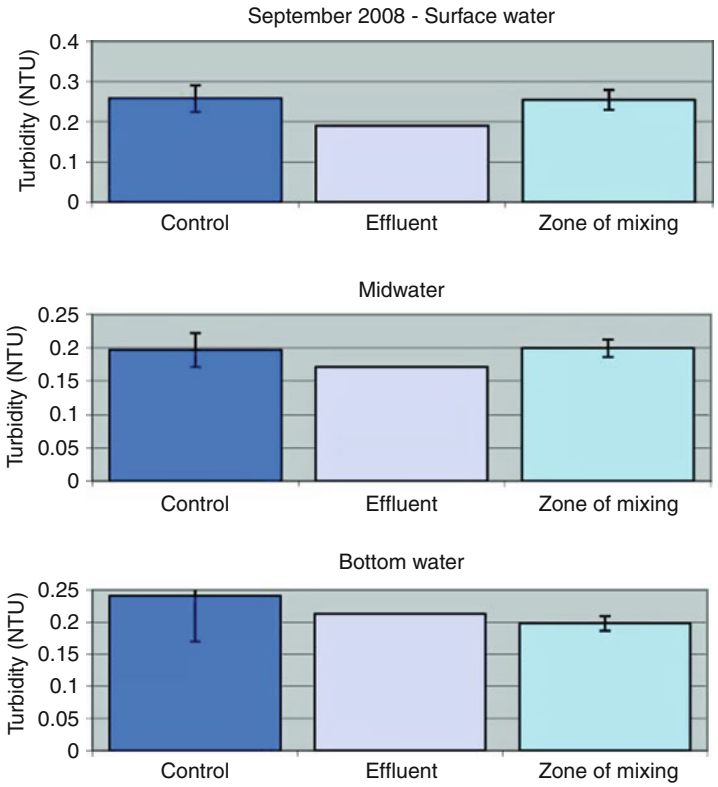
Environmental Impacts of an Open Ocean Mariculture Operation in Kona, Hawaii. Figure 5

Sampling stations under a prevailing N-setting current are shown. Under a S-setting current, control and compliance stations will be reversed. ZOM = Zone of Mixing

cameras, the original permit provided that no benthic monitoring would be required. Over time, however, permit requirements were tightened to include grab sample monitoring of substrate chemistry and infaunal micromollusk community structure, and video monitoring using drop cameras. These samples have been conducted quarterly, and reports and video footage have been posted on Kona Blue's website [4].

These results generally indicate that there has been no measureable impact on the benthic community around the farm site. There have been episodic perturbances of substrate chemistry immediately underneath the cage footprint, with a few instances of anoxic conditions during 2007, during periods when a new feed distribution system was being tested. This resulted in some pulverization of pellets, and reduction of feed to a "slurry," rather than discrete pellets. Once the feed system was refined, the substrate returned to its more normal condition, there was no further significant nutrient enrichment of the substrate.

Filamentous algae have also been visible in the drop-camera videos from around the farm site. These appear to have been detached from the cage mesh or the mooring lines, as the algae are not attached to the



Environmental Impacts of an Open Ocean Mariculture Operation in Kona, Hawaii. Figure 6
Typical turbidity data from monthly sampling around the Kona Blue farm site. There is no discernible difference in water quality between the two Control sites (upcurrent), one Effluent site (immediately downcurrent) and four Zone of Mixing sites (4,000 ft downcurrent) of the farm site

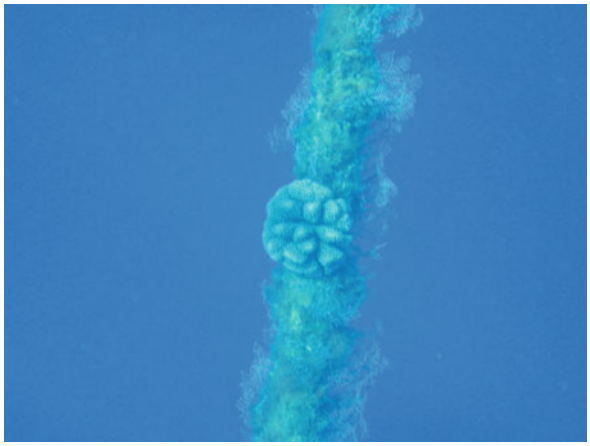
coarse sand substrate. Presumably, these algae are dispersed during periods of high current.

Monitoring of infaunal micromollusc assemblages in the substrate samples has also demonstrated that there has been no significant change in the community structure resulting from the farm presence (see reports on-line: [4]).

Impacts on the Adjacent Coral Reef Community A comprehensive survey of marine biota was conducted on the reef directly adjacent to the existing farm lease area, just south of Unualoha Point [5]. The survey of the benthic biota of the fringing reef crest used protocols identical to those employed by the State's Division of Aquatic Resources, in their West Hawaii Reef Management Task Force Survey. This provided an extensive set of "control" sites: the other benthic and fish data from the sites along the 90 miles of coastline on West Hawaii. A series of four transects of 25 m × 2 m extended parallelly to the reef crest, immediately shoreward of the seaward edge of the reef. Video footage was made of these transects, and digitized for selection of random points on the video frames.

The Makako Bay–Unualoha site has been repeatedly resurveyed since the original 2003 survey. Although no formal reports have been compiled, there have been no significant changes in benthic community composition or fish populations reported.

Biofouling on the Farm Structures There is also profuse growth of macro-invertebrate biofouling on the grid-lines and buoys of the mooring array, as well as on the bridle lines that attach the cages to the grid and the rims of the cages themselves (Fig. 7). This fouling includes diverse macroalgae, bivalves (several species of mussels and oysters: *Pteria* sp and *Pinctada*



Environmental Impacts of an Open Ocean Mariculture Operation in Kona, Hawaii. Figure 7
A *Pocillopora damicornis* coral colony on a mooring grid line around the Kona Blue net pens (within about 15 m of net pen stocked with fish). The presence of coral colonies that are highly sensitive to nutrient enrichment on moorings and buoys confirms that the operation has no significant impact on marine biota in the area

spp), corals (primarily *Pocillopora* and *Porites*), sea urchins (primarily *Echinothrix calamaris*) nudibranchs (*Stylocheilus longicauda*) and sponges. These all settle out of the plankton onto the farm structures, and their presence does not represent any significant or even measureable reduction in the available recruits to the nearby coral reef area. The growth of the corals, particularly, is compelling evidence that the presence of the fish farm operation is not deleterious to benthic organisms.

Apart from the one brief instance of anoxic conditions beneath the net pens, there have been no other adverse impacts on benthic communities in, underneath, or around the net pen area.

Pests, Parasites, and Pathogens Kona Blue employs an integrated pest management strategy to optimize fish health, reduce interactions or minimize impacts on wild fish stocks, and reduce any potential environmental impacts from therapeutant use. As *Seriola rivoliana* is a new species, any therapeutant use must be conducted under an Investigational New Animal Drug (INAD) permit. INAD permits operate under the oversight of US Fish and Wildlife Service (USFWS), and the Food and Drug Administration (FDA), with State oversight through Office of Conservation and Coastal Lands (within Department of Land and Natural Resources) and Clean Water Branch (CWB, within the Department of Health). Federal Environmental Protection Agency (EPA) has oversight through the NPDES (National Pollutant Discharge Elimination System), which is administered by CWB.

As with almost all farmed animals, *S. rivoliana* is subjected to small external pests – in this case, the skin fluke, *Neobenedenia* sp, that attaches itself to the fish's skin. These flukes do not pose any risk to human health, and do not themselves detract from the quality of the harvested product, but may cause irritation to the fish. If left unchecked, the flukes can become a health problem for the animal, as the fish rub themselves on the netting to ease the irritation. Kona Blue uses occasional treatments of dilute hydrogen peroxide solution (at effective dosage rates of 200–300 ppm) to control levels of skin flukes among the fish in the net pens. Hydrogen peroxide (H_2O_2) breaks down rapidly in sunlight to form oxygen and water. Hydrogen peroxide is also considered an acceptable Organic aquaculture treatment under the draft USDA Organic aquaculture guidelines, and USDA Organic agriculture standards.

Under the permits in place at the existing site, such therapeutant use must demonstrate that there is no risk to the fish under treatment, or to the environment, or to human health. Monitoring of the effluent from any bath treatment at 100% concentration is mandated under the "Whole Effluent Toxicity" (WET Test) section of the NPDES permit. Results to date from the existing farm operation confirm that there are no significant environmental impacts from the use of the hydrogen peroxide. Ongoing effluent monitoring for WET test bioassays using larval fish (Pacific topsmelt, *Atherinops affinis*; conducted by Nautilus Laboratories in San Diego) demonstrate no significant difference in the rates of larval fish survival between control samples taken 4,000 ft upcurrent of the net pen, and samples taken of the whole effluent (100% concentration of the bath treatment water) at the conclusion of the bath treatments. There is therefore no mechanism for any measureable impact on the pelagic or benthic communities, or the surrounding water quality from the use of this therapeutant.

In addition, monitoring of wild kahala (*Seriola rivoliana*) stocks indicates that there is no significant proliferation of *Neobenedenia* sp. in the population around the farm area. Broodstock are collected periodically from around the farm area, to replenish the wild stocks in Kona Blue's hatchery. These fish are usually taken by commercial fishermen along the "drop off" of the marlin fishing grounds, about 1 mile to the South of the farm, and are sampled for ectoparasites upon capture, by immersion in a freshwater dip. Although these fish are usually infested with a number of other ectoparasites, the prevalence of *Neobenedenia* sp has never averaged much more than one individual per fish. By contrast, a parasitic copepod (sea lice, similar to *Caligus*) infests wild fish at average rates of around ten individuals per fish, and yet is not found at all on the farmed fish, and does not proliferate within the net pens.

A number of innovations, either in progress or planned, should also further reduce the proliferation of *Neobenedenia* on fish inside the net pens. The farm is being reconfigured to fewer, larger Sea Station net pens. With a planned reduction in the number of net pens, a reduction in the surface area-to-volume ratio of the remaining net pens (from double-cone net pens to a more cylindrical shape), the improved surface material characteristics and rigidity of the Kikkonet™ plastic monofilament net mesh (which make it easier to clean), and the improved access for offshore crew to regularly clean the nets from the surface (thereby breaking the skin fluke life cycle by dislodging the adhesive eggs on the mesh), the proliferative tendencies of the skin fluke should be further reduced.

Kona Blue does not use prophylactic antibiotics, but has, under the same regulatory oversights described above, and with veterinary guidance, used Florfenicol® to treat *Streptococcus iniae* infections that sometimes afflict juvenile fish after the stresses of transfer offshore. These treatments last for 10 days, and are also accompanied by WET test water quality monitoring. These WET tests have repeatedly demonstrated no impact on marine biota. A vaccine is available for *S. iniae*, which would avoid the need for these treatments, but regulatory requirements ironically prevent the use of the vaccine at this time. (The vaccine would qualify as an Organic treatment under draft USDA Organic aquaculture guidelines). *S. iniae* infections are not an issue with larger fish, once they have overcome the initial stress of transfer from the nursery to offshore.

Much of the concern over proliferative capacities for fish farm pests, parasites, or pathogens is derived from conflicts between salmon farming and wild salmon runs. Some research – though disputed – suggests that sea lice infestation rates can be exacerbated by the presence of salmon farms and can then be detrimental to survival rates of juvenile salmon as they migrate past the farms to the sea. Most marine fish, however, are broadcast spawners. Juvenile marine fish are therefore dispersed over vast areas of ocean and reef, and do not usually have vulnerable migratory patterns. Given such a distinct difference in life histories between salmonids and marine fish, there would seem to be limited applicability of the salmon and sea-lice research, or the concerns with impacts on vulnerable life stages, to open-ocean mariculture.

Interactions with Wild Fish Kona Blue cultures only Kona Kampachi® (*Seriola rivoliana*) on the offshore site, but the pertinent State permit also allows the company to possibly culture other amberjack (the other kahala species, *S. dumerili*), mahimahi (*Coryphaena hippurus*), and Pacific threadfin (*Polydactylus sexifilis*).

Aggregative Effects on Wild Fish Stocks The existing operation does have an aggregative impact on some species of fish in the area, but this is considered neither deleterious nor significant. Fish are attracted to the site for a number of possible reasons: the fouling on the net pen, the occasional release of small quantities of uneaten food from the net pen during periods of strong currents, and the aggregative nature of objects in open water (as for Fish Aggregation Devices). The makeup of the resident and transient fish communities around the net pens varies over time.

Pelagic or larger demersal fish frequently occurring around the Kona farm site include mackerel scad (opelu: *Decapterus macarellus*), ulua (giant trevally, *Caranx ignobilis*), wild kahala (*Seriola rivoliana* and *S. dumerili*), and barracuda (kaku, *Sphyraena barracuda*). Occasionally, schools of rainbow runners (kamanu, *Elegatis bipinnulatus*) and false albacore tuna (kawakawa: *Euthynnus alletteratus*) move through the net pen area. Larger pelagic fish, such as yellowfin tuna (ahi: *Thunnus alabacares*) and wahoo (ono:

Acanthocybium solandri) are also occasionally attracted to the area by the baitfish, or by the net pens themselves.

A number of other, smaller fish that are more normally associated with coral reefs settle out of the plankton and assume residence either around the subsurface buoys or around the cages themselves. Such residents include schools of Sergeant majors (*Abudefduf abdominalis*), dascyllids (*Dascyllus albisella*), chromids (primarily *Chromis hanui* and *C. ovalis*) wrasses (primarily *Coris* spp and *Thalassoma* spp), and kyphosids (*Kyphosus* spp). As these fish are settled from the plankton, their presence is not considered a significant detraction from the biomass or diversity of the fish fauna on the adjacent reef.

Escaped Fish Interaction with Wild Stocks Concerns about potential negative impacts of escaped fish are often cited as one of the reasons for objections to fish farming. However, this issue is most pressing only where non-native fish are cultured in areas where escapes might become established or compete with local species, such as Atlantic Salmon in the Pacific Coast of Canada. Kona Kampachi®, by contrast, is native to the waters of Kona. In addition, Kona Blue recognizes that the innovative net pen engineering employed means that there is some possibility of escape incidents over the initial proving period and development of refinements. In consideration of this, Kona Blue has deliberately not applied any selective breeding in the hatchery, and has not used any broodstock beyond F2 (i.e., all broodstock are either wild-caught, or first- or second-generation captive-reared). There is, therefore, no mechanism for development of any significant difference in the genetic makeup of the fish inside the net pen from the fish in the wild. This reduces any potential impact from escapes to merely direct ecological impacts.

Furthermore, the concerns with the effects of fish farm escapees on wild fish genetics are, again, largely a consequence of the conflicts between salmon-farming interests and wild salmon conservationists. Yet wild salmon stocks are unique, in that each river system or stream may have a genetically discrete stock from the adjacent watershed. Any blurring of this finer-scale differentiation, by interbreeding between escaped salmon and wild stocks, could represent a loss of genetic diversity. However, these concerns are not germane to farming of marine fish in the open ocean. As marine fish are broadcast spawners, there is only a coarse zoogeographic genetic granularity. Tagging research demonstrates that *Seriola* and other carangids migrate frequently between islands in the Main Hawaiian Archipelago. One *Seriola* migrated from French Frigate Shoals, in the Northwestern Hawaiian Islands, to the Big Island – a distance of 678 miles (over 1,000 km) over 3.6 years, at liberty [6]. The potential genetic impacts of Kona Kampachi® escapees on the wild stocks of *S. rivoliana* are therefore minimal.

Those Kona Kampachi® that have escaped from the Kona Blue net pens – either through "leakage" as divers enter or leave the pen through a submerged zipper, or from breaches in the netting – are invariably subjected to very heavy predation pressure. Individual escapees survive outside of the zipper for usually less than a minute before being eaten by either the ulua or the bottlenose dolphins that are frequently in the area. The long-term prospects for survival and reproductive success of any escapees are therefore highly dubious. In addition, any escapees that do survive in the wild are presumably entering a wide-open ecological niche, due to the severe depletion of other deep-water species – such as the deep-water snappers – by commercial fishing. There is little likelihood of escapees competing in any significant manner with the few remaining wild snapper stocks.

Other Wildlife Interactions

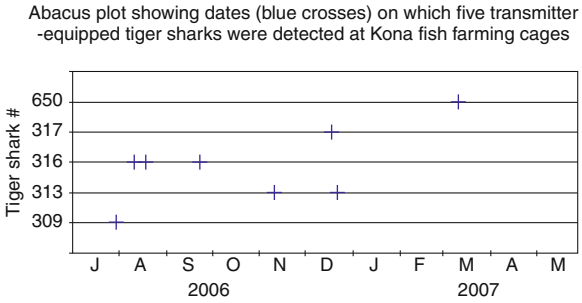
Sharks The single overarching feature of shark interaction with the offshore fish farm site has been – contrary to conventional wisdom and activist concerns prior to the farm deployment – the general absence of sharks around the net pens. For the first 8 months of operation, only one fleeting shark sighting occurred: a small tiger shark (mano: *Galeocerdo cuvier)*. Observations by farm workers suggest that there is a general pattern of brief influxes of tiger sharks to the area in the months of September and October of each year. Most of these animals appear individually, or in pairs, with a range of sizes from 8 to 15 ft in length, and they do not generally seem to take up residence on the farm site. Most tiger sharks only show interest in dead fish inside the net pens, and generally exhibit no interest in or aggression toward the farm workers.

In the first year of operation, however, a single tiger shark appeared to take up residence at the farm site. As the animal began to show aggression toward inanimate objects such as surface buoys, and then farm divers, it was humanely dispatched. Recognizing the long-term unacceptability of such predator control measures, Kona Blue sought alternative means of addressing this issue. A Shark Management Plan was then developed in consultation with State Aquatic Resources personnel in Kona and other experts, which included a range of measured responses, and nonterminal resolution if animals ever again become problematic at the site.

In subsequent years, tiger shark sightings usually increased in frequency at the farm site in the late-September early-October period. However, sharks were neither persistent, nor consistent. Farm operations had become more adept at removing dead fish, and the Shark Management Plan allowed divers to continue to work safely. One animal – or rarely two, contemporaneously – may appear at the site, and remain for an hour or so, before moving away, presenting little inconvenience to farm operations, and no real risk to diver safety.

Kona Blue has also, in collaboration with DAR and HIMB researchers, established a receiver station on the farm site, as part of the larger research program for tracking tiger shark movements along the West Hawaii coastline. The first data series obtained suggested that the observations by the farm work crews were correct – that tiger sharks only very infrequently pass by the site, and rarely do they show any interest in the operation. From July 2006 to May 2007, there were a total of eight (8) records of tagged tiger sharks in the Kona Blue farm area. None of these sharks took up residence. One animal passed by the farm site three times in 2 months, another animal was recorded twice in 2 months, and three other animals had single records. (Fig. 8).

Over 2008 and 2009, however, further tiger shark tagging trials showed that two animals appeared to regularly return to the farm site over periods of up to 5 months. Two other sharks ranged over the entire Kona coast area, but for several weeks at a time were recorded exclusively from the farm site. All animals eventually moved on; one was later detected off Maui. While these results suggested that the farm site had become a "waypoint" for the animals over a few months, the "long-term entrainment (e.g., years) of tiger sharks is unlikely" [7].



Environmental Impacts of an Open Ocean Mariculture Operation in Kona, Hawaii. Figure 8
Frequency of tagged tiger shark occurrence at Kona Blue farm site: 2006–2007. Five tagged sharks were recorded over an 11-month period, with the most frequently occurring shark being present three times over a 2-month period. No animals took up residence, or showed any strong site affinity

There have also been sightings of sandbar sharks (mano: *Carcharhinus plumbeus*) around the net pens. Initially, these were rare (none in the first year of operation), but since October, 2006, the frequency of sightings and number of sandbars has increased. These animals are usually seen in small groups (one to four sharks), below the net pens at depths of over 100 ft. They rarely rise up to the level of the net pens. Sandbar sharks are more secretive, and cannot readily be distinguished by any markings. No sandbar sharks were caught during the tagging trials in 2008–2009 [7]. It is therefore unclear if these are always the same individuals, or if they represent a larger population of animals that periodically move through the area.

In the period from June to August of 2008, there were a series of breaches of varying sizes in the Dyneema® webbing of one net pen that corresponded to shark bites. The same net pen was also breached in August 2009 by a small Galapagos shark that entered the net pen. The Galapagos was captured and released alive by company divers, unharmed except for a small dorsal fin notch for later identification. In each instance, breaches were sealed immediately on discovery. These incidents underscore the vulnerability of even sturdy Dyneema® nylon mesh, and have led to a plan for wholesale installation of Kikkonet® rigid plastic webbing across the farm. This material has been used in *Seriola* culture in Japan for over 25 years,

and has been successfully used in crocodile and shark-infested waters by a sea-cage barramundi farmer in North Queensland, Australia. Kona Blue therefore anticipates that the use of Kikkonet webbing will reduce mesh breaches to negligible levels, and significantly reduce escapes and the attractant nature of the escapes to the bottlenose dolphins and sharks.

Overall, the evidence from the Kona Blue site confirms that there are no significant negative impacts from any aggregating effects of the net pens on sharks. The evolution of a nonterminal, humane plan for managing sharks on the farm site underscores the importance of commercial experience to improve open-ocean farming practices.

Turtles The threatened green sea turtle (*Chelonia mydas*) is common in the nearshore waters of the main Hawaiian Islands. The endangered hawksbill turtle (*Eretmochelys imbricata*) is infrequently found in Hawaiian waters. The principal nesting site for the green turtle is in the Northwest Hawaiian Islands, on French Frigate Shoals [8]. No turtles have been observed in the area of the farm site, but it is possible that they occasionally transit through the site. If they were to do so, the taut-line mooring system and stiff-mesh net pens will prevent animals from becoming entangled.

Seabirds The submerged net pens used by Kona Blue do not significantly impact seabird populations. The farm area itself is infrequently used as a foraging area by seabirds. Most seabird activity in the area is confined to the fishing "grounds," which extend to the northwest of Keahole Point.

Monk Seals There are four conceivable ways for open-ocean fish farming to have a significant negative impact on rare, threatened, or endangered wildlife, such as monk seals, dolphins, or whales. The project may (1) present a significant obstruction to natural migratory patterns, either (2) attract, or (3) repel the animals and thereby disrupt their normal behavior, or (4) the animals may become entangled in the ropes or mesh of the net pens or moorings.

Monk Seals have been observed at the existing farm operation on two occasions, both in association with escape incidents from the nylon mesh nets on the surface nursery pens that were previously in use at that site. (These nylon mesh surface net pens were removed in 2006, as Kikkonet was, at that time, not yet available outside of Japan.) On each of these occasions, the Monk Seal was preying on the small, escaped Kona Kampachi®, but once the school was effectively eradicated by predators, the Monk Seals moved away. A radio tag allowed movement of one monk seal to be tracked from the Unualoha site to a beach on Maui the following day, clearly affirming that the animal did not take up residence, or become conditioned to the availability of escapees.

Dolphins Makako Bay, almost half a mile to the south of the farm site, is frequented by large schools of spinner dolphins (*Stenella longisrostris*), on nearly a daily basis. These animals usually follow a diurnal pattern of movement from the Makalawena shelf area to the north, along the reef edge to the shallow areas of Makako Bay, where they rest for some time during the middle of the day. Some concerns were expressed during preliminary hearings about the potential for the farm operation to interfere with the spinner dolphin patterns of movement or resting habits [5]. There is no evidence to suggest that this has been the case. There have only been some occasions over the 5 years of operation offshore when divers or workers on the farm site have witnessed spinner dolphins coming anywhere near the net pens. The net pens clearly do not impede the usual pattern of spinner dolphin movement toward Makako Bay; they do not attract or repel the animals, nor do they affect the resting pattern of the dolphins.

Over the last 3 years, the existing farm operation has demonstrated a propensity to attract bottlenose dolphins (*Tursiops truncatus*). No bottlenose dolphins were previously present on the farm site, but the animals have begun to appear regularly at the site since about October, 2006. Patterns of dolphin movement are best characterized as one or two animals, every day or so, with occasional instances of groups of up to seven or eight animals. There is no regularity to the animals' appearance on the farm site: they may be present all day, or only in the morning, or only in the afternoon.

Kona Blue staff monitor and report on dolphin activity to HIHWNMS and NOAA's PIRO PRD. The bottlenose dolphins are probably attracted to the farm site by a combination of (1) the presence of the

mid-water structures acting as a Fish Aggregating Device and the associated fish community that is present around the net pens, (2) the occasional provisioning from "leakage" escapes when divers enter or exit a net pen, and from the rare larger escape incidents when predators have breached the Dyneema nylon webbing, and (3) interaction with divers outside of the net pen, as the divers move about the farm from boat to net pen and back.

One individual dolphin has taken up residence over 2009 and 2010. This animal was suffering from a large fishing hook and leader line that had become lodged in its jaw, and it was present on the farm site almost continuously during this period. For many months, the dolphin was lethargic and lost weight, but more recently (as of late 2009) has appeared to be more active and in better condition [9]. The aggregative effective of the net pens for this one animal might therefore be interpreted as beneficial.

No other individual bottlenose dolphin has taken up permanent residence at the farm site. There are no other animals present on the farm site on around one-quarter to one-third of days. Even when other animals are present, they are often only there for part of the day, rather than the entire day. In October–November, 2008, for example, dolphins were present for some period of time on 22 days out of 34 days [10]. There were dolphins present at the farm site for some or all of the day on 65% of the days. On 35% of days, there were no dolphins reported as observed on the site. Only on 1 day were six dolphins present. Most other days, there were one or two animals present for some portion of the day.

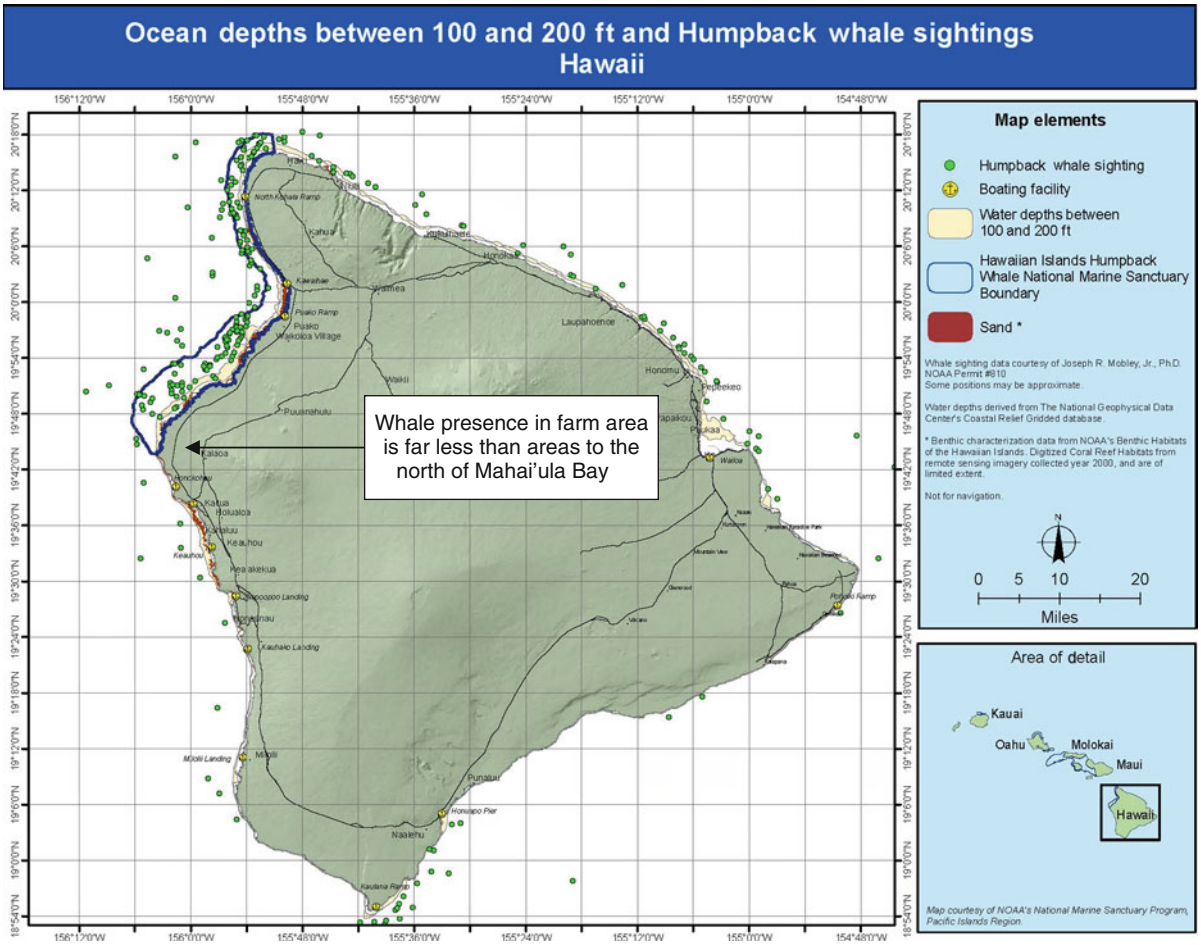
Other dolphin species may be found in and around the proposed farm lease area, but they are usually most commonly seen on the "grounds" to the south of the site. Spotted dolphins (*Stenella attenuata*), rough-toothed dolphins (*Steno bredanensis*), and false killer whales (*Pseudorca crassidens*) have all been observed on the "grounds," or in other offshore waters of the Kona Coast, but have not been reported from the farm site.

In summation, although there has been behavior modification in one compromised individual, the presence of the farm operation has not had a significant negative impact on dolphin behavior. The overall long-term impact on dolphins from the farm operation will probably be further reduced. Modifications to net pens currently under way should help to alleviate the attractive nature of the farm to the dolphins, by reducing the potential for escapes through mesh breaches, and for leakage escapes, and by reducing the amount of time that divers need to operate outside of the net pens. Kona Blue will continue with the ongoing monitoring and reporting of marine mammal activity around the farm site, and continues to collaborate in this with HIHWNMS staff, PIRO PRD staff.

Humpback Whales Populations of the endangered humpback whale (*Megaptera novaeangliae*) winter in the Hawaiian Islands, and the project site lies around 1 mile inside the southernmost boundary of the Hawaiian Islands Humpback Whale National Marine Sanctuary (HIHWNMS). Humpbacks are known to frequent the entire Kona coast area in winter. The whales move throughout the general area, usually following a longshore track (north to south, or vice versa).

Concerns about the reduction in whale habitat by the existing project were previously expressed by HIHWNMS and DLNR/DAR officials. Some concerns were also earlier expressed with the potential for entanglement of whales in the mooring lines of the net pens. A comprehensive analysis of available records of whale entanglement (NMFS Stock Assessments), a review of interactions between marine mammals and Hawaii's fisheries [11], and details of marine mammal strandings compiled by NMFS Pacific Area Office (NMFS-PAO) shows that most whale entanglement events occur in slack net mesh (such as drift nets or fish weirs), slack vertical lines (such as crab pot or lobster pot floats), or surface lines (such as long-lining gear). Among all these observations, there is no record from any US aquaculture operation of entanglement of humpback whales, or other marine mammals, in the taut moorings or net panels of fish net pens. With heavy mooring gear, and taut lines and mesh, the potential for entanglement is considered negligible [12, 13].

Furthermore, it appears that the waters in the vicinity of Keahole Point are not as heavily frequented by the whales as are other waters of the Sanctuary, further to the north (Fig. 9). Observations from workers at the farm site suggest that the farm does not interfere with the movement of the humpback whales, beyond the immediate and obvious exclusion from the waters inside the net pens. The distance of around half-mile



Environmental Impacts of an Open Ocean Mariculture Operation in Kona, Hawaii. Figure 9
Typical Humpback whale sighting patterns around the Big Island of Hawaii

from the inshore side of the net pens to the shoreline offers ample room for the whales to move around the eastern end of the farm structures, without any chance for any funneling or bottleneck effects.

There is no definitive pattern of whales avoiding, or being attracted to the cages. Whales are occasionally seen within the lease area. On one instance, the farm workers witnessed a humpback on the surface inside the mooring grid array; the animal appeared to negotiate its path between the net pens and mooring lines with ease.

As part of the company's Marine Mammal Monitoring Plan (MMMP), farm workers provide data for assessing whale abundance and patterns of movement around the farm site. The MMMP describes Federal recommendations or instructions in the unlikely event of any entanglement, and also details ongoing reporting requirements for any close interaction with humpback whales, or any physical interaction between the farm array and other marine mammals.

Recreational Use Impacts The farm site lies offshore from the Natural Energy Laboratory of Hawaii Authority and the Kona International Airport, and as such, has little effect on shore-based recreation. The heavily used public recreation area of Kekaha Kai State Park (Mahai'ula) lies more than 3 miles further to the north.

A survey of recreational activity in the general area, north of Keahole Point was conducted prior to the farm installation, from August to September, 2001, in

conjunction with the original farm site environmental assessment [14]. The survey covered 2 months of summer conditions, which was considered the best means of ensuring that the data represented the heaviest use of the area. The overarching finding of the survey was that the area is only used for transit: of the 150 observations made over the 61 consecutive days of the survey, only one boat was seen within the farm site – a boat transiting through the area. Most activity in the general Keahole-to-Unualoha area was recreational dive boats and commercial dive tour operations along the reef and shoreline south of Unualoha Point (directly inshore from the proposed farm site), and in Makako Bay itself.

Observations by the Kona Blue staff on the farm site suggest that this trend continues – the use of the farm lease area is merely for transit. Fishing boats now occasionally troll lines close to the central area, to try to take advantage of the aggregative effects of the net pens. There are no records of catch rates around the farm, but anecdotal evidence indicates that catches are primarily ono (wahoo, *Acanthocybium solandri*), with infrequent catches of ahi (yellow-tuna, *Thunnus alalunga*).

Kona Blue's permit allows restricted public activities in the lease area, precluding anchoring, scuba diving, spearfishing, or swimming within the 90 acres. These limits are considered the minimum needed to protect the company's investment, to limit their liability (and retain insurance coverage), and to assure public safety. Fishing by the public from unanchored boats (trolling, or linefishing from drifting boats) is still permitted, but with the caveat that any fishing lines that become entangled in the net pen mooring lines must be left in place and cannot be retrieved by divers. The company also requests that fishermen not troll through the center of the farm site because of the potential for fishing lines to entangle divers, or for lures to hook into mooring lines or nets. Boats transiting the net pen area are also requested to observe a slow "no-wake" boat-speed to maximize safety for divers. Unguided recreational scuba diving or unauthorized commercial scuba dive tours are not permitted within the lease area because of liability, safety, and security concerns.

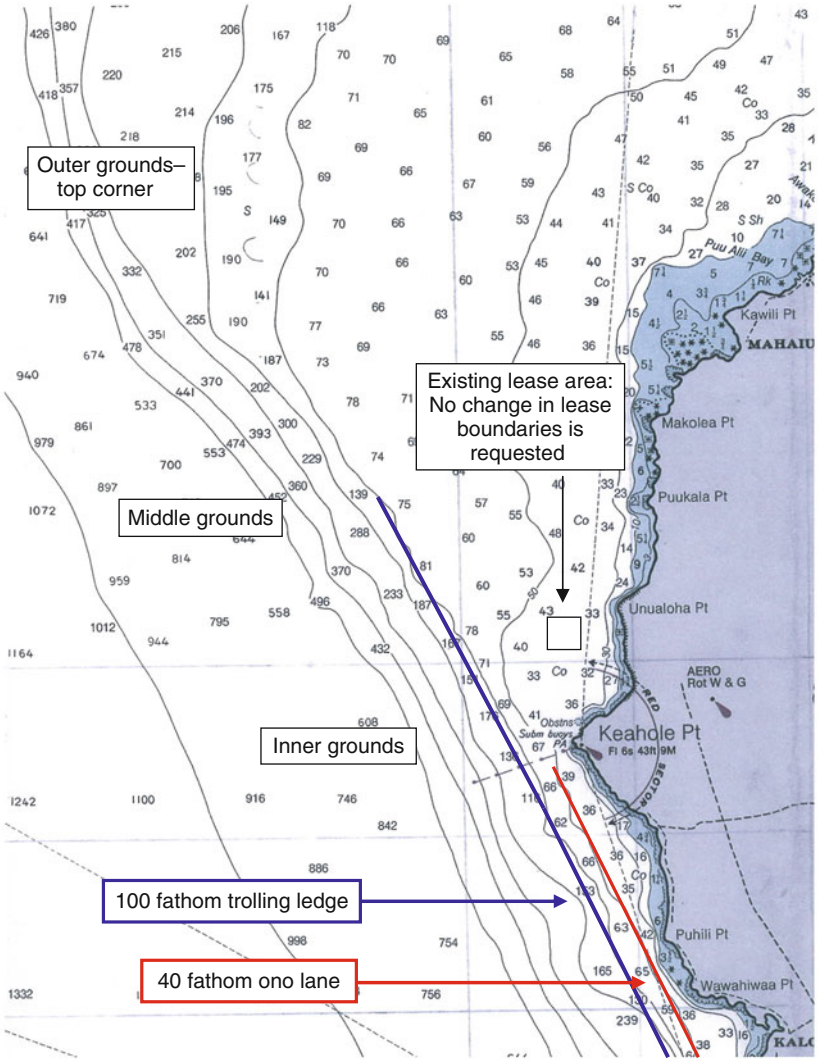
The loss of access to recreational activities within this relatively small area of ocean space is not considered significant. Kona Blue's ongoing observations affirm that there is virtually no fishing or other recreational use of the lease area, or the areas adjacent to the lease area, beyond trolling, which is probably enhanced by the farm's presence.

Viewplane Aesthetics Community value judgments and perceptions of how the oceans should be used largely govern the impact of the project on the community's aesthetic enjoyment of the area. In community meetings, Kona Blue generally enjoys strong support for the broad goals of the company. There is wide recognition of the severely depleted status of bottom fish species in Hawaii. The awareness of the global fisheries crisis has recently been amplified by several scientific studies, such as that of Worm et al. [15], which projected a collapse of world fish stocks by 2048, unless significant remedial changes are made to fisheries and marine ecosystem management.

The visual impact of the project is minor, compared with the adjoining properties of Kona International Airport and the aquaculture operations at the Natural Energy Laboratory of Hawaii Authority (NELHA). The major visual impact from the farm operation is from the experimental surface pens and the feed barge. There is also the additional presence of work and dive boats, and harvest boats, on some days. However, the impacts of these structures and activities are not significant, given the distance from the nearest residences, more than 3 miles away.

There is general community acceptance that the project fits in well with the overall ambience of innovative aquaculture at NELHA, and the need for Kona to develop alternative industries beyond tourism. Fisherfolk and other mariners recognize the validity of the criteria that Kona Blue has used to select this site (c.f. deeper or shallower sites), and have not expressed a strong preference for the project to be located elsewhere. Applicants for farm permits in other areas of the Kona Coast (around Kawaihae) have, on occasion, been told that their project would more appropriately be located "down near NELHA and Kona Blue."

Cultural Resources, Practices, and Mechanisms for Impact Prior to the 1801 lava flow that inundated the area, Keahole was the site of the largest fish pond in the Hawaiian islands. The Pai'ea pond (reputedly



Environmental Impacts of an Open Ocean Mariculture Operation in Kona, Hawaii. Figure 10
Kona Blue's offshore fish farm site in relation to primary fishing areas. The farm site is well inside of both the 100 fathom (200 m) trolling ledge along the "grounds" offshore of Keahole Point and the 40 fathom (80 m) ono lane. Reef fishing and opelu ko'a are found well inshore of the proposed site, along the edge of the reef, in waters up to 120 ft deep (40 m). Fishing grounds for opelu at night are usually deeper than 40 fathoms (80 m)

King Kamehameha's favorite pond) was approximately 3 miles long and 1/2 mile wide; canoes were used to traverse from one side to the other. The farm site is directly offshore from where Pai'ea once stood. Fish farming could therefore be considered historically and traditionally appropriate to the area.

The farm lease area is over a mile from the traditional marlin, tuna, and wahoo fishing grounds (Fig. 10). The site is too deep for free-diving or scuba diving activity but suitable for "blue-water" spearfishing. Usually, however, blue-water spearfishing is practiced close to a point or drop-off, rather than over bare sand substrate around 200 ft deep. There are no significant benthic plant or animal populations in the farm lease area, and there are virtually no benthic or pelagic fishing activities in this depth range. Kona crabs and nabeta (*Xyrichtys pavo*) are the only benthic resources that occur on sand bottom at this depth,

but informants suggest that the currents are too strong for any significant fishing effort this close to Keahole Point [16].

The only potentially impacted cultural resource that was cited during extensive discussions with community and kupuna (elder) groups for the original farm site was the several opelu ko'a ("holes" or schooling places for mackerel scad – *Decapterus macarellus*) that occur in the general region. The locations of these ko'a are considered to be part of traditional marine lore, and are considered inappropriate for publication, or for sharing outside of the families or community groups who have traditionally fished these ko'a. However, in private meetings with the most knowledgeable kupuna, the locations of the traditional opelu ko'a were determined to be outside of the proposed project location [17]. Opelu aggregations usually occur in water around 120 ft deep, close to reef drop-offs, and well shoreward of the farm area.

Access to, or practice of any other customary activities has not been significantly constrained by the farm array or operations. The exclusive control over the waters (and the fish) inside the net pens is consistent with traditional and cultural practices that identified fish traps or lobster traps – and the animals therein – as the private property of the trap owner. The same principles apply here.

Global Impacts: Fish Meal and Fish Oil Usage

Fish Meal and Fish Oil Usage

Fish such as *Seriola rivoliana* (Kona Kampachi®) usually feed toward the top of the trophic chain in the wild. They therefore possess digestive systems and nutritional requirements that are adapted for feeds with high protein and lipid levels, and low levels of carbohydrates.

Fish meal and fish oil usage in fish feeds can be considered a valid use of a natural, sustainable, renewable resource, so long as the fishery from where the fish meal and fish is sourced is responsibly managed. Although stocks such as the Peruvian anchovetta fishery are sustainable in the sense that they are very well managed, they are not scalable. If mariculture is going to fulfill its potential for increasing seafood consumption to meet growing demands, then some alternative sources of proteins and oils will be required.

Kona Blue has therefore been focused on reducing the inclusion rate of fish meal and fish oil, such as Peruvian anchovies, from targeted reduction fisheries and increasing the use of agricultural oils and proteins, such as soy, canola, wheat, corn and poultry meal, and oil.

Improving Feed Conversion Efficiencies: An Evolutionary Approach Though efficient use of fish meal and fish oil from targeted reduction fisheries is both rational and justifiable, this by no means suggests that these resources are unlimited, or that alternatives should not be searched for. If open-ocean mariculture is to develop into a food production system that can provide a significant proportion of the nutritional needs of a growing planet, then additional sources of sustainable proteins and oils for feedstuff must be found for this industry. The arc of Kona Blue's feed development strategies is perhaps instructive of directions that open-ocean mariculture, as a global industry, might follow to achieve such scalable sustainability.

Initially, Kona Blue Water Farms fed the Kona Kampachi® with a diet that was considered "organic" by European standards. At the time, USDA did not have (and still does not have) Organic standards for aquaculture feeds. In the EU, however, Organic fish food was considered to be that which was most similar to the animal's diet in the wild. This feed, therefore comprised largely comprised fish meal and fish oil derived from Peruvian anchovies.

With the recognition of the need for more scalable feedstuff alternatives, however, Kona Blue worked with the feed vendor to develop a new diet that lowered the inclusion rate of fish meal and fish oil from Peruvian anchovies to a combined total of 50%. This diet included soybean meal, wheat gluten, canola, and other grain proteins and oils. The biological efficiency for this diet, however, was still suboptimal, with a fish-in:fish-out ratio (FIFO) of over 2:1. (i.e., an input of more than 2 lb of anchovies for each pound of Kona Kampachi® produced).

The inclusion rate of agricultural proteins in diets for marine piscivorous fish is limited by the presence of a range of "anti-nutritional factors" in the grains and less-purified meals. (Aside: although often described as carnivorous, most marine fish such as groupers, snappers, jacks, and bream, are perhaps more accurately

described as "carbohydrate intolerant." They require diets that are high in protein and lipid, and low in carbohydrate. There is no specific nutritional requirement that these fish eat meat). For this reason, soybean meal is restricted to about 20% of the diet for most marine fish. To reduce the fish meal and fish oil inclusion rate further, and to further lower the FIFO, would therefore require proteins and oils from other sources. By-products from both edible fishery processing and poultry processing were therefore included in the revised Kona Blue diet, allowing the Peruvian anchovy inclusion rate to be further reduced to 30% of the ration: 20% fish meal and 10% fish oil.

Inclusion of poultry processing by-products, however, meant that some customers, such as Whole Foods Markets (WFM), a high-end organic and natural foods retailer, would no longer carry Kona Kampachi®, even if the poultry used for the by-products was of Organic origin. This position by WFM was out of consideration for those of their customers that were vegetarians, but still wanted to eat fish. WFM asserted that these customers would not want to eat that fish if fish had eaten a pellet that contained proteins or oils that were derived from mammals or birds. Kona Blue appealed to WFM to review their position, given the importance of reducing mankind's global footprint on the oceans, that is, the reliance of humans on natural marine resources – but as of 2010, there has been no change in this policy.

Kona Blue has recently tested two diets that completely eliminate from the Kona Kampachi® diet any fish meal and fish oil sourced from targeted reduction fisheries, and any land animal processing by-products. These innovative diets use processed by-products from sustainably managed fisheries intended for human consumption. As the trimmings from these sources would otherwise have been discarded, used as fertilizer, or burnt as fuel, the use of these fish meal and fish oil products in the Kona Kampachi® diet represents an ideal reuse of natural resources. These diets therefore would result in a zero FIFO ratio, that is, no targeted reduction fishery by-products included in the diet of the end product.

Alternative Feedstuffs for Open-Ocean Mariculture

Kona Blue is involved in testing a range of alternative feedstuffs for Kona Kampachi® diets, which also offer potential for other species of marine fish. Alternative soy products, other agricultural grain concentrates, yeast, and other single cell proteins, edible fishery by-products and – more recently, with the boom in microalgae culture for biodiesel production – defatted microalgae by-products, have all either been tested, or are under development for Kona Kampachi® feed trials.

Kona Blue has tested a range of soy-based diets, with soy protein concentrates and omega-3 oil rich strains of soybeans. These trials suggest that the inclusion rate of soy protein concentrates cannot, by itself, exceed the same 20% threshold that limits soybean meal. Above this level, growth rates and feed conversion ratios are depressed. With the inclusion of taurine in the formula, however, soy protein concentrates could replace fish meal as the source of protein up to 40% of the diet with no detriment to fish growth rates or feeding efficiencies.

There is a diverse array of edible fishery processing by-products that are available for use in aquaculture diets, and this direction offers tremendous potential for further development. The processing by-products from most wild salmon runs, for example, are woefully underutilized, and are often disposed of directly back into the rivers from which the fish are taken. Logistical and economic constraints limit the use of these trimmings, however, as the processing plants are usually small and isolated, the salmon runs are only of short duration, and storage and transport of fish meal or fish oil by-products from these villages to reduction facilities and feed mills is a challenge. Development of fish silage systems offers one potential, partial solution.

However, even the less-seasonal, larger-scale processing of farmed salmon in more centralized plants presents difficulties for the utilization of by-products. For biosecurity reasons, most fish feed plants will not run salmon-derived feed stuffs through their machinery because of the potential for contamination of feeds from viruses, bacteria, or other pathogenic vectors that may be found in the by-products. Screening for known pathogens is not an adequate solution: even though the chance could be considered very slim that some unknown pathogen may be unwittingly dispersed via extruded feed, the potential catastrophic consequences of such widespread and rapid disease dissemination are sufficient to ensure that no such chance be offered. This

therefore excludes almost all large feed mills in salmon-farming regions from using salmon by-products.

Similar inefficiencies are found in the reuse of trimmings from the pollock fishery (*Theragra chalcogramma*) in the northern Pacific. This fishery primarily processes most of the catch at sea, into surimi. Trimmings from these fish constitute around 65% of the wet weight of the catch. For a fishery that has averaged around 1.3 million metric tonnes, this then represents around 850,000 tonnes of wet weight by-product annually that could be converted into fish meal and fish oil. For many years, much of this by-product was discarded back into the ocean, or the rendered fish oil was burnt in the diesel generators of the processing vessels. Some 8 million gallons of fish oil in Alaska is largely disposed of as biodiesel [18]. More recently, some proportion of these trimmings have been used to make a high-quality white fish meal that is largely exported to Asia, where it is valued in feeds for farmed eels. However, the proportion of by-product that is reused or recycled is not reported. Again, economics and logistics conspire against development of a rational supplement to targeted reduction fisheries. The increasing prices of fish meal and fish oil, however, driven by the growing demand for animal feeds from developing economies (notably China and India) may be a greater incentive to resolve these constraints. Edible fishery by-products may yet play a significant role in aquacultue feedstuff sourcing.

There is ample evidence that some or all of these innovative feedstuffs could help to reduce the demand for fish meal and fish oil from clupeids in the medium- to long-term.

Is Aquaculture "Fishing down the Food Chain"?

Much interest has been recently focused on the problem of "fishing down the food chain," beginning with Pauly et al.[19], and Taylor et al.[20]. This is the trend over time for commercial fisheries – driven by serial stock depletion – to shift their target species to those lower on the trophic pyramid. Fishermen first start out exploiting the high-value, top-end predators, then move on to mid-level predators, and then down toward herbivores and detritivores – what was previously considered bycatch. Fisheries generally start out targeting the larger, sweeter-tasting species – tunas, snappers, groupers, and such. As these become increasingly scarce, fishermen apply greater fishing power, and fish longer and deeper, retaining or targeting what was previously considered "trash." The argument portends that at some stage, the food web is reduced to an ocean full of jellyfish. "Fishing down the food chain" is a condemnation of the inherent unsustainability of most commercial fisheries management – or rather, mismanagement.

Fish farming has somehow been implicated in this practice on the basis of farmed fish being fed pellets that are partly made up of fish meal and fish oil derived from anchovies, menhaden, sardines, or the like. These fish (collectively, the clupeiforms) usually form the first step in the ocean food chain beyond primary production. Some scientists and anti-aquaculture advocates misconstrue or deliberately misinterpret the complexities of ecological and economic cause-and-effect, and represent the use of clupeiforms as feed for farmed fish as wanton. This has been led by respected institutions such as the Monterey Bay Aquarium [21, 22], but has also spilled into mainstream media, such as the *NY Times* [23], *Conservation Magazine*'s article on "10 Solutions to Save the Ocean" [24], *The Ecologist* [25], and *The Economist* [26]. The notion that aquaculture is guilty of "fishing down the food chain" is now lodged within the public consciousness.

The bottom of the food chain, however, is where fishing should preferentially be done. It makes far more sense to use herbivores or planktivores from the base of the trophic pyramid as either human food or feed for farmed fish, than to be targeting top-end predators. This makes economic sense, but it also makes sense from other perspectives: it is better for the ocean's ecosystems, it is better from the viewpoint of bioenergetics transfer through the trophic pyramid, it is better for consumer health, and it makes for better fisheries management.

The economics are simple: Peruvian anchovies and menhaden are not highly valued in the market, so they are cheap. Maybe this will change in time, and prices for anchovies and sardines will increase, as more people develop a taste for oily baitfish, but it is more likely that most consumers will still prefer larger piscivorous marine fish as sashimi or fillets.

The ocean's ecosystem offers several reasons why the bottom of the trophic pyramid is a better place

for humans to extract nutrition from the sea. It is, most simply, a matter of mass and mathematics. Herbivorous fish are more abundant, with greater biomass. Catching 1,000 t of Peruvian anchovies has little impact on the 6 million ton spawning biomass (around 0.025%). By contrast, 1,000 t of tuna represents around 10% of the Bluefin Tuna spawning stock in the Western Atlantic, the biomass of which is currently estimated at less than 10,000 t [27].

Moreover, Clupeiforms are classic "r-selected" species, with their smaller body size, faster maturing, and shorter life spans [28]. They are highly opportunistic: a decrease in population size in Peruvian anchovies often results in increased recruitment from the next spawning. From an ecological perspective, these species are precisely where fishing effort should be targeted, not the larger, more vulnerable, slower-growing "K-selected" species at the top of the food chain. In agricultural terms, most of the crops that humans raise are strongly "r-selected" – wheat, corn, barley, rice, while targeting a "K-selected" species in agriculture might be the equivalent of chopping down oak trees to eat the acorns.

Herbivorous clupeiforms also grow and reproduce faster. Menhaden stock resilience to fishing pressure is "high" [29], with a population doubling time of only 15 months. Northern Bluefin Tuna, by contrast, have "low" stock resilience, and a minimum population doubling time of 4.5–14 years [30]. Therfore, if half the menhaden were harvested, it would take 15 months for the stock to recover. However, if half the tuna population was taken, it would take, at a minimum, between 4.5 and 14 years to recover. Southern bluefin tuna also do not begin to spawn until they are perhaps 11 years old, and may live to "at least 40 years of age" [30]. However, Peruvian anchovies are sexually mature within 1 year, and only live for around 3 years. The 3-year old anchovies then die and fall to the ocean floor.

The public health imperative should also provide impetus to source fish meal and fish oil from lower down the food chain. Menhaden and anchovies filter algae and zooplankton directly from the water. They are therefore high in heart-healthy omega-3 oils, yet low in the persistent organic pollutants, such as mercury and PCBs. These pollutants, however, are concentrated as they move further up the food chain. It is primarily top-level predators – sharks and tuna – that are on FDA advisories for pregnant and nursing mothers, and children. By contrast, an aquaculture species that can achieve a feed conversion efficiency of close to 1:1 (FIFO, or Fish In : Fish Out) contain essentially the same contaminant loading as the clupeiforms at the base of the food chain.

Clupeiform fisheries are also more readily managed, with relatively simple stock dynamics and ecosystem interactions. The major inputs to clupeiform stocks are the spawning biomass and primary productivity, which is usually driven by the strength of the nutrient-rich upwelling. Most of the fisheries occur within the EEZ of a single nation, where there are direct incentives for sound management and enforcement, and where access can be regulated. Tuna and swordfish, by contrast, are highly migratory species. Donut-holes of high-seas waters, beyond any country's 200-mile zone, provide opportunities for distant-water fishing nations to concentrate their boats and effort. Attempts at managing tuna stocks are typified by the International Commission for the Conservation of Atlantic Tunas (ICCAT), which has 46 members, and almost no enforcement capabilities. And while Hawaii's long-line fishery targeting big-eye tuna may be very well managed, for example, heavily subsidized European or Asian purse-seiner fleets target the juveniles of the same stock in the South-Western Pacific.

Moreover, the carbon footprint of clupeiform fisheries is minimal. These fish are usually taken by purse-seiners, working close to the coast, encircling schools containing hundreds of tons at a time. The carbon footprint for species higher on the foodchain is much higher, with fish being caught by diesel-powered trawlers or trollers, or – for bluefin tuna and swordfish – by harpooning the fish, one at a time.

Most importantly, however, it is far better from a bioenergetic perspective to target fish closer to the bottom of the food chain. Applying the 10% trophic transfer rule means that the 1 lb of wild tuna sashimi on a consumer's plate needed to eat 10 lb of anchovies – or its equivalent in fish meal and fish oil. Or maybe, if there were two steps in the trophic pyramid, each pound of wild tuna required 100 lb of anchovies to first be converted into 10 lb of mackerel.

Aquaculture, by contrast, is always a single step – clupeiforms-to-crop. But aquaculture can also use alternative agricultural proteins and oils, such as corn

and wheat gluten, soy proteins and oils, canola, and other animal processing by-products. These other proteins and oils reduce the fish meal and fish oil inputs to the extent that some of the purported "carnivores" can thrive on a diet that is around 20% fish meal and fish oil. On the "sustainability quotient" – the number of pounds of fish-in to produce 1 lb of fish-out (the FIFO) can then attain the perfectly efficient goal of parity, or 1:1 (i.e., every pound of Peruvian anchovies in the farmed fish diet produces 1 lb of product). The result is efficient conversion of a low-value anchovy into a high-value marine fish, without disrupting the fragile top of the trophic pyramid.

Larger, wild fish are more bioenergetically wanton. Wild fish lose energy through inefficient digestion, in hunting prey, trying to avoid predation, spawning, and succumbing to natural mortality. As wild fish grow larger, they also become increasingly inefficient – a greater proportion of energy is needed to maintain the animal's metabolism. Any bycatch will compound these inefficiencies further. The global bycatch ratio is around 0.28 lb of discard for every pound of target species.

Earlier estimates [20] suggested that farmed fish might be more efficient than wild fish, based on a single trophic step, by a factor ranging from 2 to 5. Combining the life cycle inefficiencies, trophic inefficiencies, and bycatch inefficiencies of wild fish, however, means that farmed fish may be more efficient than wild fish by a factor of around 60 (Table 1, and [31]).

This reasoning does not advocate for greater fishing effort on anchovies. To the contrary – caution is called for. While most of these stocks are sustainably managed at current levels, they could not withstand any greater pressure. These clupeiform stocks should continue to be very closely monitored and highly regulated. Large marine protected areas should also be established to allow some clupeiform-based ecosystems to flourish in their natural state (rather than attempting ecosystem based management). But it is imperative that the fisheries at the base of the food chain be better managed, and environmentally sound aquaculture endorsed so that pressure can be taken safely off the top of the food chain.

Fishing at the bottom of the food chain should therefore be encouraged preferentially over any other kind of fishing. This is not a function of recent overfishing: even 100 years ago, this principle would have still held true. People always *should have been* fishing at the bottom of the food chain. To continue to accuse aquaculture as being part of the problem of "fishing down the food chain" is therefore disingenuous. Aquaculture is an important part of the solution to the feeding of the growing humanity. To assert otherwise confuses the consumer and discourages the policy shifts needed toward more sustainable aquaculture, and healthier oceans.

Future Directions

The Challenge

Open-ocean mariculture must expand, but it must expand in an environmentally responsible manner. While opponents may cite the precautionary principle as reason to not move forward, or to do so only cautiously, with experimental site permits or restrictive legislation, there is an imperative for action. Extractive pressures cannot be increased on already depleted wild fishery resources, and the public health costs of limited seafood consumption cannot be accepted any more. These two trends must be turned around by finding alternative sources of healthful seafood. Open-ocean mariculture is the only practical means of achieving this. To urge inaction, then, is in effect advocating for either a greater fishing pressure on wild stocks, or the increasing human mortality and suffering from heart disease and stroke. If the consequences of inaction are so inevitable and so severe, and the potential consequences of action are only slight and temporary, then the precautionary principle insists that action must be taken. Therefore, the requisite regulatory framework for industry growth must expediently be set in place and the needed technologies and support industries developed to proceed forward.

The single greatest challenge will remain that of effecting a change in the mind-set of the environmental community to the extent that there is broad acceptance of the need for expansion of open-ocean mariculture as a conservation tool, that is, as an alternative to targeting larger wild fish. Until this is accomplished, then, this industry will continue to be smeared with irrational fears, community prejudice and consumer bias, and the promise it offers will be left woefully unfulfilled.

Environmental Impacts of an Open Ocean Mariculture Operation in Kona, Hawaii. Table 1 Relative ecological efficiencies of farmed and Wild-Caught fish. The table shows the compounded cost in terms of anchovy-equivalents for farmed and wild-caught fish. Low-end estimates and high-end estimates are provided for each type of fish and compared cross-ways to obtain a lowest relative rate and highest relative rate

	Farmed fish		Wild-Caught fish		Global mean
	Low-end estimate	High-end estimate	Low-end estimate	High-end estimate	Ratio of wild to farmed
Life cycle efficiency[a]	1	1	3	10	6
Trophic transfer efficiency[b]	1	8	10	100	7.3[c]
"Bycatch" efficiency	1	1	1[(4)]	11[e]	1.3[d]
Compounded "cost"	1	8	30	11,000	57

The lowest relative rate extrapolated from this table is that the least-sustainably farmed fish are around 4× more ecologically efficient than the most sustainably harvested wild fish (i.e., 30:8). The highest relative rate is that the most sustainably farmed fish could be 11,000× more ecologically efficient than the least-sustainably harvested wild fish (i.e., 11,000:1). The Global Mean of wild fish efficiency to farmed fish efficiency is around 57×

[a]There are no published estimates of the relative life cycle efficiencies of farmed versus wild fish. However, fish that reach reproductive age in captivity can see Feed Conversion Ratios increase by factors of 5 or 10 over juvenile and sub-adult fish. Natural mortality and the nutritional cost of maintenance of basal metabolic processes during periods of food depravation also increase the "Economic" Feed Conversion Ratio for wild fish populations

[b]In 1997, food conversion efficiencies (FCE) for farmed marine fish and farmed salmon were around 5:1 and 3:1, respectively (Naylor et al. 2000). By 2010, however, FCEs are projected to reach 1.5:1 for farmed marine fish, and as low as 1.2:1 for farmed salmon (Tacon 2005). Kona Blue has been able to culture Kona Kampachi® on a diet that equates to a 1:1 ratio of wet-fish-in to wet-fish-out. However, if a less-sustainably farmed fish is fed a pellet high in fish meal and fish oil (say, to meet the Scottish Soils Association's Organic standards, with around 80% fish meal and fish oil), this diet could equate to around 4 lb of wet anchovy-equivalents for every 1 lb of dry pellet (a wet-fish to fish-meal ratio of 5:1 is considered standard). On this diet, most commercially farmed species might have food conversion ratios of around 2:1 (dry pellet to wet fish), implying an FCE of 8 lb of wet-fish-in for every 1 lb of wet-fish-out

[c]Tacon's (ibid) estimate of FCEs for farmed salmon and farmed marine fish might be conservatively pooled at, say, 1.5:1, that is, 1.5 lb of anchovy-equivalents for every pound of farmed fish produced worldwide. There is a differential of around 1.1 trophic levels between global fishery landings (with a mean trophic level of around 3.3) and the Peruvian anchovetta fishery (with a trophic level of around 2.2: Pauly et al, [19]). At a presumed 10% biomass transfer efficiency up each trophic level, this implies 11 lb of anchovy-equivalents to produce a pound of harvested wild fish. The median ratio of wild to farmed trophic transfer efficiencies can therefore be estimated at 11:1.5, or 7.3:1 overall

[d]Harrington et al. (2005), report a "nationwide discard-to-landings ratio of 0.28" (i.e., for 3.7 million tons landed, some 1.06 million tons were discarded). However, for highly selective fishing methods, such as harpooning, bycatch is effectively zero, as for farmed fish

[e]For finfish, the ratio of bycatch to target fish (in the Northern Pacific) can be as high as 11:1 because the bycatch is either too young, out of season, or the vessel has no permit to keep it (Alverson 1998)

Further! Deeper!

The Kona Blue operations to date have produced annual harvests of around 500 T, and have demonstrated clearly that this can be achieved without any significant impact on ocean ecosystems or resources. The key now is to ensure that these impacts remain insignificant, as the industry scales. Expansion opportunities, in terms of broader acceptance and greater access, will be conditional on future farm sites being located further offshore and in increasingly deeper waters. The industry therefore needs to develop the technologies to support these trends and to ensure that carrying capacities and prudent biosecurity practices are adhered to as the industry grows.

There are economic and environmental drivers for larger-scale open-ocean mariculture operations in

deeper water, further offshore. As the automation systems for net pen management become increasingly sophisticated [32], sea state becomes less of an impediment to more remote, more exposed sites. The major disincentive then becomes travel time to and from a site. Beyond about a 20 mile distance, it is increasingly difficult to maintain a farm site with day-workers, and some on-site residence becomes necessary. This, then, argues for further scaling: once a farm site is manned 24 h, with staff changes twice-weekly or weekly and periodic delivery of feed and other supplies, there are strong commercial reasons for the operation to grow in scale to support the inherent fixed costs.

Larger scale net pens present some challenges in the open ocean, particularly with fish handling, but there are dvantages as well. Larger pens are more cost-effective in terms of cost per unit of volume (i.e., cost per cubic meter) and in terms of managing the stock. A farmer manages a net pen, rather than a fish: a net pen of 3,000 m^3 and 50,000 fish requires roughly the same level of management as a net pen of 24,000 m^3 and 400,000 fish. Similarly, where there is a significant cost to the netting material, or cost to maintaining the netting, then the lower surface area to volume ratios of larger net pens are increasingly attractive. Larger net pens also require larger hatcheries, to produce sufficient fish in one cohort to stock the pen, and this results in greater hatchery efficiencies.

New netting materials under development could revolutionize the net pen designs. Kikkonet™ appears to offer significant advantages over multi-strand nylon or cotton webbing, with greater rigidity and predator-breach resistance reducing the risk of escapes and easier cleaning capabilities with the single monofilament material. Similar advantages may be offered by new brass alloy materials under development, which almost completely eliminate biofouling and the attendant fish health concerns, as well as offering improved resistance to breaches from predators or mechanical tearing. Both Kikkonet™ and brass webbing, however, require rigid frames in open-ocean environments: constant wave and current movement can quickly destroy netting material if the net pen frame allows any excess movement. Each of these materials represents a significantly higher capital cost than nylon or cotton netting, but there are tremendous operational savings to be gained from reduced risk of failure and reduced labor for net changing, net washing, antifoulant dipping, and net loft work.

Although much discussion has focused on the advantages of surface and submerged net pens and the relative operational efficiencies of each, this may be the single most important deciding factor for pen design: rigid-framed nets such as the submersible Sea Station® and Aquapod® can support more robust, rigid netting materials. Flexible framed nets such as PolarCirkel®, or those that rely on gravity to maintain net shape, such as Wavemaster® can only support pliable nets of nylon and cotton in the higher wave and current conditions offshore. Where sea conditions or predator prevalence demand the more robust, rigid mesh forms of brass or Kikkonet, then submersible rigid-framed pens would appear to have operational advantages.

Letting Go

The potential for untethered "trans-ocean drifter net pen" fish farms has, up to now, been the stuff of science fiction [3]. However, the concept of untethered pens offers the potential for far larger scaling of operations, with almost negligible potential for any environmental impact; a net pen in very deep water is a nonpoint source for effluent impacts on water quality and substrate, and there is almost no potential for interaction with wild fish stocks (apart from aggregative effects). There are also advantages for fish health management on the farm – a drifter pen is essentially perpetually fallow. Drifter pens that ride regional ocean eddies or powered pens (either towed by a surface vessel, or where the fish containment is integrated into the vessel hull) are already moving from concept to prototype; within 5–10 years, some form of untethered net pen may become a commercial reality. Several examples are worth noting:

In June, 2008, a trial in Puerto Rico tested a submerged, self-propelled, 3,200 m^3. Aquapod as a demonstration of untethered aquaculture operations. The system was able to achieve 30 cm/s forward speed by using two electrically driven 2.5 m diameter propellers powered by a diesel generator set onboard a small towed vessel. The Aquapod was able to hold position in 25 cm/s currents and was easily maneuverable. The concept of remote-controlled or

autonomous operation was judged feasible using cage-mounted sensors and buoy-mounted GPS and communications.

In October 2009, the State of Hawaii approved a tuna farm permit for a 247 acre site offshore of the Kohala Coast (north of the Kona Blue farm site) in water over 1,320 ft deep, for up to 12 untethered Oceanspheres. With no anchors, it is proposed that these fish farming platforms will be held in position by self-propulsive forces powered by a hybrid Solar Ocean Thermal Energy Generator. Hawaii Oceanic Technology, Inc. plans to deploy the first of these net pens in 2011.

A regional drifter pen concept under development by Kona Blue – christened the *Velella* system – is projected to remain within a prescribed geographical area without anchoring, by riding the eddies in the lee of oceanic islands such as Hawaii, or by riding the gyres found in semi-enclosed seas, such as the Sea of Cortez or the Gulf of Mexico. The advantages of this concept are that it then enables the operation to consistently stock, feed, tend, and harvest the fish in the pen, as well as changing crew and other maintenance tasks. By being untethered, the *Velella* can be located in very deep water, beyond normal mooring depths, and any potential environmental impacts are reduced to de minimis levels.

As untethered net pens do not occupy a fixed geographical space, they do not require a lease but rather are more properly regulated as non-powered vessels. Where there is no point source effluent from a motile pen, the monitoring and regulatory requirements may also be those applied to vessels, rather than fixed farm locations. Projects such as *Velella* might also pass through or be deliberately sited in international waters, where no permits are presently required and where no regulatory framework is currently in place. This regulatory vacuum should be remedied, to both govern its growth but also encourage the development of this technology.

IMTA

Much interest is often focused on Integrated Multi-trophic Aquaculture (IMTA) as a means of improving the sustainability of open-ocean fish farming, by mitigating effluent impacts and more fully utilizing the nutritional inputs. In nearshore systems, the siting of filter-feeding bivalves around fish farm net pens in IMTA systems has been shown to reduce particulates in the water column. Similarly, siting macroalgal culture systems downcurrent of the fish farm can also reduce dissolved organics. These polyculture systems also offer secondary products (such as edible seaweeds and mussels) that are themselves marketable.

In open-ocean mariculture systems, however, the applicability and utility of IMTA is somewhat dubious. The priority for siting open-ocean mariculture operations should be to strive for greater water clarity, depth, and current movement to optimize fish health and minimize any potential impacts on the effluent. These criteria are contrary to the desired characteristics of an IMTA operation, which presumes some entrainment of waters after it passes through the fish pen, with enrichment of the effluent providing benefits to the filter feeders and phototrophs. If open-ocean mariculture operations do indeed have no measureable impact on water quality, then presumably there is no benefit to be gained from co-siting the fish with filter feeders and plants.

Furthermore, the capital and maintenance costs for the secondary production systems would be prohibitive. Open-ocean mariculture, in the foreseeable future, will need to focus on high-value species such as tuna, yellowtails, snappers, and groupers to provide a reasonable return. Only with the development of far greater operational efficiencies, in later years, will lower-value finfish species become economically viable. The commercial returns from deploying and maintaining even lower-valued macroalgae and bivalve culture lines around an offshore site would be even further deferred.

In addition, the co-siting of mussels and seaweed, say, around an open-ocean site represents engineering and biological risks to the fish farm operation. The additional drag from the long-lines would add tremendous strain on the mooring system for the net pens. If moored separately, there would still be concerns that the secondary producer moorings could fail under load and entangle with the fish's net pen or moorings. The resting stages of pathogens or parasites might also be

harbored in the cultured species or ecosystem that surrounds the long-lines, resulting in a proliferative feedback loop and elevated levels of these pests in the cultured fish.

The overarching goal of open-ocean mariculture is growing high-value species in near-pristine waters, with little potential for their interaction with surrounding biologically active substrates. The notion of burdening an offshore operation with lower-value production systems is antithetical to this goal. The fish carrying capacity should allow the natural assimilative capacities of the surrounding ecosystem to fully absorb the farm's ecological footprint. The nutritional by-products, that is, the nutrients in the effluent from open-ocean mariculture systems can still promote productivity on a broader scale, especially in oligotrophic tropical waters. However, a deeper ecological perspective would suggest that there is no need for man to capture this productivity for commercial gain. The oceans can use these inputs in other ways; they are not necessarily "lost."

Article Outline

Glossary

Essential nutrients There are 16 mineral elements that are essential for plant growth. They are referred to here by their symbols: nitrogen, N; phosphorus, P; potassium, K; calcium, Ca; magnesium, Mg; sulfur, S; boron, B; iron, Fe; manganese, Mn; copper, Cu; zinc, Zn; molybdenum, Mo; sodium, Na; chlorine, Cl; silicon, Si; nickel, Ni.

Fertilizer efficiency This refers to the additional grain or other agricultural product produced per unit of additional nutrient applied in fertilizer. A related concept is Fertilizer Recovery, which is the additional mass of a nutrient in the aboveground parts of a crop expressed as a proportion of the additional nutrient applied in fertilizer.

Macronutrients N, P, and K.

Micronutrients Cl, Fe, Mn, B, Zn, Cu, Mo, and Ni.

Soil microbial processes These include mineralization, which is oxidation of organic matter and the release of mineral nutrients; immobilization, which is the reverse process of incorporating mineral nutrients into organic matter; and nitrification, which is conversion of ammonium to nitrate.

Definition of the Subject

Fertilizers are compounds or mixtures delivered as solids, liquids or gases, that supply essential nutrients to crops in soluble forms that are convenient and safe to handle. Fertilizers may be applied to the soil or directly to foliage. All nutrients except N are manufactured by concentrating and refining ores extracted from mines. N fertilizers are manufactured from ammonia, which is synthesized from N_2 and H_2. Science contributes to fertilizer use with improved products and methods to increase fertilizer efficiency, profitability of nutrient used, and reducing adverse environmental effects. Technology contributes to fertilizer use by improving the efficiency of manufacture and the complex logistics of delivering hundreds of million tons of products to farms safely, economically, and on time. Fertilizers can be both inorganic and organic, but this contribution refers mostly to inorganic or manufactured fertilizers, since these provide most of the nutrients now added to soil and crops.

Introduction

Fertilizers are indispensable because nutrient supplies from the soil are normally inadequate for the high-yielding crops needed to supply food and fiber for the growing human population. Fertilizers replenish nutrients removed by previous crops and supplement the supply of nutrients from the soil to a level that will produce the farmer's target yield. Fertilizer may also improve the quality of human food, stockfeed, and fiber. The nutrients in fertilizer are a nonrenewable resource and, if they escape from the field, can cause environmental damage. This article discusses the sustainability of fertilizer in relation to these issues.

Before the invention of fertilizers, the only ways that farmers could accumulate nutrients on a field was to

fallow before growing a crop, or to transfer animal manure from grasslands and barns to cropped land, either directly or by grazing livestock on grassland by day and enclosing them by night in a field prior to cropping. An additional source of N has been, and still is, the residues of previous legume crops, pastures, and green manures. With these natural nutrient sources, land is temporarily taken out of crop production. Fertilizer allows land to be used for continuous production.

The consumption of the macronutrients in fertilizer, N, P and, K has grown rapidly since the middle of the twentieth century and has increased the food supply more rapidly than the growth of the human population (Table 1). The increase in fertilizer supply has been even more rapid than the food supply. It is difficult to overstate the importance of fertilizers in sustaining humanity: Stewart et al. [1] concluded from the results of experiments that production of 30–50% of the world's food is a result of commercial fertilizers and Smil [2] calculated from nutrient balances that that nourishment of 40% of the world's population depended on N fertilizers.

The use of the macronutrients is uneven around the world, as shown in Fig. 1. On all continents, fertilizer provides relatively more N than P or K. The usage of all three nutrients in Europe and North America most closely approaches crop requirement while usage in Asia and Africa is relatively high in N. The K applications are negligible in Oceania and Africa probably because soil levels of K tend to be relatively high in dry regions.

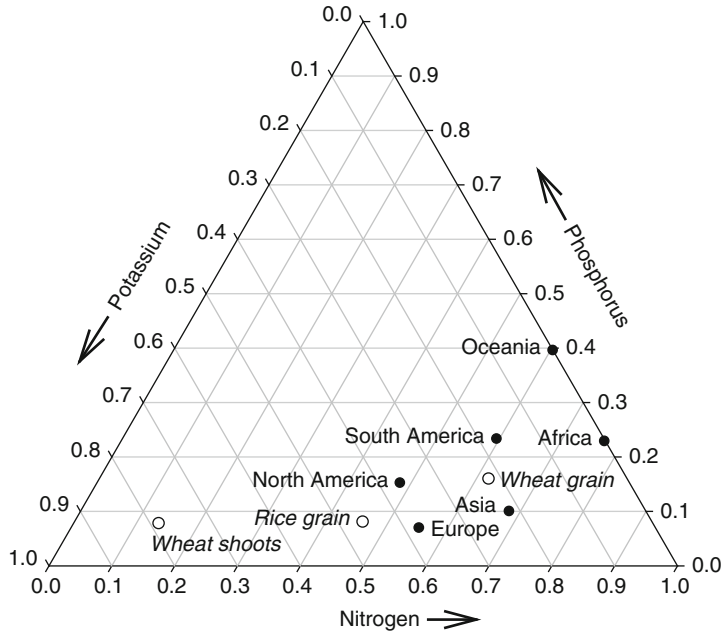
This article discusses the sustainability of fertilizers from the perspectives of resources and logistics involved in supplying fertilizer to the farm, the on-farm effects on productivity, and on-site and off-site environmental effects.

Mining and Manufacture of Fertilizers

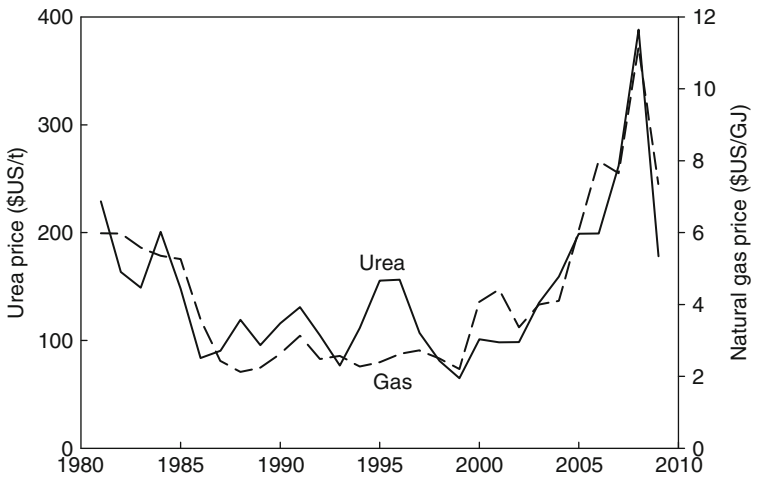
The raw materials for fertilizer manufacture, apart from N, are mined from ore deposits. In the century before 1920, most fertilizer N was also extracted from mines and, before that, from accumulations of nitrate in soil where farm animals had been housed for long periods. Much of this nitrate was used to manufacture gunpowder and other explosives as well as for fertilizer. The increasing demand for explosives and N fertilizer in the nineteenth century led to brutal mining industries that extracted guano (vitrified fecal deposits from sea birds, mostly on tropical islands) and nitrates, a sorry history told by Bown [7].

In modern mining industries, the nutrient compounds in the ore are concentrated by chemical or physical processes into fertilizers that are stable and available for plant uptake. In some cases, two or more nutrient elements are combined, by chemical reaction or physical mixing, into compound fertilizers. Most fertilizers are applied as solids, and single-element and compound fertilizers are normally manufactured as relatively homogeneous granules, which flow freely, minimize water absorption, produce little dust, and which can be transferred efficiently between storages and applied to the soil using machinery or by hand. Most nutrients are available as several different chemical compounds. Examples of these compounds and the manufacturing processes are described by Tisdale et al. [8].

Nitrogen fertilizers are produced from ammonia, which is synthesized by the Haber-Bosch process under conditions of high temperature and pressure using N_2 and H_2 [2]. The usual source of H_2 is natural gas, and the price of N fertilizer is closely linked to the natural gas price (Fig. 2).



Fertilizer Science and Technology. Figure 1
Variation between continents in the proportions of N, P, and K used in fertilizer, and some examples of the proportions of these nutrients contained in whole crops (fertilizer data from FAOstats, rice data from Dobermann and Fairhurst [5], and wheat data from Bar-Tal et al. [6])



Fertilizer Science and Technology. Figure 2
The price of urea generally follows the price of natural gas, which represents the main production cost [9]

Many highly productive farming systems directly inject anhydrous ammonia into the soil. The advantage of ammonia is its high N concentration (82%) and hence low transport cost. Offsetting this is the need for expensive containment vessels, typically made from thick steel, and other costs of ensuring safety. The use of ammonia is confined to application at or before the time of sowing because of toxicity to growing plants.

Applications of a large N amount at these times can cause yield reductions, as discussed below.

Ammonia is used to produce many forms of N fertilizer. The most common is urea, which has the advantages that it contains a relatively large percentage of N (46% N) and is safe to handle, unlike ammonium nitrate (34% N), which can be made to explode, and anhydrous ammonia, which is toxic to humans and animals at low concentrations in the atmosphere. Other common N-containing fertilizers are the solid ammonium phosphates (10–20% N) and the solution of urea-ammonium nitrate (28–32% N).

Fertilizer Distribution, Marketing, and Price

Most fertilizer in developing countries is granular and is sold in 40–50 kg bags and broadcast by hand, apart from a small but increasing amount applied by machine at the time of sowing. In developed countries, most of the solid fertilizer is supplied in bulk and increasing amounts of liquid fertilizer are used because of the convenience of pumping the product between vessels during transport and application. These advantages can compensate for the additional cost of transporting the water in which the nutrients are dissolved. Most of the advantages of liquid are for on-farm handling, so an efficient system is for fertilizers to be delivered as solids from the manufacturer to the reseller who then dissolves the solids just before delivery to the farm. The advantages of liquid fertilizer (and gaseous anhydrous ammonia) are greatest for highly productive regions where farms are close to resellers and where it is possible to grow two or more crops each year and spread the cost of specialized equipment for mixing and applying fertilizer over a large crop area. Resellers extend the time of distribution by offering discounts for early use, but this can be at the expense of reduced fertilizer efficiency. One of the hazards of liquid fertilizer is soil compaction due to the mass of water and nutrients contained in equipment at the time of sowing or in spray carts for post-sowing applications.

Extensive dryland farming systems in developed countries use solid fertilizers where the transport costs are high. Solid fertilizer has an advantage for topdressing because granules can typically be mechanically thrown up to 10–15 m on each side of an implement, which is consistent with the 10–15-m width of seeders and 20–30-m width of boom sprays used for controlled traffic. The maximum spreading distance of granules may impose limitations as seeders and spray booms continue to get wider.

Some of the largest financial and environmental costs of fertilizer are related to transport. Products with low concentrations of nutrients are necessarily expensive to transport and their use is confined to specialized applications, for example calcium nitrate, which contains only 16% N, for some vegetables. During the second half of the twentieth century, there has been a general increase in nutrient concentrations leading to reduced cost of transport to the farm and handling on the farm. Nevertheless, the weight of fertilizer means that transport is expensive and low-cost transport methods such as ship, barge, and rail are preferable to road transport. Transport costs are minimized when fertilizer is back-loaded on vehicles carrying agricultural produce to cities. Transport makes up a large part of the on-farm cost of fertilizer in rural areas of sub-Saharan Africa and presents a major obstacle to increasing crop yields [10].

The transport cost is even greater for manures and compost than they are for inorganic fertilizer. Dry animal manures typically contain less than 2% N and 0.4% P, so they cannot be economically carried far from the source. Instead, manures tend to be applied in a radius up to tens of kilometers. Where there is a large source of manure, such as a feedlot or large dairy, the available nutrients can overload the capacity for crop uptake, so that nutrients may accumulate in the soil within a few years. Where the manure contains potentially toxic material such as Cu contained in pig manure, nutrient loading of the soil needs to be closely monitored.

Fertilizer represents the main demand for N, P, and K, but for the micronutrients, usage for fertilizer manufacture is much less than for manufacturing industry. In the case of Zn, annual world production is about 20 million tons, but the amount of Zn contained in all cereal grains is less than 0.1 million tons per year.

The use of compound fertilizers has advantages in ease of handling and may be cheaper than single-element fertilizers. For example, the nutrients in ammonium phosphates are generally cheaper to the farmer than when they are purchased separately, for

example as urea and triple superphosphate. In such situations, compound fertilizers can be profitable for the farmer, even if one of the nutrients is not particularly deficient. However with some NPK blends, there may be situations where crops do not respond to all nutrients contained in the fertilizer, and where the compound fertilizer is expensive, the whole product may be unprofitable to use. Such a situation applied to many farms in the Philippines where yield of rice did not respond to either P or K in a NPK compound fertilizer [11]. In this situation, application of the NPK was unprofitable on one third of farms and there was no simple way of determining which fields were deficient in which nutrient element. In such situations, the simplest solution is to make single-element fertilizers available so that strip trials conducted by farmers can show which nutrients give profitable responses [12].

The main fertilizers such as urea, MAP (monoammonium phosphate), and DAP (diammonium phosphate) can be regarded as generic and unspecialized commodities that are traded freely. They are sold by manufacturers to distributors on world markets that are generally open and transparent. An insight to the wholesale market is available online [13]. There is little opportunity for manufacturers or distributors to compete other than through price and service. Intense price competition does not support the extension services offered by many fertilizer companies until the 1980s or 1990s.

Marketing is generally in the hands of agribusiness employees and media campaigns. Increasingly, advice about fertilizers is supplied to farmers at or near the point of sale by fee-for-service agronomists employed by fertilizer vendors. This represents a conflict of interest between the need for agribusiness to maximize sales and minimize carryover of fertilizer inventory, and the need of farmers to apply the fertilizer at an optimum amount and timing. Independent advice to farmers is important since fertilizer usually represents the single greatest cost of crop production.

Since generic fertilizers do not provide large profits, manufacturers or distributors aim to develop unique products that are easy to use or contain additives that increase fertilizer-use efficiency. Examples are additives to N fertilizers that inhibit urea hydrolysis and so limit the potential for ammonia volatilization, or nitrification inhibitors that restrict the production of nitrate and hence loss by leaching and denitrification [14]. The cost of these additives may not necessarily be justified by additional profit, and they need to be assessed on a case-by-case basis [15]. Some urease and nitrification inhibitors are powerful biocides and have effects other than on N relations, for example, the nitrification inhibitor nitrapyrin has fungicidal activity, so any yield benefits may not be due only to effects on N supply to crops [16]. Slowing the release of nutrients from fertilizer by coating granules with a polymer is another possible means of maintaining adequate nutrient levels near the roots [17]. The cost-effectiveness of these products also needs to be assessed on a case-by-case basis. The most promising markets for fertilizer additives are where subsidies are offered to minimize N release into the environment.

World fertilizer prices fluctuate, depending on variations in supply and demand. The fluctuations for particular products can be massive, for example, the urea price spike in the mid-1990s when Chinese fertilizer companies suddenly increased urea imports (Fig. 2). The cost of fertilizers generally can also fluctuate strongly, as in 2008 when fertilizer price increased in tandem with a rise in world grain prices (Fig. 3). It is clear from Fig. 3 that the price of grain and cost of fertilizer tend to readjust to maintain a reasonably constant cost:price ratio of about 6, even when grain price or fertilizer cost are disrupted by an external shock.

The price of fertilizer in many markets has been subsidized by governments, generally leading to fertilizer overuse, inefficient methods of application and, in some cases, excess agricultural production that is dumped on world markets. In some countries, the subsidy is through supply of natural gas at less than world price for ammonia production. Fertilizer subsidies have similar effects to subsidies on the price of agricultural production, in that they lead to overproduction because the optimum application rate of fertilizer is affected by the ratio of product price to fertilizer cost. Subsidies on agricultural products and fertilizers have long been criticized because they depress the price of agricultural products in world markets and so reduce the incomes of unsubsidized producers. Criticism is also justified because the overfertilization promoted by subsidies is a major cause of environmental damage [19, 20].

(**a**) Farm-gate cost of fertilizer N and price of wheat, both expressed in $A and (**b**) the cost to price ratio for N and wheat grain (updated from Angus [18]). Costs and prices are expressed in Australian dollars ($A) since these represent world prices undistorted by subsidies

Fertilizer Effects on Agricultural Productivity

In their textbook on plant nutrition, Mengel and Kirkby [21] identify 16 mineral elements as essential for plants. Three of these, Na, Cl, and Si, are normally present in plant tissue at concentrations greater than needed for optimum growth and Ni is rarely or never included in fertilizers. Table 2 lists the remaining 12. A further two, cobalt and selenium, are not essential for plants but are essential animal (and human) nutrients and can be supplied in fertilizer or administered directly to farm animals. The other essential animal and human nutrient, iodine, is not normally supplied through fertilizer.

The concentration of the nutrients in plant tissue varies enormously; for example, N is 100,000 times more concentrated than Mo in cereal grain. The potential yield response to a nutrient, when it is deficient, can be estimated from the inverse of the nutrient concentration. So, for example, if the N concentration in grain is 0.02, as shown in Table 2, a first approximation of potential grain response is 50 kg grain per kg of additional N, assuming that the N concentration of the grain is unchanged by the fertilizer. In reality, not all the fertilizer N is present in the grain. In the case of wheat, 0.7 is a reasonable estimate of the proportion of aboveground N contained in mature grain. A better approximation of the maximum grain response to applied N is then $50 \times 0.7 = 35$ kg grain per kg N. Table 2 shows the equivalent calculation for all nutrients. This approach applies only to the first small application of a nutrient and does not account for the diminishing returns of yield to additional applications.

Table 2 also presents estimates of the maximum net financial return calculated from the maximum grain response, the cost of nutrients in fertilizer, and the price of grain. Note again that these are the maximum responses and returns, and real returns are normally much less because not all the fertilizer is recovered by crops. The costs and prices are necessarily assumptions and will vary greatly between markets and between years. However, the differences between nutrients are so great that even with approximations they serve to show some important points.

The maximum responses of additional grain per unit of nutrient applied in fertilizer in Table 2 can

Fertilizer Science and Technology. Table 2 Typical concentrations of nutrients in cereal grain, *C*, and the proportion of the aboveground nutrient in the grain [21], called the harvest index for the nutrient (HI). The maximum grain response to the nutrient is given by HI/C. The maximum net financial return is given by [*G*(HI/*C*) − F]/F where *F* is the cost of nutrient in fertilizer and *G* is grain price, assumed here to be $US 0.2/kg

Nutrient	Concentration in grain (*C*)	Proportion in grain (HI)	Maximum fertilizer efficiency (HI/*C*) (kg grain/kg fertilizer)	Nutrient cost ($US/kg)	Maximum net returns ($/$)
N	0.02	0.7	35	1.0	6
P	0.003	0.7	233	5.0	9
K	0.004	0.2	50	0.8	12
Ca	0.005	0.7	140	0.2	140
Mg	0.003	0.5	167	1.1	30
S	0.003	0.4	133	0.2	130
B	0.0001	0.1	1,000	12	15
Fe	0.0002	0.3	1,500	3	100
Mn	0.00002	0.5	25,000	5	1,000
Cu	0.00002	0.5	25,000	5	1,000
Zn	0.00002	0.5	25,000	5	1,000
Mo	0.0000002	0.5	25,000,000	35	150,000

serve as benchmarks. When a crop is growing on soil that is believed to be deficient in a nutrient, it should give a yield response comparable with these benchmarks. If it does not it is likely that the nutrient is not seriously deficient or there is a limitation other than the deficiency that is limiting efficient utilization of the nutrient.

The maximum financial crop responses to the micronutrients such as Zn, Cu, and Mo are so large that they are normally applied if there is even a suspicion of deficiency. There are many farming systems where micronutrients still give major grain responses, for example in central Turkey, where widespread Zn deficiency was identified in the 1990s [22]. Continued vigilance is needed in all farming systems in case micronutrients become deficient.

Even for N and P fertilizer, the maximum financial responses are large enough to provide a profit even when the efficiency of recovery is low. In these examples crop recovery of only one sixth of the applied N or one ninth of the applied P gives a break-even return on cost of the fertilizer.

The grain-yield responses to fertilizers are usually much less than these maxima and a great deal of research goes into increasing fertilizer efficiency. Where deficiencies are severe and there is only one nutrient lacking, visual symptoms can be compared with standard illustrations [23]. For less acute deficiencies, a traditional method is to calibrate yield against a soil test and identify the critical nutrient concentration that gives near-maximum yield [8]. The process of soil testing consists of sampling the soil in a field with many cores, combining the samples, and analyzing for nutrient concentration.

Soil tests are not the only methods for determining nutrient status and Table 3 shows examples of methods to estimate N status, including tests related to the nutrient status of vegetative plants. Tests of plant tissue are generally more reliable than soil tests because the volume of soil sampled by plant roots is normally more than the soil volume explored by coring [24, 25].

There are limitations to basing optimum fertilizer application only on tests of soil or plant nutrient status. The approach is suitable for a cropping system in which prices and yields do not vary greatly from year to year, but is less useful where the variation is large. The optimum fertilizer application varies with the ratio of

Fertilizer Science and Technology. Table 3 Tests of N status

Pre-sowing tests	Tests during crop growth
Field history	Tissue N concentration
Total N in the topsoil	Tissue nitrate concentration
Mineral N in the topsoil	Sap nitrate concentration
N released during soil incubation	Shoot density
Previous grain protein	Leaf chlorophyll concentration
	Leaf color compared with standards
	Lower leaf senescence

Fertilizer Science and Technology. Table 4 Example of a nutrient budget for N fertilizer applied to wheat

Crop N demand	
Target yield	4 t/ha
Target grain protein	12%
N in grain[a]	84 kg/ha
N in aboveground crop[b]	120 kg/ha
Soil N supply	
Soil mineral N at sowing[c]	50 kg/ha
N mineralization during crop growth	80 kg/ha
N available for crop uptake (50%)[d]	65 kg/ha
Fertilizer N requirement	
Additional N required in the crop[e]	55 kg/ha
Fertilizer N required[d]	110 kg/ha

[a]Grain N is the product of yield and grain N, assuming that 1 kg of N = 5.7 kg of grain protein
[b]Assuming grain N is 70% of aboveground N
[c]Soil mineral N sampled to a depth of at least 60 cm
[d]Assuming 50% of soil and fertilizer mineral N is available for crop uptake
[e]Difference between crop demand and soil supply

grain price to fertilizer cost, and the optimum fertilizer rate is high when the ratio of grain price is high relative to fertilizer cost.

The optimum fertilizer rate also depends on yield potential, and higher rates are justified by increasing yield potential. Soil and plant tests emphasize the supply of nutrients but it is important to place equal emphasis on crop nutrient demand. Table 4 shows an example of a nutrient budget, based on a method developed by Myers [26], to illustrate the importance of N supply and demand.

When the quality of the grain is affected by fertilizer, it is necessary to consider the responses of both yield and quality and the ratios of fertilizer cost to the grain price and quality premiums. Angus [27] presents a method to estimate the economic optimum fertilizer for wheat in relation to responses by grain yield and protein.

A well-known but generally erroneous notion about nutrients is the Law of the Minimum, which claims that only one nutrient can limit yield of a particular crop. Where one nutrient is drastically deficient, the Law of the Minimum is a fairly good rule of thumb, for example when a micronutrient such as Zn gives a spectacular yield response. More generally, this Law is deceptive, and crops and cropping systems tend to regulate the quantity of nutrients in the soil by luxury extraction of those that are adequate or surplus, and poor extraction of those that are deficient. The different rates of extraction continue until many nutrients become co-limiting and are required for the yield to reach the biological potential [28].

The weakness of the Law of the Minimum can be seen from the many experiments where fertilization with any one of several nutrients can increase yield (e.g., [11]). Fertilizer management therefore usually needs to consider more than one nutrient. Where several nutrients simultaneously limit yield, the combined effect may be additive, meaning that the yield response of the combined nutrients is the same as the sum of yield responses of the nutrients applied singly. In other situations there may be a positive (or negative) interaction, meaning that the effect of the nutrients when applied together is greater (or less) than the sum of the effects of the individual nutrients. As with many aspects of fertilizer management, there is no alternative to conducting experiments on farms to quantify crop responses to nutrients and their interactions. This rest of this section discusses the macronutrients, N, P, and K, and, as examples of minor and micronutrients, S and Zn.

Nitrogen

Nitrogen is used in greater quantity than other nutrients but the financial returns are often less (Table 1). Nitrogen fertilizer has a reputation for low efficiency and many studies show that a crop typically recovers about half the fertilizer N applied, but the proportion can vary from zero to almost complete recovery [24]. The reasons for incomplete recovery are numerous but often the soil can supply as much N as the crop can take up, and any additional N remains in the soil where it may be lost in several processes. Nitrogen losses include leached nitrate, gaseous ammonia volatilization from urea and ammonia-based fertilizer, and nitrous oxide (N_2O) and N_2 from denitrification. Urea is at particular risk of loss, mainly because the soil becomes alkaline around a dissolving granule, so that any ammonium formed is rapidly converted to ammonia, which volatilizes.

Another cause of low crop recovery is immobilization of fertilizer N by soil microbes. This process is not necessarily a loss, since the N can be present in the soil organic matter (SOM) for one or more seasons, during which it is normally mineralized and taken up by later crops.

Nitrogen is unusual among the nutrients in that excess application often causes a reduction in crop yield. In wet and high-yielding environments the reasons for yield reductions are lodging, because the crop becomes tall and top-heavy, and because of disease in thick foliage. In dry conditions, excess N stimulates growth, which can lead to exhaustion of soil water before maturity. Another and often more important reason is that high N levels reduce the concentration of water-soluble carbohydrates in the stems, which is an important source of assimilates for grain growth [29]. The time of application of N fertilizer is important in methods to avoid losses. Responses to topdressing N on wheat during the stem elongation phase are comparable to the responses to the same amount of N applied at sowing in both highly productive environments in Europe [30] and in water-limited environments in Australia [31]. Fertilizer N applied at sowing promotes rapid seedling growth, which leads to more risk of lodging, foliar disease, and haying-off than the same amount of N applied at stem elongation or later. Even when growing rapidly, small plants cannot take up large amounts of N, so mineral N in the soil at the time of sowing is at risk of loss from leaching and denitrification.

Mid-season application of N is effective because it coincides with the period of maximum crop uptake and so closely matches supply with demand. Application of N during or after the stem elongation phase in cereals usually increases grain protein more than application at sowing.

The N losses from irrigated rice can be particularly high. De Datta [32] reported that the average recovery of N fertilizer in rice experiments was 35–40%. Extensive research showed that the main pathways for N loss from lowland rice are ammonia volatilization and denitrification when urea is broadcast onto wet soil or shallow water. This research did not show ways to minimize losses and Fujisaka [33] suggested that research should focus more on methods to increase N efficiency rather than quantify the loss pathways. Subsequent agronomic research showed that with suitable methods of application the recovery of N, supplied as urea, can be as high as 75% for tropical rice [34] and 90% for temperate rice at a commercial scale [24].

The most efficient ways to increase N use efficiency (NUE) are different in each region and with each cropping system. Practices that are often effective are injecting fertilizer into the soil rather than broadcasting it on the surface and delaying application of some or all of the fertilizer so that the supply of N is well synchronized with the crop demand. Other ways to increase NUE are to ensure that other factors are not limiting. These limitations can include deficiency of other nutrients, weeds, herbicide damage, and root disease. An example of the importance of overcoming such limitations is apparent in a 40% increase in dryland wheat yield in Australia during the 1990s, which coincided with the adoption of canola break crops and higher applications of N fertilizer. Angus [18] suggested that break crops controlled widespread root disease and provided suitable conditions for a large yield response to N fertilizer.

There have also been reports of improvements of NUE in a single season by classical plant breeding [35] or modification of single genes [36]. Genetic improvements in N use efficiency are promising but it is not yet clear whether they are consistent across environments and seasons, and whether they are as cost effective as the established and reliable improvements in crop management.

There is a widespread and recurring problem of farmers applying more than the economically optimum rate of N fertilizer. The problem was apparent in Europe and the USA from at least the 1970s [20] and the same pattern of overuse emerged in many other countries, including China since the 1980s [37]. N fertilizer applied in excess of crop requirements is sometimes called "insurance nitrogen" [38], implying that farmers are prepared to pay for the excess provided that the yield is maximized. Another explanation lies in the concept of "farming styles" of van der Ploeg [39], which interprets farming practices in relation to farmers' goals. Farmers who want to boast of the highest district yields apply heavy inputs with little regard for input costs and net profit. These competitive individuals are uninterested in the profit-maximizing paradigm of agricultural science. To reverse the pattern of fertilizer overuse, it is important to redirect their competitiveness to efficiency rather than yield.

The reason that overfertilization is more common with N than other nutrients is not clear, but may be related to the rapid and visible response by crops. Within 5–10 days of N application, crops usually become greener and taller, which gratifies farmers, at least when they first observe the response. To this extent, N fertilizer provides its own advertising. The greener and taller fertilized crops may or may not yield more than those that receive no additional fertilizer. Reasons for a lack of yield response may be that the real yield limitation is not N but some other limitation such as water deficit, disease, deficiency of another nutrient, frost, weeds, or herbicide damage. Since the 1990s, the application rates of N fertilizer have been static or falling in Europe and North America but crop yields have continued to rise [40]. Apparently, farmers and advisers in these regions are learning the lesson that the previous rates were excessive and the time of application was too early.

Phosphorus

Soil contains P as both soluble and insoluble inorganic phosphates and in organic forms including phytates, which make up more than 50% of the soil P. Fertilizer P adds to the soluble pool that can be taken up by crops, but the longer it remains in the soil the more is precipitated as insoluble iron and aluminum compounds in acid soil, or as insoluble calcium compounds in alkaline soil. Soils vary in the speed with which they precipitate soluble P, so soil tests are needed to measure plant-available P and the optimum rate of P fertilizer [8]. Tests of soil P and other nutrients based on ion exchange resins often give closer relations with plant uptake than other extraction methods [41]. Plant P tests are not as useful as plant N tests because P is applied at or before sowing.

Fertilizer management is designed to maximize and prolong P availability to the crop. The most powerful method is to include all the P in a band near the seed so as to maximize plant access before the P becomes unavailable due to precipitation. As with N fertilization, it is important to supply only enough for the crop since some of the excess P is likely to be precipitated. This applies whether the fertilizer is in the solid or liquid form. Liquid forms of P fertilizer are relatively more effective than solid forms on alkaline soils because the precipitated P is still partly available [42].

Most P in the soil is attached to clay particles and is not readily leached from any but the sandiest soils. Because most soil P is close to the surface it is unavailable when the topsoil dries out, so fertilizer injection below the surface can improve the efficiency of uptake in dry environments [43]. Because of the advantages of banding and deep placement, all the P fertilizer needs to be applied at the time of sowing.

Potassium

Crops require a large supply of K but remove little in grain. Most of the K taken up by plants remains in the straw and returns to the soil when the straw decomposes or is burnt, provided the ash that remains after burning is not blown away in the wind. Once in the soil, K is not readily leached because of its positive charge and tends to be used by crops with greater efficiency than N or P. An exception is on soils that contain a large proportion of 2:1 clay minerals, where K is strongly fixed and becomes unavailable to roots.

Other Nutrients

The other nine nutrients commonly applied as fertilizers are not all discussed individually and the reader is

referred to nutrient aspects by Mengel and Kirkby [21] and fertilizer aspects by Tisdale et al. [8]. This section discusses S and Zn because of their increasing importance.

Sulfur is present in the soil as sulfate, which as an anion is subject to leaching. Until the later part of the twentieth century, it was inadvertently applied in many regions. One form was in superphosphate, which was used for its P content (9%) but supplied S (11%) as well. The "high analysis" fertilizers, which largely replaced superphosphate, contain relatively small amounts of S. Another source of S for plants was atmospheric deposition as oxides of S from smokestacks, particularly on smelters of metal sulfides. This source of S is also decreasing because smokestacks are being fitted with "scrubbers" to reduce air pollution. Fertilizer S will be increasingly needed to replace these sources.

Zinc is important for not only increasing crop growth, but also as an essential human nutrient that is becoming seriously deficient. Zinc deficiency is widespread in soils and plants, particularly in west and south Asia [44], and methods and products are available in some countries to correct Zn deficiency [23]. Some, but not enough, compound fertilizers in developed countries include Zn but in many developing countries, Zn is available only as zinc sulfate. Sometimes this expensive compound is diluted by unscrupulous retailers with salts that look similar, such as ammonium sulfate, so the product is an ineffective source of Zn (R.J. Buresh, 2011, personal communication).

Much of the Zn content of plants is transferred from the soil to plant roots by arbuscular mycorrhizal fungi (AMF). The large surface area of AMF filaments increases the ability of plants to explore the soil for immobile nutrients such as Zn. AMF are highly effective in soils with low nutrient status, but the modern farming practices of high levels of P fertilizer and growing brassica break crops tends to reduce AMF activity and increase the need for Zn fertilizer. Breeding plants for increased Zn uptake from soil can be effective in the short term but without supply of Zn fertilizer will exhaust soil reserves and hasten the onset of severe deficiency [45].

Fertilizer Recommendations and Decision Support

Methods for prescribing the fertilizer amount evolved from blanket recommendation provided by advisers, meaning the same practice irrespective of fields or seasons. Soil tests and nutrient budgets, as described earlier, give more differentiated prognoses of response can be used to develop "rules of thumb," which are usually accepted by busy farmers. Computer-based decision support systems can take account of many factors that are known to affect nutrient response but are not as widely adopted as simple systems and rules of thumb. McCown [46] concluded that adoption of decision support systems had not met the promise they offered.

Fertilizers and Precision Agriculture

Precision agriculture is a set of principles that has developed since the 1990s, aimed at managing crops at a scale of several meters rather than as a whole field. It relies on a global positioning system (GPS) that estimates location with precision ranging from 4 to 0.02 m, spatial data about crop production such as maps from a yield monitor, biomass images from a satellite or aircraft, or spatial data about soil conditions such as electrical conductivity [47]. Fertilizer can be managed by precision agriculture by varying the application rate according to the demand by the crop and/or the supply from the soil in different zones in a field. The farmer or adviser first prepares a prescription specifying the fertilizer rate for each zone and programs this in a computer carried in a tractor. This computer continuously determines where the tractor is located relative to the zones in the field, based on signals from the GPS receiver, and controls an actuator on the fertilizer implement that delivers the appropriate rate of fertilizer in each zone.

Yield maps provide useful data for deciding on fertilizer strategies and tactics. If one part of a field is consistently low yielding and it has previously received the same amount of fertilizer as the rest of the field, then it is likely that soil nutrient levels have accumulated. This pattern is common in the case of P fertilizer, and provides evidence to reduce the application rate on low-yielding zones. Variable applications of N fertilizer

are a common use of yield maps. An example is in response to natural variation in soil organic matter, with additional N supplied to low-fertility zones [48]. Another example is in response to "unnatural" soil variation due to land leveling, where "cuts" expose subsoil containing low nutrient levels and "fills" consist of additional amounts of topsoil that is relatively fertile.

In these examples, additional fertilizer is designed to compensate for low soil nutrient status. If yield variation is due to soil properties other than nutrient status, then it may be inappropriate to compensate for low yield with more fertilizer and the best strategy is the exact opposite, that is, to apply more fertilizer to zones that consistently give the highest yields. An example of this situation is when spatial yield variation is due to the differences in the available soil water supply. Angus et al. [49] investigated yield and crop response to N across fields that varied in subsoil constraints of salinity, sodicity, and high concentration of boron. They showed that wheat yield and the crop response to N fertilizer were greatest on parts of a field with the least subsoil constraints, and yield responses to applied N were least on zones with the most severe constraints. Even in the absence of subsoil constraints, the soil water-holding capacity can control yield of dryland crops, and the highest rates of N fertilizer should be applied to zones with large water-holding capacity [50]. Spatial soil variation is often best measured by electromagnetic induction, which directly measures apparent electrical conductivity, which is a proxy for other properties [51].

Where the response of a crop to fertilizer depends on its N status rather than other soil conditions, an optical sensor can provide useful information about a static or on-the-go estimate of crop N status. Optical systems using infrared sensors, such as the Greenseeker [52] and N-Sensor [53], can estimate N status of crops at a scale of about 1 m^2 while mounted on a tractor or fertilizer distributor, and can regulate the fertilizer rate on-the-go. A simple system using a domestic digital camera can provide equivalent information for a single scene [54].

The previous examples applied when the spatial yield patterns are consistent between years. A more complex approach is needed when the fertilizer response is inconsistent between zones and between years. For example in a dry season, N fertilizer may increase yield in low-lying, wet zones of a field but reduce yield in hilly, dry zones. Conversely, in a wet season, N fertilizer may be most effective in the hilly zones. The best response to this situation is not clear. One possibility is to examine yield maps for several years and manage fertilizer for an average season. Another is to delay the decision to apply fertilizer until the seasonal pattern is apparent. It may also be possible to minimize yield variation due to water movement by land-forming and drainage.

Fertilizers in Organic Farming

Many consumers are prepared to pay premiums for organically grown produce and a small proportion of farmers want to supply food produced by one of the organic farming systems. For certification of organic produce, the several organic farming systems generally require nutrients to be applied as manure and unprocessed minerals but not as processed fertilizer. Application of sufficient manure can provide optimum crop nutrition and until recently it was assumed that there were no disadvantages to the nutrient relations of organic farming. Research compiled by Kirchmann and Bergström [55] shows that this assumption is invalid because there is consistently more N leaching under organic than conventional systems, apparently because the soil N supply is not well synchronized with crop N demand. These results suggest that the nutrient relations of organic farms may be less sustainable than conventional farms. Many governments subsidize organic farming systems and thus support unsustainable nutrient management.

In another comparison of organic and conventional farming systems, Fagerberg et al. [56] showed that nutrient levels of the organic part of a split farm remained adequate for several years after conversion from conventional, but that later some nutrients become depleted and productivity fell. The likely reason was that these nutrients had accumulated during several decades of fertilizer application before half the farm was converted to organic farming.

Residual nutrients from previous fertilizer application are not the only source of N in organic farming. In parts of north America and western Europe, the deposition of mineral N from the atmosphere contributes a large part of crop requirement [20].

The sources are ammonia emitted from manure in intensive animal industries and nitrogen oxides emitted from vehicles. Both sources of N originate from industrial operations, so it is difficult to understand how any farming conducted in such regions can be designated as organic.

Some strands of organic farming propose application of plant extracts and microbial preparations to the soil to promote crop growth, and such products have spread in the decades since there was regulation of agricultural chemicals. Reports of the effectiveness of some of these products were reviewed by Edmeades [57], who concluded that they gave no significant yield benefit when used as recommended. A manufacturer of one such product objected to Dr. Edmeades' comments and took legal action against him in New Zealand courts. Dr. Edmeades won the case but effectively lost his scientific career and wasted a year enmeshed in the legal system [58]. It is not clear how reputable science should deal with claims that "alternative" products provide production and environmental benefits out of all proportion to their nutrient composition. Even if one such product is proved to be ineffective and removed from the market, it is likely that others will take its place. A solution may be to strengthen consumer protection laws so that manufacturers can be penalized for making unsubstantiated claims.

Environmental Benefits of Fertilizers

Fertilizers provide environment benefit by increasing soil organic matter in nutrient-deficient soils. For example, superphosphate provided P and S for vast areas of deficient soil in Australia, which provided that trigger for biological nitrogen fixation by pasture legumes [59]. Even more spectacular increases in soil organic matter came when micronutrient deficiencies were corrected with fertilizers in the Western Australian sandplain. These are the only positive environmental effects of fertilizer and other effects are neutral or negative.

Pollution of Surface Water and Groundwater

When there is nitrate in the soil and the water supply from precipitation and irrigation exceeds evaporation, the nitrate will be leached and eventually enter the groundwater. Levels of groundwater nitrate began to increase in the second half of the twentieth century, most notably in Europe and North America, and have stubbornly remained high. For example, Johansson and Gustafson [60] reported that after N-fertilizer application to an arable field in southern Sweden was discontinued, there was a delay of 20 years before the concentration of subsoil nitrate decreased.

The best-known environmental damage from nutrients is water pollution in lakes, rivers, and parts of the ocean. The pollution causes hypoxia, algal blooms, and death of pelagic fish in many water bodies, the largest of which are the Gulf of Mexico [61], the Baltic Sea [62], and the Yellow Sea [63]. The delay in affecting nutrient levels in such water bodies is probably longer than for groundwater, as shown by the constant levels of dissolved N in the Baltic Sea 10 years after N fertilizer usage almost stopped in the eastern Baltic countries after the breakup of the Soviet bloc [62].

Both N and P from fertilizer contribute to pollution of large water bodies but even if N from fertilizer were not present, blue-green algae would be able to obtain their N requirements from biological fixation. Other evidence for the importance of P in water pollution is that the size of the "dead zone" in the Gulf of Mexico is more closely related to the discharge of P than of N [64]. The source of nonpoint P pollution may not be confined to fertilizer, and streambanks disturbed by humans and grazing animals have the potential to release soluble P into water bodies. A promising method to reduce phosphate release into streams is to exclude grazing animals from riparian strips.

Systems to limit nutrient pollution of water have included fertilizer taxes and quantitative limits of nutrient loading from both fertilizer and manure. N fertilizer was taxed in Sweden for many years but there was little change in the rate of N application to crops. In the Netherlands, a system of nutrient accounting of inputs and outputs limits the nutrient balance of farms to reduce nutrient movement into groundwater and streams [65]. A promising method is to define sensitive zones, based on infiltration rate or proximity to streams, where fertilizers are banned, limited, or taxed [66].

Intensive research continues on the nitrogen cascade, a phrase that recognizes a chain of intended and unintended consequences when reactive N moves on land and in the air and water. An example of coordinated research in western Europe is given by Sutton et al. [67].

Greenhouse Gas and Ammonia Emissions

Nitrous oxide (N_2O) and N_2 are released from soil into the atmosphere by the processes of nitrification [68] and denitrification [69]. N_2O absorbs long-wave radiation and remains in the atmosphere for a long time so its greenhouse effect is much greater than that of CO_2. The International Panel on Climate Change estimates the emission of N_2O from agriculture as a percentage of the N fertilizer applied. This approach takes no account of nitrification and denitrification of non-fertilizer sources, mainly from mineralization of organic N. Since fertilizers provide about half of the N used for food production, the contribution of the organic N to N_2O emission is probably underestimated. The most promising strategy to reduce N_2O loss are to minimize waterlogging, since denitrification proceeds most rapidly in anaerobic conditions.

Gaseous loss of NH_3 is greatest when ammonium is on or near the surface of an alkaline soil, or in the floodwater of rice. Windy conditions at the soil surface also contribute to rapid loss. In the worst conditions, the loss of fertilizer N can be up to 10–15% per day [15], but the loss can be reduced or eliminated by injecting ammonia-based fertilizers below the soil surface, or, if topdressing is unavoidable, by applying fertilizer before forecast rain, so that the granules are dissolved and transported below the soil surface.

Soil Acidification

Ammonia-based fertilizers, including urea, acidify the soil when protons are released during nitrification. Soil pH falls more rapidly in light-textured and poorly buffered soils than in heavy-textured and highly buffered soils, but the process continues irrespective of soil type. The consequence of acidification is reduced plant growth, not because of the protons, but because of increasing concentrations of aluminum and manganese in the soil solution that accompany reduced pH. The most common cure is to apply lime, which represents a deferred and indirect cost of N fertilizers and an environmental cost since the reaction of lime on acid soil releases CO_2. A less common response is to apply nonacidifying fertilizers such as those containing nitrate, but these are more expensive than ammonia-based products.

Does N Fertilizer Deplete Soil Organic Matter (SOM)?

Until recently, there was a general belief that N fertilizer had little or no effect on SOM but this was challenged from analysis of soil data from the Morrow Plots, a long-term experiment at the University of Illinois in Urbana. Khan et al. [70] analyzed soil C and Mulvaney et al. [71] analyzed soil N from these plots and came to the startling conclusion that adding N fertilizer decreased SOM, apparently because the N fertilizer stimulated soil respiration. If true, this conclusion would prove that the modern N fertilizer industry is unsustainable.

Reid [72] and Powlson et al. [73] criticized these interpretations of the Morrow data. Their criticism was that the experiment had been confounded because the plot that received a large N dose from 1965 to 2005 had previously (1904–1966) received large annual doses of manure that had built up SOM to very high levels. After the manuring finished on that plot in 1967, the SOM decreased simply because it was above the equilibrium level for the environment, and not because of N fertilizer. This is a strong argument because there is ample evidence that soil maintains a high level of SOM only if there is a constant input of organic matter to offset soil respiration, and this material contains C, N, P, and S at ratios close to that of SOM. Kirkby et al. [74] surveyed data on SOM content and estimated that the average C:N:P:S ratio of humus was 1000:80:20:14. After manuring stops, the SOM decreases for many decades until it returns to the equilibrium for the environment [73]. The decrease in SOM in the Morrow plots can be explained more by the oxidation of manure than the effect of N fertilizer. The specific criticisms by Reid [72] and Powlson [73] about the confounded treatments have not been challenged after 3 years of debate on the subject [75] so it appears that the concern about N fertilizer depressing SOM was a false alarm.

Nutrient Transfer from Farmland to Natural Terrestrial Environments

It has long been known that nutrients move from farmland to natural environments on land, as well as to freshwater and oceans, as described above. Pathways for nutrient transfer are water, gas, dust, and wild

animals [76]. Movement by water is likely to remain in the stream system so is relatively unimportant for transfer to terrestrial environments. The only nutrient moved as gas is ammonia, and the main agricultural source of which is housed animals rather than emissions from fertilizer, although the original source of the nutrients is mostly fertilizer.

Nutrient movement in dust has not been widely discussed in the agricultural literature but is of more interest for earth science. Nutrients move in dust when wind lifts clay particles, which normally contain a large proportion of organic matter [77]. When the wind abates, the particles may land on another agricultural field where the nutrient transfer is relatively unimportant, and in natural environment where the nutrients may cause environmental damage.

The other source of nutrient transfer is through animals. Where farmland is adjacent to natural vegetation, it is common to see wild animals grazing on crops and pastures during the morning and evening and retreating into the cover of bush during the day. Examples are deer in Europe and North America, kangaroos in Australia, and birds almost everywhere. The obvious attraction to animals of the margin between farm and bushland is access highly nutritious feed on the farms and cover in the natural vegetation. Nutrient transfer occurs through urine and dung deposited in the bushland. A consequence of nutrient enrichment of natural vegetation from all sources is eutrophication of the landscape, analogous to eutrophication of water [78], with weedy annual plants competing with native perennials. Nutrient transfer over short distances could place limits on the development of mosaic farming systems where farming and natural vegetation are distributed through a landscape according to land capability.

Human Health

Heavy metals can enter the human food chain from fertilizer. Cadmium (Cd) is the most toxic and is a contaminant in many phosphatic fertilizers [79]. When Cd is applied to a field it accumulates first in crops, grazing animals, and then in the tissue of people who consume the products. The most promising way of reducing Cd levels in fertilizer is by manufacturing phosphatic fertilizer from sources of rock phosphate that contain low levels of Cd [80].

Another supposed health hazard from fertilizer was nitrate, but the concern turned out to be a false alarm. From the 1940s until the 1990s, nitrate was believed to cause blue-baby syndrome (methemoglobinemia) because some cases of this disease that were associated with groundwater containing high nitrate levels, and this was the main reason for an official limit of 50 mg/L of nitrate in drinking water. Evidence reviewed by Addiscott [20] showed that nitrate at this concentration was harmless and that the original basis for this limit was faulty because water containing high nitrate concentrations also contained bacterial contamination, which was the real culprit for methemoglobinemia.

There are however beneficial effects of fertilizers on human health through micronutrients that are essential for human health. The best example is Zn, which is widely deficient in the human diet. The World Health Organization concluded that human Zn deficiency was one of the most serious causes of poor health [81]. Low levels and low bioavailability of Zn in human food are the cause. Increased use of zinc fertilizer would be a boon to human health, particularly to people who rely on a vegetarian diet, since plant products contain less Zn than meat. In view of the difficulty in correcting Zn deficiency in crops, supplementation of human food with Zn may be more effective [45].

Resource Availability

World food supply relies on increasing amounts of nonrenewable resources to provide fertilizers. In the case of N, the resource involved is energy, and about 1% of the world's supply of fossil fuels is consumed in its production. Production of all the other nutrients depends on mining as well as relatively small amounts of energy used in manufacture and transport.

The energy cost of producing N fertilizer has decreased as technology improved. For example, the amount of natural gas needed to synthesize ammonia in the most efficient plants halved in the last 40 years of the twentieth century, and by 2000 was within about 25% of the highest possible efficiency [2]. With diminishing scope for improved efficiency and exhaustion of natural gas, it is likely that the real cost of N fertilizer will rise.

The nutrient at greatest risk of exhaustion is P. Cordell et al. [82] estimated that "peak phosphorus" had been reached and that reserves would be exhausted by 2030. This conclusion is based on the extrapolation of sigmoid curves of production, similar to those used to predict the exhaustion of crude oil reserves. Alternative approaches reviewed by Cornish [83] comes up with estimates of reserves lasting at least until 2100, based on current rates of extraction and the amounts and quality or known reserves compiled by the US Geological Survey. Whether the reserves will last for 30 or 100 years, there is increasing concern that P will be the most limiting nutrient in the long term. The most promising ways of prolonging supplies is to reduce overuse of P fertilizer and find ways to minimize phosphate fixation in soils. If exhaustion of P is as imminent as the worst predictions, it will be necessary to find ways of recycling at the important points of loss, which are in food preparation and in human urine. Recycling options are discussed by the Global Phosphorus Research Initiative [84].

Reserves of high-quality K fertilizers are likely to outlast those of P and probably N [83]. One concern about K supplies is that they are concentrated in the hands of relatively few producers who could be in a position to corner the market. Another concern is that the largest reserves of K fertilizer in Canada and Russia are remote from the regions of greatest K deficiency in Asia.

Future Directions

Existing science and technology shows that crops can respond reliably and profitably to fertilizers when used cautiously. This involves applying fertilizer so that the combined supply from fertilizer and the soil is sufficient for, but does not exceed, crop requirement. This principle has not penetrated far into farming systems, and fertilizer management varies from generally inadequate applications in sub-Saharan Africa to excess use of N in East Asia. Many farms in Europe and North America have passed the period of excess N use. However the efficiency of fertilizer use is still generally low and improvement will require incremental research on farms to refine methods to apply fertilizer efficiently and in ways that are compatible with farming systems. As farming systems change, as they inevitably will, fertilizer management will have to change also. The most promising methods are to arrange fertilizer rate, time of application, spacing and depth of placement to synchronize supply with crop demand, and to adjust these parameters in relation to zones in the field and region. The methods will have to be cost effective, so it will be important to continue to develop methods to manage low-cost fertilizers appropriately rather than resorting to high-cost additives, which may have to be supported by subsidies. Science should also critically evaluate and comment on "alternative" fertilizer products and systems that make outrageous claims and will lead to reduced food security if widely used.

More fundamental science should be directed to liberating the large amounts of unavailable soil nutrients, while recognizing that release of these bound nutrients will only delay the need for additional fertilizer. The largest environmental improvements related to nutrient overuse are likely to come from research to increase fertilizer efficiency on farms. The delay between conduct of farm-related research and its benefits on a regional scale can be many decades [85], so well-resourced field research needs to be maintained.

Acknowledgments

Tony Good provided insights into fertilizer technology and John Passioura and Mark Peoples made helpful suggestions about the article.

Genetic Engineering of Crops for Insect Resistance

John A. Gatehouse
School of Biological and Biomedical Sciences, Durham University, Durham, UK

Article Outline

Glossary

Coding sequence The part of a gene which determines the sequence of the protein product

Domain A region of a protein which forms a distinct 3-D structure, and will often form this structure even when separated from the rest of the protein

Genetic engineering Introduction of a specific DNA sequence into an organism by artificial means

Insect orders Lepidoptera=butterflies and moths; diptera=flies; coleoptera=beetles; hemiptera/homoptera=sucking insects such as aphids

Mutagenesis Alteration to a DNA sequence, often resulting in alteration to the sequence of a protein which the DNA specifies

Oligomerization Formation of polymers containing a relatively low number of repeating units

Proteolysis Introduction of breaks in the chain of amino acids making up a protein by a proteinase

Transgenic Organism into which a gene has been introduced by genetic engineering technology

Definition of the Subject

Genetic engineering of crops for insect resistance is the introduction of specific DNA sequences into crop plants to enhance their resistance to insect pests. The DNA sequences used usually encode proteins with insecticidal activity, so that in plants which contain introduced DNA, an insecticidal protein is present. However, other strategies to improve plant defenses against insects have been explored. Genetically engineered crops that are protected against major insect pests by production of insecticidal proteins from a soil bacterium, *Bacillus thuringiensis*, have become widely used in global agriculture since their introduction in 1996.

Introduction

Twenty years have elapsed since the first publications describing transgenic plants, which showed enhanced resistance to insect herbivores, as a result of the expression of a foreign gene encoding *Bacillus thuringiensis* (*Bt*) toxin [1–3]. In the intervening years, crops expressing these toxins have become widely used in global agriculture, and have led to reductions in pesticide usage and lower production costs [4] At the same time, the predictions made by lobby groups supporting "organic" crop production, that irreversible environmental damage would be caused by genetically engineered (GE) crops resistant to insect pests, have not been realized [5]. Despite all the controversy that GE crops have caused in many countries, it is difficult to dispute that the use of this technology to combat insect pests has had a positive impact on global agriculture.

This entry has two aims: first, to provide a summary of how and why *Bt* toxins have become the insect resistance genes of choice for commercial GE crop applications, and to anticipate some further developments of this technology; second, to consider some of the other approaches to engineering insect resistance in

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

plants, and to assess their potential for future development in the development of sustainable agriculture.

Insecticidal Proteins from *Bacillus thuringiensis*

The presence of insecticidal toxins in the soil bacterium *Bacillus thuringiensis* (*Bt*) has enabled both the bacteria themselves, and genes derived from them, to be exploited as plant protectants. The toxicity is almost invariably based on proteins produced during sporulation of the bacteria, which form crystalline deposits associated with the spores. The insecticidal *Bt* proteins are encoded by genes present on plasmids, and the presence of these plasmids is the main feature which distinguishes *Bt* from other spore-forming bacilli [6]. Preparations of *Bt* spores have been used since the 1920s as a conventional, spray insecticide (and, as a "natural" product, are approved for use in organic agriculture), but their efficacy in the field is limited by inactivation and low persistence.

The ecological niche occupied by *Bt* appears to be simple to define. The life cycle starts with a spore and associated crystalline protein body which may be present in the soil. On being eaten by an insect, the protein deposit associated with the spore is dissolved and digested, converting the crystalline protoxin to an active toxin. The insect is then killed, and the carcass provides nutrients for the growing bacteria, which multiply rapidly. When the insect carcass is exhausted, the bacteria sporulate; the spores are dispersed, and the cycle recommences. However, this cycle is clearly too simplistic, as the target insects for *Bt* toxins are only rarely soil dwellers, and the dose of spores required to kill an insect larva is too large for dispersed spores to have much effect. Although *Bt* is widely distributed, levels of the bacterium in soils are generally too low to have any effect on insects, and spraying plants with spores does not result in persistent protection as a result of the establishment of a high bacterial population. The species has been described as an opportunistic pathogen, which has evolved the sporulation mechanism as a "backup" system to ensure its survival under unfavorable conditions [7]. *Bt* is naturally present in the phylloplane, as well as in soil, and has been detected on cabbage foliage [8], and in vegetative form on clover [9] at low levels, without any insecticidal effect. However, the insecticidal characteristic must be of benefit to the bacterium, since most of the insecticidal proteins are encoded by plasmids, and the plasmids are maintained in the *Bt* population as a whole, despite the obvious metabolic costs of producing large quantities of spore-associated proteins. Not only are toxin-encoding plasmids maintained, but there is also a huge reservoir of diversity in the toxins themselves, and much effort has been put into screening bacterial isolates for strains of *Bt* with novel pesticidal activities [10].

Bt toxins are now classified on the basis of amino acid sequence similarity (an earlier classification system based on pesticidal activity has been superseded), in a systematic hierarchical system [11]. For the purposes of this contribution, only the major distinctions need be considered. There are four types of insecticidal proteins produced by *Bt*:

1. Proteins associated with *Bt* spores, usually as crystalline deposits; three domain structure; single toxins; designated by the symbol Cry
2. Proteins associated with *Bt* spores, usually as crystalline deposits; binary toxins and other similar proteins, including truncated versions of three-domain toxins; also designated by the symbol Cry
3. Proteins associated with *Bt* spores, usually as crystalline deposits; single domain structure; cytolytic; single toxins; designated by the symbol Cyt
4. Proteins expressed vegetatively by *Bt*; single chain and binary toxins; designated by the symbol Vip

Each type of toxin is subdivided (on the basis of sequence similarity) into families (number; same number $\geq$45% sequence identity) and then further subdivided using capital letters (same letter $\geq$78% sequence identity), small letters (same letter $\geq$95% sequence identity) and numbers successively. The resulting system yields designations for specific toxins such as Cry1Aa. A single *Bt* strain can produce spores which contain only a single toxin, or a complex mixture, such as the *Bt* subspecies *israelensis*, whose spores contain Cry4Aa, Cry4Ba, Cry10Aa, Cry11Aa, Cyt1Aa, and Cyt2Ba toxins [12].

All four types of proteins have been proposed for use as crop protection agents, although Cyt toxins have not as yet been used in commercial insect-resistant transgenic plants, and three-domain Cry toxins are by far the most commonly used type. Cry and Cyt toxins belong to the class of proteins referred to as bacterial

pore-forming toxins, and show structural similarity to the α-helical and β-barrel groups of toxins, respectively (where α-helical and β-barrel refer to the structures of the membrane-spanning parts of the toxin; reviewed by Parker and Feil [13]).These pore-forming toxins show common features of activity; they are produced as water-soluble proteins, and interact with specific receptors on cell surfaces, often after proteolytic activation by host proteinases. Binding to cell surfaces triggers a conformational change leading to oligomerization, which allows insertion into the cell membrane through promotion of a fluid, partially denatured structure. Insertion of the toxin into the membrane can either cause cell death directly, or result in effects on intracellular metabolism which lead to cell death.

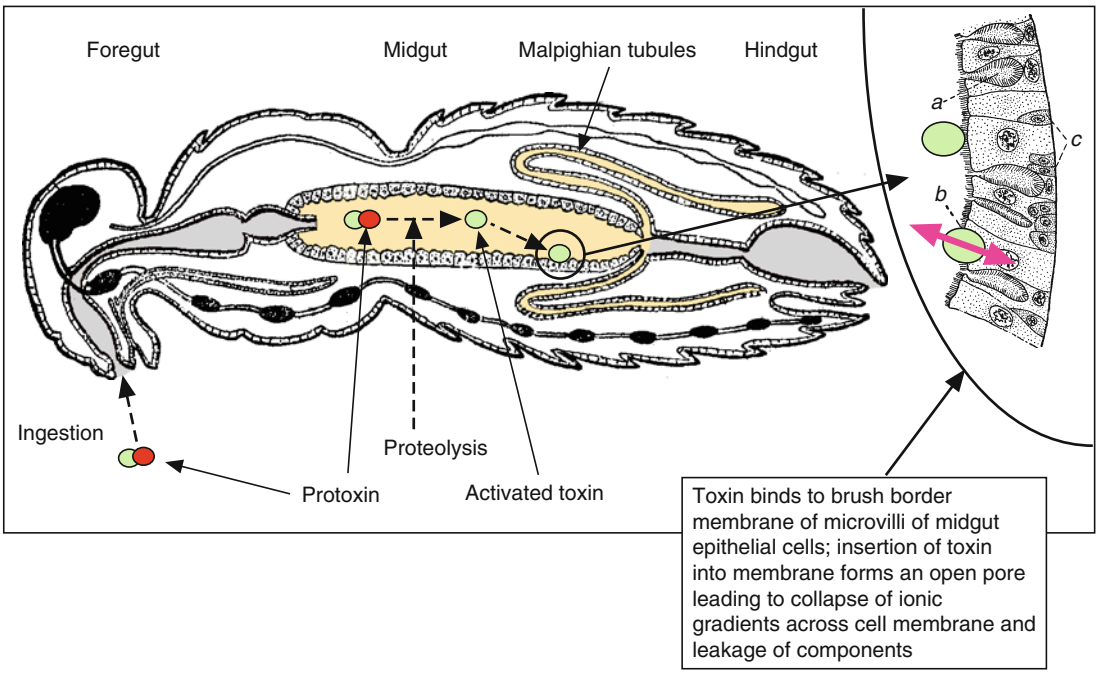
How Do *Bt* Toxins Work?

Three-Domain Cry Toxins

The mechanism of action of the "conventional" three-domain Cry toxins is now well understood, and can be divided into four stages:

1. Solubilization of the protoxin, and proteolytic activation by proteinases in the insect gut to produce active toxin
2. Interaction of the toxin with one or more receptors on cell surfaces in the insect gut epithelium
3. Oligomerization of the toxin
4. Insertion of the oligomerized toxin into cell membranes, leading to the formation of open pores, and cell death (see Fig. 1)

Following the pioneering work of Ellar's group [14] tertiary structures of six different three-domain Cry toxins are known – Cry1Aa [15], Cry2Aa [16], Cry3Aa [14], Cry3Bb [17], Cry4Aa [18], and Cry4Ba [19]; whereas most structures are for the active form, the structure of Cry2Aa includes the N-terminal pro-region. These toxins all show a high degree of structural similarity, and thus the formulation of a general model for their mode of action is justified. The three domains present in the active forms of these proteins are designated I, II, and III, and are normally contained in a single polypeptide of approximately 600 amino acid residues (in some cases proteolytic cleavages are



Genetic Engineering of Crops for Insect Resistance. Figure 1
Action of *Bt* toxins on the insect gut epithelium. Death of insect results from disintegration of gut epithelium (due to cell death) and proliferation of gut microflora

present within the active three-domain structure as a result of protoxin activation, resulting in multiple polypeptides making up the toxin, but the overall three-domain structure is conserved.). While conservation of structure and sequence is observed in the active forms of three-domain toxins, many toxins are synthesized with C-terminal extensions, which are variable in sequence between *Bt* strains, and in length between Cry families. The presence of C-terminal extensions leads to a large degree of heterogeneity in the size of the protoxins present in bacterial spores, with sizes ranging from approximately 600 amino acids (similar to the active toxin) to approximately 1,200 amino acids. These C-terminal extensions are not required for toxin function, and are removed during toxin activation, although their removal is not sufficient for toxicity to be shown. They are thought to play a role in the formation of crystalline inclusions in the bacterium during the spore-forming process.

The three domains of the active toxin are clearly distinguished in their structures.

1. Domain I, approx. 260 aa, contains seven α-helices, of which six are amphipathic and one hydrophobic. This structure is typical of pore-forming toxins, with the hydrophobic and amphipathic helices being responsible for membrane insertion and pore formation. The hydrophilic sides of the amphipathic helices form the surface lining the pore, so that polar species such as ions are able to cross the membrane.
2. Domain II, approx. 170 aa, forms a "β-prism" structure, with three β-sheets, and exposed loops on its surface.
3. Domain III, approx. 160 aa, has a compact structure with two anti-parallel β-sheets in a "jellyroll" formation, and is structurally similar to carbohydrate-binding domains such as the cellulose-binding domain in cellulases [20]. A general model for three-domain toxins is shown in Fig. 2.

The Proteolytic Activation Process Ingestion of the Cry protoxins by the insect leads to solubilization of the proteins, and exposure to digestive proteinases in the insect gut. Although removal of the C-terminal protoxin region occurs at this stage, the essential step in protoxin activation is the proteolytic cleavage and removal of an N-terminal peptide, which varies from approx. 25–60 amino acids in different Cry proteins. A non-activatable Cry1Ac mutant toxin could not form pores in insect membrane vesicles derived from gut epithelial cells [21], and it is thought that the N-terminal peptide "masks" a region of the toxin involved with interaction with receptors [16]. The activated toxin is fairly resistant to further proteolytic cleavage, which enables it to survive long enough in the gut to reach its site of action, the gut epithelial surface (Fig. 1).

This summary overlooks a number of factors which contribute to toxicity. First, the location of the proteolysis may be important, since many insects, such as diptera (flies), carry out digestion in the foregut, which is chitin-lined and does not contain epithelial surfaces, or even outside the insect altogether, by secreted saliva or regurgitated gut contents. Under these circumstances, the toxin will need to be more resistant to proteolysis, or more effective, since the time between activation and reaching the site of action will be longer. Secondly, gut conditions vary significantly between insects from different orders, or even within orders; in general, larvae of lepidoptera (moths and butterflies) have a highly alkaline midgut environment (pH 10–11 in many major crop pests), whereas larvae of coleoptera (beetles) have an acidic gut environment (pH approx. 5 for many species). These differences in conditions will affect both the activation and survival of the protein, although they may be less relevant to steps taking place at the gut surface, where there is a separation from the gut lumen by the peritrophic membrane (a macroscopic porous chitin-based structure) and by lipids sloughed off from the gut surface. Finally, the nature of the digestive enzymes present in the insect gut differs considerably between different orders; whereas most insects use serine proteinases with an alkaline pH optimum as their major endoproteinases, many coleopteran larvae use cathepsin-type cysteine proteinases with an acidic pH optimum (similar to lysosomal proteinases). On the other hand, protoxin activation does not appear to be very sequence specific. Many lepidopteran-specific Cry proteins can be activated in vitro by mild treatment of the protoxin with bovine trypsin, yielding products that appear to be similar to those formed in vivo. This suggests that it is the

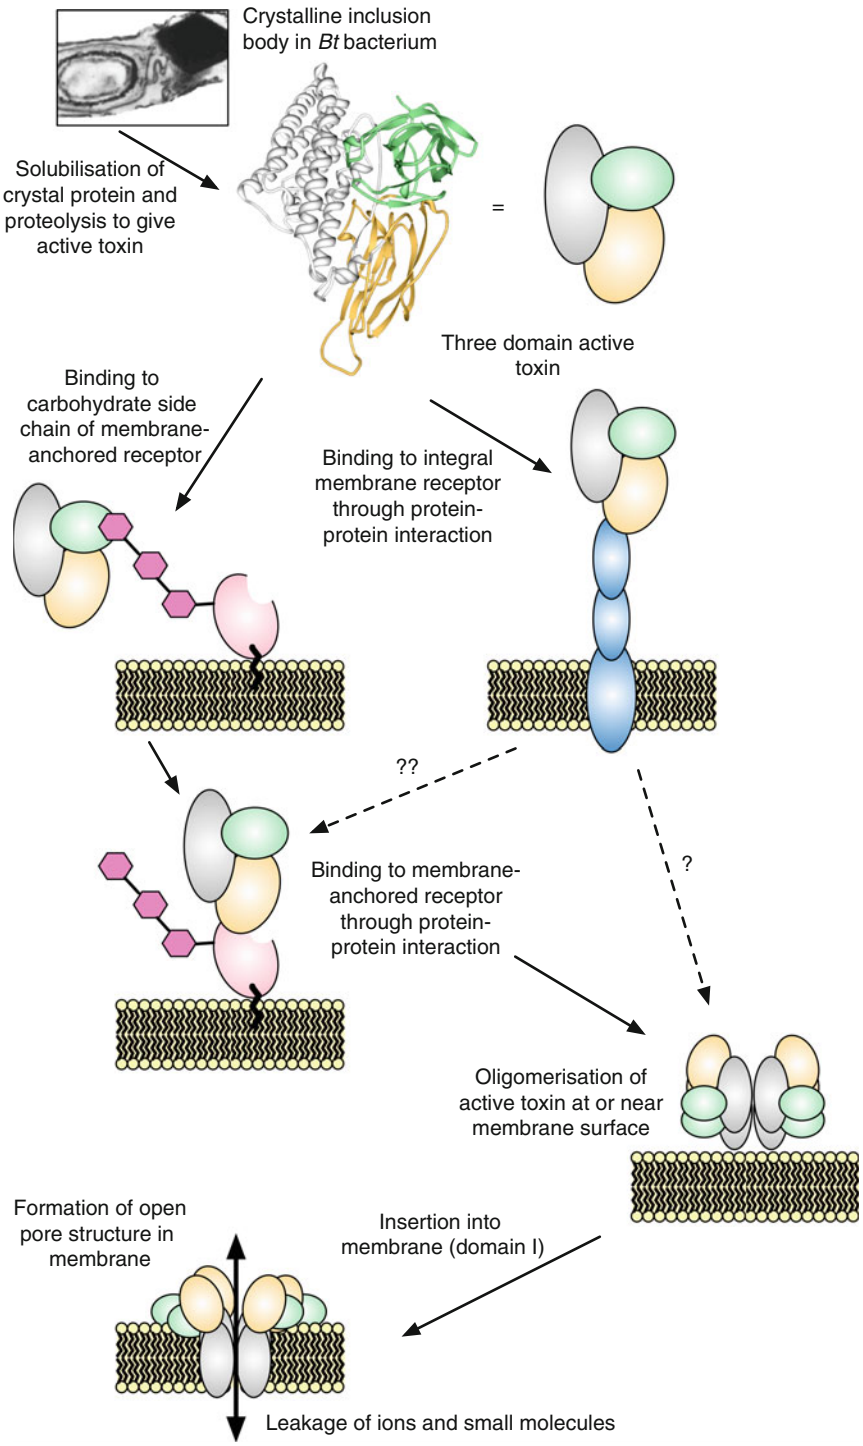
Model structure for three-domain *Bt* toxins. Ribbon diagram showing backbone structure of *Bt* toxin Cry1Aa (PDB 1ciy; [15]); structure of active toxin shown. The three domains are color coded: domain I, silver; domain II, orange, domain III, green. Features as shown on diagram

three-dimensional structure of the protoxin that determines where proteolysis takes place, unless forcing conditions are used.

Interactions with Receptors Proteins to which Cry proteins bind in the insect gut are termed "receptors," although the specificity of interaction is determined by the Cry protein itself, and the ligands to which it binds do not show the properties of receptors as normally understood. Binding takes place on the microvillar membranes of the cells forming the midgut epithelium, and involves interactions with relatively abundant proteins, either attached to the cell membrane by glycosylphosphatidyl-inositol (GPI)-anchors, or integral to the membrane with large extracellular domains. The overall process is summarized in Fig. 3.

Methods for identifying receptors to which Cry proteins bind have largely been based on immunoblotting of proteins prepared from brush border membrane vesicles (BBMV). This method is not a good mimic of conditions in vivo, and may result in interactions with lower affinity, or which are dependent on protein conformations maintained by membranes, not being observed. Nevertheless, the major binding partners for Cry proteins which have been identified show binding when assayed as purified proteins, and as components of BBMVs, with binding constants in the range 1–100 nM.

The initial identification of membrane-anchored aminopeptidase N [23] and an integral membrane cadherin-like protein designated *Bt*-R1 [24] as Cry1A toxin receptors in lepidopteran insects has been supplemented more recently by identification of a 270 kDa glycoprotein [25] and alkaline phosphatase (membrane anchored; [26]) as additional potential receptors. Alkaline phosphatase appears to be the major receptor in mosquitoes [27]. A recent proteomic



Genetic Engineering of Crops for Insect Resistance. Figure 3

Mechanism of action of three-domain *Bt* toxins. The scheme shown is adapted from the "two-receptor" model [22]

analysis has identified further potential receptors, such as V-ATP synthase subunit 1 [28]. However, this analysis also showed binding to actin, which could not be present at the cell surface, showing that results from blotting experiments need to be interpreted critically.

Functional roles as "receptors" for aminopeptidase N and cadherin *Bt*-R1 in Cry protein toxicity are supported by numerous studies. Strains of lepidopteran insects resistant to Cry1 toxins have been identified which show mutations in the gene encoding *Bt*-R1, leading to the production of a truncated cadherin lacking the extracellular domains [29, 30]. The correlation with loss of function of cadherin with loss of susceptibility to Cry toxins suggests that binding to the extracellular domains of cadherin is a necessary step for toxicity. Binding of Cry1A toxin to the cadherin extracellular domains has been demonstrated in vitro, and the binding regions have been identified in some detail [31]. Both gain-of-function and loss-of-function assays have been used to provide further evidence for involvement of cadherin in toxicity; when transiently expressed in mammalian cells that were not normally susceptible to Cry toxin, Bt-R1 genes from silkworm conferred sensitivity to Cry1A toxins [32]; whereas suppression of cadherin expression by RNA interference in tobacco hornworm (*Manduca sexta*) decreased sensitivity to Cry1Ab toxin [33]. In the case of aminopeptidase N, similar correlations between resistance to *Bt* toxin and lack of expression of specific isoforms of the protein have been observed [34], but more direct evidence has come from downregulation of aminopeptidase by RNA interference using double-stranded RNA. This technique has been carried out in lepidopteran larvae, giving decreased sensitivity to Cry1C toxin [35], and in lepidopteran cell cultures, giving decreased sensitivity to Cry1Ac [36]. A gain of function experiment in which transgenic fruit flies (*Drosophila*) expressing lepidopteran aminopeptidase N became sensitive to the lepidopteran-specific toxin Cry1Ac [37] showed elegantly and convincingly that this receptor plays a key role in toxicity. Binding to aminopeptidase N involves interaction of Cry toxins with the carbohydrate side-chains of the protein [38, 39], with specificity toward GalNAc residues being shown (this sugar can inhibit binding; [40]). Binding to carbohydrate facilitates subsequent protein–protein interactions, which are thought to be necessary for toxicity [41]. Functional evidence for alkaline phosphatase acting as a Cry toxin receptor has again been provided by correlative observations, in that insect lines resistant to Cry1Ac toxins have lower alkaline phosphatase levels than susceptible lines [26]. Interactions with protein-bound carbohydrate also seem to be involved in the binding of Cry toxins to alkaline phosphatase.

The roles of the different domains of Cry proteins in the interaction with receptors are clearly distinguished. Despite the presence of the N-terminal propeptide which must be removed for activity, domain I plays little or no role in the interaction with receptors, whereas domain II is responsible for most protein–protein interactions (see Fig. 2), and domain III is responsible for binding to carbohydrates. This division of roles is consistent with the observation that a single toxin can interact with more than one type of "receptor"; for example, Cry1Ac interacts with both Bt-R1 and aminopeptidase N [22]. The protein–protein interactions mediated by domain II have been localized to variable loop regions on the surface of the domain, whereas the carbohydrate-binding region of domain III is a typical binding site cleft, which is spatially well-separated from the domain II loops.

Oligomerization Oligomerization is a common feature in bacterial pore-forming toxins, and Cry proteins appear to conform to the model, with the formation of oligomeric structures (probably tetramers) observed for toxins from the Cry1 and Cry3 families. Mutants of the Cry1Ab protein that have impaired oligomerization ability, but bind to the receptor, show much reduced toxicity or no toxicity toward lepidopteran larvae [42]. Similarly, monomeric Cry proteins have much lower intrinsic pore-forming abilities on synthetic membranes than oligomerized preparations [43]. Oligomerization is promoted by binding to a receptor; in the case of Cry1Ab protein binding to the cadherin Bt-R1 receptor, this process involves an additional proteolytic cleavage at the N-terminal end of the protein, in domain I [44]. The proteolytic cleavage, carried out by host enzymes, may aid the oligomerization process. The importance of oligomerization in promoting toxicity has been shown by two complementary studies. First, a peptide corresponding to the region of cadherin to which Cry1A binds has been shown to act as a synergist, increasing the toxicity of

Cry1A toward lepidopteran larvae [45], presumably as a result of the binding between the peptide and Cry1A promoting oligomerization of the toxin prior to interaction with the gut epithelium. Secondly, mutants of Cry1Ab toxin have been produced which contain deletions corresponding to the proteolysis in helix 1 of domain I which occurs on binding to cadherin. These mutated toxins form oligomers in the absence of cadherin binding, and are effective against insects that have cadherin expression suppressed, or which have a cadherin mutation which leads to resistance to unmodified toxin [33]. These results have led to a current view that cadherin is the primary receptor for Cry toxins, since it is necessary to promote oligomerization, with other molecules taking the role of "secondary receptors" [33].

Insertion into the Cell Membrane The oligomeric Cry protein must partially unfold in order for the pore-forming domains (domain I) to insert into the membrane. In the case of bacterial pore-forming toxins active against mammalian cells, this partial denaturation process is stimulated by acidic pH at the cell surface [13]. A similar mechanism could occur with Cry proteins active against lepidopteran insects, although the gut pH is very alkaline; the partial denaturation could still be triggered by a decrease in pH at the cell surface. The pH optimum for aminopeptidase N in lepidopteran larvae (8.0; [46]) is at least 2 pH units less than bulk gut content pH (>10), suggesting that a decrease in pH occurs near the cell surface. The involvement of lipid rafts, microdomains which are less fluid than the membrane as a whole, in pore formation has been suggested [47]. However, membrane-anchored proteins are selectively associated with these lipid rafts, and it is not clear whether lipid rafts are necessary for pore formation, or whether their involvement is a result of the presence of receptors. The trans-membrane cadherin-like *Bt*-R1receptor is not associated with lipid rafts.

A current model for pore formation by Cry1A toxins suggests that interaction with two receptors is necessary; an initial binding step with the cadherin-like *Bt*-R1 receptor leads to toxin oligomerization, followed by interaction of the oligomer with the aminopeptidase N receptor and insertion into the membrane [22, 48]. While this model is plausible, the details of the mechanism of toxicity must differ for different toxins, and a "two-receptor" model should not be assumed to be generally applicable. The gain of function experiments described above show that only one receptor is necessary for toxicity to be shown, and only a few lepidopteran-specific Cry toxins have been shown to interact with cadherin-like proteins [49]. If the major determinant of Cry protein toxicity is the assembly of oligomeric complexes at the surface of cells in the gut epithelium, then this requirement can be met in diverse ways, involving different "receptor" proteins to localize the toxin and promote oligomerization (although the interaction is always likely to involve the most abundant proteins at the cell surface). A "global" diversity of interactions is not inconsistent with specificity when interactions between specific toxins and hosts are considered.

Once the insertion of Cry toxin into the cell membrane leads to pore formation, the gut epithelial cell is unable to maintain its internal solute balance, as the open pore allows free exchange of ions and other small molecules between the gut lumen and the cytoplasm. The cytoplasm of gut cells has markedly different concentrations of ions (including H^+) than the gut lumen; this difference in concentrations is used to drive active transport processes, such as amino acid transport [50]. Free movement of ions thus causes massive disruption to cell physiology, leading to death. The leakage of cell contents also causes proliferation of gut microflora, so that dying insects show massive bacterial infection of collapsing gut tissue. Cry proteins may also produce toxic effects through interference with signaling pathways. Binding of Cry1Ab to the transmembrane *Bt*-R1 receptor has been shown to activate a G-protein-mediated intracellular signaling pathway, resulting in the formation of cAMP by adenylyl cyclase, and activation of protein kinase A [51]. This process led to cytological changes typical of *Bt* toxin activity.

Binary Cry and Vip Toxins

The binary Cry toxins are exemplified by toxins active against corn rootworm [52]. These toxins are only active as a combination of two proteins, designated as families Cry34 (14 kDa protein) and Cry35 (44 kDa protein). The two proteins are the product of a single

operon in the commonly used *Bt* strains. The binary toxin acts on the insect gut epithelium, and leads to swelling and vesicle production from epithelial cells, resulting in the disappearance of microvilli, and extensive disruption of the epithelium. However, it is not clear whether these symptoms are solely a result of open pore formation, or whether other modes of toxicity, such as ADP-ribosylation (see below) are occurring. No structural information on these proteins is available at present. There is evidence that the 44 kDa toxin protein Cry35 is evolutionarily related to an insecticidal toxin from *Bacillus sphaericus* [53]. The *B. sphaericus* toxins have received some attention due to their toxicity toward mosquitoes and other dipteran insects. They also bind to membrane-anchored receptors (α-glucosidase, in the case of the mosquito *Culex pipiens* [54]) and cause disruption of the gut epithelium [55]. However, their detailed mechanism of action is not known. Like Cry34/35, the *B. sphaericus* proteins are binary toxins, although in this case one component does show limited activity in the absence of the other. The designation of the corn rootworm binary *Bt* toxin by the symbol Cry obscures the fact that these toxins have little in common with the three-domain toxins, besides being found in crystalline deposits in *Bt*, and being insecticidal as a result of acting on the insect gut epithelium.

The *Bt* insecticidal Vip1/2 proteins (active against corn rootworm) are also binary toxins with similarity to the *B. sphaericus* toxins [56]. The mechanism of action of Vip1/2 toxins involves ADP-ribosylation by the active component, which disrupts actin polymerization in cellular microfilaments, similar to other bacterial ADP-ribosylating toxins such as botulinum toxin [57]. The inhibition of actin polymerization leads to massive disruption of cellular functions. The Vip1Ac binding component of the binary toxin interacts with membranes to form oligomeric channels, allowing the active component to gain access to the cell cytoplasm [58].

A further class of Vip proteins, Vip3, (active against lepidoptera) has been identified; these protein are single chain toxins which lyse insect gut cells by pore formation in membranes, and have no sequence similarity to Vip1/2 [59, 60]. Vip3 binds to brush border membrane vesicles prepared from target insect gut epithelial cells, but does not bind to the same receptors as Cry1 and Cry2 proteins [61]. Binding to 80 and 100 kDa membrane proteins is observed in ligand binding experiments [62], but these receptors have not been characterized. These proteins are promising candidates for further development; chimeric toxins containing regions from different Vip3 toxins have been produced and show extended ranges of toxicity toward lepidopteran pests [63].

Cyt Toxins

The cytolytic Cyt toxins, also found in crystalline inclusions in some *Bt* strains, are single polypeptides, of approx. 250 amino acids; the N-terminal region contains α-helices which wrap around a C-terminal β-sheet core in the three-dimensional structure [64]. Pore formation results from insertion of the β-sheet region into membranes [65]. Unlike the three-domain Cry toxins, this membrane insertion is not receptor-mediated [66]; the Cyt toxins insert directly into membranes, and are thus cytolytic to a wide range of cells. Like the three-domain Cry toxins, Cyt toxins are synthesized as inactive protoxins which are activated by proteolysis. Activation involves removal of propeptides from both the N- and C-termini of the protoxin; in the case of Cyt2Aa, 32 aa are removed from the N-terminus and 15 aa from the C-terminus to generate active toxin [67]. This process does not require specific proteinases.

The combination of Cry and Cyt toxins found in crystalline inclusions in some *Bt* strains, specifically in the strains of *Bt* subsp. *israelensis* active against mosquito larvae, is highly effective as a toxin due to synergistic interactions between its components. Not only are the three domain Cry protein components in these crystals more effective toxins in the presence of Cyt proteins, but the Cyt proteins also prevent resistance to Cry proteins from developing when insects are exposed to purified protein preparations under laboratory conditions [68]. This synergistic effect could result from the two types of toxin producing complementary disruption of the insect gut epithelial cell membranes, but evidence has been presented that Cry and Cyt toxins can interact directly. Specifically, Cry11Aa and Cyt1Aa bind strongly to each other, both in solution and in a membrane-bound state, and binding of Cry11Aa to mosquito gut epithelial cell

membranes was enhanced by pretreating the membranes with Cyt1Aa [69]. The interaction with Cyt1Aa takes place through the loop region in Cry11Aa involved in protein–protein interactions with its "normal" receptor (membrane GPI-anchored alkaline phosphatase). Insertion of Cyt1Aa into gut cell membranes, which is not dependent on receptor mediation, thus generates additional "receptors" for Cry11Aa, increasing its toxicity, and preventing resistance developing by mutation of the insect-encoded "receptor."

Expression of Genes Encoding *Bt* Insecticidal Proteins in Transgenic Plants

Expression of Three-Domain Cry Toxins from Transgenes in the Nuclear Genome

Almost all the insect-resistant transgenic crops currently in use express three-domain Cry proteins from *Bt* as their protective agent. The initial laboratory-based experiments expressed Cry1 toxins in plants to give protection against lepidopteran larvae, and this has remained the main focus of *Bt* gene utilization up to the present day. However, the three-domain Cry proteins pose a number of problems in terms of expression in plants. The technology involved in achieving sufficient levels of accumulation of these proteins to give adequate levels of protection was initially challenging, but developed rapidly, so that within 5 years of the initial reports of engineered resistance, the methodology for gene manipulation was essentially complete. The slower pace of transfer of this technology into major crop species observed subsequently has had much more to do with technical difficulties in plant transformation (particularly regenerating viable plants), than with any problems at the level of gene constructs. The minimum level of Cry protein expression in leaf tissue to give high levels of mortality of sensitive lepidopteran larvae under laboratory conditions is approximately 0.05% of total protein, but to give effective field protection against species which are less sensitive to *Bt* toxins, and to manage resistance to the toxin in pests (see later), levels of expression an order of magnitude higher (i.e., 0.5% of total protein) are desirable.

Engineering genes encoding three-domain Cry proteins for expression in transgenic plants has been extensively described (the review by Mazier et al. [70], gives a particularly comprehensive survey), but a short summary of the main considerations which had to be taken into account is relevant here. These were:

1. How much of the protein coding sequence should be expressed in plants?
2. Which promoters should be used to drive expression of the Cry protein coding sequence in plants?
3. How should the coding sequence be altered to avoid poor expression?

Protein Coding Sequence The C-terminal part of protoxins for three-domain Cry proteins is variable, and absent in some toxins. Its role in directing the formation of crystalline inclusions in *Bt* sporulation is not required when the proteins are expressed in plants (and might result in disruption of cells unless the protoxin was exported into intracellular spaces). All constructs which result in insecticidal activity have omitted this part of the molecule from the coding sequence expressed in plants. The initial research suggests that a complete protoxin accumulates in plant tissue at levels 10–50-fold less than a protoxin truncated so the C-terminal region is absent [3]. Since removal of the C-terminal region of the protoxin does not result in active toxin being produced, retention of the N-terminal activation peptide ensures that the initial protein product in transgenic plant tissue is not active, and proteolytic activation takes place as normal within the gut of insect herbivores. The coding sequence utilized thus corresponds to the three-domain structure shown in Fig. 2, plus the additional N-terminal propeptide.

Promoters The problems experienced in achieving levels of expression of Cry proteins high enough to confer effective protection meant that the initial use of promoter sequences which only gave low levels of expression, such as those from *Agrobacterium tumefaciens* Ti plasmids, was rapidly superseded by strongly expressed promoters, most of which were based on the Cauliflower Mosaic Virus 35S RNA promoter (CaMV 35S). Constitutive expression of the Cry protein in all plant tissues does not appear to cause significant problems either in a yield penalty, or

deleterious effects due to the accumulated protein. However, tissue-specific promoters have also been used, such as the ribulose-bisphosphate carboxylase small subunit promoter (e.g., [71]) or the phosphoenolpyruvate carboxylase promoter (e.g., [72]), both of which are specific for green tissue. The CaMV 35S promoter was initially considered to be specific for dicots, but further experience showed that it could also be functional in monocots, and, with suitable modification, could be used to direct Cry protein expression (e.g., [73]). However, many researchers have preferred to use promoters derived from constitutively expressed monocot genes in Cry protein expression constructs for use in cereal transformation (e.g., the maize ubiquitin-1 promoter; [74]). Root-expressed promoters have been used in constructs designed to protect cereals against corn rootworm [75].

Considerable research has also been undertaken on the use of promoters whose expression is only induced under specific conditions. The use of wound-induced promoters to direct Cry protein expression has the apparent advantage that production of Cry proteins in transgenic plants is, for the most part, only induced on attack by insect pests. Any potential deleterious effects on phenotype caused by production of the toxin in transgenic plants would therefore be minimized, and toxin residues in plant tissues would be reduced. A wound-inducible maize proteinase inhibitor gene promoter has been used to direct expression of Cry1B in transgenic rice, and has been shown to give effective protection against insect attack (against striped stem borer; [76]). However, the protection afforded by transgene constructs containing wound-inducible promoters is lower than when constitutive promoters are used, both in the laboratory and in the field [77].

While achievement of expression levels of *Bt* toxins sufficient to confer protection in transgenic plants is now considered routine, considerable technical problems may still need to be overcome when specific crop species are considered (e.g., soybean; [78]). These include the construction of the synthetic coding sequence for the toxin, choice of an appropriate promoter for the expression construct, developing protocols for efficient transformation and regeneration of the plant species, and production of homozygous progeny lines containing the transgene.

Engineering the Coding Sequence to Optimize Expression The initial experiments in which Cry toxins were produced in transgenic plants showed that only low levels of Cry protein were accumulated, generally of the order of 0.01% of total protein, or less. Levels of Cry proteins were at least one order of magnitude lower than when plant proteins were expressed using similar promoters in expression constructs, leading to the deduction that the Cry protein coding sequence contained features which decreased protein production as a result of posttranscriptional events. Cry protein coding sequences are generally A-T rich compared to plants (coding%GC in *Bacillus thuringiensis*, 36%; in *Arabidopsis thaliana*, 45%; in *Oryza sativa*, 55%; Codon Usage Database, http://www.kazusa.or.jp/codon/) and codon usages thus differ significantly. Cry protein genes were reengineered, modifying the nucleotide sequence without altering the encoded amino acid sequence, to change the codon usage to one more appropriate for plants, resulting in either partially or wholly synthetic genes (reviewed by Mazier et al. [70]). Codon optimization for both dicots and monocots has been carried out. Codon-optimized synthetic genes show accumulation levels of Cry proteins of up to 1% of total protein in leaf tissue, which is adequate for complete protection of plants against pest insects [79].

The basis for poor expression of Cry proteins in transgenic plants has received comparatively little attention. Evidence suggests that the major problem is not codon usage, but instability of RNA transcripts [80, 81]. Expression of unmodified Cry protein coding sequences leads to accumulation of short, polyadenylated transcripts resulting from incorrect recognition of polyadenylation addition signal sequences within the protein coding sequence [82]. Specific modification of A-T-rich regions within the coding sequence of Cry1Ac toxin putatively responsible for transcription termination and polyadenylation (both AATAAA signal addition sequences and ATTTA upstream motifs) has been shown to lead to increased protein expression in transgenic tobacco [83]. Changing codon usage to increase GC content has eliminated these A-T-rich regions in synthetic Cry protein genes, which therefore can produce high levels of stable mRNA.

Expression of Three-Domain Cry Toxins from Transgenes in the Chloroplast Genome

The bacterial origin of the chloroplast is reflected in differences in both the genome composition and organization, and the biochemistry of transcription and translation within the organelle, compared to the nuclear genome and transcription and translation in the nucleus and cytoplasm. The bacterial origin of the genes encoding Cry proteins suggests that expression in the plastid, from transgene constructs introduced into the plastid genome, might result in high levels of protein production. This prediction was confirmed in 1995 with a report showing that incorporation of a construct containing a complete coding sequence for the Cry1Ac protoxin protein and the plastid rRNA operon promoter into the genome of tobacco chloroplasts led to accumulation of Cry1Ac protoxin (approx. 130 kDa – i.e., with the C-terminal crystal-forming region intact) in tobacco leaves to levels of 3–5% of total protein [84]. The high level of Cry protein accumulation meant that transformed plants were effectively protected against attack by several major lepidopteran pests, even beet armyworm (*Spodoptera exigua*), a species relatively insensitive to *Bt* toxins.

Despite this highly promising initial report, expression of Cry proteins via plastid transformation has not been widely adopted, and is not used in the current commercial crops. Reasons for this are difficult to pinpoint; there are significant technical problems in achieving stable transformation of plastids, since all of the copies of the plastid genome in the cell (up to 10,000) must be transformed [85], and plastid transformation has been problematic in species other than tobacco [86]. Nevertheless, methods exist to overcome these problems [87]. Cry1, Cry2, and Cry9 proteins have been expressed in plastids of tobacco [88–91], and Cry1Ab has been expressed in soybean plastids [92], all giving high levels of protection against lepidopteran pests to the resulting plants. Overexpression of the Cry2Aa2 operon is particularly effective in giving broad-spectrum protection against a range of pests.

Commercial introduction of transgenic insect-resistant crops based on plastid transformation is almost certainly feasible, but may as yet be restricted by economic considerations, or concern over long-term stability of the transgene phenotype. The maternal inheritance of plastid-encoded characteristics shown by most plants, which means that pollen cannot disperse the transgene to non-transgenic plant stocks, is a further advantage to the method, which could be used to overcome objections to coexistence of transgenic and "organic" agricultural practices by environmental pressure groups.

Expression of Other Genes Encoding Insecticidal *Bt* Toxins

Gene constructs for expression of other *Bt* toxins follow the same principles as those outlined above for three-domain Cry toxins. For example, corn expressing the binary Cry34/35 toxin (for protection against corn rootworm) was transformed with a construct containing a constitutive promoter (maize ubiquitin-1) and synthetic coding sequences for the 44 and 14 kDa polypeptides [52], giving expression levels of up to 0.9% and 0.2% respectively of total soluble proteins in plant tissues. Details of the constructs used for expressing these, and other *Bt* toxins, are apparently not reported in the scientific literature.

Taking Transgenic Plants Expressing *Bt* Toxins into the Field

Dealing with Pest Resistance to *Bt* Toxins

The development of successful strategies for commercial deployment of "first generation" insect-resistant crops expressing a single three-domain Cry toxin has focused on a single major potential problem, the development of resistance to the insecticidal compound by the targeted pest species. Development of resistance to exogenously applied chemical pesticides has occurred in over 500 insect species [93], and field resistance to *Bt* sprays has been observed in the lepidopteran pest diamondback moth (*Plutella xylostella*). Resistance to *Bt* toxins can be produced in the laboratory within a small number of generations of many pests, showing that resistance alleles are present in pest populations at a nonnegligible level, although resistance to high doses of specific toxins is only shown in individuals homozygous for the resistance allele. This topic has been ably

reviewed in the context of the commercialization of *Bt* crops by [94]. The most common mechanism of resistance to Cry toxins in insects is mutation in a toxin receptor, leading to a failure to bind sufficient levels of toxin for lethal effects to be shown; however, the involvement of more than one "receptor" in current models for three-domain Cry toxin mechanisms of toxicity (see above) implies that multiple genetic loci for resistance in the pest are possible. Other mechanisms, such as altered proteolysis of toxins, have been proposed to account for the resistance to multiple toxins which can be produced in the laboratory.

The practical solution to prevent the development of resistance in pest populations, the "high-dose/refuge" strategy, has been extensively reviewed elsewhere [94]. In its simplest form, this strategy couples transgenic plants that are expressing sufficient levels of a specific toxin to kill all pest insects which are homozygous negative, or heterozygous, for a resistance allele, with a reservoir of untransformed plants which maintain a population of pests which have a normal frequency of resistance alleles. It assumes that the frequency of occurrence of resistance alleles is low ($<10^{-3}$). Surviving pests on the transgenic plants will be almost all homozygous positives for the resistance alleles, but will be few in number due to the low frequency of occurrence of these alleles. The nontransformed plants will produce a large number of pest insects, most of which are homozygous negative for resistance alleles. Provided that transgenic and untransformed plants are not spatially separated, mating between resistant insects selected on transgenic plants will be a rare event, and most progeny will be homozygous negative or heterozygous for resistance alleles, and thus susceptible to the insecticidal activity of the transgenic plants. In this way, both the pest population is suppressed, and any increase in the frequency of resistance alleles in the population is minimized by the continuous "diluting out" effect.

This approach has been almost wholly successful in controlling pest resistance to *Bt* toxins in agricultural use of transgenic crops over 10 years. That it has been so successful may be a result of factors other than those originally considered, since the assumption that *Bt* toxin resistance alleles occur at a very low frequency in natural populations has been called into question. Although some insect populations show resistance allele frequencies in the 10^{-3} to 10^{-2} range (e.g., tobacco budworm, *Heliothis virescens* in USA; [95]; *Sesamia nonagrioides* in Spain and Greece; [96]), estimates for pink bollworm (*Pectinophora gossypiella*) in Arizona, USA in 1997 were as high as 0.16 [97]. No evidence for selection for resistance was observed, since the frequency of resistance alleles did not increase over a 3-year monitoring period in which transgenic cotton expressing *Bt* toxins was extensively employed. A subsequent follow-up study [98] confirmed that frequencies of resistance alleles in this insect had not increased over an 8-year monitoring period, with values generally $<10^{-2}$, despite almost continuous exposure to Cry1Ac via transgenic cotton. The possibility that resistance alleles in the insect carry a significant fitness penalty is one additional factor that could account for these observations.

The success of the refuge strategy is dependent on farmers sacrificing part of their crop (untransformed plants) to maintain a pest population. This has been successfully enforced in the industrialized agriculture of developed countries, but may be more difficult to ensure when insect-resistant transgenic crops become available to rural farmers. Although greater agricultural diversity may play the same role as the refuge strategy in maintaining a pest population and decreasing selection pressure, emergence of resistance in pests to *Bt* crops has been delayed, not eliminated, and further strategies to manage it will be necessary.

Pests That Are Not Susceptible to *Bt* Toxins

As described above, most of the *Bt* toxins that have been investigated, and introduced into transgenic crops, are active against lepidopteran or coleopteran insect pests. This is partly a result of the practical requirements of agriculture, since these orders include most of the major pests. However, there are significant insect herbivores which remain outside the range of activity of *Bt* toxins that have been expressed in transgenic plants.

Dipteran pests, such as fruit flies and root flies, are serious pests in many crops, and *Bt* toxins active against diptera have been thoroughly investigated. A major problem with introducing protection against these pests into plants is that *Bt* strains active against dipteran insects usually contain a mixture of toxins, often

including both Cry and Cyt proteins (see above). These toxins act synergistically, and individual components are only of low toxicity. Introduction of genes encoding the mixture of toxins found in a typical dipteran-active *Bt* strain into a transgenic plant has yet to be attempted, although it is not beyond the capacity of existing technology.

The major order of insect herbivores outside the range of *Bt* toxins is Hemiptera, which includes aphids, plant- and leafhoppers, whitefly, and other sap-suckers which feed directly on the contents of phloem and/or xylem vessels, predominantly sucrose and free amino acids. These insects are important pests and virus vectors. No *Bt* toxins with activity against them have been found. The reason for this is not clear; receptors similar to those in other insect orders are present in these insects [99], but generally they contain very low levels of digestive proteolytic activity, as a result of ingesting nitrogen in the form of amino acids rather than protein. This lack of digestive proteolytic activity may interfere with activation of *Bt* toxins, and prevent enough activated toxin to have effects on the insect being present in the gut.

Why Haven't Plants Evolved Their Own *Bt*?

Despite the problems encountered in managing resistance of pests to *Bt* toxins, transgenic plants expressing these insecticidal proteins have proved their value in the field. However, the necessity for resistance management suggests that this solution to defense of plants against insect herbivores may not be viable on an evolutionary timescale. Endogenous expression of *Bt* toxins is not a "natural" method of defense against herbivores, since plants do not produce similar insecticidal proteins themselves. This failure on the part of plants to exploit a viable strategy for protection seems puzzling, and the obvious explanation, that plants lack the capacity to produce *Bt* toxin-like proteins, is not correct. Since introduction of suitably modified *Bt* genes gives adequate levels of protein expression for protection, there is no reason why plants could not have evolved a similar capacity. As discussed in the following section, plants have evolved a diverse array of defensive mechanisms, but make little use of proteins which are highly toxic to insect herbivores. Possibly, this is due to the relative ease with which insects can develop resistance to protein toxins which exert a very strong selection pressure on the population; although alternative hypotheses, such as the balance between investing plant resources into defense versus growth not favoring this strategy, or practical difficulties for a sessile organism in delivering toxins, should also be considered. Unfortunately, the experiments which would enable this issue to be investigated, namely, an evaluation of the "fitness" of *Bt*-expressing plants in a natural ecosystem in competition with varieties relying on endogenous defenses, and the persistence of *Bt* genes in a natural population, are unlikely to be carried out in the near future, due to obvious regulatory issues.

Whatever the reason for plants "in the wild" not using defensive proteins similar to *Bt* toxins, there is no reason to suppose that transgenic plants with engineered insect resistance will not continue to be useful in the artificial growing conditions of agriculture. Manipulation of crop plants by conventional breeding has successfully introduced characteristics such as large seed size, which were not present, and would not be viable, in their wild progenitors. Characteristics introduced into cultivated plants by plant genetic engineering do result from a process that is fundamentally different from selection, but both conventional breeding and genetic engineering are aiming for the same end results, agriculturally desirable phenotypes. Their products should be evaluated by similar criteria.

Developments to "First-Generation" Crops Expressing *Bt* Toxins

Plants Expressing Multiple Toxins ("Pyramiding")

The specificity of a single Cry toxin toward specific target pests can be a problem in the field where a secondary, minor pest species can replace the primary pest and cause serious damage to crops. An obvious method to counter this problem is to add or introduce a second *Bt cry* gene into the crop to extend the range of pests against which protection is afforded. The availability of a wide range of gene constructs encoding Cry toxins has made this a realistic possibility, with crossing singly transformed lines, or repeated transformation, or transformation with a construct containing two genes as alternative methods for introducing the

genes into one line. Monsanto's Bollgard transgenic cotton was improved by introducing a second *Bt* gene as early as 1999. Laboratory trials showed that cotton plants expressing both Cry1Ac and Cry2Ab proteins were more toxic to bollworms (*Helicoverpa zea*) and two species of armyworms (*S. frugiperda* and *S. exigua*) than cotton expressing Cry1Ac alone, even though doses in this trial were sublethal [100]. Subsequent evaluations in greenhouse and field trials [101] confirmed the superior insect resistance of plants expressing both toxins.

A further potential advantage of transgenic plants expressing two Cry proteins with differing specificities, that target different receptors in the insect, is in preventing the appearance of resistance in the pest, since multiple mutations are required to produce the loss of sensitivity to the toxins. This hypothesis was confirmed directly in work reported by [102], in which transgenic broccoli plants expressing either Cry1Ac, or Cry1C, or both proteins were produced. Plants were exposed to a population of diamondback moth (*P. xylostella*) which carried Bt resistance genes at a relatively low frequency in an extended greenhouse experiment, and results showed that selection over 24 generations led to a significant delay in the appearance of resistance in insects exposed to the pyramided two-gene plants. The success of these experiments has led to suggestions that the refuge approach to resistance management may be redundant for crops expressing multiple toxins [103]. However, some care is needed in the selection of genes in relation to potential pests, as resistance to multiple toxins has been observed in several cases. For example, a strain of the lepidopteran cotton pest *H. virescens* which has simultaneous resistance to Cry1Ac and Cry2Aa has been identified, in which the genetic bases of resistance to each toxin are different [104].

Many subsequent programs which have aimed to produce insect-resistant crops expressing *Bt* toxins have adopted the two-gene approach to broaden and improve protection against diverse pests, and to prevent resistance developing in insects (e.g., [105]). Although engineering to produce combinations of different three-domain Cry toxins is the most common approach, other potential resistance genes have been included also, such as those encoding Vip proteins [106], or even proteinase inhibitors (e.g., cowpea trypsin inhibitor; [107]). The "pyramiding" or "stacking" of resistance transgenes has been enthusiastically adopted by commercial organizations, and the recent announcement of a transgenic maize variety containing eight different transgenes by Monsanto and Dow Agrosciences [108] exemplifies this trend. This variety contains insect-resistance genes derived from both companies' research programs, active against corn rootworm and lepidopteran pests (Herculex RW = Cry34Ab1 + Cry35Ab1, Herculex I = Cry1F; YieldGard VT Rootworm/RR2 = modified Cry3Bb1, YieldGard VT PRO = Cry1A.105 + Cry2Ab2), as well as two herbicide tolerance genes (giving resistance against glyphosate and glufosinate-ammonium), and is intended to be a "one-stop" solution to pest and weed problems.

Domain Exchange in Three-Domain Cry Toxins

The separate roles played by the different domains in the process of interaction of three-domain *Bt* toxins with their receptors, and their structural independence, suggested to investigators that hybrid toxins, in which domains from different naturally occurring toxins were grafted together, would be likely to be active, and could show novel specificities in their activity toward insects. This process can be made to occur in vivo in *Bacillus thuringiensis*, using a site-specific recombination vector [109], or can be carried out in vitro using conventional molecular biology techniques, followed by expression in a microbial host. Transfer of domain III between different Cry1 proteins led to identification of this domain as conferring primary specificity to different lepidopteran species, and the generation of hybrids with broader specificity than naturally occurring toxins [110]. Subsequent work generated a Cry1Ab-Cry1C hybrid, which was highly toxic to *S. exigua*, an insect resistant to Cry1A toxins [111], and identified Cry1Ca domain III as sufficient to confer toxicity toward *Spodoptera* in a variety of hybrids [112]. In contrast to the results obtained when exchanging domain III, exchange of domain I between different Cry1 toxins did not yield biologically active proteins [113].

A measure of the potential for improvement in "natural" *Bt* toxins is shown by experiments reported by [114], in which a hybrid Cry protein, constructed by fusing domains I and III from Cry1Ba with domain II

of Cry1Ia, was expressed in transgenic potato. Plants expressing the hybrid toxin at levels up to 0.3% of total soluble protein were produced, and not only showed resistance to the lepidopteran pest potato tuber moth (*Phthorimaea operculella*), but also had a high level of resistance to Colorado potato beetle. The "parental" Cry proteins have high toxicity towards lepidopterans, but only very limited toxicity towards coleopterans such as the potato beetle. The hybrid has effectively created a novel toxicity, which is suggested to be based on interaction with a novel receptor.

Mutagenesis of Three-Domain Cry Toxins

Modification of *Bt* toxins by site-directed mutagenesis to increase toxicity towards target pests has been employed as an alternative to the "domain swap" approach. Most mutagenesis experiments on *Bt* toxins have been carried out to explore structure-function relationships in these proteins (see above; reviewed by Dean et al. [115]), but the accumulated knowledge of which parts of the protein determine specificity of interactions with receptors in the insect have been exploited to produce variants with increased activity toward target pests.

The key role of domain II in three-domain Cry proteins in mediating interactions with insect receptors was shown by a mutagenesis experiment in which altering amino acid residues in the loop regions in this domain of Cry1Ab increased its toxicity toward larvae of gypsy moth (*Lymantria dispar*) by up to 40-fold, with a corresponding increase in binding affinity to brush border membrane vesicles [116]. These results were based on expression of the recombinant protein in microbial hosts. A similar strategy was used to increase the toxicity of Cry3A protein toward target coleopteran pests [117], and of Cry4Ba toxin [118, 119] and Cry19Aa toxin [120] toward mosquito larvae. The level to which rational design of toxins is possible is shown by the engineering of toxicity toward mosquito larvae into the lepidopteran-specific toxin Cry1Aa [121]. Alternatively, a directed evolution system based on phage display technology for producing toxins with improved binding to a receptor, and thus increased toxicity, has been described [122]. Mutagenesis of domain I has also been attempted, with claims that alteration of alpha helix 7 in Cry1Ac to resemble the corresponding helix in diphtheria toxin led to increased toxicity toward cotton bollworm (*Helicoverpa armigera*) larvae [123].

The impressive achievements of toxin engineering at the level of recombinant proteins, have led to the technology being used for gene constructs designed for expression in transgenic plants, although toxins with unmodified amino acid sequences continue to be widely used (largely as they give adequate protection). One example where toxin engineering has been successfully carried out is the current commercial transgenic corn variety with resistance to corn rootworm, MON863, which expresses a modified version of the *Bt* Cry3Bb1 toxin [75]. Unmodified Cry3Bb1 is active against a number of coleopteran species, including Colorado potato beetle and corn rootworm [124], but toxicity toward western corn rootworm (*Diabrotica virgifera virgifera*) was not sufficient to give adequate protection at levels of expression achievable in corn. Modifications to the amino acid sequence increased the toxicity of the protein toward corn rootworm approximately eightfold. The nature of the modifications has not been described in the scientific literature, and is only available through reference to a series of patents (see [75]).

Fusions

As a logical extension to the transformation of plants with separate gene constructs encoding two Cry proteins, some workers have chosen to produce a single construct containing a single translationally fused coding sequence encoding both proteins. This approach has been successfully demonstrated by producing a Cry1Ab-Cry1B translational fusion protein in transgenic maize [125], although there is no apparent advantage over simpler methods for introducing two genes. The Cry1Ab-Cry1B fusion protein has also been expressed in transgenic rice [126], which was fully resistant to yellow stem borer (*Scirpophaga incertulas*).

A more interesting possibility is the introduction of extra functionality into Cry toxins by addition of sequences from other proteins which could lead to binding interactions with more potential receptors in the insect gut, extending the range of toxicity and hindering development of resistance. In work reported by Mehlo et al. [127], the galactose-binding lectin

domain (B-chain) from the ribosome-inactivating protein ricin was fused C-terminally to domain III of Cry1Ac, producing a Cry1Ac-ricin B-chain fusion protein. The fusion protein thus has the ability to bind to galactose residues in side chains of glycoproteins or glycolipids in the insect gut epithelium, as well as *N*-acetyl galactosamine residues which are bound by domain III. The fusion protein was expressed in transgenic maize and rice plants, and was shown to afford a high level of protection to larvae of stemborers (*Chilo suppressalis*) and leaf armyworm (*Spodoptera littoralis*), whereas plants expressing the unmodified Cry1Ac were susceptible to both insects. The transgenic maize plants were also resistant to a homopteran plant pest, the leafhopper *Cicadulina mbila*, although it is possible that this was an effect of the lectin domain in the fusion (see later section Lectins), since *Bt* toxins are not effective against homopteran insects.

The engineering of extended binding properties into three-domain Cry proteins to increase the range of toxicity toward insect pests is clearly possible, but needs to be approached with some caution. There is a risk that the extended range of activity will include mammalian toxicity, which would negate one of the major advantages of these insecticidal proteins.

Exploitation of Endogenous Plant Defensive Mechanisms Against Insect Herbivores

Plants have a range of endogenous mechanisms to defend themselves against insect herbivores, and use both static defense mechanisms based on the accumulation of pre-synthesized insecticidal compounds, and active defense mechanisms in which gene expression is induced as a result of insect damage (response to wounding, and responses to insect secretions), leading to the synthesis of insecticidal compounds [128]. Conventional breeding has sought to exploit endogenous insecticidal genes within a plant species, but the use of transgenic technology allows defensive compounds and mechanisms to be transferred between species, or allows the control of existing defensive systems to be altered to improve their effectiveness. The molecular biology involved in transfer of genes between plant species is technically straightforward, and does not involve the kind of reengineering necessary to make bacterial genes suitable for use in plants. This approach to increasing insect resistance in transgenic plants has almost as long a history as engineering for *Bt* Cry toxin expression, but to date has not resulted in a commercial product, or widescale adoption in agriculture. Some of the reasons for the lack of practical outcomes for this strategy will be discussed below.

Proteinase Inhibitors

Protein proteinase inhibitors (PIs) are ubiquitous in plant species. They are major components of both "static" and "active" defense in that they are accumulated in specific tissues ("static" defense), and are the major end-product in the induced response to wounding ("active" defense). They are generally small proteins, ranging in size from 4 to 25 kDa, with many different sequence families having been identified. They form tightly bound complexes with their target proteinases, which usually involve a "loop" on the inhibitor fitting into the enzyme active site (Fig. 4), blocking the site, and inactivating the enzyme. The observation that most of these inhibitors were active against digestive serine proteinases from higher animals, and not endogenous plant proteinases (where serine proteinases are comparatively rare, and not involved in protein digestion) suggested that they were defensive compounds, and bioassays in which purified PIs were fed in artificial diet confirmed that an antimetabolic effect was exerted on insect herbivores which relied on protein digestion for nitrogen supply, shown as a slower growth rate, retarded development, and increased mortality (reviewed by Garcia-Olmedo et al. and Ryan [130, 131]). Besides a direct effect on digestion of ingested proteins, PIs cause a loss of nitrogen to the insect by preventing the reabsorption of nitrogen used to produce digestive proteinases, which are normally (self)-degraded in the gut rather than excreted. The role of these proteins in induced defense against insects was shown by blocking the normal wounding response in transgenic tobacco plants by suppression of expression of the prosystemin gene, which produces the peptide hormone systemin, using antisense RNA. The transformed plants were unable to synthesize wound-induced PIs and were significantly more susceptible to herbivory by lepidopteran larvae [132]. The importance of the wounding response to plant defense in natural ecosystems has been

Genetic Engineering of Crops for Insect Resistance. Figure 4

Structure of a complex between a typical plant protein proteinase inhibitor (*PI*) and a target proteinase (from PDB 2g81; [129]). Structure shown in backbone representation is the complex between beta-trypsin (*top*, secondary structure color-coded in red and blue) and a Bowman-Birk PI from cowpea (*Vigna unguiculata*; *bottom*, gold). This inhibitor ("CpTI") has been expressed in transgenic plants to give partial resistance to lepidopteran larvae. The side chains responsible for the specificity-defining ion-pair interaction (dotted ellipse) are shown in ball-and-stick representation; they are Asp189 (S1′) in the substrate binding pocket of the enzyme, and Lys26 (S1) on the active site loop of the inhibitor. Other interactions take place across the contact surface between inhibitor and enzyme to form a tightly bound complex

extensively studied by Baldwin's group (reviewed in [133]); this outstanding body of work has established a synthesis of responses in the plant under attack, responses in neighboring plants, and responses of natural enemies of insect herbivores, with communication via volatile signals produced by the plant under attack.

A seed-expressed Bowman-Birk-type serine proteinase inhibitor from cowpea, which contained two inhibitory sites active against bovine trypsin (CpTI) was the first plant PI to be produced in another species [134], using a gene construct containing a CaMV 35S promoter. The resulting transgenic tobacco plants expressed CpTI at up to 1.0% of total soluble protein, and decreased growth and survival of tobacco budworm (*H. virescens*) by up to 50%, with similar effects on other lepidopteran larvae. Subsequent experiments carried out with wound-induced PIs showed that these also had similar effects when constitutively expressed in transgenic plants; for example, the tomato inhibitor II gene, when expressed in tobacco, was also shown to confer insect resistance [135], as did potato PI-II [136]. Both CpTi and PI-II were subsequently expressed in rice, where partial protection against stem borers was observed [137, 138]. The constitutive expression of foreign PIs could be mimicked in transgenic tomato plants by constitutive expression of the prosystemin gene (see above) leading to constitutive expression of wound-induced tomato PIs [139]. Tobacco plants modified in this manner show partial resistance to insect herbivores similar to that produced by expressing foreign PIs [140].

The problem with this strategy for producing insect-resistant plants soon became obvious; in contrast to the expression of Cry proteins, which, when optimized, routinely gave transgenic plants virtually complete protection against susceptible pests (mortality100%, damage minimal) expression of PIs only produced partial resistance. Investigation of the digestive biochemistry showed that exposure to PIs in the diets of lepidopteran and coleopteran herbivores resulted in the appearance of proteinase activities which were insensitive to the inhibitor(s) present [141, 142], or were able to degrade the ingested PIs [143]. These insects contain large families of genes encoding dietary proteinases, whose expression could be up- or downregulated by dietary inhibitors [144]. In effect, these insect herbivores were preadapted to be partially resistant to dietary PIs, as a result of similar or identical compounds being present routinely in their diet. Although expression of resistance to PIs in herbivorous

insects has a fitness penalty, shown by reduced growth on diets to which inhibitors are added, or on plants which are expressing foreign PIs, or over-expressing endogenous PIs (see above), this is not sufficient to cause mortality at a level which affords more than partial protection. In some cases, low levels of expression of a foreign PI in transgenic plants can actually result in improved insect performance, as when tobacco and *Arabidopsis* plants expressing mustard trypsin inhibitor 2 were exposed to larvae of cotton worm (*S. littoralis*; [145]).

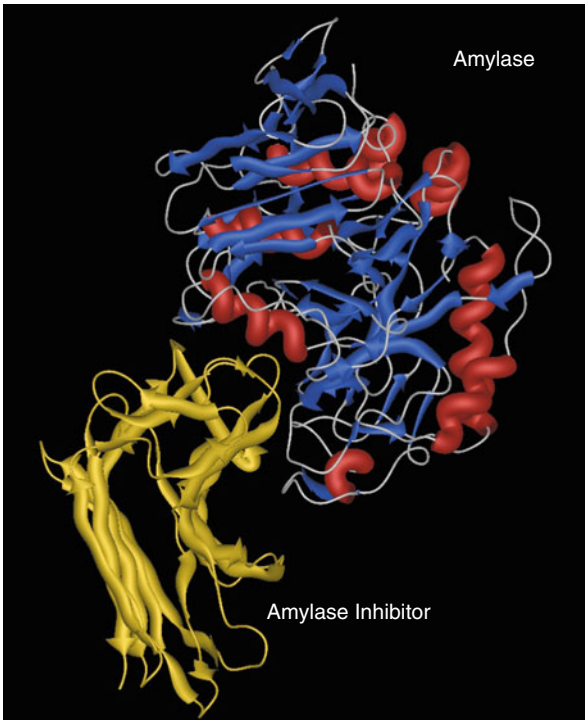
A number of investigators have attempted to select PIs for expression in transgenic plants which are optimally active against the dietary proteinases present in specific insect pests. Attempts to develop inhibitors active against specific lepidopteran digestive serine proteinases induced by dietary PIs have not been successful. On the other hand, not all pest insects rely on serine proteinases for digestion. Many herbivorous coleopteran larvae utilize cysteine proteinases, rather than serine proteinases, as their major digestive endoproteinases, and these proteinases can be inhibited by cystatins, a family of proteins present in all kingdoms of organisms. Enzyme assays in vitro were used to characterize digestive proteinases of a coleopteran pest, *Chrysomela tremulae,* as cysteine proteinases, and to show that a cystatin from rice, oryzacystatin, was an effective inhibitor. Transgenic poplar seedlings expressing oryzacystatin were produced, and leaves from these plants were shown to be toxic to larvae of the pest [146]. This promising result does not seem to have been followed up. Expression of oryzacystatin in transgenic potato only gave partial protection against larvae of Colorado potato beetle [147], suggesting preadaptation in this pest, which is known to employ a diverse range of digestive proteinases. In an attempt to use proteinase inhibitors which insects would not be preadapted to, synthetic multidomain cysteine proteinase inhibitors based on domains found in animal and plant sources (kininogen, stefin, cystatin C, potato cystatin, and equistatin) were assembled and expressed in transgenic potato; the plants were deterrent to thrips, and gave partial resistance in greenhouse trials, but complete protection was not observed [148, 149]. Attempts to express the sea anemone cysteine/aspartic proteinase inhibitor equistatin itself in transgenic potato did not give significant levels of resistance to Colorado potato beetle, due to degradation of the inhibitor in the plant [150]. Multiple proteinase inhibitors (potato PI-II and PCI) active against two families of proteinases, serine proteinases and carboxypeptidases, have been expressed in transgenic tomato plants [151], but still only afforded partial protection against lepidopteran larvae due to adaptive mechanisms present in the insects.

In conclusion, the expression of suitable PIs in transgenic plants can give protection against lepidopteran and coleopteran pests, but has not been able to produce results comparable with those achieved by use of *Bt* toxins.

Amylase Inhibitors

The widespread occurrence of protein inhibitors of mammalian amylases in plants has become accepted as another defensive mechanism against herbivores (reviewed by Franco et al. [152]). Like proteinase inhibitors, these are generally small proteins, resistant to proteolysis, ranging in size from approx. 8–30 kDa. Although they are also active against insect amylases, it is not clear to what extent these proteins contribute to insect resistance in most cases, since the relatively low nitrogen content of plant tissues compared to insects means that most herbivorous insects are nitrogen limited, not carbon limited, and starch digestion is unlikely to be a limiting factor in growth. However, in the case of coleopteran herbivores whose larvae attack seeds specifically, such as seed weevils (bruchids), there is good evidence for α–amylase inhibitors from legume seeds being highly insecticidal [153], and in being causative factors in the resistance of specific varieties of legumes to bruchids [154]. These proteins belong to a different sequence family than the more common types of α–amylase inhibitors found in cereals, and are similar to legume lectins in sequence [155].

Like proteinase inhibitors, amylase inhibitors form tightly bound complexes with their target amylase (Fig. 5), although the same interaction of a loop on the inhibitor with the active site of the enzyme is not possible, since the enzyme substrate is a polysaccharide, not a polypeptide. The mechanism of toxicity clearly involves inhibition of starch digestion, since bruchid larvae exposed to the α–amylase inhibitor from French



Genetic Engineering of Crops for Insect Resistance. Figure 5

Structure of a complex between a plant protein α-amylase inhibitor and an insect amylase enzyme (from PDB 1viw; [156]). Structures shown in backbone representation; α-amylase from larvae of the coleopteran storage pest *Tenebrio molitor* (yellow mealworm beetle) is shown *top right*, in red and blue (secondary structure color coding); the α-amylase inhibitor from *Phaseolus vulgaris* (French bean) is shown in gold *bottom left*. This inhibitor has been expressed in several transgenic legume species to give resistance to coleopteran pests. The inhibitor shows the typical "all β-sheet" structure of the legume lectin family of proteins. Interaction between the binding loop of the protein and the starch-binding site of the enzyme occurs across the contact surface, sterically blocking access by polysaccharides to the active site

bean (*Phaseolus vulgaris*) show induction of amylase enzymes [157], although other mechanisms of toxicity may also be present, since these proteins can cause 100% mortality in susceptible insect species at levels of <1.0% of total protein. Alternatively, these highly specialized herbivores may lack the adaptive mechanisms to plant defensive proteins shown by species that feed on a wide range of plant foodstuffs [128]. High levels of toxicity toward insects have not been observed in general with amylase inhibitors. For example, α–amylase inhibitors are not strongly toxic to lepidopteran larvae, where the alkaline environment of the gut may interfere with the formation of inhibitor-enzyme complexes. The α–amylase inhibitor from French bean is inactivated by high pH.

The isolation of a lectin-like α–amylase inhibitor gene from *P. vulgaris* [155] stimulated research in this area, and in a ground-breaking series of experiments, this gene was assembled into a construct with a strong seed-specific promoter (from the *P. vulgaris* seed lectin gene), and expressed in seeds of transgenic garden pea. The resulting seeds contained up to 3% of the foreign protein, and were highly resistant to larvae of cowpea and Azuki bean weevils [158], which do not normally attack garden peas in the field, but are stored product pests, and to larvae of the pea weevil *Bruchus pisorum* [159], which is a field pest of garden pea. In all cases larval development from eggs laid on seeds was halted at a very early stage, and damage to the crop was minimal. Subsequent experiments showed that transgenic azuki beans could also be protected against bruchid storage pests [160], and that transgenic garden pea was protected against pea weevil under field conditions [161]. The success of this strategy led to hopes that the *Phaseolus* α–amylase inhibitor gene could be incorporated into a range of crops, particularly other grain legumes such as lentils, mungbean, groundnuts, and chickpeas to give protection against a variety of bruchids. Technical problems with transformation of some of these crop species have delayed this goal being achieved, but transgenic chickpeas expressing high levels of the *Phaseolus* α–amylase inhibitor have been successfully produced [162].

Despite the success of this strategy, full agricultural deployment of transgenic crops expressing the *Phaseolus* α–amylase inhibitor gene has not taken place. Commercial reasons have played a major part in preventing widescale adoption, but safety concerns have also arisen. The protein product of the *Phaseolus* α–amylase inhibitor gene expressed in pea shows minor structural differences to the native product (i.e., expressed in *P. vulgaris*) as a result of differences in posttranslational processing (differences in the extent of glycosylation, and in minor components

resulting from proteolysis). Whereas consumption of the native form of the *Phaseolus* α–amylase inhibitor by mice did not result in immunological responses, consumption of transgenic peas expressing this protein led to the presence of circulating antibodies directed against it, and systemic immunological responses including inflammatory responses (i.e., allergic responses) to inhaled or injected protein [163]. In contrast to some earlier work claiming that consumption of transgenic plant material was harmful, this study has been published in a fully peer-reviewed journal and the quality of the research has not been disputed. Further research will be necessary to identify, and remove, the cause of this increased antigenicity. An additional potential drawback was revealed by feeding trials of transgenic peas expressing *Phaseolus* α–amylase inhibitor with pigs and chickens. These trials did not show immunological effects on animal health, but did show that starch utilization by the animals was significantly decreased due to the presence of the inhibitor in the transgenic peas when compared to non-transgenic peas, consistent with the effect of the protein on higher animal amylases [164, 165]. This factor would limit the utility of transgenic peas as animal feed.

Lectins

Lectins, or carbohydrate-binding proteins, occur throughout the plant kingdom, and in many species are accumulated in plant tissues as defensive proteins, being particularly abundant in seeds and other storage tissues, where they can account for up to 1% or more of total protein (reviewed by Peumans and van Damme and van Damme et al. [166, 167]). They are multimeric proteins containing polypeptides which range from 10 to 35 kDa in size. The insecticidal activity of lectins was first observed in assays with larvae of coleopteran species (e.g., LE QA done [168, 169]), where retardation of development, and in some cases, mortality, was observed when lectins were incorporated into diets at 1–5% of total protein. Lectins have only relatively low antimetabolic effects on lepidopteran larvae when fed in diet [170], possibly as a result of high gut pH inactivating the carbohydrate-binding activity. The mechanism of toxicity of these proteins remains obscure, but is dependent on carbohydrate binding.

Although transgenic tobacco and potato plants expressing lectins from garden pea [171] and snowdrop [172] have been produced by standard transformation techniques, and have been shown to confer partial resistance to lepidopteran larvae (>50% reductions in plant damage, with increased larval mortality and decreased growth), the availability of better insecticidal genes specific for these pests has directed this approach toward different targets. Homopteran plant pests, which are not affected by known *Bt* toxins, were shown to be susceptible to lectin toxicity when the proteins were delivered via artificial diet [173]. Susceptibility varied between species, and between lectins, but LC_{50} values as low as 6 μM have been estimated (for snowdrop lectin fed to rice brown planthopper (*Nilaparvata lugens*); [174]). Expression of the mannose-specific snowdrop lectin (*Galanthus nivalis* agglutinin; GNA) in transgenic rice plants was carried out, using both a phloem-specific (rice sucrose synthase) and a constitutive (maize ubiquitin-1) promoter [175]. The resulting plants were partially resistant to rice brown planthopper, with reductions of up to 50% in survival of immature insects to adulthood, and reduced development and fertility of survivors. Results were confirmed by independent transformations of indica rice varieties [176]. GNA-expressing rice was also resistant to other homopteran plant pests, such as green leafhopper (*Nephotettix virescens*; [177]) and whitebacked planthopper (*Sogatella furcifera*; [178]). Plants expressing both GNA and Cry1Ac were protected against both brown planthopper and striped stem borers (*C. suppressalis*), but no synergistic effects between the two insecticidal proteins was observed [179]. Further progress on this research has been limited, due to concerns about possible adverse consequences to higher animals of ingesting snowdrop lectin. While earlier data must be regarded as unreliable, a recent study found that no adverse effects of consumption of transgenic rice expressing GNA by rats, although significant differences in some parameters to a control group were observed [180]. GNA expression has also been engineered into potato [181] and maize [182], to give partial resistance to peach–potato aphid (*Myzus persicae*) and corn leaf aphid (*Rhopalosiphum maidis*), respectively. However, these insects are insensitive to lectin toxicity, and only marginal effects on fecundity were observed.

Introduction of foreign lectin genes into plants has become established as a potential method for engineering insect resistance, although with the lectins tested at best only partial protection against homopteran pests is conferred, and some species are relatively insensitive to the effects of lectins. As is the case with PIs, it is likely that plant pests are preadapted to the presence of lectins as defensive compounds, and are able to tolerate the toxic effects to varying degrees, although responses induced in insects by ingested lectins have not been characterized. Attempts have been made to select lectins which are the most effective toxins against target insect pests; a mannose-specific lectin expressed specifically in garlic leaves (ASA-L) was observed to show a high level of toxicity toward homopteran pests [183]. A gene encoding this lectin has been engineered into a variety of transgenic plant species, including tobacco [184] and Indian mustard [185], in both cases producing partial resistance to aphid species, with reduced survival and fecundity. Expression of this lectin in transgenic rice using constitutive [186] or phloem-specific promoters [187] gave protection against homopteran pests comparable to, or slightly better than, earlier transformations using gene constructs encoding GNA. The transgenic rice plants expressing ASA-L were shown to decrease transmission of Rice Tungro Virus by its insect vector (green leafhopper), presumably by causing decreased feeding by the pest [188].

Despite these encouraging results, widescale adoption of transgenic crops expressing lectins will probably not occur unless a major commercial company is able to gain exclusive marketing rights, and invests in pushing the transgenic varieties through the regulatory process. This is unlikely to happen, as the technology is not readily protectable by patenting.

Oxidative Enzymes

Induction of polyphenol oxidase (PPO) synthesis is one of the end-results of the plant wounding response [189], and it would seem reasonable to suppose that increased levels of this enzyme would lead to enhanced resistance to insect attack. PPO activity leads to tissue browning, which has been correlated with enhanced insect resistance. The oxidative cross-linking of tannins to proteins catalyzed by PPO decreases protein digestibility, and limits nitrogen availability [190]. However, there is little or no evidence that PPO levels are correlated with insect resistance (e.g., [191]). High-level, constitutive over expression of a poplar PPO gene in transgenic poplar seedlings led to levels of PPO up to 50x higher than normal in plant tissues [192], but these plants had only marginal effects on larvae of the lepidopteran insect pest forest tent caterpillar (*Malacosoma disstria*). No feeding deterrence was observed, and there was no effect on larval growth or survival except under conditions where larval survival was poor on controls. PPO activity was detected in insect gut and frass, so the negative results were not due to enzyme inactivation. The conclusion that herbivorous insects are preadapted to be able to deal with PPO activity, as a result of exposure to the wounding response on an evolutionary timescale (in a similar manner to preadaptation to PIs – see above) is difficult to avoid.

Peroxidase activity is also induced when plants are stressed, or attacked by pathogens, as part of a lignification response, and several attempts have been made to over-express peroxidases in transgenic plants to enhance insect resistance, despite a lack of clear-cut evidence that peroxidase activity in plant tissues is toxic to insect herbivores. Initial results using tobacco as the host plant, with over-expression of tobacco anionic peroxidase, showed only marginal effects [193], although limited broad-range protection against a variety of pests was observed in the field [194]. The limited protection afforded by this technique argues against further development.

Other Plant Proteins

Ribosome inactivating proteins (RIPs) and chitinases have also been viewed as defensive proteins in plants, although it is not clear that they are part of defense against insect herbivores. Both types of proteins have been expressed in transgenic plants, with variable results in conferring insect resistance. Expression of a maize RIP in transgenic tobacco resulted in very low levels of protection against corn earworm (*H. zea*), which were barely statistically significant [195]. Plant chitinases in general show low toxicity toward insects, but a poplar chitinase, designated WIN6, was selected on the basis that its expression was induced by insect attack. Expression of WIN6 in trangenic tomato plants

led to partial protection against larvae of Colorado potato beetle, with retardation of larval development observed [196]. Expression of the chitin-degrading enzyme *N*-acetylhexosaminidase from *Arabidopsis* in various transgenic plant tissues also gave some protective effects against lepidopteran larvae [197], but it is difficult to see what advantages over other strategies this approach could give. Orally ingested insect chitinases are strongly toxic to lepidopteran larvae (e.g., [198]). However, expression in transgenic plants gave only partial protection against insect herbivores [199], or, in one case, increased susceptibility to attack [200]. Expression of chitinase A from baculovirus AcMNPV in transgenic tobacco gave similar results, with only small effects on lepidopteran larvae and aphids [201].

Engineering Secondary Metabolism for Plant Defense

Compounds synthesized as the end-products of secondary metabolism play major roles in both constitutive and induced defense against insect herbivores in many plant species (reviewed by Wittstock and Gershenon [202]). The idea that these compounds could be used as insecticides has been a part of agriculture for thousands of years, and has been exploited successfully by synthetic chemistry in the production of classes of insecticides such as pyrethroids, based on terpenoid esters produced by flowers of pyrethrums (Chrysanthemums). Although the concept of synthesizing a foreign, insecticidal secondary metabolite in a transgenic plant developed concurrently with plant transformation technology, the biosynthesis of most secondary compounds was poorly understood, and the necessity of cloning and introducing a series of genes expressing biosynthetic enzymes to produce a secondary metabolite was considered beyond the techniques available at the time. Anticipation of problems in ensuring controlled co-expression of a series of biosynthetic genes has proved to be over-pessimistic, and plants containing multiple expressing transgenes have been produced without difficulty.

The explosion of knowledge brought about by large-scale cDNA sequencing programs and the *Arabidopsis* genome program has resulted in a much better understanding of secondary metabolism, with many biosynthetic pathways now reasonably well understood, and clones encoding biosynthetic enzymes available. The first successful demonstration that a foreign secondary compound could confer insect resistance in a transgenic plant [203] exploited a biosynthetic pathway for cyanogenic glycosides. The cereal *Sorghum bicolor* produces a cyanogenic glycoside, dhurrin, by a biosynthetic pathway starting from the amino acid tyrosine, a product of primary metabolism. Two oxidation reactions catalyzed by cytochrome P450 oxidases generate *p*-hydroxymandelonitrile, which is then glycosylated by a UDP-glycosyltransferase to form dhurrin. The three sorghum enzymes responsible were cloned and assembled into expression constructs using constitutive (CaMV 35S) promoters [204], and *Arabidopsis* plants were successively transformed with a construct containing both P450 oxidase sequences, and the glycosyl transferase sequence. All the enzymes were localized correctly (to endoplasmic reticulum membranes) and functioned properly. Surprisingly, little disruption to endogenous metabolism was observed in the transgenic plants expressing medium levels of dhurrin, and accumulation of pathway intermediates was not observed. The implication is that the plastic nature of plant metabolism can accommodate and regulate activity in new biosynthetic pathways that are introduced. The resulting plants included individuals producing levels of dhurrin similar to sorghum plants in leaf tissue (up to 4 mg/g fresh weight) and produced hydrogen cyanide on tissue damage (due to the hydrolysis of dhurrin by an endogenous *Arabidopsis* enzyme). The dhurrin-expressing plants showed enhanced resistance to attack by the flea beetle *Phyllotreta nemorum*, a specialist feeder on crucifers; adult beetles avoided feeding on dhurrin-expressing leaves when offered a choice, and larvae under no-choice conditions either failed to initiate feeding, or on initiating feeding showed a significant level of mortality. These initial results clearly imply that production of high levels of dhurrin in transgenic *Arabidopsis* caused phenotypic abnormalities, but subsequent refining of the technology allowed accumulation of dhurrin at up to 4% dry weight in *Arabidopsis* tissues without deleterious effects on plant growth [205]; expression levels of the UPD-glycosyl transferase must be high enough to prevent accumulation of the *p*-hydroxymandelonitrile intermediate.

Although these results represent science of the highest quality, this method is of marginal usefulness for crop protection as it stands, due to the dhurrin end product being toxic to higher organisms, due to the production of hydrogen cyanide when it is hydrolyzed. Worse, many insect herbivores, particularly those which have a polyphagous feeding habit, can detoxify cyanide [206]. However, the feasibility of engineering secondary metabolism in crop plants has now been established. Expression of the cassava cyanogenic glycosides, linamarin and lotaustralin (derived from valine and isoleucine respectively), has also been achieved in *Arabidopsis* [207], and grape vine root cultures have been engineered to produce dhurrin [208], although in this case no protection against root aphids was observed. Other types of secondary metabolites have also been exploited; production of the alkaloid caffeine from its precursor xanthosine in tobacco was achieved by the introduction of three genes encoding *N*-methyl transferases [209]. The resulting plants contained up to 5 μg/g fresh weight caffeine in leaves, and showed a strong feeding deterrent effect toward a generalist lepidopteran herbivore, *Spodoptera litura*. An alternative approach to modifying secondary metabolism was taken by [210], who introduced a gene encoding β-glucosidase from *Aspergillus niger* into tobacco plants, and demonstrated that transgenic plants expressing the enzyme had insecticidal activity toward whiteflies (*Bemisia* spp.) and dipterans (flies), putatively due to hydrolysis of unidentified glycosides in the plant (although the greater density of secretory trichomes observed in transgenic plants may also have been significant). Further developments in this area can be expected.

Besides engineering, secondary metabolism to produce defensive compounds normally present in other plant species, the biosynthetic capacity of plants can be used to produce a variety of volatile secondary compounds used for communication. Better understanding of the terpenoid biosynthesis pathways has led to the production of a number of transgenic plants with altered volatile composition (reviewed by Aharoni et al. [211]). Suppression of expression of a cytochrome P450 oxidase gene expressed in trichomes by RNAi led to transgenic tobacco plants which deterred aphid colonization [212], due to the final step in production of the diterpenoid cembratriene-diol being blocked, resulting in accumulation of the precursor, cembratriene-ol. These compounds are both volatile and components of trichome secretions. Transgenic *Arabidopsis* plants constitutively over-expressing a dual linalool/nerolidol synthase in plastids produced significant amounts of linalool, both as a free alcohol (volatile) and as glycosylated derivatives, and were repellent to aphids (*M. persicae*) when tested in a choice experiment [213]. Modifications to isoprenoid synthesis in *Arabidopsis* have also been shown to attract predatory mites, which could protect plants by destroying pests [214]. This strategy of attracting natural enemies to pests has also been exemplified by transforming *Arabidopsis* with the maize terpene synthase gene TPS10, which is responsible for producing sesquiterpene volatiles emitted by maize. The resulting plants emitted the volatiles normally produced in maize and attracted parasitoid wasps which attack maize pests [215]. A different approach to utilizing terpene production in transgenic plants exploits the activity of the sesquiterpene (E)-β-farnesene as an alarm pheromone in aphids, which causes cessation of feeding and avoidance, as well as acting as an attractant for aphid predators and parasitoids [216]. *Arabidopsis* was transformed with an (E)-β-farnesene synthase gene from mint, under control of a constitutive promoter (CaMV 35S); resulting plants produced (E)-β-farnesene as a volatile. The transgenic plants showed significant levels of aphid deterrence in choice experiments, and were attractive to the aphid parasitoid *Diaeretiella rapae*. Experiments which engineer the volatiles emitted by plants are an exciting area of research at present, which has established the role that volatiles emitted by plants play in the interactions between plants, herbivores, and natural enemies at the tritrophic level. This technology has yet to show that it is a practical method for crop protection in the field, but practical applications look likely to follow.

Some Novel Approaches

Many other approaches to engineering insect resistance in transgenic plants have been proposed, and progressed to varying degrees. The following section gives an overview of some of the most promising of these approaches, which have been taken forward to the stage of demonstrating feasibility by producing insect-resistant plants.

Of necessity, many other interesting ideas have had to be omitted, such as transformation of plants with transcription factors which alter gene expression [217, 218], or the use of transgenic plants expressing potentially toxic proteins from insects [219] or insect peptide hormones [220]. Despite the lack of commercial deployment of any of the insect-resistant transgenic plant other than those expressing proteins derived from *Bt*, this field of research is active and new approaches will continue to be put forward and evaluated.

Photorhabdus luminescens Insecticidal Proteins

Photorhabdus luminescens is an enterobacterial symbiont of entomophagous (insecticidal) nematodes of *Heterorhabditis* species, used for small-scale biological control of insect pests. The bacteria are present in the nematode gut, and when nematodes enter an insect host, bacterial cells are released into the insect circulatory system. The bacterial cells release toxins which cause cell death, leading to a lethal septicemia, providing a substrate for both bacteria and nematodes to grow on [221, 222]. The toxins are present as high-molecular-weight (M_r approx. 10^6) complexes, which are toxic when injected or fed to insects from four major orders of agricultural pests. The complex has been separated into four components, encoded by genetic loci *tca*, *tcb*, *tcc*, and *tcd*; the products of *tca* and *tcd* are toxic individually when fed to lepidopteran larvae. The mechanism of action of the toxins remains unresolved. Subsequent investigation has shown that *Photorhabdus* contains a large number of potentially insecticidal components, some of which are only toxic by injection, whereas others are orally toxic (reviewed by ffrench-Constant [223]); a variety of mechanisms of toxicity, including promotion of apoptosis, seems to be exploited by the bacterium. This presence of a reservoir of redundant insecticidal activities, reminiscent of the situation in *Bacillus thuringiensis*, led to *Photorhabdus* being put forward as a successor to *Bt* as a source of insecticidal genes for expression in transgenic plants.

In order to be able to exploit insecticidal genes, investigators have sought to isolate single toxic proteins from *Photorhabdus*. Two proteins, designated toxin A and toxin B, were isolated from culture supernatant and shown to be orally toxic [224]. They exist as high-molecular-weight complexes (approx. 860 kDa) in solution, and each consist of two polypeptides, 201 and 63 kDa molecular weight. The mature polypeptides are produced from single precursor protoxin polypeptides of 283 kDa by proteolysis by endogenous bacterial proteinases. The 283 kDa protoxin A is the product of a gene designated *tcdA in Photorhabdus,* which has been cloned and assembled into expression constructs for use in transgenic plants. Expression levels of mRNA and protein were improved by adding 5′ and 3′ UTR sequences from a tobacco osmotin gene, but the coding sequence was not reengineered. Expression in transgenic *Arabidopsis* gave plants that contained intact protoxin, with a range of expression levels [225]; expression of toxin A at levels above 0.07% of total soluble protein in leaves gave almost complete protection against larvae of the lepidopteran tobacco hornworm (*M. sexta*). The toxin is not species specific, and leaf extracts were also toxic to the coleopteran corn rootworm (*Diabrotica undecimpunctata*). Commercial development of this technique is highly likely.

Entomophagous nematodes of *Steinernema* species also contain mutualistic bacteria, of *Xenorhabdus* species, which produce insecticidal toxins. These proteins could also be exploited to produce insect resistance in transgenic plants, but have not yet received as much attention as *Photorhabdus* toxins [223].

Cholesterol Oxidase

The identification of a protein from *Streptomyces* that was highly insecticidal to larvae of the coleopteran pest cotton boll weevil (*Anthonomus grandis*) resulted from a screening program assaying culture filtrates of different bacterial species [226]. The protein, which was toxic at levels comparable to a *Bt* three-domain Cry protein, was identified as a cholesterol oxidase. It was able to lyse the midgut epithelium in the insect. The mechanism of action involves the activity of the enzyme, since no activity is seen in lepidopteran larvae where the gut pH is high, and the enzyme has low activity, but may also involve effects on membrane-bound alkaline phosphatase [227]. Oxidation of membrane sterols such as cholesterol in the insect gut epithelium can destabilize membranes, leading to cell lysis as observed. However, expression of this protein in transgenic plants could prove problematic, since

it is equally capable of oxidizing sterols in plant cell membranes. The encoding gene for the cholesterol oxidase was isolated, and assembled into expression constructs containing either the complete coding sequence, the mature protein coding sequence, or the coding sequence fused to a chloroplast targeting peptide from the *Arabidopsis ribulose* bisphosphate carboxylase (RuBisCO) small subunit gene [228]. No codon optimization was carried out. Transgenic tobacco plants were produced by transformation of the nuclear genome, and all constructs were shown to result in synthesis and accumulation of active enzyme. The constructs which omitted the chloroplast targeting peptide caused protein to accumulate in the cytoplasm, and these plants were developmentally abnormal, possibly as a result of interference with plant sterol hormone signaling pathways. Plants in which the enzyme was localized in chloroplasts were phenotypically normal. Leaf tissue from all transgenic plants was toxic to boll weevil larvae when fed as a component of an artificial diet.

This work does not seem to have been progressed beyond the stage of a demonstration of concept, and no further references to it are present in the scientific literature. This gene would seem a good candidate for introduction into the chloroplast genome to engineer insect resistance, although potential effects on chloroplast membrane systems would remain a drawback.

Avidin as an Insecticidal Protein

Exploitation of the biotin-binding properties of the avian egg white protein avidin (and its bacterial functional homologue, streptavidin) in a variety of biochemical techniques has obscured its role as a defensive protein, which is toxic to bacteria. The antibacterial activity is based on its essentially irreversible binding of biotin, leading to this essential enzyme cofactor being unavailable. The insecticidal activity of avidin was recognized in 1993, when assays carried out in artificial diet showed toxicity to coleopteran and lepidopteran larvae at levels as low as 10 ppm in diet (estimated as of the order of 0.01% of total protein), although the level necessary to show toxicity was up to 100x higher for other pest species. The toxic effect was eliminated by addition of biotin to diets, suggesting that the mechanism of avidin insecticidal activity is also through biotin sequestration. Both growth reduction and mortality were observed, and the suggestion was made that gene constructs expressing avidin could provide protection against insect pests in transgenic plants [229]. Subsequent assays confirmed that susceptibility to avidin as an insecticide varies widely between different insect species, and that biotin carried over in the egg between generations had a significant effect on subsequent avidin toxicity [230].

Initial reports of expression of avidin in transgenic maize were focused on producing the protein as a high-value product [231]. An expression construct containing a codon-optimized avidin coding sequence with an N-terminally fused signal peptide from barley α-amylase, driven by the maize ubiquitin-1 promoter, resulted in expression levels of avidin of >2.0% of total protein in seed. Seed from these plants was subsequently bioassayed for resistance to larvae of three different coleopteran storage pests, including red flour beetle (*Tribolium castaneum*), with 100% mortality at avidin levels above 100 ppm of seed (approx. 0.1% of total protein). However, not all pests were as susceptible; larvae of the larger grain borer, *Prostephanus truncatus*, were effectively insensitive to avidin, whether added to artificial diet or expressed in transgenic plant material. The engineered maize was nontoxic to mice over 21 days [232]. Subsequent reports confirmed the insecticidal effects of avidin expressed in transgenic plants: these include protection of tobacco against noctuid lepidopterans [233], using vacuolar targeting sequences from potato proteinase inhibitors to direct avidin accumulation in the vacuole at levels up to 1.5% of total leaf protein [234]; protection of apple against lepidopteran pests [235]; and protection of rice against coleopteran stored grain pests, using a similar approach to that used for maize [236]. Targeting of the foreign protein to vacuolar or similar compartments is important; expression of streptavidin in tomato using plant and bacterial signal peptides and strong promoters led to developmental abnormalities in the plants, which could be corrected by topical application of biotin, suggesting that sequestration of cellular biotin is equally detrimental for plants as well as insects [237].

Despite many promising results, this technology appears to have failed to gain any acceptance for agricultural crops, as illustrated by a recent study in which seed meal from transgenic avidin-expressing maize was tested as an insecticide for topical application to stored maize [238]. Studies have shown that avidin can increase the protection afforded by *Bt* expression in transgenic plants against insect pests which have limited susceptibility to the toxin (e.g., potato expressing Cry3A; [239]), but it is clear that little further development in this area is taking place.

RNA Interference Using Double-Stranded RNA

Downregulation of gene expression by double-stranded RNA (dsRNA) corresponding to part or all of a specific gene transcript has been used as a research technique in insect genetics since 1998. The method has been based on delivery of synthetic dsRNA produced in vitro by injection into insect cells or tissues, which is clearly not practical for applications in crop protection. However, recent results have shown that dsRNA can be introduced into insects as a component of artificial diet, and is effective in downregulating genes normally expressed in gut tissue. This technique has been used to downregulate the production of a gut carboxylesterase in larvae of the lepidopteran *Epiphyas postvittana* (light brown apple moth; [240]), leading to suppression of mRNA in the insect. More significantly, two recent papers show that dsRNA can be delivered to insect pests by expression in plant material, and that this can lead to an insecticidal effect when pests are exposed to plants. Transgenic tobacco and *Arabidopsis* plant material expressing dsRNA directed against a cotton bollworm detoxification enzyme (cytochrome P450 gene CYP6AE14) for gossypol suppressed expression of the gene, and caused the insect to become more sensitive to gossypol in the diet, leading to reduced performance compared to controls [241]. A similar technique was used to suppress expression of a V-type ATPase in larvae of the coleopteran *Diabrotica virgifera virgifera* (Western corn rootworm); transgenic corn plants producing dsRNA directed against this gene showed protection against feeding damage by the insect [242]. The feasibility of using dsRNA in crop protection strategies has thus been demonstrated. This approach holds great promise for future development, as it allows a wide range of potential targets for suppression of gene expression in the insect to be exploited.

Insect-Resistant Genetically Engineered Crops and Sustainability

The success of Bt-expressing crops in the field has been a direct result of taking "sustainability" into account in their introduction, particularly with respect to managing the emergence of pest resistance to the toxins through the refuge strategy, as described earlier. Even organizations hostile to Genetic Engineering technology, such as organic growers in the USA, have reported that *Bt* cotton and corn have reduced insecticide usage significantly (by up to 0.2 kg/ha/year), showing that these crops are compatible with the goals of "sustainable" agriculture [243].

The "sustainability" of transgenic insect-resistant crops has also been examined in terms of potential effects on the wider ecosystem in which the plants are grown. Numerous studies have been carried out to effects on predators and parasites at the third trophic level, and on nontarget insects and other invertebrates. Some initial reports which did report negative effects were based on dubious assumptions, or used experimental designs which had little relevance to field conditions (e.g., the supposed threat to monarch butterflies posed by transgenic *Bt* corn; reviewed by Gatehouse et al. [244]). Nevertheless, it must be the case that if a pest population is decreased as a result of endogenous resistance in crops, then there will be a "knock on" effect to the wider ecosystem, and particularly to predators and parasites of the pest species, when the resistant crop is compared to a nonresistant one that is not treated with pesticide. However, this is not a realistic comparison, since in agricultural practice a crop that does not have endogenous resistance is treated with exogenous insecticides. The use of the refuge strategy allows significant pest populations to be present, and thus can support both beneficial insects which attack the pest, and a wider ecosystem, which would be destroyed by exogenous insecticide application.

Looking to the future, wider use of insect-resistant transgenic crops could contribute positively to "sustainability" in agriculture in general, by further decreasing

insecticide usage and thereby decreasing energy inputs. However, the "sustainability" of the insect-resistant crops themselves is going to come under increasing pressure, as less controlled deployment of insect-resistant plants evades the present compulsory use of the refuge strategy, and use of crop varieties with multiple *Bt* toxins renders the refuge strategy apparently less necessary to prevent pest resistance to *Bt* toxins developing. Field resistance to *Bt* crops has been observed recently (reviewed by Tabashnik et al. [245]), but is manageable using existing practices, or modifications of them. The sustainability of relying on one mechanism of crop protection can be questioned, especially as plants in general have evolved mixed defense strategies [246]. In the longer term, a wider range of strategies for producing insect-resistant plants is going to be necessary, not only to deal with the potential for nonspecific resistance to *Bt* toxins, but to extend the range of crop pests that can be targeted, and further reduce the application of pesticides.

Future Directions

After 20 years, insect-resistant transgenic crops have been a greater success in some ways than the early experiments suggested, but have failed to meet all the hopes that were initially raised. The success is self-evident when the widescale adoption of the technology in certain crops such as cotton and maize is considered, and documented evidence of reductions in damage to human health and the environment as a result of decreases in the use of exogenously applied pesticides. The failure does not lie in any technical shortcomings in the science, although improvements and new strategies are always possible; it lies in a failure to disseminate the technology as widely as should have been the case, so that it remains largely in the hands of commercial organizations, and is limited to the major crops. Is it an unrealistic hope to anticipate that after another 20 years, amateur gardeners in developed countries will be able to choose to buy seed to grow genetically engineered cabbages, which will be resistant to cabbage white butterfly larvae, in their allotments and gardens? Or that rural farmers in developing countries will have free access to engineered rice varieties, suitable for their growth conditions, that are resistant to pests such as stemborers? Both these aims have been scientifically achievable for at least the last 10 years, and it is surely about time that a more rational approach, which cuts through both the largely futile debate about the rights and wrongs of plant genetic engineering, and the protectionism of agrochemical companies, was taken to address the looming problem of producing enough crops to meet humanity's needs.

Article Outline

Glossary

GE *Genotype by environment interaction* is differential genotypic expression across environments that may cause that a genotype selected among the best in one location to perform poorly in another. GE weakens association between phenotype and genotype, reducing genetic progress in breeding programs. In statistical terms, GE describes a situation in which the simultaneous effect of two classification variables (genotype and environment) on a continuous dependent third one, such as yield, does not follow an additive model.

MET A *multi-environment trial* is a series of trials sampling the target environmental range in which a particular set of genotypes is evaluated.

QTL A *quantitative trait locus* is a region in the genome associated with a particular quantitative phenotypic trait, such as crop yield, resource-use-efficiency, phenology, or height. QTL analysis is a statistical method that links phenotypic data (specific trait measurements on a series of individuals) and genotypic data (usually in the form of molecular markers taken on the same individual) in order to explain the genetic basis of complex traits. QTL number and the variation they explain on the phenotypic trait give clues about the genetic control of that trait, for example, if plant height is controlled by many genes of small effect, or by a few genes of large effect.

QTLxE QTL by environment interaction is differential QTL effect across environments that may cause that a favorable QTL in one environment may become irrelevant, or even unfavorable, in another.

Specific and wide adaptation A genotype is considered stable if it yields well relative to the productive potential of the environments in which is grown. If such concept of stability is shown for a wide agroecological array of environments, a genotype is considered to have general, wide, or broad adaptation. If stability is confined to a limited range, a genotype is said to have specific or narrow adaptation.

Definition

One of the first decisions farmers have to take is the selection of the variety to be grown in their fields based on expectation of economic returns, generally, in the form of the highest attainable yield. This is a critical choice that strongly determines the sustainability of the agricultural system. However, this is by no means trivial as it is very hard to identify the "best" variety across a diverse set of environments subjected to complex biotic and abiotic factors and interactions generally causing significant changes in varietal rank. Therefore, a major objective in plant breeding programs is to determine the potential adaptation of advanced breeding lines across a range of agroecological conditions. William S. Gosset (who signed as "Student [1]" in a landmark publication introducing the t distribution) wrote at the onset of modern breeding that the ultimate purpose of field experimentation was to determine what varieties pay farmers best. He thought that the design of experiments should aim, not only at determining the average yield, but also at identifying varieties whose yield, being within those of high average value, were relatively less responsive to variation in soil and climate.

Breeding programs normally aim to release cultivars to be successfully grown over a rather large cropping area, varying in soil quality attributes and in

average climate, and across several growing seasons, with interannual variations in climatic conditions. The target environment is defined as the set of soil × climatic conditions in which the released cultivars will be grown and to which the cultivars must be adapted. Therefore, a key step in applied plant breeding is the identification of advanced genotypes broadly or narrowly adapted across a wide range of target environments. Breeders focus in the first segregating generations on direct phenotypic selection of highly heritable traits, such as plant architecture and phenology to concentrate in later stages on complex quantitative traits like yield and end-use quality. Marker-assisted selection aims at complementing this phenotypic selection with direct marker screening for, mostly, oligogenic-controlled traits. The traditional approach to estimate the genotypic value in the context of breeding, varietal registration, and recommendation is deployment of extensive field evaluation schemes in a series of sites in which the assessed genotypes could be potentially grown. These collections of trials are generally denominated multi-environment trials (METs) in which a set of genotypes is evaluated in a series of trials that sample the target environmental range. Data from METs are typically summarized in the form of genotype by environment tables of means. Simple inspection of such tables of means will often reveal the presence of genotype by environment interaction (GE) or differences in performance of genotypes that are trial dependent. They also allow for the identification of those genotypes that are partially or generally adapted to the environmental range, showing specific or narrow versus general or wide adaptation, respectively.

The traditional outcome of METs is the identification of "which" cultivar and "where" has performed well. These studies are empirical, based on simple statistical characterizations of genotypic responses across environments and do not provide any physiological insight into the basis of the genotypic response to environmental changes. However, as one wants to move forward toward a *predictive* breeding scenario, the challenge beyond "which" and "where" is "why" narrow or wide adaptation happens, in terms of a thorough understanding of both the environment, the physiological behavior of the different cultivars and, eventually, of the genes responsible for adaptation. Identifying the "why" is not only a matter of satisfying curiosity: It would potentially allow more precise breeding through the direct manipulation of the genes responsible for the different adaptation patterns.

Introduction

Statistical analyses that detect and describe GE have been comprehensively reviewed [2–14]. Means across environments in METs are only adequate estimates of varietal performance in the absence of GE. When GE is significant, average values across environments may hide subsets of environments where genotypes differ markedly in relative performance.

As for any other statistical two-factor model, there are different types of interactions which originate from departure from additivity. In Fig. 1, the average for each of two genotypes, G1 and G2, for the dependent variable of interest, for example yield, is shown for three environments. Figure 1a represents the situation in which differences were detected only between environments. Figure 1b shows an additive model in which differences for both main effects, genotypes and environments, were observed but no GE. Figure 1c shows a quantitative or non-crossover interaction; in this scenario, genotypes with superior means can be recommended for all environments. In plant breeding, the most important GE is of the crossover or qualitative type (Fig. 1d), which implies changes in the rankings of genotypes across environments). In this case, variety G2 may be recommended for environment E1 but not for E2 and E3.

When there are genotypic differences among the varieties tested and the target environments include different soils and variable climate, MET analyses more often than not detect crossover GE (only MET with limited genotypic and/or narrow environmental diversity might reveal negligible or nonsignificant interaction). Thus, identification of superior genotypes is complicated by qualitative GE and largely depends on extensive field testing conducted over years at different locations. Therefore, there is a strong need to deploy powerful statistical models for MET data taking into account GE and their breeding implications.

Crossover interactions represent a double-edged sword [10]. Whereas they make breeding, testing, selection, and varietal recommendation more difficult, if the

Performance of two hypothetical genotypes in three environments showing: (**a**) Only environmental differences; (**b**) No GE; (**c**) Quantitative, non-crossover, GE; (**d**) Qualitative, crossover, GE

underlying ecophysiological grounds of GE are known, identification of genotypes better adapted to certain specific niche conditions, allowing for increased genetic gains, is possible. If the traits conferring adaptation to these specific environments and/or the genes that control them are revealed, direct implementation in breeding may be feasible either by choosing parents for a new cross possessing the adaptive attributes or by directly selecting for the presence of such attributes in the progenies (through direct measurement of the attributes or through genotypic selection, see below).

METs are often carried out over a number of sites and years that are considered to be representative of the target environments. Standard analyses of variance partition the GE term into genotype by locations (GL), genotype by years (GY), and genotype by locations by years (GLY) interactions. The relative size of these terms allow for a statistical assessment of the spatial and temporal components of adaptation. If GL dominates over the other components, then specific adaptation is exploitable by identifying subsets of homogeneous locations for variety release and recommendation. Where GY and GLY terms dominate, as most often happens, no simplification involving spatial subdivision of growing regions is possible. In this context, specific recommendations may be only possible after counting with robust models trustworthily predicting the main climatic conditions of the growing season in advance to sowing.

Recent efforts have searched for the genetic factors underlying GE and, thus, to describe adaptation patterns. Quantitative trait loci (QTLs) responsible for individual complex traits (see, e.g., [15]), such as yield and adaptation have been reported in several populations for most crop species. QTL related to adaptation show different effects in different environments. The magnitude of individual QTL effects (expressed as the amount of GE variation explained

by a particular QTL) varied among populations and across environments. Therefore, implementation of marker-assisted selection strategies for these QTLs in applied breeding programs remains a challenge. Modern GE studies have introduced external environmental, physiological, and/or genetic information to develop statistical models whose parameters relate better to physiological knowledge [16, 17], and therefore offer better possibilities for implementation of QTL selection methodologies in breeding programs.

Breeding Implications

Historically most of the genetic progress in the last decades at the global level, particularly in cereals, has been attained through increases of yield potential and disease resistance. Genetic gains in yield under non-limited growing conditions, i.e., improving yield potential, have often brought about parallel gains in yield under a wide range of more realistic, largely stressful, growing conditions [18–20]; because physiological traits behind improved yield potential may often be constitutive and provide yield advantage over a range of conditions [21]. Thus, improving simultaneously for yield potential (which is directly linked to both attainable and on-farm yields; [22]) and for disease resistance has conferred not only clear progress under high-yielding conditions but also wide adaptation.

Thus, it is critical to further improve yield potential [23]. Lessons from the past allow to optimistically trusting that relatively simple traits might be found that affect yield potential and wide adaptation simultaneously (e.g., [24]). For instance, the incorporation of simple key traits such as reduced height might have such a great impact that may be the basis of a Green Revolution due to its capacity of increasing yield both under potential and most non-potential conditions. Genetically reducing the capacity of the stems to grow through introgression of semidwarfing genes determined firstly an increased partitioning of biomass accumulated during stem elongation to the growing spikes [25, 26]; then the additional availability of resources in the growing spikes allowed floret development to proceed normally in more floret primordia consequently increasing the number of grains [27] and therefore parallel improvements in yield, as cereals are most frequently sink-limited during grain filling even under nonoptimal environments [28, 29]. However, as further reducing height would not keep improving yields [30], it is critical identifying alternative traits that being rather simple were still putatively related to yield across a wide range of conditions. Difficulties in identifying such traits is reflected in the fact that despite continuous breeding efforts in the last decade, current genetic progress in yield potential fall short of both those attained before (see [31] and references therein) and that required to match expected increases in demand [23]. Future improvements in yield potential would largely depend upon the identification of alternative traits that being relatively simple are putatively related to yield in a wide range of conditions representing the target environments of the breeding program. In this context, a thorough examination of GE will be critical both for identifying traits in a top-down approach dissecting yield into physiologically sound traits across conditions representing the target environments, and for determining the stability of the relationship between the identified trait(s) and yield.

In an even more general context, GE has important implications in applied breeding programs [5]. Based on the magnitude and nature of GE, breeders have to decide whether to aim for wide or for specific adaptation. This decision determines the choice of locations for selection, the allocation of limited resources in advanced line testing, and the assessment of the potential trade-off between empirical, molecular, and physiological screening of parents and advanced lines. Related to wide adaptation is the question of breeding sites: Can selection under optimum high-input environments identify genotypes adapted to more stressed environments? Salvatore Ceccarelli and Stefania Grando at ICARDA have produced a significant number of contributions on the issue of wide versus specific adaptation in barley (see [32] and their own references therein for a review). They have strongly advocated the exploitation of specific adaptation for optimum use of resources particularly in marginal environments, arguing that selection for high yield potential has not increased yield under low-input conditions. However, success of the CIMMYT wheat program aiming at wide adaptation is based on a completely different approach. Rather than focusing on any specific environmental

conditions, continuous selection cycles, referred to as shuttle breeding, are carried out in alternative and extremely diverse high yield potential environments differing in altitude, latitude, photoperiod, temperature, rainfall, soil type, and disease spectrum. As a result, CIMMYT wheat genotypes have shown high yield potential and wide adaptation across large geographical regions, perhaps with the exception of very marginal; in fact, poor adaptation of CIMMYT genotypes to specific environments often reflected susceptibility to specific plant diseases.

Field experimentation aims at covering a representative sample of environmental variation. However, the need for adequate resource allocation raises the question of whether multilocation testing in a limited number of years can adequately sample the array of environmental conditions where a variety can be grown. If the MET analysis of variance identifies GY as the most significant term, testing for many crop cycles should be preferred. However, this is not suitable given the increasing pressure to develop new cultivars. Therefore, breeders often substitute temporal for spatial environmental variation, assuming that GL is similar in nature to GY and that GLY is absent. Resource allocation for varietal experimentation schemes depends on the relative magnitude of the variance components for the genotype and GE interaction terms. Given the small number of years available for testing, and the frequently dominant effect of GY and GLY interactions, there is little point in a very extensive series of trials in a given year with a high proportion of genotypes retained throughout. Integrated mixed model analyses for the selected genotypes across the breeding stages can counterweigh for the limited number of years in the later stages of field testing.

A series of papers have suggested the use of reference and probe genotypes to characterize environmental variation and assess GE repeatability [33]. By defining a common reference set of genotypes consistently grown across locations and years, a breeder could define a long-term target environment and weight results from each location in a given year in accordance with its across-year representativeness. Probe genotypes with differential response to known biotic and abiotic conditions could also be used to characterize environments. However, practical application of these two principles is not common. Genetic gains for unidentified biotic and abiotic stresses by direct selection on extensive MET are possible. A more sound approach could be the growing of genotypes in a few key environments with well-characterized levels of the target stress. Manipulation of the breeding environment and selection of key parents for crossing should result in improved genetic gains. However, this second approach requires a clear understanding of the major stress as well as the facilities to reproduce it.

A germplasm strategy is also needed for breeding for wide and specific adaptation. For most crops, there is an important gap between elite and unimproved gene pools as most breeders focus on germplasm reflecting decades of intensive crossing, selection, and recombination [34]. However as genetic gains attained by conventional breeding decrease, more emphasis should be given to the use of new genetic variability both through pre-breeding or through construction of new parent for crosses, incorporating desired traits from local land races and related wild species, or from other unrelated organism through transgenesis.

The first studies on GE were based on standard variety trials across a series of environments. That allowed identification of the wide or narrow adaptation of the checked cultivars, but little could be said on the genetic basis of adaptation. Extensive field testing of biparental crosses (e.g., [35]), either in the form of doubled haploids, or recombinant inbred lines populations, allows for the assessment of the genetic control of plant adaptation based on standard linkage and QTL analyses, but their use is limited by the level of polymorphisms between parents. In contrast, diverse genotypic panels accumulating multiple recombination events provide ample genetic variation for association studies. However, their main limitation is the high incidence of false-positive associations due to the difficulty to distinguish between true and pseudo linkage between molecular markers and traits of interest, due to population substructure and correlated selection [36]. More recently, other more complex crossing systems have been proposed to exploit the advantages of both linkage analysis and association mapping. This is the case, for example, of the so-called MAGIC (multiparent advanced generation intercross) [37], the nested association mapping (NAM) design based on a huge set of recombinant inbred lines derived from

a large number of founder genotypes [38, 39], and AMPRIL (a multiparent recombinant inbred line population) [40].

The use of physiological criteria in analytical breeding is critical for success [41–44]. Breeders develop a deep knowledge of their target environments and of the agroecological adaptation of their genetic materials. However, whereas intensive work is continuously been carried out by crop physiologists in the area of yield potential and adaptation, not many breeders regularly incorporate new physiological criteria in their mainstream-breeding program. In any case, physiological assessment of adaptation is needed to complement breeders' impressions particularly in the first and last stages of a breeding program: selection of parents and assessment of adaptation of new advanced lines. Similarly, despite exciting progress in molecular marker-assisted selection, applied breeding still depends heavily on direct phenotypic selection of advanced genotypes.

In the rest of this entry, two different aspects will be presented: First, an example of the physiological implications of GE through the study of a trait, time to flowering, that has a clear effect on adaptation; second, a series of increasingly complex statistical models to characterize genotypic adaptation, to identify genotypes showing wide or specific adaptation and to dissect the genetic complexity behind this integrative trait. Although these sections may look quite disconnected, a thorough knowledge of crop physiology and/or their genetic control could allow construction of more powerful integrated statistical models incorporating as genetic covariables this information in order to improve the understanding of the nature of GE. Conversely, the statistical models can identify certain genotypes which, if well characterized, could allow for empirical identification of key adaptative traits.

Traits Determining Adaptation

The number of physiological traits with a potential effect in determining yield and adaptation is extraordinarily large. In an excellent *Crop Physiology* manual recently edited by Sadras and Calderini [45], many traits are reviewed and organized according to different criteria from capture and efficiency in the use of resources to crop development and plant architecture. Many trade-off exists between traits that, if ignored, will slow down genetic progress for both potential and actual farmer yields. Araus et al. [43] have also reviewed a number of potentially useful physiological criteria for breeding, particularly, in the framework of C3 cereals under Mediterranean conditions. Crop physiology as a whole is beyond the objectives of this entry. Therefore, the focus is on the single most important crop trait determining plant adaptation, time to flowering, as an example of a key trait to describe the underlying mechanisms and implications for GE.

Time to Flowering

Crop phenology – life cycle as influenced by seasonal variations in climate – has been widely recognized as the most important single factor determining adaptation and thereby crop performance. In determinate species, it allows for matching crop development with availability of resources, avoiding abiotic stresses due to climatic conditions such as late spring frosts and terminal drought. To maximize attainable yield, the most "critical phases" for yield determination have to be match with the most favorable (or least unfavorable) growing conditions. In some cases (Northern Hemisphere), the obvious way to achieve this is sowing cold-tolerant genotypes early enough to have full growth in early spring, but in the warmer Southern Hemisphere similar maximum yields can be achieved sowing in winter with significantly shorter phases, provided the critical phases are ideally timed [46–49]. Crop phenology is, thus, not only a key adaptative trait, but it may also affect yield potential, since different structures are produced throughout the crop cycle, and some of them may be more important than others in determining yield potential [50]. If the pattern of water deficit in the target region is relatively predictable, manipulation of genes responsible for crop phenology is the most sustainable approach to increase attainable yield and plant adaptation.

The importance of flowering time has been shown, for example, with the fast and diverse shifts in heading time, or in vernalization and photoperiod responses, due to natural selection: When the same bulk population is grown under contrasting environments [51]; when comparing different sowing dates [52]; when

studying the contrasting developmental patterns of genotypes adapted to particular regions [53–55]; or in retrospective studies showing changes in heading date over time due to breeding, particularly in areas where the crop was introduced more recently (e.g., bread wheat in Australia; [48]; durum wheat in certain regions of Spain; [56]). Therefore, crop phenology is an important source of GE for yield when testing genotypes from regions differing in climatic conditions [57, 58].

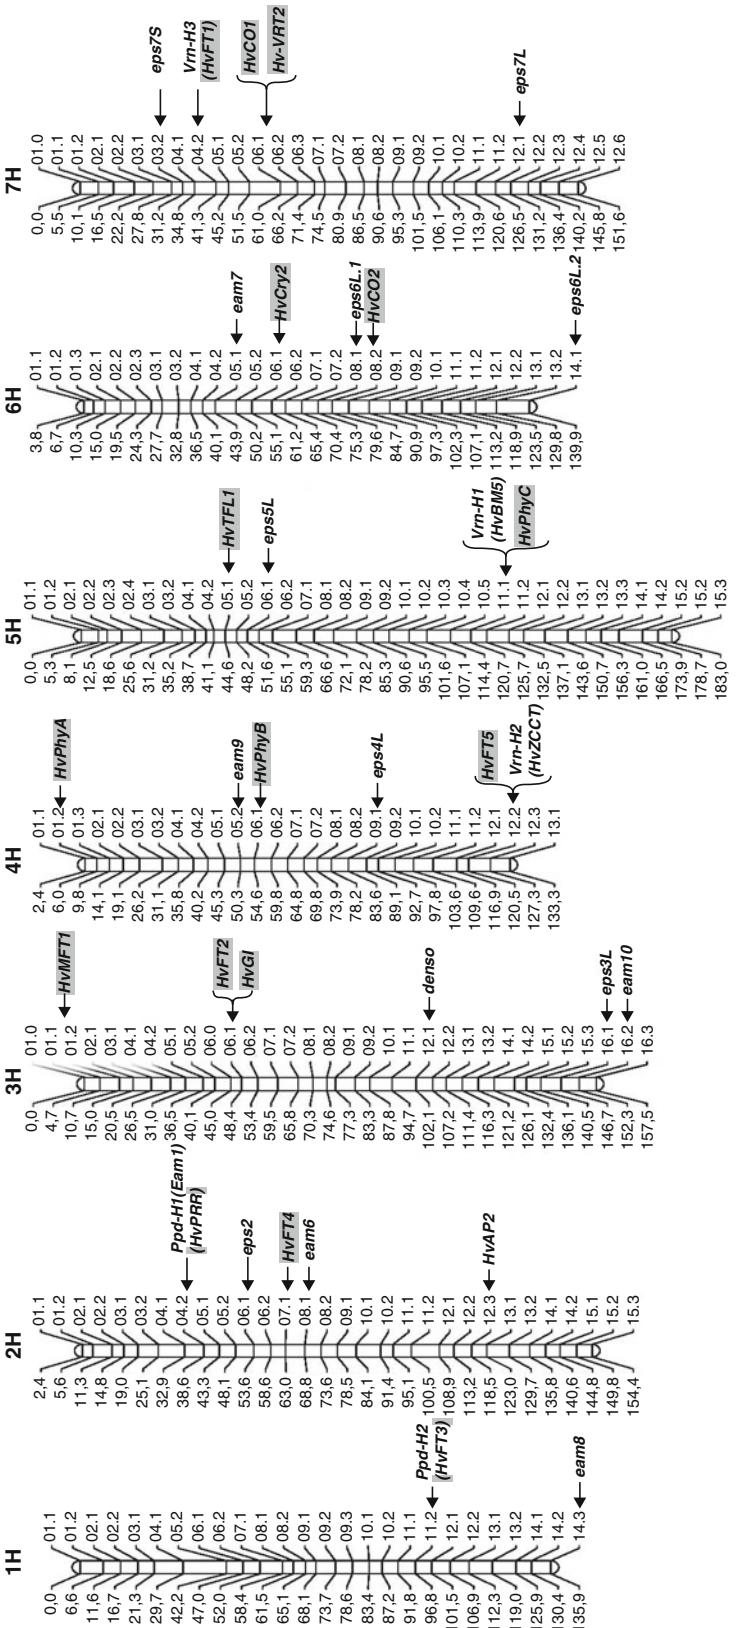
The three major factors determining flowering time are differential responses to photoperiod and vernalization and intrinsic earliness or earliness per se [50]. Further evidence from recent studies in wheat [59–61] support the idea that earliness per se genes represent basically genotypic differences in the response to non-vernalizing temperatures [62, 63]. The wide genotypic differences for these factors are considered as responsible for the spread of winter cereals, worldwide to a wide range of latitudes and altitudes [49, 64].

Genetic Factors Controlling Time to Flowering

At the gene or marker level, the importance of flowering time in crop performance is shown, for example, through the geographical distribution of alleles of major genes such as photoperiod (*Ppd*) and vernalization (*VRN*) responsive genes [49, 64, 65]. The co-location of QTLs for heading with QTLs for yield (e.g., [35, 66–69]), which may help to define an optimal window for heading or combination of alleles in the tested environments [70]. Moreover, in some of these studies, QTLs with strong effects on heading collocated with some of the QTLs for yield that exhibited strongest QTL by environment interactions [35, 69–71]. Recent studies have shown, through factorial regression, that a great part of the effect of these QTLs for heading (underlying QTLxE for yield) can be explained by the different sensitivity of the alleles to environmental conditions such as temperature during different parts of the crop cycle [11, 72].

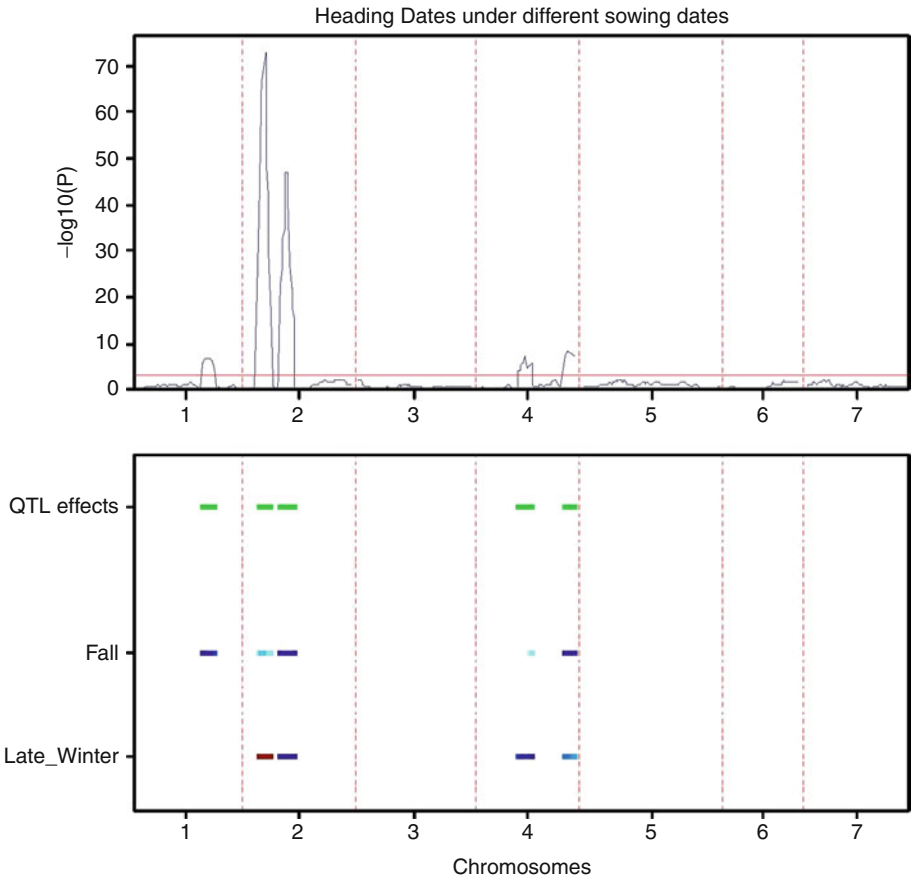
In the last decade, candidate genes have been identified for major loci controlling flowering time in barley and wheat: The photoperiod responsive gene *Ppd*-H1 in barley and its wheat homologues *Ppd*-D1, *Ppd*-B1, and *Ppd*-A1 are *PRR*-like genes [73, 74]. In both species, the photoperiod-responsive allele accelerates flowering under long-day conditions, but in barley, the greatest differences between sensitive and insensitive alleles are found under long-day conditions or high latitudes, while in wheat, under short day conditions or low latitudes [49, 64, 75, 76]. *HvFT3* is the candidate gene for another gene related to photoperiod in barley, *Ppd*-H2, whose active allele is expressed and accelerates flowering only under short photoperiod or low latitudes [75, 77]. The vernalization genes *VRN*-H1 and its homologues *VRN*-A1, *VRN*-B1, and *VRN*-D1 in wheat are MADS-box transcription factors similar to *APETALA1* in *Arabidopsis* [78–80]. *HvZCCT* and *TaZCCT* are the candidate genes for *VRN*-H2 and its wheat homologue *VRN*-Am2, respectively [81, 82]. The alleles at these loci and their interactions determine the sensitivity to vernalization (e.g., [82, 83]). Finally *VRN*-H3 and its homologues *VRN*-A3, *VRN*-B3, and *VRN*-D3 are *FT*-like genes, which also interact with PPD and VRN genes [77, 84, 85]. Other reported genes that determine differences in heading time are the "earliness per se" loci (*eps*) identified in barley by Laurie et al. [75], the series of "early maturing" (*Eam*) loci [86–89], and the gene HvAP2 [90]. However, except for the latter, no candidate genes have been found yet for them and their role is much less clear.

Figure 2 shows the location of the mentioned loci for barley, as well as for some other genes which are homologues to flowering genes in rice and *Arabidopsis* but whose effect on heading is unknown in barley. In wheat, other less characterized loci have also been identified, as the gene *Eps*-2B on 2BS [91, 92]; *Eps*-Am on 1AL sensitive to temperature [59, 60]; *VRN*-D4 close to the centromere in 5D [93], and other earliness per se genes on 5AL [94]. Additionally other loci have been found to have an effect on heading time in different regions than the loci mentioned above, although most of them with smaller effects: by the use of aneuploids in wheat [49, 95] or through QTL mapping both in barley (e.g., [35, 66–69]) and wheat (e.g., [92, 96–98]). These studies would confirm that heading time is under a strong but complex genetic control [49, 95]. Although particular VRN and PPD alleles may be more frequent in some geographical areas, variation has been found between genotypes within regions, so it is possible finding different combinations of VRN and PPD alleles in successful genotypes well adapted to particular regions, which would reinforce the idea that several



Genotype by Environment Interaction and Adaptation. Figure 2

Barley consensus function map showing the location of the vernalization, photoperiod, and earliness per se loci described in the text, as well as some other genes which are homologues to flowering genes in rice and *Arabidopsis*, whose direct effects on heading are still unknown in barley. Distances are given in Kosambi cM and linkage groups are oriented with short arms at the *top*



Genotype by Environment Interaction and Adaptation. Figure 3

Genome scan for heading date for the Steptoe × Morex doubled haploid population grown in fall and late winter sowing in Spain in 2009. *Top*: $-\log_{10}$ (*p* values) for the test on QTL+QTL.E effects are shown. The *red horizontal line* indicates the 5% genome-wide significance threshold. *Bottom*: *Upper most line* in *green* gives all genomic positions for which null hypothesis of no QTL+QTL.E is rejected. For the fall and late winter sowing environment, all positions for which there is environment-specific QTL expression are indicated with colors: *blue* showing that the allele from Steptoe delays heading, while *red*/*brown* shows that the Morex allele delays heading

other genes may be important in the control of flowering time [64]. As sensitivity to vernalization expresses at earlier stages of development than that to photoperiod, the fact that different combinations of VRN and PPD alleles may confer a similar time to heading or anthesis may also open room for fine-tuning developmental partitioning of a certain time to flowering into different lengths of vegetative and reproductive phases, which might be relevant in improving adaptation (see below).

A very simple quantitative genetic analysis of heading date (HD) for the Steptoe × Morex doubled haploid barley population [35] sown in fall and late winter in 2009 in Spain can be deduced from Fig. 3 which also illustrates alternative types of QTLxE interactions. In the top part of the figure there is, for a MET situation, a whole genome scan according to a composite interval mapping strategy [99] as implemented by Biometris, Wageningen University and Research Center, in GenStat (version 13th, [100]). All markers in the seven barley chromosomes are represented in sequential order on the X-axis. On the Y-axis is the *p* value, expressed on a minus logarithmic scale, for the successive regression models,

including not just the marker or position of interest, but additional markers that act as cofactors. With $-\log_{10}$ (p value) increasing, the evidence for a QTL at that position becomes larger. The bottom part of the figure shows firstly, in green, a one-dimensional summary of the profile in the upper panel, that is, all positions for which the joint null hypothesis of no QTL main effect and QTLxE interaction was rejected. Below the overall test for QTL effects across environments, for each individual environment, in this case defined by fall and late winter planting, an approximate test for environment-specific QTL effects is given in yellow-brown-red (QTL allele second parent increases trait) or light blue-dark blue (QTL allele first parent increases trait). Two major QTLs seem to determine heading date for the genotypes in these two trials, both on the short arm of Chromosome 2H, corresponding to two known genes, Ppd-H1 and Eam6, on Fig. 2. A very strong qualitative or crossover interaction QTLxE interaction is shown for Ppd-H1; the Morex allele (yellow-red) in the late winter sowing (under long-day photoperiod) delays heading, whereas the Steptoe allele at this locus (blue) delays heading under short days on the fall sowing. Non-crossover interaction is shown for Eam6. The presence of the Steptoe allele always delays heading, but more under fall sowing (darker blue effect) than under late winter sowing. Other minor QTLs are shown in chromosomes 1H and 4H.

Genetic Factors Controlling Duration of Subphases of Time to Flowering

The effect of these genes or QTLs may vary not only due to different conditions in temperature and photoperiod, or to epistatic interactions with other genes or QTLs, but also they may have different effects on the different phases of the crop cycle. This may be interesting for improving both adaptability and yield potential. Studying the genetic control of different pre-heading phases could bring about a better understanding of crop development patterns and more tools to fine-tuning it. For example, some adaptative characters, such as the avoidance of late frosts in spring, could be better assessed by knowing the duration of the phase from sowing to terminal spikelet rather than total time to anthesis (e.g., [101]). Moreover extending the duration of stem elongation, without modifying total time to anthesis, which is a key trait for adaptability as shown above, has been proposed as a trait to further increase yield potential [102, 103]. This has been proposed because the stem elongation phase is critical for yield determination, as the number of fertile florets at anthesis, which determines the final number of grains, is set during this phase [104, 105].

Several authors have shown that there is partially independent variability between different pre-heading phases (variability in pre-heading phases between genotypes with similar time to heading), both in wheat [106–108] and barley [109–114]. Other authors have shown that responses to vernalization, photoperiod, and temperature can each differ greatly among genotypes and between phases [50, 62, 115, 116]. In some studies using chromosome substitution lines, near isogenic lines and/or single chromosome recombinant lines, hexaploid wheat Ppd-D1 and Ppd-B1 alleles had different effects on the duration of pre-heading phases and on their response to photoperiod, although results seemed to depend on the genetic background and the environmental conditions of each experiment (see results and review by [117]). Recently Lewis et al. [61] found that alleles of a cultivar and a wild line of *Triticum monoccocum* for Eps-Am had different effects on the leaf initiation and the spikelet initiation phases (due to different sensitivity to temperature), but not on stem elongation, while they had little effect on total time to heading. On the other hand, many of the QTLs responsible for a different genetic control between pre-heading phases had little or no effect on total time to heading, so they may be more difficult to detect when assessing only heading time [111, 118]. Some of these differences in the length of pre- and post-heading phases were maintained under different conditions of photoperiod and temperature [119].

Statistical Approaches for GE Characterization

Means across environments are adequate indicators of genotypic performance only in the absence of crossover GE. When present, the use of means across environments ignores the differential reaction of genotypes to environmental changes. In an analysis of variance, introduction of the GE interaction term, $(GE)_{ij}$ for $i = 1$ to g genotypes and $j = 1$ to e environments, creates

as many parameters as there are GE combinations, making predictions of phenotypic responses for environments that were not in the set of trial environments impossible. Most approaches for the study of GE interaction and adaptation depart from ANOVA models with GE interaction terms and are therefore purely empirical descriptions of phenotypic performances of a set of genotypes across a fixed sample of environments. However, if the physiological or environmental underlying causes determining GE interaction can be determined, identification of genotypes better adapted to certain specific environmental conditions would be possible and, thus, larger genetic gains would be achievable. Furthermore, if the traits conferring adaptation and their genetic control are revealed, direct implementation in breeding may be feasible.

This entry reviews three types of statistical approaches used in GE interaction for breeding and variety development: (1) regression on the environmental mean, best known as Finlay–Wilkinson regression, or joint regression analysis; (2) linear-bilinear models, like AMMI and GGE; and (3) factorial regression models (see specific references for these methods below). These methods differ not only on the information they provide, but also in their predictive ability for breeding. A discussion of these three types of models from a common statistical perspective can be found in [120, 121]. The approaches aim at substituting the $(GE)_{ij}$ term by a linear or bilinear approximation using fewer parameters (Table 1). The replacement of double-indexed ANOVA GE interaction parameters by single-indexed regression and bilinear parameters introduces predictive properties.

Regression on the Mean

The most widely used and abused statistical method in breeding programs for characterizing GE has been the regression-on-the-mean analysis first proposed by Yates and Cochran [122] and made popular by Finlay and Wilkinson [123] (FW), and also named joint regression analysis. This method summarizes phenotypic responses to environmental changes as straight lines differing in both intercept (related to genotypic main effect) and slope (which estimates environmental sensitivity); GE interaction is revealed by differences in the slopes of individual genotypes. These straight lines are produced upon regressing individual genotypic means per environment on average site performance across all genotypes in that environment, where the regression is done across the full set of environments.

The rationale behind FW is that in the absence of explicit environmental information, a good estimate of the agronomical value of any environment may be given by the average phenotypic performance of all genotypes in that environment. This method has an important conceptual drawback. Two environments may have a similar low average yield for two completely different agroecological reasons, for example, presence of a disease and an episode of a late spring frost just before flowering. This model assumes the genotypic sensitivity to these two stresses to be approximately the same when the different stresses produce the same environmental means. Therefore, the use of the model is best restricted to those rare cases in which environmental differences are driven by just a single major biotic or abiotic factor; in these cases, the linear regression on the mean model may reflect linear differences in relation to the predominant stress factor. However, if environmental differences are due to a major stress, why not using, rather than the average phenotypic value at every environment, a direct estimate of the genotypic sensitivity to this stress as in the factorial regression method described below?

Regression-on-the-mean models are conceptually simple: The differential genotypic responses are summarized by their slopes, but it is very important to point out that their value and use should depend on the proportion of GE sum of squares that can be described by the differential environmental sensitivities of the genotypes. Figure 4 presents an example for which the Finlay and Wilkinson model should have never been used; however, it has been presented in this entry as similar reports are still too often seen in many publications. It summarizes a small MET consisting of seven barley varieties (Var_1 to Var_7) grown at ten Spanish environments according to model III in Table 1. In the part of this figure, there are the simple linear regression models for the seven varieties. If nothing else is shown, it can be wrongly assumed that there are substantial differences among genotypic slopes. This is also shown on the top table that includes

Genotype by Environment Interaction and Adaptation. Table 1 Overview of statistical models for GE analyses from two-way genotype by environment table of means derived from MET

General model	Specific model	Model	Data required	Statistical models for $E(Y_{ij}) - \mu$	Key information provided[a]
Reference models	*Additive*	I	Phenotypic data[b]	$G_i + E_j + e_{ij}$	Average cultivar yields
	Full interaction	II	Phenotypic data	$G_i + E_j + (GE)_{ij}$	Departures from additivity for each environment
Regression on the mean	*Finlay and Wilkinson*	III	Phenotypic data	$G_i + E_j + \beta_i E_j + e_{ij}$	Cultivar sensitivity (in form of slopes) to changes in environmental productivity
Bilinear models	*AMMI*	IV	Phenotypic data	$G_i + E_j + \sum_{k=1}^{K} a_{ki} b_{kj} + e_{ij}$	Joint adaptation patterns of genotypes to environments
	GGE	V	Phenotypic data	$E_j + \sum_{k=1}^{K} a'_{ki} b'_{kj} + e_{ij}$	Identification of the "winning genotype" for each uniform subset of environments
Factorial regression models	*Factorial regression model*	VI	Phenotypic and environmental data	$G_i + E_j + \beta_i z_j + e_{ij}$	Cultivar sensitivities (β_i) to changes in any environmental variable z
	Genotypic factorial regression model: QTL.E model	VII	Phenotypic and genotypic (marker information) data	$x_i\rho + E_j + x_i\rho_j + e_{ij}$	Marker (x) potentially associated to QTL and to QTL.E and the corresponding QTL (ρ) and the QTL.E (ρ_j) effects[c]
	Integrated factorial regression model	VIII	Phenotypic, genotypic, and environmental data	$x_i\rho + E_j + x_i(\lambda z_j) + e_{ij}$	QTL sensitivity to changes in environmental variable z[d]

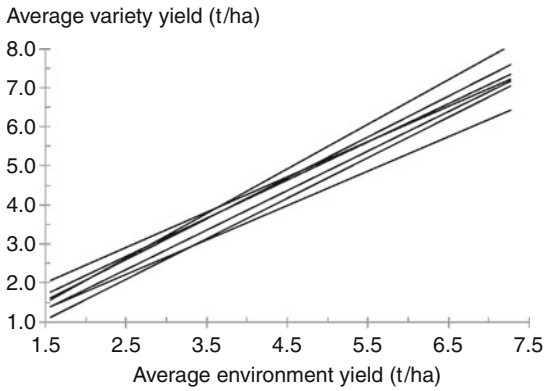
[b]Phenotypic response of the $i = 1...g$ genotype at the $j = 1...e$ environment

[c]In the presence of QTL.E, ρ_j adjusts the average QTL expression across environments, ρ, to a more appropriate level for the individual environment j. This model can be easily extended to x_s markers throughout all the genome

[d]λ is a constant that determines the extent to which a unit change in z, an environmental covariable, influences the effect of a QTL allele substitution. This model can be easily extended to x_s markers and z_t environmental variables

regression estimates. When independent simple linear regression analyses are fitted for the seven genotypes, the slopes varied from 0.88 to 1.14 and the individual straight lines were very significant (R^2 from 84% to 98%; p values from 1.8×10^{-04} to 7.1×10^{-08}). However, these R^2s do not mean anything in the GE context. They simply confirm that the genotypic yield increases with the mean environmental yield, which is obvious in the way that this model is built. Based on these estimates, it can be wrongly stated, for example, that Var_3 (slope equal to 1.14) apparently benefits more to improvements in the overall productivity of the environment than Var_6 (1.01) and particularly than Var_2 (0.88) which, with the lowest sensibility, does worst than expected. However, this model is completely inadequate for this MET and the previous estimates are useless and misleading and should have never been determined. The standard errors of the slopes, which can be used to assess the significance of the differences among slopes, ranges from 0.06 to 0.14, with an average standard error of the difference equal to 0.16. They are too large for detecting significant



Estimates	Var_1	Var_2	Var_3	Var_4	Var_5	Var_6	Var_7
Mean (t/ha)	4.21	3.6	4.41	4.32	3.71	3.92	4.23
Slope (s.e.)	0.98 (0.08)	0.88 (0.11)	1.14 (0.06)	0.90 (0.14)	1.04 (0.14)	1.01 (0.09)	1.05 (0.08)
R^2	0.95	0.88	0.98	0.84	0.88	0.94	0.95

Source of variation	Degrees of freedom	Sum of Squares	Semipartial R^2 (%)	Mean Squares	F-value	*p*-value
E	9	210.58	89.0	23.40	63.08	<0.0001
G	6	5.97	2.5	1.00	2.68	0.0237
GE	54	20.03	8.5	0.37		
Heterogenity of slopes	*6*	*1.42*	*7.1*	*0.24*	*0.61*	*0.7207*
Residual	*48*	*18.61*	*92.9*	*0.39*		

Genotype by Environment Interaction and Adaptation. Figure 4
Inappropriate use of the Finlay and Wilkinson analysis for a MET consisting of seven barley genotypes grown in ten environments in Spain

differences between genotypic slopes. Furthermore, joint regression analysis of variance table (bottom part of Fig. 4) shows that the observed differences among the genotypic slopes (Heterogeneity of slopes) only explains 7.1% of the GE sum of squares, which is not statistically significant (p value = 0.721).

Bilinear Models (AMMI and GGE)

The usefulness of the integration of ecophysiological and statistical tools in the interpretation of GE interaction is examined based upon the joint application of two multiplicative models for interaction: the additive main effects and multiplicative interaction (AMMI) model [6], and the factorial regression model [120, 124]. Both provide information and insight beyond the classical analysis of variance of two-way genotype by environment tables. AMMI represents an empirical approach (based on yield itself) to analyze GE interaction. Factorial regression attempts to describe interaction by including external genetic, phenotypic, and environmental information (e.g., morphophysiological traits, climatic data, etc.) on the levels of the genotypic and environmental factors. It implies a more analytical approach to the understanding of GE.

The Finlay and Wilkinson model belongs to a wider class of statistical models named linear-bilinear which estimate genotypic sensitivities to one or more environmental characterizations that are just linear functions of the phenotypic data [124–127]. However, the additive main effects and multiplicative interaction (AMMI) model [128–131] and the GGE models [132, 133] represent more powerful, and thus, useful examples of linear-bilinear models in plant breeding. These two model classes generate for every genotype and for every environment a series of K scores, which

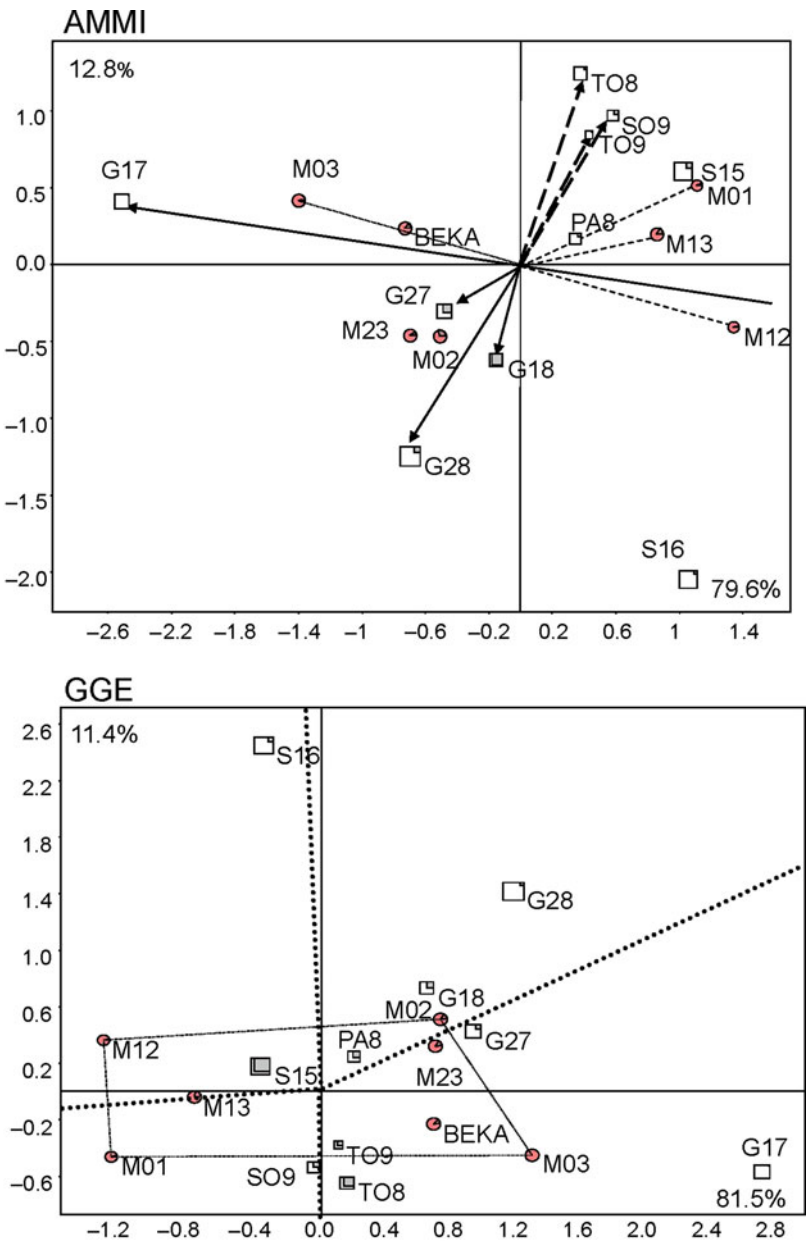
summarize the differential sensitivity of the genotypes to the prevalent, and typically unknown, stresses present in the analyzed MET.

The AMMI model successively partitions the $(GE)_{ij}$ interaction term from the basic ANOVA reference model into a series of K multiplicative terms or products of the form $a_{ki}b_{kj}$, where, for the kth term, a_{ki} refers to the genotypic sensitivity of genotype i to an hypothetical environmental variable b_k, which has value b_{kj} in environment j (Table 1, model IV). Alternatively, b_{kj} refers also to the environmental potentiality of environment j to an hypothetical genotypic variable a_k, which takes value a_{ki} for genotype i. The K hypothetical environmental (genotypic) variables have the property of discriminating maximally between genotypes (environments). The number of multiplicative terms to be retained for an appropriate estimate of the GE interaction, K, can be estimated in various ways, see, for example, Gollob [130], Gauch [6], and Cornelius [134]. From a practical point of view, the AMMI model is fitted in two steps. First, an additive ANOVA model is fitted containing the main effects for G and E and then the residuals from the additive model are used to construct the GE interaction matrix. This interaction matrix is then subjected to a singular value decomposition that generates the above-introduced genotypic and environmental scores [128, 130, 131].

Key outputs of the AMMI analysis are the genotypic and environmental scores for the K retained axes, along with the proportions of the interaction sum of squares explained by the multiplicative terms. The output of the $K = 2$ AMMI model, retaining just the first two interaction axes (IPCA1 and IPCA2), can be directly visualized by means of a biplot [5, 128, 135]. If both axes together explain most of the GE interaction, interpretation of the biplot is very simple and potentially extremely useful for understanding GE interaction. The ith genotype is placed in the biplot according to the (a_{1i}, a_{2i}) genotypic scores; similarly, the jth environment is defined by its two IPCA environmental scores (b_{1j}, b_{2j}). Distance of a genotype or environment to the origin is proportional to the GE interaction generated by that genotype or environment, respectively. Genotypes placed close together show similar adaptation patterns. Close environments generate similar GE interactions.

The actual interaction of genotype i in environment j can be estimated by the projection of the genotype position (a_{1i}, a_{2i}) on the jth environmental vector that goes from the origin (0,0) to (b_{1j}, b_{2j}), that is the line that goes through the origin with slope equal to b_{2j}/b_{1j}. The distance between the genotype projection on the line to the origin also provides information about the absolute magnitude of the interaction of genotype i in environment j. Genotype i will be well adapted to environment j, that is, positive interaction, if the projection is in the direction of the environmental vector and negative otherwise. The sign of the interaction of the genotype i in environment j can be estimated by the cosine between the ith genotypic and the jth environmental vector. It will be positive if both vectors form acute (close to 0°) angles, negative if the angle is obtuse (close to 180°), and nonexistent (no interaction) if they form a right angle (close to 90°). In a similar way, two environments whose vectors form an acute angle generate a similar type of GE interaction across genotypes, the environments have positive genetic correlation. If the two environmental vectors form an angle close to 180°, whichever genotype is well adapted in one environment will be poorly adapted to the other, the environments have a negative environmental interaction. Finally if both environmental vectors form a right angle, the genotypic behavior at one environment will be independent of the behavior at the other site, the genetic correlation is zero.

The upper part of Fig. 5 shows an AMMI biplot generated by a set of seven genotypes grown at ten environments. The genotypes are shown by circles and they represent a barley variety Beka, three derived single nonallelic mutants, M01, M02, M03, and the three binary mutant combinations, M12, M13, M23. The environments are shown in the biplot by squares which represent location by year combinations across Spain. Production of these mutants and analysis of these data was presented elsewhere [136, 137]. In this MET, the GE interaction is well described by the AMMI $K = 2$ model, as both axes explain together more than 90% of the GE sum of squares. The average yield of each environment and genotype is shown proportional to the area of its corresponding symbol. Within each symbol there is a, generally small, darker sector that represents the proportion of its sum of squares not



Genotype by Environment Interaction and Adaptation. Figure 5

AMMI and GGE biplots for a MET consisting of seven barley genotypes grown at ten environments in Spain (Data taken from [105]). See text for a detailed description of genotypes and environments

explained by this model. In this case all environments are well represented except for G27 y G18, which generate GE interactions not correctly described by the AMMI $K = 2$ model. Beka is placed close to the origin and, thus, it is the genotype that interacts least with the ten environments; on the contrary, M12 and M03 are the two genotypes that interact most with the environments. G17 and S16 are the two environments which showed the largest GE interaction, that is, whose genotypic yields depart most from their averages. PA8, near the origin, produced yields close to the average across all environments.

The relative position of both genotypes and environments can provide some clarification on the nature of the GE interactions in this MET. The first IPCA seems to be associated with differential behavior of genotypes carrying the first mutation, M01, M12, and M13, with positive scores in comparison to the other genotypes. These mutants are particularly poorly adapted to Granada (G in the biplot, especially G17). The second axis, which is quantitatively less important, seems associated with mutant 2 (M02, M12 y M23), which shows negative scores on this axis, whereas the other genotypes have positive scores; the specific adaptation of this mutant to the environments is not as clear.

The angle formed by any two environmental vectors is related to the relative similarity among environments, say, the genetic correlation, as determined by the genotypic yields. In this case, the relative yields of the genotypes in Toledo (TO8 y TO9) seem very similar to Soria (SO8). They all form acute angles with cosine and correlation close to 1. T09, with a smaller size square, had lower yields that the others. By comparing the angle of these three environmental vectors with the vector determined by G28 (very obtuse angle closed to 180° and cosine and correlation close to −1), it can be deduced that those genotypes that behave relatively well in G28 perform poorly in the other three sites and vice versa. The analysis of the genotypic projection on environmental vectors gives clues about specific adaptation patterns. For example for G17, M03 showed a good adaptation to this environment, whereas M12 was particularly poorly adapted there. This AMMI analysis was done on the MET data used for the analysis in Fig. 4. Whereas the Finlay and Wilkinson method was able to explain only 7% of the GE sum of squares, the AMMI model for $K = 2$ retained 90% of the GE sum of squares. Furthermore, as described in the previous paragraphs, the known structure of the seven genotypes developed through artificial mutagenesis, suggested a model with a plausible genetic meaning.

The environmental and genetic scores are simple statistical estimates derived from MET phenotypic data, without any direct physiological meaning. However, these empirical estimates can be associated to physiological processes by correlating the environmental scores to explicit environmental measurements, such as soil or meteorological variables; these correlations can often provide meaningful agroecological information about the nature of GE interactions [11, 14, 138–140].

Another member of the linear-bilinear model class is the GGE model [132, 133], in which single value decomposition is done on the sum of the G and GE components by just subtracting the environmental means (environmental centered) on the two-way table of means (Table 1, model V) rather than on GE interactions alone, as done in AMMI. A GGE biplot for $K = 2$ provides additional information of potential interest to breeders, as it allows for the direct identification of the "winning" genotype in any potentially uniform subset of environments. To do so, the most extreme genotypic scores are connected delimiting an irregular polygon enclosing all other genotypes, that is, a convex hull is constructed. In the previous example (Fig. 5, bottom) this is an irregular quadrilateral defined by M12, M02, M03 y M01. Next, lines perpendicular to each side of the polygon/convex hull are drawn (thicker lines in Fig. 5, bottom) up to the boundaries of the biplot. In this way sectors are created, called mega environments, which contain environments that behave relatively uniform with respect to the genotypes. The "winning genotype" in a mega environment is the genotype that is placed at the vertex of the polygon inside that mega environment. For example, M12 is the best-adapted genotype in the mega environment defined by S15 and, particularly, S16. Mutant M03 is the most productive genotype in G18 and G28. Of course, this interpretation is subjected to the condition that most of G+GE variability is retained in the first two GGE axes.

Factorial Regression Models

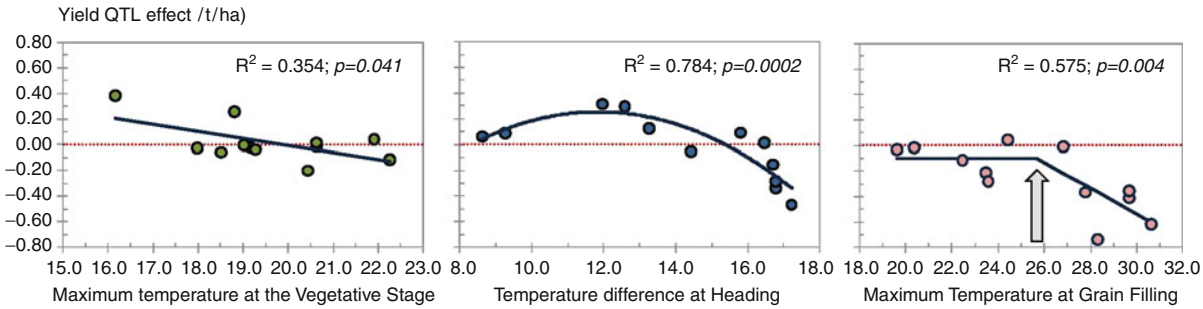
Factorial regression models were developed to incorporate additional explicit environmental information (variable z in Table 1 model VI) into a model [120, 121] for GE interaction and estimate the genotypic sensitivity of each of g genotypes (β_i in Table 1 model VI) to these independent variables (regressors, covariables). The regression on the mean or FW analyses reported before may be seen as a specific case of factorial regression, in which the average yield in each environment is used as an explicit environmental characterization. In the general form, any explicit agroecological variable

individually recorded for each environment could be used as independent explanatory variable. Average yield can be a reflection of a certain meteorological variable, such as available soil water. In this situation, this variable recorded for each environment could be used as explanatory independent variable to describe GE interaction (variable z in model VI Table 1). The genotypic slopes will have a more direct physiological meaning when they estimate, for example, sensitivity to changes in available soil water, which is an approximation to water use efficiency. In a triticale MET, GE interaction for grain yield was regressed on soil pH and the genotypic slopes directly assessed the sensitivities to changes in soil pH [141]. Extension to multiple environmental variables and complex response curves is conceptually simple and easily computable using standard statistical packages. As for any multiple regression models, a central question is the choice of variables for description of GE interaction. Continuous monitoring of the environment generates huge numbers of environmental covariables, which will complicate identification of the most relevant ones. Purely statistical selection procedures often lead to physiologically incomprehensible models. Therefore, agroecological insights of genotypes and environments should augment and prevail over purely statistical considerations. A helpful prescreening of environmental covariables can sometimes be done by correlating covariables to scores derived from AMMI or GGE analyses [11].

Factorial Regression Models Incorporating Explicit Genotypic Information Genotypic covariables can also be used to partition the G and GE terms. Molecular markers such as DNA polymorphisms for anonymous sequences or for functional genes are the most useful and readily available genetic covariables. For a codominant marker in a diploid species with potential genotypes *AA*, *Aa*, and *aa*, the number of *A* alleles (2, 1, and 0 to represent genotypes *AA*, *Aa*, and *aa*, respectively) could be used as a genetic covariable, x, in a factorial regression model (Table 1, model VII). If multiple markers across the whole genome are sequentially used, factorial regression has the ability to detect, locate, and estimate QTL main effects and QTL by environment interactions. For marker positions adjacent to a QTL, the ρ slope in model VII (Table 1) estimates directly the effect of a QTL allele substitution. Similarly, the $(GE)_{ij}$ interaction can be further partitioned into a term for differential QTL expression across environments, ρ_j, and a residual GE interaction. For a full genome scan, factorial regression models can be fitted on grid of genomic positions, on markers and in between markers, when necessary. Virtual markers, in between observed markers, can be easily generated from flanking marker information (see [142]). Factorial regression models which include genetic covariables can be potentially used for any set of genotypes for which genetic predictors can be constructed, from standard biparental offspring populations and unrelated diverse association panels, to more complicated intercross systems, such as MAGIC [37], NAM [38, 39], and AMPRIL [40] described before. The QTL.E interaction model shown in model VII (Table 1) is based on application of a simple marker regression to our data. To construct multiple QTL models, a composite interval mapping approach can be followed by incorporating cofactors, or markers that correct for QTL elsewhere, on the genome.

Factorial Regression Models Incorporating Explicit Environmental and Genotypic Information The final goal of any MET is to understand the nature of GE interaction in terms of differential sensitivity of the different QTLs or genes to external environmental variables. This is also possible by means of factorial regression models [11, 13, 72, 92]. Differential QTL expression for environments, ρ_j, can be regressed on any environmental covariable, z, to relate the differential QTL expression directly to key environmental variables responsible for GE. This is done by substituting the QTL.E term, $x_i\rho_j$, with a linear regression $x_i(\lambda z_j)$ and a residual term. λ is a constant that determines the extent to which a unit change in z, the environmental covariable, influences the effect of a QTL allele substitution. The statistical model used is listed as model VIII in Table 1 which can be easily extended to multiple markers (x_{si}) and various environmental variables (z_{tj}).

Van Eeuwijk et al. [143, 144] and Boer et al. [99] provide examples of differential QTL expression in maize data to environmental variables; by incorporating marker information and environmental covariables describing the environment,



Genotype by Environment Interaction and Adaptation. Figure 6

Differential sensitivities of three major QTLs to temperature, recorded at three different growing periods for the Steptoe × Morex doubled haploid population (Data taken from the North American Barley Genome Project). Twelve sites with environmental characterizations were available. Three different models were used: a straight-line regression model, a second-degree polynomial, and a "broken-stick" factorial regression model

these models allow for prediction of differential genotypic sensitivities to environmental changes. An example of the output of these fully integrated genotypic and environmental models is shown in Fig. 6, which shows an analysis for the "Steptoe × Morex" double haploid population data from the North American Barley Genome Project, grown at 12 sites and with environmental covariables at hand. Three main QTLs were responsible of GE interaction [71]. Differential QTL effects across environments could be associated to three different environmental variables related to temperature taken at three different growth periods and according to three alternative models: a simple linear regression model, a second degree response, and a "broken-stick" model (Fig. 6). Furthermore, two out of three QTL.E interactions showed a "crossover" type interaction: The sign of the QTL effect changed according to the value of the environmental external variable. This figure clearly illustrates the importance of QTL.E interaction for complex traits such as grain yield in barley.

The Mixed Model Framework: Modeling Variance-Covariance Structures

Table 1 shows different alternatives for modeling the expected responses of a genotype to environmental changes, without any specific concern about the implicit assumptions of the analyses of variance. Standard linear models take for granted that error terms are independent and have constant variance. However for MET, these assumptions are overly simplistic as variances within environments and correlations between environments tend to be heterogeneous. For the sake of brevity and simplicity, how the mixed model framework also allows for modeling of the variance-covariance component of the data has not been described. However, the optimal statistical modeling for MET data should focus first in finding an adequate variance-covariance model for the random terms and then, as discussed above, search for a parsimonious model for the expected responses. Choice of variance-covariance model can have strong implications. In the case of QTL modeling, QTL may erroneously be declared significant or nonsignificant because of over or under estimation of effect sizes and standard errors [72, 145]. The mixed model framework, which combines modeling of means and variances, provides a more appropriate modeling environment for GE and QTL.E interactions offering flexibility with regard to assumptions on heterogeneity of variances and on correlations across environments [17].

Computer Software for GE Analyses

Annicchiarico [3] lists a series of user-friendly computer software available for many GE analyses. CROPSTAT is a freely available package developed by the International Rice Research Institute [146] that has specific modules for FW and AMMI analysis. MATMODEL available in a free version [147] also provides AMMI and joint regression modeling and it

is particularly useful for handling missing data. INFOGEN [148] within the INFOSTAT system [149] also includes most described tools for the analysis of MET. At the same time, there are also dedicated commercial softwares, such as GGE BIPLOT [132], useful for joint regression, AMMI, and GGE. Obviously, all general statistical packages can easily be programmed to fit all linear-bilinear models described in this entry in a fixed model context, whereas some like GenStat, ASREML, and SAS also allow fitting mixed bilinear models. SAS instructions for many GE analyses are presented in Kang [100]. GenStat [150] includes specific procedures for FW, AMMI, and GGE analyses. Version 13 of GenStat (2010) also includes dedicated menus for QTL and QTL.E analyses for segregating crosses and for association analyses. GenStat has a policy of free licensing of older versions to institutions in developing countries and for educational purposes in the form of the GenStat Discovery version.

Future Directions

Plant breeding research experiences fast changes. Nowadays, at the genomic side, sequencing and single-nucleotide polymorphism (SNP) technology is becoming increasingly cheap for not only model species, but also for crop species. Besides information at the DNA level, genomic information at RNA, protein, and metabolite level starts to become common. As a consequence, huge amounts of data start to become available for characterizing genotypes at various genomic levels. Similar developments can be observed for monitoring the environment. Environmental characterizations can be stored over the growing season for all environmental factors that are believed to be relevant.

In the past, genotypic and environmental information was the bottleneck; however, the current focus has shifted to access to the right plant material and their correct phenotyping. High-throughput phenotyping techniques are being developed that facilitate monitoring of individual plants at arbitrary small intervals over the growing season. However, high-throughput phenotyping schemes taken in individual cell/tissue/organ/single plant level may not mean anything at the crop level. Up-scaling from processes taking place in a fraction of a second and in a fraction of space to relevant crop traits (produced in a hectare through several months) has consistently failed in the past and remains a challenge. Crop physiology can play a key role in understanding multi-trait interactions for up-scaling from gene to crop.

The strongly increased availability of phenotypic, genomic, and environmental information begs for new statistical techniques that allow the increased information to be used in an effective way. Various requirements can be defined. First, phenotypic information will increasingly concern a wide array of traits that are repeatedly measured over time. Correlations between these traits will need to be explicitly modeled, as will be the correlations between the repeated measurements for the same trait. Information from multiple environments can be treated in the same way as information from multiple traits, although correlations between the same trait in different environments may ask for other models than the correlations between different traits in the same environment and different traits in different environments. Standard mixed model procedures will fail, as too many variances and covariances/correlations will require estimation. A way out may be too regularize the pattern of variances and covariances by inserting biological information in the estimation in the form of alternative statistical tools, such as priors (Bayesian methods) or penalties (penalized multivariate regressions). One popular way of reducing the number of correlation parameters is by imposing network structures on sets of trait by environment combinations, thereby effectively fitting sparse matrices to the inverses of the correlation matrices. The graphical lasso is an example of such an approach [151].

Turning to increased marker numbers and selecting meaningful genotype to phenotype models in the face of 100,000s of SNP markers demand new statistical approaches. As identification of individually contributing SNPs in such conditions is very difficult, an alternative strategy emphasizing prediction from markers above identification of markers is rapidly gaining popularity. In genomic selection, the idea is to use all markers simultaneously for predicting marker-based breeding values that help in ranking individuals on genetic merit [152–154]. Bayesian and penalized regression techniques help to regularize the estimates for individual marker contributions, as it will be evident that with standard regression techniques it is impossible to estimate hundreds of thousands of

marker effects. Mixed models can in this context be interpreted as an example of a Bayesian technique in which the prior for the marker effects is a normal distribution. Equivalently, mixed models can be seen as penalized regressions in which the ratios of variance components determine the penalties (shrinkage factors). As an illustration, one may regress a phenotypic trait on a large set of markers, assuming the effects of the markers of individual chromosomes to follow normal distributions with chromosome-specific variances. The predicted values for the genotypes from such a mixed model represent the genomic breeding value. This breeding value can be used for selection purposes. Examples of genomic selection for multiple environments are still hard to find.

The increased information from intensive environmental monitoring can be used to improve prediction of genotypic performance by integrating it with other types of genotype-specific information in crop growth models [16, 17, 155–157]. The environmental information is fed into a suitable crop growth model and when physiological parameters of the crop growth model can be specified at genotype-specific level, the crop growth model can produce predictions for individual genotypes in any environment for which a full environmental characterization is given. An integration of crop growth modeling with genomic selection is possible when the values for the genotype-specific physiological parameters in the crop growth model are inserted from Bayesian or mixed genomic selection models.

The increased amounts of phenotypic, genomic, and environmental data pose strong demands on our statistical ingenuity, but interesting solutions start to appear on the horizon. In this forthcoming scenario, elaborations of mixed models, Bayesian techniques and penalized methods will play a major role in the analysis of GE interactions.

Article Outline

Glossary

Direct farm income benefit Improvements in income arising from changes in yield and production levels or associated with cost reductions/productivity enhancements associated with the use of transgenic crops.

Herbicide tolerance Tolerance to a herbicide (e.g., glyphosate) delivered by genetic modification techniques. This allows a crop to be sprayed with the "tolerant herbicide" without harming the crop but providing good weed control.

Insect resistance Resistance to a pest (e.g., corn-boring pests) delivered by genetic modification techniques. This allows a crop to be grown without having to use alternative methods of pest control, notably the use of insecticides.

Nonpecuniary benefit Additional farm-level benefits to direct farm income benefits that are more intangible and difficult to measure in monetary terms (e.g., additional management flexibility).

No tillage agriculture The use of a production technique in which the soil is not tilled/plowed. It is in contrast to traditional plow-based production systems and allows farmers to save on fuel use and contributes to improved soil water retention and reduced soil erosion.

Second crop soybeans The planting of a crop of soybeans after another crop (often wheat) in the same growing season. This allows a farmer to obtain two crops from the same piece of land in one season.

Definition of the Subject

The application of biotechnology to commercial agriculture on a widespread basis has occurred since 1996. The extent of this adoption in terms of crops and (biotechnology) traits is explored and the associated economic impacts for the period 1996–2008 are assessed, to help identify some of the main reasons why farmers have adopted the technology.

Introduction

This article examines specific global socioeconomic impacts on farm income over the 13-year period 1996–2008. It also quantifies the production impact of the technology on the key crops in areas where it has been used. The analysis concentrates on farm income effects because this is a primary driver of adoption among farmers (both large commercial and small-scale subsistence). It also considers more indirect farm income or nonpecuniary benefits, and quantifies the (net) production impact of the technology. More specifically, it covers the following main issues:

- Impact on crop yields
- Effect on key costs of production, notably seed cost and crop protection expenditure
- Impact on other costs such as fuel and labor
- Effect on profitability
- Other impacts such as crop quality, scope for planting a second crop in a season and impacts that are often referred to as intangible impacts such as convenience, risk management, and husbandry flexibility
- Production effects

The contribution is based largely on extensive analysis of existing farm-level impact data for biotech crops. While primary data for impacts of commercial cultivation were not available for every crop, in every year and for each country, a substantial body of representative research and analysis is available and this has been used as the basis for the analysis presented.

As the economic performance and impact of this technology at the farm level varies widely, both between, and within regions/countries (as applies to any technology used in agriculture), the measurement of performance and impact is considered on a case-by-case basis in terms of crop and trait combinations. The analysis presented is based on the average performance and impact recorded in different crops by the studies reviewed; the average performance being the most common way in which the identified literature has reported impact. Where several pieces of relevant research (e.g., on the impact of using a GM trait on the yield of a crop in one country in a particular year) have been identified, the findings used have been largely based on the average of these findings.

This approach may both, overstate, or understate, the real impact of GM technology for some trait, crop and country combinations, especially in cases where the technology has provided yield enhancements. However, as impact data for every trait, crop, location, and year is not available, the authors have had to extrapolate available impact data from identified studies to years for which no data are available. Therefore, the authors acknowledge that this represents a weakness of the research. To reduce the possibilities of over/understating impact, the analysis:

- Directly applies impacts identified from the literature to the years that have been studied. As a result, the impacts used vary in many cases according to the findings of literature covering different years. Hence, the analysis takes into account the variation in the impact of the technology on the yield based on its effectiveness in dealing with (annual) fluctuations in pest and weed infestation levels as identified by research.
- Uses current farm-level crop prices and bases any yield impacts on (adjusted – see below) current average yields. In this way, some degree of dynamic has been introduced into the analysis that would, otherwise, be missing if constant prices and average yields indentified in year-specific studies had been used.
- Includes some changes and updates to the impact assumptions identified in the literature based on consultation with local sources (analysts, industry representatives) so as to better reflect prevailing/changing conditions (e.g., pest and weed pressure, cost of technology).
- Adjusts downward the average base yield (in cases where GM technology has been identified as having delivered yield improvements) on which the yield enhancement has been applied. In this way, the impact on total production is not overstated.

Other aspects of the methodology used to estimate the impact on direct farm income are as follows:

- Impact is quantified at the trait and crop level, including where stacked traits are available to farmers. Where stacked traits have been used, the individual trait components were analyzed separately to ensure estimates of all traits were calculated.
- All values presented are nominal for the year shown and the base currency used is the US dollar. All financial impacts in other currencies have been converted to US dollars at prevailing annual average exchange rates for each year.
- The analysis focuses on the changes in farm income for each year, arising from the impact of GM technology on yields, key costs of production, notably seed cost and crop protection expenditure and also the impact on costs such as fuel and labor (inclusion of impact on these categories of cost are, however, more limited than the impacts on seed and crop protection costs because only a few of the papers reviewed have included consideration of such costs in their analyses). Therefore, in most cases the analysis relates to impact of crop protection and seed cost only.
- Crop quality (e.g., improvements in quality arising from less pest damage or lower levels of weed impurities that result in price premia being obtained from buyers) and the scope for facilitating the planting of a second crop in a season (e.g., second crop soybeans in Argentina following wheat that would, in the absence of the GM herbicide-tolerant

(GM HT) seed, probably not have been planted). Thus, the farm income effect measured is essentially a gross margin impact (impact on gross revenue less variable costs of production) rather than a full net cost of production assessment. Through the inclusion of yield impacts and the application of actual (average) farm prices for each year, the analysis also indirectly takes into account the possible impact of biotech crop adoption on global crop supply and world prices.

This article also examines some of the more intangible (more difficult to quantify) economic impacts of GM technology. The literature in this area is much more limited and in terms of aiming to quantify these impacts, largely restricted to the US-specific studies. The findings of this research (notably relating to the USA, and drawing on Marra and Piggot [1, 2] are summarized and extrapolated to the cumulative biotech crop planted areas in the USA over the period 1996–2008.

Lastly, this article includes estimates of the production impacts of GM technology at the crop level. These have been aggregated to provide the reader with a global perspective of the broader production impact of the technology. These impacts derive from the yield impacts (where identified), but also from the facilitation of additional cropping within a season (notably in relation to soybeans in South America).

Economic Impact of Transgenic/Biotech Crops

The section below is structured on a trait and country basis highlighting the key farm-level impacts.

Herbicide-Tolerant Soybeans

The USA

In 2008, 92% of the total US soybean crop was planted to genetically modified herbicide-tolerant cultivars (GM HT). The farm-level impact of using this technology since 1996 is summarized in Table 1.

The key features are as follows:

- The primary impact has been to reduce the soybean cost of production. In the early years of adoption, these savings were between $25/ha and $34/ha. In recent years, estimates of the cost savings have been in the range of $30–$85/ha (based on a comparison of conventional herbicide regimes in the early 2000s that would be required to deliver a comparable level of weed control to the GM HT soybean system). In 2008, the cost savings declined relative to earlier years because of the significant increase in the global price of glyphosate relative to increases in the price of other herbicides (commonly used on conventional soybeans). The main savings have come from lower herbicide costs (while there were initial cost savings in herbicide expenditure, these increased when glyphosate came off-patent in 2000. Growers of GM HT soybeans initially applied Monsanto's Roundup herbicide but over time, and with the availability of low-cost generic glyphosate alternatives, many growers switched to using these generic alternatives (the price of Roundup also fell significantly post 2000) plus a $6–$10/ha savings in labor and machinery costs.
- Against the background of underlying improvements in average yield levels over the 1996–2008 period (via improvements in plant breeding), the specific yield impact of the GM HT technology used up to 2008 has been neutral (some early studies of the impact of GM HT soybeans in the USA, suggested that GM HT soybeans produced lower yields than conventional soybean varieties. Where this may have occurred, it applied only in early years of adoption when the technology was not present in all leading varieties suitable for all of the main growing regions of the USA. By 1998/1999, the technology was available in leading varieties and no statistically significant average yield differences have been found between GM and conventional soybean varieties.
- The annual total national farm income benefit from using the technology rose from $5 million in 1996 to $1.42 billion in 2007. In 2008, the farm income was about $1.2 billion. The cumulative farm income benefit over the 1996–2008 period (in nominal terms) was $11 billion.
- In added value terms, the increase in farm income in recent years has been equivalent to an annual increase in production of between +5% and +10%.

Argentina

As in the USA, GM HT soybeans were first planted commercially in 1996. Since then, use of the technology

Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Table 1 Farm-level income impact of using GM herbicide-tolerant (GM HT) soybeans in the USA 1996–2008

Year	Cost savings ($/ha)	Net cost saving/increase in gross margins, inclusive of cost of technology ($/ha)	Increase in farm income at a national level ($ millions)	Increase in national farm income as % of farm-level value of national production

2007	85.2	60.48	1,417.2	6.01
2008	68.6	43.88	1,219.5	4.25

Sources and notes:

1. Impact data 1996–1997 based on Marra et al [3], 1998–2000 based on Carpenter and Gianessi [4] and 2001 [5] onward based on Sankala and Blumenthal [6, 7] and Johnson and Strom [8] plus updated 2008 to reflect recent changes in herbicide prices
2. Cost of technology: $14.82/ha 1996–2002, $17.3/ha 2003, $19.77/ha 2004, $24.71/ha 2005 onward
3. The higher values for the cost savings in 2001 onward reflect the methodology used by Sankala and Blumenthal, which was to examine the conventional herbicide regime that would be required to deliver the same level of weed control in a low/reduced till system to that delivered from the GM HT no/reduced till soybean system. This is a more robust methodology than some of the more simplistic alternatives used elsewhere. In earlier years, the cost savings were based on comparisons between GM HT soy growers and/or conventional herbicide regimes that were commonplace prior to commercialization in the mid-1990s when conventional tillage systems were more important

has increased rapidly and almost all soybeans grown in Argentina are GM HT (99%). Not surprisingly, the impact on farm income has been substantial, with farmers deriving important cost saving and farm income benefits both similar and additional to those obtained in the USA (Table 2). More specifically, it covers the following main issues:

- The impact on yield has been neutral (i.e., no positive or negative yield impact).
- The cost of the technology to Argentine farmers has been substantially lower than in the USA (about $1–$4/ha compared to $15–$25/ha in the USA: see Table 1) mainly because the main technology provider (Monsanto) was not able to obtain patent protection for the technology in Argentina. As such, Argentine farmers have been free to save and use biotech seed without paying any technology fees or royalties (on farm-saved seed) for many years and estimates of the proportion of total soybean seed used that derives from a combination of declared saved seed and uncertified seed in 2008 were about 75% (i.e., 25% of the crop was planted to certified seed).
- The savings from reduced expenditure on herbicides, fewer spray runs, and machinery use have been in the range of $24–$30/ha, although in

Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Table 2 Farm-level income impact of using GM HT soybeans in Argentina 1996–2008

Year	Cost savings ($/ha)	Net saving on costs (inclusive of cost of technology ($/ha)	Increase in farm income at a national level ($ millions)	Increase in farm income from facilitating additional second cropping ($ millions)
1996	26.10	22.49	0.9	0
1997	25.32	21.71	42	25
1998	24.71	21.10	115	43

2005	30.20	28.96	471	527
2006	28.72	26.22	465	699
2007	28.61	26.11	429	1,134
2008	16.37	13.87	233	765

Sources and notes:

1. The primary source of information for impact on the costs of production is Qaim and Traxler [9, 10]. This has been updated in recent years to reflect changes in herbicide prices
2. All values for prices and costs denominated in Argentine pesos have been converted to US dollars at the annual average exchange rate in each year
3. The second cropping benefits are based on the gross margin derived from second crop soybeans multiplied by the total area of second crop soybeans (less an assumed area of second crop soybeans that equals the second crop area in 1996 – this was discontinued from 2004 because of the importance farmers attach to the GM HT system in facilitating them remaining in no tillage production systems). The source of gross margin data comes from Grupo CEO
4. Additional information is available in Appendix 1
5. The net savings to costs understate the total gains in recent years because two thirds to 80% of GM HT plantings have been to farm-saved seed on which no seed premium was payable (relative to the $3-$4/ha premium charged for new seed)

2008, savings fell back to about $16/ha because of the significant increase in the price of glyphosate relative to other herbicides. Net income gains have been in the range of $21–$29/ha, although in 2008 a lower average level of about $14/ha has occurred.

- The price received by farmers for GM HT soybeans in the early years of adoption was, on average, marginally higher than for conventionally produced soybeans because of lower levels of weed material and impurities in the crop. This quality premia was equivalent to about 0.5% of the baseline price for soybeans.
- The net income gain from the use of the GM HT technology at a national level was $233 million in 2008. Since 1996, the cumulative benefit (in nominal terms) has been $3.57 billion.
- An additional farm income benefit that many Argentine soybean growers have derived comes from the additional scope for second cropping of soybeans. This has arisen because of the simplicity, ease, and weed management flexibility provided by the (GM) technology, which has been an important factor facilitating the use of no and reduced tillage production systems. In turn, the adoption of low/no tillage

production systems has reduced the time required for harvesting and drilling subsequent crops and hence has enabled many Argentine farmers to cultivate two crops (wheat followed by soybeans) in one season. As such, 20% of the total Argentine soybean crop was second crop in 2008 (3.4 million hectares), compared to 8% in 1996. Based on the additional gross margin income derived from second crop soybeans (see Appendix 1), this has contributed a further boost to national soybean farm income of $765 billion in 2008 and $5.19 billion cumulatively since 1996.

- The total farm income benefit inclusive of the second cropping was $998 million in 2008 and $8.76 billion cumulatively between 1996 and 2008.
- In added value terms, the increase in farm income from the direct use of the GM HT technology (i.e., excluding the second crop benefits) in the last 3 years has been equivalent to an annual increase in production of between +2% and +7%. The additional production from second soybean cropping facilitated by the technology in 2008 was equal to 20% of total output.

Brazil

GM HT soybeans were probably first planted in Brazil in 1997. Since then, the area planted has increased to 62% of the total crop in 2008 (until 2003 all plantings were technically illegal).

The impact of using GM HT soybeans has been similar to that identified in the USA and Argentina. The net savings on herbicide costs have been larger in Brazil due to higher average costs of weed control. Hence, the average cost saving arising from a combination of reduced herbicide use, fewer spray runs, labor and machinery savings were between $30/ha and $81/ha in the period 2003–2008 (Table 3). The net cost saving after deduction of the technology fee (assumed to be about $20/ha in 2008) has been between $9/ha and $61/ha in recent years. At a national level, the adoption of GM HT soybeans increased farm income levels by $592 million in 2008. Cumulatively over the period 1997–2008, farm incomes have risen by $2.74 billion (in nominal terms).

In added value terms, the increase in farm income from the use of the GM HT technology in 2008 was equivalent to an annual increase in production of +2.6% (about 1.54 million tons).

Paraguay and Uruguay

GM HT soybeans have been grown since 1999 and 2000 respectively in Paraguay and Uruguay. In 2008, they accounted for 90% of total soybean plantings in Paraguay and 99% of the soybean plantings in Uruguay (as in Argentina, the majority of plantings are to farm saved or uncertified seed). Using the farm-level impact data obtained from the Argentine research [9, 10] – we are not aware of any published country-specific impact research having been conducted in these two countries) and applying this to production in these two countries, Fig. 1 summarizes the national farm-level income benefits that have been derived from using the technology. In 2008, the respective national farm income gains were $58.8 million in Paraguay and $7.9 million in Uruguay.

Canada

GM HT soybeans were first planted in Canada in 1997. In 2008, the share of total plantings accounted for by GM HT soybeans was 73% (0.88 million hectares).

At the farm level, the main impacts of use have been similar to the impacts in the USA. The average farm income benefit has been within a range of $14–$40/ha and the increase in farm income at the national level was $12.6 million in 2008 (Table 4). The cumulative increase in farm income since 1997 has been $116 million (in nominal terms). In added value terms, the increase in farm income from the use of the GM HT technology in 2008 was equivalent to an annual increase in production of about 1% (34,500 tons).

South Africa

In 2001, GM HT soybeans were planted commercially in South Africa. In 2008, 184,000 ha (80%) of total soybean plantings were to varieties containing the GM HT trait. In terms of impact at the farm level, net cost savings of between $5/ha and $9/ha have been achieved through reduced expenditure on herbicides (Table 5), although in 2008, with the significant increase in glyphosate prices relative to other herbicides, this has fallen back to $2/ha. At the national level, the increase in farm income was $0.32 million in 2008. Cumulatively, the farm income gain since 2001 has been $4.13 million.

Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Table 3 Farm-level income impact of using GM HT soybeans in Brazil 1997–2008

Year	Cost savings ($/ha)	Net cost saving after inclusion of technology cost ($/ha)	Impact on farm income at a national level ($ millions)	Increase in national farm income as % of farm-level value of national production

Sources and notes:

1. Impact data based on 2004 comparison data from the Parana Department of Agriculture [11] Cost of production comparison: biotech and conventional soybeans, in USDA GAIN report BR4629 of 11 November 2004. www.fas.usad.gov/gainfiles/200411/146118108.pdf for the period to 2006 [11]. From 2007 based on Galveo [12]
2. Cost of the technology from 2003 is based on the royalty payments officially levied by the technology providers. For years up to 2002, the cost of technology is based on costs of buying new seed in Argentina (the source of the seed). This probably overstates the real cost of the technology and understates the cost savings
3. All values for prices and costs denominated in Brazilian Real have been converted to US dollars at the annual average exchange rate in each year

Romania

In 2008, Romania was not officially permitted to plant GM HT soybeans, having joined the EU at the start of 2007 (the EU has not permitted the growing of GM HT soybeans to date). The impact data presented below therefore covers the period 1999–2006.

The growing of GM HT soybeans in Romania had resulted in substantially greater net farm income gains per hectare than any of the other countries using the technology:

- Yield gains of an average of 31% have been recorded [14]. This yield gain has arisen from the substantial improvements in weed control (weed infestation levels, particularly of difficult to control weeds such as Johnson grass have been very high in Romania. This is largely a legacy of the economic transition during the 1990s, which resulted in very low levels of farm income, abandonment of land, and very low levels of weed control. As a result, the weed bank developed substantially and has been subsequently very difficult to control, until the GM HT soybean system became available [glyphosate has been the key to controlling difficult weeds like Johnson grass]). In recent years, as fields have been cleaned up of problem weeds, the average yield gains have decreased and were reported at +13% in 2006 (source: farmer survey conducted in 2006 on behalf of Monsanto Romania).
- The cost of the technology to farmers in Romania tended to be higher than other countries, with seed being sold in conjunction with the herbicide.

Sources and notes:
1. Impact data (Data source: Monsanto South Africa – data provision not a reference)
2. All values for prices and costs denominated in South African Rand have been converted to US dollars at the annual average exchange rate in each year

For example, in the 2002–2006 period, the average cost of seed and herbicide per hectare was $120–$130/ha. This relatively high cost however, did not deter adoption of the technology because of the major yield gains, improvements in the quality of soybeans produced (less weed material in the beans sold to crushers that resulted in price premia being obtained in the early years – no longer relevant post 2005), and cost savings derived.

- The average net increase in gross margin in 2006 was $59/ha (an average of $105/ha over the 8 years of commercial use: Table 6).
- At the national level, the increase in farm income amounted to $7.6 million in 2006. Cumulatively in the period 1999–2006, the increase in farm income was $44.6 million (in nominal terms).
- The yield gains in 2006 were equivalent to an 9% increase in national production (the annual average increase in production over the 8 years was equal to 10.1%).
- In added value terms, the combined effect of higher yields, improved quality of beans, and reduced cost of production on farm income in 2006 was equivalent to an annual increase in production of 9.3% (33,230 tons).

Mexico

GM HT soybeans were first planted commercially in Mexico in 1997 (on a trial basis) and in 2008, a continued trial area of 7,330 ha (out of total plantings of 88,000 ha) were varieties containing the GM HT trait.

At the farm level, the main impacts of use have been a combination of yield increase (+9.1% in 2004 and 2005, +3.64% in 2006, +3.2% 2007, and +2.4% 2008) and (herbicide) cost savings. The average farm income benefit has been within a range of $54–$89/ha (inclusive of yield gain, cost savings, and after payment of the technology fee/seed premium of $34.5/ha) and the increase in farm income at the national level was $0.04 million in 2008 (Table 7). The cumulative increase in farm income since 2004 has been $3.35 million (in nominal terms). In added value terms, the increase in farm income from the use of the GM HT technology in 2008 was equivalent to an annual increase in production of about 0.5%.

Bolivia

GM HT soybeans were officially permitted to be planted in 2008, although "illegal" plantings have occurred for several years. For the purposes of analysis

in this section, impacts have been calculated back to 2005, when an estimated 0.3 million hectares of soybeans used GM HT technology. In 2008, an estimated 453,000 ha (63% of total crop) used GM HT technology.

The main impacts of the technology are as follows (Table 8):

- An increase in yield arising from improved yield control. The research work conducted by

Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Table 8 Farm-level income impact of using GM HT soybeans in Bolivia 2005–2008

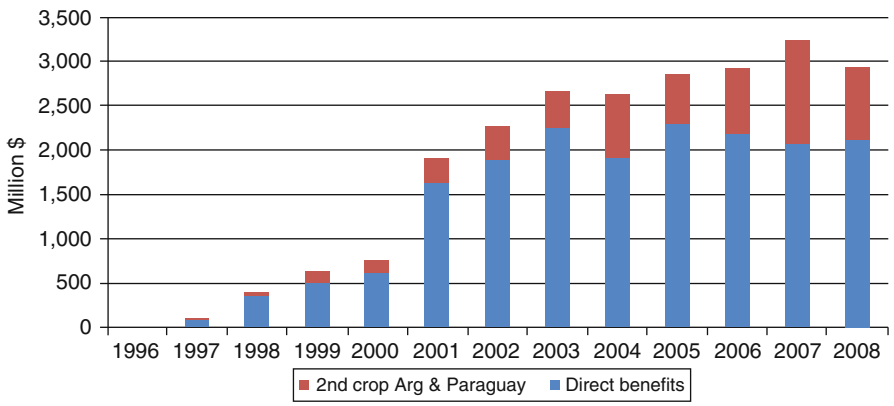
Sources and notes:
1. Impact data based on Fernandez et al. [19]. Average yield gain assumed +15%, cost of technology $3.32/ha



Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Figure 2
Global farm-level income benefits derived from using GM HT soybeans 1996–2008 (million $)

Fernandez et al. [19] estimated a 30% yield difference between GM HT and conventional soybeans although some of the yield gain reflected the use of poor-quality conventional seed by some farmers. In the analysis presented, a more conservative yield gain of +15% has been used.

- GM HT soybeans are assumed to trade at a price discount to conventional soybeans of −2.7%, reflecting the higher price set for conventional soybeans by the Bolivian government in 2008.
- The cost of the technology to farmers has been about $3.3/ha and the cost savings equal to about $9.3/ha, resulting in a net cost of production change of +$6/ha.
- Overall, in 2008, the average farm income gain from using GM HT soybeans was about $80/ha, resulting in a total farm income gain of $36.3 million. Cumulatively since 2005, the total farm income gain is estimated at $83.4 million.

Summary of Global Economic Impact

In global terms, the farm-level impact of using GM HT technology in soybeans was $2.12 billion in 2008 (Fig. 2). If the second crop benefits arising in Argentina are included, this impact rises to $2.92 billion. Cumulatively since 1996, the farm income benefit has been

(in nominal terms) $17.9 billion ($23.3 billion if second crop gains in Argentina and Paraguay are included).

In terms of the total value of soybean production from the countries growing GM HT soybeans in 2008, the additional farm income (inclusive of Argentine second crop gains) generated by the technology is equal to a value-added equivalent of 4.3%. Relative to the value of global soybean production in 2008, the farm income benefit added the equivalent of 4.1%.

These economic benefits should be placed within the context of a significant increase in the level of soybean production in the main GM adopting countries since 1996 (a 63% increase in the area planted in the leading soybean producing countries of the USA, Brazil, and Argentina).

These economic benefits mostly derive from cost savings although farmers in Mexico, Bolivia, and Romania also obtained yield gains (from significant improvements in weed control levels relative to levels applicable prior to the introduction of the technology). If it is also assumed that all of the second crop soybean gains are effectively additional production that would not have otherwise occurred without the GM HT technology (the GM HT technology facilitated major expansion of second crop soybeans in Argentina and to a lesser extent in Paraguay) then these gains are de facto "yield" gains. Under this assumption, of the total cumulative farm income gains from using GM HT soy, $5.56 billion (24%), is due to yield gains/second crop benefits and the balance, 76%, is due to cost savings.

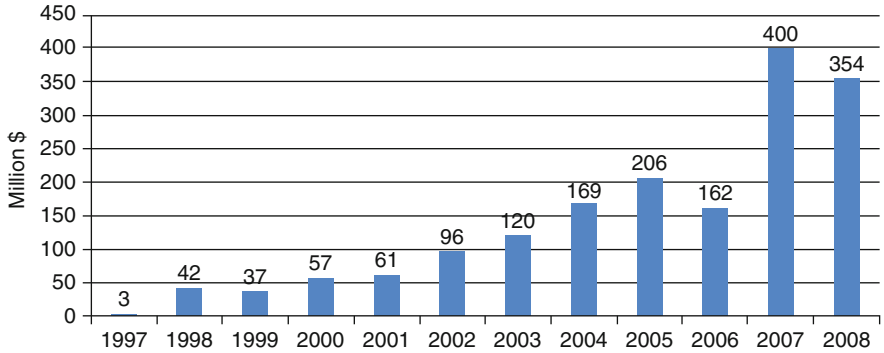
Herbicide-Tolerant Maize

The USA

Herbicide-tolerant maize has been used commercially in the USA since 1997 and in 2008 was planted on 63% of the total US maize crop. The impact of using this technology at the farm level is summarized in Fig. 3. As with herbicide-tolerant soybeans, the main benefit has been to reduce costs, and hence improve profitability levels. Average profitability improved by $20–$25/ha in most years ($17.6/ha in 2008 – affected by the significant increase in glyphosate prices relative to other herbicides). The net gain to farm income in 2008 was $354 million and cumulatively, since 1997 the farm income benefit has been $1.7 billion. In added value terms, the effect of reduced costs of production on farm income in 2008 was equivalent to an annual increase in production of 0.71% (2.17 million tons).

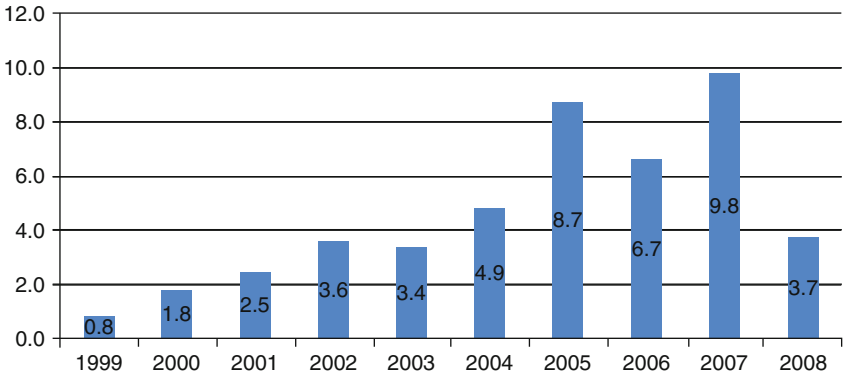
Canada

In Canada, GM HT maize was first planted commercially in 1997. By 2008, the proportion of total plantings accounted for by varieties containing a GM HT trait was 51%. As in the USA, the main benefit has been to reduce



Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Figure 3

National farm income impact of using GM HT maize in the USA 1997–2008 (Source and notes: Impact analysis based on Sankala and Blumenthal [6, 7] and Johnson and Strom [8] and updated for 2008 to reflect changes in herbicide prices. Estimated cost of the technology $14.83/ha in years up to 2004, $17.3/ha in 2005, $24.71/ha 2006 onward. Cost savings (mostly from lower herbicide use) $33.47/ha in 2004, $38.61/ha 2005, $29.27/ha 2006, $42.28/ha 2007, and $40.87/ha 2008)



Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Figure 4
National farm income impact of using GM HT maize in Canada 1999–2008 ($ million) (Source and notes: Impact analysis based on data supplied by Monsanto Canada. Estimated cost of the technology $18-$32/ha, cost savings (mostly from lower herbicide use) $31–$45/ha)

costs and to improve profitability levels. Average annual profitability has improved by between $12/ha and $18/ha up to 2007, but fell to about $6/ha in 2008 (due to the higher price increases for glyphosate relative to other herbicides). In 2008, the net increase in farm income was $3.7 million and cumulatively since 1999 the farm income benefit has been $45.8 million. In added value terms, the effect of reduced costs of production on farm income in 2008 was equivalent to an annual increase in production of 0.22% (23,500 tons: Fig. 4).

Argentina

GM HT maize was first planted commercially in Argentina in 2004 and in 2008, varieties containing a GM HT trait were planted on 805,000 ha (35% of the total maize area). It has been adopted in two distinct types of area, the majority (80%) in the traditional "corn production belt" and 20% in newer maize-growing regions, which have been traditionally known as more marginal areas that surround the "Corn Belt." The limited adoption of GM HT technology in Argentina up to 2006 was mainly due to the technology only being available as a single gene, not stacked with the GM IR trait, which most maize growers have also adopted. Hence, faced with an either GM HT or GM IR trait available for use, most farmers have chosen the GM IR trait because the additional returns derived from adoption have tended to be (on average) greater from the GM IR trait than the GM HT trait (see below for further details of returns from the GM HT trait). Stacked traits became available in 2007 and contributed to the significant increase in the GM HT maize area relative to 2006.

In relation to impact on farm income, the following observations were made:

- In all regions, the cost of the technology (about $20/ha) has been broadly equal to the saving in herbicide costs.
- In the Corn Belt area, use of the technology has resulted in an average 3% yield improvement via improved weed control. In the more marginal areas, the yield impact has been much more significant (+22%) as farmers have been able to significantly improve weed control levels.
- In 2008, the additional farm income at a national level from using GM HT technology has been +$61.6 million, and cumulatively since 2004, the income gain has been $113.8 million.

South Africa

Herbicide-tolerant maize has been grown commercially in South Africa since 2003, and 6,46,000 ha out of total plantings of 2.43 million hectares were herbicide tolerant in 2008. Farmers using the technology have found that small net savings in the cost of production have occurred (i.e., the cost saving from reduced expenditure on herbicides has been greater

than the cost of the technology), although in 2008, due to the significant rise in the global price of glyphosate relative to their herbicides, the net farm income balance was negative, at about −$2/ha. This resulted in a total net farm loss arising from using GM HT technology of $1.43 million, though since 2003, there has been a net cumulative income gain of $3.77 million.

Philippines

GM HT maize was first grown commercially in 2006, and 2008 was planted on 270,000 ha. Information about the impact of the technology is limited, although industry sources estimate that, on average farmers using it have derived a 15% increase in yield. Based on a cost of the technology of $24–$27/ha (and assuming no net cost savings), the net national impact on farm income was +$15.9 million in 2008. Cumulatively, since 2006, the total farm income gain has been $27.1 million

Summary of Global Economic Impact

In global terms, the farm-level economic impact of using GM HT technology in maize was $433.5 million in 2008 (82% of which was in the USA). Cumulatively since 1997, the farm income benefit has been (in nominal terms) $1.9 billion. Of this, 92% has been due to cost savings and 8% to yield gains (from improved weed control relative to the level of weed control achieved by farmers using conventional technology).

In terms of the total value of maize production in the main countries using this technology in 2008, the additional farm income generated by the technology is equal to a value-added equivalent of 0.3% of global maize production.

Herbicide-Tolerant Cotton

The USA

GM HT cotton was first grown commercially in the USA in 1997 and in 2008 was planted on 68% of total cotton plantings.

The farm income impact of using GM HT cotton is summarized in Table 9. The primary benefit has been to reduce costs, and hence improve profitability levels, with annual average profitability increasing by between $21/ha and $49/ha (the only published source that has examined the impact of HT cotton in the USA is the work by Sankala and Blumenthal [6, 7], and Johnson and Strom [8]. In the 2001 study, the costs saved were based on historic patterns of herbicides used on conventional cotton in the mid/late 1990s. The latter studies estimated cost savings on the basis of the conventional herbicide treatment that would be required to deliver the same level of weed control as GM HT cotton. Revised analysis has, however, been conducted for 2008 to reflect changes in the costs of production (notably cost of the technology (in particular "Roundup Ready Flex technology"), higher prices for glyphosate relative to other herbicides in 2008 and additional costs incurred to control weeds resistant to glyphosate in some regions) in the years up to 2004. Since then, net income gains have fallen to between $1/ha and $5/ha. The relatively small positive impact on direct farm income in 2008 (and in the last few years) reflects a combination of reasons, including the higher cost of the technology, significant price increases for glyphosate relative to price increases for other herbicides, and additional costs incurred for management of weeds resistant to glyphosate (notably *Palmer Amaranth*). Overall, the net direct farm income impact in 2008 is estimated to be $2.5 million (this does not take into consideration any nonpecuniary benefits associated with adoption of the technology: see Section 3.9). Cumulatively, since 1997, there has been a net farm income benefit from using the technology of $799 million.

Other Countries

Australia, Argentina, South Africa, and Mexico are the other countries where GM HT cotton is commercially grown; from 2000 in Australia, 2001 in South Africa, 2002 in Argentina, and 2005 in Mexico. In 2008, 79% (50,460 ha), 38% (124,000 ha), 75% (9,750 ha), and 40% (50,000 ha) respectively of the total Australian, Argentine, South African, and Mexican cotton crops were planted to GM HT cultivars.

We are not aware of any published research into the impact of GM HT cotton in South Africa, Argentina, or Mexico. In Australia, although research has been conducted into the impact of using GM HT cotton (e.g., Doyle et al. [20]) this does not provide

Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Table 9 Farm-level income impact of using GM HT cotton in the USA 1997–2008

Year	Cost savings ($/ha)	Net cost saving/increase in gross margins, inclusive of cost of technology ($/ha)	Increase in farm income at a national level ($ millions)	Increase in national farm income as % of farm-level value of national production

Source and notes:

1. Impact analysis based on Sankala and Blumenthal [6, 7] and Johnson and Strom [8] and own analysis for 2008
2. Estimated cost of the technology $12.85/ha (1997–2000) and $21.32/ha 2001–2003, $34.55 2004, $68.22/ha 2005, $70.35/ha 2006, $70.61/ha 2007, and £71.56/ha 2008

quantification of the impact. Drawing on industry source estimates, the main impacts are as follows:

- *Australia*: No yield gain and cost of the technology in the range of $30–$45/ha up to 2007. The cost of the technology increased with the availability of "Roundup Ready Flex" and in 2008 was about $63/ha. The cost savings from the technology (after taking into consideration the cost of the technology have delivered small net gains of $5–$7/ha, although estimates relating to the net average benefits from Roundup Ready Flex are about $25/ha in 2008 [20]. Overall, in 2008, the total farm income from using the technology was about $3 million and cumulatively, since 2000, the total gains have been $8.3 million.
- *Argentina*: No yield gain and a cost of technology in the range of $30–$40/ha, although with the increasing availability of stacked traits in recent years, the "cost" part of the HT technology has fallen to $24/ha. Net farm income gains (after deduction of the cost of the technology) have been $8–$18/ha and in 2008 were just under $10/ha. Overall, in 2008, the total farm income from using GM HT cotton technology was about $7.4 million, and cumulatively since 2002, the farm income gain has been $34.2 million.
- *South Africa*: No yield gain and a cost of technology in the range of $15–$25/ha. Net farm income gains from cost savings (after deduction of the cost of the technology) have been $30–$60/ha. In 2008, the average net gain was $33.6/ha and the total farm income benefit of the technology was $0.37 million. Cumulatively since 2001, the total farm income gain from GM HT cotton has been $2.2 million.
- *Mexico*: Average yield gains of +3.6% from improved weed control have been reported in the first 3 years of use, although no yield gain was recorded in 2008. The average cost of the technology has been in the range of $60–$66/ha and typical net farm income gains of about $80/ha, though in 2008, with no yield gains this fell back to $16/ha.

Overall, in 2008, the total farm income gain from using GM HT cotton was about $1.35 million and cumulatively since 2005, the total farm income gain has been $11.7 million.

Summary of Global Economic Impact

Across the five countries using GM HT cotton in 2008, the total farm income impact derived from using GM HT cotton was +$14.6 million. Cumulatively since 1997, there have been net farm income gains of $855.8 million (93% of this benefit has been in the USA). Of this, 96% has been due to cost savings and 4% to yield gains (from improved weed control relative to the level of weed control achieved using conventional technology).

Herbicide-Tolerant Canola

Canada

Canada was the first country to commercially use GM HT canola in 1996. Since then, the area planted to varieties containing GM HT traits has increased significantly, and in 2008 was 83% of the total crop (5.43 million hectares).

The farm-level impact of using GM HT canola in Canada since 1996 is summarized in Table 10. The key features are as follows:

- The primary impact in the early years of adoption was increased yields of almost 11% (e.g., in 2002 this yield increase was equivalent to an increase in total Canadian canola production of nearly 7%). In addition, a small additional price premia was achieved from crushers through supplying cleaner crops (lower levels of weed impurities). With the development of hybrid varieties using conventional technology, the yield advantage of GM HT canola relative to conventional alternatives (the main one of which is "Clearfield" conventionally derived herbicide-tolerant varieties. Also, hybrid canolas now account for the majority of plantings (including some GM hybrids) with the hybrid vigor delivered by conventional breeding techniques (even in the GM HT [to glyphosate] varieties) has been eroded. As a result, our analysis has applied the yield advantage of +10.7% associated with the GM HT technology in its early years of adoption (source: Canaola Council study of 2001) to 2003. From 2004, the yield gain has been based on differences between average annual variety trial results for "Clearfield" (conventional herbicide-tolerant varieties) and biotech alternatives. The biotech alternatives have also been differentiated into glyphosate tolerant and glufosinate tolerant. This resulted in the following observation: for GM glyphosate-tolerant varieties no yield difference for 2004, 2005, and 2008 and +4% 2006 and 2007. For GM glufosinate-tolerant varieties, the yield differences were +12% 2004 and 2008, +19% 2005, +10% 2006 and 2007. The quality premia associated with cleaner crops (see above) has not been included in the analysis from 2004.
- Cost of production (excluding the cost of the technology) has fallen, mainly through reduced expenditure on herbicides and some savings in fuel and labor. These savings have annually been between about $25/ha and $36/ha. The cost of the technology to 2003 was however marginally higher than these savings resulting in a net increase in costs of $3– $5/ha. On the basis of comparing GM HT canola with "Clearfield" HT canola (from 2004), there has been a net cost saving of between $5/ha and $10/ha, although in 2008 this was $17/ha.
- The overall impact on profitability (inclusive of yield improvements and higher quality) has been an increase of between $22/ha and $48/ha up to 2003. On the basis of comparing GM HT canola with "Clearfield" HT canola (from 2004), the net increase in profitability has been between $23/ha and $66/ha.
- The annual total national farm income benefit from using the technology has risen from $6 million in 1996 to $364 million in 2008. The cumulative farm income benefit over the 1996–2008 period (in nominal terms) was $1.64 billion.
- In added value terms, the increase in farm income in 2008 has been equivalent to an annual increase in production of 6.3%.

The USA

GM HT canola has been planted on a commercial basis in the USA since 1999. In 2008, 95% of the US canola crop was GM HT (380,230 ha).

Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Table 10 Farm-level income impact of using GM HT canola in Canada 1996–2008

Year	Cost savings ($/ha)	Cost savings inclusive of cost of technology ($/ha)	Net cost saving/ increase in gross margins ($/ha)	Increase in farm income at a national level ($ millions)	Increase in national farm income as % of farm-level value of national production
1996	28.59	−4.13	45.11	6.23	0.4
1997	28.08	−4.05	37.11	21.69	1.17
1998	26.21	−3.78	36.93	70.18	3.43
1999	26.32	−3.79	30.63	90.33	5.09
2000	26.32	−3.79	22.42	59.91	5.08
2001	25.15	−1.62	23.10	53.34	5.69
2002	24.84	−3.59	29.63	61.86	6.17
2003	28.04	−4.05	41.42	132.08	6.69
2004	21.42	+4.44	19.09	70.72	4.48
2005	23.11	+4.50	32.90	148.12	6.56
2006	34.02	+16.93	50.71	233.13	8.09
2007	35.44	+17.46	66.39	341.44	7.54
2008	36.36	+17.56	66.63	364.23	6.35

Sources and notes:

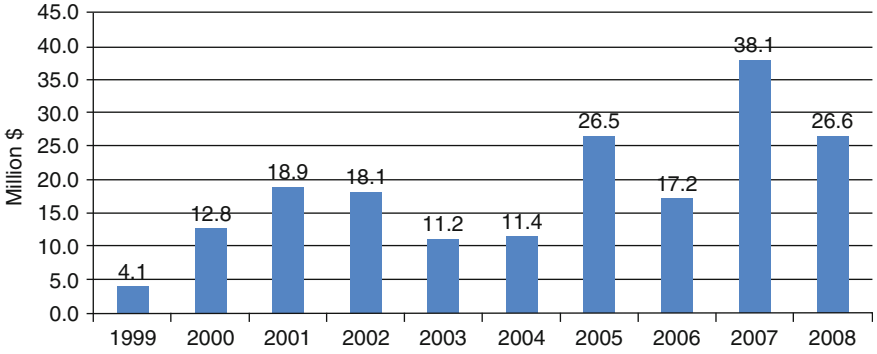
1. Impact data based on Canola Council study [21] to 2003 and Gusta et al. [22]. Includes a 10.7% yield improvement and a 1.27% increase in the price premium earned (cleaner crop with lower levels of weed impurities) until 2003. After 2004, the yield gain has been based on differences between average annual variety trial results for Clearfield and biotech alternatives. The biotech alternatives have also been differentiated into glyphosate tolerant and glufosinate tolerant. This resulted in the following observation: for GM glyphosate-tolerant varieties no yield difference for 2004, 2005, and 2008 and +4% 2006 and 2007. For GM glufosinate-tolerant varieties, the yield differences were +12% 2004 and 2008, +19% 2005, +10% 2006 and 2007

2. Negative values denote a net increase in the cost of production (i.e., the cost of the technology was greater than the other cost (e.g., on herbicides) reductions

3. All values for prices and costs denominated in Canadian dollars have been converted to US dollars at the annual average exchange rate in each year

The farm-level impact has been similar to the impact identified in Canada. More specifically, the following observations were noted:

- Average yields increased by about 6% in the initial years of adoption. As in Canada (see above) the availability of high-yielding hybrid conventional varieties has eroded some of this yield gain in recent year relative to conventional alternatives. As a result, the positive yield impacts post 2004 have been applied on the same basis as in Canada (comparison with Clearfields: see Canada above).
- The cost of the technology has been $12–$17/ha for glufosinate-tolerant varieties and $12–$33/ha for glyphosate-tolerant varieties. Cost savings (before inclusion of the technology costs) have been $35–$45/ha ($22/ha in 2008) for glufosinate-tolerant canola and $40–$79/ha for glyphosate-tolerant canola.
- The net impact on gross margins has been between +$22/ha and +$90/ha ($5/ha in 2008) for glufosinate-tolerant canola, and +$28/ha and +$61/ha for glyphosate-tolerant canola.
- At the national level, the total farm income benefit in 2008 was $26.6 million (Fig. 5) and the cumulative benefit since 1999 has been $185 million.
- In added value terms, the increase in farm income in 2008 has been equivalent to an annual increase in production of about 10.3%.



Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Figure 5
National farm income impact of using GM HT canola in the USA 1999–2008 (Source and notes: Impact analysis based on Sankala and Blumenthal [6, 7] and Johnson and Strom [8]. Decrease in total farm income impact 2002–2004 is due to decline in total plantings of canola in the USA (from 612,000 in 2002 to 316,000 ha in 2004). Positive yield impact applied in the same way as Canada from 2004)

Australia

GM HT canola was permitted for commercial use in the two states of Victoria and New South Wales in 2008, and was planted on 10,100 ha in that year (2008/09). Ninety-five percent of these plantings had tolerance to the herbicide glyphosate and the balance were tolerant to glufosinate.

A fairly comprehensive farm survey-based analysis of impact of the glyphosate-tolerant canola was commissioned by Monsanto, which involved interviews with 92 of the 108 farmers using this technology in 2008/09 [23, 24]. Key findings from this survey are as follows:

- The technology was made available in both open-pollinated and hybrid varieties, with the open-pollinated varieties representing the cheaper end of the seed market, where competition was mainly with open-pollinated varieties containing herbicide tolerance (derived conventionally) to herbicides in the triazine (TT) group. The hybrid varieties containing glyphosate tolerance competed with nonherbicide-tolerant conventional hybrid varieties and herbicide-tolerant "Clearfield" hybrids (tolerant to the imidazolinone group of herbicides), although, were used in 2008, all of the 33 farmers in the survey using GM HT hybrids did so mainly in competition and comparison with "Clearfield" varieties.
- The GM HT open-pollinated varieties sold to farmers at a premium of about $Aus3/ha (about $2.5 US/ha) relative to the TT varieties. The GM HT hybrids sold at a seed premium of about $Aus 9/ha ($7.55 US/ha) compared to "Clearfield" hybrids. In addition, farmers using the GM HT technology paid a "technology" fee in two parts; one part was a set fee of $Aus500 per farm plus $Aus 10.2/ton of output of canola. On the basis that there were 108 farmers using GM HT (glyphosate tolerant) technology in 2008, the average "up front" fee paid for the technology was $Aus5.62/ha. On the basis of average yields obtained for the two main types of GM HT seed used, those using open-pollinated varieties paid $11.83/ha (basis: average yield of 1.16 tons/ha) and those using GM HT hybrids paid $Aus12.95/ha (basis: average yield of 1.27 tons/ha). Therefore, the total seed premium and technology fee paid by farmers for the GM HT technology in 2008–2009 was $Aus20.45/ha ($17.16 US/ha) for open-pollinated varieties and $Aus 27.57/ha ($23.13 US/ha) for hybrid varieties. After taking into consideration, the seed premium/technology fees, the GM HT system was marginally more expensive by $Aus3/ha ($2.5 US/ha) and $Aus4/ha ($US 3.36/ha) respectively for weed control than the TT and Clearfield varieties.
- The GM HT varieties delivered higher average yields than their conventional counterparts: +22.11% compared to the TT varieties and +4.96% compared to the "Clearfield" varieties.

Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Table 11 Farm-level income impact of using GM HT canola in Australia 2008 ($US)

Year	Average cost saving ($/ha)	Average cost savings (net after cost of technology ($/ha)	Average net increase in gross margins ($/ha)	Increase in farm income at a national level ($)
2008	19.18	−20.77	93.37	943,054

Source derived from and based on Monsanto survey of license holders 2008

Notes:

1. The average values shown are weighted averages
2. Other weighted average values derive include yield +21.1% and quality (price) premium of 2.1% applied on the basis of this level of increase in average oil content

In addition, the GM HT varieties produced higher oil contents of +2% and +1.8% respectively compared to TT and "Clearfield" varieties.

- The average reduction in weed control costs from using the GM HT system (excluding seed premium/technology fee) was $Aus 17/ha for open-pollinated varieties (competing with TT varieties) and $Aus 24/ha for hybrids (competing with Clearfield varieties).

In the analysis summarized below in Table 11, these research findings have been applied to the total GM HT crop area on a weighted basis in which the results of GM HT open-pollinated varieties that compete with TT varieties were applied to 64% of the total area and the balance of area used the results from the GM HT hybrids competing with "Clearfield" varieties. This weighting reflects the distribution of farms in the survey, in which 59 (64%) of the farmers indicated they grew open-pollinated varieties and 33 (34%) grew hybrids. The findings show an average farm income gain of $US 93/ha and a total farm income gain of $0.93 million in 2008.

Summary of Global Economic Impact

In global terms, the farm-level impact of using GM HT technology in canola in Canada, the USA, and Australia was $392 million in 2008. Cumulatively, since 1996, the farm income benefit has been (in nominal terms) $1.83 billion. Within this, 79% has been due to yield gains and the balance (21%) has been from cost savings.

In terms of the total value of canola production in these three countries in 2008, the additional farm income generated by the technology is equal to a value-added equivalent of 6.9%. Relative to the value of global canola production in 2008, the farm income benefit added the equivalent of 1.5%.

GM Herbicide-Tolerant (GM HT) Sugar Beet

GM HT sugar beet was first grown commercially in the USA in 2007 (under 1,000 ha), although it was 2008 before sufficient quantities of seed were available for widespread commercial cultivation. In 2008, just under 258,000 ha of GM HT sugar beet were planted, equal to about 63.5% of the total US crop. The highest levels of penetration of the technology (85% plus of total crop) occurred in Idaho, Wyoming, Nebraska, and Colorado, with about 50% of the crops in the largest sugar beet growing states of North Dakota and Michigan being GM HT.

Impact of the technology in these early years of adoption has been identified as follows:

(a) *Yield*: Analysis by Kniss [25] covering a limited number of farms in Wyoming (2007) identified positive yield impacts of +8.8% in terms of additional root yield (from better weed control) and +12.6% in terms of sugar content relative to conventional crops (i.e., the GM HT crop had about a 3.8% higher sugar content, which amounts to a 12.8% total sucrose gain relative to conventional sugar beet once the root yield gain was taken into consideration). In contrast, Khan [26] found similar yields reported between conventional and GM HT sugar beet in the Red River Valley region (North Dakota) and Michigan. These contrasting results probably reflect a combination of factors including:

- The sugar beet growing regions in Wyoming can probably be classified as high weed problem areas, and as such, are regions where obtaining effective weed control is difficult using conventional technology (timing of application is key to weed control in sugar beet, with optimal time for application being when weeds are small). Also some weeds (e.g., Kochia) are

resistant to some of the commonly used ALS inhibitor herbicides like chlorsulfuron. The availability of GM HT sugar beet with its greater flexibility on application timing has therefore potentially delivered important yield gains for such growers.

- The GM HT trait was not available in all leading varieties suitable in all growing regions in 2008, hence the yield benefits referred to above from better weed control have to some extent been counterbalanced by only being available in poorer performing germ plasm in states like Michigan and North Dakota (notably not being available in 2008 in leading varieties with rhizomania resistance). It should be noted that the authors of the research cited in this section both perceive that yield benefits from using GM HT sugar beet will be a common feature of the technology in most regions once the technology is available in leading varieties.
- The year 2008 was reported to have been, in the leading sugar beet growing states, a reasonable year for controlling weeds through conventional technology (i.e., it was possible to get good levels of weed control through timely applications), hence the similar performance reported between the two systems.

(b) Costs of production

- Kniss's work in Wyoming identified weed control costs (comprising herbicides, application, cultivation, and hand labor) for conventional beet of $437/ha compared to $84/ha for the GM HT system. After taking into consideration the $131/ha seed premium/technology fee for the GM HT trait, the net cost differences between the two systems was $222/ha in favor of the GM HT system. Kniss did, however, acknowledge that the conventional costs associated with this sample were high relative to most producers (reflecting application of maximum dose rates for herbicides and use of hand labor), with a more typical range of conventional weed control costs being between $171/ha and $319/ha (average $245/ha).
- Khan's analysis puts the typical weed control costs in the Red River region of North Dakota to be about $227/ha for conventional compared to $91/ha for GM HT sugar beet. After taking into consideration the seed premium/technology fee (assumed by Khan to be $158/ha), the total weed control costs were $249/ha for the GM HT system, $22/ha higher than the conventional system. Despite this net increase in average costs of production, most growers in this region used (and planned to continue using), the GM HT system because of the convenience and weed control flexibility benefits associated with it (which research by Marra and Piggot [1]) estimated in the corn, soybean, and cotton sectors to be valued at between $12/ha and $25/ha to US farmers). It is also likely that Khan's analysis may understate the total cost savings from using the technology by not taking into account savings on application costs and labor for hand weeding.

For the purposes of our analysis, we have drawn on both these pieces of work, as summarized in Table 12. This shows a net farm income gain in 2008 of over $21 million to US sugar beet farmers (average gain per hectare of just under $83/ha). With the availability of GM HT technology in more of the leading varieties, it is expected that the farm income gains associated with yield gains will be greater in subsequent years.

GM Insect-Resistant (To Corn-Boring Pests: GM IR) Maize

The USA

GM IR maize was first planted in the USA in 1996 and in 2008, seed containing GM IR traits was planted on 57% (18.14 million hectares) of the total US maize crop.

The farm-level impact of using GM IR maize in the USA since 1996 is summarized in Table 13:

- The primary impact has been increased average yields of about 5% (in 2008 this additional production is equal to an increase in total US maize production of +2.41%).
- The net impact on cost of production has been a small increase of between $1/ha and $9/ha (additional cost of the technology being higher than the estimated average insecticide cost savings of $15–$16/ha).
- The annual total national farm income benefit from using the technology has risen from $8.76 million in

Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Table 12 Farm-level income impact of using GM HT sugar beet in the USA 2007–2008

Year	Average cost saving ($/ha)	Average cost savings (net after cost of technology ($/ha)	Average net increase in gross margins ($/ha)	Increase in farm income at a national level ($ millions)	Increase in national farm income as % of farm-level value of national production
2007	353.35	222.39	584.00	472,680	0.03
2008	142.50	−8.58	82.88	21,380,290	1.83

Sources derived from and based on Kniss [25] and Khan [26]

Notes:

1. The yield gains identified by Kniss have been applied to the 2007 GM HT plantings in total and to the estimated GM HT plantings in the states of Idaho, Wyoming, Nebraska, and Colorado, where penetration of plantings in 2008 was 85% (these states account for 26% of the total GM HT crop in 2008), and which are perceived to be regions of above average weed problems. For all other regions, no yield gain is assumed. Across the entire GM HT area in 2008, this equates to a net average yield gain of +3.28%
2. The seed premium of $131/ha, average costs of weed control respectively for conventional and GM HT systems of $245/ha and $84/ha, from Kniss were applied to the crop in Idaho, Wyoming, Nebraska, and Colorado. The seed premium of $158/ha, weed control costs of $227/ha and $249/ha respectively for conventional and GM HT sugar beet, identified by Khan were applied to all other regions using the technology. These states account for 26% of the total GM HT crop in 2008. The resulting average values for seed premium/cost of technology across the entire 2008 GM HT crop was therefore $151.08/ha and the average weed control cost saving associated with the GM HT system (before taking into consideration the seed premium) was $142.5/ha

Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Table 13 Farm-level income impact of using GM IR maize in the USA 1996–2008

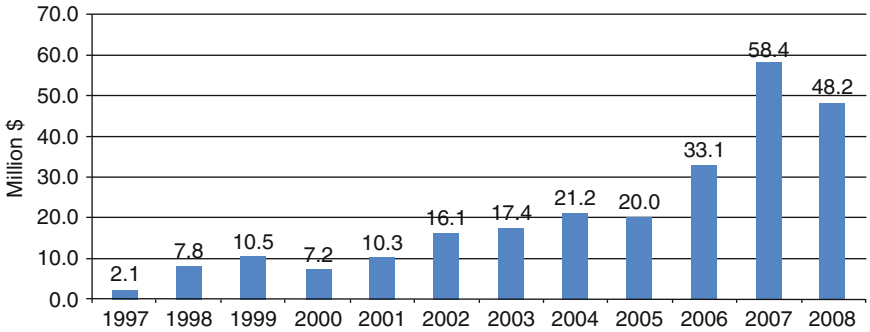
Sources and notes:

1. Impact data based on a combination of studies including the ISAAA (James) review [27], Marra et al. [3], Sankala and Blumenthal [6, 7], and Johnson and Strom [8], Gianessi and Carpenter [28]
2. Yield impact +5% based on average of findings of above studies
3. Insecticide cost savings based on the above references
4. – (minus) value for net cost savings means the cost of the technology is greater than the other cost savings



Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Figure 6

National farm income impact of using GM IR maize in Canada 1996–2008

Notes:

1. Yield increase of 5% based on industry assessments (consistent with US analysis). Cost of technology and insecticide cost savings based on US analysis,

2. GM IR area planted in 1996 = 1,000 ha,

3. All values for prices and costs denominated in Canadian dollars have been converted to US dollars at the annual average exchange rate in each year

1996 to $1.22 billion in 2008. The cumulative farm income benefit over the 1996–2008 period (in nominal terms) was $5.12 billion.

- In added value terms, the increase in farm income in 2008 was equivalent to an annual increase in production of 2.4%.

Canada

GM IR maize has also been grown commercially in Canada since 1996. In 2008, it accounted for 62% of the total Canadian maize crop of 1.2 million hectares. The impact of GM IR maize in Canada has been very similar to the impact in the USA (similar yield and cost of production impacts). At the national level, in 2008 the additional farm income generated from the use of GM IR maize was $48.2 million and cumulatively since 1996 the additional farm income (in nominal terms) was $252 million (Fig. 6).

Argentina

In 2008, GM IR maize traits were planted on 75% of the total Argentine maize crop (GM IR varieties were first planted in 1998).

The main impact of using the technology on farm profitability has been via yield increases. Various studies (e.g., see ISAAA review in James [27]) and Trigo and Cap [29] have identified an average yield increase in the region of 8–10%, hence an average of 9% has been used in the analysis up to 2004. More recent trade source estimates provided to the authors put the average yield increased in the last 2–3 years to be between 5% and 6%. Accordingly, our analysis uses a yield increase value of 5.5% for the years from 2004.

No savings in costs of production have arisen for most farmers because very few maize growers in Argentina have traditionally used insecticides as a method of control for corn-boring pests. As such, average costs of production have increased by $20–$22/ha (the cost of the technology).

The net impact on farm profit margins (inclusive of the yield gain) has, in recent years, been an increase of about $20/ha. In 2008, the national level impact on profitability was an increase of $41 million (an added value equal to 2.15% of the total value of production). Cumulatively, the farm income gain since 1997 has been $269.7 million.

South Africa

GM IR maize has been grown commercially in South Africa since 2000. In 2008, 56% of the country's total maize crop of 2.42 million hectares used GM IR cultivars.

Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Table 14 Farm-level income impact of using GM IR maize in South Africa 2000–2008

Year	Cost savings ($/ha)	Net cost savings inclusive of cost of technology ($/ha)	Net increase in gross margin ($/ha)	Impact on farm income at a national level ($ millions)
2000	13.98	1.87	43.77	3.31
2001	11.27	1.51	34.60	4.46
2002	8.37	0.6	113.98	19.35
2003	12.82	0.4	63.72	14.66
2004	14.73	0.46	20.76	8.43
2005	15.25	0.47	48.66	19.03
2006	14.32	−2.36	63.75	63.05
2007	13.90	0.22	182.90	225.70
2008	11.74	−4.55	87.07	117.73

Sources and notes:

1. Impact data (Sources: Gouse [30–32] and Van der Weld [33])
2. Negative value for the net cost savings = a net increase in costs (i.e., the extra cost of the technology was greater than the other (e.g., less expenditure on insecticides) cost savings
3. All values for prices and costs denominated in South African Rand have been converted to US dollars at the annual average exchange rate in each year

The impact on farm profitability is summarized in Table 14. The main impact has been an average yield improvement of between 5% and 32% in the years 2000–2004, with an average of about 15% (used as the basis for analysis 2005–2007). In 2008, the estimated yield impact was +10.6% (source: Van der Weld [33]). The cost of the technology $8–$17/ha has broadly been equal to the average cost savings from no longer applying insecticides to control corn-boring pests.

At the national level, the increase in farm income in 2008 was $117.7 million and cumulatively since 2000 it has been $476 million. In terms of national maize production, the use of GM IR technology on 56% of the planted area has resulted in a net increase in national maize production of 5.9% in 2008. The value of the additional income generated was also equivalent to an annual increase in production of about 5.1%.

Spain

Spain has been commercially growing GM IR maize since 1998 and in 2008, 22% (79,270 ha) of the country's maize crop was planted to varieties containing a GM IR trait.

As in the other countries planting GM IR maize, the main impact on farm profitability has been increased yields (an average increase in yield of 6.3% across farms using the technology in the early years of adoption). With the availability and widespread adoption of the Mon 810 trait from 2003, the reported average positive yield impact is about +10%. There has also been a net annual average saving on cost of production (from lower insecticide use) of between $37/ha and $61/ha (Table 15). At the national level, these yield gains and cost savings have resulted in farm income being boosted, in 2008 by $17.9 million and cumulatively since 1998 the increase in farm income (in nominal terms) has been $77.9 million.

Relative to national maize production, the yield increases derived from GM IR maize were equivalent to a 2.2% increase in national production (2008). The value of the additional income generated from Bt maize was also equivalent to an annual increase in production of 2.1%.

Other EU countries

A summary of the impact of GM IR technology in other countries of the EU is presented in Table 16. This shows

Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Table 15 Farm-level income impact of using GM IR maize in Spain 1998–2008

Year	Cost savings ($/ha)	Net cost savings inclusive of cost of technology ($/ha)	Net increase in gross margin ($/ha)	Impact on farm income at a national level ($ millions)
1998	37.40	3.71	95.16	2.14

that in 2008, the additional farm income derived from using GM IR technology in these six countries was +$2.5 million, and cumulatively over the 2005–2008 period, the total income gain was $11.1 million.

Other Countries

GM IR maize has been grown commercially in the following countries:

- *The Philippines* since 2003. In 2008, 280,000 ha out of total plantings of 2.6 million (7%) were GM IR. Estimates of the impact of using GM IR (Sources: Gonsalves [36], Yorobe [37], and Ramon [38]) show annual average yield increases in the range of 14.3–34%. Taking the midpoint of this range (+24.15%), coupled with a small average annual insecticide cost saving of about $12–$13/ha and average cost of the technology of about $33/ha, the net impact on farm profitability has been between $37/ha and $109/ha. In 2008, the national farm income benefit derived from using the technology was $33.5 million and cumulative farm income gain since 2003 has been $61.2 million.
- *Uruguay* since 2004, and in 2008, 110,000 ha (73% of the total crop) were GM IR. Using Argentine data as the basis for assessing impact, the cumulative farm income gain over the 3 years has been $3.9 million.
- *Brazil* starting in 2008, when 1.45 million hectares were planted to varieties containing a GM IR trait. Based on analysis from Galveo [12], the average yield impact was +4.66%, the cost of the technology was $21.6/ha, insecticide cost savings were $42/ha, and the average improvement to farm income equal to $48.12/ha. Overall, the increase in farm profitability associated with the adoption in 2008 was $69.8 million;
- *Honduras*. Here farm-level "trials" have been permitted since 2003, and in 2008, an estimated 9,000 ha used GM IR traits. Evidence from Falck Zepeda et al. [39] indicated that the primary impact of the technology has been to increase average yields (in 2008 +24%). As insecticides have not traditionally been used by most farmers, no costs of production savings have arisen, coupled with no additional cost for use of the technology (which has been provided free of charge for the trials). In our analysis, we have, however assumed a cost of the technology of $30/ha, and based on this, the estimated farm income benefit derived from the technology was $1.1 million in 2008 and cumulatively since 2003 the income gain has been $2 million.

Summary of Economic Impact

In global terms, the farm-level impact of using GM IR maize was $1.56 billion in 2008. Cumulatively since 1996, the benefit has been (in nominal terms) $6.34 billion. This farm income gain has mostly derived from improved yields (less pest damage) although in some countries farmers have derived a net cost saving associated with reduced expenditure on insecticides.

In terms of the total value of maize production from the countries growing GM IR maize in 2008, the additional farm income generated by the technology is equal to a value-added equivalent of 2.2%. Relative to the value of global maize production in 2008, the farm income benefit added the equivalent of 1.2%.

Insect-Resistant (Bt) Cotton (GM IR)

The USA

GM IR cotton has been grown commercially in the USA since 1996 and by 2008, was used in 63% (1.93 million hectares) of total cotton plantings.

The farm income impact of using GM IR cotton is summarized in Table 17. The primary benefit has been increased yields (by 9–11%), although small net savings in costs of production have also been obtained (reduced expenditure on insecticides being marginally greater than the cost of the technology). Overall, average profitability levels increased by $53–$115/ha with Bollgard I cotton (with a single Bt gene) between 1996 and 2002 and by between $87/ha and $118/ha in 2003–2008 with Bollgard II (containing two Bt genes and offering a broader spectrum of control). This resulted in a net gain to farm income in 2008 of $189 million. Cumulatively, since 1996, the farm income benefit has been $2.44 billion. In added value terms, the effect of the increased yields and reduced costs of production on farm income in 2008 was equivalent to an annual increase in production of 6.3% (165,400 tons).

Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Table 17 Farm-level income impact of using GM IR cotton in the USA 1996–2008

Year	Cost savings (net after cost of technology ($/ha)	Net increase in gross margins ($/ha)	Increase in farm income at a national level ($ millions)	Increase in national farm income as % of farm-level value of national production

2. Yield impact +9% 1996–2002 Bollgard I and +11% 2003 onward Bollgard II
3. Cost of technology: 1996–2002 Bollgard I $58.27/ha, 2003–2004 Bollgard II $68.32/ha, $49.62/ha 2005, $46.95/ha 2006, $25.7/ha 2007 and 2008
4. Insecticide cost savings $63.26/ha 1996–2002, $74.10/ha 2003–2005, $41.18/ha 2006, $28.4/ha 2007 and 2008

China

China first planted GM IR cotton in 1997, since when the area planted to GM IR varieties has increased to 64% of the total 5.95 million hectares crop in 2008.

As in the USA, a major farm income impact has been via higher yields of 8–10% on the crops using the technology, although there have also been significant cost savings on insecticides used and the labor previously used to undertake spraying. Overall, annual average costs have fallen by about $145–$200/ha and annual average profitability improved by $123–$472/ha. In 2008, the net national gain to farm income was $859 million (Table 18). Cumulatively, since 1997, the farm income benefit has been $7.6 billion. In added value terms, the effect of the increased yields and reduced costs of production on farm income in 2008 was equivalent to an annual increase in production of 17.1% (1.38 million tons).

Australia

Australia planted 83% of its 2008 cotton crop (total crop of 146,000 ha) to varieties containing GM IR traits (Australia first planted commercial GM IR cotton in 1996).

Unlike the other main countries using GM IR cotton, Australian growers have rarely derived yield gains from using the technology (reflecting the effective use of insecticides for pest control prior to the availability of GM IR cultivars), with the primary farm income benefit being derived from lower costs of

Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Table 18 Farm-level income impact of using GM IR cotton in China 1997–2008

Sources and notes:

1. Impact data based on Pray et al. [41, 42], which covered the years 1999–2001. Other years based on average of the 3 years, except 2005 onward based on Shachuan (2006) – personal communication
2. Negative cost savings in 2000 reflect a year of high pest pressure (of pests not the target of GM IR technology), which resulted in above average use of insecticides on GM IR using farms
3. Yield impact +8% 1997–1999 and +10% 2000 onward
4. Negative value for the net cost savings in 2000 = a net increase in costs (i.e., the extra cost of the technology was greater than the savings on insecticide expenditure – a year of lower than average bollworm problems
5. All values for prices and costs denominated in Chinese Yuan have been converted to US dollars at the annual average exchange rate in each year

production (Table 19). More specifically, the following observations were made:

- In the first 2 years of adoption of the technology (Ingard, single gene Bt cotton), small net income losses were derived, mainly because of the relatively high price charged for the seed. Since this price was lowered in 1998, the net income impact has been positive, with cost saving of between $54/ha and $90/ha, mostly derived from lower insecticide costs (including application) more than offsetting the cost of the technology.
- For the last few years of use, Bollgard II cotton (containing 2 Bt genes) has been available offering effective control of a broader range of cotton pests. Despite the higher costs of this technology, users have continued to make significant net cost savings of $186–$212/ha.
- At the national level in 2008, the net farm income gains were $24.2 million and cumulatively since 1996 the gains have been $214.9 million.
- In added value terms, the effect of the reduced costs of production on farm income in 2008 was equivalent to an annual increase in production of 37% (105,000 tons).

Argentina

GM IR cotton has been planted in Argentina since 1998. In 2008, it accounted for 73% of total cotton plantings.

Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Table 19 Farm-level income impact of using GM IR cotton in Australia 1996–2008

2007	−251.33	212.1	11.73	40.90
2008	−264.26	199.86	24.23	37.40

Sources and notes:

1. Impact data based on Doyle [43], Taylor [44], CSIRO [45] for bollgard II since 2004
2. All values for prices and costs denominated in Australian dollars have been converted to US dollars at the annual average exchange rate in each year

The main impact in Argentina has been yield gains of 30% (which has resulted in a net increase in total cotton production (2008) of 22%). This has more than offset the cost of using the technology. In terms of gross margin, cotton farmers have gained annually between $25/ha and $249/ha during the period 1998–2007. At the national level, the annual farm income gains in the last 5 years have been in the range of $2–$27 million (Fig. 7). Cumulatively since 1998, the farm income gain from use of the technology has been $95.4 million. In added value terms, the effect of the yield increases (partially offset by higher costs of production) on farm income in 2008 was equivalent to an annual increase in production of 14.6%.

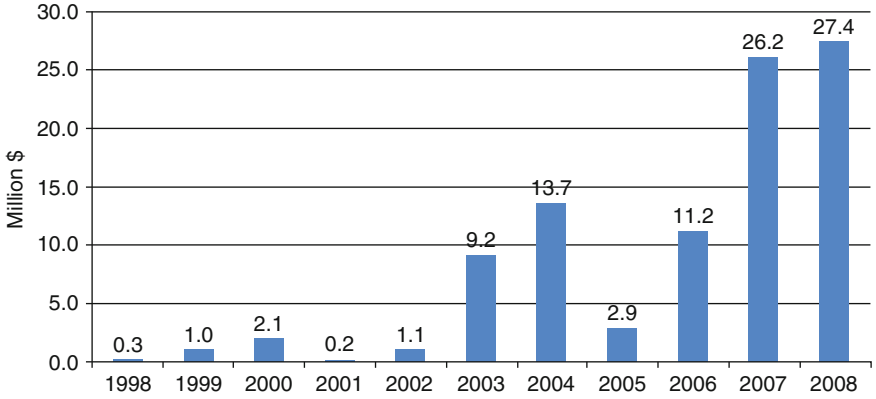
Mexico

GM IR cotton has been planted commercially in Mexico since 1996. In 2008, GM IR cotton was planted on 70,000 ha (56% of total cotton plantings).

The main farm income impact of using the technology has been yield improvements of between 6% and 9% over the last 6 years. In addition, there have been important savings in the cost of production (lower insecticide costs). Overall, the annual net increase in farm profitability has been within the range of $104/ha and $354/ha between 1996 and 2008 (Table 20). At the national level, the farm income benefit in 2008 was $10.5 million and the impact on total cotton production was an increase of 5.2%. Cumulatively since 1996, the farm income benefit has been $76.4 million. In added value terms, the combined effect of the yield increases and lower cost of production on farm income in 2008 was equivalent to an annual increase in production of 5.4%.

South Africa

In 2008, GM IR cotton (first planted commercially in 1998) was planted on 7,750 ha in South Africa (84% of the total crop).



Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Figure 7
National farm income impact of using GM IR cotton in Argentina 1998–2008
Sources and notes:
1. Impact data (Sources: Qaim and De Janvry [46, 47]), Elena [48] and for 2005 and 2006 Monsanto LAP, although cost of technology in 2005 from Monsanto Argentina. Area data: source ArgenBio
2. Yield impact +30%, cost of technology $86/ha ($40/ha 2005), cost savings (reduced insecticide use) $17.47/ha
3. All values for prices and costs denominated in Argentine Pesos have been converted to US dollars at the annual average exchange rate in each year

The main impact on farm incomes has been significantly higher yields (an annual average increase of about 24%). In terms of cost of production, the additional cost of the technology (between $17/ha and $24/ha for Bollgard I and $40–$50/ha for Bollgard II (2006 onward) has been greater than the insecticide cost and labor (for water collection and spraying) savings ($12–$23/ha), resulting in an increase in overall cost of production of $2–$32/ha. Combining the positive yield effect and the increase in cost of production, the net effect on profitability has been an annual increase of between $27/ha and $232/ha.

At the national level, farm incomes, over the last 5 years have annually increased by between $1.2 million and $1.7 million (Fig. 8). Cumulatively since 1998, the farm income benefit has been $21 million. The impact on total cotton production was an increase of 20.1% in 2008. In added value terms, the combined effect of the yield increases and lower costs of production on farm income in 2008 was equivalent to an annual increase in production of 14.5% (based on 2008 production levels).

India

GM IR cotton has been planted commercially in India since 2002. In 2008, 6.97 million hectares were planted to GM IR cotton, which is equal to 77% of total plantings.

The main impact of using GM IR cotton has been major increases in yield [54] found average yield increases of 45% in 2002 and 63% in 2003 (average over the 2 years of 54%) relative to conventionally produced cotton. More recent survey data from Monsanto [16] confirm this high-yield impact (+58% reported in 2004) as do data from IMRB [55], which found an average yield increase of 64% in 2005, and IMRB [56], which found a yield impact of +50% in 2006. With respect to cost of production, the average cost of the technology (seed premium: $49–$54/ha) up to 2006 was greater than the average insecticide cost savings of $31–$58/ha resulting in a net increase in costs of production. Following the reduction in the seed premium in 2006 to about $20/ha, farmers have, on average made a net cost saving of about $25/ha. Coupled with the yield gains, important net gains to levels of profitability have been achieved of between $82/ha and $356/ha. At the national level, the farm income gain in 2008 was $1.79 billion and cumulatively since 2002 the farm income gains have been $5.14 billion (Table 21).

The impact on total cotton production was an increase of 31% in 2008 and in added value terms, the combined effect of the yield increases and higher costs of production on farm income in 2008 was equivalent

Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Table 20 Farm-level income impact of using GM IR cotton in Mexico 1996–2008

Year	Cost savings (net after cost of technology ($/ha)	Net increase in gross margins ($/ha)	Increase in farm income at a national level ($ millions)	Increase in national farm income as % of farm-level value of national production

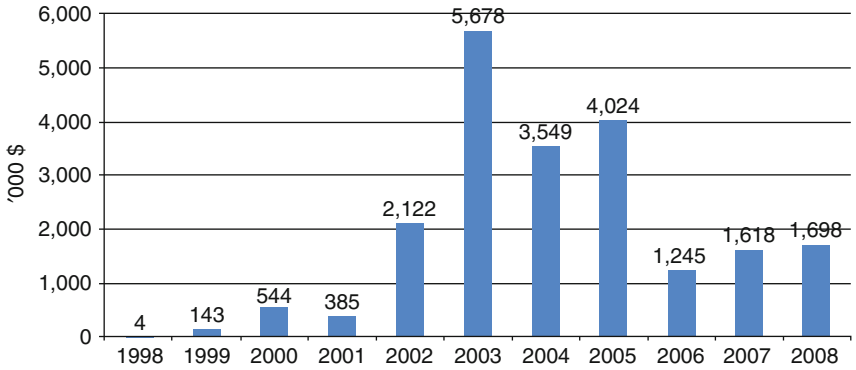
1. Impact data based on Traxler et al. [49] covering the years 1997 and 1998. Yield changes data in other years based on official reports submitted to the Mexican Ministry of Agriculture by Monsanto Comercial (Mexico). Also, Martinez-Carillo and Diaz-Lopez [50]
2. Yield impacts: 1996 +37%, 1997 +3%, 1998 +20%, 1999 +27%, 2000 +17%, 2001 +9%, 2002 +7%, 2003 +6%, 2004 +7.6%, 2005 onward +9.25%
3. All values for prices and costs denominated in Mexican Pesos have been converted to US dollars at the annual average exchange rate in each year

to an annual increase in production of 24% (based on the 2008 production level that is inclusive of the GM IR related yield gains).

Brazil

GM IR cotton was planted commercially in Brazil for the first time in 2006, and in 2008 was planted on 178,000 ha (20% of the total crop). This represents a fall in the share of total plantings relative to 2007, when GM IR traits were planted on 32% of the crop. This decline in plantings largely reflects the relative performance of the seed containing the GM IR traits compared to the leading conventional varieties, in which the GM IR trait has not been available. In 2006, on the basis of industry estimates of impact of GM IR cotton relative to similar varieties, an average yield gains of +6% and a net cost saving (reduced expenditure on insecticides after deduction of the premium paid for using the technology) of about +$25/ha were realized. In 2007 and 2008, however, analysis by Galveo [12] and Monsanto Brazil [57] suggests that the yield performance of the varieties containing GM IR traits has been lower (by −3.6% and −2.7% respectively for 2007 and 2008). As a result, the net farm income of using the technology was (after taking into consideration insecticide cost savings and the seed premium), on average, −$34.5/ha in 2007 and a small net gain of about $2/ha in 2008. At a national level in 2008, GM IR cotton technology delivered a net gain of about $0.35 million (a net loss of $12.3 million in 2007). Cumulatively, the total farm income impact has been positive at about $5 million.



Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Figure 8
National farm income impact of using GM IR cotton in South Africa 1998–2008
Sources and notes:
1. Impact data based on Ismael et al. [51], Kirsten et al. [52], Morse et al. [53]
2. Yield impact +24%, cost of technology $14–$24/ha for Bollgard I and about $50/ha for Bollgard II, cost savings (reduced insecticide use) $12–$23/ha
3. All values for prices and costs denominated in South African Rand have been converted to US dollars at the annual average exchange rate in each year
4. The decline in the total farm income benefit post 2003 relative to earlier years reflects the decline in total cotton plantings. This was caused by relatively low farm-level prices for cotton in 2004 and 2005 (reflecting a combination of relatively low world prices and a strong South African currency). In more recent years, cotton has become less competitive relative to alternatives such as corn because of higher world grain prices

Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Table 21 Farm-level income impact of using GM IR cotton in India 2002–2008

Year	Cost savings (net after cost of technology ($/ha)	Net increase in gross margins ($/ha)	Increase in farm income at a national level ($ millions)	Increase in national farm income as % of farm-level value of national production
2002	−12.42	82.66	3.69	0.26
2003	−16.2	209.85	20.98	0.47

Sources and notes:
1. Impact data based on Bennett et al. [54] and IMRB [55, 56]. As 2008 was reported to be a year of below average pest pressure, the average yield gain used was reduced to +40%
2. All values for prices and costs denominated in Indian Rupees have been converted to US dollars at the annual average exchange rate in each year

Other Countries

- *Colombia*: GM IR cotton has been grown commercially in Colombia since 2002 (20,000 ha planted in 2008 out of a total cotton crop of 40,000 ha). Drawing on recent analysis of impact by Zambrano et al. [58], this shows the main impact has been through a significant improvement in yields of +32%. On the cost impact side, this analysis shows that farmers using GM IR cotton tend to have substantially higher expenditures on pest control than their conventional counterparts, which when taking into consideration the approximate $70/ha cost of the technology results in a net addition to costs of between $200/ha and $280/ha each year (relative to typical expenditures by conventional cotton growers). Nevertheless, after taking into consideration the positive yield effects, the net impact on profitability has been positive. In 2008, the average improvement in profitability was about $33/ha and the total net gain from using the technology was $0.91 million. Cumulatively, since 2002, the net farm income gain has been $13.9 million.
- *Burkino Faso*: GM IR cotton was grown commercially first in 2008. Based on analysis of precommercial trials by Vitale et al. [59, 60], the main impact of the technology is improved yields (by +20%) and savings in insecticide expenditure of about $62/ha. Based on a cost of technology of about $42/ha, the net cost savings are about $20/ha, and inclusive of the yield gains, the estimated net income gain in 2008 was $124/ha. The total aggregate farm income gain in 2008 was therefore $1 million.

Summary of Global Impact

In global terms, the farm-level impact of using GM IR cotton was $2.9 billion in 2008. Cumulatively, since 1996, the farm income benefit has been (in nominal terms) $15.61 billion. Within this, 65% of the farm income gain has derived from yield gains (less pest damage) and the balance (35%) from reduced expenditure on crop protection (spraying of insecticides).

In terms of the total value of cotton production from the countries growing GM IR in 2008, the additional farm income generated by the technology is equal to a value-added equivalent of 19.3% (based on the 2008 production level inclusive of the GM IR related yield gains). Relative to the value of global cotton production in 2008, the farm income benefit added the equivalent of 11.1%.

Other Biotech Crops

Maize/Corn Rootworm Resistance

GM rootworm-resistant (CRW) corn has been planted commercially in the USA since 2003. In 2008, there were 13.7 million hectares of CRW corn (43% of the total US crop).

The main farm income impact (Impact data based on Sankala and Blumenthal [6, 7], Johnson and Strom [8], Rice [61]), and Alston et al. [62]) has been higher yields of about 5% relative to conventional corn. The impact on average costs of production has been +$2/ha to −$10/ha (based on an average cost of the technology of $35–$42/ha and an insecticide cost saving of $32–$37/ha). As a result, the net impact on farm profitability has been +$28/ha to +$79/ha.

At the national level, farm incomes increased by $4.6 million in 2003, rising to $1.1 billion in 2008. Cumulatively since 2003, the total farm income gain from the use of CRW technology in the USA corn crop has been $2 billion.

CRW cultivars were also planted commercially for the first time in 2004 in Canada. In 2008, the area planted to CRW-resistant varieties was 119,380 ha. Based on US costs, insecticide cost savings and yield impacts, this has resulted in additional income at the national level of $8.65 million in 2008 (cumulative total since 2004 of $13 million).

At the global level, the extra farm income derived from biotech CRW maize use since 2003 has been just over $2 billion. In 2008, the additional farm income generated from use of the technology was equal to 0.9% of the value of the global maize crop.

Virus-Resistant Papaya

Ring spot-resistant papaya has been commercially grown in the USA (State of Hawaii) since 1999, and in 2008 (85% of the state's papaya crop was GM virus resistant (700 ha).

The main farm income impact of this biotech crop has been to significantly increase yields relative to conventional varieties. Compared to the average yield in the last year before the first biotech cultivation (1998), the annual average yield increase of biotech papaya relative to conventional crops has been within a range of +15% to +77% (29% in 2008). At a state level, this is equivalent to a 25% increase in total papaya production in 2008.

In terms of profitability (Impact data based on Sankala and Blumenthal [6, 7] and Johnson and Strom [8]), the net annual impact has been an improvement of between $3,000/ha and $29,000/ha, and in 2008 this amounted to a net farm income gain of $5,790/ha and an aggregate benefit across the state of $4 million. Cumulatively, the farm income benefit since 1999 has been $53.4 million.

Virus-resistant papaya is also reported to have been grown in China in 2008, on 4,500 ha. No impact data on this technology has been identified.

Virus-Resistant Squash

Biotech virus-resistant squash has also been grown in some states of the USA since 2004 and is estimated to have been planted on 2,900 ha in 2008 (17% of the total crop in the USA – mostly found in Georgia and Florida).

Based on analysis from Johnson and Strom [8], the primary farm income impact of using biotech virus-resistant squash has been derived from higher yields, which in 2008, added a net gain to users of $26 million. Cumulatively, the farm income benefit since 2004 has been $107 million.

Insect-Resistant Potatoes

GM insect-resistant potatoes were also grown commercially in the USA between 1996 and 2000 (planted on 4% of the total US potato crop in 1999 (30,000 ha). This technology was withdrawn in 2001 when the technology provider (Monsanto) withdrew from the market to concentrate on GM trait development in maize, soybeans, cotton, and canola. This commercial decision was also probably influenced by the decision of some leading potato processors and fast-food outlets to stop using GM potatoes because of perceived concerns about this issue from some of their consumers, even though the GM potato provided the producer and the processor with a lower cost, higher yielding, and more consistent product. It also delivered significant reductions in insecticide use Carpenter and Gianessi (2002).

Indirect (Nonpecuniary) Farm-Level Economic Impacts

Apart from the tangible and quantifiable impacts on farm profitability presented above, there are other important, more intangible (difficult to quantify) impacts of an economic nature.

Many of the studies of the impact of biotech crops have identified the following reasons as being important influences for adoption of the technology:

Herbicide-Tolerant Crops

- Increased management flexibility and convenience that comes from a combination of the ease of use associated with broad-spectrum, post-emergent herbicides like glyphosate and the increased/longer time window for spraying. This not only frees up management time for other farming activities but also allows additional scope for undertaking off-farm, income-earning activities.
- In a conventional crop, post-emergent weed control relies on herbicide applications before the weeds and crop are well established. As a result, the crop may suffer "knock-back" to its growth from the effects of the herbicide. In the GM HT crop, this problem is avoided because the crop is both tolerant to the herbicide and spraying can occur at a later stage when the crop is better able to withstand any possible "knock-back" effects.
- Facilitates the adoption of conservation or no tillage systems. This provides for additional cost savings such as reduced labor and fuel costs associated with plowing, additional moisture retention, and reductions in levels of soil erosion.
- Improved weed control has contributed to reduced harvesting costs – cleaner crops have resulted in reduced times for harvesting. It has also improved harvest quality and led to higher levels of quality price bonuses in some regions and years (e.g., HT soybeans and HT canola in the early years of adoption respectively in Romania and Canada).

- Elimination of potential damage caused by soil-incorporated residual herbicides in follow-on crops and less need to apply herbicides in a follow-on crop because of the improved levels of weed control.
- A contribution to the general improvement in human safety (as manifest in greater peace of mind about own and worker safety) from reduced exposure to herbicides and a switch to more environmentally benign products.

Insect-Resistant Crops

- Production risk management/insurance purposes – the technology takes away much of the worry of significant pest damage occurring and is, therefore, highly valued. Piloted in 2008 and more widely operational from 2009, US farmers using stacked corn traits (containing insect resistance and herbicide-tolerant traits) are being offered discounts on crop insurance premiums equal to $7.41/ha.
- A "convenience" benefit derived from having to devote less time to crop walking and/or applying insecticides.
- Savings in energy use – mainly associated with less use of aerial spraying and less tillage.
- Savings in machinery use (for spraying and possibly reduced harvesting times).
- Higher quality of crop. There is a growing body of research evidence relating to the superior quality of GM IR corn relative to conventional and organic corn from the perspective of having lower levels of mycotoxins. Evidence from Europe (as summarized in Brookes [35] has shown a consistent pattern in which GM IR corn exhibits significantly reduced levels of mycotoxins compared to conventional and organic alternatives. In terms of revenue from sales of corn, however, no premia for delivering product with lower levels of mycotoxins have, to date, been reported although where the adoption of the technology has resulted in reduced frequency of crops failing to meet maximum permissible fumonisin levels in grain maize (e.g., in Spain), this delivers an important economic gain to farmers selling their grain to the food using sector. GM IR corn farmers in the Philippines have also obtained price premia of 10% [37] relative to conventional corn because of better quality, less damage to cobs and lower levels of impurities.
- Improved health and safety for farmers and farm workers (from reduced handling and use of pesticides, especially in developing countries where many apply pesticides with little or no use of protective clothing and equipment).
- Shorter growing season (e.g., for some cotton growers in India), which allows some farmers to plant a second crop (notably maize) in the same season. Also some Indian cotton growers have reported knock on benefits for beekeepers as fewer bees are now lost to insecticide spraying [63].

Some of the economic impact studies have attempted to quantify some of these benefits (e.g., Qaim and Traxler [9] quantified some of these in Argentina (a $3.65/ha saving (−7.8%) in labor costs and a $6.82/ha (−28%) saving in machinery/fuel costs associated with the adoption of GM HT soybeans). Where identified, these cost savings have been included in the analysis presented above. Nevertheless, it is important to recognize that these largely intangible benefits are considered by many farmers as a primary reason for adoption of GM technology, and in some cases farmers have been willing to adopt for these reasons alone, even when the measurable impacts on yield and direct costs of production suggest marginal or no direct economic gain.

Since the early 2000s, a number of farmer-survey based studies in the USA have also attempted to better quantify these nonpecuniary benefits. These studies have usually employed contingent valuation techniques to obtain farmers valuations of nonpecuniary benefits. A summary of these findings is shown in (Table 22).

Aggregating the Impact to US Crops 1996–2008

The approach used to estimate the nonpecuniary benefits derived by US farmers from biotech crops over the period 1996–2008 has been to draw on the values identified by Marra and Piggot ([1, 2]: Table 22) and to apply these to the biotech crop planted areas during this 13-year period. Figure 9 summarizes the values for nonpecuniary benefits derived from biotech crops in the USA (1996–2008) and shows an estimated (nominal value) benefit of $855 million in

2008 and a cumulative total benefit (1996–2008) of $5.99 billion. Relative to the value of direct farm income benefits presented above, the nonpecuniary benefits were equal to 21% of the total direct income benefits in 2008 and 25.6% of the total cumulative (1996–2008) direct farm income. This highlights the important contribution this category of benefit has had on biotech trait adoption levels in the USA, especially where the direct farm income benefits have been identified to be relatively small (e.g., HT cotton).

Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Table 22 Values of nonpecuniary benefits associated with biotech crops in the USA

Survey	Median value ($/ha)
2002 IR (to rootworm) corn growers survey	7.41
2002 soybean (HT) farmers survey	12.35
2003 HT cropping survey (corn, cotton, and soybeans) – North Carolina	24.71
2006 HT (flex) cotton survey	12.35 (relative to first generation HT cotton)

Source: Marra and Piggot 2006 and 2007 [1, 2]

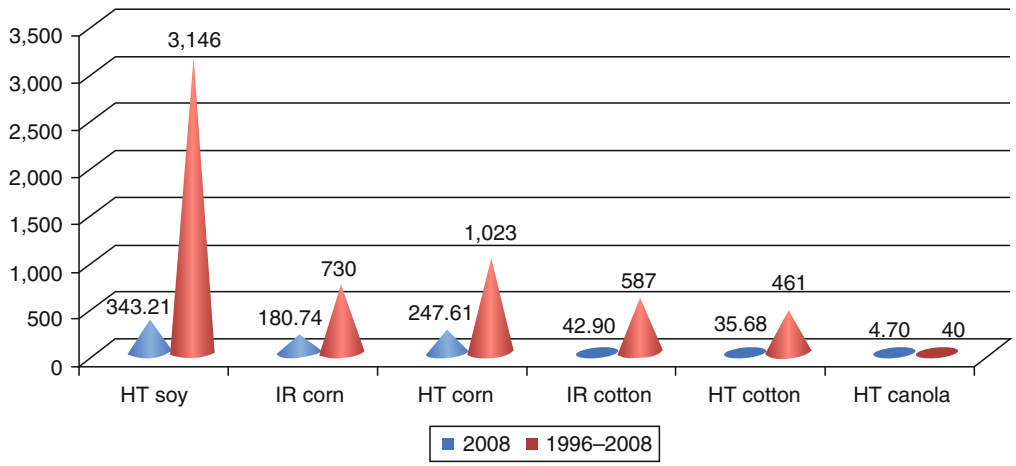
Estimating the Impact in Other Countries

It is evident from the literature review that farmers in other countries, who use GM technology, also value the technology for a variety of nonpecuniary/intangible reasons. The most appropriate methodology for identifying these nonpecuniary benefit valuations in other countries would be to repeat the type of US farmer surveys in other countries. Unfortunately, the authors are not aware of any such studies having been undertaken to date.

Production Effects of the Technology

Based on the yield assumptions used in the direct farm income benefit calculations presented above and taking account of the second soybean crop facilitation in South America, biotech crops have added important volumes to global production of corn, cotton, canola, and soybeans since 1996 (Table 23).

The biotech IR traits, used in the corn and cotton sectors, have accounted for 99% of the additional corn production and almost all of the additional cotton production. Positive yield impacts from the use of this technology have occurred in all user countries (except GM IR cotton in Australia: this reflects the levels of *Heliothis* pest control previously obtained with intensive insecticide use. The main benefit and reason for adoption of this technology in Australia has arisen from significant cost savings (on insecticides) and the associated environmental gains from reduced insecticide use)



Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Figure 9
Nonpecuniary benefits derived by US farmers 1996–2008 by trait ($ million)

when compared to average yields derived from crops using conventional technology (such as application of insecticides and seed treatments). Since 1996, the average yield impact across the total area planted to these traits over the 12-year period has been +7.1% for corn traits and +14.8% for cotton traits (Fig. 10).

Although the primary impact of biotech HT technology has been to provide more cost-effective (less expensive) and easier weed control versus improving yields from better weed control (relative to weed control obtained from conventional technology), improved weed control has, nevertheless occurred, delivering higher yields in some countries. Specifically, HT soybeans in Romania improved the average yield by over 30% in early adoption years and biotech HT corn in Argentina and the Philippines delivered yield improvements of +9% and +15% respectively.

Biotech HT soybeans have also facilitated the adoption of no tillage production systems, shortening the production cycle. This advantage enables many farmers in South America to plant a crop of soybeans immediately after a wheat crop in the same growing season. This second crop, additional to traditional soybean production, has added 73.5 million tons to soybean production in Argentina and Paraguay between 1996 and 2008 (accounting for 99% of the total biotech-related additional soybean production).

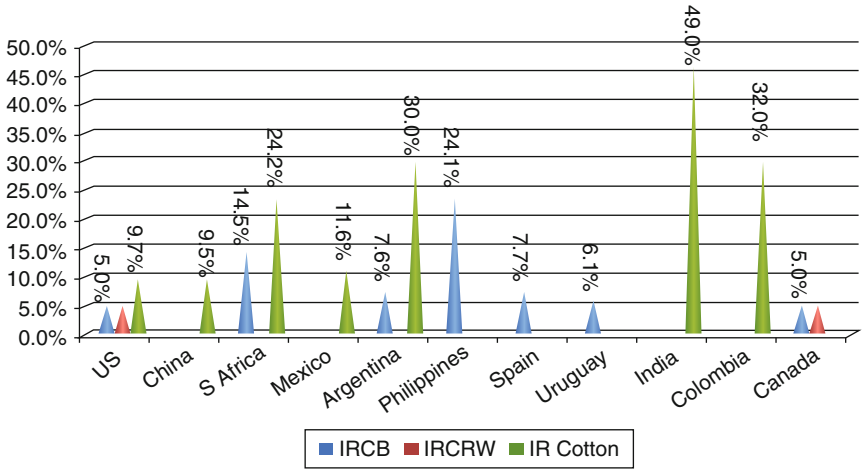
Using the same sensitivity analysis as applied to the farm income estimates presented in the executive summary to the production impacts (one scenario of consistent lower than average pest/weed pressure and one of consistent higher than average pest/weed pressure), Table 24 shows the range of production impacts.

Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Table 23 Additional crop production arising from positive yield effects of biotech crops

	1996–2008 additional production (million tons)	2008 additional production (million tons)
Soybeans	74.0	10.1
Corn	79.7	17.1
Cotton	8.6	1.8
Canola	4.8	0.6

Summary of Economic Effects of Transgenic/Biotech Crops

Overall, GM technology has had a significant positive impact on farm income derived from a combination of enhanced productivity and efficiency gains (Table 25). In 2008, the direct global farm income benefit from biotech crops was $9.37 billion. This is equivalent to having added 3.6% to the value of global production of



Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Figure 10

Global Economic Impact of Transgenic/Biotech Crops (1996–2008). Table 24 Additional crop production arising from positive yield effects of biotech crops 1996–2008 under different pest/weed pressure assumptions and impacts of the technology (million tons)

Crop	Consistent below average pest/weed pressure	Average pest/weed pressure (main study analysis)	Consistent above average pest/weed pressure
Soybeans	73.8	74.0	74.3
Corn	48.0	79.7	140.9
Cotton	6.2	8.6	11.8
Canola	3.3	4.8	5.2

Note: No significant change to soybean production under all three scenarios as 99% of production gain due to second cropping facilitation of the technology

the four main crops of soybeans, maize, canola, and cotton. Since 1996, farm incomes have increased by $52 billion.

The largest gains in farm income have arisen in the soybean sector, largely from cost savings. The $2.93 billion additional income generated by GM herbicide-tolerant (GM HT) soybeans in 2008 has been equivalent to adding 4.3% to the value of the crop in the biotech growing countries, or adding the equivalent of 4.1% to the $71 billion value of the global soybean crop in 2008. These economic benefits should, however be placed within the context of a significant increase in the level of soybean production in the main biotech adopting countries. Since 1996, the soybean area in the leading soybean producing countries of the USA, Brazil, and Argentina increased by 63%.

Substantial gains have also arisen in the cotton sector mainly from the adoption of GM insect-resistant (GM IR) cotton (through a combination of higher yields and lower costs). In 2008, cotton farm income levels in the biotech adopting countries increased by $2.9 billion and since 1996, the sector has benefited from an additional $15.6 billion. The 2008 income gains are equivalent to adding 19.3% to the value of the cotton crop in these countries, or 11.1% to the $26 billion value of total global cotton production. This is a substantial increase in value-added terms for two new cottonseed technologies.

Significant increases to farm incomes have also resulted in the maize and canola sectors. The combination of GM insect resistant (GM IR) and GM HT technology in maize has boosted farm incomes by $10.24 billion since 1996. In the canola sector (largely North American) an additional $1.83 billion has been generated.

Of the total cumulative farm income benefit, $31.2 billion (60%) has been due to yield gains (and second crop facilitation), with the balance arising from reductions in the cost of production. Within this yield gain component, 76% derives from the GM IR technology and the balance to GM HT crops.

Table 26 summarizes farm income impacts in key biotech adopting countries. This highlights the important farm income benefit arising from GM HT soybeans in South America (Argentina, Brazil, Paraguay, and Uruguay), GM IR cotton in China and India, and a range of GM cultivars in the USA. It also illustrates the growing level of farm income benefits obtained in South Africa, the Philippines, and Mexico.

In terms of the division of the economic benefits obtained by farmers in developing countries relative to farmers in developed countries, Table 27 shows that in 2008, 50.5% of the farm income benefits have been earned by developing country farmers. The vast majority of these income gains for developing country farmers have been from GM IR cotton and GM HT soybeans. Over the 13 years, 1996–2008, the cumulative farm income gain derived by developing country farmers was also 50% ($26.2 billion).

Examining the cost farmers pay for accessing GM technology, Table 28 shows that across the four main biotech crops, the total cost in 2008 was equal to 27% of the total technology gains (inclusive of farm income gains plus cost of the technology payable to the seed supply chain: the cost of the technology accrues to the seed supply chain including sellers of seed to farmers, seed multipliers, plant breeders, distributors, and the GM technology providers).

For farmers in developing countries the total cost was equal to 15% of total technology gains, while for farmers in developed countries the cost was 36% of the total technology gains. While circumstances vary between countries, the higher share of total technology gains accounted for by farm income gains in developing countries relative to the farm income share in developed countries reflects factors such as

Totals for the value shares exclude "other crops" (i.e., relate to the four main crops of soybeans, maize, canola, and cotton). Farm income calculations are net farm income changes after inclusion of impacts on yield, crop quality, and key variable costs of production (e.g., payment of seed premia, impact on crop protection expenditure)

weaker provision and enforcement of intellectual property rights in developing countries and the higher average level of farm income gain on a per hectare basis obtained by farmers in developing countries relative to that obtained by farmers in developed countries.

Concluding Comments

Biotechnology has, to date delivered several specific agronomic traits that have overcome a number of production constraints for many farmers. This has resulted in improved productivity and profitability for the 13.3 million adopting farmers who have applied the technology to 115 million hectares in 2008.

During the last 13 years, this technology has made important positive socioeconomic and environmental contributions. These have arisen even though only a limited range of biotech agronomic traits have so far been commercialized, in a small range of crops.

The biotechnology has delivered economic and environmental gains through a combination of their inherent technical advances and the role of the

technology in the facilitation and evolution of more cost-effective and environmentally friendly farming practices. More specifically, it covers the following main issues:

- The gains from the GM IR traits have mostly been delivered directly from the technology (yield improvements, reduced production risk, and decreased the use of insecticides). Thus farmers (mostly in developing countries) have been able to both improve their productivity and economic returns while also practicing more environmentally friendly farming methods.
- The gains from GM HT traits have come from a combination of direct benefits (mostly cost reductions to the farmer) and the facilitation of changes in farming systems. Thus, GM HT technology (especially in soybeans) has played an important role in enabling farmers to capitalize on the availability of a low-cost, broad-spectrum herbicide (glyphosate) and in turn, facilitated the move away from conventional to low/no tillage production systems in both North and South America. This change in production system has made additional positive economic contributions to farmers (and the wider economy) and delivered important environmental benefits, notably reduced levels of GHG emissions (from reduced tractor fuel use and additional soil carbon sequestration).
- Both IR and HT traits have made important contributions to increasing world production levels of soybeans, corn, cotton, and canola.

Total	4,632.6	4,734.6

Developing countries = all countries in South America, Mexico, Honduras, Burkino Faso, India, China, the Philippines, and South Africa

The impact of GM HT traits has, however contributed to increased reliance on a limited range of herbicides and this has contributed to some limited development of weed resistance to these herbicides. Some degree of reduced effectiveness of glyphosate (and glufosinate) against certain weeds is to be expected and the extent to which this may develop further, will depend on farming practice and behavior relating to mixing, rotation, and sequencing of herbicides. Where resistance has occurred, this has resulted in low-dose rate applications of other herbicides in weed control programs (commonly used in conventional production systems) occurring and hence, has marginally reduced the level of net environmental and economic gains derived from the current use of the biotechnology. Nevertheless, to date, the overall environmental and economic gains arising from the use of biotech crops have been substantial.

GM Crop Risk Debate, Science and Socioeconomics

Klaus Ammann
Botanical Garden, University of Bern, Bern, Switzerland

Article Outline

Introduction

The General Strategic Situation of the Debate About Green Biotechnology Today

The aim of this text is to set the framework for a better communication about science and regulation, and production of GM crops. GM stands for Genetic Modification, basically an unfortunate denomination, because actually *all* crops are genetically modified, but it is a worldwide accepted term for genetically engineered crops, including transgenes, auto- and allotransgenes, cis- and infra-genes, and synthetic genes, for details see Beardmore [1]. By including gene stacking of various kinds, the situation is getting even more complex [2]. With the introduction of in Vivo Mutation (with Zink-Finger Technology and the latest transformation method transcription activator-like family of type III effectors [TALEs]) the situation will change even more, the age of a high precision and targeted change of genomes has only begun and will develop rapidly, see section Innovation in Agriculture on All Levels Will Speed Up and Makes it a Necessity to Rethink Regulation Basically and Radically, Most often in the Direction of Lowering the Regulatory Hurdles with details. The term LMOs (Living Modified Organisms), which is generally used in the United Nations Biosafety Protocol (Cartagena Protocol) is nothing but a "Living Proof" that the scientific basis of the Protocol remains questionable, since firstly the term is creating misunderstandings and secondly it is based on an erroneous assumption that GM crops are basically different from conventional crops, as is discussed with detail in the sections Molecular Processes Similar in Natural Mutation and Transgenesis and Dissent over Differences Between GM- and Non-GM Crops Causes Transatlantic Regulatory Divide. More detailed clarification about the terminology of GMOs is given in a text block of the published Statement of the Pontifical Academy of Sciences: [3].

- There are many different terms used to describe the processes involved in plant breeding. All living organisms are made up of cells in which are contained their genes, which give them their distinctive characteristics. The complete set of genes (the genotype) is encoded in DNA and is referred to as the genome; it is the hereditary information that is passed from parent to offspring. All plant breeding, and indeed all evolution, involves genetic change or modification followed by selection for beneficial characteristics from among the offspring. Most alterations to a plant's phenotype or observable traits (such as its physical structure, development, biochemical and nutritional properties) result from changes to its genotype. Plant breeding traditionally used the random reshuffling of genes among closely-related and sexually compatible species, often with unpredictable consequences and always with the details of the genetic changes unexplored. In the mid-twentieth century this was supplemented by mutagenesis breeding, the equally random treatment of seeds or whole plants with mutagenic chemicals or high-energy radiation in the hope of generating phenotypic improvements; this, too, gave rise to unpredictable and unexplored genetic consequences from which the plant breeder selected the beneficial traits. Most recently, techniques have been developed allowing the transfer of specific, identified and well characterized genes, or small blocks of genes that confer particular traits, accompanied by a precise analysis of the genetic and phenotypic outcomes: this last category is called 'transgenesis' (because genes are transferred from a donor to a recipient) or 'genetic engineering' (abbreviated to GE in this report) but, in truth, this term applies to all breeding procedures.

GM Crop Risk Debate, Science and Socioeconomics. Figure 1
Gartner Hype cycle, extended view from [6] after Fig. 3. Technologically aggressive ("Type A") enterprises are relatively comfortable adopting the technology, and moderately aggressive ("Type B") enterprises start to investigate and pilot the technology. Conservative ("Type C") enterprises remain wary (From [6])

The strategic situation in the debate on GM crops is difficult, but not desperate, particularly in Europe – this is an evaluation shared by lots of experts of the debate about agricultural biotechnology; in Europe, it is negatively affecting research and researchers [4]. We have reached in Europe the peak of anxiety related to GM-crops since the introduction of the new technologies, and some opponents to transgenic crops have taken advantage of this situation. They have organized themselves in a veritable protest industry, see section The Dispute Between Scientists and Opponents Today. Nevertheless, the next years should lead to reassurance and scientific consolidation on biotechnology views. We encounter the same repeating dynamics as described for previous technology introductions [5]. The Gartner Hype Cycle [6] adds another dimension to technology life cycle models: it characterizes the typical progression of an emerging technology from user and media overenthusiasm through a period of disillusionment to an eventual understanding of the technology's relevance and role in a market or domain (Fig. 1).

In the details of the cycle [6], amended by the author – specified for the technology push in transgenic cropdevelopment – it should be noted that there are differences between the development of the technologies in the mind of Linden and Fenn and agricultural technologies, where life sciences, combined with regional and cultural diversity, results in a much more diversified picture, often not following the below described phases.

- **2.1 Technology Trigger.** The Technology Trigger is a technological breakthrough, public demonstration, press release or other event that generates significant publicity and industry interest in an emerging technology. Typically no usable products exist, only research and laboratory prototypes (from the first transgenic plants in the 80ties [7]. Venture capitalists may provide some early funding just after the Trigger, if they expect the technology to be a fast runner.

- **2.2 On the Rise.** On the rise to the Peak of Inflated Expectations, media articles explain the technology and discuss its potential impact on business and society. First-generation products emerge like the Flavr-Savr-Tomato [8], but they usually are highly specialized products or extremely difficult to use or with other hitches in the introductory phase. Products are high margin because vendors are still trying to recover R&D costs, and the technology is expensive compared to its cost of production. For example, in 2002, Bluetooth products such as headsets cost $200, while the final silicon cost of Bluetooth chips likely will be approximately $5. This is a good stage for venture capitalists to enter the market, before evaluations are at their apex. During this phase, some particularly aggressive enterprises may start to pilot the technology, particularly if it contributes to critical business issues. These enterprises work closely with the vendors to create customized solutions for their requirements

- **2.3 At the Peak of Inflated Expectations.** As the Peak crests, the number of vendors offering the technology increases. These vendors are primarily startup companies and small vendors that try to use the increasing amount of hype for their marketing benefit. A growing number of enterprises start to examine how the technology may fit within their business strategies, although most do not take action at this stage. Venture capitalists may be interested in selling some of the startups that they equipped with early funding. As problems with first-generation products become visible (e.g., emerging pest resistance in the Bt cotton regions [9, 10] and the latest success message of Huang et al. [11], often because the technology is pushed to its limits, negative publicity starts to push the technology into the Trough of Disillusionment, often the pertinent publications are pushed for negative statements beyond the limit of scientific rules (for example, Web services in 2002 and biometrics in 2003 and two example from the debate on non-target insects related to Bt crops: a) the case of the monarch butterfly [12] and b) Lovei et al. [13] giving false alarm for ladybirds and its prompt rebuttal by Antony Shelton et al. [14]).

- **2.4 Sliding into the Trough of Disillusionment.** Because the technology does not live up to enterprises' and the media's overinflated expectations, it is rapidly discredited. Some of the early trials end in highly publicized failures. Media interest wanes, except for a few cautionary tales. A significant amount of vendor consolidation and failure occurs. Later-stage investors may be interested in funding vendors during this phase because equity is fairly inexpensive after the "microbubble" at the Peak of Inflated Expectations has burst. However, amid the disillusionment, trials are ongoing and vendors are improving products based on early feedback regarding problems and issues. Some early adopters find some benefit in adopting the technology. For some slow-moving technologies (for example, biometrics), workable and cost-effective solutions emerge and provide value in niche domains, even while the technology remains in the Trough. The Trough of Disillusionment coincides with the "chasm" in Geoffrey Moore's classic book, "Crossing the Chasm" [15]. During this stage, vendors need to launch their products from a few early adopters to adoption by a majority of enterprises to begin the climb up the Slope of Enlightenment. There is no real parallel in the GM crop history, except that the differences in GM crop regulation and perception between the Americas and Europe caused a deep transatlantic divide [16].

- **2.5 Climbing the Slope of Enlightenment.** Focused experimentation and real-world experience by an increasingly diverse range of enterprises lead to a better understanding of the technology's applicability, risks and benefits. Vendors seek mezzanine or later-round funding for marketing and sales support to pull them-selves up the Slope. Second- and third-generation products are launched by the leading seed companies, and methodologies and tools are added to ease the development process, see the

sections under 1.2. The service component declines as a percentage of the sale. Technologically aggressive ("Type A") enterprises are relatively comfortable adopting the technology, and moderately aggressive ("Type B") enterprises start to investigate and pilot the technology. Conservative ("Type C") enterprises remain wary. At the beginning of the slope, the penetration often is significantly less than 5 percent of the potential market segment. This will grow to approximately 30 percent and more as the technology enters the Plateau of Enlightenment. Examples of more or less unexpected enhancements in science and risk assessment of transgenic crops come from a higher precision of gene transfer methods (see sections under 1.2.), also compare to the latest developments in resistance management with a clear success story this year [11].

- **2.6 Entering the Plateau of Productivity.** The Plateau represents the beginning of mainstream adoption, which began in the Americas much earlier from 2000 onwards, when the real-world benefits of the technology are demonstrated and accepted, see the consecutive reports on the world development of transgenic crops on www.isaaa.org. Technologies become increasingly embedded into solutions that increasingly are "out of the box," with decreasing service elements as the technology matures (example conservation tilling). The majority of Type B, then Type C, enterprises adopt the technology. As a high-profile technology matures, an "ecosystem" often evolves around it. The ecosystem supports multiple providers of products and services, and also a market for related products and services that extend or are based on the technology (for example, virtual private networks in 2003 or the growing market for suppliers of molecular laboratories or the growing market for electronic equipment for precision agriculture).

  The final height of the Plateau varies according to whether the technology is broadly applicable or benefits only a niche market, depending heavily on crop and region.

- **2.7 Post-Plateau.** As a technology achieves full maturity and supports thousands of enterprises and millions of users, producers and consumers, its hype typically disappears, as seen in the Americas. Only a few specialist magazines continue coverage of new aspects of implementing and maintaining the technology. Often there may be innovations around this technology that will follow their own Hype Cycles (new crop varieties on stress resistance, on bio-fortification, pharmaceutical crop lines etc.).

- **3.0 The Time-to-Maturity Assessment.** Technologies do not move at a uniform speed through the Hype Cycle. It often takes years for a technology to traverse the Hype Cycle — some technologies like GM crops may take decades, with considerable regional differences. There are three adoption speeds:

  "Fast-track" technologies go through the Hype Cycle within two to four years. This occurs when the performance curve inflects early in the life cycle of a technology. These technologies find themselves adopted without much fanfare, bypassing the Peak of Inflated Expectations and Trough of Disillusionment. Many enterprises are unaware of their sudden maturity and applicability, such as what has happened with instant messaging and Short Message Service.

It is interesting to note that the Showalter "hystories" on the introduction of most new technologies [5] report no real damage in their subsequent introductory phase, or the benefits were so overwhelming that the debate was soon fading away. This alone demonstrates clearly that it is the sociocultural environment strongly influencing the risk debate [17]. The most recent events seem to hint that Europe finally finds to a more de-contracted way of looking at GM crops: The new report of the Royal Society [18] tries to unite conventional and biotechnology approaches for the sake of making progress on agricultural management in developing countries:

- Past debates about agricultural technology have tended to involve different parties arguing for either advanced biotechnology including GM, improved conventional agricultural practice or low-input methods. We do not consider that these approaches are mutually exclusive: improvements to all systems require high-quality science. Global food insecurity is the product of a set of interrelated local problems of food production and consumption. The diversity of these problems needs to be reflected in the diversity of scientific approaches used to tackle them. Rather than focusing on particular scientific tools and techniques, the approaches should be evaluated in terms of their outcomes.

It might well be that we arrive sooner than expected from a period of disillusionment to an eventual understanding of the technology's relevance and role in a market or domain.

Innovation in Agriculture on all Levels will Speed up and Makes it a Necessity to Rethink Regulation Basically and Radically, most Often in the Direction of Lowering the Regulatory Hurdles

Unfortunately, regulatory legislation is in its nature static, needs a long time to be settled in international negotiations, and then, finally, settled and approved with an important number of signatory states as the Cartagena Protocol; therefore, it is nearly impossible to make the necessary changes based on good science. At the time of the establishment of the Cartagena Biosafety Protocol, the similarities between nontransgenic and transgenic organisms on the molecular level were not widely known, although properly published (see latest review with early publications [19]), and a correction about these grave errors (recently called by the author as "Genomic Misconception," publication in preparation) in concept is now nearly impossible – details in section GM- and Non-GM-Crop Differences Over-Estimated, the "Genomic Misconception". But the situation is not getting better: the accelerating speed of scientific progress and discoveries used for new (agricultural) technologies is breathtaking. A short overview is provided in the following sections.

New Biotechnology Approaches in Plant Breeding, Introduction In an early paper, Britt et al. give an overview on many molecular possibilities which will develop for new breeding successes [20], they address the current status of plant gene targeting and what is known about the associated plant DNA repair mechanisms. One of the greatest hurdle that plant biologists face in assigning gene function and in crop improvement is the lack of efficient and robust technologies to generate gene replacements or targeted gene knockouts. They also face an old problem in plant breeding summarized under the complex term of epigenetics [21, 22], a problem corrected in conventional plant breeding by careful and often tedious selection processes. Unfortunately, opponents abuse epigenetics as a seemingly new problem for genetic engineering [23], avoiding the mention of modern molecular insight and its ease to correct such problems in a more targeted way. It is clear that transgenesis will remain a solid technology for breeding, but new approaches will appear – as science is always open for progress and new breakthroughs. Here, we only mention shortly progress from another more holistic perspective of systems biology: the dynamics of Metabolomics [24], and also the growing speed of discovery in proteomics [25], techniques which will increasingly augment more common types of experimentation, especially as they provide the capacity of generating data sets that can be compared across studies and laboratories [26], and because quantitative proteomics data are generated with unprecedented sensitivity, accuracy, and reproducibility. There are many new biotechnologies enhancing the speed of achieving targeted breeding successes such as the high throughput marker finding technology [27, 28], only a few can be mentioned here:

***Cis*- and Intragenic Approaches** A new technology has now proven to be a successful strategy: As Romments describe it, cisgenetics is a welcome way of combining the benefits of traditional breeding with modern biotechnology. It is an understandable enthusiasm of the first researchers using this technology to emphasize the positive sides by also comparing to transgenesis as an "old-fashioned" method with its problems. But things are certainly not so easy: In sections Molecular Processes Similar in Natural Mutation and Transgenesis and Dissent Over Differences Between GM- and Non-GM Crops Causes Transatlantic Regulatory Divide, it is made clear that on the genomic level, particularly on the level of molecular processes, there is no difference between transgenic and nontransgenic crops (supported by an important body of scientific literature), and this is certainly also true to cisgenic and intragenic varieties. This is why it is questionable and based on false grounds to make claims that those new methods in transformation would be safer, as Giddings has made it clear in his letter [29], and his arguments against the views of [30–32] and later publications [33–35] could have been targeted as well: they try to demonstrate that the new cisgenics and intragenics are safer than transgenics, which is not

based on any facts, rather it is based on accepting without scientific scrutiny the negative public perception on transgenic crops. It is also wrong to use without clarification the term "alien genes" in view of confirmed and widely accepted universality of DNA and genomic structures.

However, there is nothing to say against the application of such new methods per se, as [33, 34] can demonstrate:

- The classical methods of alien gene transfer by traditional breeding yielded fruitful results. However, modern varieties demand a growing number of combined traits, for which pre-breeding methods with wild species are often needed. Introgression and translocation breeding require time consuming backcrosses and simultaneous selection steps to overcome linkage drag. Breeding of crops using the traditional sources of genetic variation by cisgenesis can speed up the whole process dramatically, along with usage of existing promising varieties. This is specifically the case with complex (allo)polyploids and with heterozygous, vegetative propagated crops. Therefore, we believe that cisgenesis is the basis of the second/ever green revolution needed in traditional plant breeding. For this goal to be achieved, exemption of the GM-regulation of cisgenes is needed.

Reverse Screening Methods: Tilling and Eco-Tilling Two rather independent publications [36, 37] with largely incongruent literature lists promote a new technology of finding useful genes within the genome of the crops involved: They both promote powerful reverse genetic strategies that allow the detection of induced point mutations in individuals of the mutagenized populations, can address the major challenge of linking sequence information to the biological function of genes, and can also identify novel variation for plant breeding [37]. Rigola et al. [36] develop reverse genetics approaches which rely on the detection of sequence alterations in target genes to identify allelic variants among mutant or natural populations. Current (pre-) screening methods such as *tilling* and *eco-tilling* are based on the detection of single base mismatches in heteroduplexes using endonucleases such as CEL 1. However, there are drawbacks in the use of endonucleases due to their relatively poor cleavage efficiency and exonuclease activity. Moreover, prescreening methods do not reveal information about the nature of sequence changes and their possible impact on gene function. Rigola et al. [36] present a *KeyPointTM* technology, a high-throughput mutation/polymorphism discovery technique based on massive parallel sequencing of target genes amplified from mutant or natural populations. Thus, *KeyPointTM* combines multidimensional pooling of large numbers of individual DNA samples and the use of sample identification tags ("sample barcoding") with next-generation sequencing technology. Rigola et al. [36] can demonstrate first successes in tomato breeding by identifying two mutants in the tomato eIF4E gene based on screening more than 3,000 M2 families in a single GS FLX sequencing run, and discovery of six haplotypes of tomato eIF4E gene by re-sequencing three amplicons in a subset of 92 tomato lines from the EU-SOL core collection. This technology will prove to be useful and does not need for its own breakthrough to refer to a scientifically unjustified critique of transgenesis. Whether the new technology will replace the transgenic "Amflora potato" has still to be proven by further scrutinizing of the results of the equivalent trait [38].

Zinc Finger Targeted Insertion of Transgenes Plant breeding has gone through dynamic developments, from marker-assisted breeding to transgenesis with steadily improved methods to the latest development of the Zink-finger enzyme-assisted targeted insertion of transgenes in complex organisms [39–42]. Zinc-finger nucleases (ZFNs) allow gene editing in live cells by inducing a targeted DNA double-strand break (DSB) at a specific genomic locus. However, strategies for characterizing the genome-wide specificity of ZFNs remain limited. According to [43], comprehensive mapping of ZFN activity in vivo will facilitate the broad application of these reagents in translational research.

The development toward more insertion precision and less genomic disturbance is so rapid that promoters of organic farming will see dwindling one of their pet arguments even more rapidly: Genomic disturbance of modern breeding is certainly less important and will even be negligible compared to the old breeding methods, still promoted stubbornly by the

organic plant breeding community [44]: It is very likely that the transcriptomic disturbances will be even smaller in future – compared to the clumsy and tedious methods of conventional breeding, see also the latest developments in sections TALEs: Transformation Method Transcription Activator-like Family of Type III Effectors and Precision Engineering Through DNE Meganucleases below.

TALEs: Transformation Method Transcription Activator-like Family of Type III Effectors The generation of double-strand DNA breaks (DSBs) promotes homologous recombination in eukaryotes and can facilitate gene targeting, additions, deletions, and inactivation. Zinc-finger nucleases have been used to generate DSBs and subsequently for genome editing, but with low efficiency and reproducibility. In contrast, the transcription activator-like family of type III effectors (TALEs) contains a central domain of tandem repeats that could be engineered to bind specific DNA targets. The new method is capable of generating site-specific DNS Breaks and has great potential for site-specific genome modification in plants and eukaryotes in general [45]. See also comments on the newswire CNBS [46] on the discovery:

- Dr. Mahfouz has developed a "repair tool" (molecular scissors) made out of protein that does two things: it finds the exact place on the genome where it is to be cut using a genetic "postcode" and then deletes, adds or edits the gene with great accuracy and precision.

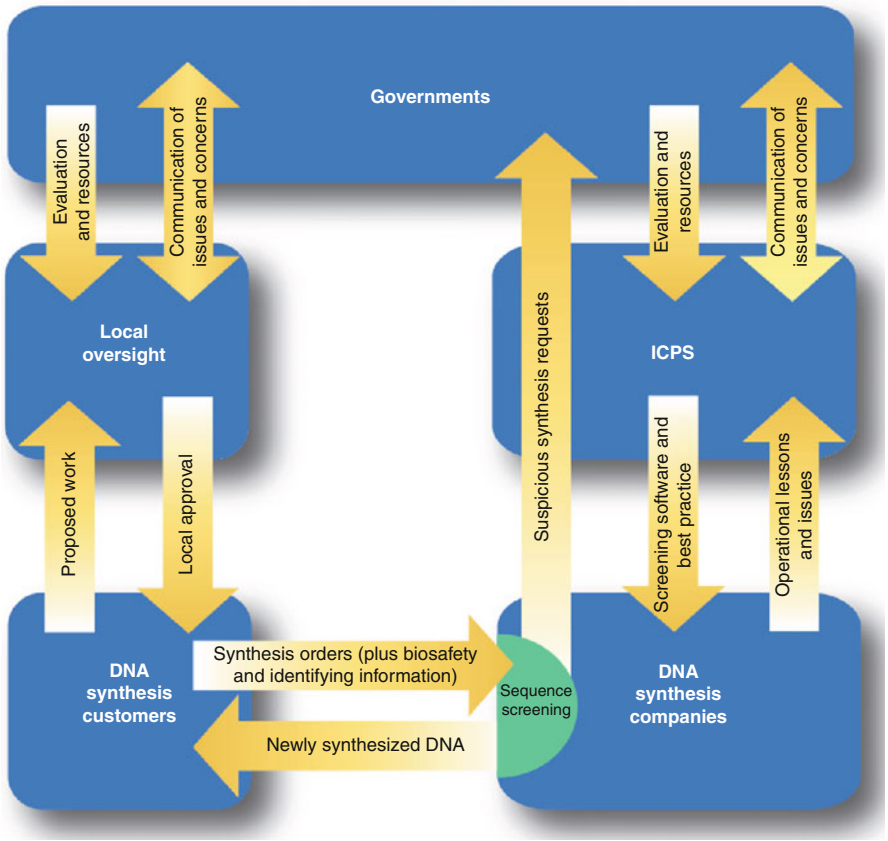
  Dr. Mahfouz's work has the potential for much broader applications including human health. This new technology could enhance the technique that may be used to substitute "good" genes for bad, or to cut out or silence the defective genes that cause disease.

  Commenting on the research, KAUST Provost Stefan Catsicas saw the technology as a scientific breakthrough and, if the patent is eventually successful, having potentially promising revenues. Dr. Nina Fedoroff, Professor of the Life Sciences at Penn State University, said the Mahfouz paper "shows the practicability of creating DNA-cutting enzymes tailored to cut a desired target sequence with very high specificity. This is an excellent step forward toward creating very specific genetic improvements in crop plants, while avoiding the potential risks many are concerned about with more conventional genetic modification strategies. Moreover, the paper gives the first evidence that this particular strategy will work in plants." Professor Fedoroff is "delighted to see such cutting-edge contributions emerging from a university as young as KAUST!".

Precision Engineering Through DNE Meganucleases Engineered DNE meganucleases can be used for cloning and molecular analysis purposes in much the same ways as conventional restriction enzymes. The important difference, of course, is that meganucleases recognize much rarer DNA sequences than restriction enzymes. This makes them particularly well suited to the manipulation of extremely large DNA sequences such as intact genomes. Importantly, DNE meganucleases cleave to leave four base pair 3' overhangs suitable for "sticky-end" cloning. The first application with a new tool called Directed Nuclease Editor™ in plant breeding by Bayer Crop Science http://www.precisionbiosciences.com/ seems promising: The meganucleases have been first used to do precision work in human gene therapy, but an outlook into various other applications was announced as early as 2003 [47–49].

Synthetic Biology In some 150 laboratories, synthetic biology is intensively researched, and it seems clear that the future will bring here some unexpected revolutions: A new field, synthetic biology, is emerging on the basis of these experiments [50], where chemistry mimics biological processes as complicated as Darwinian evolution. According to [51], the emerging field of synthetic biology is generating insatiable demands for synthetic genes, which far exceed existing gene synthesis capabilities. Tian et al. claim that technologies and trends potentially will lead to breakthroughs in the development of accurate, low-cost, and high-throughput gene synthesis technology – the capability of generating unlimited supplies of DNA molecules of any sequence or size will transform biomedical and any biotechnology research in the near future. And, according to [52], already in 1998 the redesigning of nucleic acids has been judged in an optimistic way, this was confirmed in an important Nature review in 2005 [53].

The real breakthrough came with the synthesis of an organism including its reproduction, achieved after



GM Crop Risk Debate, Science and Socioeconomics. Figure 2

Our framework calls for the immediate and systematic implementation of a tiered DNA synthesis order screening process. To promote and establish accountability, individuals who place orders for DNA synthesis would be required to identify themselves, their home organization, and all relevant biosafety information. Next, individual companies would use validated software tools to check synthesis orders against a set of select agents or sequences to help ensure regulatory compliance and flag synthesis orders for further review. Finally, DNA synthesis and synthetic biology companies would work together through the ICPS, and interface with appropriate government agencies (worldwide), to rapidly and continually improve the underlying technologies used to screen orders and identify potentially dangerous sequences, as well as develop a clearly defined process to report behavior that falls outside of the agreed-upon guidelines. ICPS, International Consortium for Polynucleotide Synthesis (From [58])

years of research and a firm belief in success, typical of the senior author of the mega project still continuing, [54–57].

A pragmatic view of a new regulatory scheme answering the new biosafety tasks of synthetic biology is proposed by [58] (Fig. 2):

This kind of new regulatory approach will be necessary in order to avoid unnecessary hindering of research progress in synthetic biology, a demand supported with other innovative suggestions for interactive procedures [59]. Another balanced view [60] demonstrates also the new risks arising from synthetic organisms and the accidental (or purposeful) release in the environment. As always, the ethical awareness and behavior has to be developed further, agreeing with [61] not in a way which gives forfeit power to social sciences. What we really need is a new interfaculty, interdisciplinary or, even better, transdisciplinary discursive scheme as proposed in sections Long Term Discourse and Decision Making

Processes and The Second Generation Systems Approach as a New Decision Making Process.

What happened some 35 years ago in the US National Institute of Health in the words of Henry I. Miller [62] should be a warning.

> Thirty-five years ago, the US National Institutes of Health adopted overly risk-averse guidelines for research using recombinant DNA, or "genetic engineering," techniques. Those guidelines, based on what has proved to be an idiosyncratic and largely invalid set of assumptions, sent a powerful message that scientists and the federal government were taking seriously speculative, exaggerated risk scenarios – a message that has afflicted the technology's development worldwide ever since.

A final remark: In a way, the artificial altering of genes producing Bt toxins can, strictly spoken, also be summarized under synthetic biology since the specifically altered Bt toxins in order to facilitate resistance management of Bt crops: Bruce Tabashnik, who works on problem solving programs for Bt crops with field research and new concepts of resistance management [63]: Relative to native toxins, the potency of modified toxins was >350-fold higher against resistant strains of *Plutella xylostella* and *Ostrinia nubilalis*. Previous results suggested that the modified toxins would be effective only if resistance was linked with mutations in genes encoding toxin-binding cadherin proteins [64]. Tabashnik et al. report evidence from five major crop pests refuting the Soberon hypothesis.

Illusions and Realities on Educational Effects in the Debate, the Dialogue Between Science and the Public

There is no doubt that there is hope and need to simply start and/or maintain an open dialogue between major stakeholders among young scientists, politicians, industry, and society [65], although there are many obstacles such as asymmetric relationships among the partners, which can render the discourse complex and unpredictable. And it is uncontested here that education on all school levels has its justified place; this has again been shown with empirical results from Spain [66, 67]. Gensuisse should also be mentioned here with educational activities in schools and a popular open day of Genetics in major Swiss cities organized by researchers and institutes every year [68]. And education on biotechnology in the developing world is especially important, if done in a participative way, and with proper ramifications in all institutions of communication, science, and regulation: In April 2007, biosafety and biotechnology scientists, regulators, educators, and communicators from Kenya, Tanzania, and Uganda met to examine the status and needs of biosafety training and educational programs in East Africa [69].

Thus, educational efforts on all levels are not in vain, and deplorably there are too few academic institutions active in biotechnology education [70]. The structure of the debate has shifted: Today, the GM crop debate is steered by scientific *and* pseudoscientific arguments. And this also includes an element of hope for the pro-scene: Slowly but surely the pseudoscientific arguments are fading away for the opponents, since there is no serious incident known despite the fact that millions of hectares are grown with GM crops worldwide [71].

There is a widespread mistrust against new technologies where everybody feels it will change their own life, and this often happens in a phase where the benefits are not yet clearly visible, especially for the consumers/users. But it is not correct to reduce those difficulties to an exclusive criticism of the so-called deficit model [72–74] where the people just have to be educated and then they would refrain from negative emotions. A question mark on the exclusive use of the "deficit model" is justified, but surprising conclusions emerge from the above-mentioned critics themselves: They do not discard altogether the traditional deficit model, rather they propose to combine it with the *contextual approach*, thus emphasizing the complex and interacting nature of the knowledge-attitude interface. This highlights the sophistication and value of lay understandings of science that can exist in the absence of formal scientific knowledge [75, 76]. Surprisingly, positive are results of polls which are conducted by Philip Aerni with more closeness to the real life and careful avoiding of polling mistakes [77], the study concludes:

> The results of our discrete choice analysis show that Swiss consumers treat GM foods just like any other type of novel food. We conclude from our findings that consumers tend to appreciate transparency

> and freedom of choice even if one of the offered product types is labeled as containing a genetically modified ingredient. Retailers should allow consumers to make their own choice and accept the fact that not all people appear to be afraid of GM food. [77]

There is growing consensus that scientific knowledge extends beyond the simple learning of "facts" that can be straightforwardly defined and measured [78]. From this perspective, privileging formal scientific knowledge as the sole basis of rational preference formation leads us to overlook other knowledge domains that may be equal or even more important determinants of attitudes toward science.

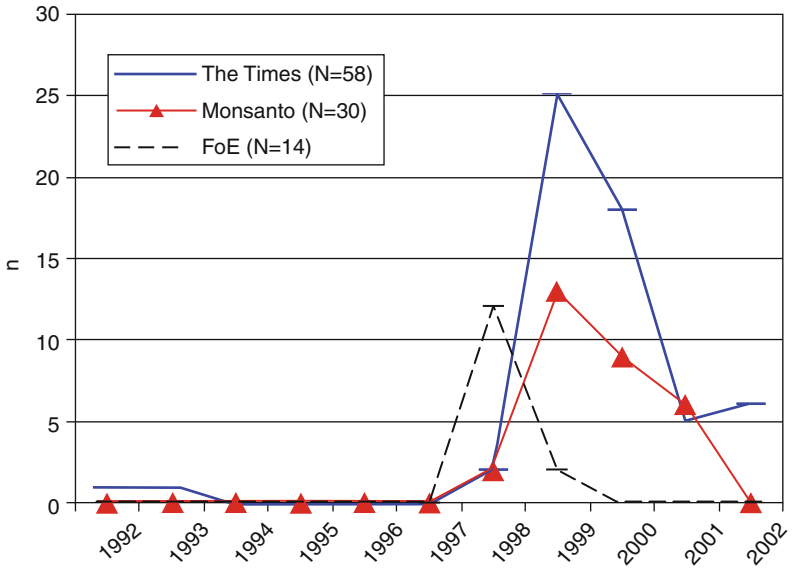
These insights have been condensed into a feasible discursive method of the *Systems Approach* initiated by Churchman [79] and refined by Rittel et al. [80–82]. Details on the methodology are given under sections Long Term Discourse and Decision Making Processes and The Second Generation Systems Approach as a New Decision Making Process, where the *solutions* are discussed.

It is an illusion to solve ill-fated GM-disputes by just adding social and cultural aspects, or that the dispute should, so to say, start from the other end of the controversy ignoring the biosafety science [83] or even worse to primarily appeal to feelings and emotions of the public and indulge in entertaining but ultimately meaningless discussions in order to catch the interest of the public – we should not mimic the strategy of the protest corporations. That said, this does not mean that sociocultural aspects including emotions should be neglected – even the boulevard press sends out strong signals for learning processes. Vaughan's [84] plea is that regulatory officials should engage in an interactive process of information and opinion exchange that is reasonable and effective within vastly different socioeconomic and cultural contexts, This is often a challenge to government employees concentrating on office work routine. Patricia Osseweijer [85, 86] offers an interesting compromise: a mix of science, ethics, and emotions with her "Three E-Model" Entertainment (getting attention), Emotion (identification), and Education (information and skills for [future] decision making). It has been developed on the basis of long-term experience and observation of public communication by individuals in the Department of Biotechnology of the Delft University of Technology [87, 88].

Despite all possible refinements and enhancements in the dialogue with the public, we should not underestimate the negative role of the opponents of genetic engineering in plant breeding organized as professional protest corporations, see section The Costs and Loss Benefits of Overregulation.

How the Internet is Influencing the Debate The Internet as a worldwide literacy practice environment is still underestimated, nevertheless it has created a new situation in communication, providing a new dynamic field for research and knowledge accumulation [89]. It has created an Internet-based debate culture with all its ramifications from classic email over blogs and better organized social media to twitter and this not only in nanotechnology [90], but also in other research realms and E-business [91]. The evolution in this kind of debate is still going on with unprecedented dynamics and is not yet fully understood in all its consequences [92], [93], and [94]. The hope is that easier communication through the Internet will invite a *collaborative* instead of *confronting* modus [95]. Some advice on how to behave in chats and blog debates on the Internet might be useful [96]; compare a list of useful websites and databases on biosafety by DeGrassi et al. [97] and [98]. A list of pertinent websites can be expanded ad libitum, the present state of error of 2011, with all the personal bias in [99].

Informatics and the new ease to access huge amounts of scientific information on the Internet causes a democratization effect on the science debate. But this can only then lead to positive developments if the new flood of information is also well organized and provided people make serious efforts to analyze the available information, so that our understanding of complex scientific knowledge can indeed be improved. As Janetzko (2008) shows, it is not enough to make use of the most common search machines, only professionally organized searches and databases on scientific literature can help and create some limited reliability and sustainability of scientific knowledge. And: clearly, the usual citation clusters among opinion-buddies will not suffice. And it should be emphasized: Electronic ease does not replace the tough job of scholarly reading and



GM Crop Risk Debate, Science and Socioeconomics. Figure 3
Web site pages addressing the "Frankenfood" and "Frankenstein food" issues at Monsanto, the *Times*, and the Friends of the Earth Web sites. jcmc.indiana.edu/vol8/issue4/hellsten.html

understanding. It will be a difficult task for the future to divide up clever knowledge accumulation and genuine thinking work among active scientists. A caveat already signaled by Seneca: Thoughtful Action creates more wisdom than knowledge accumulation, can be interpreted related to social electronic networking in two ways: On one side, the immense intensification of social networking via the Internet creates among other things a new possibility for post-publication reviewing and filtering out the really relevant publications and ideas. On the other hand, it hinders systematically the deepening of your own knowledge in an individual way, and be it only by reading every year a dozen or two really relevant book publications.

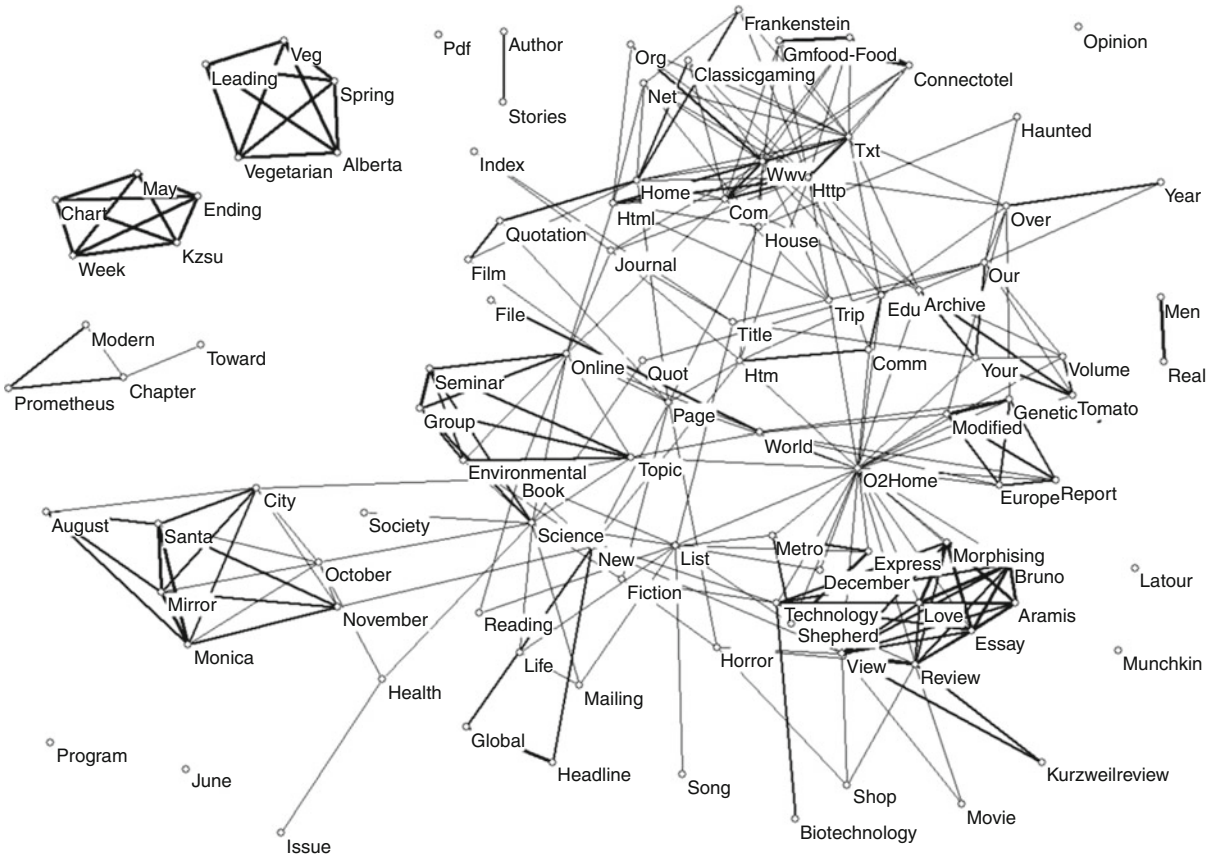
This major shift from paper to electronics is also creating new methods of *quantitative* analysis of scientific work: see the Scientometrics Wikipedia: http://en.wikipedia.org/wiki/Scientometrics. Actually, this newly emerging science can provide with caveats and insights into changes in research priorities, reveal citation habits, evaluate journals with new scales, etc. [100–103]. A typical example is given in the analysis of the coming and going of the Frankenfood myth [104], with a somewhat surprisingly early and sharp peak of appearances of the word Frankenfood in websites for 1998, followed by a sharp decline to virtually zero 2 years later (Fig. 3).

This figure is confirmed in [104] with the following statements and figures (Figs. 4 and 5):

The comments in [104]:

- Our interpretation of these results is as follows: the decline of the organizing power of the metaphor was rapid in 1999 and 2000 when the metaphors of 'Frankenfood' and 'Frankenstein food' began to be outdated. Due to its generalized meaning, the metaphor was used increasingly across domains and therefore lost its domain-specificity and the ability to organize distinctions among domains. This might also explain why the NGOs stopped using the metaphor in 2000 (HELLSTEN, 2003). From [104]

Scientometrics can do much more, [105] have shown the potential of a sophisticated statistical analysis combined with modeling of community interactions in the web: Besides tracking just the description-to-acquisition behavior of users, scientometrics can do much more by longer observation periods which offers the chance to make richer inferences about both group and individual user intentions – trends of intruding into human behavior and making



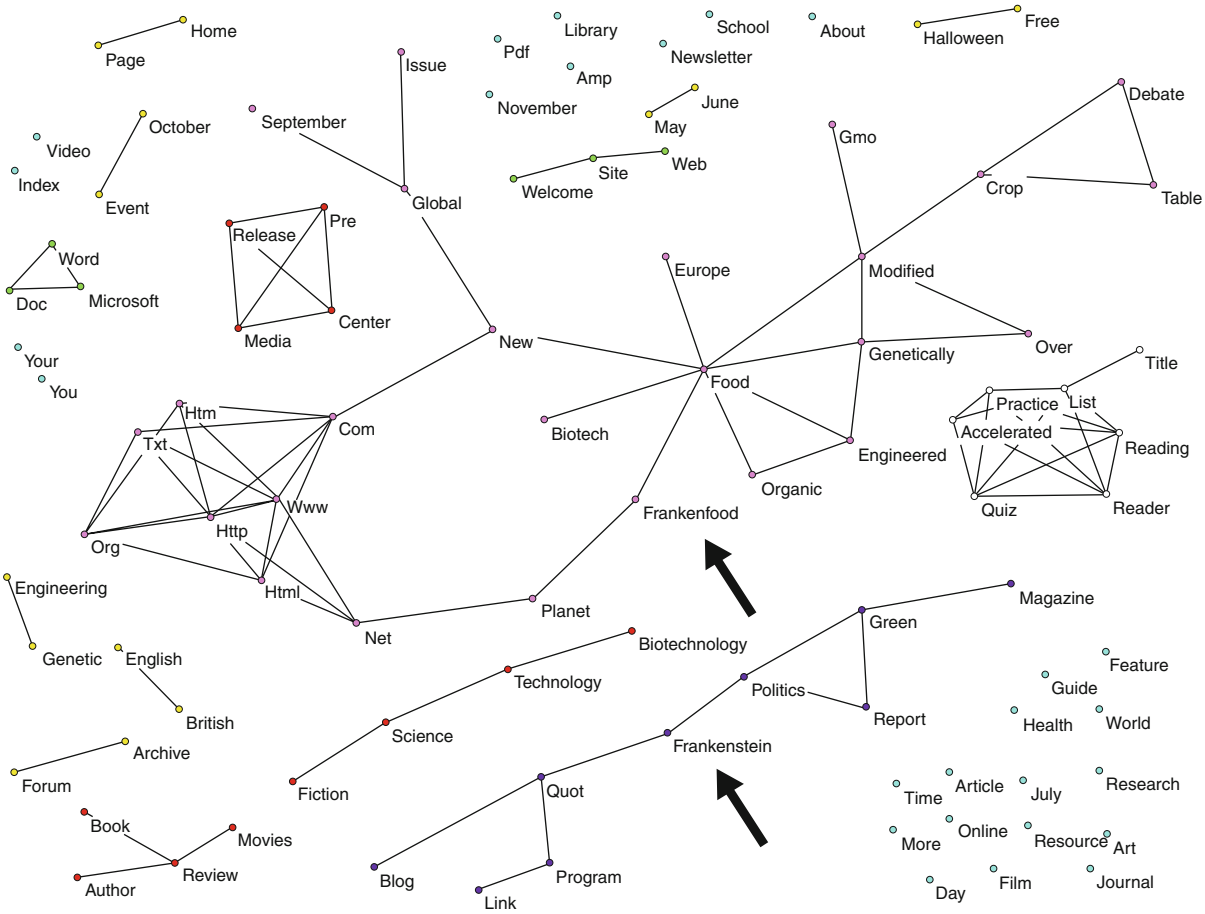
GM Crop Risk Debate, Science and Socioeconomics. Figure 4
The cosine map of 107 words used more than once in the 205 documents on Frankenfoods in 1999 (cosine $\geq$ 0.1) (From [104])

conclusions, which are actually beyond Orwell's imagination. Yet we should have no illusions, since a lot of work and application is already going on in the marketing and advertisement scene, which has also an often manifested interest in knowledge accumulation methods [106, 107]. It is somehow amazing to realize that the academic world in most fields of specialization have not yet reached the realms of professional knowledge accumulation and consolidation – not to speak about an efficient way of reaching out from knowledge accumulation to efficient development of new technology. Scientometrics would have the potential to get instrumentalized in research and development, with some good chance to be used also in new peer review processes.

A *qualitative* evaluation of science should involve additional elements – see below under peer review in the section Developments in Risk Handling of GM Crops on regulation.

Deplorably, important networks are often only known in specific reader clusters, these awareness gaps should be minimized. We need knowledge exchange, jumping over geographical and ideology fences.

Science Education and New Developments on the Internet In a successful initiative, Ron LaPorte and his group "Supercourse" started in 2002 [108] a new educational Internet-based system: In his view, Journals do not have an exclusive "right" to science. A publication and a scientific presentation do virtually the same thing – they share scientific knowledge. Publication and presentation have been separate but could "morph" into a single entity. This metamorphosis is taking place and is driven by a juggernaut called



GM Crop Risk Debate, Science and Socioeconomics. Figure 5
The cosine map of 100 words used more than 31 times in the 6,101 documents on Frankenfoods in 2003 (cosine $\geq$ 0.1) (From [104])

PowerPoint, Microsoft's graphics and slide presentation software, and today enriched with more media from Twitter over YouTube to all the numerous blog systems, networking enhanced with RSS, etc. More on the Supercourse program in [109–113], also in connection with the Bibliotheca Alexandrina in Egypt: [114] Another possibility on a well-organized collection of Powerpoint slides is offered for free by the University of California by Peggy Lemaux and Barbara Alonso, University of California http://ucbiotech.org/resources/slide_archive/index.html. A series of over 100 slideshows is offered by the bibliography of the author; new slide shows are continuously added, they can be downloaded from [115]. An important new development started 2002 at the Bibliotheca Alexandrina, where a new world center of electronic knowledge is emerging, which is based on thoughtful new structures [116].

On Biosafety Education Biosafety is today a permanent topic on local, national, and international level, and basically, it is good to see educational activity. As demonstrated in this contribution, the topic of biosafety is highly controversial, and so are the views on the various educational activities. The most blatant misunderstandings in biosafety education stem again from the "Genomic Misconception," which forces authors seemingly to focus on transgenic crops alone, which is scientifically unacceptable as we will see in section GM- and Non-GM-crop Differences

Over-estimated, the "Genomic Misconception". A symptomatic example on the enumeration of risks related to transgenic crops is given by Craig et al. [117]: All risks duly mentioned can be attributed just as well to conventional crops. The only difference between modern and conventional breeds can be found in risk mitigation, which is much easier in the case of the transgenic crops. Here, just two recent examples related to the successful prevention of upcoming resistant pest insects (a problem arising in all kinds of agricultural management systems): [63] and [11]. It is deplorable, that most biosafety education is still based on the erroneous "Genomic Misconception," which results automatically into a biosafety risk view focusing on the process of transgenesis instead of working on a product-oriented basis. More about the "Genomic Misconception" is discussed in section GM- and Non-GM-crop Differences Over-estimated, the "Genomic Misconception".

Proposal for a Website of Websites There are simply too many websites (see ASK-FORCE Organization and Related Websites) and not enough coordination, so there is a need for networking structures among the most important websites, a *network of networks* with all the fancy new buttons available like RRS, etc. There should be a place where people see with one glance on the first page what news they can expect on various important sites. It should also not be difficult to add possibilities for an individual choice.

Those website connection activities need professional support with some secretarial/managerial help. We must work out ways in which the broad public can easily reach rebuttals on all the myths, facts, and benefits in the debate on green biotechnology. It will not be difficult to establish a platform for a better communication among the most important websites – in the field of agricultural biotechnology, there are a few very successful ones, but this is not the whole task. We need to look deeper into the theory of networks in order to be really successful; comprehensive reviews demonstrate how complex the networking task really is [118, 119].

As of now, this is just an idea and needs to be discussed with Internet and website specialists. One of the main difficulties will be to establish permanent existence, this is why it would be best to use structures having proofed long years' activities and assured permanence, such as ISAAA, the International Service for the acquisition of Agri-Biotech Applications, www.isaaa.org. After all, the leading webmasters and coordinators agree that it is time to *enhance collaboration through better communication*, see section ASK-FORCE Organization and Related Websites. ASK-FORCE. The task on uniting the most relevant websites and blogs should not be underestimated, see the list already given above [99].

Developments in Risk Handling of GM Crops

General Views on the Dialogue Related to Regulation of GM Crops

The dialogue between scientists and regulators is very complex, as accurately described by Saner [120]. This should be a reminder that it is not about facts alone:

- It should be clear without explanation that each and every rational decision is a combination of facts and values – a decision requires judgment. The agents of judgment are, of course, people, and this leads us to an entirely different interface – that between scientists and policy-makers.

We should keep this in mind when we concentrate here on the *science* of GM crop regulation. See also the analysis of the debate in The General Strategic Situation of the Debate About Green Biotechnology Today. These philosophical thoughts of Saner are at the basis of the discursive methodology for complex decision-making processes, [121–123]. For details, see below in this contribution in sections Long Term Discourse and Decision Making Processes and The Second Generation Systems Approach as a New Decision Making Process.

A valid overview on the regulatory science and traceability related to GM crops has been published by Gasson and Burke [124, 125], there is no intention to repeat these reviews.

Biotechnology and Economics

How Economics Are Influencing the GM Crop Debate The example of the Flavr Savr Tomato demonstrates that in earlier times, even in Europe, GM food was well received, but several factors just made it clear

that economic success was missing [8, 126–128]. And regulation of this pioneer work needs to get a new look; with modern screening methods, the gene silencing on the molecular level revealed some surprises [129].

Economics play a very important role in the process of technology acceptance: This can be illustrated with the present day feed import situation in Europe. First it should be mentioned, that it is the trade policy of Europe still going the wrong way, which causes a lot of difficulties in the transatlantic dialogue: As Graff et al. [130] explain:

> ▶ European policies blocking genetically engineered crops are conventionally attributed to the concerns of European consumers, but they can be attributed to the self-interests of European industry and farmers as well. Biotech policies maintained in the name of consumer interests are helping European chemical firms to slow their losses in the global crop protection market and are helping European farmers differentiate their conventional crops on environmental and safety grounds, maintain their agricultural subsidies and win new non-tariff trade protections.

The recent development in feed supplies, see Lawrence in *The Guardian* [131], in the EU provides argument, and the reports and letters below give excellent examples:

- Food Chain Dossier 2009: http://www.botanischergarten.ch/Feed/Food-Feed-Chain-Dossier-20090616.pdf
- DG AGRI feed report: http://www.botanischergarten.ch/Feed/EC-DG-AGRI-Rep-feed-situation-UnapprovedGMOs-200709.pdf
- EU Report on Pipeline: http://www.botanischergarten.ch/Feed/Stein-EU-Report-GMO pipeline-LLP-2009.pdf
- Letter to the President of the EU Commission Barroso: http://www.botanischergarten.ch/Feed/Letter-big-Producers-Tolerance-Value-Barroso-20090624.pdf

Strict labeling and thus a discrimination of European meat from animals fed with GM crops will soon be impossible as a political goal due to *economic* reasons – as it is also scientifically not justifiable [132, 133].

An interesting thesis with economic arguments is promoted by Paarlberg [134]: Today, Africa's production of GM crops is exported mainly to other African countries, and this might go on this way in the coming years, so the reasoning that Africans would destroy export opportunities to Europe by developing their own GM crops is not really convincing. But in reality, there is growing concern: Commercial fear over potential loss of export sales to Europe and East Asia is also a reason for mounting pressure on biosafety approvals in developing countries. Consumer misgivings toward GM food in rich countries combined with restrictive import and labeling policies are prompting GM-free agricultural production in developing countries. The long-term costs of these negative trends could be enormous [135]. Good arguments for this view are produced with lots of facts on economics and negative labeling effects of European developed countries, published by Gruère et al. [136–138]:

> ▶ In this context, the marketing decision of avoiding GM ingredients in food items rapidly became a quality attribute employed in the competition among the retails chains of Europe, Japan and South Korea. A report by the international NGO, Greenpeace, which has encouraged companies to adopt GMfree policies, provides evidence of the widespread adoption of such practices in Europe [139] as follows:
>
> - Fourteen of these retailers have a policy of not selling GM-branded products under their company name for all European countries. These include Carrefour, Auchan, Sainsbury's, Safeway, Marks & Spencer, Coop Switzerland, Coop Italia, Migros, Big Food Group, Somerfield, Morrison's, Kesko, Boots, and Co-op UK.
> - Seven of these retailers have a non-GM policy for their own branded products for their main markets (mainly in their home countries). These include Tesco, Rewe, Metro Group, Casino, Edeka, Schwarz group, Tengelmann).
> - Out of the top 30 European food and drink producers, 22 have a non-GM commitment in Europe, including Nestle, Unilever, Coca Cola, Diageo, Kraft Foods (Altria), Masterfoods (Mars), Heineken, Barilla, Carlsberg, Dr. Oetker, Arla Foods, InBev (Interbrew), Heinz, Chiquita, Cirio del Monte, Orkla, Ferrero, Northern Foods, Eckes Granini, Bonduelle, Kellogg and McCain.

- Thirteen of these 22 multinationals have a company-wide non-GM policy beyond Europe. These include Diageo, Heineken, Barilla, Carlsberg, Arla Foods, Dr. Oetker, Chiquita, Cirio del Monte, Orkla, Ferrero, Northern Foods, Eckes Granini, and Bonduelle [138].

Some companies even go beyond banning processed products derived from GM ingredients to include requirements on GM-free animal feed in animal products. Virtually all supermarkets sell only poultry fed with non-GM feeds, whereas the policies for dairy products, beef, and pork vary. The usual crude Greenpeace mix of facts and interpretation helped efficiently to push the companies for the European market to go GM crop free [139, 140]. The simple fact of labeling allows opponent NGOs to drive a polemic campaign of pompous "contamination" reports, thus delivering junk science "evidence" that there is some risk involved in the numerous events of minute admixtures of transgenes traces.

In India, there is a clear positive trend visible since some years after some difficulties in the beginning because local traits had to be created for the many Indian regions and also because there was right from the beginning a black market with illegal cotton traits developing (which often did better commercially than the legal ones. Presently, there are 38 traits of GM cotton in India [141].

The whole complex story has been recently summarized by [142]:

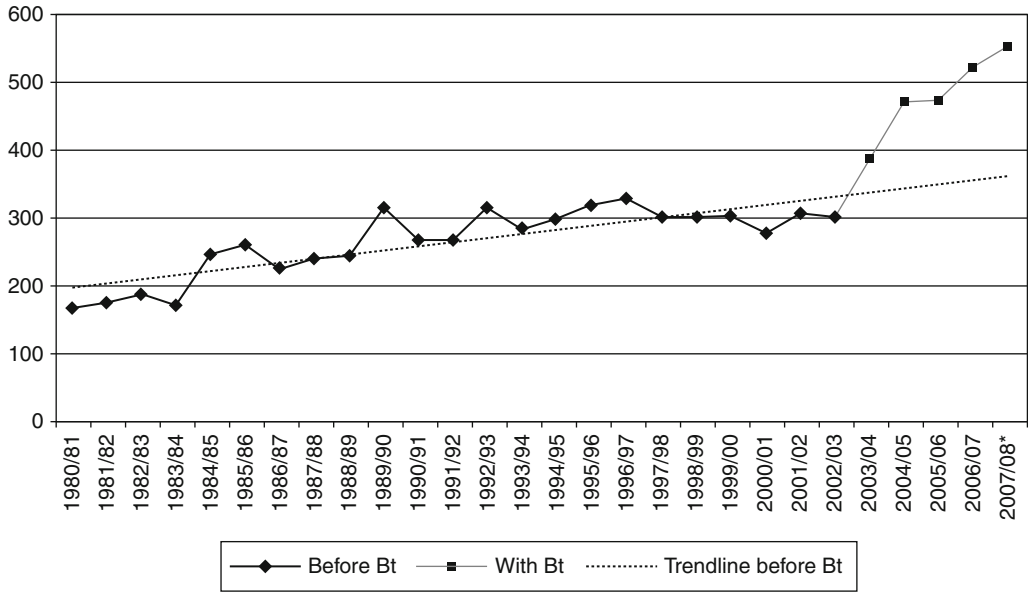
- On average, Bt-adopting farmers **realize pesticide reductions of roughly 40%, and yield advantages of 30-40%. Profit gains are at a magnitude of US $60 per acre**. These benefits have been sustainable over time. Farmers' satisfaction is reflected in a high willingness to pay for Bt seeds. Nonetheless, in 2006 Indian state governments decided to establish price caps at levels much lower than what companies had charged before. This intervention has further increased farmers' profits, but the impact on aggregate Bt adoption was relatively small. Price controls might have negative long-term implications, as they can severely hamper private sector incentives to invest in new technology. [142]

At the end of the day the profitability of Bt cotton is now uncontested, see comments of Müller-Jung Frankfurter Allgemeine: [143]

Also the old wrong connection between suicides of Indian farmers and the introduction of GM cotton in India has been thoroughly falsified [144, 145]. This does not hinder activists like Vandana Shiva from continuing with cheap propaganda linking GM crops with the sad tradition of farmers' suicides in India, which started decades before the introduction of GM crops and beginning activities of multinational seed companies. Here are two of the many graphs from [145] (Figs. 6 and 7):

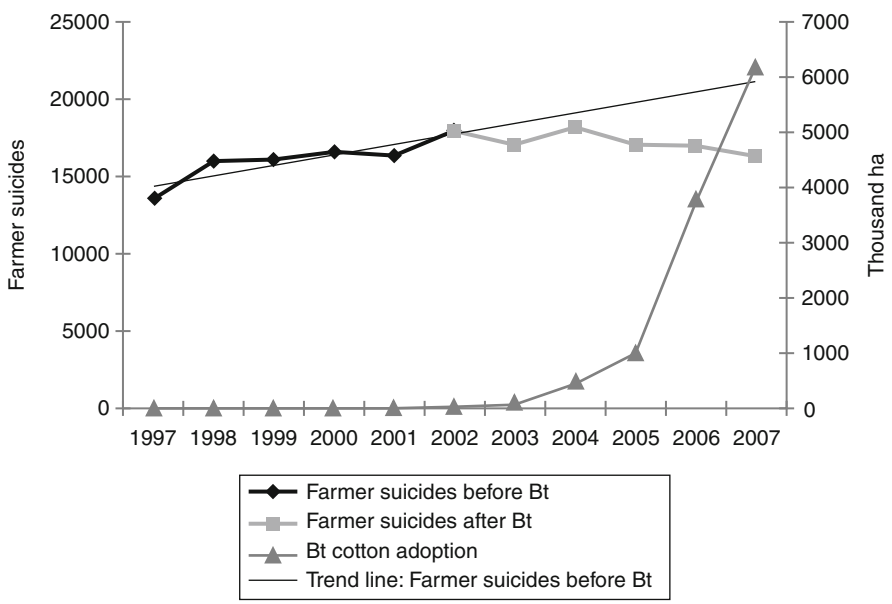
- **Abstract.** Bt cotton is accused of being responsible for an increase of farmer suicides in India. In this article, we provide a comprehensive review of evidence on Bt cotton and farmer suicides. Available data show no evidence of a 'resurgence' of farmer suicides. Moreover, Bt cotton technology has been very effective overall in India. Nevertheless, in specific districts and years, Bt cotton may have indirectly contributed to farmer indebtedness, leading to suicides, but its failure was mainly the result of the context or environment in which it was planted [145].

- **From the discussions.** The absence of irrigation systems in drought-prone areas (especially in Maharashtra), combined with specialisation in high-cost crops, low market and support prices, and the absence or failure of the credit system, is a clear recipe for failure. It is possible, therefore, that under the conditions in which it was introduced, Bt cotton, an expensive technology that has been poorly explained, often misused and initially available in only a few varieties, might have played a role in the overall indebtedness of certain farmers in some of the suicide-prone areas of these two states, particularly in its initial years. But none of these possible links has been explicitly demonstrated with a sufficiently robust analysis. One implication of this study is the critical need to distinguish the effect of Bt cotton as a technology from the context in which it was introduced. Revealed preferences based on farmer adoption rates and official or unofficial data all point toward the overall success it has had in controlling pest damage and therefore raising average yields in India. In particular, the increasing adoption rate in two suicide-prone states, Andhra Pradesh and Maharashtra, indicates that farmers in these states found this technology economically beneficial.



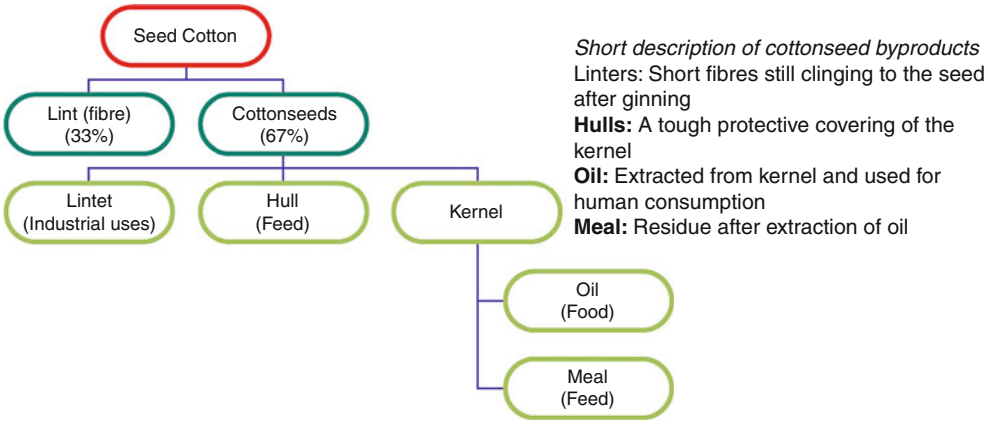
GM Crop Risk Debate, Science and Socioeconomics. Figure 6

Average cotton yields in India (kg/ha), 1980–2007 (Source: International Cotton Advisory Committee (2008). Note: Data for 2007/2008 is an estimate. From [145])



GM Crop Risk Debate, Science and Socioeconomics. Figure 7

Farmer suicides and Bt cotton area in India, 1997–2007 (Source: Combined data from Table 1 and Table 2. From [145])



GM Crop Risk Debate, Science and Socioeconomics. Figure 8
Cotton seed byproducts (From [148])

In contrast, marketing constraints and institutional issues may have played a significant role. Our analysis suggests the need for a better extension system, more controlled seed marketing system, anti-fraud enforcement and better information dissemination among farmers in all regions, before the introduction of any costly new technologies like Bt cotton. Farmers should also be encouraged to diversify their farming and non-farming activities to spread the risks they may incur.

The second implication is that, as farmer suicides are not new or specific to recent cases or to the introduction of Bt cotton, they point toward the failure of the socioeconomic environment and institutional settings in rural dry areas of India. This has nothing to do with cotton or the use of new technology and would suggest many potential policy changes. In several states, such as Karnataka and Andhra Pradesh, some policy changes have already been proposed. Lastly, much more and better federal and state investment could help prevent the 80 percent or more other cases of suicides.

This does not hinder activists like Vandana Shiva from proclaiming Indian farmers' suicides to be the fault of international corporations: [146] and lately also at a Barilla webinar July 20, 2011 in Milano: http://www.barillacfn.com/en/biotecnologie, she also does not shy away from connecting the sad tradition of farmers suicides in India with the emergence of GM crops, despite hard facts as demonstrated above. In the same picture you can see her pompous literature list she gives in her curriculum of "over 300 scientific publications in important journals" – a quick test in the comprehensive database of the Web of Knowledge http://apps.isiknowledge.com/ reveals some 47 papers, most of them in less important journals and magazines – so much about her scientific achievements.

A new perspective is open since 2006 for the production of cotton seed (oil for human consumption), seed meal for feed, made possible thanks to the detoxification (gossypol) successfully done by modern breeding including genetic engineering [147], see the latest summary on the matter (Fig. 8) [148]:

This latest development will open new doors for the cotton production and marketing.

The Political Economy of Biosafety Regulation in Agriculture An in-depth analysis of how politics is influenced by multiple factors of discursive processes, influenced by economics, has been developed by Graff et al. [149]. They are giving highly differentiated insights in the network of self-interests with some interesting examples of units influencing in their own interest the debate on GM crops: opponents of genetically engineered crops and also industrial units fearing losses in pesticide sales. Often these important socioeconomic elements in the regulatory debate are neglected and it seems to be difficult for all the regulatory analysis to bring together socioeconomic *and* molecular plant breeding aspects.

- This article develops a political-economy framework to analyze the formation of agricultural biotechnology policies. Going beyond accounts, that largely attribute differences between US and European regulatory environments to consumer attitudes, we consider the impact of what amounts to a Schumpeterian process of "creative destruction" across the entire range of relevant economic sectors and interests. **The analysis suggests that in Europe and in some developing countries a "strange bedfellows" constellation of concentrated economic interests (including incumbent agrochemical manufacturers, certain farm groups, and environmental protest activists)** act in rational self-interest to negatively characterize GM technology in the public arena and to seek regulations that block or slow its introduction. In contrast, those interests most likely to experience welfare gains from biotechnology are the more diffused and less informed – including consumers and small farmers. The most profound implications of overregulation of agricultural biotechnology are (1) delays in the global diffusion of proven technologies, resulting in a lower rate of growth in the global food supply and higher food prices, and (2) disincentives for investing in further R&D, resulting in a slowdown in innovation of second generation technologies anticipated to introduce broad consumer and environmental benefits." [149]

Ayal and Hochman [150], started in some intricate experimental setups working on the cognitive processes underlying choice behavior. With a mix of behavioral actions combined with opinion polls they found that people *do not rely on limited arguments only, but tend to integrate all acquired information into their choice processes*. This could explain the delay in such opinion finding and decision-making processes influencing politics over years, described in the Gartner hype cycles, see The General Strategic Situation of the Debate About Green Biotechnology Today.

Although this would be an epic theme, we shall concentrate here more on the debate of the *Science* of regulation and some discursive elements.

Brazil, A Case Where Politics Positively Influences the Development and Adoption of GM Crops

Studying the biosafety law of Brazil, the similarities with the European legislation cannot be overlooked: Both legislations are process-oriented and obey strict rules on biosafety assessment, including field experimentation:

A closer look at the Brazilian legislation [151] shows the similarities to the European legislation.

- Article 3. Under this Law, it shall be considered:
  V – genetically modified organism – GMOs: an organism the genetic material of which – DNA/RNA has been modified by any genetic engineering technique;

And compare some exclusion rules, typically reducing the safety assessments strictly to the process of genetic engineering.

- Article 4. This Law is not applicable when a genetic modification results from the following techniques, provided they do not imply in using a GMO as the receiver or donator:
  I – mutagenesis;
  I – the formation and use of animal hybridome somatic cells;
  III – cellular fusion, including plant cells protoplasm, which can be produced from traditional culture methods;
  IV – the self-cloning of naturally processed non-pathogenic organisms.

The same is the case in the European law:

[152], in the introduction the definition of GMOs is given:

- In order to protect human and animal health, food and feed consisting of, containing or produced from genetically modified organisms (hereinafter referred to as genetically modified food and feed) should undergo a safety assessment through a Community procedure before being placed on the market within the Community.

The intention of this "exclusive" definition is clear in this European Law: it should be restricted to GMOs which are wrongly defined as "genetically modified crops," a scientifically questionable denomination, since in the strict sense of modern genomic science this means to include all crops and horticultural traits having been modified also by conventional breeding. This kind of now false but routine denomination is a symbol for the disregard of proper science in regulation.

A further comparison demonstrates that legislations in Europe and Brazil are both rather strict, the decisive difference is that in Brazil there are clear (political) decision-making rules, whereas these are lacking in Europe. Until lately, the decisions were depending on majority voting rules of the European states, and this caused a lot of confusion and an almost complete stall in decision-making. This is why Commissioner Dalli [153], in July 2010 opened a debate on delegating some important decisions to the national level: Comments from http://www.gmo-compass.org/eng/news/523.docu.html

- (13 July 2010) As expected, the EU Commission decided on 13.07.2010 changes in the legal regulation of green biotechnology. Accordingly, Member States should be able to prohibit the cultivation of genetically modified (GM) crops that have been approved EU-wide. As the next step, the EU Parliament and Council of Ministers must agree.

The outcome will again depend on complex negotiations and it is not sure whether Commissioner Dalli and the EU will come to concrete legislative results. And, except for some modest GMO corn cultivation in Spain, the present day acreage of GM cultivars remains disappointingly low [154].

In contrast to the complex and stalled situation on European GMOs, the case in Brazil documents in the last few years successful regulation of GMOs: Recent reports document steadily growing acres on GMO crops in Brazil: [155, 156]

- The 1st survey on agribiotechnology in Brazi l for the 2010/11 growing season showed there was a substantial growth in the adoption rate of biotech soybeans, corn, and cot ton. The Brazilian farmers are expected to plant 17.2 million hectares with GM soybean cultivars, or 75.6% of the total harvested surface, in 2010/11.

For a general survey of the Brazilian situation, see the recent publication of Mendonca-Hagler et al. [157], where a clearly optimistic picture is developed. The abstract reads:

- Biotechnology is a Brazilian priority, and has been recognized for its potential to promote sustainable development. The Government recently announced an ambitious program for Science and Technology, which includes strategies to develop modern biotechnology, continuing three decades of public investments on capacity building and infrastructure, aimed principally at the development of technologies applied to health, agriculture and the environment (MCT 2008 http://www.mct.gov.br/). Research initiatives have focused on genomics, proteomics, genetically modified organisms (GMOs), gene therapy, stem cells, bio-fuels and nanotechnology, among other biotechnological topics. Research projects in Brazil have been mainly developed in public universities and institutions funded by federal and state agencies, with a minor participation from the private sector [158]. Genomics, an area of considerable success in the country, was launched a decade ago by S. Paulo State Research Foundation (FAPESP), with the organization of a virtual institute, called ONSA, comprising several laboratories with the main task of sequencing the genome of the citrus pathogenic bacterium Xylella fastidiosa [159, 160].

The success of this genomic network stimulated biotechnology startup companies and projects with the focus on other genomes, such as sugarcane and coffee, including functional genomics and proteomics. Following in the footsteps of the ONSA network, the Ministry of Science and Technology created a National Genome Project Consortium involving institutions located in the major regions of the country, with the task of sequencing eight microbial and two plant genomes. Recently, they concluded the sequence of Chromobacterium violaceum, a bacterium with exploitable properties, such as the ability to produce a bactericidal purple pigment (violacein) and bioplastics [161]. Later on, several states launched their own genome programs. A group from Rio de Janeiro, part of the Riogene network, recently sequenced the genome of the nitrogen-fixing bacterium Gluconoacetobacter diazotrophicus, a sugarcane endophyte involved in enhancing growth of large crops without the addition of nitrogen fertilizer [162, 163], see also the websites of EMBRAPA http://www.embrapa.br/english and the Ministerio Biotecnologia e Tecnologia http://www.mct.gov.br/.

Agriculture plays an important role in the Brazilian economy, being responsible for ca. 40% of the exports and employing 20% of the active work force. About

> one third of the Brazilian GDP comes from agribusiness. Traditionally, this country has been competitive in tropical agriculture, supported by strong research programs on conventional and modern technologies. Intense capacity building initiatives resulted in the formation of a critical mass of scientists working in molecular biology and agricultural sciences [158]. Despite these favorable factors, the adoption of GM crops has been delayed due to intense opposition organized by environmental groups and additional difficulties resulting from a conflicting regulatory framework. In this overview, we address the current status of Brazilian biosafety legislation, and discuss the perspectives for the development of molecular biotechnology in Brazil.

This view is confirmed in a recent editorial in *Nature*, [164], interestingly enough with the same emphasis as above on gene sequencing projects which are the basis of independent biotechnological research and development in Brazil.

Also, the latest success of approving regulatory decisions is symptomatic of the positive biotech climate in Brazil: The first fully developed transgenic crop in Brazil has been approved for commercialization, published in 2007: [165]. The press release of the president of AnBio (National Biosafety Association) Leila Oda emphasizes also the socioeconomic importance of this approval: [166].

Without going into a survey on the Brazilian opponent's activities and reports in detail, here just a typical example published by a medical group (not linked in any way with environmental toxicology) [167] on how science is distorted in order to make a negative and totally unfounded point against glyphosate is given. This paper produces negative toxicological effects on clearly doubtful experimental scenarios: experimental Xenopus frog embryos were *injected* with glyphosate, as mentioned in the introduction.

- We show here that sublethal doses are sufficient to induce reproducible malformations in Xenopus and chicken embryos treated with a 1/5000 dilution of a GBH formulation (equivalent to 430 μM of glyphosate) or in frog embryos **injected with glyphosate alone (between 8 and 12 μM per injected cell).** GBH treated or glyphosate injected frog embryos showed very similar phenotypes, including shortening of the trunk, cephalic reduction, microphthalmy, cyclopia, reduction of the neural crest territory at neurula stages, and craniofacial malformations at tadpole stages.

This absurd experiment methodology contradicts all internationally agreed rules on environmental toxicology testing, as described and cited in detail in [168].

But opponents are well organized on an international level, and promptly, the Paganelli paper is cited in many of those reports, here is just one example: [169]. In this extensive report, dozens of papers are cited which do not match the high quality standards of biosafety science; they are cited because they produce negative results related to modern soybean agriculture. The following is an example on how the authors do not even shy away from distorted reporting of published results.

- Very few studies directly examine the effects of GM foods on humans. However, two studies examining possible impacts of GM RR soy on human health found potential problems.

  Simulated digestion trials show that GM DNA in GM RR soy can survive passage through the small intestine and would therefore be available for uptake by the intestinal bacteria or cells [170]. Another study showed that GM DNA from RR soy had transferred to intestinal bacteria before the experiment began and continued to be biologically active [171]. These studies were not followed up. GM proponents often claim that GM DNA in food is broken down and inactivated in the digestive tract. These studies show that this is false.

Actually, if you read the above Newcastle study properly, you notice that the GM DNA is completely decomposed in the colon, the only traces measurable were found in fresh, undigested stomach probes of human ileostomy patients. Reading the summary alone shows the blatant incorrectness of the comments. Two previous studies, after careful reading, reveal the same results [170, 172]. The conclusion therefore is that the interpretation of [169] is false, as confirmed in the latest publication of the Newcastle research team:

- The transgene did not survive the gastro-intestinal tract of human subjects fed GM soya.

A recently published paper of Zhang is seen as a breakthrough in our knowledge on interkingdom relations between plant and animal genomics: [173].

First data, obtained with modern genomic analysis, demonstrate the surprising finding that exogenous plant miRNAs are present in the sera and tissues of various animals and that these exogenous plant miRNAs are primarily acquired orally, through food intake. MIR168a is abundant in rice and is one of the most highly enriched exogenous plant miRNAs in the sera of Chinese subjects. In addition, these findings demonstrate that exogenous plant miRNAs in food can regulate the expression of specific target genes in mammals.

This could lead to erroneous conclusions that horizontal gene transfer is possible also for the antibiotic resistance genes and even for genes expressing Bt toxins into mammals and humans, and one can see already that opponents to genetic engineering take advantage of the news by clear misinterpretation of the results: They use it as an argument for the unforeseen risks of the technology. See the comments of anonymous scientists in GMwatch [174]:

- The study is yet another nail in the coffin of the already discredited 'safety assessment' process for GM foods in the EU and elsewhere. These assessments do not consider the effects described.

This rather naive statement is typical of the thinking of GM crop opponents: Firstly, they mix up in an unscientific way various categories of transgenes; secondly, they mix up scientific progress and the inevitable adaptation of risk assessment methodology with the present day regulatory rules in place in the laboratories. It is a matter of simple scientific consensus that biosafety assessment has to adapt in methodology with the progress of genetic engineering: on one side, Zink-Finger and TALES methods (details see Zinc Finger Targeted Insertion of Transgenes and TALEs: Transformation Method Transcription Activator-like Family of Type III Effectors.) with all their precision and elegance are prone to simplified risk assessments after detailed studies. On the other hand, technologies using small RNA molecules will undoubtedly force risk assessment researchers to adapt to appropriate methods of analysis, as already proposed by [175]:

- In the future, the predictive ERA process will need to be flexible and adaptable for analysis of the next generation of crops engineered using RNAi and HD-RNAi. As a first step, regulatory agencies and risk analysts need to become familiar with the science of RNAi and its application to plant biotechnology. A concerted effort is needed to develop a pool of expertise to ask the right questions about potential hazards and exposures, to ensure that relevant data are collected and to characterize uncertainty in risk assessments.

  Regulators will have to evaluate the design and implementation of research protocols for laboratory experiments and confined experimental field trials. Scientific questions will need to be answered about off-target effects, non-target effects and the impact of genetic mutations and polymorphisms. Understanding the stability, persistence and half-life of small RNAs in various aquatic and terrestrial ecosystems will be essential for the characterization of exposure pathways. New diagnostic tools will probably be required for the identification and quantification of small RNAs for a range of purposes, including crop identity preservation, monitoring and segregation. Ideally, these tools should have a low detection limit and a high degree of specificity for each RNAi crop, while being relatively inexpensive, functional under field conditions and operable by individuals with diverse backgrounds and training. With all this in mind, it should be possible for stakeholders, regulators and citizens to develop policies and ERA frameworks for RNAi and HD-RNAi crops. [175]

It is correct that small RNA molecules are considered and used for GM plant improvements, as suggested by [175]. And it is also correct that the risk assessment of GM crops up to now does not specifically include the effects described by Zhang et al., that is, that small miRNAs are obviously passing mammal stomach environments and can be integrated in the organism and even be active genetically. This seems to be routine in the evolution of life (and undoubtedly calls for verification and further studies). And the question arises whether we should *automatically* include in the risk assessment small miRNAs, the answer should be *no*: rather it should be another reason to switch European and UN-Risk assessment to product-oriented mood, following the conclusions drawn in the section on the GM- and Non-GM-crop Differences Overestimated, the "Genomic Misconception".

The above examples of misleading statements and publications of the opponents lead in a logical way to the following section on the quality of scientific papers:

Peer Review in the Biosafety Science Debate on Regulation

Before we start talking about regulation, a word on the science debate shall precede, which depends on the process of peer review, but it may be flawed in many ways, although there is no real good alternative in sight, despite some attempts to change this situation like the proposal to involve respected science journalists. But there are objections: journalists might become part of the system [176] and give up indirectly their strict impartiality and neutrality – which is, maybe, anyway an illusion. Or it might be that they may simply not have the scientific expertise as demonstrated recently in a contribution of a science journalist in Nature [177], extensive critical comments in ASK-FORCE contribution on the Rosi-Marshall publication on aquatic insects, see [178] (more comments about this study are given below). It should also be admitted, that a fresh look of a "greenhorn" might reveal new aspects of the GMO battle.

The quality of biotechnological research is also influenced by the research environment offered to students and is evaluated in a differentiated way for Europe by Reiss et al. [179]. Peer review is a very fragile instrument and needs constant inquiry, as demonstrated also on the Wikipedia website on the subject of peer review http://en.wikipedia.org/wiki/Peer_review. It should also be seriously considered that the present day peer review system is basically "faith based," as described with convincing details by [180].

A trend toward a magazine style is documented for some important journals as *Nature* and others. The facts show that the percentage of externally peer-reviewed articles has dropped dramatically. Facts will be given in a forthcoming publication of R. Laporte, F. Linkov, and K. Ammann.

We should also include a new element in the reviews and evaluation of science as proposed by Lubchenco [181]: the scientific community should formulate a new *Social Contract for science.*

> This contract would more adequately address the problems of the coming century than does our current scientific enterprise. The contract should be predicated upon the assumptions that scientists will (1) address the most urgent needs of society, in proportion to their importance; (2) communicate their knowledge and understanding widely in order to inform decisions of individuals and institutions; and (3) exercise good judgment, wisdom, and humility. The paper concentrates, according to the zeitgeist of the publication date, too much on environmental issues alone, today we should put into the center of our science strategy debates **humanity as a whole – and this means to take care of the most urgent needs, namely to work on the eradication of hunger**.

However, this process should not be mollified on the costs of hard science. The line between science and pseudoscience is often difficult to draw.

An interesting new aspect has been introduced by the Supercourse Group with Faina Linkov and Ron LaPorte: [182]. It is true that quality control of Internet texts need rethinking, and it is also important to analyze in a critical way peer review of print material: Their comments can be summarized as follows: High-quality, Internet-distributed lectures are not basically different from written science publications, they also must be documented and references properly. A further element could be a method of quality management introduced originally for the industry by Edwards Deming Wikipedia of Edward Deming http://en.wikipedia.org/wiki/W._Edwards_Deming, who very successfully taught management and quality control also in Japan in the 1950s.

Two more initiatives should be mentioned here, they can be summarized under a kind of *post-publication peer review.*

Faculty of 1,000 System With a total of nearly 84,000 articles reviewed by May 2011, the system has accumulated an important body of comments, see http://f1000.com/, the comments, although really critical sentences are not foreseen, the system is now linked to The Scientist and provides helpful orientation about important publications. Some examples have been evaluated by the author [183].

Frontiers of Science Frontiers of Science has been developed over 2 years in consultation with scientists and other faculty, as well as with students and postdoctoral fellows, to address manifest intellectual, logistical, and pedagogical issues, see http://www.sciencecore.columbia.edu/s2.html and http://www.fos-online.org/

Declaration of a New Global Business Ethos as a Barrier Against Undue Influence on the Publication Policy of Scientific Journals On October 6, 2009, Hans Küng, Josef Wieland and Klaus Leisinger presented the Declaration of a NEW GLOBAL BUSINESS ETHOS at the United Nations in New York http://www.novartisstiftung.org/platform/content/element/3177/Newsletter_3-09_2.pdf.

Although coming from a pharmaceutical company like Novartis, multinational seed companies will (or should) most likely join. Such efforts are important, because there is a constant pressure of undue influence on scientific papers, although resisted successfully by most researchers, but the influence of multinational (in this case pharmaceutical) companies can be hidden but nevertheless powerful:

An example of such influence by units sponsoring scientific journals has popped up in Australia: See the debate around the withdrawal of six Australia-based Elsevier "fake" journals sponsored by the pharmaceutical industry, see the statement of Elsevier's CEO Michael Hansen [184] and [185–187]. This kind of influence might still be under control, and peer review is usually functioning in an unbiased way – but the difficulties are deep-rooted, and it is a constant fight for quality, as is summarized comprehensively by Scott [188].

It is a cheap and intellectually intolerable slogan of opponents of genetic engineering in agriculture when they discredit researchers for their relationships with industry, since the great majority of researchers all over the world act as independent persons, although sometimes also funded by industry. The sole quality criteria on science are transparency in applied methods agreed upon by the science community and the reproducibility of the data. For more details see section More on the Quality of Scientific Publications.

In the "dangerous" waters of corporate influence, we need renewed efforts of scientometric analysis, as given earlier in a report of bio-era: [189]. The top part of table 5 reveals the few really successful seed companies in relation to the top universities with agricultural research regarding R&D (Fig. 9):

The top 35 R&D orgnizations in agricultural biotechnology

RANK	PARENT ORGANIZATION	SHARE OF INDUSTRY R&D OUTPUT
1.	Monsanto	29.82%
2.	Du Pont / Pioneer	10.98%
3.	Bayer / Aventis	10.14%
4.	Dow	5.81%
5.	Syngenta	5.80%
6.	Savia / Seminis	2.57%
7.	USDA	2.38%
8.	BASF	1.71%
9.	Cornell University	1.25%
10.	Stine Seed Farm Inc	1.15%
11.	Florigene	1.08%
12.	University of California	1.05%
13.	Exelixis	0.98%
14.	Iowa State University	0.91%
15.	Rutgers University	0.83%
16.	University of Guelph	0.79%

GM Crop Risk Debate, Science and Socioeconomics. Figure 9

Table 5, upper part, with a ranking of biotech companies and universities in the USA, from [189], calculation rules above

The calculation rules for the table below:

- The four R&D measures are weighted equally. For example, having 10% of industry patents is just as significant as having 10% of commercialized products. Share of industry R&D output = (share of industry patents + share of industry patent citations + share of industry field trials + share of industry commercialized products)/4 [189].

More on the Quality of Scientific Publications Coming back to the peer review on the quality of scientific papers, all the above statements do not mean to say goodbye to the factual and methodological scrutiny per se – even after a paper is already published. With a focus on the GM food safety research Chassy and Parrott [168] summarize the criterions on how to

judge whether a food study is believable or not: (a) Making sure the samples tested are comparable samples. (b) Testing composition to make sure the tests and controls are comparable. (c) The need for an acceptable balanced and nutritious diet. (d) Why the dose is important. (e) What statistics do and do not tell us. (f) The importance of peer review and scientific publication. (g) Guidelines for dealing with conflicting information. (h) Ethical considerations. A very important additional point is emphasized by Kostoff [190]: "Multiple technical experts should average out individual bias and subjectivity." Two blatant examples of lack of peer review properly done are, among others, discussed in ASK-FORCE (with some additions related to recent publications, all cited in the renewed blog:

- The case of Bt endotoxins supposedly affecting aquatic organisms by Rosi-Marshall et al. [191]

  See comments in ASK-FORCE blog No. 3 on Rosi-Marshall et al. 2007b: [178] (including also the latest publications of [192]. The study has been criticized heavily by [193] and [194], the main points of critique, summarized in a letter to the editor of PNAS [195]: No indication about the nature of Bt toxin, nor any data about its origin. Unscientific extrapolation from lab to field experiments, suppression of an important result of Fig. 3: low toxicity of normal Bt toxin levels for aquatic organisms etc. It is good to know that the authors of the original study admitted some mistakes and tuned down their alarmist interpretation in the first study:
- The case of the Austrian mice experiments supposedly affecting fertility after some generations [196]. After lots of public and scientific debate, which caused serious and unfounded damage to the image of Bt crops, the study results were distributed on hundreds of websites of GM crop opponents. But critique came up, and since there was no publication in a peer reviewed journal available, the rebuttals were not published in journals either. The whole bitter debate is summarized extensively in two ASK-FORCE blogs: [197].

  The subsequent official retraction done by the Austrian Government itself is hidden in an European Commission Health and Consumers Directorate-General Summary Record of the Standing Committee on the Food Chain and Animal Health from October 19, 2008: European Commission Health and Consumer Directorate-General, Summary Record of the Standing Committee on the Food Chain and Animal Health Held in Brussels October 19, 2008: http://ec.europa.eu/food/committees/regulatory/scfcah/modif_genet/sum_19102009_en.pdf

  See also the published comments of Ammann in [198]:

> Studies that look at non-obvious risks are a welcome addition to the literature, say critics, but poorly conducted studies do more harm than good. "It's just bad science," says Ammann. "There are a lot of scientists producing these studies in a very sloppy way. They bolster public fear yet do nothing to resolve conflicts or move the field forward". And:
>
> But the authors aren't to blame, says Klaus Ammann, emeritus professor at the University of Bern in Switzerland. They are merely the latest victims of what has become the political gerrymandering of science to bolster and support anti-GM sentiment in Europe. "The Austrian government had exhausted all legal avenues to ban cultivation of GM crops," Ammann says. "The Ministry of Health decided to avoid the peer-review process and announce study results at a conference, hide the data from scientists, and let the activists run amok with the help of uncritical media." Indeed, in the ensuing months the Austrian government has backpedaled. The Ministry of Health responded to a request to interview Zentek or other authors with the following: "We asked the scientists to reevaluate their statistical analysis. Additionally the external evaluation will soon be started. I kindly ask you to wait with your proposal until the reevaluation is completed." [198]

- The case of a review by Dona and Arvanitoyannis [199]. This review would never pass tests designed by Tang et al. [200], which can detect biased filtering of citations and words: According to Tang et al., it is important to distinguish between *subjectivity classification* retrieved from opinionated and factual statements, and combine it with a multiclass *sentiment classification*, and to get a better scale by using neutral training examples. An extensive scientific analysis on [199] has been placed in ASK-FORCE with critical comments: [201]

A caveat at the end of this paragraph on peer review is appropriate. Although it is in principle necessary to ask ethical questions, we should first concentrate on the scientific assessment of a professional peer review strictly following a factual agenda such as [168, 202] are demanding. Only then when this filter has been passed successfully, it is important to go into ethical and socioeconomic questions. But as often, it is the farmers and the market regulating efficiently, and – no surprise – they follow quite naturally socioeconomic principles. It is wrong to mix scientific and ethical questions as de Melo et al. and Interman et al. are asking for [203, 204], the result is then to accept for discussion a paper like the one of [205], which has been seriously and repetitiously criticized on a factual basis by EFSA [206–208]. Such papers should not be seen as a publication which takes also into account a "balanced view," because they are flawed in the first place. Papers from the laboratory of Séralini are then often cited as done by *independent* scientists, which is not very convincing, since digging into the financial support of Séralini and his CRIIGEN lab it is highly interesting to realize that they also receive funds which come from opponents of GMO technology, such as Sevene Pharma, commercializing homeopathic products which claim to detoxify various toxic products [209] and more. CRIIGEN has been created with the financial support of the retailer Carrefour, which has also contributed financially to certain studies of Séralini and his group. Interestingly enough, Carrefour, the second largest food distributor in the world, sells its own brand of "GMO-free" products. . .Source: [210].

- The result of this discussion: it will be necessary to call for new, Internet-based methods to create a more efficient peer review system. A nucleus of such a system is given in Ron LaPorte's supercourse system http://www.pitt.edu/□super1/.

GM- and Non-GM Crop Differences Overestimated, the "Genomic Misconception"

Early Phase of Risk Assessment In the wake of molecular breeding, in particular with the first successes of "gene splicing," the safety debates started soon after the discovery of the DNA structure by Watson & Crick [211–213], followed by the Asilomar Conference [214, 215] – see also some historical accounts [7, 216, 217]. The fascination about the novelty of transgenesis was justified, but also overwhelming, and the many unforeseen scientific breakthroughs following were unprecedented in the history of molecular biology. Unfortunately, the enthusiasm also lashed back in an overacting in risk assessment, when the first GM crops went into production. The debate on how GM crops should be regulated started very early with an emerging divide between regulation in the USA and Great Britain, including later the whole of Europe [218, 219]. Some more traces of early disputes about regulatory decisions in the USA and in Great Britain can be seen in letters to Nature in 1992: [220, 221]. Some support tighter regulation including field biosafety assessments, others fear strangulation of biotechnology research. During the wake of the Cartagena Biosafety Protocol most countries adopted (around 2003) the European way of risk analysis of genetic engineering, emphasizing process-oriented regulation and rejecting product-oriented regulation.

The seemingly absolute novelty of genetic engineering on the molecular level has been contested already in the early days of molecular biology in the 1930s and 1950s with the discovery of cellular systems for genome restructuring discovered with the classic papers of McClintock [222, 223] and with later commentaries of Fedoroff [224, 225], also summarized under "natural genetic engineering" [226, 227].

Molecular Processes Similar in Natural Mutation and Transgenesis Genetic engineering has been brought into evolutionary perspective of natural mutation by authorities such as Werner Arber: his view remains scientifically uncontested that molecular processes in transgenesis and natural mutation are basically similar [228–232]. In a recent paper, Werner Arber [19] reemphasized those similarities on a broader organismal and evolutionary basis; the abstract reads:

- By comparing strategies of genetic alterations introduced in genetic engineering with spontaneously occurring genetic variation, we have come to conclude that both processes depend on several distinct and specific molecular mechanisms. These mechanisms can

be attributed, with regard to their evolutionary impact, to three different strategies of genetic variation. These are local nucleotide sequence changes, intragenomic rearrangement of DNA segments and the acquisition of a foreign DNA segment by horizontal gene transfer. Both the strategies followed in genetic engineering and the amounts of DNA sequences thereby involved are identical to, or at least very comparable with, those involved in natural genetic variation.

Therefore, conjectural risks of genetic engineering must be of the same order as those for natural biological evolution and for conventional breeding methods. These risks are known to be quite low. There is no scientific reason to assume special long-term risks for GM crops.

For future agricultural developments, a road map is designed that can be expected to lead, by a combination of genetic engineering and conventional plant breeding, to crops that can insure food security and eliminate malnutrition and hunger for the entire human population on our planet. Public-private partnerships should be formed with the mission to reach the set goals in the coming decades. "from [19].

The same claim is made with a more organismic view by Hackett [233].

It is therefore no surprise that a natural transgene species has been discovered in a widespread grass genus [234]. An extensive overview on "natural transgenic organisms" is given in the excellent blog of David Tribe GMO pundit on natural transgenics: http://gmopundit2.blogspot.com/2005/12/collected-links-to-scientific.html.

Recent publications demonstrate that transgenesis, for example, has less impact on the transcriptome of the wheat grain than traditional breeding [235–237] (more details see [44, 238]).

One should also take into account that many of the conventional breeding methods such as colchicination [239, 240] and radiation mutation breeding [241] can be obviously more damaging to the genome, and it is, in addition, not possible to clearly define what impact the untargeted process could have caused. Or, on the other hand, as [242] have demonstrated, that irradiation-induced wheat – Aegilops biuncialis intergenomic translocations will facilitate the successful introgression of drought tolerance and other alien traits into bread wheat. In their review, [243] criticized the biased statements of [244, 245] who focus in an unjustified manner on transgenesis alone when describing unwelcome mutations. Still, it has to be admitted that repair mechanisms on the DNA level are powerful [246–248]. It is thus not logical that opposition within organic farming toward genetic engineering is now expanding also to some of those conventional breeding methods, some go even so far as to reject marker-assisted breeding – symptomatic for the organic agriculture scene, this trend is based on the myth of "intrinsic integrity of the genome" [249, 250], for which term it is not possible to find a proper scientific definition, which inevitably should be based on comparisons [44]. The addition of rejected breeding methods would ultimately lead to an absurd situation where most of the modern time traits would have to be rejected and breeding would be forced to virtually start from scratch.

Basically, many of the first-generation GM crops should be today subject to a professional debate on *deregulation*, and there is good and sturdy reason to state that many of these GM crops should not have been treated in such a special way in the first place, they can be compared in their risk potential to many crops created with traditional methods.

- This should not be misunderstood as a plea for general deregulation of GM crops, rather for a strictly science-based, risk-based regulation and clearly for a shift from process-based regulation toward product-based regulation.

Dissent over Differences Between GM- and non-GM Crops Causes Transatlantic Regulatory Divide This actually includes a critical questioning about some basic rules of the United Nations Convention on Biological Diversity (CBD). Transgenic crops of the first-generation should not have been *generally* subjected to regulation purely based on the *process* of transgenesis alone; rather it would have been wiser to have a close look at the *products* in each case, as John Maddox already proposed in 1992 in an editorial in Nature [251]. This is also the view of Canadian regulators [252–254], where the *novelty* of the crop is the primary trigger for regulation. This transatlantic contrast has been

commented by many [16, 218, 255–258], and although for many years a solution and mediation seemed to be too difficult, contrasts can be overcome:

In a letter to the executives of the Convention on Biological Diversity (CBD), the Public Research and Regulation Initiative (PRRI) http://www.pubresreg.org/index.php?option=com_docman&task=doc_download&gid=490 is asking for a scientific discussion in order to exempt a list of GM crops from the expensive regulatory process for approval, here is only the final statement:

- Bearing in mind that the **method of transformation itself is neutral**, *i.e.,* that there are no risks related to process of transformation, PRRI believes that there are several types of LMOs and traits for which - on the basis of the characteristics of the host plant, the functioning of the inserted genes and experience with the resulting GMO - **it can be concluded that they are as safe as its conventional counterpart with respect to potential effects on the environment, taking also into account human health**.

Unfortunately, there was no substantial reaction from the leading Cartagena organizers.

To be quite explicit once more, this does not mean to exempt transgenesis from biosafety assessment as a whole, but it should say that "several types of LMOs and traits, where the inserted genes demonstrate in large scale commercialization (of course after risk assessment done in due course) can be deemed as safe as conventional counterparts according to several years of beneficial agricultural practice, should be exempt under article 7.4 of the Cartagena Protocol for further expensive and time-consuming risk assessment and regulatory procedures. This motion has now officially been repeated by PRRI (Public Research and Regulation Initiative at the occasion of the COP10-MOP5 negotiations in Nagoya, Japan, see the interventions on the website www.pubresreg.org with recent additions.

In a recent paper, an indiscriminate continuation of food biosafety research is questioned on the basis of all the above arguments by Herman et al. [259] with good reason:

- Compositional studies comparing transgenic crops with non-transgenic crops are almost universally required by governmental regulatory bodies to support the safety assessment of new transgenic crops. Here we discuss the assumptions that led to this requirement and lay out **the theoretical and empirical evidence suggesting that such studies are no more necessary for evaluating the safety of transgenic crops than they are for traditionally bred crops.**

Perspectives for Solutions, a Synthesis of Divergent Views in 2.4

These new perspectives create hope that solutions can be found. Even within the difficult and for GMOs totally negative legal environment of the Cartagena Protocol, there are some slim possibilities:

In a first phase some of the widespread transgenic crops like transgenic maize with the Cry1Ab endotoxin could be exempt from regulation. This is indeed possible according to art. 7.4 in the Cartagena Protocol. In COP-MOP5 2010, in Japan (Fifth meeting of the Conference of the Parties serving as the Meeting of the Parties to the Cartagena Protocol on Biosafety (COP-MOP 5), 11–15. 10. 2010 Nagoya, Japan http://bch.cbd.int/protocol/meetings/) it should be possible, to amend the protocol with the introduction of a dynamics which allows to start the regulatory process with an initial phase focusing on the process of transgenesis, first following procedures proposed for nontarget insects by [260, 261].

Indeed, in COP10-MOP5 in Nagoya October 2010, PRRI www.pubresreg.org has made a request for the exemption of widely adopted Bt maize crops of the endotoxin type of Cry1Ab, see the press release for the context (PRRI press release: http://www.pubresreg.org/index.php?option=com_docman&task=doc_download&gid=586), here the original text as read at the plenary meeting in Nagoya: PRRI Statement on exemptions MOP5: http://www.ask-force.org/web//PRRI-MOP5/PRRI-MOP5-statement-Strategic-Plan-delivered.pdf:

- Third, there is an underlying misperception that there are demonstrated cases of adverse effects. This is incorrect. Over the last 15 years GM crops have been planted over a billion hectares by tens of millions of farmers in the developing and developed world. These crops

have been grown in numerous different environments, and they have been consumed in billions of meals. The substantial scientific evidence accumulated shows that there are **no** verifiable reports of any adverse effect to environment or human health.

The Strategic plan includes an indicator "Number of reports to the BCH on the identification of LMOs or specific traits that may have adverse effects". Such an indicator makes little sense, because it is never possible to rule out that any organisms, LMO or non LMO, may have adverse effects. What is crucial is the question whether they are likely or unlikely to have adverse effects, and PRRI proposes that the strategic plan includes these two questions. PRRI is ready to submit examples of categories of LMOs of which the risk assessments and accumulated evidence indicate that they are unlikely to have more adverse effects on biodiversity or human health than their non modified counterparts, and that consequently those LMOs can be exempted from the AIA procedure on basis of article 7.4 of the Protocol.

In future, it should also be possible to shift eventually the focus on the product, making it possible to abbreviate the regulatory process wherever possible and feasible. The ultimate goal of new regulatory concepts should be to minimize obstacles for new and urgent necessities in crop development, such as Swaminathan and Raven are proposing [262, 263]. The author remains pessimistic, since the whole cumbersome process of legal changes in the Cartagena Protocol is also systematically hindered by a strong anti-GMO lobby, having made its way through the institutions to higher and powerful positions within the Cartagena administration quite successfully, starting from MOP1 all the way up through MOP5, thus influencing negatively all change of regulatory appeasement and lowering regulatory costs. Unfortunately, the recent overview of the European legislation on GM crops does not generate much optimism either: [264].

A second negative trend is triggered by a growing community of risk assessment researchers, who have a vested interest to keep the pot cooking, examples can be downloaded at the website of GENOK www.genok.com and also from the website of the Third World Network http://www.twnside.org.sg/ with its intricate mixture of activist statements and questionable and peer-reviewed scientific contributions. Other similar examples supporting this view can be downloaded over the Freiburger Oekoinstitut http://www.oeko.de/ and on the website of ENSSER, European Network of Scientists for Social and Environmental Responsibility http://www.ensser.org/

A conceptual framework is proposed by IFPRI/ISNAR in 2002, the International Service for National Agricultural Research [265]; a careful evaluation of process-based versus product-based triggers in regulatory action can also lead to a merger of both seemingly so contrasting concepts into a legalized decision-making process on which trigger should be chosen in a case-by-case strategy:

- Process-based triggers are the rule in almost all countries that have developed national biosafety regulatory systems; there are exceptions, however, where the novelty of the trait determines the extent of regulatory oversight and not the process by which the trait was introduced. While such a product-based approach to defining the object of regulation is truest to the scientific principle that biotechnology is not inherently more risky than other technologies that have a long and accepted history of application in agriculture and food production, it is less prescriptive than process-based regulatory systems.

Many of the debates on those two concepts suffer from a lack of clear-cut definitions, it will be important to have a close look at the Canadian regulatory system and the definition of PNTs (Plants with Novel Traits). In Canada, the trigger for risk assessment is the *novelty* of the plant rather than the *methods* used to produce it. The difficulties start there, where a clear definition of PNTs is needed to come to a decision. It means that plants produced using recombinant DNA techniques, chemical mutagenesis, cell fusion, cisgenics, or any other in vitro technique leading to a novel trait need to undergo risk assessment in the Canadian system. No wonder the Canadian definition of novel traits is rather wordy, but remains broad minded:

- A plant variety/genotype possessing characteristics that demonstrate neither familiarity nor substantial equivalence to those present in a distinct, stable population of a cultivated seed in Canada and that have

been intentionally selected, created or introduced into a population of that species through a specific genetic change.

Conclusions: There can be no doubt that product-based regulatory approaches are truest to the scientific principle that biotechnology is not inherently more risky than other technologies that have a long and accepted history of application in agriculture and food production, it is also less prescriptive than process-based systems, see for more details McLean et al. [265].

The Costs and Lost Benefits of Overregulation

The Issue

The Cartagena Protocol on Biosafety (CPB) has now been adopted by 157 parties http://www.cbd.int/biosafety/signinglist.shtml. It still builds on the principle that GM crop plants might bare risks in contrast to the conventional crops, objective of CPB: http://www.cbd.int/biosafety/articles.shtml?a=cpb-01. The huge apparatus on risk assessment based on this protocol is building on the principle that the mechanism of transgenicity is totally artificial and is not found in nature. Modern molecular science insights have proven the contrary, as shown in ASK-FORCE AF-9 [201] on the molecular basis of transgenesis. This results in maintaining the concept of an asymmetric risk assessment of innovation of GM crops. The possible exemption of widespread GM crops in Art. 7.4 (Cartagena Protocol on Biosafety, Article 7: http://www.cbd.int/biosafety/articles.shtml?a=cpb-07) is not even considered officially up to now.

Summary

An excellent summary graph is given in [266] in Fig. 10b: innovations active in the R&D pipeline were growing at an increasing rate during the period before 1998, but declined after 1998. Apart from competition of reasonably close nontransgenic substitutes, the authors consider one regulatory reason to be the main culprit: The halting of regulatory approvals in 1998 in Europe. Although the authors consider the full extent of reasons still to be conjectural, their data suggest that changes in regulatory environment may have been a cause. In a combination of high costs for lost implementation and high costs for regulatory approvals, the present state and operational experience has grown into a major obstacle of modern crop breeding (Fig. 11).

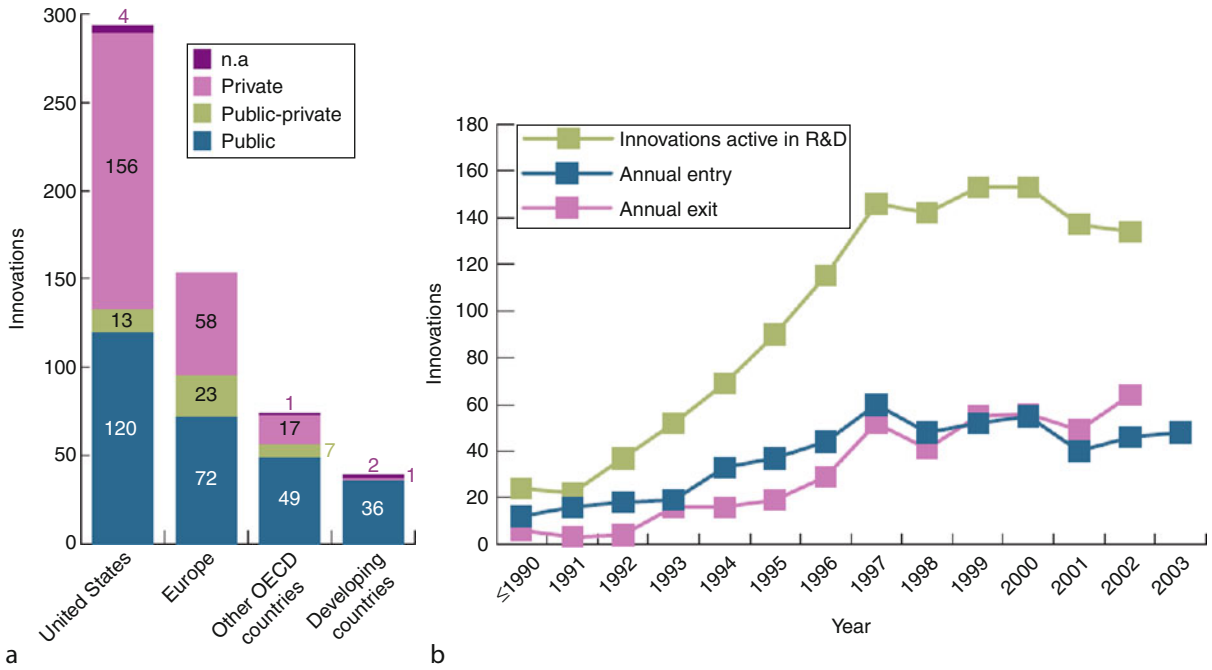
- Commentary from Table 1 in [266]: The primary survey combined records from scientific publications, field trial records, and regulatory filings to identify 558 transgenic plants with quality improvements and determine how far they had progressed through stages of R&D by 2004, including those that had only been published in the scientific literature; those that had reached initial field trials (defined as having completed 1–3 field trials), mid-stage field trials (4–9 field trials) or advanced field trials (>10); those that had entered regulatory filings; and those that were commercialized. The secondary survey canvassed expectations of firms and analysts about the likelihood and time frame for future commercialization of transgenic product quality innovations. Complete one-to-one correspondence between individual observations of the two surveys was not possible.

In a recent publication [267] document the same dramatic negative trend for specialty GM crops is demonstrated:

Costs and Lost Benefits Worldwide and Europe

An excellent summary graph is given in [266] in Fig. 6 above: innovations active in the R&D pipeline were growing at an increasing rate during the period before 1998, but declined after 1998. Apart from competition of reasonably close nontransgenic substitutes, the authors consider one regulatory reason to be the main culprit: The halting of regulatory approvals in 1998 in Europe. Although the authors consider the full extent of reasons still to be conjectural, their data suggest that changes in regulatory environment may have been a cause.

The full extent of the GM crop development pipeline can be evaluated in websites like the Information Systems for Biotechnology alone from the USA, there are (October 23, 2009) 14,204 notifications with 1,586 full field release permits registered in this Database, ISB: Information Systems of Biotechnology: Field Test Releases in the US: http://www.isb.vt.edu/cfdocs/fieldtests1.cfm



GM Crop Risk Debate, Science and Socioeconomics. Figure 10

Innovation in Ag-Biotech. (**a**) Location and sector of organizations conducting R&D for the 558 transgenic product quality innovations identified. Private sector consists of corporate and privately held firms. Public sector consists of government research laboratories, universities, and nonprofit research institutes. (**b**) Annual entry, exit, and the numbers of innovations active in the R&D pipeline were calculated from observations of the 558 innovations tracked in the primary survey. The number of active innovations stopped growing in 1998, after which those new innovations that entered were more likely to be published and less likely to move toward commercialization. Figure 1 from [266]

Overall, the present day regulatory regime detains public research in molecular breeding considerably due to enormously high regulation costs. More information about this effect on the development of GM trees is in Strauss and McLean [268, 269]; the abstract reads:

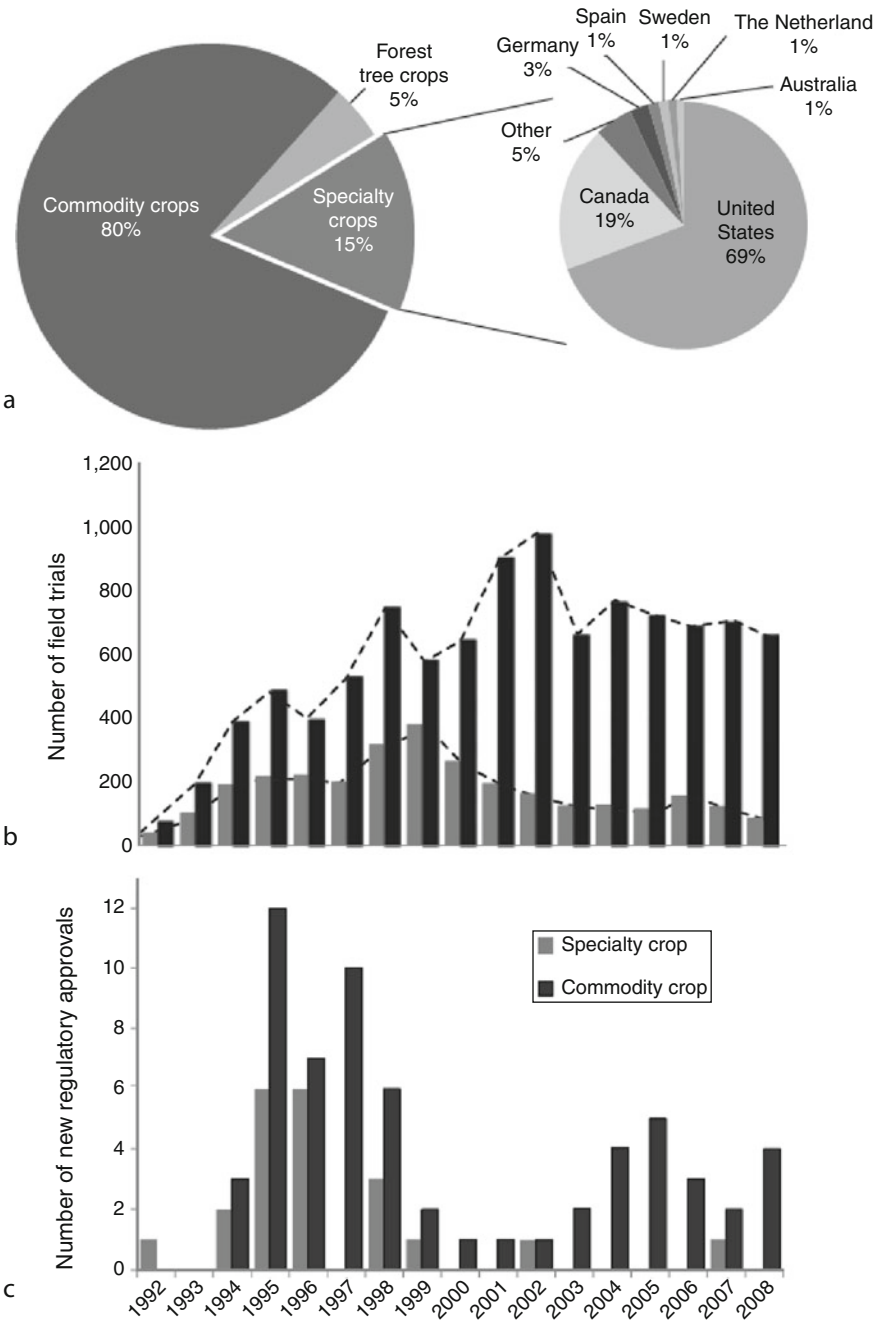
- **Against** the Cartagena Protocol and widespread scientific support for a case-by-case approach to regulation, the Convention on Biological Diversity has become a platform for imposing broad restrictions on research and development of all types of transgenic trees.

Some comprehensive tables on the massive costs of regulation of the major commodity crops are given by Kalaitzandonakes [270]. The compliance costs for herbicide tolerant maize alone have been calculated based on the events in 2006 for the USA. They amount to US $6,180,000–14,510,000 – a sum most likely to be prohibitive for any trait developed by a public institution.

Another case is reported by Piero Morandini from Italy. A scientific assessment on a field trial on Bt maize is delayed in publication by the Italian Government, although (or because?) it yields very positive results [271, 272].

- The grain yield data (tons/ha, GM crop *vs*. their conventional counterparts) were rather spectacular: 15.9 *vs*. 11.1 and 14.1 *vs*. 11.0, translating into a 43 and 28% yield increases for the P67 and Elgina, respectively. These data have already been released by the INRAN (National Institute for Research on Food and Nutrition, a research institution funded and run by the government) in 2006, albeit without the emphasis they deserved.

  The delay in properly communicating these data can be considered as a very costly omission. In fact, taking into account the total area of maize cultivation in Italy together with yield differences, maize prices



GM Crop Risk Debate, Science and Socioeconomics. Figure 11

Field trials and regulatory approvals. (**a**) Using the UNU-MERIT database, field trials conducted in 24 developed countries between 2003 and 2008 were separated on the basis of commodity, forest tree, or specialty crop. From this, the specialty crops were further subdivided based on the country in which the field trial was conducted. (**b**) The numbers of field trial permits acknowledged or issued in the USA are plotted by year for commodity crops and specialty crops. (**c**) The 84 unique transgenic events that have been granted regulatory approval by one or more countries are plotted by year of approval. If the year of approval varied among countries, the first year of regulatory approval granted by any agency for a given event was used. From [267]

and pest pressure, **these data translate into a forfeited value of between roughly € 300 million and € 1 billion a year because Italian farmers are not allowed to plant Bt maize.**

A summary of the Lombardia maize case has also been published in Nature Biotechnology [273]. Unfortunately, the original research report is still not published, it is "resting" in an Italian government drawer. . .

The present day regulatory "cropping apartheid" of high tech farming versus organic farming, large-scale farming against smallholders seriously hampers the development of GM crops, which could foster a more ecological production [44, 274] [275] and [276] – in short, Gene Peace instead of Greenpeace.

Costs and Lost Benefits in Developing Countries

Even more drastically, in the developing world, there is regulatory legislation in place hindering the development of transgenic crop breeding for the benefit of the poor, Driessen, Herring, Paarlberg [277–280].

Doubling agricultural research investment per se (no regulatory costs included in the calculation), would reduce poverty in Sub-Saharan Africa by 9% according to Alene & Coulibaly [281]. But these prospects are seriously hindered and as a result are practically nullified by the exorbitantly high regulatory costs during the implementation phase. Moreover, GM-free private standards set up by food companies and distributors in developed countries have influenced biosafety policymaking in developing countries: Gruère and Sengupta [282] found 29 cases where private importers have affected policy decisions in numerous countries due to irrational fear of export losses. This is based on two generally misleading premises: (1) Europe or Japan represents the only market for exports, and (2) non-GM segregation is too costly. It is amazing to realize, that many of the cases rely on unpublicized lobbying activities, and because of the lack of comprehensive evidence, many cases do not provide straightforward evidence of causality links between importers or traders and policy decisions. There is evidence that development of GM crops in Africa is mainly based on public research, and that the private sector only reluctantly invests in projects for developing countries, although the situation is getting better in the last few years [283, 284].

A blatant case of eco-imperialism is reported from Zambia by Andrew Apel in GMobelus: http://www.gmobelus.com/news.php?viewStory=234, where the Norwegian Government has partly sponsored a $400,000 laboratory, for which GENOK has contributed equipment and training, thus guaranteeing a research policy hostile to GM crops, in accordance with the official policy of the Zambian government, that characterizes GM crops as poisonous. The Norwegian GENOK is a well known anti-biotech NGO, with a very negative attitude toward GM crops, not shying away from spreading myths on allergy caused by pollen of transgenic maize in the Philippines; This is documented in the controversy between GENOK and Rick Roush: http://www.botanischergarten.ch/Allergy/Traavik-Roush-Philippines-controversy-2004.pdf, also supported in favor of Genok without a shred of evidence by John Vidal from the Guardian: http://www.guardian.co.uk/science/2004/feb/27/gm.science. Typically enough, the laboratory's priority will be to detect and search for genetically modified seeds and crops. Former Zambian researcher Ed. Rybicki, now working in Cape Town, said "that the lab would better serve Zambia and the whole region by looking at genuine threats, studying local biodiversity and even making transgenic crops themselves", as reported by SciDev Net http://www.scidev.net/en/news/zambia-s-molecular-biology-lab-fully-functioning-a.html?utm_source=link&utm_medium=rss&utm_campaign=en_news. Indeed, it is rather ironical that many of the biosafety educational efforts undertaken by organizations, highly critical to transgenesis, are turned into the "contrary": the biotechnological methods introduced in those countries are now also used for research and development of GM crops. A comprehensive report on agricultural biotechnology by Alhassan [285] demonstrates that high regulatory hurdles would hinder a reasonable development of modern agriculture in Africa.

Gruère and Smale [286, 287] report in a carefully calculated assessment that if rice cultures in India, Bangladesh, Indonesia, and the Philippines would be based on present day GM traits, the benefits amount to US$4,331 million. For the USA, an earlier assessment calculates similar sums of benefits related to the introduction of biotechnology in agriculture [288].

There has been much more written about regulatory costs and their negative follow-ups. Here only a small selection of important papers [130, 261, 289–294] is given.

The Golden Rice Development Hampered Through Overregulation. Biofortification as an Ideal Sustainable Way of Foreign Aid in Agriculture

In the case of the Golden Rice this tedious and costly regulation forced upon the regulatory authorities by the CBD solely based on the process of transgenesis has serious ethical consequences as documented in http://www.agbioworld.org/biotech-info/topics/goldenrice/index.html and in [270, 295]. A delay of the introduction of the biofortified rice is directly causing each year hundreds of thousands of children to die or to go blind due to severe vitamin A deficiency. Unreasonable and unscientific regulatory obstacles cause massive delay in approvals, especially in developing countries of S.E. Asia [296–311]. The initiator of the Golden Rice Ingo Potrykus project complains bitterly about the unjustified delays due to overregulation in a Nature article: [312].

Specifically related to the developing world, we should refrain from the old myths that international corporate companies are dominating the field – on the contrary Public Research is responsible for 85% of crop developments, 7% private local companies, and only 1% multinational companies according to figures from Cohen [284], supported by FAO statistics [313]. The myth that patenting rules are seriously hampering the spread of helpful biotech crops in poor countries has been seriously contested [314–316].

As an example, the Golden Rice project will result in biofortified rice traits, which will be distributed to the farmers free of royalties. The Asian farmers will also be able to multiply seeds without paying royalties. The homepage of the project is the main information source http://goldenrice.org/. More about the subject can be found in the important and comprehensive Handbook of Intellectual Property Rights of Krattiger et al. 2007 [317], and more: [318–321].

Biofortification programs are prone to get the highest index numbers in the evaluation system for foreign aid programs of Lempert [322]. Biofortification of indigenous landraces by systematically crossing-in the valuable and royalty free traits to enhance the nutritional value is certainly one of the best ways to sustainably help indigenous people suffering from any kind of malnutrition. In all cases known, the technology transfer is royalty free, secured by contracts.

Use of an indicator to assess the quality and success of developing aid projects defined by [322] reveals that most of the major NGO and UN actors in the field of development are actually providing relief rather than development and are creating dependency by treating symptoms rather than long-term solutions. The indicator points to the specific areas where they need to improve in order to fulfill sustainability criteria including tests of whether aid distorts financial markets and business competition, erodes appropriate government functions, and reverses colonial institutions and ideologies that interfere with sustainable consumption within a resource base.

Estimates in costs for vitamin A capsules are clearly incompatible with the living standard in developing countries; a major distribution campaign would result in millions of dollars. Neidecker-Gonzales [323] produced in their study the following figures:

- Total costs are lowest (roughly US$0.50 per capsule) in Africa, where wages and incomes are lowest, US$1 in developing countries in Asia, and US$1.50 in Latin America. Overall, this study derives a much higher global estimate of costs of around US$1 per capsule.

A bibliography of publications of the Golden Rice and Biofortification demonstrates the importance of this field of research; out of a general bibliography of 1,640 references a list of over 200 important papers is assembled: http://www.botanischergarten.ch/Golden-Rice/Bibliography-Golden-Rice-WOS-KA-20091008-links-abstracts.pdf.

It should be mentioned that biofortification strategies are also proposed for feed [324]. Straw from harvested crops can be adapted to higher feeding straw quality for cattle.

Conclusions drawn by Ingo Potrykus [325], the creator of the Golden Rice:

- The huge potential of plant biotechnology to produce more, and more nutritive, food for the poor will be lost, if GMO-regulation is not changed from

being driven by "extreme precaution" principles to being driven by "science-based" principles.

Changing societal attitudes, including the regulatory processes involved, is extremely important if we are to save biotechnology, in its broadest applications, for the poor, so that public institutions in developing as well as industrialized countries, can *harness its power for good.*

As a whole, the new, well-documented review paper of Adenle [326] delivers overwhelming evidence that GM crops are urgently needed in the developing world:

- The world needs fast and reliable solutions to fast growing population and the problems of hunger, malnutrition, ravaging diseases, poverty and global warming crisis. One of ideal technological innovations such as GM technology can be part of solutions to these problems. It is imperative to understand that GM technology cannot establish its ground if continuously faced with the baggage of constraints as discussed above. Moreover, it is not surprising to gather from a variety of literatures that most developing countries lack capacity building and still struggling with the establishment of biosafety system that can facilitate GM field trials and commercial release of GM products. Some of the challenges associated with the development of modern biotechnology still boil down to the fact that individual country government and international organisations have not clearly identified a coherent strategy and enabling policy instrument to deal with the problems. While some progress have been made on GM technology in terms of research and development, capacity building, and biosafety regulation in developed countries and a few developing countries, concerted effort is still needed to make it an accessible technology for every country. [326]

The Dispute Between Scientists and Opponents Today

The Role of Some Activist NGOs in the Debate

There is a continuous need for dialogue with regulators, the public, and specifically consumers, since the new technology emerging from modern life science is affecting all aspects of human life, including food, reproduction, etc. We do have an unfortunate trend toward irrational and antiscience argumentation in the GM crop dispute as clearly diagnosed by [327] in his book "The March of Unreason"), see also [328, 329].

This said, we should not create misunderstandings. There is no room for appeasement politics today when it comes to the activist NGOs like Greenpeace and Friends of the Earth, or websites like the Institute of Science in Society (I-SIS) and GM-Watch. Those professional organizations have proven repetitiously not to be interested in peer-reviewed science in a debate on the science and the sociocultural issues. They rather rely on unconfirmed reports in order to follow their own ideological and commercial interests. Any rational discourse with such organizations would be very welcome, but needs to be based on the latest peer-reviewed science. Their usual tactics is to appeal on fear. A good example from Greenpeace has been described on the EFB forum website http://www.efb-central.org/index.php/forums/viewthread/13/ about baseless accusations that 1,600 sheep have died from feeding Bt cotton leaves. A critique on the distorted picture on Indian cotton cultivation by NGOs is given by Herring [330] with lots of figures, facts, and extensive documentation.

Another blatant example of junk science has been launched recently by Greenpeace on You Tube "Genetic engineering: The world's greatest scam?" http://www.youtube.com/watch?v=1H9WZGKQeYg full of misinformation and hatred against multinational seed companies.

We are also confronted with violence – activities clearly documented and justifiably named and pursued as terrorism [331]. Also, in Europe, there are regularly occurring field destructions [332], which hamper seriously biosafety research – what an irony! Eco-terrorism is not confined to Europe, problems of such kind are very real also in the USA [333]:

According to the Federal Bureau of Investigation (FBI), the Earth Liberation Front, together with its sister organization, the Animal Liberation Front (ALF) has committed from 1997 to 2003 more than 600 criminal acts that have resulted in more than $43 million in damages. Moreover, attacks have been perpetrated in virtually every region of the USA against a wide variety of targets.

Recently, Greenpeace destroyed government field research in Australia [334] and defended the act of eco-terrorism with very thin arguments – and promptly lost lots of supporters and sympathy: Even

some old friends and supporters of Greenpeace (but not all) distanced themselves from the action: [335]. A list of field destruction actions in Europe has been compiled by Marcel Kuntz [336]. This list, far from being complete, demonstrates that activists have lost their moral compass in recent years: [337, 338].

One of the best rebuttals of cheap anti-GMO propaganda coming in attractive book editions, widely distributed in international events by the author Jeffrey Smith [339, 340] has been published on the Internet by Bruce Chassy http://academicsreview.org/reviewed-content/genetic-roulette/. It is actually a scientific comment, section-by-section, based on the best available peer-reviewed literature.

More chagrin emerges from the mounting pressure from within the academia, where, for instance, German university leaders in Giessen ordered to cease field research on GM crops which is unwelcome in the eyes of the extremists, [341] and there are serious complaints about the difficult atmosphere for biotech researchers in Germany [4].

Another symptomatic row is presently taking place in India, related to the approval of Bt brinjal, where activists are in a desperate attempt to stop the regulatory approval of Bt brinjal with outrageous and completely unfounded rumors like "GM brinjal will render the soil sterile," But contradictions have been posted as well: the most recent and comprehensive summary report published by Kameswara Rao [342], which is a review of massive evidence for the safety of Bt Brinjal and the detrimental heavy use of pesticides for the production of conventional Brinjal. It is ironic that one of the main arguments for proponents of the Bt Brinjal moratorium in India is now seriously questioned. There was the seemingly clear evidence on a crop biodiversity center for Brinjal in India, which called for extra protection of indigenous genomes. But recent extensive genomic analysis has clearly demonstrated that Brinjal is originating in Africa [343].

As an exemplary dispute, you can also follow the exchange of letters between the Public Research and Regulation Initiative (PRRI) and Friends of the Earth (FoE) [344]. Some of those anti-GMO activist groups get hefty funding from governments in the EU, as documented accurately by Andrew Apel and his GMobelus website: Europe's massive funding of world-wide activism. Compare also his recent article on the same subject, focusing on global aspects: [345].

The current set of arguments of GM crop opponents is often a mix of anti-American, antiglobal, postmodern, and even antiscience notions, [346], a strategy which has now been taken over very successfully by NGOs like Greenpeace and Friends of the Earth as global actors. These leading protest forces have helped, particularly in Europe, to build up a postmodern negative picture of biotechnology as a whole [347]. In this light, it is easy to act as "opinion leaders" with pseudoscientific arguments. The feedback mechanisms through the media and a network of citations of all the flawed stories make it possible for the global opponents to maintain confirmation of negation mechanisms. We are in a situation where the opponents already try to claim victory, penetrate highest political levels in governments and international organizations like the United Nations, some produce strikingly flawed reports on GM crops.

An analytical article about media and NGO activities in New Zealand has been published by Motion and Weaver [348]: by attracting media attention through dramatic protests, Greenpeace risks to jeopardize its reputation. The abstract reads:

> The challenges of attracting positive media attention are likened to a contest in which various organizations attempt to promote and circulate their version of events; however, this is particularly difficult when attempting to circulate less established, unpopular or critical knowledge. Although complying with, and managing, news values is an important starting point, the need to move beyond news values to consider the commercial values and realities of media organizations is highlighted. In this paper, a case study is undertaken of the Greenpeace media relations in New Zealand when a proposed controversial expiry of a moratorium to release genetically modified organisms into the environment. The predicament for Greenpeace is that in attracting media attention through dramatic protests it risks jeopardizing its reputation as a credible news source that can influence the framing of news stories. Insights are offered into the need for organizations to understand and manage the story or knowledge to be circulated and comply with contradictory news values.

Related to this paragraph on NGOs, it is necessary to write a word on the press: Newspapers and other media usually are mirroring what is important in the public debate, and the NGOs are clever in manipulating both the public and the press, after all, it is easy to provoke with fear and scaremongering, and the majority of journalists of all calibers are also committed to their own product, position, and its commercial situation.

A classic example is the coming and going of the Frankenfood Myth, see Fig. 3 and http://en.wikipedia.org/wiki/The_Frankenfood_Myth. Interestingly enough, this myth had its sharp peak in the press statistics around 1998 (see Fig. 3) and since then it has vanished from the headlines [104] as a major buzz word.

Those mechanisms have been precisely described by Burke for the situation in Great Britain some years ago [349]. But it is also clear that in the last 5 years more balanced voices appeared in the press, although there is no room to extend this topic here, just one recent example from the London Financial Times may suffice [350].

The GM Crop Battle, the Dispute Among Scientists, the Use of Strong Language

First, let us not forget some words of Antony Shelton [291], the most important words can translate into a slogan: "Quality of science must back up personal opinions," the abstract reads:

> In agricultural biotechnology there are roles and responsibilities of scientists, scientific journals, the public media, public agencies, and those who oppose or advocate a specific technology and serious consequences for science in general when those roles and responsibilities go awry. Scientists may feel the pressure of competition, especially in an academic setting. Personal views may continue to decide which issues one will work on, but the quality of science must back up those personal opinions. Common sense tells us that scientific inquiry and the publication and reporting of results to the scientific community and general population should be performed with high standards of ethical behavior, regardless of one's personal perspective on agricultural biotechnology.

One of the arising problems is that there has been recently a tendency to mollify peer review for the sake of politically correct so-called critical views of genetic modification of crops, with some blatant examples of flawed pseudocritical papers having passed for publication in highly respected scientific journals – a few examples have been commented by [351]. Some of those papers just passed due to flawed peer review, others passed despite rejection by some peer scientists, obviously for the sake of public debate (and for the promotion of the journal), see as an example the rather thin justifications of the editor in chief of Lancet Richard Horton to go ahead with the publication of Pusztai's rat experiments [352–356]. For more details about this controversy, see in ASK-FORCE on Pusztai [357], it is an anatomy of the case in 46 pages on the Pusztai affair, which had a big influence on the regulatory climate on GM crops in Great Britain and the world.

It is only between 2005 and 2011 that a certain fatigue of new negative arguments against GM crops is developing, and it is interesting to note that opponents, lacking real negative health and environmental effects, now shift their emphasis on negative arguments in socioeconomics. There are hardly any new issues in food safety and environmental impact to be dealt with in the last few years. This might also be the reason why in a desperate routine of repetitious "negative," GM crop stories get into journals, often also on rehashed events which have been clearly rebutted scientifically many years before. Those "news stories" often pass uncontested and get printed in "news" media due to a mix of short memory effects of uninformed editors and readers of all kind, or worse, they are purposefully repeated by activists counting on short memory of press and public.

A strange effect should also be mentioned that scientists, who defend good science in biosafety research, sometimes get blamed because they use straightforward language when criticizing flawed papers. A paper on such debates has been published by Nature [177], see the comments in a contribution of ASK-FORCE [178] on a paper on aquatic organisms supposedly harmed by Bt toxins of GM maize by Rosi-Marshall [191] and [192]. There are several controversial hints in this Nature story put forward by science journalist Emily Waltz, who is neither specialized nor experienced in the hot scientific regulatory debate on GM crops, suggesting that to criticize flawed papers

with "strong language" is detrimental to the progress of scientific research. This statement was supported by interviewed writers such as Ignazio Chapela (famous for starting the controversy of the Mexican gene flow of transgenic maize with a letter to Nature [358], which later turned out containing insufficient evidence for publication [359], see the latest summary in [360]. Another interview Waltz conducted in the cited *Nature* piece with David Schubert, who tries as a pharmacist to give advice in biosafety rules of GM food, and with his strong anti-corporate mood publishes fraud accusations against pro-GMO scientists [361]. Both interviewees Chapela and Schubert defend independent scientific whistle blowing, but themselves they have a proven negative agenda about GM crops, see more controversy papers: [295, 362, 363]. In the meanwhile, several letters to the editor of Nature have been written commenting the feature of Emily Waltz in Nature, they are all cited in [178], the majority is not supporting her thesis.

Incidentally: Strong language has been used before in the history of science, remember some really bitter and hefty disputes about the history of discovery of the double helix structure of DNA between Watson and Crick [216], who later made their peace again.

Other numerous examples of a fight out in the open are documented about evolution when Darwin proposed his revolutionary ideas. Two citations of strong language may suffice: in a debate on natural selection [364] writes on a dispute with William Bateson:

- By these admission almost the last shred of that teleological fustian with which Victorian philosophy loved to clothe the theory of evolution is destroyed. Those who would proclaim that whatever is right will be wise henceforth to base this faith frankly on the impregnable rock of superstition and to abstain from direct appeals to natural fact.

Another clear example of sharp and relentless scientific controversy on evolutionary biology with strong language has been described in detail by Strick [365], among the numerous juicy examples:

- His [Bastian's] tone was sharp in response to Huxley's public accusations that his technique was sloppy (a much more high-powered attack than Huxley ever adopted in private when attempting to correct young scientists). Huxley replied with an equally sharp tone, now saying sweepingly that "what Bastian got out of his tubes was exactly what he put into them," *i.e.* contaminants.

And one last word about strong language: The word "abuse" has been printed by Nature in the Battlefield paper [177] very prominently in the subtitle, when attacking a group of authors including me who criticize flawed papers in the GM crop debate with blunt, but still polite words – what an irony! – And to be quite clear, no complaints from my side. . . .

Negative Effects of Modern Breeding Methods in Food and Environmental Safety do (or Should) not Pass Strict Scientific Procedure Rules and Peer Review or They Are Based on an Unscientific Focusing on Transgenesis Instead on Management Mistakes

If researchers would follow strict procedural rules, the world of scientific biosafety debate would be far less complex, here are a few papers standing for such in fact uncontestable rules: [168, 260, 261, 267, 312, 366–369]. It is a fact that for some years basically no new arguments against agricultural biotechnology (in particular clearly related to transgenesis) on an agronomic base can be put forward for the most widespread crops, which have run through multiple regulatory processes in many countries.

This does not mean that transgenic crops are completely free of problems, but, in fact, it is that in comparison with conventional crop problems these are minor and manageable in a more efficient way. One of the basic mistakes of GM crop criticism is the unilateral focus on the risks of transgenes inserted, instead of comparing, in a fair and scientific (holistic!) way, with conventional cropping [370].

Still, a growing number of herbicide tolerant weeds are emerging: [371–374]. Powels [375] rightly points to the monotonous fields of glyphosate-resistant soybean landscapes, where the herbicide-tolerant weeds emerge more rapidly:

- Indeed, in spite of longterm use, the evolution of glyphosate-resistant weed populations in non-GRC, burndown systems has been very limited. Thus, functionally competent gene traits endowing glyphosate resistance are relatively rare and not easily enriched in

> plant populations [376], [377]. This is why glyphosate is a remarkably robust herbicide from a resistance avoidance viewpoint. However, as reviewed above, it is clear that, where there is very intense glyphosate selection without diversity, glyphosate resistant weed populations will evolve. In particular, the evolution of glyphosate-resistant weed populations is a looming threat in areas where transgenic glyphosate-resistant crops dominate the landscape and in which glyphosate selection is intense and without diversity. [375]

But it is also a fact that the emergence of glyphosate-resistant weeds is happening on a much slower pace than that of conventional herbicides [378].

Some critical science journalists question the strategies and behavior of the global opposition players. In a kind of last bid, questionable reviews are published, either containing lots of negative *assumptions* [379] or wrong toxico-analytical concepts resulting in an exaggerated risk assessment for nontarget insects as the lacewings as promoted by Hilbeck et al. [380–382] and contradicted clearly in Romeis [383]. Other examples of questionable eco-toxicological conclusions have been drawn by producing or reviewing flawed data or statistics, or drawing questionable conclusions, see the debate on Ermakova's flawed rat experiments: [384], more details in a contribution to the ASK-FORCE [385]. Typical other examples recognizable on filtered citation lists are Dona et al. and Séralini et al. [199, 386]. Séralini conducted his experiments in disrespect of the internationally approved rules of biosafety experiments established by the OECD [387, 388] and also avoided the citation of certain contradicting peer-reviewed references. Many of those papers have been or will be treated in ASK-FORCE [389], where you can read about new or recently updated ASK-FORCE contributions, for more details see section ASK-FORCE Organization and Related Websites.

It also must be said (remember Saner's statements at the beginning of this section) that vested interests can be spotted with some biosafety researchers, who are in need of research grants and thus paint a negative picture on biosafety; they symptomatically have difficulties to distinguish between the "nice-to knows" and the "need-to knows." Example: see the ASK-FORCE contribution [178] on the publication of [13], a paper which is flawed in several ways. It has been completely rebutted by Shelton et al. [14], the questions asked in the Lovei paper are irrelevant for Bt maize cultivation, since the Bt-toxin-technology is overwhelmingly beneficial for majority of nontarget insects [390–394]. One of the major flaws of the Lovei paper is that they used low quality prey for their laboratory feeding studies. A thorough analysis of risk assessment research has been recently published by Raybould [261]: We need to carefully distinguish between basic ecological research and purposeful and targeted risk assessment research which concentrates on the real agronomic risks and needs [395, 396].

The question and negative answer given in the letter of the Public Research and Regulation Initiative (PRRI) to the Secretariat of CBD [397] is fully justified, *and PRRI stands ready to expand on the points made in this letter.*

- 1. Are there LMOs or traits that have caused adverse effects?

  No. Since the first application of genetic modification in the 80s, many thousands of field trials have been conducted with GM organisms (to date mostly plants), and since 1996 many hundreds of millions of hectares have been planted with GM crops by many millions of farmers and consumed by hundreds of millions of consumers in developed and developing countries, without any verifiable reports of adverse effects on the environment or human or animal health.

  In fact, taking a broader look, experience with those GM crops has shown environmental and socio-economic benefits in terms of increases in yield, significant reductions in use of pesticides, fossil fuels and soil erosion, less mycotoxins in grains, as well as increased farmers health and income.

Final remarks: Coming back to the first statement of Saner [120] given under General Views on the Dialogue Related to Regulation of GM Crops, value-laden scientific activity cannot be avoided, but minimized – if you refrain to work with flawed data, with filtered citation lists, and with reviews pontificating on negative assumptions. The only remedy is to work with high-quality data produced in a methodologically transparent way following international agreement.

It is appropriate to end this rather pessimistic section with a positive note, not free of irony:

As Gupta [398] recently stated, there is hope that the introduction of strict biosafety rules in the Cartagena Protocol, originally aiming at a slowing down or even at stopping the transboundary movement (and indirectly development) of GM crops, now seems to turn into its contrary:

- Through analyzing the dynamics of GMO-related information disclosure to the global Biosafety Clearing House (BCH), I argue that the originally intended normative and procedural aims of disclosure in this case to facilitate a GMO-importing country's right to know and right to choose prior to trade in GMOs are not yet being realized, partly because the burden of BCH disclosure currently rests, ironically, on importing countries. As a result, BCH disclosure may even have market-facilitating rather than originally intended market-regulating effects with regard to GMO trade, turning on its head the intended aims of governance by disclosure.

Debate Improvements: What can we do to Enhance the Situation?

Foremost, it is important to *shift from pro-reactive to proactive mode*. This does not automatically mean to filter away negative views on GM crops and to organize a eulogy on the benefits, the pro-active mode should actually engage a new mode of debate, which is more discursive, more structured and definitely concentrates on a solution-oriented decision-making process. It is time for action – as far as a strict scientific view is allowing this. There are several websites working hard on sorting out the strictly science-oriented messages in biotechnology, as mentioned below. We should not, as it often happens, in our struggle against the negative pseudo facts focus on the risk alone and thus trap ourselves in a negativistic perspective.

Rather we should address in a balanced way the obvious (or lost) benefits as well. But this alone will not provoke a turnaround. This shift must be embedded in a discourse with concerned people and organizations and it must clearly oppose untruthful strategies of the global protest corporations and thus also refrain from using the same countertactics. One of the appropriate organizations for this activity will be the two platforms: (1) Public Research and Regulation Initiative PRRI www.pubresreg.org run by public researchers and (2) also the European Federation of Biotechnology http://www.efb-central.org/, so that public science will get a more important place in the international regulatory debate (but also where private seed companies are not fundamentally battled in a naïve neo-Marxist scheme). In many meetings strictly based on science and organized by PRRI, both platforms are well received. The project outline can be described as follows:

ASK-FORCE Organization and Related Websites

There is a flood of papers which cast doubt on the GM crops already regulated in many countries. Most (if not all) of these papers are written in a bad quality, either with flawed methodologies not internationally agreed upon, or with conclusions which are not supported by the data [13], rebutted by [14], details see in [178]. There are also many reviews published in a scientific style, but unfortunately either with a strongly biased set of references or with unsupported assumptions and doubtful conclusions – contradicted by peer-reviewed publications often not cited. In some cases, the flaws are more hidden: Experimental data are achieved on clearly theoretical schemes, working with outdated Bt maize and nontarget butterflies which have in their biology, in nature, no connection to maize fields: [399]. It is therefore important to set the record straight and to try to rebut at least the most important and blatant cases.

Within an EU project with Marc van Montagu and Piet van der Meer, which has been granted to PRRI, a blog was launched with the name ASK-FORCE on the PRRI website www.pubresreg.org with the secretarial help of Kim Meulenbroeks (until 2008) and presently Zuzana Kulikova. A list of about 130 items [400] has been compiled with international help and will be entered step-by-step in the grid of the following six sections. (1) General (2) Human and Animal Health (3) Environmental Safety (4) Agriculture (5) Public Perception (6) Developing Countries.

Up to now, 11 contributions have been published on the Internet; for links and contributions see [389]. These were reviewed by the experts of the steering committees of Public Research and Regulation Initiative and the European Federation of Biotechnology,

some also by the experts united in the blog community of AgBioWorld http://www.agbioworld.org/. All three lists contain some of the best specialists on green biotechnology from all around the world for reviewing and commenting.

In order to become more proactive, we need to develop forward-looking strategies. It is up to the scientists to ask questions to the opposition, and in particular to the professional distorters of the scientific facts. This must escalate into public campaigns if (what is to be expected) those specific questions are ignored. Carefully built contacts with science writers are important here, as a help for networkers a selected list is given here http://www.ask-force.org/web/ASK-FORCE-Summary/Contacts-ASK-FORCE-2011.pdf

Long-Term Discourse and Decision-Making Processes

Let me first be quite clear that I think a dialogue with the professional protest corporations is, as a rule, a waste of time (specifically Greenpeace and Friends of the Earth, not to mention some other organizations). Their only interest is to keep the pot cooking and make sure that the population remains in a state of fear. They should be addressed with a confrontational strategy, which is included in ASK-FORCE. Often such NGOs get the willful help of the press, which acts according to the old proverb (Macbeth, Shakespeare) "evil always fascinates – goodness rarely entertains" [401], see also the arguments produced by Andrew Moore [402]. While some press products concentrate on mirroring public concerns, a press more or less close to boulevard strives to foster its marketing with the help of sensational headlines, creating stories which sell better, but indirectly they are exacerbating the problems. We are also not going to talk about a special discourse, as described by Erjavec [403], related to the politics of the EU commission.

Nevertheless we have to address all segments of the public with its concerns, feelings, and interests. And the discourse we are going to concentrate on is solution oriented. This should be done according to the discursive rules of the management strategies of the second generation, the *Systems Approach* (see under The Second Generation Systems Approach as a New Decision Making Process). As a basic reference with description and citations, see the classic book of Churchman [79]. If we follow some ground rules, this should not be too complicated.

The Second-Generation Systems Approach as a New Decision-Making Process

Instead of making questionable concessions (example: "let's not talk about transgenic crops" as often done by Nestlé and Unilever, with notable exceptions [404] within these two companies!), the dialogue should be organized in an atmosphere of "Active Listening" [405] and understanding in which, apart from the strict rules of scientific argumentation we should send signals that the new technologies also trigger socioeconomic and cultural feedbacks. This will be the key to solve *Wicked Problems* [406], which contain also sociocultural elements besides a set of hard, often contradictory facts [122]. In his usual cynic precision, George Bernard Shaw defined the ultimate problem in the dialogue between scientists and lay people: "Every profession is a conspiracy against the laity."

The new discourse is not about the usual stakeholder meetings; rather it is about instigating modern planning processes of the second generation in evidence based but open ended decision-making processes. This *Systems Approach of the second generation* contrasts to linear planning with predetermined targets and dominating deontic thinking (e.g., of the industrial corporations and government agencies), it contrasts also to *the Systems Approach of the first generation* (e.g., Apollo moon landing with clear target).

The Rationale of New Management and Decision-Making Processes

> ▶ Some problems are so complex that you have to be highly intelligent and well informed just to be undecided about them. Laurence J. Peter [407]

These new strategies should dissolve the traditional stakeholder concept in favor of a much more efficient system respecting *different kinds of knowledge* and other rules (such knowledge differentiation is also known from learning processes, which are related to our decision-making dynamics [408].

There are more practical reasons to employ into the Systems Approach and its concept of different kinds of

knowledge, as Zwart [409] rightly emphasizes: Ever since we have realized that the low number of human genes (approximately, 22,500) cannot be interpreted as a narcissistic offence, since organisms are so highly complex, including the emerging consciousness of our human brain, genomics takes us now beyond a genetic deterministic understanding of life, this must have consequences on societal research and debate as well. Policies for self-improvement will increasingly rely on the use of complex interpretation. *Therefore, the emphasis in our discourse must shift from issues such as genetic manipulation and human enhancement to issues involved in governance of novel forms of information.* The same can be said on the side of agriculture. Ikerd [410] develops with the means of the systems approach a more holistic picture of agricultural management.

Fairclough [411] as a linguist gives an in-depth and critical analysis on discourse related to globalization with lots of facets, and again with a totally different set of terminology, he also presents negative examples of discourse. Objectivism treats globalization as simply objective fact, which discourse may either illuminate or obscure, represent or misrepresent. In the Churchman systems approach, there is no such thing as an objective approach, rather it is objectivation. Ideologism focuses upon how particular discourses of globalization systematically contribute to the legitimation of a particular global order which incorporates asymmetrical relations of power such as those between and within countries.

Scoones et al. [412] come to similar conclusions as the Churchman school, but this time related to agricultural policy, the paper explores the national and transnational character of mobilization against GM crops in India, South Africa, and Brazil in the 10-year period up to 2005. The paper argues for a better understanding of national political and economic contexts which must be taken into account, alongside on how the GM debates articulate with other foci for activism and the complex and often fragile nature of alliances that make up activist networks. It is important to understand that the debate about GM crops has become a much wider one: about the future of agriculture and small-scale farmers, about corporate control and property rights, and about the rules of global trade, see also the new report of the Royal Society [18]. In sum, a debate should not just focus on the pros and cons of a particular set of technologies – after all, they have proven safe – it is more about politics and values and the future of agrarian society. Again we see the plea for the complexity of "*wicked problems*" to be solved.

The downside is that those planning processes of the second-generation are time consuming and need a careful and tedious procedure in developing the most important and difficult *zero-step* – before such decision making can be started. It also implies an exchange of knowledge between the parties beforehand, in order to minimize *hidden agendas*. It also must be emphasized that those decision-making processes do not lead necessarily to a predefined goal, they are often *open-ended* and demand flexibility among the discourse participants, who need to remain open-minded.

The more questions we ask the more answers are possible and vice versa. Limitations of technological solutions are always hidden in the open ecological and social systems: Just compare the (in)famous case of DDT sprayings in the past [413–415]. Today, it is clear that with linear planning, DDT has been banned for ecological and health reasons, not considering the wider argument field of malaria prophylaxes. This inconsiderate DDT ban has caused millions of malaria deaths in Africa. Today, reasonable domestic use of DDT has again lowered the malaria threat measurably. Constraints in possible secondary effects in ecology should be examined carefully. This is well demonstrated in the case of the Monarch larvae being killed by Bt-Maize-Pollen, the result of a laboratory study published in Nature [416] where the subsequent press interpretation got way out of proportion – even though the author Losey himself warned about the limitations of this small lab study. Would researchers have asked the farmers, they would have been able to say that feeding time of the young larvae do rarely overlap with the time of pollen shed of maize, and that the plants the Monarchs are feeding upon are fiercely fought as a weed. Subsequent field studies revealed that there is no problem arising from extensive Bt maize planting for the Monarch larvae [12].

In order to tackle wicked problems, you need to go through *an extensive process of argumentation*, also called objectification, not to be mixed up with an "objective approach" to the problem.

There is rational planning, but there is no way to start to be rational: One should always start a step

earlier, since there are important trends and facts which will make straightforward rational thinking and acting in solving wicked problems useless. It is not the theory component, but rather the political component of the knowledge, which determines the vector of the action. This is the *zero-step* so important in the publications of Horst Rittel [121, 122].

As an example: The fact, that experts can be wrong and farmers know better in certain situations in agriculture because they are better observers out in the field and because they are very experienced in traditional knowledge [417].

The knowledge needed in solving wicked planning problems is not concentrated in a single head. It is absolutely essential to let all partners be involved in the problem solution process, which includes part of the population (mainly farmers' organizations and consumer organizations), the Governmental Regulators, the Non-Governmental Organisations, the Life Science Companies, and the Scientists. There is no monopoly of knowledge. Having illustrated the difficulties in solving wicked problems, we need a new approach in problem solving, in order to avoid the pitfalls of ignoring bottom up feedbacks.

You only can keep to this rule if you are also following another important rule. All partners in the planning process have to avoid hidden agendas, which is certainly eased by a minimum amount of respect paid to each other partner. Nobody should be criticized for speaking up in his own interest.

A caveat: It would be naive to just believe in the discursive capacities of the civil society, contrary to what Gerhards [418] has shown – that Habermas' support for the discursive model is based on the assumption that actors of the civil society argue much more discursively and on a higher level of rationality than other collective actors do. But empirical results show that actors of the civil society are, maybe, even less discursive than other actors.

It is primarily the paradox of rationality which has been severely underestimated in the systems approach of the first generation when tackling *wicked problems*.

How to Solve Wicked Problems in Biotechnology and the Environment What we need in such cases is an action-oriented approach. Risk Assessment and Management must be seen as a planning strategy of the second generation in developing a professional framework for *decision making*.

Strategies have to be developed to recognize the consequences of our doing on one side, and to specify our knowledge on the other side. This knowledge has to be gained step by step and case by case. If we want to clearly distinguish our present state knowledge from appropriate decisions to be made *not* based on our views and opinions, we need to go through the following steps:

- What is the problem?
- What do we want?
- What are the alternatives?
- How do we compare them?
- How can we reach the solution?

All participants need to keep in mind that there are *various types of planning knowledge* (arranged according to the five questions asked above).

Examples given here are lumped together as simple keyword illustrations, taken out of their context in real planning examples, and they cannot be regarded as an example of a realistic situation; this would be exactly the task of a planning process of the second generation.

Factual knowledge is the knowledge of what actually happens (quantitative data or empirical, observational data). Gene flow species by species/region by region/facts about insect resistance in agriculture.

- *Deontic Knowledge*, the very important knowledge of what ought to be. The knowledge about new crops which enhance agricultural production/new agricultural techniques to avoid erosion/new biological approaches to fight insect pests etc.
- *Explanatory Knowledge* explains why things are so or why certain effects will happen. Here, you already start to determine the direction of the solution. The way Bt proteins are acting on specific pest and beneficial insects/what are the main reasons of unwelcome erosion effects/mechanisms of vertical gene flow/mechanisms of resistance development.
- *Instrumental knowledge* on how to steer certain processes, on how to achieve certain goals, knowledge which needs to be balanced against regulation and safety. The way how to build Bt and other genes into crops and how to stabilize them/how to avoid

vertical gene flow/how to avoid unwelcome soil erosion/how to avoid early upcoming pest resistance.
- *Conceptual knowledge* which would allow avoiding conflicts before they pop up. This is the knowledge about complex situations, taking into account all previous kinds of knowledge and also weighing them against arguments coming from open ecological and societal systems. Concepts about transgenic crops compatible to the ideas of a sustainable agriculture. Lawyers and judges also may work with this kind of procedural knowledge.

You need to go through an *extensive, time-consuming process of argumentation*, also called objectification, not to be mixed up with an "objective approach" to the problem. The hopes of this process are:

- To forget less, to raise the right issue
- To look at the planning process as a sequence of events
- To stimulate doubt by raising questions, to avoid short-sighted explicitness
- To control the delegation of judgment. Experts have no absolute power; scientific knowledge is important, but always limited.

There is no such thing as "scientific planning."

- Solving practical problems as to develop sustainable transgenic crops cannot be dealt with by "scientification of planning." Dealing with wicked problems is always political because of its deontic premises (means that you have to involve knowledge what ought to be) and because we deal with traditional knowledge. Science only generates factual, instrumental, and in the best case explanatory knowledge.
- The planner (here the manager of an action plan) is not primarily an expert, but a *mid-wife of problem solving,* a teacher more than a doctor. Moderate optimism and careful seasoned disrespect, casting doubt is a virtue, not a disadvantage of an action plan manager.
- The planning process of wicked problems has to be understood as an *argumentative process*, it should be seen as a venture (or even *ad*venture) within a conspiracy framework, where one cannot anticipate all the consequences of plans.
- Systems methods of the *second generation* are trying to make this deliberation explicit, to support it and to find means in order to make this process more powerful and to get it under better control *for all participants.* Methods like the computer-based argument mapping systems of can be helpful [419].
- It helps making such processes more successful if they are conducted in the spirit of the *Symmetry of Ignorance* [420] – this is the secret of the active listening which often leads to acceptable outcomes and trust.

This seems to be a rather theoretical approach with lots of restrictive rules, but actually it is, on the contrary, an opening for much more freedom in dialogue. Also, it is more practical and efficient in creating results and contrasts with the traditional stakeholder concept where hidden agendas prevail in often disguised authoritarian structures. Such discursive processes are described in detail [80, 121–123, 421–425]. A comprehensive and voluminous monograph on risk-related debate methods has been published by Ortwin Renn [426], see especially the texts related to risk communication with essays 7 and 8 and section 8 on risk participation with numerous references, but notably lacking completely the papers on the "Systems Approach" of the Churchman/Rittel/Webber school.

In a French paper, the origin of negatively connoted words in the debate on GM crops like "contamination," "pollution," "Frankenfood," etc., Moirand [427] clearly reveals the links to negative events like BSE, dioxin scandals, and of course Tchernobyl, etc., thus explaining new words like "mad soya" and "mad colza" in the media. Moirand concludes that a new type of discourse is needed, but also Renn [426] does not refer to the very pragmatic and promising systems approach of Churchman and Rittel.

There are many more schools promoting discourse and new decision-making processes, also in specialized journals, only a few can be summarized here for space reason: [75, 76, 78, 84, 119, 120, 411, 427–441].

See Patrick Moore's practical examples of decision-making processes solving environmental and sustainability problems in forestry, consult his own website Green Spirit http://www.greenspirit.com/index.cfm. These processes need time. Patrick Moore [442–444] has gone successfully through such processes in the

difficult task of reconciliation between the needs of timber production and environmental constraint; he needed months of debate to come to reasonable decisions.

Another good example on how group discourses have good learning effects, has been described by Snyder et al. [258]: Although the US government has assured stakeholders of their safety, the EU continues to be an outspoken opponent. This can largely be attributed to a lack of trust in the regulatory process, and especially a cynical perspective on the underlying science and institutions that govern approval. Such disparities were illustrated in 2003 when the USA donated GM maize to aid African countries stricken by famine. Under purported EU threats, negative propaganda by NGOs, and stressing retaliatory trade sanctions, African officials refused the aid. An examination of this episode contrasts the potential discord between those affected and those who formulate government policy. Using resources from both sides of the debate, this scenario summarizes the pertinent issues regarding EU's refusal to the import of transgenic crops. A group discussion and debate protocol was developed for facilitating small group and entire class consideration of the scenario while strengthening student critical thinking skills.

It helps, if you prepare carefully scenarios before people start the process, a method which has been successfully applied to the reconciliation processes in South Africa after abolishing apartheid by Adam Kahane, one of the principal mediators [445]. He also followed another wise rule: Should only people participate in such processes who are part of the problem. Another excellent example of long-term discourse is described in many aspects by von Grebmer et al. [437]:

- By working collectively the process will be more open, transparent, inclusive and accountable, and sensitive to the normative dimensions of the issues critical to the participants. The themes and processes outlined in this article set the stage for the discussions, internally and between countries, that will shape the policies of agricultural biotechnology in the region. If the dialogue can frame the discussion and be enriched by the information generated from actions taken, it can sustain the interest and commitment of the stakeholders, and more successfully direct biotechnology toward reducing hunger and poverty in the region.

There are too many scientists remaining in the ivory tower, shying away from public debates. They fear losing their independence, a fear which is not just unfounded, but actually it is the contrary: remaining in the academic ivory tower means having lost your independence, since science is not an art per se, it is full of importance for society and humanity. A strong plea in this direction is coming from [446]. Although science should remain at the heart of invention and the drive to make our lives better, scientists should, instead of always having "the answers" ready, should not be afraid to engage in a contradictory evidence-based mode.

In one of the most successful examples of long-term discourse, the author participated as an invited expert in a public hearing in 2000. Strikingly, it was done without the theoretical load described above, but with lots of financial and logistic help from the New Zealand Government, in particular from the Royal Commission on Genetic Modification. A report was finalized after a 14-month inquiry into the risks and benefits of genetic modification. It heard from over 400 experts, including scientists, environmentalists, and ethical specialists. It considered more than 10,000 public submissions and heard the view of many others during a series of public meetings, hui, and workshops around New Zealand.

The Royal Commission's major conclusion was that New Zealand should proceed cautiously with genetic modification (GM) but not close the door to the opportunities offered by the new technology http://www.mfe.govt.nz/issues/organisms/index.html. The discourse is still continuing. Again, it is visible that the discourse is less confrontational and may lead to innovative solutions in the future [447]:

- The debate about genetic modification (GM) can be seen as characteristic of our time. Environmental groups, in challenging GM, are also challenging modernist faith in progress, and science and technology. In this paper we use the case of New Zealand's Royal Commission on Genetic Modification to explore the application of science discourses as used by environmental groups. We do this by situating the debate in the framework of modernity, discussing the use of science by environmental groups, and deconstructing the science discourses evident within environmental groups' submissions to the Commission. We find

science being called into question by the very movement that has relied on it to fight environmental issues for many years. The environmental groups are challenging the traditional boundaries of science, for although they use science they also present it as a culturally embedded activity with no greater epistemological authority than other knowledge systems. Their discourses, like that of the other main actors in the GM debate, are thus part of the constant renegotiation of the cultural construct of 'science'.

However, this process should not be mollified on the costs of hard science. The line between science and pseudoscience is often difficult to draw.

A Remark About the Psychology of the GMO Debate To be written in the next coming days.

It should also be possible to think and act in relation to the reconciliation of science and spirituality, since it will be an important element besides the ratio of science, the ethics of our societal activities, and the emotional elements in human life. But it will be difficult to separate the cheap esoteric chaff from the precious seeds of true spirituality, as Helmut Reich's writings demonstrate [448]. We must endeavor new fields of thought, as done by Papazova Ammann [449], a Bulgarian-born Swiss philosopher with roots in the schools of Muntjan and Rittel.

- What do we need as visionaries: Progress or Development? This is my question today, as I deal with the topic of Biovisionaries here in the Library of Alexandria. I ask this question because I am convinced that we need to build a new culture of questioning. We need a culture orienting itself by authentic questions. How can we develop taste and the ability to distinguish between those questions which are cognitive, statement-oriented and those which are authentic, close to life and to people? What is more important: cognizance or decision for action? How can we move between Statements and Questions? Statements reflect the need to understand the world. But they are the result of past experience and are often contained in frameworks which are coined by society. They may even protect old routines which hinder innovation. Questions, in contrast to statements, can transform our judgements and prejudices. Questions give birth to energy for new orientation, for a more conscious future. This orientation towards the future, towards vision provokes those choice-questions, and they alone will open the way for an urge to change the world. Visions need people who are free! The quality of freedom is inherent in the question. We must strive for this quality through choice-questions. If we cannot befriend these choice-questions with science, it will disengage from the questioners and will not be human science anymore. Thus we need a new humility of thinking – as it has been wonderfully defined by the German philosopher Heidegger: "The question is the devoutness of thinking".

Conclusions Only a multifaceted dialogue over a considerable time span will lead to success. The Internet scene is developing fast and new communication software tools are available now, so careful scrutiny for such a network of networks need to be done first, and the big players like Google and competing networks should be consulted as well.

Personal experience in dialogue with many networkers reveals that sometimes important networks are only known in specific clusters, these lacunas should be closed for many reasons – see section Illusions and Realities on Educational Effects in the Debate, the Dialogue Between Science and the Public. Knowledge exchange, jumping over national fences, and coordination will be a follow-up effect, without even declaring it to be the goal of such activity. As for now, this is just an idea and needs to be discussed with Internet and website specialists. After all, the leading webmasters and coordinators agree that it is time to *enhance collaboration through better communication.*

ASK-FORCE can contribute to this process in making sure that professional peer-reviewed risk assessment papers are fed into the dialogue processes and are ideally fed into a life decision–making process with relevant participants.
