Article Outline

Glossary

Cereals Monocotyledon plant grains that accumulate starch as the main storage substance for subsequent germination. Two types have been distinguished – cereals that contain gluten and are used for bread-making (wheat, oats, barley, rye) and cereals that do not contain gluten (rice, maize).

Genotype × environment interaction Relative changes in genotype performance when grown under different environments.

Grain development Structural and functional changes that occur in the fertilized flower producing a mature grain capable of germinating.

Grain growth Irreversible increase in grain weight and size caused by cell division, expansion, and reserves accumulation.

Grain quality Group of grain characteristics and measurable attributes (objectively or subjectively) to meet the clients' requirements (i.e., customer, industry, consumers).

Oilseeds Dicotyledon plant grains that accumulate oil as the main storage substance for subsequent germination. Oilseed crop seeds (sunflower, rapeseed, ground pea) are composed of 40–50% oil and 20–30% protein while proteo-oil crop seeds (soybean, lupine) comprise 15–30% oil and 30–40% protein.

Photoassimilates Carbohydrates (sugars, starch, or fructans, depending on the species) synthesized by the green plant parts and translocated to actively growing organs, like grains. Photoassimilates may originate from current photosynthesis or reserve remobilization.

Source–sink balance Quantitative relationship between plant photosynthetic capacity (source) and number of organs under active growth (sink) that are sustained by the former.

Plant stress Changes in plant metabolism in response to environments that endanger plant survival or hinder reaching maximum reproductive capacity.

Definition of the Subject

Grain quality is frequently regarded by agronomists and breeders to be as important as yield. Quality characteristics are the reason why only few plant species are used to satisfy most human requirements for food and fiber [1]. Grain quality comprises a group of characteristics that collectively determine the usefulness of the harvested grains for a particular end use. Therefore, to breed and manage grain crops to achieve a specific quality standard and to be able to predict the quality of a particular crop in a particular growing environment is rather important. Achieving this objective is dependent upon the knowledge of the factors modifying grain composition, and consequently grain quality.

As grain markets have become more specialized, there is a growing pressure on farmers to produce grains with greater uniformity and with certain characteristics [2]. Appropriate husbandry to obtain grains with high and stable "quality" will likely be of increasing importance in achieving economic benefits. It is well known that grain quality is modified by the environment and the crop management practices used by farmers. However, the strategies and tools required to produce grains with certain quality characteristics

are not as well established as the ones for achieving high yields. In this context, improving the understanding of the factors that determine grain quality has become increasingly important.

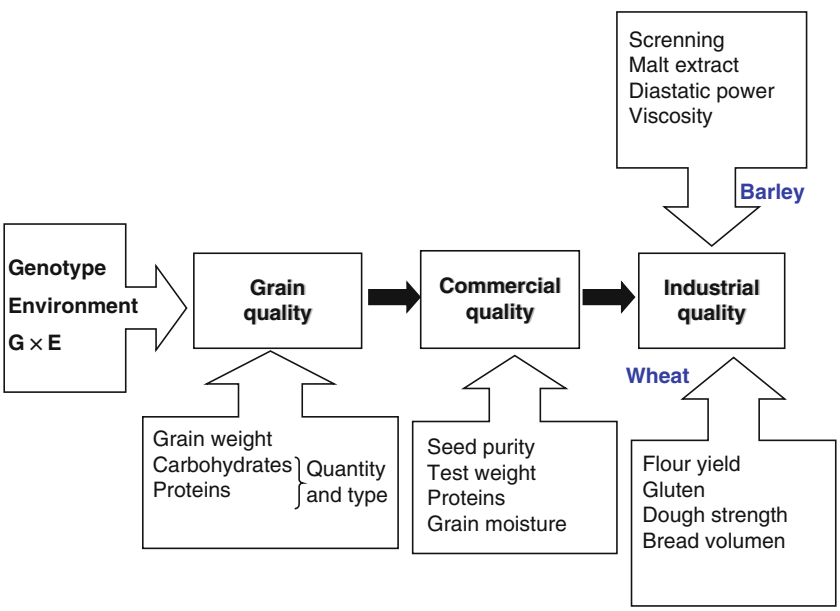
Grain Quality: Concept and Importance

In field crops, the quality of the end product is related to the composition and structure of the seed at harvest maturity. Seed composition and structure at harvest are determined by the genotype, the environment, and the crop management practices used during the crop growing cycle. It is not possible to propose a unique grain quality definition for any specie because it changes depending on the product end use. There is a proper criterion on the concept of quality for each specific end use and for each stage of the commercial chain in every crop (i.e., from harvest in the field, through grain dealers to the industry, Fig. 1). In this context, quality will be considered in relation to the criteria used by those involved in the various aspects of growth and utilization of the grain. As an example, for wheat and barley (Fig. 1), grain quality at the moment of harvest in the field is related to grain size (and weight) and the carbohydrates and protein composition. When the grain is sold to the grain dealer, seed purity, test weight, grain moisture, and protein percentage are the main characteristics that are taken into account for the prize (Fig. 1). After this stage, other attributes may be relevant and they will depend on the involved industry. For baking industry, flour yield and dough strength will be of maximum importance in wheat, while barley for producing beer will take into account the screening percentage, malt extract, and diastatic power, which in turn is related with nitrogen content.

This article aims to summarize key elements of grain structure, grain growth, and synthesis of major grains components in field crops in order to highlight the main attributes which modify grain quality.

Grain Structure

Harvested cereal and oilseed organs may comprise true seeds (soybeans, rapeseed) or fruits (seeds and maternal-accompanying structures, like sunflower achenes or wheat, barley, rice, maize, and sorghum caryopses). Seeds develop from fertilized ovules and consist of three genetically different tissues: (a) the embryo developed from a zygote (diploid, representing the next



Grain Quality in Oil and Cereal Crops. Figure 1
Schematic postharvest processing and storage of wheat and barley production and main quality attributes in each step

generation), (b) the endosperm (usually triploid), and (c) the seed coat formed out by integuments, representing the maternal tissues of the ovule [3]. The proportion of these three components differs in mature seeds of cereals and oilseeds; endosperm is preponderant in cereals while the embryo prevails in oilseeds. With a few exceptions, the development of the endosperm always precedes that of the embryo; and the seed coat development precedes both. These genetically different parts interact closely during development and germination, and recent studies demonstrate the complexity of the connections and regulations among the different seed tissues [4, 5]. After fertilization and seed setting, grains are the primary sink in the plant. Grain filling requires important amounts of photoassimilates supplied by the mother plant through actual photosynthesis and/or the remobilization of stored carbohydrates from vegetative structures. No vascular connection exists between the mother plant and the developing embryo [5, 6] so grain growth is therefore sustained by water and solute movement through cell membranes regulated by both mother plant and seed.

Seed-attached structures include coats (testa and tegmen) and other diverse maternal-originated structures, like the lemma and palea in cereals, pods in soybeans, siliques in rapeseed, and hull (ovary wall attached to the floral receptacle) in sunflower. These structures can greatly influence grain quality appreciation. The seed coat color in different types of beans (*Phaseolus*) impacts consumers differently according to the region, causing rejection of some genotypes albeit their good nutritional properties. Sorghum caryopsis with or without tannins are another example of the importance of grain coats affecting seed quality. Some seed coats can provide nutrients, like the B-group vitamins and micronutrients in cereal brans. In addition, they contribute to other important biological and technological functions, protecting the seed from mechanical damage in postharvest, or by affecting the industrial grain processing (wheat grinding, barley malting, rice parboiling). Seed coats can also impact seed dormancy and germination processes [7]. During recent years, seed-attached structures have received special attention as influencing the potential grain size and volume [8–11].

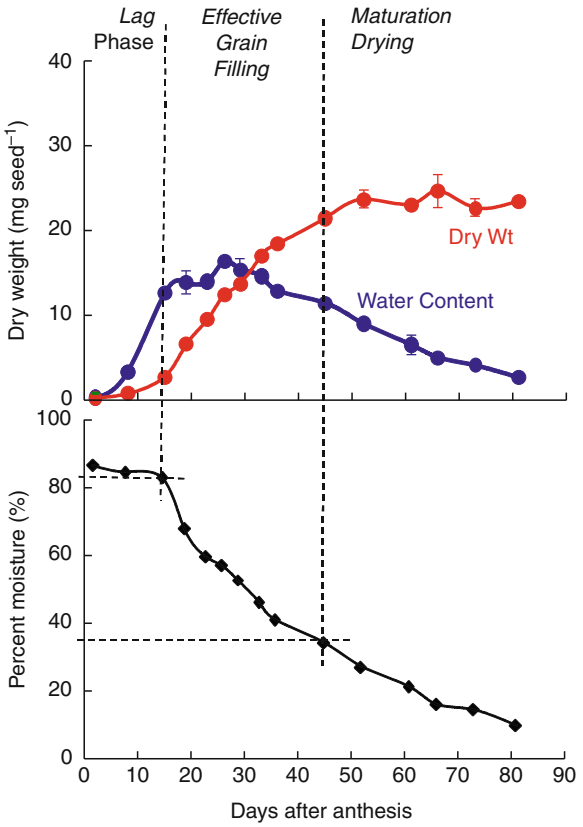
Seeds store carbohydrates (starch, oil) and proteins (soluble and insoluble). The places where these reserves are accumulated vary widely between cereals and oilseeds. In cereals, the tissue that specializes in storing starch and protein is the endosperm. In contrast, oil seeds do not have a specialized storage tissue; oil and protein accumulate in embryo and cotyledon cells. The well-developed starchy endosperm of cereals, with an outer aleurone layer, can comprise as much as 80% of the dry weight of the mature seed. The mature endosperm consists of dead cells packed with starch granules embedded in a protein matrix. The embryo is relatively small, accounting for only about 1–2% of the seed dry weight in wheat, and is usually located on one side of the seed near the point of attachment of the seed to the mother plant [3, 6]. The non-endospermic true seed of oilseeds consists of a large embryo with two cotyledons and the embryo axis. The majority of the reserve materials are stored in the cotyledons, which make up as much as 70% (sunflower) to 90% (soybean, rapeseed) of the total seed dry weight [6].

Grain structure is important since it determines grain and industrial processing quality. Cereal endosperm structure is defined by the number, shape, and size of the starch granules, together with the quantity and type of proteins in the protein matrix. Endosperm structure is used to classify wheat according to its hardness (soft, hard), thus affecting its industrial processing quality (milling capacity and flour yield). In addition, endosperm structure is used to separate dent and flint maize according to the quantity and partitioning of the floury and horny endosperm (greater proportion of horny endosperm in flint maize). Other endosperm structure characteristics that affect grain quality are vitreousness and color, both important for maize, rice, and bread and pasta wheat. Grain structure is also important for defining oilseed quality. In sunflower, the proportion of hull and embryo is an important attribute that defines oil yield, since the hull does not store oil and therefore reduces the oil concentration in the embryo. In the past 30 years, genetic improvement has reduced the hull proportion of sunflower oilseed, increasing the oil percentage on the whole seed [12]. However, thin hulls are usually harder to remove during industrial processing, so other improvement strategies are needed to increase the percentage of sunflower oil in the future. Grain structure has, therefore, a strong impact on the commercial and industrial quality of the grain, and

for this reason its attributes are present in grain marketing regulations worldwide.

Grain Growth and Source–Sink Balance

Seed Biomass During grain filling, the pollinated flower undergoes cell division and differentiation and forms a mature grain (development), which increases in size and weight (growth), reaching mature grain dry weights of 30–50 mg (wheat-barley), 250–400 mg (maize), 20–25 mg (rice), 30–50 mg (sunflower), 150–400 mg (soybeans), and 2–5 mg (rapeseed). Growth and development dynamics can be described by analyzing the rate and time period of grain growth (Fig. 2). The latter are useful tools to explain changes in the final grain weight due to genotypic and environmental factors. Species differ in their biomass per seed, and ample intra-specific differences are also observed [6].



Grain Quality in Oil and Cereal Crops. Figure 2
Dynamics of individual seed dry weight (Dry Wt), water content per seed, and seed moisture of wheat seed

Commercial genotypes used by farmers in maize, wheat, and soybean show differences in seed size, and this variability is even larger when exotic material is considered.

Seed biomass accumulation is commonly partitioned into three phases: the lag phase, the effective seed-filling period, and the maturation drying phase (Fig. 2). The lag phase is a period of active cell division. It is characterized by a rapid increase in water content with almost no dry matter accumulation. Following the lag phase, cells within the seed enter a differentiation and maturation phase, and a period of rapid dry matter accumulation resulting from the deposition of seed reserves. This phase is generally referred to as the effective seed-filling period. As in the lag phase, water content continues to increase rapidly and eventually establishes the maximum volume of the seed. Species vary considerably as to when maximum seed water content is achieved during seed filling [13]. In maize kernels, maximum water content occurs near mid seed filling [14], while in soybean seeds maximum water content is achieved at a later stage, when 70–80% of the final seed size has been achieved [15] and conversely, sunflower reaches it earlier with only 30% of final grain dry weight [10]. During the third phase of development, seeds loose water content, reach "physiological maturity" (maximum dry matter accumulation), and enter a quiescent state [3]. Seed water concentration declines throughout the three stages of seed development (Fig. 2). This decline is most obvious after seeds reach physiological maturity, but it also occurs during rapid seed filling as water is displaced by reserves [14–16].

The progress of dry matter accumulation in developing seeds and the concurrent loss of water are closely related phenomena. Studies with maize, wheat, soybean, and sunflower [17–20] have shown that final seed size is achieved at, or near, a minimum water concentration. Also, results from several studies have shown that seed water concentration accurately predicts the percent of maximum seed size achieved at any moment during seed filling in wheat, soybean, maize, and sunflower [17–20]. Such results support the notion that the duration of seed filling is determined by the interaction between reserve deposition and declining cellular water content, where deposition of reserves such as starch, protein, or lipids replace water

until a critical minimum water concentration is reached [6, 20, 21]. Species differ in the seed water concentration when they achieve maximum seed biomass [13]. For example, soybean seeds reach maturity at ~62%, maize seeds at ~36%, and wheat seeds at ~37% moisture. Although minor compared to differences across species, it has been shown that when an ample set of cultivars within a species is analyzed, variability for this trait can also be observed [22].

The rate of seed growth during the effective seed filling is highly dependent upon the number of sites for reserve deposition. The usual estimate of seed sink capacity is the number of differentiated cells during the lag phase. In maize, wheat, and other cereals, the number of endosperm cells is highly related to the rate of seed growth during rapid seed filling. In legumes such as soybean or pea, the number of cotyledon cells is highly related to the rate of seed growth. Thus, rate and duration of grain filling are important to define the final grain weight, an important attribute of grain quality.

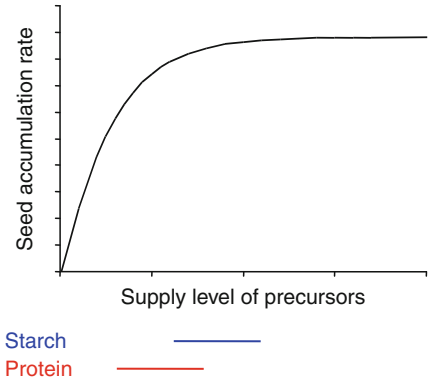
Source–Sink Balance In higher plants, nutrients from assimilation sites (sources) are delivered to sites of nutrient utilization (sinks) through an interconnected network of sieve elements. Partitioning of phloem-delivered nutrients between competing sinks is governed by their relative ability to unload major osmotic species from the importing phloem sieve elements [23]. This process depends upon a set of intercellular (post-sieve element) transport events which are integrated with growth or storage functions of the recipient sink tissues [24].

Species differ on the seed size at maturity [25], and this interspecific variability is more related the amount of assimilates available per seed during the early lag phase than during the effective seed-filling period [21]. At flowering, plants adjust the number of seeds and the potential seed size to the growth environment [21], and species differ in how they distribute available assimilates into more seeds or more potential seed size at around the period when seed number is being determined [26]. Seed size is mainly determined by the genotype, although the environment can affect the final size as well. Water availability and temperature are two environmental conditions that can create important changes in the size of the seeds at maturity.

The amount of assimilates available per seed is usually referred as the source–sink balance, and is used to describe the relation between the total amount of available assimilates and the sink number. This ratio is used to simplify the idea of assimilate availability per sink, and the way the source–sink ratio has been estimated can vary widely. Different researchers have used plant growth per seed, green leaf area per seed, sucrose availability per seed, and alternative approaches including plant growth per day per unit of sink growth per day. The source–sink balance that the seeds experience during their growth is adjusted at around flowering, when plants are setting the number of seeds.

Because plants grow in a nonuniform environmental condition, the source–sink balance during the period when seeds are accumulating biomass can change. An example can be a defoliation caused by an insect eating leaves attacking the crop at mid grain filling (which would reduce the source–sink balance of the crop) or a drought stress reducing plant growth (also reducing the source–sink balance). The source–sink balance becomes relevant because not all seed components vary to the same degree when assimilate availability per seed is altered, so the seed composition and quality may change [27–29].

Jenner and coworkers developed a theoretical model to understand how changes in the amount of assimilates available per seed can affect seed composition [28]. Their model is based on the idea that each one of the seed components can be more or less affected by changes in the level of precursors available for the growing seed because not all components are receiving from the mother plant the same level of precursors needed for their deposition within the seed. An example is illustrated in Fig. 3, where changes in the level of precursors will most surely not affect the starch content of the seed but changes in the level of precursors needed for protein synthesis will affect the protein content and the final protein concentration. This model helps explain why changes in plant growth (that affect the precursor levels) will most surely not affect starch content but will surely affect the protein content of the seed. Recent studies conducted on soybean [30] and maize compositions [27, 31] agree with this model.



Grain Quality in Oil and Cereal Crops. Figure 3
Level of precursors available per seed to synthesis of different components of seeds (Adapted from [28])

Synthesis of Major Components

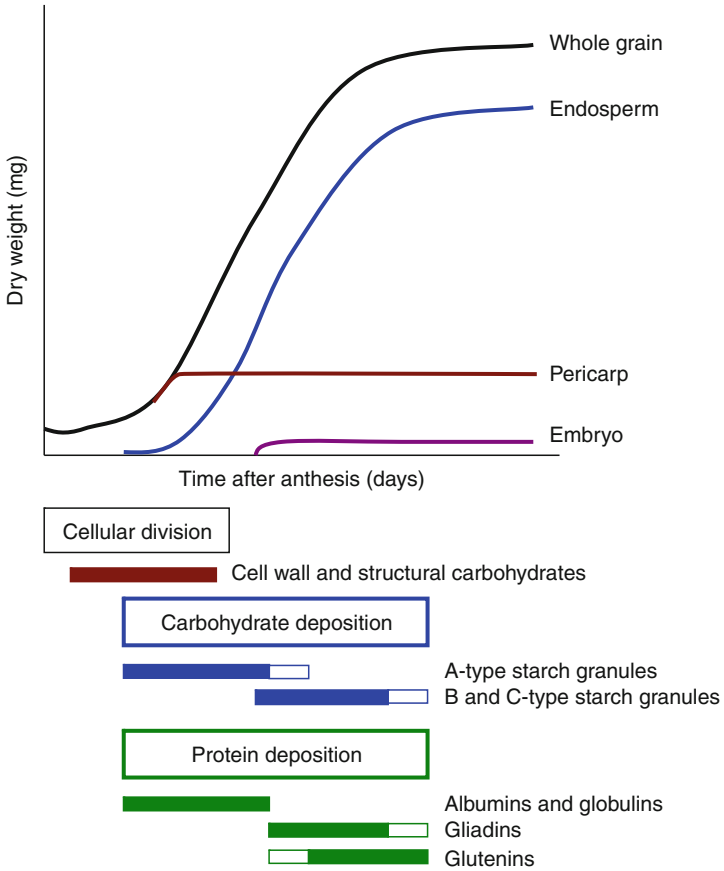
Grain growth involves growth processes of various structures (seed coats, embryo, endosperm) and accumulation of different substances (starch, oil, protein). Grain components are not synthesized simultaneously nor do they occur at the same rate; thus, physical and chemical grain composition varies during grain filling. This is an important aspect when dealing with industrial and nutritional grain quality.

As an example, the different parts of a wheat grain and the main components synthesized during grain filling are shown in Fig. 4. Starch is the main component in wheat, comprising 70–80% of the final grain weight. Different types of starch granules of varying numbers, shapes, and sizes are synthesized into the endosperm cells. The A-type granules are bigger and quantitatively more important than the succeeding B- and C-type granules. Starch is composed of amylose and amylopectin at a 3:1 ratio, except in waxy genotypes where amylopectin is more abundant.

In wheat bread, proteins comprise 5–20% of the final grain dry weight and include albumins and globulins (30–40%); gliadins and glutenins (60–70%). Albumins and globulins have enzymatic and metabolic functions and are located in the embryo and aleurone layer; gliadins and glutenins form the gluten and are reserve proteins, confined in the endosperm [32]. During grain filling, metabolic proteins are synthesized first and predominate until 10–15 days after anthesis. Reserve proteins accumulate during the effective filling phase; gliadins are the first to be detected (10–15 days after anthesis) while glutenins are deposited later (15–20 days after anthesis). Gliadins give viscosity to the mass while the glutenins confer elasticity, and both result in viscoelastic gluten appropriate for a good loaf volume. Since the gliadins:glutenins ratio changes during grain filling, crop exposure to stressful conditions (i.e., high temperature, water stress) during this phase will modify the total protein mass and the gliadins: glutenins ratio, affecting baking quality.

Grains from other species have different grain component synthesis patterns. For example, in maize there is only one type of starch granule and although starch is synthesized through the entire effective filling phase amylose accumulation occurs after amylopectin. Reserve proteins (5–14% of the final grain weight) are accumulated during the entire effective filling period as well, forming protein bodies in the endosperm cells. Oil accumulation (3–15% of the final grain weight) takes place at the end of the filling phase and most of the oil is found in the embryo. In oilseeds, oil and protein are the main reserve substances; carbohydrates are scarcely accumulated (<20%). Sunflower seeds contain 40–55% oil and 10–20% protein, while soybean seeds contain greater protein percentages (35–50%) and lower oil percentages (10–25%). Both protein and oil are deposited in the embryo cells during the linear grain filling phase. Oil deposits form oleosomes or lipid bodies of spherical shapes, while reserve proteins form dense and irregular protein bodies [33, 34].

During grain filling oilseeds, protein synthesis usually occurs after oil synthesis. Oil is formed by triglycerides, which are composed of one glycerol molecule combined with three fatty acids. Fatty acids differ in the number of carbon atoms (typically between 14 and 22 in vegetable oils) and the number of double bonds between carbon atoms. The different proportions of fatty acids modify the physicochemical and industrial properties of oils. Oils with high saturated fatty acid percentages (without double bonds; like palmitic and stearic acids) are semisolid at room temperature, with a high melting point and a higher resistance to oxidation (fat degradation due to oxygen presence). However, consumption of these oils (especially palmitic acid) increases cholesterol levels in the bloodstream. On the contrary, oils with high proportions of monounsaturated fatty acids (like oleic acid) and



Grain Quality in Oil and Cereal Crops. Figure 4
Grain filling dynamics of a cereal (wheat) and synthesis of major grain components (Adapted from [29])

polyunsaturated fatty acids (like linoleic and linolenic acids with two and three double bonds, respectively) are liquid at room temperature, have a lower melting point, and a higher susceptibility to oxidation as the number of double bonds increase; these oils are healthier than saturated fatty acids. During grain filling, the proportion of fatty acids varies according to the species and crop varieties. In traditional sunflower genotypes, the oleic:linoleic ratio decreases during grain filling while total oil accumulation increases. In contrast, in "high oleic" sunflowers, the oleic proportion is high and constant during grain filling due to the low activity of the enzyme responsible for the linoleic synthesis deriving from oleic acid [35, 36]. Oil final composition varies greatly among oilseed species, and genetic improvement has achieved a wide variety of fatty acid compositions within the same species resulting from physical and chemical mutagenesis that affect specific enzyme functions responsible for the presence of double bonds in fatty acids [37, 38]. These enzymes are also affected by the environment, producing changes in grain oil content and composition.

Main Factors Affecting Grain Quality

Genotypic Effects

Some few grain attributes are mainly driven by the genotype, and the environment has relatively low influence. For example, the color of the wheat grain (white, yellow) is strongly determined by the ability of genotype to accumulate lutein, and the character "high oleic" in oilseed genotypes is associated with genetic mutations defective for the enzyme that desaturates oleic acid. Genotypes within the same species can

Grain Quality in Oil and Cereal Crops. Table 1 Grain composition ranges reported in different species

Species	Grain composition range	Source
Soybean	33–42% protein	[35]
Sunflower	20–30% oil (confectionary type)	[33, 38]
	40–55% oil (oil type)	
Wheat bread	5–20% protein	[40]
Corn	5–14% protein	[31]
	8–12% protein (pop corn type)	[41]
	5–10% oil (high oil content)	[42]

present large differences in grain composition. For example, in commercial genotypes of soybean, the difference in protein percentage can easily vary from 33% to 42% [39]. This variability can be observed for any seed component in any species [40–42], as ample natural variation is common (Table 1).

Earlier studies working on understanding the genetic basis of genotypic differences in seed composition were based on the use of mutants, and these usually yielded qualitative differences in seed composition. For example, a commercial genotype of maize usually contains ~40% amylopectin and ~60% amylose, and a waxy mutant contains 100% amylopectin and no amylose. At present time, a large number of mutants have been discovered and used within any species as specialty quality genotypes.

The modification of the fatty acid profile of oil seeds has been one of the main tasks faced by oilseed breeders over the past 40 years. Success in this field has been of paramount importance for the worldwide expansion of some oilseed crops. The elimination of erucic acid (a harmful fatty acid) from rapeseed oil was the first step toward the development of canola (zero-erucic, low-glucosinolate rapeseed) as one of the major sources of vegetable oil in the world. Other landmarks in oilseed breeding for seed oil quality have been the development of high oleic, low linolenic acid canola, low linolenic acid linseed and soybean, high oleic acid sunflower, high saturated sunflower, and sunflower lines with modified tocopherol (antioxidant compounds) composition. Most of these traits defining seed oil quality have been found to be governed by a reduced number of genes (one to three major genes, with several alleles for each locus in most cases), and this fact implies that the practical management of single quality traits in breeding programs is relatively easy if compared with polygenic traits (as grain yield, grain weight or protein and oil content). Additionally, the fatty acid composition of the seed oil is determined by the genotype of the developing embryo (not the whole plant), so mutagenesis and selection can be carried out at a single-seed level, using the half-seed technique.

In wheat, improving yield potential without negatively affecting grain quality is difficult, mainly because increases in grain yield are generally accompanied by a decrease in grain protein content, which is strongly associated with bread-making quality. Wheat breeders give grain quality the same level of importance as yield potential and disease resistance. In contrast to the low heritability of protein content, grain hardness and yellow pigment are highly heritable and can be readily improved through conventional breeding. Plant breeders select at least one parent with the desired quality when designing their crossing strategies, particularly as end-use requirements frequently determine the fate of potential new cultivars, but the stage in the breeding process at which quality determination takes place will influence which tests (micro or macro tests) are applied, according to the sample size available.

At present, natural variation for seed composition is being studied identifying quantitative trait loci (QTLs) for different seed components (oil, protein), as any seed component is a quantitative trait governed by many genes and each one with an individual small effect. The study by Blanco and coworkers can be mentioned as an example, where the authors studied seed protein concentration in wheat where three major QTLs were detected [43]. This methodology is currently becoming very popular and has yielded molecular markers associated with seed component traits that can help understand the genetic bases of the trait and be used by breeders and the industry.

Environmental Effects

As mentioned earlier, the majority of quality traits are greatly modified by the environment and by genotype–environment interactions. Grain weight and protein concentration are found within this group of traits.

Environment variables like high temperature, water and nitrogen (N) availabilities have been the most studied modifying grain quality.

The response in grain composition to a particular stress depends mainly on the stress characteristics (i.e., intensity, duration of the stressful period, opportunity of occurrence, and the interaction that this stress may have with other stresses to which the crop is exposed to). The relevance of the intensity and duration of the stress on the magnitude of the change in grain composition is self-explained (the more severe and the longer a stress is, the greater change in composition produced, though not necessarily this implies that the relationship is linear). The timing of occurrence is also critical, as shown in Fig. 4 not all stages are equally critical for the final determination of grain quality: if the stress coincides with critical stages for synthesis and deposition of the components, the changes will result far stronger than that of stresses occurring is less-critical stages. Therefore, the grain composition responses to stressful factors may range from virtual insensitivity (if punctual synthesis reductions are compensated by recovering when no stress occurs) to different ranges of quality reductions to even crop failure to produce a certain quality level.

Seed growth and development are responsive to temperature, but their responses vary with the temperature range considered [44]. As a general rule, the rate of seed development increases as temperature increases, reducing the duration of seed-filling period. At lower temperatures, seed growth rates decrease linearly as temperatures fall below 15°C in wheat, soybean, rice, sunflower, and maize. Seed growth rates increase when temperatures rise from 20°C to 30°C; however, this increase does not offset the linear decrease in seed-filling duration, resulting in lower grain weights [44]. In most cases, moderately high temperatures (20–30°C) prevail during grain filling, although short periods of very high temperatures (>30–32°C) may occur reducing seed growth rate and causing the early end of grain filling period. In addition, the earlier the heat stress, the greater the impact on grain weight [45, 46]. Brief periods of high temperatures can cause reductions in grain weight, but these effects can be overlooked if only the average temperature during post-flowering period is considered. Thus, moderately high temperatures (20–30°C) during the post-flowering period reduced grain weight mainly through shortening the grain filling period, while very high temperatures (>30–32°C) even for a few days can reduce grain weight by reducing grain filling rate and the early cessation of grain growth period. Both aspects of post-flowering temperature should be considered especially because climatic change could bring about high-temperature scenarios in the next decades, together with an increase in heat-stress events [47, 48].

Grain quality and composition are also affected by temperature. Several experiments suggest that the temperature effects on seed composition are related to dry matter metabolism and accumulation. The timing, intensity, and duration of occurrence of heat stress may alter final grain quality according to the grain component synthesis process involved (carbohydrates, proteins, oils). Interestingly, there are some reports on the possibility of recovery post-stress [49, 50]. In wheat and barley, protein percentage increases with increasing temperatures (15–30°C) because the negative impact of high temperatures on starch synthesis is greater than the impact on protein synthesis, thus decreasing the starch proportion in the grains [28]. High temperatures also affect protein quality, generally increasing gliadin:glutenin ratio, which causes weak dough with a low bread-making quality. The temperature impact on wheat grain quality will therefore depend on the balance between the positive (higher protein) and negative (greater gliadin:glutenin ratio) effects. Temperature also affects oil fatty acid composition in oilseeds [51]. The higher the temperatures during grain filling, the higher the fatty acid saturation (i.e., greater proportions of oleic acids and lower proportions of linoleic and linolenic acids) due to the reduced activity of unsaturation enzymes in grains [52]. Temperatures registered during the night in early grain filling phases have shown to have the best predictive values for modeling the final oil composition in sunflower [53]. Progress in modeling the quality of other grains is underway [54].

In field crops, high-temperature occurrences are commonly associated to water stress, increasing the negative temperature effects. Drought stress produces a shortage of assimilates and often reduced N availability, which cause a reduction in grain growth. In general, a drought episode occurring after flowering

has a similar effect as an increase in temperature – the quantity (mg grain^{-1}) of protein per grain remains stable, while starch accumulation in grain is significantly reduced, resulting in smaller grains with a greater protein percentage [55]. In oilseeds, post-flowering droughts decrease grain oil percentages and increase protein percentages [56, 57] indicating that carbon metabolism is affected to a greater extent than N metabolism. Water stress has a smaller impact on fatty acid composition; in general, droughts do not modify the saturation degree in oils except under severe stress conditions which produce an early grain-filling cessation [58].

N availability also affects final cereal and oilseed grain composition. In general, when soil N availability is low, cereal crop yields respond positively to N fertilization. A dilution effect occurs when N taken up by the crop is partitioned in a greater number of grains, which reduces grain protein percentage. If N availability is further increased, both crop yield and grain protein percentage are increased. In addition, the stage of development when N is added is important in defining wheat grain quality. N applications around flowering increase nitrogen availability per grain, increasing protein percentage. It is reported that increases in N availability result in increases of gliadin:glutenin ratio, which in turn produce a weakening of the dough [59]. In oilseeds, a greater soil N availability increases crop yield and grain protein percentage. Consequently, oil percentages in grain decrease due to the negative relationship between oil and protein (expressed as a percentage of the grain weight). Nitrogen application effects on the grain fatty acid composition are smaller and more variable compared to temperature and water stress effects [60, 61]. A greater knowledge on the physiological processes that regulate the responses to these environmental factors is essential to decide the management of the crop to produce grain for a specific end use.

Management Strategies

Although both grain yield and quality are determined throughout the growing season, important decisions that will strongly affect them should be taken before planting [62]. The farmer's choice of genotype and the amount of nitrogen available are central for successfully combining the genotype potential for yield and quality with the environmental availability of resources. As stated earlier, final grain quality is the result of the interaction between the genotype, the natural environment, and the crop management practices [63]. In extensive production systems, it is not possible to provide each stage of the crop cycle with the optimal combination of environmental factors to reach the highest possible yield and quality, therefore, a trade-off is to make preplanting decisions to ensure that critical crop stages for the definition of yield and quality are given a preferential environment [62]. Nevertheless, knowledge of the effects of environment and G × E interaction is still rather imprecise, so management strategies with the objective of increasing yields, while obtaining high quality, are difficult to design.

There are a number of grain quality attributes that are strongly governed by the genotype and therefore choosing the proper genotype in relation to the final end use of the grain is critical. In several countries, for trading purposes wheat is classified into distinct categories of endosperm hardness (soft, semihard, and hard). Grain hardness is determined by the packing of grain components in the endosperm cells [40] and according to this attribute, the end product can vary from pasta (hard endosperm), biscuits (soft endosperm), to bread (hard endosperm). Usually, this classification can be more detailed and complex [64]. In the case of sunflower, oil fatty acid composition is genetically controlled [65], and the oil composition has been modified mostly by altering the function of major genes through mutagenesis [38].

Addition of nitrogen fertilizer is one of the most frequent management practices for altering grain quality (and of course grain yield). It is difficult a priori to know the effect of adding nitrogen to grain quality as many other factors are intervening and modify the final expected result. In the case of wheat crops, the initial amount of nitrogen in the soil, the specific moment of fertilization, the amount of available water, and rain pattern during the growth cycle as well as plant density at sowing and genotype nitrogen use efficiency are the main factors that interact and may modify the final response in grain quality. In general, it is accepted that regardless of the species, the increase in grain yield leads to a decrease in the protein to starch or oil ratio. This negative relationship between yield and grain

N concentration reflects the fact that carbon assimilation and accumulation during the grain filling period is sink-limited [66] while nitrogen accumulation in grains is usually source-limited [67], as a result of dilution effects. The final protein concentration will thus depend on the balance between the source capacity to provide nitrogen and the strength of the sink for accumulating carbohydrates [68].

Future Directions

The compositional requirements for a particular grain vary from one product to the other depending on its end use. In addition, grain quality is a dynamic concept as it changes constantly as new uses can be developed for particular grains. The three major pillars of grain composition are: the genotypes, the environments during grain growth, and their interaction.

On the genetic pillar, the knowledge gained in the recent past has been extraordinary. Based on the molecular tools developed, a number of genes and QTLs involved in the determination of particular grain components (in turn determining grain quality attributes) have been identified and mapped in several crops, and it seems easy to predict that in the near future almost any breeding program in the world will be able to manipulate these genetic factors with certainty.

Regarding the environment during grain filling, important and useful findings have been reported in relation to high temperatures, and in lesser extent in water stress, and nitrogen availability. Few studies have attempted to examine the interactions between these environmental factors on grain quality attributes. It has been recently reported that high-temperature stress effects may be mitigated under high nitrogen availability for wheat and barley [69–71].

Undoubtedly, the challenge for breeders and agronomist is dealing with G × E interactions [72]. Therefore, there is a need for increasing current knowledge on the physiology of quality traits in order to obtain both high yield and high quality through breeding and management strategies. This will also help predict grain composition through a series of genotypes and environments.

Using agronomic simulation models properly calibrated and validated for the target population of environments can be a tool for understanding and predict final grain composition. The incorporation of grain quality modules into crop simulation models is increasing (European Journal of Agronomy 25, 2006). Grain protein content was the first trait incorporated into modeling as well as grain size (grain weight) which is a quality criteria especially valued by millers in the case of cereals but also for oil extraction in oil crops. Recently, more detailed concepts have been incorporated such as the type of protein [73] and oil quality [74]. It is expected that incorporating genetic data into simulation routines will be done in the near future.

Article Outline

Glossary

Exclusion The ability to maintain low concentrations of toxic ions in the plant shoot.

Ionic stress The stress imposed on a plant by the accumulation of salts to toxic concentrations in cells, particularly those of the shoot, leading to premature death.

Genetically modified plant A plant which has been transformed by artificial means with single or multiple genes from another variety or species.

Osmotic stress The stress imposed on a plant by the accumulation of high concentrations of salt around the root, which reduces plant growth.

Osmotic tolerance The ability of a plant to maintain growth under osmotic stress.

Saline soil Soils affected by excess accumulation of salts. Accumulation of sodium chloride (NaCl) on agricultural land has a severe impact on crop yield.

Salt tolerant plant A plant with the ability to grow and set seed in saline environments without significant reductions in plant biomass or yield.

Selective breeding Where two plant species with desirable phenotypes are bred together in an attempt to produce an offspring with both traits.

Tissue tolerance The ability to withstand high concentrations of toxic ions in the shoot.

Definition of the Subject

Plant growth and yield are severely affected by saline soils. High concentrations of salt in the soil make it difficult for plants to take up water, while the accumulated salts in cells, particularly the sodium (Na^+) and chloride (Cl^-) ions, are toxic to plant metabolism. These two factors result in a reduction in plant growth, an increase in the rate of leaf senescence, and a loss in crop yield. The fact that significant areas of farmland worldwide are affected by salt brings with it potentially serious implications for crop yield.

Introduction

Saline soils have been defined as areas where the electrical conductance (ECe; a means of measuring the amount of ions in the soil) is greater than 4 dS/m. It is at around 4 dS/m (approximately 40 mM NaCl) that most plants start to exhibit significant reductions in yield [1]. Over 800 million hectares of land worldwide are affected by saline soils; this accounts for more than 6% of the total land area of the world [2]. Most of this salt-affected land has arisen from natural causes, such as the weathering of rocks, which releases a variety of soluble salts including Cl^-, Na^+, calcium, magnesium, sulfates, and carbonates [3]. Other sources of salt accumulation include the deposition of salts from seawater that is transported by wind and rain, as well as from salts carried in rainwater. It has been estimated that rainwater contains 6–50 mg/kg of sodium chloride (NaCl) which, over time, results in large-scale salt depositions [1].

In addition to the natural processes of salinization, farmland areas are affected by secondary types of salinity which are a consequence of human activities such as land clearing and/or irrigation. This secondary form of salinity results in the raising of water tables and an increase in the concentration of salts around plant roots. Approximately 32 million hectares of the 1,500 million hectares farmed by dryland agriculture are affected by secondary salinity, while 45 million hectares of the 230 million hectares of irrigated land are salt

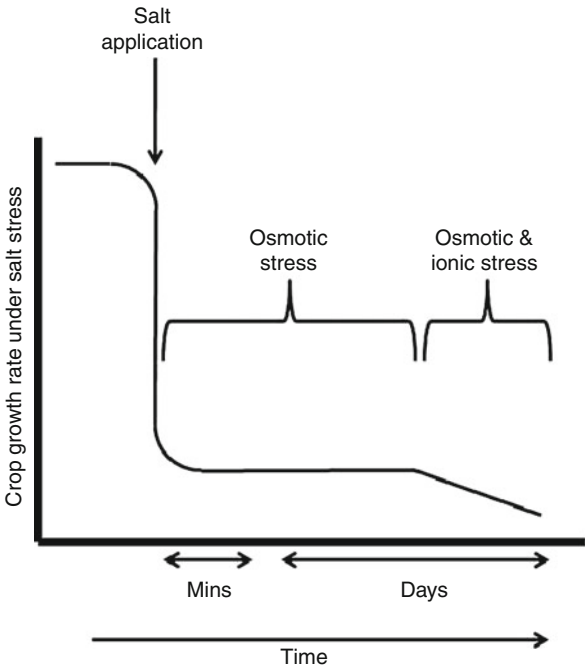
affected [2]. Although it accounts for only 15% of the total cultivated area, irrigated land is twice as productive as dryland agriculture. Consequently, losses of yield which result from an increase in soil salinization in irrigated areas have a disproportionally large effect. Unfortunately, the areas of farmland affected by salinization are increasing and irrigated land is particularly at risk [1].

The deleterious effect of soil salinity on agricultural yields is enormous. To solve this problem will require a variety of approaches including altering farming practices to prevent soil salinization; the implementation of remediation schemes to remove salt from soils; and programs aimed at increasing the salt tolerance of crop plants, either through traditional breeding or by genetic manipulation technologies. By increasing crop salinity tolerance, plant varieties can be generated which will grow on marginal saline soils while longer term land management practices are being introduced. However, before crop salinity tolerance can be improved, an understanding is required of the two separate stresses imposed on a plant when it is grown on a saline soil: osmotic stress and ionic stress.



Increasing Salinity Tolerance of Crops. Figure 1
The effect of salt stress on the growth rate of a crop plant. Plants experience an immediate reduction in growth rate after exposure to salt as a result of osmotic stress. Overtime, the effect of ionic stress increases as shoot Na^+ concentrations build to toxic levels (Adapted from [1])

Effects of Salt Stress on Plant Growth

Osmotic Stress

Osmotic stress affects a plant as the salt concentration around the root reaches 4 dS/m and results in an immediate reduction in shoot growth [1, 4, 5] (Fig. 1). Osmotic stress reduces the rate at which growing leaves expand, the rate of emergence of new leaves, and the development of lateral buds. As this stage of salt stress concerns the inability of a plant to maintain water relations, the cellular and metabolic processes involved are similar to those observed in drought-stressed plants [6]. In dicotyledonous crop species, such as soybean, this osmotic stress results in reductions in the size of leaves and the number of branches [1]; in the monocotyledonous cereals, such as wheat, barley, and rice, the major effect is a reduction in total leaf area and number of tillers [6, 7].

Although it is the roots that are initially exposed to the saline soil, it is actually the growth of the shoot which displays a greater sensitivity to salt; root growth recovers quickly even after exposure to high levels of NaCl [4, 8]. The reduction in leaf development has been attributed to the high salt concentration outside the roots and not to toxic levels of Na^+ or Cl^- within the tissues of the plant [9–11]. This is supported by experiments where plants demonstrate reduced shoot growth when grown in a mixture of salts which individually are at concentrations below those necessary for ionic toxicity but together cause osmotic stress [7, 12]. The mechanisms underlying this down regulation of leaf growth and shoot development remain unclear, but a decrease in shoot area is likely to reduce water use by the plant, thereby conserving soil moisture and preventing an increase in the soil salt concentration. It has been suggested that this reduction in growth rate is regulated by long distance signals in the form of plant hormones and, as the reduction in growth rate is independent of carbohydrate or water supply, is not due to nutrient deficiency [13, 14]. However, it is not just vegetative growth that can be affected by osmotic stress but also the reproductive development of a crop

plant – osmotically stressed plants have been found to exhibit either early flowering and/or a reduced number of flowers [1].

Osmotic stress has other detrimental effects on crop plants. On the surfaces of their leaves, plants have stomatal pores, tiny holes through which carbon dioxide (CO_2) enters the leaf for use in photosynthesis and carbohydrate production, and water and oxygen leave the plant. Due to reduced water uptake, osmotically stressed plants close these stomatal pores [1, 15]. The consequent reduction in CO_2 assimilation results in a reduction of carbohydrate production which is detrimental to crop yield. Many plants are able to compensate partially for the reduction in the amount of CO_2 entering the leaf by producing smaller, thicker leaves with more densely packed chloroplasts although this is expensive in terms of expenditure of energy [1]. The decrease in photosynthesis caused by the closure of stomatal pores has the secondary effect of a build up of reactive oxygen species (ROS) [16, 17]. Reactive oxygen species are high energy forms of oxygen, such as superoxide and hydrogen peroxide, which can damage plant DNA and proteins. These ROS accumulate in plant leaves when the energy absorbed from sunlight by chloroplasts cannot be used to synthesize carbohydrates as there is insufficient CO_2 in the leaf to provide the carbon source. If left unchecked these ROS can cause significant damage to plants so cells must produce a range of enzymes, such as superoxide dismutase, ascorbate peroxidase, and catalase, to detoxify and convert the ROS into harmless forms [16, 17]. These detoxifying enzymes are naturally present in plants to protect leaves from sudden burst of sunlight, such as that which occurs when the sun emerges from behind a cloud, but more must be manufactured in response to salt stress, this again being an energy expensive process.

Ionic Stress

Ionic stress has a slower speed of onset than osmotic stress (Fig. 1). It occurs only when the Na^+ or Cl^- accumulation in older leaves reaches a high concentration which results in premature leaf senescence [1, 4, 6, 18]. All salts at high concentrations can affect plant growth but in saline soils it is the Na^+ and Cl^- ions which cause the most detrimental effects on growth. For some plant species, especially citrus, soybean, and grapevines, it is the accumulation of Cl^- ion in the shoot which leads to toxicity, as Na^+ is retained within the roots and the stem [18–22]. However, for most crop plants including the cereals, Na^+ reaches toxic concentrations before Cl^- and is the ion responsible for most of the damage caused to plants [1].

Na^+ and Cl^- are delivered to the shoot in the transpiration stream, that is, in the water which is being transported from the root to the shoot in the xylem of the plant. For most plants, the movement of Na^+ and Cl^- back from the shoot to the roots via the phloem is relatively small, most of the salt delivered to the shoot remaining there [1, 18]. High concentrations of Na^+ in the shoot can cause a range of metabolic and osmotic problems for plants [1, 23]. The metabolic toxicity of Na^+ is largely as a result of its ability to compete with K^+, which is required for many essential cellular functions. Over 50 essential enzymes have been shown to be activated by K^+. Consequently, high levels of cellular Na^+, which will increase the cellular Na^+:K^+ ratio and decrease the availability of K^+, can disrupt a variety of enzymatic processes [24]. In addition, protein synthesis requires high concentrations of K^+ so that tRNA can bind to ribosomes [25]. A reduction in the amount of available cellular K^+ due to high concentrations of Na^+ will disrupt protein synthesis [26]. As older leaves have ceased expanding they cannot use additional water to dilute the salt being transported into, and this leads to an increase in the senescence of older leaves. Consequently, a failure to exclude Na^+ from the shoot over time will result in the accumulation of toxic levels of ions leading to premature senescence and leaf death [4, 27]. If the rate of leaf death is greater than leaf production, the photosynthetic capacity of the plant will be reduced, the plant will be unable to supply carbohydrates to any new leaves, and the growth rate of the plant will decrease.

There is also an osmotic component to ionic stress. During ionic stress, Na^+ and/or Cl^- remain when water from the transpiration stream evaporates and can, therefore, accumulate to high concentrations in the leaf apoplast [5, 28]. These high extracellular concentrations of ions will result in water leaving cells with a consequent severe impact on cellular function. High concentrations of Na^+ and Cl^- in the leaf also present another osmotic problem, that of maintaining cellular water potential below that of the soil, thereby

facilitating water uptake for growth. Under conditions of elevated salt concentrations in the soil, plants need to accumulate solutes in order to maintain water uptake. Under such circumstances, the most readily available and energy efficient solutes are the Na^+ and Cl^- ions; however, high cellular concentrations of these ions are toxic. Although Na^+ and Cl^- can be stored within the vacuole of a cell or in the apoplastic space, plant cells have difficulty in maintaining low cytosolic Na^+ and Cl^- [29–31]. Therefore, in order to reduce the water potential within the cell, plants need to synthesize solutes which can be accumulated at high concentrations in the cytoplasm of cells without interfering with metabolism [32, 33]. The synthesis of such compatible solutes, however, is energetically expensive and can make significant demands on the energy resources of a plant.

Overall, in comparison with non-stressed plants, salt stressed plants grow more slowly and die more rapidly. It has been estimated that, due to its immediate effect on plant growth, the osmotic stress has a greater impact than ionic stress on the growth rate of a crop [1]. Ionic stress affects plants only at a later stage and has a lesser effect than osmotic stress, particularly at moderate salinity levels. Only when salt levels are high or if a plant is extremely salt sensitive will the ionic effect be greater than the osmotic.

Variation in Plant Salinity Tolerance

Plants vary widely in their response to saline soils. Many show reduced rates of growth and yield while others, such as the salt tolerant saltbush (*Atriplex amnicola*), only reach an optimal growth rate when a moderate level of salt is present [1, 34]. Depending on their sensitivity to saline soils, plants can be divided into two groups: the salt sensitive glycophytes, which are relatively easily damaged by salt; and the salt tolerant halophytes which can tolerate, and may even require, high concentrations of salt in the soil. Indeed, the halophytic saltbush has been shown to survive at concentrations of salt similar or higher than that of seawater [34]. It has been estimated that only 2% of plant species are true halophytes, while the majority of species, including most crops, are glycophytes [35]. Within the monocotyledonous cereals, rice (*Oryza sativa*) is one of the most salt sensitive [36–39], and shows a significant decrease in growth and yield when exposed to moderate levels of NaCl. By contrast, barley (*Hordeum vulgare*) is significantly more salt tolerant [1, 40]. While not as tolerant as barley, the hexaploid bread wheat (*Triticum aestivum*), which contains the genomes of three different wheat species (AABBDD), is moderately salt tolerant and is able to exclude 97–99% of Na^+ entering the shoot. The tetraploid durum wheat (*T. Turgidum* ssp *durum*), which has the genomes of two species (AABB), is more salt sensitive than bread wheat as it lacks genes for salinity tolerance found on the bread wheat D genome and can exclude only 94–95% of the Na^+ entering the root [6, 30]. In durum wheat, there is a clear deleterious relationship between the amount of Na^+ that accumulates in its shoot and the yield of the plant: the higher the Na^+ concentration, the lower the yield [41].

The variation in salinity tolerance of dicotyledonous crop species is even greater than that observed in the cereals. On a scale of salt sensitivity, sugar beet has been reported as salt tolerant, cotton and tomatoes intermediate in tolerance, and chickpea, beans, and soybean as sensitive to salt [42, 43]. Many fruit trees, such as citrus, are classified as very salt sensitive [43]. A number of legumes have been shown to be extremely salt sensitive, even more so than rice; others, such as alfalfa (*Medicago sativa*) are more salt tolerant than barley [1]. In addition to this variation in salinity tolerance between different crop species, variation also exists within species, some varieties and lines having significantly greater salinity tolerance than others [40–44].

Mechanisms of Salt Tolerance

Osmotic Tolerance

Osmotic stress immediately reduces the expansion rate of shoots and roots. It also results in the closure of stomatal pores. Plants that are more tolerant to osmotic stress will exhibit greater leaf growth and stomatal conductance. This would be desirable in irrigated farmland where water is not limiting, but may be problematic in dryland agricultural systems if the soil water content is depleted before the end of the growing season.

Although it is believed that considerable variation for osmotic tolerance may exist within crop species, until recently this was not easily measured. The estimation of growth rates requires daily measurements of

leaf growth or measurements of stomatal conductance [7, 41, 45–47]. These methods are usually either time consuming or have required destructive measurements of plant material to ensure accuracy. Nondestructive imaging technologies have been developed which use digital photographs to calculate plant area and mass [48], or infrared thermography to measure leaf temperature and, thereby, stomatal conductance [49]. These technologies have been used to measure the growth rates of plants in saline environments and, hence, measurement of osmotic tolerance. Variation for osmotic tolerance has now been observed in durum wheat [45, 49] and in wild relatives of wheat, such as *T. monococcum* which is a modern day variety of the plant which donated the A genome to both durum and bread wheat [48].

Ionic Tolerance

Na^+ can accumulate in the shoots of plants to reach toxic levels at concentrations which are below those required of Cl^- for toxicity. Consequently, most studies have focused on revealing any variation in shoot Na^+ accumulation and on the transport of Na^+ within the plant. Ion concentrations in specific tissues can easily be measured at a specific developmental age, and either image analysis [48] or a meter that measures chlorophyll content can be used to measure leaf senescence.

Ionic Tolerance: Exclusion A long established mechanism for salinity tolerance in crop plants is the exclusion of ions, particularly Na^+, from the shoot. Due to the ease of experimentation, this is the mechanism perhaps most studied. A strong correlation between salt exclusion and salt tolerance has been shown for many crops, such as in durum wheat [41, 50], rice [51, 52], barley [40, 53, 54], lotus [55], and *Medicago* [56]. Na^+ enters a plant initially from the soil through the root and is then rapidly transported to the shoot in the water of the transpiration stream. Roots are able to maintain relatively constant levels of NaCl by exporting excess salt either back to the soil or to the shoot. As a result, there is a higher accumulation of Na^+ in the shoot compared with the root. If the net delivery of Na^+ to the shoot could be reduced, this may enable a plant to become more salt tolerant. There are four distinct components that can be modified in order to reduce shoot Na^+ and Cl^- concentrations, all of which occur in the root: reduction in the initial influx of ions from the soil into the root; maximization of the efflux of ions from the roots back to the soil; reduction of the efflux of ions from the inner root cells into the xylem cells which are carrying water and ions to the shoot in the transpiration stream; and maximization of ion retrieval from the transpiration stream into root cells thereby retaining Na^+ and Cl^- in the root.

Ionic Tolerance: Tissue Tolerance Tissue tolerance is the ability to accumulate Na^+ or Cl^- ions in the absence of any detrimental effects on plant health. Tolerance requires the toxic ions to be compartmentalized into areas where they can do no damage. At the cellular level, this usually involves avoiding the accumulation of Na^+ and Cl^- in the cytoplasm of the plant cell where most of important metabolic processes occur. One strategy of tissue tolerance involves compartmentalization of ions within the vacuole, a large plant cell organelle which can be used as a storage structure. Employing such a mechanism will allow a plant to accumulate high concentrations of Na^+ and Cl^- within the shoot, while avoiding all of the toxicity effects. There already exists a large body of evidence for variation between different varieties of crops in terms of the rates of accumulation of shoot Na^+ and Cl^-, as well as for the concentrations of these ions which the different varieties can tolerate.

Generation of Salt Tolerant Crops

Salt tolerant crop plants may be generated only once there is a clear understanding of the mechanisms underlying salinity tolerance, and of the variation between plant species in effecting such mechanisms. Once identified, the benefit of introducing these salinity tolerance mechanisms into crops must be considered. For example, there would be little point in introducing into a cereal the salinity tolerance mechanisms from a slow growing highly tolerant halophyte if that mechanism involved a slow growth phenotype which would result in the cereal taking years to reach maturity for flowering. In addition, a salt tolerant crop plant must do as well as a sensitive plant when grown in the absence of salt. A high yielding salt sensitive crop which shows a 50% yield reduction under salt stress

will still be of greater value to a farmer than a salt tolerant variety which displays little reduction in yield but which produces only 40% as much grain as the salt stressed sensitive variety in the first place.

Crop plants developed to have increased tolerance to both ionic and osmotic stresses would be able to grow at productive rates throughout the life cycle, and the severe losses of yield experienced for most crops growing on saline soils would be reduced. It should also be noted that it may be necessary to develop crop plants with different salinity tolerance mechanisms depending on the environment in which the plants will grow. Crops grown by dryland agriculture may benefit particularly from possessing tissue tolerance mechanisms, as the accumulation of high concentrations of ions within the vacuoles of the plant cells may assist the plant in retrieving more water from the soil. By contrast, an osmotic tolerance strategy, combined with Na^+ exclusion, may be more beneficial to crops grown under irrigation so that water availability is not an issue but the Na^+ content in that water may be high.

Two approaches may be taken to improve the salt stress tolerance of current crops: the exploitation of natural variation in salinity tolerance between different varieties and species of crops; or, the generation of transgenic plants with altered gene expression to increase salinity tolerance. Both approaches have advantages and disadvantages as discussed below.

Exploitation of Natural Variation

For many crop species there exists large natural variation in salinity tolerance mechanisms, with some lines and varieties producing significant yields under salt stressed environments. The screening of 5,000 accessions of bread wheat led to the identification of 29 accessions which produced seed when grown in 50% seawater [57], while screening of 400 Iranian wheats identified several accession with high grain yield under both salt stressed and control environments [58]. Varietal differences in yield in saline conditions have been observed in many crops such as durum wheat [41, 45, 59], barley [60, 61], soybean [62], citrus [19, 63], chickpea [42, 64], and rice [65, 66]. The selection and breeding of these salt tolerant varieties with the current elite varieties grown by farmers would be a step forward in the generation of salt tolerant plants.

The selective breeding of lines with desirable salt tolerance traits with those lines possessing desirable traits for yield is an approach for generating salinity tolerant crops that has been practiced for thousands of years. One limitation with this approach is the time and space necessary to grow offspring from these crosses, test their salinity tolerance, obtain viable seed, and then repeat the crossing with a parent to produce the next generation. Recently, new molecular technologies have been developed which have aided this approach considerably. Different varieties and species have different DNA sequence. The difference between the DNA may be subtle, such as between varieties of the same species where there may be a single nucleotide change in the coding sequence of a gene, or the differences can be extreme, such as the gene duplications or deletions observed between species. Modern molecular techniques enable the detection of these differences between individuals, varieties, and species and allow the design of molecular markers which recognize specific differences in the DNA between two individuals. Using these molecular markers as DNA landmarks it is possible to produce a map of plant chromosomes which can be divided into regions. By finding differences in regions of DNA between two varieties of plants and then observing the phenotype of the offspring produced by breeding the two original varieties, it is possible to identify regions in DNA linked to that phenotype. These regions are often called quantitative trait loci (QTL). By identifying two different plant varieties with differences in salinity tolerance and by observing molecular markers that are different between the two parents, it is possible to identify QTL linked to salinity tolerance by screening their offspring. As salt tolerance is a complex trait, both genetically and physiologically, it is not uncommon to observe several QTL associated with tolerance.

QTL have now been identified for salinity tolerance in a number of plant species including barley [67, 68], tomato [69], rice [70], citrus [63], bread wheat [71], and durum wheat [41]. When QTL have been discovered, one approach is to then identify the gene in that region of DNA which is responsible for the salt tolerance phenotype. The *SKC1* QTL identified on chromosome 1 in rice and the *Nax1* and *Nax2* loci observed in durum wheat on chromosomes 2A and 5A, respectively, have been narrowed down to genes belonging

to a family of Na^+ transporters [70, 72, 73], which have been shown previously to be important for exclusion of Na^+ from the shoot [74–79]. Once a QTL has been discovered, the plant which contains that important piece of DNA for salt tolerance can be bred with salt sensitive varieties to introduce into them the salt tolerant phenotype. As a molecular marker will be linked to the QTL, it is not necessary to screen every offspring produced from this cross with a salt sensitivity assay, rather, it is possible to identify which of the offspring have the piece of DNA important for salt tolerance by screening for the molecular marker linked to the salt tolerance QTL. While this does not necessarily speed up the length of time it takes an individual plant to reach maturity, it does reduce the necessity to screen hundreds of plants in saline conditions looking for those that are salt tolerant, so that more focus can be placed on breeding tolerance traits into crops.

While one approach is to identify a variety of a crop with good salt tolerance and then cross it to other members of that species, a second approach is to introduce salt tolerance traits from related species or near-wild relatives.

Bread wheat and durum wheat are two separate plant species, but because of their genetic background there is the possibility of breeding these two species together to exchange valuable traits. Durum wheat is a tetraploid (AABB) containing two genomes from an ancient ancestral cross, the A genome and the B genome. Bread wheat is a hexaploid (AABBDD), with the same A and B genomes as durum wheat and also a third genome, the D genome [80]. It is possible to breed a bread wheat and durum wheat together to produce a pentaploid hybrid offspring, which has an AABBD genome. During sexual reproduction, there is the possibility of the chromosomes from the different wheat backgrounds to swap DNA, a process called recombination, thereby transferring genes from bread wheat to durum wheat and vice versa. Importantly, however, only chromosomes from the same genome can recombine, i.e., durum genome A with bread genome A and not durum genome A with bread genome B. By crossing this offspring with either bread wheat or durum wheat it is possible to re-obtain tetraploid durum wheat and hexaploid bread wheat, only now containing genes from the other species. This has been done successfully to transfer disease resistance genes [80] and could be used for transferring salt resistance traits between the two species. Although difficult, because durum wheat contains no D genome, it is possible to introduce genes from the bread wheat D genome into durum wheat; however, a special wheat plant, with a mutation that affects the way in which chromosomes align in recombination, is required [81]. This technique was used to transfer the K^+/Na^+ discrimination locus *Kna1* from chromosome 4D of bread wheat to chromosome 4B of durum wheat [82]. This new durum wheat line was able to maintain a high K^+/Na^+ ratio in the leaves [82, 83], thereby increasing its salinity tolerance. However, there was no significant difference in grain yield between durum plants with the bread wheat *Kna1* and those without, perhaps due to a yield penalty imposed by having a large section of the bread wheat D genome in durum wheat. Unfortunately, no agronomically acceptable durum variety containing the bread wheat *Kna1* locus has been released [80].

In addition to looking for variation in plant salt tolerance in current cultivars, there is the possibility of introducing salinity tolerance traits to crop from their near-wild relatives. These species may have been evolving in areas of high salinity, away from the selective pressures inflicted on domesticated crops. It is, therefore, likely these relatives have developed novel salt tolerance mechanisms which might be introduced into current crops. This approach is not new and there have been many attempts to introduce genes from salt tolerant wild relatives to current salt sensitive crops. Traits for salt tolerance have been discovered in wild relatives of tomato, [84], potato [85], rice [44], wheat [80, 86–88], and barley [40, 86] and several attempts have been made to introduce them to cultivated crops. Screening of eight wild *Hordeum* species, wild relatives of domesticated barley, revealed that seven of the eight had better Na^+ and Cl^- exclusion than domesticated barley under a variety of salt stressed environments. A number of these relatives, such as *H. spontaneum*, *H. marinum*, and *H. intercedens*, had significantly higher relative growth rates than domesticated barley when grown under high salinity stress [40, 89].

T. urartu (AA) is the modern day ancestor of the species that gave rise to the A genomes of

durum and bread wheat. Both *T. urartu* and other closely related A genome species, such as *T. monococcum* spp. *monococcum* and *T. monococcum* spp. *aegilopoides*, show greater Na^+ exclusion than durum wheat [80, 90]. Lines of *T. monococcum* also show great variation in both osmotic and Na^+ tissue tolerance [48] and are, therefore, a potential source of novel genes for salinity tolerance. It is possible to cross these species with durum wheat and transfer salinity tolerance traits. One success story of breeding a salinity tolerant crop has been the introduction of a Na^+ exclusion trait into durum wheat from a near-wild relative *T. monococcum*. Screening of multiple durum wheat lines for Na^+ exclusion from the shoot identified a durum landrace, line 149, with significantly lower shoot Na^+ than cultivated durum [59]. It was discovered that Na^+ exclusion in these lines was controlled by two major genes, *Nax1* and *Nax2*, which had been introduced into durum from a cross with *T. monococcum* [91]. These two genes have now been introduced separately into the Australian durum wheat Tamaroi and have undergone field trials.

Another wild relative source for wheat is from *Aegilops tauschii*, which is the modern day version of the species that donated the D genome to bread wheat – there appears to be no modern day equivalent of the B genome [80]. Several screens of *Ae. tauschii* have identified lines with lower shoot Na^+ accumulation and enhanced K^+/Na^+ discrimination than durum wheat, although the phenotype was comparable to bread wheat [29, 71, 92]. As the natural environment of *Ae. tauschii* is dry and moderately saline [80], there exists the possibility of introducing novel salinity tolerant genes into wheat. One possibility is the re-creation of the original cross that generated bread wheat by breeding durum wheat (AABB) with *Ae. tauschii* (DD), thereby creating a synthetic wheat (AABBDD) with a genome similar in style to bread wheat. While the technique is tricky, it has been successful in the past [92]. The advantage of this technique is that the Na^+ exclusion locus found on the D is introduced which is not on the A or B genomes of wheat. Synthetic hexaploid lines with enhanced Na^+ exclusion have been created successfully to have Na^+ exclusion similar to that of the parent *Ae. tauschii* and significantly greater exclusion than that of the durum parent [29] at both high and moderate levels of salt. Indeed, some of the synthetic hybrids produced have significantly lower shoot Na^+ accumulation than bread wheat and often greater yield under salt stress conditions [80, 93]. These results indicate that the approach clearly has validity.

The use of wild relatives in breeding programs remains controversial as few salt tolerant crops are released through this approach [39]. Wheat was one of the earliest crops to be crossed with halophytic wild relatives but over 25 years have elapsed since that initial cross, and no new tolerant varieties has yet been released to farmers [39]. However, a recent report of significant yield advantage in a saline field site of durum wheat plants incorporating a Na^+-excluding locus, *Nax2*, from *T monococcum* appears to be particularly promising [94].

A considerable disadvantage with introducing salinity tolerance traits into crops which are already well adapted for cultivation is the introduction of undesirable traits encoded by genes which may be physically close to the desirable gene for salinity tolerance in the plant genome [80]. This is a particular problem when breeding current crop varieties with wild relatives, as cultivated crops have been designed by breeders for thousands of years to have desirable traits such as high grain yield, appropriate height and disease resistance. When new traits are introduced into crops by breeding it is not possible to introduce only the gene responsible for that trait. The piece of DNA introduced from the wild relative can be quite large and will contain many genes, for most of which the functions are unknown. If these genes have an undesirable effect which impacts on the agricultural value of the crop leading, for example, to low yield or incorrect flowering time, the crop will be of no value to a farmer. This phenomenon is known as linkage drag [39, 80]. It is possible to reduce the size of the DNA insertion from the wild species by breeding the line with a cultivated crop as, over time, fragments of the wild species DNA will be replaced by that of the cultivated crop. This process, however, can take many generations and requires the breeder to have a molecular marker specific to the Na^+ tolerance gene that has been inserted into the genome; otherwise this gene also would be lost [80].

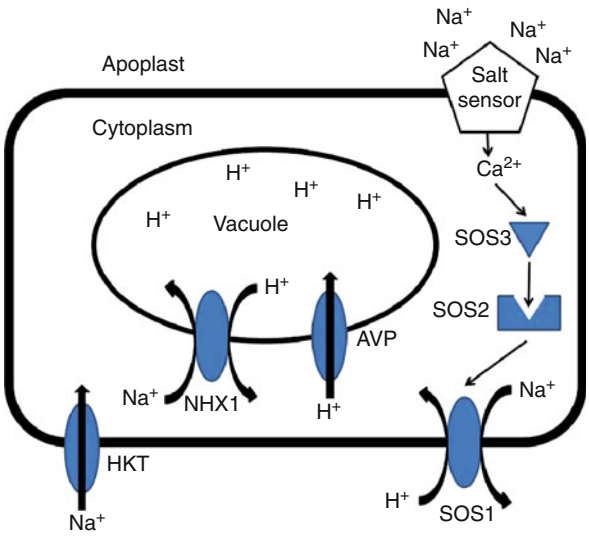
Transgenic Approaches to Generating a Salt Tolerant Crop

Transgenic approaches are attractive in the generation of salinity tolerant plants, as the sequences of genes known to encode proteins involved in salinity tolerance can be artificially introduced directly into the target variety, without the compounding effects of bringing in multiple, and often undesirable, genes through traditional breeding approaches. In theory, the transformation of commercially relevant crop plants directly with genes for salinity tolerance would help to reduce the time required before farmers can use these crops in the field.

There are numerous possibilities for generating transgenic crops with increased salinity tolerance, either by introducing novel genes for salinity tolerance into crops from other plant species, or by altering the expression of existing genes within the crop (see Fig. 2 for examples).

To date, the greatest success with the development of transgenic salinity tolerant crops has been the generation of plants which are better able to compartmentalize Na^+ in the vacuole, where Na^+ can accumulate to high levels without detrimental effects on the plant cells. Central to this process of vacuolar compartmentation is a gene encoding a vacuolar Na^+/H^+ antiporter (NHX), which transports Na^+ into the vacuole in exchange for a proton (H^+) [1, 95, 96] (Fig. 2). The activity of this transporter has been shown to increase under salinity and it is expressed in a variety of different plant species including barley [97], maize [98], sunflower [99], tomato [100], cotton [101], and Arabidopsis [102]. Constitutive expression in yeast of the *NHX* gene from Arabidopsis, *AtNHX1*, had the effect of significantly increasing the salinity tolerance of the yeast [103, 104]. Transgenic plants which have been created to constitutively overexpress the same Arabidopsis *AtNHX* gene, such as Arabidopsis [105], tomato [106], *Brassica napus* [107], and cotton [108], also show increased Na^+ accumulation in the shoot and greater salinity tolerance. These plants are, therefore, Na^+ tissue tolerators. Importantly from a farmer and a consumer point of view, Na^+ accumulation only occurred in the green tissue and not in the fruit, as in the case for tomato [106]. Of particular interest is that both increasing or decreasing the expression of the Arabidopsis *AtNHX* gene has been shown to significantly affect the expression patterns of other genes involved in salinity tolerance mechanisms [96, 109, 110]. This finding has significant implications for the generation of transgenic crops as it indicates that it may not be necessary to transform a plant with multiple salinity tolerant genes but rather with one gene which can regulate others.

Several homologues of the *AtNHX1* gene have now been identified in a number of crops including



Increasing Salinity Tolerance of Crops. Figure 2 Intracellular location of proteins in a plant cell which are encoded by candidate genes for transformation into transgenic crop plants. NHX1 is a transporter which is involved in the compartmentation of Na^+ into the vacuole by swapping a cytoplasmic Na^+ ion with a vacuolar proton (H^+). AVP is a proton pump that uses the energy released from the breakdown of PPi to move protons into the vacuole. These protons can then be used by transporters such as NHX to transport Na^+ into the vacuole. HKT proteins are involved in the transport of Na^+ from the extracellular space (apoplast) into the cytoplasm. In the salt overly sensitive (SOS) pathway, high concentrations of Na^+ are detected by a membrane bound salt sensor, which results in the release of Ca^{2+} to the cytoplasm. This cytoplasmic Ca^{2+} binds to the calcium binding protein SOS3, which activates the protein kinase SOS2. Together SOS3 and SOS2 activate the Na^+ transporting ability of the SOS1, which moves Na^+ out of the cell

wheat [111, 112], barley [113], cotton [101], *Medicago* [114], Maize [98], and rice [115, 116], and the constitutive overexpression of these gene in Arabidopsis [111], rice [115–117], wheat [118], tobacco [101], and barley [113] has also been reported to improve salinity tolerance.

Another candidate gene family for the generation of salinity tolerant transgenic crops are the vacuolar H^+ pyrophosphatase genes [1, 96, 119]. Similar to the *NHX* genes, H^+ pyrophosphatase genes, such as Arabidopsis *AVP1*, are involved in Na^+ sequestration to the vacuole. These genes do not encode proteins that are directly responsible for the transport of Na^+ into the vacuole, but rather ones that use the energy released from the breakdown of the high energy molecule inorganic pyrophosphate (PPi) to pump protons (H^+) into the vacuole (Fig. 2). PPi is produced as a by-product of a wide range of biosynthetic pathways. Use of PPi as an energy donor for the activity of the vacuolar H^+-PPase allows ATP to be conserved and improves plant cell performance under more demanding environmental conditions. Once the vacuolar H^+ pyrophosphatase proteins have transported protons into the vacuole, these protons can then be used by Na^+ transporters such as NHXs to move Na^+ into the vacuole. Analysis of plants that are growing under salt stress, such as barley and Arabidopsis, reveals that these genes are significantly upregulated [102, 113]. Arabidopsis, alfalfa (*Medicago sativa*), tobacco (*Nicotiana tabacum*), bentgrass (*Agrostis stolonifera* L.), and rice plants genetically engineered to either express *AVP1* alone, or in combination with *NHX*, have been shown to have increased salinity tolerance [111, 117, 119–122]. Transgenic alfalfa which was constitutively overexpressing *AtAVP1* maintained a greater shoot biomass than wild type alfalfa when grown on 200 mM NaCl [122]. Similarly, transgenic bentgrass expressing the *AtAVP1* gene was not greatly affected when grown on 100 mM NaCl, and was able to survive salt stress of 200 and 300 mM NaCl, levels which severely reduced the growth of wild type bentgrass [123].

In addition to the success in generating salt tolerant plants using genes involved in the mechanisms for sequestering Na^+ in the vacuole, transformation of plants with genes controlling other processes, such as exclusion of Na^+ from the plant, have also been successful. Other candidate genes for increasing the salinity tolerance of crop plants include members of the Salt Overly Sensitive (SOS) pathway.

Many aspects of plant growth, development, and responses to environmental stresses are mediated by the calcium ion (Ca^{2+}) as a secondary messenger signaling molecule. The external cue is first perceived by receptors on the plant cell membrane and this then activates a signaling cascade, using calcium, which regulates the activities of proteins and gene expression [124–127]. The SOS pathway mediates the response of a plant cell to salinity stress. The SOS pathway was so named due to the extreme salt sensitivity of plants which had mutations in key genes of this pathway [128]. Initially, three genes from these mutants, *AtSOS1*, *AtSOS2*, and *AtSOS3*, were identified in Arabidopsis as being important in salinity tolerance [129]. It should be noted, however, that the SOS name refers to a specific salt sensitive phenotype and that the genes sharing the same SOS identifier are unrelated to each other. Indeed, the proteins encoded by these genes are quite different: AtSOS1 is a plasma membrane Na^+ transporter [130]; AtSOS2 is a protein kinase belonging to a large family of Calcineurin B-like Interacting Protein Kinases (CIPKs) [125, 127]; and AtSOS3 is a plasma membrane bound Ca^{2+} binding protein which belongs to the Calcineurin B-Like proteins (CBL) [125, 127]. However, although they have completely different functions, it is the interactions of these proteins that help a plant cell survive salt stress.

It has been shown in Arabidopsis that under salt stress Ca^{2+} is released into the plant cell cytoplasm from either internal or external cellular stores and it binds to the plasma membrane bound AtSOS3 (AtCBL4). CBL proteins have specific regions which allow them to bind to specific CIPKs, such as SOS2. When Ca^{2+} becomes bound to AtSOS3, it recruits AtSOS2 to the plasma membrane where the kinase phosphorylates the Na^+/H^+ antiporter AtSOS1, thereby activating the transporter and allowing the movement of Na^+ out of the cell [1, 124, 125, 127] (Fig. 2). Although these genes were identified initially in Arabidopsis, homologues for all three genes have now been discovered in a variety of plant species, including crops, such as *Thellungiella halophila* [131], poplar [132], and rice [133]. In all of these species, the genes involved in the SOS pathway have been shown to be significantly upregulated under salt stress,

particularly in the plant roots. This would make them ideal as candidate genes for transformation into transgenic crops to increase salinity tolerance.

Arabidopsis plants that were engineered to constitutively express the *AtSOS1* gene had significantly increased salinity tolerance, showing greater biomass, increased chlorophyll retention, and reduced concentrations of Na^+ in the shoot when compared to wild type plants when grown under high saline conditions [134]. Importantly, these plants did not suffer any yield penalty when grown under non-stressed conditions. The increase in the salinity tolerance of the transgenic plants was attributed to them having a great efflux of Na^+ at the cellular level, when compared to control plants.

It is not always necessary to generate a salt tolerant plant by altering the expression level of a gene that encodes a transporter of ions. The salinity tolerance of a plant can also be increased by overexpressing genes encoding molecules that are involved in signaling or activating genes. Overexpression of the transcription factor *Alfin1* in alfalfa resulted in plants with increased root and shoot growth under both control and salt stressed conditions [135]. Enhanced expression of genes involved in signaling pathways, such as those encoding calcium binding CBL proteins and the protein kinase CIPKs, increases the salt tolerance of Arabidopsis, rice, and tobacco [136–139], presumably through enhancing the signaling response of the cell when it is under salt stress. However, the way in which some genes contribute to overall salt tolerance remains unclear. Transgenic tomato that had been transformed with the yeast gene *HAL1* showed increased salt tolerance under stressed conditions but had reduced shoot weight when grown in control conditions, significantly lower than non-transformed plants [140]. This demonstrates that there remains significantly more to understand about the timing and regulation of genes *in planta* before a transgenic salt tolerant plant can successfully be produced.

Certain genes that have been identified as important for plant salinity tolerance have nevertheless not been shown to increase the salinity tolerance of genetically modified plants when constitutively overexpressed. For example, although the *HKT* gene family has been shown to be important in salinity tolerance, the constitutive overexpression of an *HKT* gene was found to have a detrimental effect. The *HKT* gene family can be divided into those genes encoding a Na^+ transporting protein (subfamily 1) or a K^+/Na^+ transporting protein (subfamily 2) [23, 74]. Members of subfamily 2 are considered to be involved in nutrition and the uptake from the soil of ions essential to plant growth (small quantities of Na^+ can be beneficial to plant growth) [141–144], whereas members of subfamily 1 are believed to be important for plant salt tolerance [1, 23, 96]. Members of the subfamily 1 *HKT* gene family have been shown to encode proteins important for the retrieval of Na^+ from the xylem in both the root and the shoot, thereby reducing the accumulation of Na^+ in the shoot [23, 74, 75, 79, 96, 145]. The protein moves Na^+ from the transpiration stream into the cells surrounding the xylem (Fig. 2). Evidence for this function has now been found in a number of plant species in addition to Arabidopsis, such as rice [70] and wheat [72, 73]. Both naturally occurring ecotypes and mutant lines of Arabidopsis which have reduced expression of this gene show increased shoot Na^+ accumulation [75, 102, 146, 147]. However, constitutive overexpression of this subfamily 1 *HKT* gene also results in higher concentrations of Na^+ and salt sensitive plants [77]. As HKT proteins move Na^+ into cells, the increased salt sensitiveness of constitutive overexpressing plants may be due to the fact that, when the gene is expressed throughout the plant, the protein encoded by the gene transports more Na^+ from the soil into the root, resulting in more Na^+ being transported to the shoot in the transpiration stream. Expression of this gene only in the cells surrounding the xylem would result in a plant being more efficient in retrieving Na^+ from the transpiration stream.

Plants consist of multiple tissues and multiple cells. Each tissue is adapted for a specific purpose – roots for nutrient uptake, leaves for photosynthesis, stems for support – and, therefore, will not necessarily express the same genes. Genes responsible for the maintenance of photosynthesis in the leaves will not be expressed in the roots, and genes for nutrient uptake from the soil will not be expressed in floral tissue. Similarly, not all genes in a plant are expressed all the time; many genes are activated only when required. When growing in non-stressed environments there is little point in a plant using critical energy supplies to generate and

maintain proteins important for salinity tolerance. It is unsurprising, therefore, that the continuous expression throughout a plant of a gene important for salinity tolerance, such as *AtHKT1;1*, often results in detrimental effects [77]. A critical feature in the generation of crops engineered to have increased salinity tolerance is the spatial and temporal control of the transgene which has been introduced.

Recently, transgenic Arabidopsis plants have been produced with cell-specific expression of the *AtHKT1;1* gene in the root cells surrounding the xylem [148]. Unlike plants with constitutive overexpression of *AtHKT1;1*, these cell-specific plant lines showed a significant reduction in shoot Na^+ and increased salt tolerance [148].

In a different approach, rice plants designed to overexpress a gene involved in the synthesis of trehalose only when the plants experienced stress exhibited reduced shoot Na^+ concentrations and better growth in saline conditions than non-transformed plants [149]. Trehalose is a sugar involved in protecting cells from long periods of desiccation and possibly aids salinity tolerance through an ability to scavenge reactive oxygen species, thereby protecting cellular proteins [39]; however, plants with constitutive overexpression of genes for trehalose synthesis display severe stunting [150]. The use of a stress-inducible promoter is, therefore, an important control to minimize growth inhibition of transgenic plants when grown in non-stressed environments. The focus now is the identification of gene promoters (sequences of DNA which are used to activate genes) which allow the cell- and temporal-specific expressions of genes in crops.

In addition to the fine control of genes transformed into transgenic crops, there is also the need to identify gene combinations which may have the potential to increase crop salt tolerance. As has been observed, plants employ multiple salinity tolerance mechanisms to survive saline soils, all of which rely on a variety of different genes and proteins. It seems unlikely, therefore, that the generation of a successful commercial salt tolerant crop will be achieved by the constitutive overexpression of one single gene. Recent research promoting salt tolerance in plants focuses on either boosting the intracellular salt-sequestering processes, or on the Na^+ exclusion mechanisms by transferring into selected crop species genes for salinity tolerance from model organisms (such as *Arabidopsis*) or from salt tolerant plants. A complementary approach focuses on the challenging task of reducing net input of salt into plants by perturbing the function of channels and transporters involved in sodium uptake but without disturbing potassium uptake. An ideal scenario contemplates the generation of transgenic plants with an enhanced capability for vacuolar salt sequestration combined with a reduced uptake of salt. While a number of genes involved in these processes have now been identified, the challenge is to switch these genes on at the appropriate time and in the appropriate tissues where they can be most effective. In order to achieve this aim, improved knowledge is required of gene promoters that are stress-inducible and cell specific.

While it is clear that there are potentially many avenues for the generation of a genetically modified salt tolerant plant, there remain significant challenges. Although it is now possible to generate salt tolerant plants in a laboratory, it has yet to be shown whether this relates to actual yield improvements in the field. There are cases where using genetic modification to generate a salt tolerant plant has a negative effect on yield when no stress is present. It is clear, therefore, that more information on gene promoters is required to enable the activation of salt tolerant genes in specific tissues/cell types only when plants are grown in salt. Furthermore, there are areas of the world, such as Europe, where there remains considerable resistance to the acceptance of genetically modified plants. This may well be due to the lack of availability to consumers of clear, accurate information as well as the prevalence of extremist views. A more open, transparent approach by scientists is required explaining the potential advantages and disadvantages of this technology. Only then will consumers be able to make their own informed choices about genetically modified organisms.

Future Directions

Crops growing on saline soils suffer severe reductions in yield due to both ionic and osmotic stresses. As considerable areas of farmland are currently affected by saline soils much research has been undertaken to enhance crop salinity tolerance by exploitation of natural variation in salinity tolerance or through the

generation of transgenic plants expressing genes shown to be important for salt tolerance. While salinity tolerant plants have been generated by both approaches, the focus should now be on the production of viable crop plants for farmers to grow in affected areas. For this to occur, the new cultivars of tolerant plants need to be tested under rigorous field conditions and those with enhanced salt tolerance and, as equally important, no yield penalties when grown in nonsaline conditions pass to breeders for incorporation into future crops.

Approaches are still required to help speed up the generation of salinity tolerance crops through the exploitation of natural variation. Sequencing of cereal genomes will greatly speed up the identification of candidate genes underlying salt tolerance QTL, thereby enabling highly specific molecular markers that are tightly aligned to the trait. Using these markers will help reduce the effects of linkage drag bringing undesirable traits into the population.

For transgenic plants, it is clear that refined control over when and where a gene is expressed is essential. As there are now multiple candidate genes, with potential for enhancing salinity tolerance, research should now focus more on identifying the controlling elements in a plant's genome, which dictate when and where a gene is expressed, and less on the identification of candidate genes. In addition, combinations of genes which have additive effects on salinity tolerance need to be identified, thereby allowing the production of the most optimal salt tolerant plants. When these factors are known, crops can be produced which have the ability to activate multiple genes for salinity tolerance in different areas of the plant but only when saline soils are experienced.

Although further research is clearly still required, considerable progress has been made in generating salt tolerant *plants* through the exploitation of natural variations and the generation of genetically modified organisms. The next step is to deliver salt tolerant *crops* to farmers.

Integrated Pest Management

Ramon Albajes
Department of Plant Production and Forest Sciences, Universitat de Lleida, Centre UdL-IRTA, Lleida, Spain

Article outline

Glossary

Agroecosystem, agrosystem – agricultural ecosystem An ecosystem that is managed to optimize the production of a crop plant or part of it.

Biological control Use or manipulation of natural enemies (predators, parasitoids, or diseases of pests) to suppress pest populations.

Crop resistance to pests One or more qualities that some crop plant varieties have resulting in less damage by a number of pest individuals in comparison with a variety without those qualities when it is exposed to the same pest numbers.

Damage caused by a pest Damage is the monetary value lost to the commodity as a result of injury by the pest, for instance by yield reduction.

Economic injury level of a pest The pest population density at which the cost to control the pest equals the amount of damage it inflicts.

Economic threshold of a pest The pest population density at which a control measure has to be taken to prevent population from reaching the economic injury level.

Genetically modified (GM) crop, transgenic crop A crop whose genetic material has been modified by genetic engineering techniques, through which novel genes have been introduced into the crop.

Integrated pest management (IPM) A system for controlling pests in an economically, ecologically, and sociologically sound manner by the use of multiple tactics in a compatible manner. The term has many (if not all) common elements with integrated control.

Metapopulation A set of populations occupying different patches among which individuals can occasionally move.

Pest Any herbivore that feeds and causes damages on crop plants in an agroecosystem resulting in crop damages if control measures are not taken. In this entry the term "pest" includes only insects and mites but for other authors the same term would additionally include plant diseases and weeds.

Pheromones Chemicals that are released in the environment by one individual and trigger a behavioral response in other individuals of the same species.

Precision agriculture Precision agriculture aims to apply inputs only when and where they are needed and at optimal amounts according to variable field or environment characteristics.

Definition of the Subject

In addition to producing food and fiber to satisfy an increasing world population, agriculture is being asked to supply energy at reasonable prices thus contributing to the acceleration of the demand for agricultural commodities. Increase of crop yields may be achieved by maximizing the proportion of sunlight energy that is fixed by the crop plant or by reducing the amount of energy that is lost by insect pests, diseases, and weeds. More than 50% of the potential yield of agricultural crops is lost by the three causes. To diminish losses caused by insect pests

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

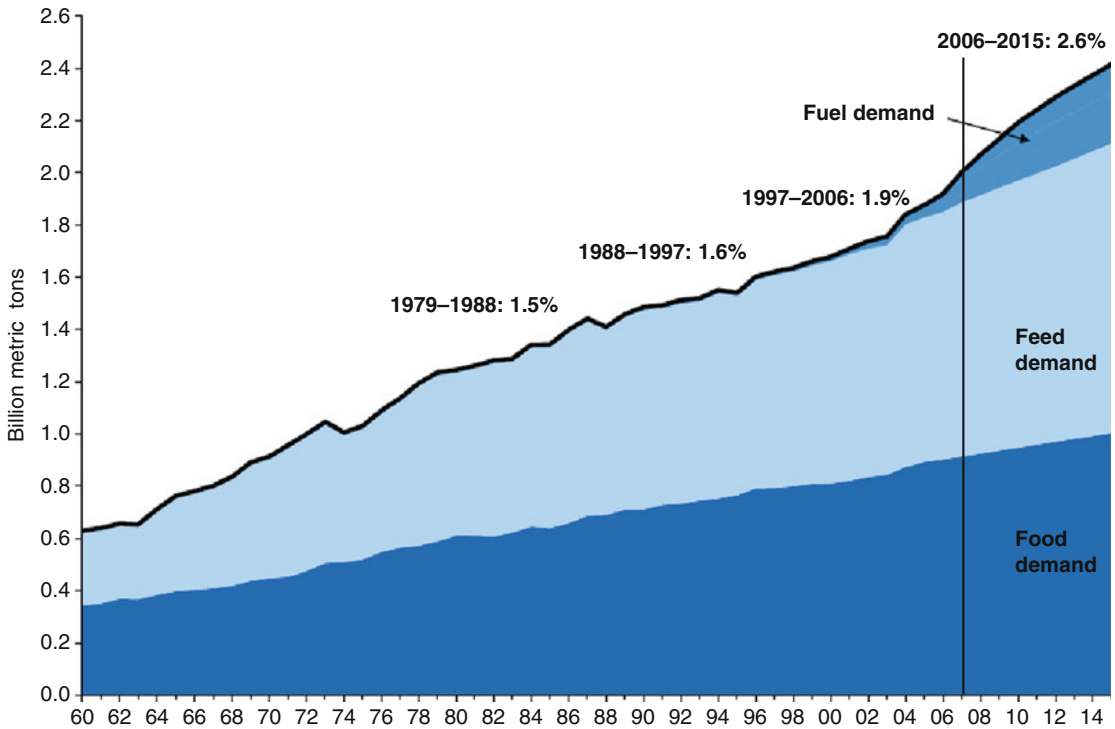
in agriculture in an economically, ecologically, and sociologically acceptable manner is the goal of integrated pest management (IPM). Given the complexity of agricultural ecosystems, IPM has to consider and manage all the elements and relationships involved in agriculture, including those related to nonagricultural ecosystems. Providing a scientific approach to better understand processes in agroecosystems in order to implement more rapidly sustainable IPM systems is a major challenge for ecology.

Introduction: Agriculture and Insect Pests

Agriculture and Productivity

Providing stable food for human subsistence has been the main goal of agriculture throughout the centuries. Probably because more than 50% of world population lives in urban areas and because developed countries do not feel threatened by hunger, society is not aware that agriculture needs to secure the world's food supplies. Increase of both world population and its income lead to increasing rates of food demand and to remarkable changes in the commodity composition of food consumption, particularly a bigger demand for livestock products.

In addition to producing food and fiber to satisfy an increasing world population, agriculture has been asked to supply energy at reasonable prices, mostly for replacing gasoline and petrol for motor vehicles. Although nowadays, as in 2007 and 2008, biofuel demand is linked to rising petrol prices, production of agricultural commodities for bioethanol and biodiesel conversion is expected to increase in the coming years, particularly if their price is competitive with petroleum. Biofuel production has accelerated the demand growth rate for agricultural commodities, which may largely exceed an annual rate of 2% in the coming years (Fig. 1). Reduction of basic food stocks, higher food prices, and increased land use may follow the stronger demand for agricultural commodities.



Integrated Pest Management. Figure 1
Evolution of demand of agricultural commodities for food, feed, and fuel use in the last 50 years (http://www.gceholdings.com/pdf/GoldmanReportFoodFeedFuel.pdf. Accessed 17 October 2009)

Complementarily, agriculture in developed countries faces increasing environmental, human health, traceability, and competition challenges. Only a significant increase of agricultural productivity and sustainable improvement of protection techniques may respond to these challenges.

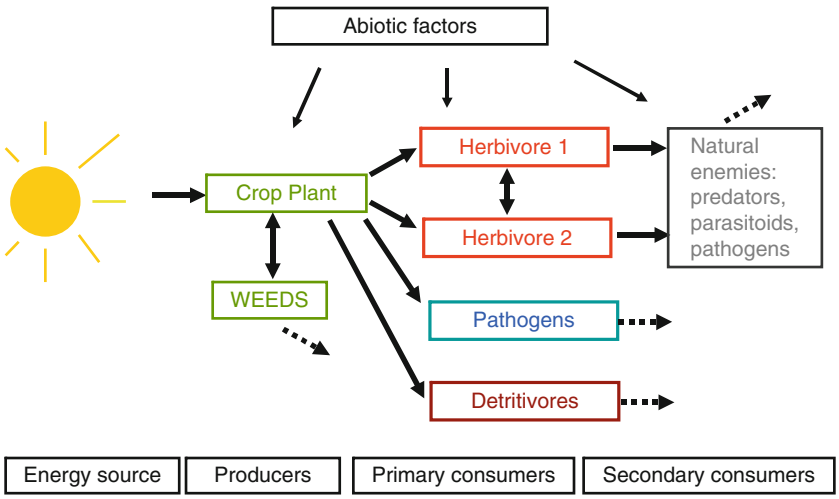
Agricultural Ecosystems: Ecological Basis for an Integrated Approach to Pest Control

It cannot be forgotten that agricultural ecosystems (also called agroecosystems) have their origin in natural ecosystems which human activity has transformed along millennia to better achieve the goal of agriculture: to provide us with sufficient food. Therefore, objectives of agroecosystems are substantially different to those of natural ecosystems; whereas, in the first case, growers manipulate the ecosystem to obtain an optimal amount of one species or part of one species (grain and not plant biomass, e.g., in cereal systems), natural ecosystems tend to perpetuate the system by themselves and do not favor one particular species or group of species. Agroecosystems differ from natural ecosystems in several ways among which two are particularly relevant in this chapter: (a) agroecosystems introduce a certain amount of energy previously processed (e.g., fuel) in comparison with the second which uses almost exclusively the energy provided by the sun; (b) agroecosystems are generally manipulated to deal with a unique plant species (the crop) and this leads to a drastic simplification of biodiversity in producer and ulterior consumer food web levels.

Composition and relationships in an agroecosystem are of crucial importance to the dynamics of its components. Figure 2 represents a simplified scheme of the main components and relationships concerning crop loss agents.

This chapter only deals with the control of those herbivores that cause damage to crops, the so-called pests. In the literature the term "pest" sometimes refers to pathogens and weeds but here the term will be restricted to herbivore species, mainly insects and mites, causing damages to crop yield if preventive measures are not adopted. In order to avoid constant repetition of words such as insects and arthropods the term "pest" will be preferred along all the text.

Maximization of crop yield in Fig. 2 may be achieved by increasing the proportion of sunlight energy that is fixed as biomass by the crop plant or by



Integrated Pest Management. Figure 2
Main components and relationships related to insect pests and their control in an agroecosystem food web. *Arrows* show the direction of energy flow between components of adjacent trophic levels. *Double arrows* show competition between components within a trophic level. *Broken arrows* show that energy flow continues but the further components involved are not represented

reducing the amount of energy that is lost by competition of weeds, by damages caused by pests, or by diseases caused by plant pathogens. The process of accumulating biomass in a crop plant to reach a yield may be compared to the process of filling a water deposit that loses water through three holes (pests, diseases, and weeds). More water may be stocked in the deposit by opening the tap (more photosynthetic production) or by repairing holes. The complex nature of the agroecosystem demands an integrated approach to manage all the components and relationships taking into account that any change in a part of them may lead to undesirable consequences in the whole system. Considering the entire complexity of the agroecosystem is crucial to develop sound integrated pest management programs.

Continuously Increasing New Insect Pests: Pest Invasion

Elements and links in the picture of Fig. 2 may change in space and time. Introduction and establishment of invasive alien species and climatic change are among the most decisive factors influencing the composition and relationships in an agroecosystem. Many of the insect pests in agriculture originated as exotic herbivores introduced in the past; this process continues to accelerate, mainly as a consequence of globalization of agricultural trading. The introduction, establishment, and spread in Europe of the Colorado potato beetle may exemplify the impact of insect pest invasions on agriculture. It originally restricted its distribution to the Rocky Mountains (USA) where it fed on wild plants. In the second half of the nineteenth century, the cultivation of potatoes close to that area allowed the beetle to multiply its populations, spread out of its original area, and distribute around the world where it has become the most harmful insect pest of potatoes in general terms. Hundreds of exotic arthropods have been documented as invading agricultural areas, establishing themselves and becoming important pests. The objective of eliminating or limiting the spread of pests has led several national and international institutions to develop legislation and tools to restrict the movement of insect species with a high potential to become agricultural pests. Regional sections of the International Plant Protection Convention have been particularly active in this direction and its Web site (www.ippc.int) is an important source of information. To categorize the risk of potential invasive alien species is a first step to adopt correct and ad hoc measures. Then, measures of exclusion, early detection, containment, or control of the most risky species may be adopted at the national or international level. Prevention of the introduction and spread of crop pests is an important first step of integrated pest management although it is sometimes difficult to implement due to the ease of international travel of both people and plants, and the increasing trade of agricultural commodities.

Injuries and Losses Caused by Pests

Pest control, and particularly integrated pest management, is therefore necessary to safeguard crop productivity against losses caused by herbivore insects and assure human nutrition. Losses caused by insect and mite pests derive mostly from their feeding activity on plants. Insects consume plant materials with their chewing or sucking mouthparts; in addition to lowering plant vigor, some insects are also able to transmit plant pathogens, with additional losses due to disease development, or injection of toxic substances that interfere with plant physiology. Consequently, potential crop yield is not attained and a variable level of losses results according to the amount of insects feeding on plants, the type of injury caused, and the susceptibility of the plant to the amount of injury infringed.

Potential and actual losses due to animal (mostly insect and mite) pests have been estimated by Oerke and Dehne in major crops [1]. Those were estimated as quite variable according to the crop and geographical area but on average they were 17.6% and 10.1% of the attainable yield in the world that give a control efficacy (percentage of losses prevented) of 42.4%. Efficacy to prevent losses from animal pests was higher than from bacterial and fungal diseases (33.8%) but considerably lower than from weeds (70.1%). These moderate values of efficacy in crop protection, which averaged 52.5% in the world, were reached in spite of particularly high pesticide consumption in Western Europe and North America.

Strategy for Integrated Pest Management

What IPM Is

The necessity to change the strategy of controlling insect pests derived from both theoretical considerations and practical collapse of control systems. Although humans were soon aware of weaknesses in relying on control systems based solely on single tactics, control failure of pesticides due to pesticide resistance in important insect pest species and the consciousness of pesticide transfer to environment might have been the detonators of strong criticism about the mass use of pesticides in the 1950s. Soon after that, scientists, especially applied entomologists, defined new concepts and terms among which were integrated control and integrated pest management (IPM) [2]. These two terms share basically the same underlying concepts although some authors have justified the different use of these two expressions [3]. A broad definition of integrated pest management is this: a pest control system in an economically, ecologically, and sociologically sound manner by the use of multiple tactics in a compatible manner.

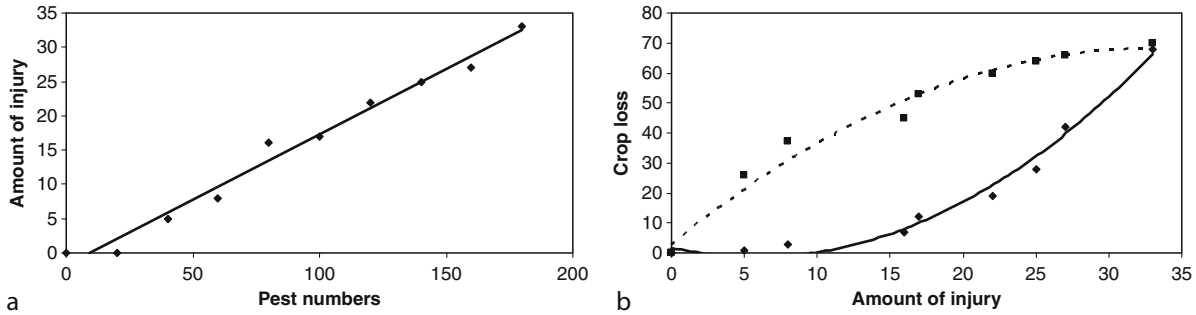
Sustainability should be an inherent qualification of IPM systems. However, development of novel insect pest control methods has often focused more on replacing chemical pesticides than implementing low input tactics, two objectives that do not necessarily progress in parallel ways. Classical biological control provides us with some examples of reduced sustainability when mass-reared natural enemies are repeatedly released to control insect pests in short-lived annual crops as practiced in some Mediterranean greenhouses. Paradoxically, many of pest natural enemies that are mass produced with energetically costly procedures and released into isolated Mediterranean greenhouses are native to the same area and could be managed to enhance their entrance into greenhouses by conservation biological control practices. Early IPM aimed to decrease the use of pesticides and, fortunately, it succeeded in many cases. The novel era of IPM should put emphasis on the agroecosystem management and various entries in the encyclopedia will give some indications on how to proceed in such direction. Nonetheless, some fundamental concepts of IPM as enounced decades ago have kept most of their validity in theory and practice. This is the case of economic threshold which is still a key concept that, under several formulations and criticisms, occupies a central point in IPM development.

Concept of Economic Threshold

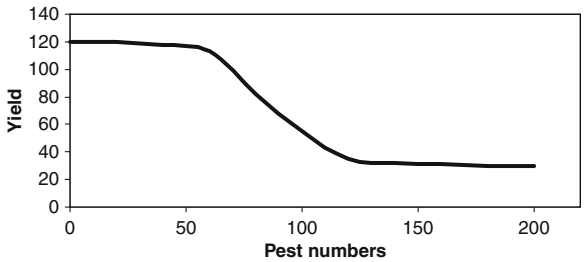
A first question that an IPM practitioner has to face when he/she detects a certain number of pests on the crop is whether intervention is justified. Some criteria to make decisions based on economic, social, ecological, and toxicological needs are necessary. Economic injury level (EIL) and economic threshold (ET) are concepts that primarily were developed to make decisions founded on economic cost-benefit analysis to include later a richer set of the so-called bioeconomic elements that relate pest numbers, crop plants responses to pest injury, and resulting crop losses. With minor modifications these two concepts of EIL and ET still form the basis of the current IPM programs providing the potential to improve economic profits but also reduce environmental impact [4].

Relationships between pest numbers and resulting crop losses are the result of two other subrelationships succeeding each other very closely in time. Pest numbers are grossly related to total injury in a linear manner, whereas the latter relates to crop loss (i.e., lowered yield) by nonlinear figures (Fig. 3) so that the result of combining both curves gives a nonlinear relationship between pest numbers and crop loss (or yield reduction), as that represented in Fig. 4, if crop loss is converted into yield reduction.

As seen in Fig. 4, yield is reduced at low pest numbers very slightly, if at all, but as pest numbers become higher yield is increasingly reduced in a near linear manner until the declining yield per pest number increase decelerates and finally becomes insensitive to pest population growth. Of course the shape and values of this relationship is a function of several factors linked with the plant and pest species. The following are the most significant: yield based on fruit is more sensitive than is biomass, injury on plant tissues contributing directly to yield are more yield reducing, dissimilar host-plant growth stages are differentially sensitive to injury in terms of yield loss in a manner that young plants have a higher capacity to recover or compensate injuries, and finally biotic and abiotic stressors other than the pest may magnify the consequences of injuries.



Integrated Pest Management. Figure 3
Relationship between pest numbers and amount of injury (*left*) and two common relationships between the amount of injury and losses caused on the crop (*right*)



Integrated Pest Management. Figure 4
The relationship between pest numbers and yield as a result of combining the relationships of Fig. 3 and converting crop loss to yield reduction

Knowledge of the curve relating pest numbers and yield is the basis for the calculation of EIL and ET. Simply defined, EIL is the lowest pest population numbers that will cause economic damage this being the amount of damage that equals control cost. EIL shows the amount of pests (and therefore the amount of injury) that can be tolerated by a crop. Operational consequences of the EIL are summarized by the ET, which determines if management action against a pest is needed. As the time needed to make a decision and to take the action may cause pest population to surpass the EIL, decisions have to be made before the population reaches the EIL and thereby prevent economic damage; this value is called economic threshold, ET. When decision making is delayed, pest population continues to grow, control methods are less efficient, and ET is lower in relation to EIL. On the contrary, if pest population is expected to decrease after reaching the EIL, ET may be higher than EIL. There are still many gaps in the knowledge of the mechanisms of herbivorous insect and host–plant relationships and this may be the cause of the insufficient development of ETs in practice; in addition, a rather confusing literature and proliferation of nomenclatures, often with no novel concepts provided, do not help in the implementation of tools for economically, ecologically, and toxicologically sound pest control.

Limitations of Economic Thresholds

In addition to the complexity of determining ET values already stressed, a number of other limitations may constrain the application of criteria for decision making in IPM. One of the limitations derives from the fact that many factors affect the amount of injury (or pest numbers) and yield (crop losses) relationship, and therefore it is quite unrealistic to use deterministic models – as those based on ET – in insect pest control. If different levels of crop loss may be associated to probabilities of occurrence, IPM practitioners may decide on a risk assumption basis. Risk is common in economic activities and growers have to compare the risk of crop losses with control costs. Furthermore, growers may have to choose among a number of control methods, each with a different cost and a different expected efficacy. To further complicate the grower's decision, the benefits of different control options – including no action – may be considered in the short or long term, which are often different. For example, application of an insecticide may be more effective at short time if the chemical has a good

knockdown but less effective later in the season if the insecticide kills most of the pest natural enemies and pest population outbreaks occur soon after chemical application. Finally, decisions concerning pest control may be altered if derived actions are adopted at farm or regional levels; in the first case, market price is unlikely to change as a consequence of actions undertaken; but when pest control actions are adopted at a regional level, resulting yields may affect the price.

Tools for IPM

Precision Agriculture and IPM

The so-called precision agriculture applied to pest control aims to apply control inputs only when and where they are needed and at optimal amounts according to variable field characteristics. Whereas it is understood that decisions must account for temporal changes in population densities, much less attention has been given to spatial heterogeneity probably because pest control actions are mostly decided and implemented at the farm level. For very mobile pests, when control implementation needs to operate over areas larger than just the farm, or simply because pest dynamics is decisively influenced by the spatial structure of the habitat, area wide pest management strategies have to be developed [5]. This has been practiced in the past, such as with human insect-borne diseases or in a few agricultural problems (i.e., locust plagues). Larger and systematic use of area wide control applied to agricultural pests has been implemented only in the last decades.

One of the most common causes for control failures is pest migration into managed areas from unmanaged areas or from areas managed at different times, particularly when the pest is able to move through several kilometers in a short time. Disposal of fields with different crops or different crop phenologies, or those submitted to different abiotic conditions in a patchwork landscape facilitates the movement of flying pests searching for the best environments to develop and reproduce. An area wide IPM approach differs from local pest management in some important characteristics. Whereas local IPM implementation focuses the control in specific parts of the habitat, the area wide approach considers the control in all potential niches. On the other hand, as area wide strategies need to consider and implement the control on a multiyear basis, this is an incentive for building a more permanent organization for such a purpose and thus leading to more professional management tools. These include geographical information systems (GIS), satellite imagery and remote sensing, online processing of climate data and weather forecasting, and kits to detect potential insecticide-resistant populations that can be useful for prevention of spreading resistance genes across the regional population. Finally, area wide implementation of IPM programs may allow the use of methods – sterile insect techniques, mating disruption, and inundative biological control – that are effective only when applied on big surfaces. Even if these and other methods may be used at individual farm level, economies of scale may derive from acquiring large amounts of materials. On the negative side of area wide IPM, there is the increased complexity of decision making if the area covered by the program is not uniform and many inputs are needed to respond with control measures adapted to each condition.

Area wide IPM application is based on a large amount of data referenced to each geographical position which needs to be stored and organized in a systematic and recoverable way. Once data are stored and organized they can be used to monitor some variables, manage resources, and develop forecasting models. GIS technology serves such a purpose. In recent years, GIS techniques have monitored the influence of crop plant, crop phenology, topographical variables, or climatic variability on insect distribution; movement of herbivore insects or predators at landscape scale; impact of crop rotations or cropping system on pest damage; agricultural production techniques, insect community structure and impact of damages caused by insect pests; and invasion and establishment processes by alien invasive insects.

Acquisition of data to feed GIS technology may be a long-lasting and tedious process and it is a major limitation for GIS application in IPM. Remote sensing – acquisition of information on an object without being in contact with it – may reduce the efforts for data acquisition. For instance, remote sensing techniques have been developed to map several types of vegetation or plants that are stressed by damage caused by

different amounts of herbivore insects and which display changes in absorption and reflectance in the visible and near infrared light due to chlorophyll content decrease, alteration of other pigments, or some other changes in the internal plant anatomy. Plants stressed by insects or diseases also may alter their temperature and thermal imagery may be used to detect these plants. Images may be field-based or taken from planes or satellites and thus cover big surfaces. Before using remote sensing to make maps of insects or insect-damaged plant distribution, accuracy of sensing images should be verified by means of ground surveys. Signals from damaged plants may not be very specific and insect populations or damage caused by one species may be overestimated.

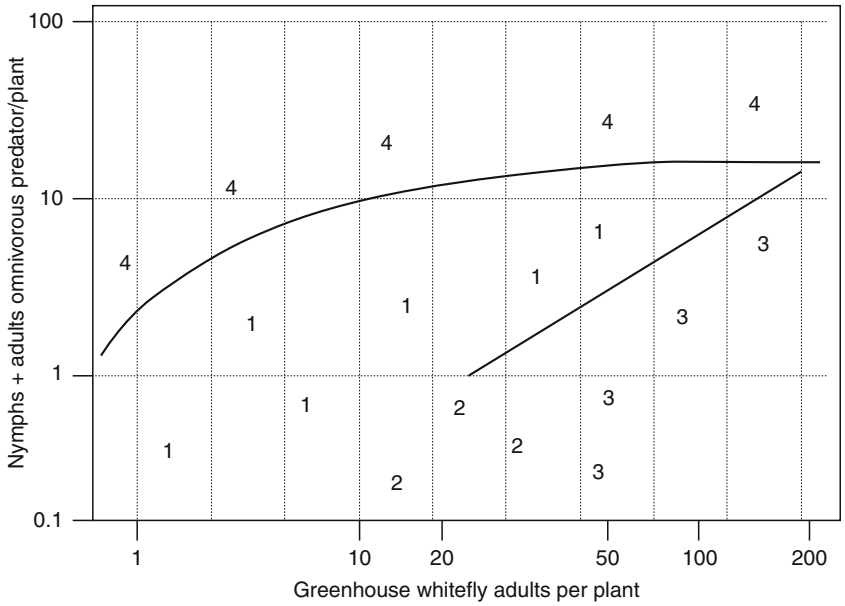
As more data are needed and available for decision making, more sophisticated are the algorithms used to process the information. Processes relating input data with conclusions leading to actions may be performed by expert personnel or by more automatic procedures as computer software; the latter are called expert systems. To consider the role that expert systems may play in IPM, let us recall the steps of any decision in pest control [6]: pest identification, assessment of injury level (density), estimation of likely crop losses, identification of control options, cost/benefit analysis, identification of constraints, integration in the larger framework of crop production [6]. Ideally, expert systems are linked with data bases that allow input and review of historical series of data to analyze past decisions in the light of real posterior events.

Expert systems not only serve for decision making in IPM but may be used as a common base for discussion among scientists or IPM practitioners in order to identify incorrect algorithms or gaps in the current knowledge or incorrect recommendations made in the past. Expert systems can also be used as training tools. Via simulation, students can examine and check situation rules to sample, make calculations, and convert the conclusions into recommendations. When expert systems are used for training or when they have to be presented for demonstration purposes, input variables, algorithms, and logical rules for decision making should be shown in a more explicit format than just computer software, for example, a set of matrices or as a decision chart such as in Fig. 5.

The decision chart in Fig. 5 was designed for field technicians to decide if insecticide treatments are needed in tomato crops. Decision algorithms take into consideration not only the amount of pest (greenhouse whitefly) but also the amount of predators (two mirid bugs) that can keep pest populations under control when the predator–prey ratio is high enough. As mirid bugs are omnivorous predators that may feed on and damage tomato fruit when lacking prey, the strategy adopted was to manage insecticide sprays. This maintained a sufficient number of whiteflies to provide predators with food and prevent tomato damage but was not too high to avoid having honeydew and sooty mold on plants and fruits. Technicians have to sample the field by choosing a number of plants at random and taking seven terminal well-developed leaves to count the number of whitefly adults and predators (adults + nymphs). According to the position in the graph of the values recorded in the field for whiteflies or predators, the decision made is: (a) doing nothing, (b) or spraying against whiteflies, (c) or predators; (d) a four region in the chart does not lead to specific recommendations. Chart is accompanied by keys to identify the targeted whitefly and the predators, some rules to take samples (including a table of random numbers), and an updated list of eligible insecticides with recommendations about their application.

Estimating Insect Population Densities

To make decisions in pest control, pest density needs to be known. As it is normally impossible to count all the insects in a habitat, it is necessary to estimate the population density by sampling. An estimation of absolute or relative population may be needed. In absolute estimations, the estimated number of individuals in a certain surface or volume may be known, whereas in relative estimation a certain and unknown proportion of the population changes in the time or space is determined. The first type of estimate is useful when we want to know if a population has reached the economic threshold or not. The second type serves to compare population numbers in time and space for monitoring purposes. If population numbers may be related to their products – for example, total amount of honeydew excreted by an aphid population – a

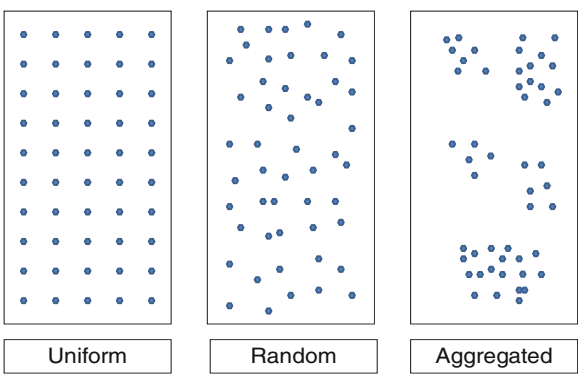


Integrated Pest Management. Figure 5
Decision chart to make recommendations for insecticide spraying in tomato crops against the greenhouse whitefly and the omnivorous predators according to the number of whiteflies and predators recorded on tomato plants. Figure has been simplified to show the most significant elements. Numbers indicate the action to be undertaken after recording densities of the omnivorous predator and the greenhouse whitefly on tomatoes in the field: (1) no action, (2) sample again in one week, (3) spray against whitefly if the recorded numbers remain in zone 2 for two consecutive weeks, and (4) spray against mirids

population index may be more useful than determining the real number of individuals.

An accurate estimate of the density of pests or natural enemies is therefore a major necessity for IPM. To estimate population densities it is necessary to sample the habitat where the population may occur and this may require knowing various aspects. Sampling universe, sampling unit, number of samples to be taken for a certain precision, and data analysis are some of the aspects to be considered in a sampling plan. Readers interested in this concept should consult the Southwood and Henderson book for wider development [7].

How individuals of an insect population are disposed in space – dispersion or distribution of the population – greatly affects the sampling program. Theoretically, three different types of population distributions may be found (Fig. 6). In *uniform distributions* individuals are evenly distributed in space whereas in *random distributions* any point in space has the same probability for occupation by an individual. Finally, most commonly, individuals are clumped on relatively few foci in *aggregated distributions*.



Integrated Pest Management. Figure 6
Three kinds of insect population distributions

Population dispersion has been described by means of aggregation indices or by fitting mathematical

distributions to experimental data. Use of aggregation indices is based on the relationship between variance and mean in the three types of distribution models. In uniform distributions variance is null independently of the mean; in random models mean equals variance; in aggregated distributions variance is higher than mean. The simplest aggregation index uses the variance/mean ratio so that when the ratio is 1 it means that distribution is at random, it is more uniform as the ratio decreases below 1 and, inversely, aggregated models show variance/mean ratios increasing higher than 1 as individuals are more clumped. Other aggregation indices relating variance and mean in different ways have been used – for example Lloyd', Morisita' indices – but most of them have shown a high dependency from sampling unit size and population density, a disturbing inconvenience to characterize a population distribution pattern. Relationship between estimated variance (s^2) and mean (m) has been empirically fitted to a power law: $s^2 = am^b$, where a and b are constants; a is largely a sampling factor while b appears to depend on the degree of aggregation of individuals and thus may be used as an aggregation index. Taylor's power law has shown to overcome some of the limitations mentioned for aggregation indices but usually needs many experimental data to fit a sound power function.

Several mathematical models have been proposed to describe population distributions; for insects many populations have been adequately fitted to the negative binomial distribution which is basically described by the parameter k, which is a measure of the degree of clumping. Although the approach of mathematical models to study population distribution patterns has given more accurate descriptions than aggregation indexes, it often depends on population density and sampling technique. In summary, none of these methods describing population distributions is free from limitations and this can explain why insect ecologists have used so large a variety of approaches to characterize patterns of insect disposition in space.

When populations are very clumped and most individuals occupy a few dense patches among empty patches a question arises: are individuals in one patch moving to another patch? If yes, how often and to which extent does this movement occur? Such a perspective deals with metapopulation ecology. Ecology has classically considered that individuals of a population are capable of unrestricted interaction with each other within a habitat. However, habitats usually occur in a patchwork within a landscape – as islands in the ocean – and populations inhabiting those habitats are consequently patchy. Populations occupying each patch may become extinct but individuals coming from other patches may recolonize that patch and rebuild a new population. Between-patch movement also may be caused by factors other than just extinction and recolonization. In any case, individuals initially belonging to a population in a certain patch occasionally may interact with individuals of other patches. The set of all populations initially occupying different patches is called a metapopulation. There has been a lot of interest in metapopulation ecology in the last decades because of its practical application. In the field of IPM, metapopulation ecology may bring new tools for analyzing the dynamics of insect populations that occur in partially isolated patches (fields or group of fields). Understanding how populations work in a metapopulation may help to increase environmental resistance to pest population development or to favor populations of pest natural enemies. Management of metapopulations and not just local populations may be a valuable approach not only for unstable annual crop systems but also for more permanent crops that are periodically disturbed (i.e., cut, pruned, sprayed with insecticides) so insects are regularly obliged to leave and recolonize fields. In the context of area wide IPM programs, metapopulation ecology may be more predictive than just considering individual populations.

Taxonomic Adscription of Major Pests

Main Animal Taxa with Damaging Species

Most agents causing injuries to crop plants are species belonging to the Phylum Arthropoda and among these the class Insecta includes the majority of arthropods that are crop pests. That is why the discipline dealing with pests and their control very often is called agricultural entomology, the science about insects in relation to agriculture. The class Arachnida, particularly the order Acari (mites), also contains some important pest species. Notice that some herbivorous insects and mites cause injuries to crop plants whereas pathogens are responsible for crop plant diseases.

The class Insecta comprises more than one million identified species and probably even more that have not been identified yet. Insects are grouped in 28 orders – this varies according to the authority– a common taxonomical level to refer to insects. Among those, seven major orders include most of the important insect pests: Orthoptera (grasshoppers and others), Hemiptera (true bugs), Homoptera (hoppers, psyllids, whiteflies, aphids, scale insects), Coleoptera (beetles), Lepidoptera (moths and butterflies), Diptera (mosquitoes, flies), Hymenoptera (ants, wasps, insect parasitoids, and others). Table 1 shows the main families of mites and insects including economically important pests and their most significant pest characteristics.

Other taxa of the animal kingdom include species that can potentially become serious pests. Mollusks (snails and slugs), fishes, reptiles, birds, and mammals may include species that in some circumstances are very damaging.

Identification of Insects and Mites

When a technician observes insects or mites on a crop, the first question that arises is "what are they?" To precisely answer this question is a key starting point for finding an efficient solution if the population grows to become a pest. A wrong answer may lead us to make incorrect decisions as many solutions are specific for each insect pest and crop. Sometimes, even specific identification is needed to adopt correct measures.

Identification of insects and mites is usually done by means of taxonomic keys. Keys are arrangements of related taxa put in clusters. Morphological characters – complemented sometimes with anatomy, appearance, or behavioral features – are mainly used to segregate individuals into clusters. The process goes from more general characteristics (i.e., with wings or wingless) and taxa to more particular characteristics until reaching species-level determination. Even for easy identifications, a certain expertise is needed. For routine identifications field technicians may perform quite well in recognizing common species; when dealing with a new species, correct identification may require sending a sample to a family-level specialist usually working in universities or musea. Availability of good insect taxonomists is therefore critical for developing sound IPM programs, not only to identify insect pests but also their natural enemies (predators and parasitoids).

Molecular techniques are still insufficiently developed to identify insects but rapid progress has been made in recent years. Molecular tools are usually developed to distinguish between two or more taxonomically close species. Molecular identification keys based on a targeted DNA sequence or marker may be useful for such purposes and have some advantages in relation to classical morphological keys. These advantages include: applicability to all developmental stages; less variation than for morphological characters; they may be applied to fragments of the individual to be identified; the technique may be applied for a variety of insects if appropriate specific material and personnel trained in molecular tools are available, in contrast with morphological-based keys that usually require family-level specialists.

Pesticides

Use of Pesticides

In the coming sections, major *control methods* are reviewed in the light of how they can contribute to the sustainability of agriculture. Ecological bases, common applications, and how they can be integrated into IPM systems are presented in each method.

Use of pesticides (mainly herbicides, insecticides, fungicides, and nematocides) in western world agriculture has decreased or been maintained in general. In Fig. 7, the amount of pesticides sold in two main consumer European countries is shown. Whereas in France, the highest consumer of pesticides in Europe, the amount of pesticides sold (mostly applied in France) has decreased significantly, in Italy the amount of pesticides is more or less stable or shows a slight increase taking into account that modern pesticides are used at considerably lower doses than classical active ingredients. Beyond differences due to variable economic and climatic conditions, an important part of the decrease in many countries has been achieved by the progress of application of IPM systems to control insect pests, diseases, and weeds.

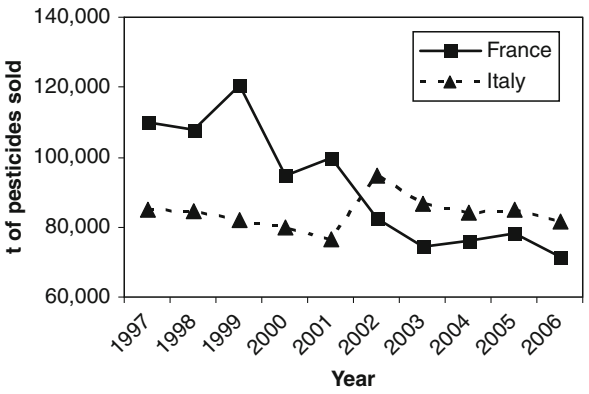
Pesticides are chemicals aimed to kill any kind of plant pest or otherwise lower their populations to prevent their reaching economic thresholds. Pesticides

Integrated Pest Management. Table 1 Main orders and families of arthropods including economically important pest species

Class	Order	Family	Main characteristics and features as pests
Arachnida	Acari	Tetranychidae	Plant-feeding spider mites. They feed on several aerial plant parts but mainly on leaf undersides with loss of photosynthetic products and water
		Eriophyidae	Microscopic mites with only two legs; they feed on plant parts often causing galls
Insecta	Orthoptera	Acrididae	Insects that at high density may aggregate in groups and migrate long distances and become very destructive on many crop and forest plants
	Hemiptera	Pentatomidae	They suck plant sap from several tissues resulting plant wilt, abortion of fruits, or tissue malformations
		Miridae	Numerous, but not only, herbivore species that feed on plant sap causing foliar chlorosis, cankers, abnormal growth, and many kinds of lesions
	Homoptera	Cicadellidae	Usually they feed on leaves where they suck juices and reduce chlorophyll contents and produce small white spots. Plant vigor decrease and disease transmission are common injuries
		Psyllidae	They feed on the phloem causing plant stunting or poor plant growth and sometimes gall forming
		Aleyrodidae	They feed on the phloem and reduce plant vigor, exude honeydew where sooty mold may develop causing fruit depreciation and some species are active plant disease vectors
		Aphididae	As mentioned for Aleyrodidae with special importance for plant virus transmission
		Coccoidea	In addition to the injuries mentioned for the other Homoptera, scale insects may inject saliva into the host causing discoloration, malformations, galls, and also esthetic damages in ornamental plants
		Diaspididae	
		Asterolecaniidae	
		Coccidae	
		Margarodidae	
		Pseudococcidae	
	Coleoptera	Scarabaeidae	As pests they mainly feed on plant roots in larval stages causing plant vigor decrease and even plant death
		Elateridae	Larvae feed below ground on roots and tiller base and kill the plant when it is young. Crops harvested for roots or tubers are more easily injured
		Curculionidae	Many species whose larvae and adults feed on several plant tissues including roots, tillers, leaves, flowers, and fruits. A very damaging family
		Chrysomelidae	Adults and larvae feed on foliage and fruit; in some other species larvae feed on roots
		Scolytidae	Larvae feed internally in tree tissues, below the bark; particularly harmful in forest trees but also in orchard and ornamental trees
	Lepidoptera	Tortricidae	Larvae feed on leaves, fruit, buds, and stems
		Pyralidae	Larvae are leaf-rollers, borers, and detritivorous attacking a large number of crops including stored products
		Crambidae	Larvae are mostly grass stem borers

Integrated Pest Management. Table 1 (Continued)

Class	Order	Family	Main characteristics and features as pests
		Noctuidae	Larvae feed on leaves, stem, and fruits devastating many crops. This is one of the most important families with many economically important species
	Diptera	Cecidomyiidae	Main injury comes from their capacity to cause galls in several plant tissues
		Tephritidae	Larvae feed internally in fruits. They have a high destructive potential
		Agromyzidae	Larvae mine leaves by feeding parenchyma cells between up and down epidermis
	Hymenoptera	Tenthredinidae	Most damage is caused by larvae feeding on leaves that reduce photosynthesis activity and thus plant vigor. They commonly defoliate forest trees but also some agricultural crop plants
		Cephidae	Larvae bore into stems of grass plants and cause their breakage



Integrated Pest Management. Figure 7
Evolution of sales of active ingredients with pesticide activity in two significant consumers in Western Europe (From http://epp.eurostat.ec.europa.eu/tgm.Accessed 6 February 2010)

include four main groups of substances according to their target: herbicides against weeds, insecticides against insects or other pests, fungicides against in general disease-causing agents, and nematocides against plant pathogenic nematodes. A number of characteristics of pesticide use may explain the success of pesticides for pest control in the last decades although probably the amount applied has started to decrease in the developed world in recent years due to the restrictions posed by the legislation and also by the progress experimented by the R&D in implementing IPM systems.

Pesticides are easy to use; growers may fill the tank and spray many hectares while sitting in the tractor and listening to the radio. When used correctly they are effective to lower pest populations and frequently cheaper than other control alternatives. In spite of the better selectivity and lower permanence of modern pesticide active ingredients, at least one pesticide is usually available in the market for each pest. Until the discovery of insecticide properties of DDT in the 1940s, most pesticides were inorganic or extracted from plants. Since the 1940s until the end of the century, the amount of pesticides applied in the world multiplied dramatically per 20 or 30 times according to the country and several chemical families were available to control insect pests. Since the 1950s, however, scientists were aware of the problems derived from the excessive confidence in the efficacy of pesticides. Fewer than 20 years of mass application of pesticides in western agriculture were sufficient to display some of their negative effects. In ulterior years, problems became harder and many field data confirmed first concerns. Development of alternatives to chemical pesticides therefore became the goal of R&D programs in most of those countries.

Problems Associated to Pesticide Use

Problems derived from inadequate and excess pesticide use include (a) risks to public health and environment (e.g., wildlife and groundwater), (b) disturbance within agrosystems due to the common toxicity to natural enemies and secondary pest resurgence,

(c) development of pesticide resistance in the targeted pests (more than 600 pest species related to agriculture and human and livestock health are nowadays confirmed to be resistant to one of more pesticides) (www.pesticideresistance.org accessed on February 10, 2010), and (d) shorter and shorter shelf life and increasing costs to innovate by producing more selective and environmentally friendly new active ingredients. Industry has tried to develop new more compatible chemicals in order to integrate selective chemicals in IPM strategies but innovation is increasingly slow and expensive. Legislation is becoming very strict for registration of new pesticides and obliges repeated registration of old active ingredients for health and environmental safety. As a consequence the number of active ingredients available for chemical pest control is decreasing constantly. It is expected that the number of active ingredients registered as insecticides in the coming years in the EU will be less than a third of those allowed at the end of the twentieth century. Lack of effective insecticides is pressing research in and the development of new and efficient IPM systems.

Controversy on pesticide use in modern agriculture cannot lead us to forget that pesticides, at the moment, have still an important role in IPM systems. Some important pests lack sufficiently effective control methods so that no-chemical methods have to be combined with chemical ones. In other, although few, cases, pests have only chemical insecticides to control them. Invasive exotic insect pests, due to short experience in their control and novelty, may be contained only by the regional application of chemical pesticides. A rigorous analysis of how sustainable is the use of each insecticide for each pest should permit detection of those pest problems in which insecticides are irreplaceable at least at short time and those other pests in which one insecticide is superfluous – therefore that pesticide can be banned – because at least one efficient nonchemical method is available. Unfortunately the control of unnecessary use of chemicals is frequently difficult but should be implemented to speed up the adoption of IPM technology.

Crop Resistance

Ecological Bases of Crop Resistance

Most pests cause plant damage when feeding. However, it is well known by interested observers of nature that not all herbivore insects may feed on any plant. Usually some insects may feed on a few close plant species (monophagous insects), or on plant species belonging to one family or only a few families (oligophagous insects), and finally some others may feed on a broad range of plants (polyphagous insects). Even polyphagous species feeding is usually restricted to a relatively small number of plants available in the habitat. These associations between herbivore insects and host plants are the result of the coevolution of the two components; in such coevolution, plants develop mechanisms to defend themselves from herbivore insects and insects try to develop mechanisms to overcome plant defenses. That a plant possesses some characteristics that diminish its access for one insect pest and that such a trait may be introduced into a host plant for pest control is an old idea. Still, until well into the twentieth century crop resistance to insects was not systematically considered as a universal tool for pest control in spite of early successes in the use of plant resistance. Probably, the most famous early case of using crop plant resistance for pest control was the control of grape phylloxera in European grapevines. Practically all the European wine industry was ruined by the entrance into Europe of the North American phylloxera aphid in the 1860s. Successful control of the pest was achieved at the very end of that century by grafting European vineyards on resistant American rootstocks.

Insect–Plant Relationships and Plant Characteristics for Crop Resistance

Many physical and chemical factors are involved in insect–plant interactions. Plant stimuli and elicited insect responses are usually studied in a sequence of five behavioral steps: (a) host habitat searching, (b) host searching within the habitat, (c) recognition of a host as suitable for feeding and ovipositing, (d) host acceptance, and (e) host suitability. Step (a) is important for species that migrate or disperse over long distances and it is only occasional for pests staying in the crop habitat. Preferred abiotic conditions of the habitat are usually the most involved signals in habitat selection whereas in host selection (step b) visual and olfactory stimuli have a major relevance to bring the herbivore close to the host plant and not only olfactory but also tactile inputs stimulate the herbivore to remain

on the plant. The host is recognized through gustatory receptors that identify particular host substances when bitten by the herbivore or when the female starts ovipositing. Similar mechanisms but different substances in the host plant cause the herbivore to continue or stop feeding or ovipositing after the recognition phase. Host adequacy for the herbivore and descendants is determined by the nutritional value of the plant and the absence of toxic compounds.

Physical and chemical plant characteristics that confer resistance to the host plant against the exploitation by the herbivore may be found in each of the behavioral steps and mechanisms and those traits may be incorporated into the crop plant genotype for pest control. Mechanisms involved in host-plant resistance to herbivores may be grouped into two main categories:

- *Antixenotic* mechanisms prevent herbivores from approaching or establishing on a plant to feed or oviposit on it. There is a varied array of chemical and physical deterrents in plants to prevent or modulate preference of herbivores for feeding/ovipositing. Chemicals may be plant volatiles that act at long distances or nonvolatiles that intervene once the herbivore has landed on the plant or after it has probed the host. Physical characteristics in plants with antixenotic properties include morphological and structural features that interfere with normal feeding or oviposition. For example, plant epidermis hairs and trichomes are common morphological features that impede normal feeding in many herbivore insects and confer resistance to hairy cultivars.
- *Antibiotic* mechanisms cause deleterious effects, including mortality, for the herbivore once it has ingested a certain amount of the host plant. Antibiotic effects on herbivores that have fed on resistant plants may be expressed in a variety of consequences, and not only mortality: lowered development rates, failure of development features like pupation or adult emergence, reduced fecundity or fertility, and irregular behavior. Antibiosis is caused by toxic plant compounds or by other nontoxic plant characteristics like low nutritional quality, unbalanced composition in nutrients, or presence of enzymes interfering with normal insect digestive physiology.

There are mechanisms of plant resistance that are not related to host-plant constitution. These are "ecological resistance," "induced resistance," and "tolerance." Although they have been often neglected in plant breeding programs, their consideration when crop cycling and crop management practices are planned may contribute greatly to reduce crop losses by pests. *Ecological resistance* derives from the phenological asynchrony of crop and pest populations that prevents or diminishes the coincidence of the most susceptible crop growth stages with the most pest stages that are able to attack the host; sowing date may thus be planned for enhancing ecological resistance. *Induced resistance* is the response of a host plant to an environmental stress that reduces herbivore insect fitness or the plant availability for the insect. Once again, many agricultural techniques, like fertilization or irrigation, may alter plant physiology to enhance or decrease induced resistance. *Tolerance* is the capacity of some crop plants or crop cultivars to recover from injuries caused by the pest so that tolerant plants may attain yields that a similar amount of pest on a nontolerant plant would reduce. Several physiological processes have been identified in plants that may compensate for the injury caused by a herbivore insect and those processes may be facilitated by good agricultural practices.

Crop Resistance and IPM

Host crop resistance has been used profusely for disease control but it is increasingly considered and applied for integrated pest management. It is largely *compatible* with other IPM tactics, particularly biological control, although interferences of the host plant in predator–prey relationships have been reported recently. Its effectiveness is cumulative as its effects on pest population is exerted on several pest generations and usually persists after a pest's long exposure to the resistance traits; however, some cases of pests that have overcome resistance barriers at midterm have been described. One of the major advantages of crop resistance as a pest control method in the framework of IPM programs is that growers may easily adopt it as no particular expertise is needed. From a point of view of environment, crop resistance is in general safe, a required trait of any IPM method.

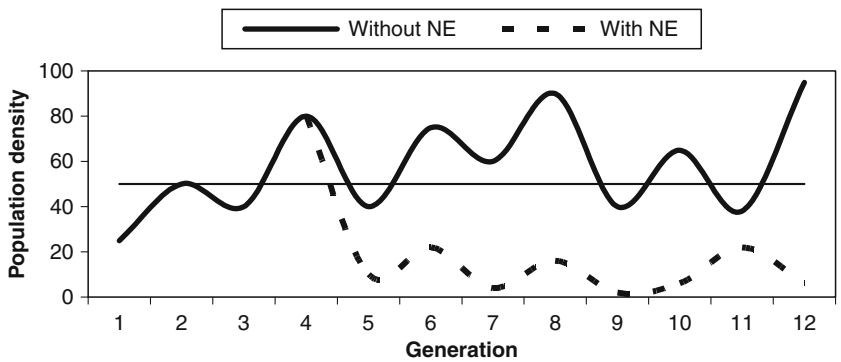
There are also some important limitations for a wider adoption of crop resistance in IPM. Frequently a long time is needed to develop a resistant cultivar, particularly in tree crops, and reaction to new and urgent problems is very slow. Modern biotechnology techniques, particularly genetic engineering (see below), are contributing to mitigate this handicap. Additionally, resistance traits are not always identified and available or they are very difficult to introduce into crop plants (also genetic engineering may favor the transfer of resistance genes between nonsexually compatible organisms). Another difficulty to implement crop resistance for pest control is the incompatibility of the resistance trait and commercial requirements; bad taste for consumers, for example, has been found in some resistant cultivars. In spite of the persistence of crop resistance mentioned as an advantage of the method, and as also mentioned earlier, local biotypes of the pest that are able to overcome or avoid resistance characters in the plant may develop and rapidly multiply as a consequence of their supremacy to exploit the resistant cultivar.

Biological Control

Ecological Basis of Biological Control

Biological control may be defined in general terms as the use or manipulation of natural enemies to suppress pest populations. Some authors include in the term any kind of nonchemical method that is biology-based. However, this is generally considered as incorrect and the narrower meaning given above is preferable. Although biological control may be practiced under several modalities, its principle is unique and responds to the scientific background of predator–prey ecology.

Natural enemies have been signaled as major components of natural control keeping populations within cyclic oscillations between maximal and minimal bounds in the framework of a "spontaneous balance of nature." Therefore the idea that exotic pests greatly increase their densities mainly due to lack of natural enemies in the new habitat led to attempts of reconstituting that balance by importation and release of exotic natural enemies. The ecological basis of biological control may be represented as shown in Fig. 8. A pest population that oscillated around a mean density very often above economic threshold is reduced to oscillations below that threshold after a release of an effective natural enemy. An important part of recent population ecology developments has dealt with prey-predator models that should provide the theoretical basis of biological control allowing it to progress from a rather empirical practice to a scientifically based technology. Unfortunately, the contribution of theoretical developments on predator–prey relationships has not been as fruitful as expected for biological control applications although they have clearly helped to progress beyond the "trial and error" stage of the first half of the twentieth century.



Integrated Pest Management. Figure 8
Fluctuations of a pest population before and after releasing an effective natural enemy. *Broken line* shows the fluctuation under the action of the natural enemy whereas *solid line* shows the dynamics of the pest without the natural enemy. *Horizontal line* represents the value of economic threshold

Understanding relationships between predators and prey and between parasitoids and hosts is important to optimize biological control practices. Prey consumption or host parasitization is the successful result of several behavioral steps of predator/parasitoid including:

- Selection of a *suitable habitat* where prey/host is more likely to occur. Predators and parasitoids may respond to biotic and abiotic characteristics of habitats where prey may be found. Several long-distance visual and olfactive stimuli from habitat components, including the proper prey/host, may be involved in habitat suitability recognition by searching predators and parasitoids.
- Once in the suitable habitat the predator/parasitoid has to *find a prey/host*. Within the habitat vision and olfaction also play a major role, but short distance stimuli may be decisive as adults sometimes look first for a prey in a random way until they come in contact with a potential prey.
- *Acceptance of a prey/host* when it is attacked by the predator/parasitoid is influenced by physical and chemical characteristics of the prey/host but also by hunger of the predator. Abundance may also determine if a prey is attacked or not.
- Prior to the final decision to consume/parasitize requires checking that a *prey/host is suitable* for the predator/parasitoid. Internal composition of prey largely determines if the predator rejects or continues to feed on it.

A relatively low amount of predatory arthropods are quite specific (they feed only on a particular family of prey) whereas generalist predators (they may feed on a wide range of prey taxa) are more common among both insects and spiders. In some groups both juvenile and adult stages are predatory but in some others only juveniles or adults prey. Parasitoids are usually more specific than predators and in general they can parasitize species belonging to one family or to a narrow range of families.

Taxonomic Adscription of Insect Natural Enemies

Natural enemies include three kinds of organisms: predators, parasitoids, and entomopathogens. Biological control only deals with the former two types whereas the third is the subject of microbial control. Predators are organisms that kill and consume a number of other organisms, called prey, along their lifespan from which they obtain the energy needed to grow, develop, and reproduce. Parasites are organisms that usually need to consume only one organism, the host, to develop and reproduce. When the host dies as a result of the action of one parasite this is called parasitoid.

Predaceous habits are relatively common in classes Insecta and Arachnida. Among insects, five orders include particularly important predators in agrosystems: Hemiptera (true bugs), Neuroptera (nerve-winged insects), Coleoptera (beetles), Diptera (flies), and Hymenoptera (wasps and ants). Among Arachnida, the order Acari includes some predatory families, particularly Phytoseiidae, and many predatory species grouped in several families belong to Araneae (spiders). Whereas predators are located in many insect and mite families, parasitoids mainly belong to certain families of Hymenoptera and a few to Diptera. Early on biological control almost exclusively used entomophagous insects but currently a wide range of organisms are being applied or manipulated to control pests. Table 2 shows those predators and parasitoids that are or have been commercially used in Europe and Mediterranean countries (http://archives.eppo.org/EPPOStandards/biocontrol_web) (accessed in December 2009).

The dozens of natural enemies included in Table 2 are only a part of those used in biological control in Europe. At least the same amount can be added when established agents managed for biological control by conservation (conservation and enhancement of natural enemies by crop and habitat management, see biological control by conservation below) are considered. Many other arthropod (e.g., dermapterans, carabids, staphylinids, coccinellids, syrphids, mirids, nabids, lygaeids, spiders, phytoseiids, and stigmaeids) and non-arthropod groups include predatory species that are or have been directly or indirectly managed to suppress pest populations in agriculture in Europe. Similarly, the same or close families to those cited in Table 2 include other species of parasitoids that have been used in biological control by conservation.

Strategies of Biological Control

To achieve pest suppression biological control may follow three main strategies: release of new natural

Integrated Pest Management. Table 2 Main predators and parasitoids that are or have been commercially provided for biological control in Europe and non-European Mediterranean countries

Phylum/order	Family	Species	Main target pests
Predators			
Insecta/Hemiptera	Pentatomidae	*Podisus maculiventris*	Lepidoptera larvae, Colorado potato beetle
		Picromerus bidens	Lepidoptera larvae
	Anthocoridae	*Orius albidipennis*	Thrips
		O. laevigatus	Thrips
		O. majusculus	Thrips
		Anthocoris nemoralis	Psyllidae in orchards
		A. nemorum	Pear psylla
	Miridae	*Macrolophus caliginosus*	Whiteflies
Thysanoptera	Aeolothripidae	*Franklinothrips megalops*	Thrips
		Franklinothrips vespiformis	Thrips
		Karniothrips melaleucus	Scales
Neuroptera	Chrysopidae	*Chrysoperla carnea*	Aphids
Coleoptera	Staphylinidae	*Aleochara bilineata*	Larvae of *Delia* sp. flies in soil
	Coccinellidae	*Adalia 2-punctata*	Aphids
		Chilocorus baileyii	Armored scale insects
		C. bipustulatus	Armored scale insects, olive black scale
		C. circumdatus	Armored scale insects
		C. nigrita	Armored scale insects, pit scales
		Coccinella septempunctata	Aphids
		Cryptolaemus montrouzieri	Mealybugs
		Delphastus catalinae	Whiteflies
		Rhyzobius lophanthae	Armored scale insects
		Rodolia cardinalis	Cottony cushion scale
		Scymnus rubromaculatus	Aphids
		Stethorus punctillum	Red spider mite
Diptera	Cecidomyiidae	*Aphidoletes aphidimyza*	Aphids
		Feltiella acarisuga	Red spider mite
	Syrphidae	*Episyrphus balteatus*	Aphids
Arachnida/Acari	Phytoseiidae	*Amblyseius barkeri*	Thrips, tarsonemid mites
		A. degenerans	Thrips
		Hypoaspis aculeifer	Sciarid flies in soil substrates
		Metaseiulus occidentalis	Spider mites
		Neoseiulus californicus	Spider mites

Integrated Pest Management. Table 2 (Continued)

Phylum/order	Family	Species	Main target pests
		N. cucumeris	Thrips
		Phytoseiulus persimilis	Red spider mite
		Typhlodromus pyri	Some spider and eriophyoid mites
	Laelapidae	*Stratiolaelaps miles*	Sciarid flies in soil substrates
	Cheyletidae	*Cheyletus eruditus*	Storage mites
Parasitoids			
Insecta/Hymenoptera	Mymaridae	*Anagrus atomus*	Leafhoppers
	Encyrtidae	*Anagyrus fusciventris*	Mealybugs
		A. pseudococci	Mealybugs
		Comperiella bifasciata	Armored scale insects
		Encyrtus aurantii	Scales
		E. infelix	Scales
		Gyranusoidea litura	*Pseudococcus longispinus* (mealybug)
		Leptomastidea abnormis	Mealybugs
		Leptomastix dactylopii	*Pseudococcus citri* (mealybug)
		L. epona	Mealybugs
		Metaphycus flavus	Soft scales
		M. helvolus	Soft scales
		M. lounsburyi	Soft scales
		M. swirskii	Soft scales
		Microterys nietneri	Soft scales
		Pseudaphycus maculipennis	Mealybugs
		Tetracnemoidea peregrina	Mealybugs
	Aphelinidae	*Aphelinus abdominalis*	Some aphids
		Aphytis diaspidis	Some armored scales
		A. holoxanthus	Armored scales
		A. lingnanensis	Some armored scales
		A. melinus	*Aonidiella aurantii* (armored scale)
		Coccophagus lycimnia	Soft scales
		C. rusti	Soft scales
		C. scutellaris	Soft scales
		Encarsia citrina	Armored scales
		E. formosa	Greenhosue whitefly
		Eretmocerus eremicus	*Bemisia tabaci* (whitefly)
		E. mundus	*Bemisia tabaci* (whitefly)
		Cales noacki	*Aleurothrixus floccosus* (whitefly)

Integrated Pest Management. Table 2 (Continued)

Phylum/order	Family	Species	Main target pests
	Aphidiidae	*Aphidius ervi*	Aphids
		A. colemani	Aphids
		A. matricariae	Aphids
	Braconidae	*Bracon hebetor*	Lepidoptera
		Cotesia marginiventris	Lepidoptera
		Dacnusa sybirica	*Liriomyza* spp. (leafminers)
		Opius pallipes	*Liriomyza* spp. (leafminers)
		Praon volucre	Aphids
	Eulophidae	*Aprostocetus hagenowii*	Cockroaches
		Diglyphus isaea	*Liriomyza* spp. (leafminers)
		Thripobius javae	Thrips
	Trichogrammatidae	*Trichogramma brassicae*	Lepidoptera
		Trichogramma cacoeciae	Lepidoptera
		Trichogramma dendrolimi	Lepidoptera
		Trichogramma evanescens	Lepidoptera
	Pteromalidae	*Scutellista caerulea*	Soft scales

enemies in a habitat (classical biological control); augmentation of natural enemies in the habitat (augmentative biological control); and conservation of those natural enemies already established in the habitat (conservation biological control) [8].

Classical biological control. Modern biological pest control began at the end of the nineteenth century when an exotic pest, the cottony cushion scale, invaded Californian citrus orchards and caused severe damages. Among other species, a predatory coccinellid beetle, *Rodolia cardinalis*, was imported from its Australian origin and released in some orchards of California. In a few years the predators spread throughout the citrus growing area and greatly reduced scale densities. Success of the strategy created much enthusiasm and many other cases of introduction of exotic natural enemies to control exotic pests followed the release of the Rodolia beetle. Some of them resulted in successful pest suppression but some other failed due to several causes. In spite of this, several benefits derived from successful and failed attempts. First, biological control was shown as a feasible technique to suppress pests. Second, a network of entomology laboratories – mainly American – spread around the world to support expeditions to look for natural enemies and some of them were the embryo of future biological control institutes. Third, successes and failures have pushed entomology science to develop the taxonomy of many families of predators and parasitoids, to furnish an ecological basis of predator–prey relationships for a more theoretically founded biological control and convince governments and policy makers that nonchemical methods may be as efficient as pesticides in controlling insect pests (if not more so). Although there are no reliable records of all introductions of new natural enemies for biological control, more than 1,000 cases have been reported in the last 100 years and about 60% provided a complete control or a substantial reduction of pest damage. A classical reference on the history of biological control in the twentieth century is DeBach [9].

A major concern and limitation of classical biological control is the potential impact that introduced exotic natural enemies may cause on native fauna. Criticism of biological control by introduction of

exotic natural enemies was soon theoretically enounced and several authors have advocated for limiting the trade of commercial biological control agents. In spite of little field data supporting the idea of strong impacts on native fauna, several countries have prepared regulations to forbid the importation of the most risky species of natural enemies. Although some principles have been established to assess risks of classical biological control agents much more knowledge on natural enemy interactions is needed. Two references may be useful for readers interested in environmental impact of biological control agents [10, 11].

Conservation biological control. As shown in Fig. 2, pest population development is the result of interactions among many biotic and abiotic components among which are herbivores and their natural enemies. In fact, pest population outbreaks are often due to agricultural practices which interfere with natural enemies that exert a certain control on herbivore populations in agrosystems. The goal of conservation biological control is to restore or enhance conditions for natural enemy survival, reproduction, and activity.

Conservation biological control may be implemented by manipulating the crop or the habitat. Main concerns of this kind of biological control are the identification of the natural enemies that can play a major role in keeping pest population at tolerable levels and what practices interfere with their functioning. Of course, pesticides are one of the principal interferences with natural enemies either by directly causing mortality or by indirectly influencing their biology, behavior, and movement at sublethal concentrations. Nowadays, data on the effects of pesticides on common natural enemies are needed before a pesticide is authorized; today, selectivity and low persistence in the environment, contrarily to that of years ago, are positive characteristics of pesticides used in pest control. Innovation in pesticide application techniques also tries to reduce the amount of pesticide and concentrates the application on certain sites, two goals that may increase selectivity in relation to natural enemies.

Certain practices to manage soil, water, and crop residues may contribute to natural enemy enhancement. Many insect pests live in the soil or have a part of their life cycle in the soil where they may be attacked by natural enemies; soil tillage has to be practiced in a safe and timely manner for such natural enemies. This includes crop residue management. After harvesting, crop plants may host a high variety of pest natural enemies; destroying crop residues also destroys pest individuals but may inflict a higher damage on natural enemy populations. Water management must provide relative humidity values that are optimal for natural enemies while damaging for pests.

Generally, the more stable is the agrosystem, the more chance natural enemies have to play their role as biological control agents. Whereas permanent crops allow population establishment and increase year after year, annual crops have to be colonized each year by natural enemies. However, cropping patterns may be designed to promote earlier and more abundant field colonization by natural enemies or enhance their survival and reproduction once the crop is established. Manipulation of sowing and harvesting dates may facilitate earlier colonization in the season and maintenance of natural enemies after season. Some other practices may also contribute to stabilize agrosystems. Some examples of crop manipulation to benefit natural enemy survival and activity include strip harvesting, variable crop phenology, and inclusion of banker plants to keep prey and predators in the field between seasons.

Crop diversification seeks to delay crop colonization by insects, both pests and natural enemies, or reduce their retention in the crop. Intercropping – growing two or more crops in the same field at the same time – can cause a more abundant colonization by natural enemies although there are records of the contrary phenomenon. In non-crop-diversified agrosystems, herbivore colonizers arrive earlier and in higher numbers and consequently higher populations of natural enemies may be built up. Crop diversification may be performed by different spatial and temporal patterns of crops in the landscape where one field is the source for colonization of neighboring fields. Diversification of landscape with nonagricultural vegetation is another way to enhance natural enemy presence and activity. Non-crop plants in inter-rows, margins, roads, "fallow" plots, etc., may provide shelter and even food for natural enemies when conditions on crop plants are not suitable for natural enemies and may facilitate the movement of predators and parasitoids among fields in a patchwork landscape.

Biological control by conservation has shown to be very efficient when practiced after a sound knowledge of the agrosystem. Furthermore it is safe as managed natural enemies are already established in the habitat and no negative effects on the environment may be expected. Unfortunately, biological control by conservation is not always possible due to a lack of effective natural enemies in the habitat or a lack of knowledge about how crop or habitat may be managed to effectively enhance predator or parasitoid action. Research needed to implement a program of conservation biological control has to be closely linked with local conditions, and solutions are not universal but related to each particular location.

Augmentative biological control. Although natural enemies exist, sometimes conservation and enhancement practices are not sufficient to increase their populations until reaching levels which are capable to suppress pest populations at desirable levels. In these cases the release of reared natural enemies is needed. Augmentative releases may be necessary when the natural enemy is not present at the place and time needed. There are two types of augmentative releases:

- A relatively low number of individuals of the natural enemy is released and the suppression is expected to be achieved by the first or ulterior descendants: *inoculative augmentation.*
- A high number of individuals are released and control is expected to be exerted by them: *inundative augmentation.*

As in the previously described biological control strategies, augmentative releases use natural enemies that are able to search, locate, recognize as suitable, and attack the prey, but supplementary characteristics in the natural enemy are required in augmentative releases. Biocontrol agents have to be reared, and in inundative releases, they have to be mass reared. Rearing techniques have to meet several economical and quality requirements. The high costs of rearing are mainly due to a lack of true artificial diets but also by the necessity of labor to manipulate materials and individuals and the necessity of producing natural enemies for a rather narrow interval of time in the year. Predators and parasitoids need to be reared on their natural herbivore prey/host or, in some cases, an easily reared alternative prey/host, as in the case of flour moth eggs that can be produced daily for millions at relatively low cost and supplied as food to rear many generalist predators. In addition, herbivores have to be reared on their natural host plant, or similar alternatives, that usually need specific temperature, humidity, and light conditions, sufficient space, and a lot of manpower. Automatic processes to produce plants and natural enemies in biofactories have been designed but much more still has to be done to lower production costs. The extra cost of producing for a few demand peaks in the year may be mitigated if an effective storage method is available. For instance, the egg parasitoids *Trichogramma* spp. may be produced throughout the year and stored for months as diapaused larvae that are reactivated in their development some weeks before they have to be applied in the field.

Continuous rearing of natural enemies in nonnatural conditions and ulterior transport to the field may alter their quality to perform as biological control agent. Genetic uniformity and inbreeding, negative selection for desirable characteristics to perform in the field, high impact of diseases in mass rearing colonies, and lack of learning opportunities of natural features may be some of the problems derived from natural enemy mass rearing. Procedures for quality control are being developed for the most common natural enemies [12]. Dispersal and search capacities, fecundity, health, correct species, and biotype are some of the characteristics checked in natural enemies for quality control.

Biological Control and IPM

Biological control is an important component of many successful IPM programs. The success of biological control has pushed pesticide companies to design new active ingredients with less impact on natural enemies. Whereas a few decades ago long persistence and broad action spectrum were two positive characteristics of new pesticides, current innovation of chemicals for integrated pest management looks for high selectivity and short persistence thus helping pesticides to become more compatible with biological control. The introduction of a new natural enemy in agrosystems to control a certain pest may allow reduced pesticide application and express the full potential of native natural enemies to control other pests.

Predator–prey interactions may be mediated by the host plant so that a natural enemy that is able to successfully control a pest on a certain crop may fail to do so on another crop. Hairy cucumber cultivars, which are more resistant to greenhouse whitefly than glabrous ones, were preferred to control the whitefly before *Encarsia formosa* was profusely used for biological control of this pest. Once the biological control was generally adopted in Dutch greenhouses, objectives of plant breeding shifted 180º and less hairy cultivars were again cultivated because these facilitated the inspection of leaves by the parasitoid to select and parasitize a host, thus improving the efficacy of greenhouse whitefly biological control. Tritrophic relationships – host plant, herbivore, and natural enemy – have to be considered before planning a biological control program. For IPM programs based on biological control, crop plant management and general cultural practices also have to be adapted to enhance natural enemy activity. Detection of those cultural practices that injure natural enemies may allow cultural modification in order to make predators or parasitoids more compatible with agricultural environments. For instance, tomato deleafing to produce more colored fruits has been found to interfere with the establishment of whitefly parasitoids that are inside the host in lower leaves. Tomatoes may be equally deleafed but leaves should be left on the soil between rows for some days until adult parasitoids emerge and fly to upper leaves to parasitize the host there.

Microbial Control

Entomopathogenic Organisms as a Natural Mortality Factor on Insect Populations

Insects are naturally affected in nature and also in agroecosystems by a varied array of pathogenic organisms, called entomopathogens, that cause diseases on insect pests. When naturally occurring epizootics are not efficient enough to lower pest populations under economic thresholds or they occur too late (natural epizootics are very dependent on natural abiotic conditions), the entomopathogen can be released into the environment at the time needed or manipulate the habitat to enhance the impact of the disease on the pest population. Entomopathogens may be mass produced and formulated for applying as a chemical pesticide. Many aspects described and discussed in biological control may be applied to microbial control. For instance, microbial control can be employed with classical, conservation, and augmentation techniques. In classical microbial control, a pathogen is isolated in a foreign insect and inoculated into a population that previously has never been exposed to that pathogen, whereas in conservation microbial control the impact of an already established pathogen is enhanced by manipulating crop or habitat conditions. Finally, augmentative microbial control inoculates a nonexotic pathogen at the time needed, or the crop field is inundated by microbial pesticides whose efficacy relies on the primary infection and not the secondary one as in the other techniques.

Main Insect Pathogens Used for Microbial Control

There are several kinds of microbes that cause diseases in insects and are used to control insect pests. Groups with more species and microbial control uses are: bacteria, viruses, fungi, and nematodes.

- Bacteria. The most known and used bacterium is *Bacillus thuringiensis* (Bt). This bacterium has some interesting properties that make its use very compatible with other IPM methods. Entomopathogenic action of Bt originates in some insecticidal toxins – the so-called delta endotoxins – that are produced by the bacterium during its sporulation and once ingested by the insect is activated in the digestive system and causes gut paralysis, feeding cessation, and later larvae show general paralysis. One of the most valuable characteristics of Bt toxins is their selectivity according to the Bt strain. Historically Bt has been used to control specific Lepidoptera pests and, to less extent, some Diptera and Coleoptera. Nowadays, the range of pests targeted by Bt toxins include species of some other insect groups. Also importantly, Bt can be produced in large scale and at a reasonable price by fermentation and then formulated like an insecticide to easily spray or powder the crop. Genes encoding the production of Bt toxins may be transferred by genetic engineering to crop plants which become resistant to insects that are susceptible to the Bt toxins introduced into the plant (see section "Crop Resistance"). Biopesticides based on Bt are

widely used in world agriculture, particularly in IPM programs and organic farming. Their relatively high prices and low permanence on the crop plant, mainly reduced by UV radiation when the crop is grown in the open air, are major limitations. Bt biopesticides are less than 1% of the pesticide world market in economic terms.

- Viruses. There are many types of insect pathogenic viruses but only baculoviruses are commercially available for insect pest control, mainly for Lepidoptera and Hymenoptera pests. Baculoviruses have a characteristic that gives them some advantages in comparison with other entomopathogens: they are able to create secondary inoculums and ulterior epizootics so that permanence of control efficacy may be longer than for other microbial control agents, although, like Bt, they are very sensible to deactivation by UV radiation. Furthermore, viruses are very selective and thus especially good for integrating their use in IPM programs. Genetic engineering techniques have shown a high potential to overcome some of the limitations of baculoviruses; higher knockdown effects and host range are two of the traits introduced in genetically modified baculoviruses. Probably their high price is the principal constraint for repeated field applications.
- Fungi. They comprise microorganisms that cause diseases on a variety of insect groups. In comparison with the two above, fungi are able to act in topical applications and do not need to be ingested to be active. This is why they are preferably used against sucking insects like whiteflies, scales, or aphids. Several fungal entomopathogens occur naturally and reduce insect pest incidence in agroecosystems but they are also mass produced and applied as biopesticides. Efficacy of fungal biopesticides is largely limited by low relative humidity although suitable formulations may attenuate this constraint; also UV-radiation protectors in fungal biopesticides are being tried to prolong their persistence on crop plants.
- Nematodes. Nematodes are a quite large group including many species that have several kinds of associations with insects. Facultative and obligate parasitism is among these. Some insect parasitic species have established a symbiotic relationship with entomopathogenic bacteria that confer to these kinds of nematodes a more virulent action against insect pests. In this case the bacterium is responsible for killing the host and, once dead, to preserve the host insect from being invaded by other microorganisms and therefore available for the nematode. These entomopathogenic nematodes are the most valuable for pest control, especially when part of their life cycle is in the soil, where nematodes are more effective. For pests that do not inhabit the soil, nematode desiccation at low humidity conditions is a major limitation of these agents for use in microbial control.

Use of Entomopathogens for Insect Control in IPM: Advantages, Disadvantages, and Techniques

Microbial control is one of the most promising methods to control insect pests within IPM programs. It is highly specific and selective for nontarget arthropods like natural enemies, it is harmless for vertebrates including man, it has very little risk of environmental pollution, it is easy to apply as most of them are formulated to be sprayed with conventional machinery, and there are techniques for engineered modified entomopathogens with improved performance. Disadvantages include short permanence in the environment for pest control, slow efficacy, moderate probability of generating resistance to the active ingredient in targeted pests, host production cost, and poor acceptance of biotechnology products by consumers in certain countries. In summary, microbial control is an easy method to integrate in IPM and should substantially replace chemical treatments if efficacy and cost problems are solved and biopesticides are perceived by public opinion as a safe replacement for chemicals.

Behavioral Control

Pheromones and Other Semiochemicals

It is well known that insects, and other animals, communicate within the same species and with individuals of other species by chemical signals; chemicals involved in communication are called semiochemicals. Intrapopulation semiochemicals are called pheromones and those devoted to communicating among species are allelochemicals. These are divided into two

categories depending if they benefit the chemical releaser (allomones) or to the receiver (kairomones). As more is known about insect behavior, more relevance is given to the role of semiochemicals in the communication governing crucial insect functions and more applications of semiochemicals are envisaged for insect control. Several kinds of semiochemicals have been investigated for both scientific and practical purposes but most attention has focused on pheromones.

Although chemical signals in insect communication had been observed some centuries ago, the chemical identification, synthesis, and demonstration of the sex attraction capacity of a pheromone was performed in the 1950s. A general enthusiasm on potentialities to govern insect behavior and suppress insect pests followed that pioneering work with considerable practical achievements but also with some limitations. The number of insect functions governed or mediated by pheromones is large; in addition to courtship behavior – the most studied for practical applications – social, physiology, trail, defense, finding, discriminating, and aggregating on the host plant are among insect biology features with pheromone involvement. The chemical nature of pheromones is quite diverse according to insect taxon and function. Pheromone composition usually has to meet two main requirements: be highly specific and be easily transportable by air currents. This double requirement is in part contradictory as volatile compounds need to be short molecules, with low molecular weights, but long enough to make possible several combinations of atoms for specificity. As pheromones are typically blends of several organic components synthesized by the insect or less commonly sequestered from the plant, specificity is achieved not only by chemical structure of components but also by the exact composition of the mixture.

Main Application of Pheromones for IPM

The main applications of pheromones for insect pest control may be included in one of the three following groups:

- Pheromones for *detection and monitoring* pest populations. One first application of pheromones is to know when and where a pest population is present. The pheromone is put in a trapping device and number of trapped individuals recorded. There are many kinds of traps that have been used; optimal trap design depends on pheromone composition and insect species. Generally, trap catch numbers will give relative estimates from which absolute numbers of pest population cannot be derived. Early warning, determination of timing for control intervention according to the pest population phenology, early detection for quarantine actions, and dispersal studies are some of the purposes that may be reached with pheromone trapping. However, decisions that need to know population numbers or densities rarely may be based solely on trap catch records unless a sound relationship between relative and absolute estimates had been previously established.
- Pheromones may be used to directly control insect pests by *mass trapping*, that is, by trapping a sufficient number of individuals from a pest population. Usually a huge amount of traps is needed to remove a significant number of individuals to lower pest damage. The rice stem borer – as other Lepidoptera – is controlled nowadays by mass trapping in the Mediterranean area. A first interesting variant of mass trapping with pheromone traps is practiced with *trap trees* in bark beetles. When a pioneer bark beetle recognizes a tree as a suitable host, it starts releasing an aggregation pheromone. This is soon followed by another attractant emitted by the tree that complements aggregation of many bark beetles on the same tree that may be destroyed, burnt, or sprayed with insecticides to kill many beetles. A second variant of mass trapping is when the attracted insect is not glued on the trap but killed or sterilized and in any case eliminated. Some of the most harmful fruit flies are caught in traps, sterilized, and released again to the environment for control as in the sterile technique programs (see below in the section "Genetic Control"). Principles of mass trapping are very simple but many limitations have prevented successful application. One major constraint of the method is its low efficacy when pest population densities are high; in these circumstances a reducing treatment is needed before applying mass trapping.

- Species in which orientation of one sex to the other for mating is performed by sex pheromones are sensitive to the application of *mating disruption* techniques. The principle, as in the other cases where pheromones are involved, is rather simple. The permeation of the air with synthetic pheromone components – or the whole pheromone blend – interferes with the orientation of the searching sex that usually is unable to meet the other sex; oviposition is thus prevented and population rapidly declines. Despite many studies conducted on the mechanisms underlying mating disruption techniques, much remains still unknown. A number of factors influence feasibility and efficacy of these techniques. Systems for pheromone delivery have to assure air permeation for all the period during which males and females may meet and mate, a requirement difficult to satisfy for very volatile molecules. Synthetic components to be delivered have to be produced and released at reasonable prices; otherwise, the technique is not competitive with insecticides that are cheaper and relatively easy to apply. Efficacy of mating disruption has repeatedly shown to be drastically limited by high pest population densities and this means that mating disruption has to be applied in early generations when populations are still low and forecasting whether they will reach economic thresholds is difficult. In many countries authorization to sell pheromones for mating disruption purposes has to follow hard administrative processes too close to chemical insecticide registration; this sometimes deters companies from investing money in research and development. Dozens of pests are controlled nowadays by mating disruption techniques with acceptable efficacies, especially to manage Lepidoptera in vineyards and fruit orchards.

Compatibility of Pheromones in IPM Systems

Pheromones are easy to integrate into IPM systems because they are very compatible with other control systems such as biological control. Selectivity of the method is a major advantage. As environmentally friendly substances they do not cause pollution problems, generally have no toxic effects on nontarget species, and permanence in the environment is low. When used for monitoring pheromones are easy to work with and field technicians do not need particular skills.

Pheromones are an elegant tool for IPM and used more and more profusely sometimes without sufficient rigor. On the other side, scientific research is not sensible enough for solving real problems that would lead to a faster adoption of pheromones in the field. As stated by Millar [13] more pragmatism is necessary in research on pheromones [13]. The deeper knowledge of how pheromones work acquired in the last decades should allow focusing our efforts on those systems that can be most effective. Furthermore, globalization of insect pests should push local and national efforts to more international cooperation because "my pest today may be your pest tomorrow" and vice versa.

Genetic Control

Genetic pest control comprises those techniques that use the insect pest for its own destruction. Genetic control consists of the release of sterilized, sterile, or incompatible individuals of one species into its wild population to cause a high proportion of sterile matings and hence reduce or eliminate the wild population. Three main methods causing sterility by different mechanisms are available for agricultural pests: sterile insects, incompatible insects, and hybrid sterility. Some other mechanisms have been exploited to control pests by genetic methods. Note that use of resistant/tolerant host crops is not considered within this section of genetic control.

In the sterile insect technique, insects are mass reared in controlled conditions, sterilized, and then released into the field. Insects can be sterilized by irradiation or by chemosterilization. Gamma irradiation, in which dominant lethal mutations arise as a result of chromosome break in treated cells, has been the most used technique in field programs. One of the key aspects to be determined before applying the technique in the field is the optimal irradiation dose to produce enough degree of sterility without causing somatic damages in the sterilized individual. The optimal dose is a function of several factors including insect species, its sex and physiological age, and the level of sterility required. Males are usually sterilized and released. Efficacy of the method relies on

the capacity of released males to compete with wild males to mate with wild females. Progeny of females mated with sterile males will die soon after egg oviposition. Ideally insect mass rearing procedures should target males for sterilizing and releasing because females may need a higher dose for sterilization and once released they may be harmful for the crop as a consequence of ovipositing.

With no doubt the successful eradication of the parasitic screwworm fly – the larvae of which eats the living tissue of warm-blooded animals including humans in some circumstances – in wide areas of North and Central America contributed decisively to an increase in the amount of funds devoted to the research and applications of the sterile insect technique. In agricultural pests there have also been a number of successful male sterile programs, particularly in fruit flies. The Mediterranean fruit fly, *Ceratitis capitata*, has been eradicated in some countries of Latin America and they have been declared medfly-free regions; those countries can export fruits to countries which have fruit flies as quarantine pests. In contrast, attempts to use sterile male techniques in several moth pests have failed mainly due to the difficulty or mass rearing the moth at reasonable prices.

Insect incompatibility has been also used in field conditions but less extensively than the sterile insect technique. One of the methods of insect incompatibility used is based on the effect of crossing sexes in two conspecific populations resulting in only partial embryonation and thus population decrease. Incompatibility may be caused by microorganisms that are present in one population and not in the other. For practical pest control purposes, the release of one sex of one geographic population into another location may result in nonviable progeny and therefore population suppression.

Finally, sterility also may be achieved by crossing individuals of two species that produce apparently normal but completely or partially sterile hybrids. If the hybrid mates with at least one of the parent species, it can be mass reared and released in the field for genetic control. An advantage of this system comes from the fact that it does not need a sterilization method and the quality of released individuals is better than in the case of irradiation.

Genetic control has been shown as successfully practicable in commercial conditions in several cases. However, some failures have taught us about the constraints of the method. Reinvasion of treated areas by gravid females is one of the common causes of failure. Real knowledge of the dispersal capacity of the targeted species should prevent applying the sterile male technique in too small areas. Area wide programs are particularly needed for sterile insect technique application to prevent early recolonization of the treated area from neighboring zones.

One of the key factors for successful pest control with the sterile male technique is the ability of treated individuals to compete with wild males for wild females. Lack of adequate information on how to assure competitive treated males and about mating behavior could have been the main failure cause of many genetic control programs. More attention was then devoted to developing quality control of mass-reared insects that are now routinely applied in many programs. A major conclusion after several years of applying genetic control programs is that the method by itself may be insufficiently effective to be uniquely applied and in many situations it may be useful when integrated in IPM systems to control the target and other interacting species.

Another perspective about the future of genetic control relates to potential contributions of insect molecular biology, more developed in model insects like the fly Drosophila but increasingly interesting for insect pests and pest natural enemies. As genetic control was soon seen as very limited by the lack of appropriate genetic material or by too reduced fitness in irradiated individuals, transgenesis may contribute to renewing the interest for genetic pest control. Introduction of desired transgenes into target insect species or the release of insects infected with engineered microorganisms – mainly rickettsia-like, Wolbachia – which mate with no infected individuals cause reduced fitness progeny. The reader curious about potential contributions of molecular biology to genetic control should consult the review by [14].

Cultural Control

As for any organism, insect populations – and thus pests – have a variable rate of increase depending on,

among other factors, biotic and abiotic factors (see Fig. 2). An insect population becomes a pest in the agroecosystems when the insect environment is favorable enough to enhance population increase until economic threshold is reached and control measures have to be adopted. To manipulate that environment to make it less favorable for pests is called cultural control. Many kinds of crop or habitat manipulations devoted to constrain pest population development or enhance natural enemy numbers and activity may be included within the term.

It is quite difficult to list the practices that may be applied to reduce pest populations or enhance natural enemies. Some of the practices routinely applied are apparently unrelated to pests and natural enemies and only when they are eliminated or modified their implication in pest control is discovered. In other cases growers abandoned cultural practices that had been used to control pests due to the efficacy and reliability of cheap pesticides and they had to rediscover their usefulness. (a) Crop rotation, for example, prevented populations of non-generalist herbivorous insects from building up high populations without moving from the same field; crop monoculture provoked a high resource concentration on the same place for a long time and facilitated insect development and reproduction.

In addition to crop rotation, some general cultural practices are used to lower pest populations: (b) removal of crop residues between two successive seasons may reduce insect survival in unfavorable seasons (e.g., cold winters or dry summers); (c) management of planting or harvesting can avoid pest populations peaking at particularly susceptible crop growth stages; (d) unbalanced fertilization use to favor some herbivore insects like aphids that can multiply per several units their rate of increase when fed on plants with an excess of nitrogen; (e) the same as in the previous point could be said for other agricultural inputs like water, mulching, or plant hormones that alter physical environment and crop plant physiology in favor of or detriment to pests.

Many cultural practices have an important impact on pest populations by enhancement of *natural enemies*. Weed management, beyond preventing damages to the crop should take into account their role in insect biology. Nonagricultural vegetation in margins and hedgerows may offer shelter, refuge, or food sources for predators and parasitoids, but also for herbivorous insects that colonize crops early in the season. This double role of margins has to be carefully studied before margin management practices are recommended. The behavioral manipulation of the insect pest and their natural enemies may allow making the protected resource (e.g., the crop) unattractive for the pest and attract it to an unprotected resource (e.g., nonagricultural plants). The opposite done for natural enemies in this kind of strategy is called "push and pull" [15]. *Intercropping* – the cultivation of two or more crops simultaneously on the same field – is another potential way to manipulate the environment for making it unfavorable to the pest. It is frequently observed that there are fewer pests in fields with intercropping than in monoculture; more attractiveness for natural enemies and less for herbivorous insects are two hypotheses to explain such a phenomenon.

Biotechnology and IPM

Emerging Biotechnological Techniques for IPM

Developments in plant biotechnology have contributed decisively to progress in agriculture in general and IPM in particular in the last decades of the twentieth century [16]. Biotechnology has been defined by the United Nations Convention on Biological Diversity as any technological application that uses biological systems, living organisms, or derivatives thereof, to make or modify products or processes for specific use (http://www.cbd.int/convention/ accessed on January 27, 2010). Probably, genetically engineered crops are the most socially known products of biotechnology applied to plant breeding. However, there are many other achievements and tools issued from plant biotechnology that have allowed progress in the scientific basis of IPM and multiple applications in the last decades and may allow even faster progress in the future. Following are some achievements of plant biotechnology that are relevant for IPM: (a) incorporation of insect resistance genes into commercial crop varieties; (b) the design of chemical and biological novel insecticides; (c) genetic modification of insect pests with lethal characters for genetic control or with beneficial traits to improve activity and efficacy of

biological control agents; (d) rapid and reliable detection of insecticide resistance before genes responsible of resistance are widespread in the pest population and control fails in the field; and (e) identification of arthropod species and biotypes for pest diagnostics or trophic studies.

Host-Plant Resistance: Integrating GM Crops into IPM Systems

Host-plant resistance has been used in IPM to a rather limited degree (see above). Host resistance to herbivore insects is generally a quantitative trait that is difficult to manage and long to be incorporated into crop plants in conventional plant breeding programs. Techniques of genetic engineering have allowed some of those problems to be overcome by faster identification of insect resistance sources by means of molecular markers associated to resistance traits and by speeding up gene transfer from those sources to crop varieties to produce the genetically modified (GM) crops. The capacity to produce entomopathogenic toxins and digestive enzymes inhibitors have been the most used characters to confer insect resistance to crop plants by means of genetic engineering techniques. However, a varied array of other characters has also been successfully introduced into crop plants for insect pest control purposes. Insecticidal capacity of an entomopathogenic bacterium, *B. thuringiensis* (Bt) is caused by some of the toxins that the microorganism produces when it sporulates. Truncated genes expressing Bt toxins (dozens of Bt toxins and corresponding genes have been identified) have been transferred to several crop and forest plants to give the so-called Bt crops and plants. More than 35 million ha of maize and 15 million ha of cotton with Bt-expressing genes (alone or stacked with other transgenes) were grown in the world in 2009 [17] to control mainly Lepidopteran pests [17]. In Spain – the European country with the largest surface of Bt maize, the only GM crop allowed for cultivation in Europe – a survey conducted among more than 400 growers on the economic, social, and environmental impact of Bt maize found this: a mean increase of 12% in the gross margin in Bt growers, more than a 50% decrease in the number of insecticides applied due to the cultivation of Bt maize; this reduction was not very high because only a minority of growers used to spray against the pest targeted by the GM crop due to low efficacy [18].

In spite of the potential contribution of Bt crops to the sustainability of IPM through the selective control of key pests and the important savings of insecticide sprays, the deployment of GM crops has been very controversial in some areas like the European Union. Major risks concern potential development of resistance to Bt toxins in targeted pests and negative effects that Bt crops could have on nontarget organisms (NTO). The development of resistance to Bt toxins in targeted pests would cause a significant loss of an important tool for selective control of certain pests in the framework of IPM programs and organic agriculture and could drastically reduce the lifetime of Bt crops. Most countries that grow Bt crops have specific programs to monitor targeted pest populations for the evolution of resistance and have implemented strategies to prevent resistance development. Until now, no Bt-resistance has been reported even in areas with almost 15 years of cultivation of Bt crops. More public attention has been paid to potential negative effects of GM crops on nontarget organisms. Most of the work conducted in this area has been devoted to Bt maize and practically no negative effects on biological control functions have been reported [19]. Consequently, Bt crops may prevent a substantial part of current insecticide usage and they can be integrated with biological control into more sustainable IPM programs.

Introduction of Traits into Insects

The introduction of deleterious or beneficial traits into insects has been achieved in several cases for varied purposes. Lethal gene inoculation into wild pest populations for genetic control may overcome some of the problems of conventional sterile insect techniques in which insects may be harmed when they are sterilized with irradiation or chemosterilization techniques and their competitive ability decreased. However, introduction of desirable traits for enhanced efficacy of biological control agents is a remarkable contribution of biotechnology to IPM. Unfortunately, most programs in that last respect have focused on insecticide-resistant genes that increase the possibility of using chemical insecticides and biological control in a compatible way. Despite this innovative approach,

which may contribute to increasing the effective application of biological control, it also may lead to increased use of chemical insecticides.

Detection and Monitoring of Insecticide Resistance

Insects, like any other organism, may become resistant to insecticide active ingredients if they are submitted to frequent pressure of that ingredient. More than 600 insect species are nowadays resistant to one or more insecticides (http://www.pesticideresistance.org/search/1/). As fewer insecticide active ingredients are available in world agriculture, more is needed to increase the lifetime of registered substances and to implement strategies for resistance development prevention.

Several tactics to prevent resistance development in the pest population may be implemented and may succeed at least to delay the wide spread of resistance genes in the targeted population. Commonly, insecticide resistance in a pest is first detected when typical doses fail to control it and usually it is too late. Even at low frequency, earlier detection of the presence of resistance genes in the targeted population before they become common is crucial for the successful implementation of any antiresistance strategy application. As resistance is caused by a varied set of mechanisms, there are also several methods to detect resistance genes. Biochemical, immunological, and molecular methods are available now for the most common insecticides that allow screening a large amount of individuals for resistance gene presence. Improved comprehension of resistance mechanisms should lead to developing more specific, faster, and cheaper methods in order to monitor more populations at reasonable prices.

Identification of Arthropods

IPM needs the correct identification of insect species (or even biotype) in multiple situations: to apply a specific and selective method to control a certain species, to release a biological control agent that needs particular characteristics only available at biotype level, to detect quarantine pests in border inspections, and to study predator diet in trophic ecological studies. Morphological features that classically have been used for insect identification are frequently unknown or they are difficult to observe for nonspecialists. Biotechnological tools also may be valuable for various ecological studies that need markers for distinguishing target individuals from nontarget ones. Some of the current applications of biotechnology for identifying insects and their functions include: markers for dispersal measurements or to estimate insect densities by capture, release, and recapture of marked individuals, silencing genes for investigation of the function of certain proteins, invasion and spreading processes, and phylogenetic relationships between taxonomical groups.

Novel Bioinsecticides and Tension Actives

As described in microbial control, entomopathogenic microorganisms are used to control pests although some factors linked with their costly production and narrow host range are limiting applicability. Entomopathogens may be genetically engineered to incorporate genes expressing foreign proteins with new insecticidal capacities, including larger host range, or proteins that negatively interfere with insect metabolism and physiology like insect hormones or juvenile hormone esterase that are involved in insect metamorphosis. A major concern about the bioengineered entomopathogens deals with the fate and permanence of foreign genes in the environment. Another promising line of biotechnological research in relation to IPM includes biosurfactants. A considerable amount of pest control agents is applied as sprays that need surfactants for correct application and spreading on target surfaces. Classical chemical surfactants are increasingly rejected by consumers and legislation due to their environmental impact and this stimulates the research on alternative biosurfactants. These are a group of heterogeneous secondary metabolites produced by a variety of microorganisms during their growth with significantly improved characteristics in comparison with homologous chemicals: those are biodegradable, have a lower per se toxicity, have more environment-friendly characteristics, require cheaper fermentative processes to produce them, are efficient at more variable conditions and at lower quantities, and have the potential of tailoring to suit specific applications. In addition to their activity as surface tension

reducers and other chemical functions, biosurfactants have shown considerable biological antifungal and antiviral activity although in many cases their mode of action is poorly understood.

Implementation of IPM: Incentives and Constraints

More than 20 years ago, Wearing [20] wrote an article reporting results of a survey conducted among researchers and extensionists of three regions of world agriculture (Australia–New Zealand, Europe, and USA) on the IPM implementation process [20]. Still in 2010, many of the conclusions remain valid and following is a summary of those aspects of IPM implementation that enhance or constrain the adoption of IPM systems in western agriculture. There is general agreement among scientists about the accelerated progress of research on pest knowledge and control as well as the slow adoption of the new methods in practice. Knowing the key elements in the technology transfer and implementation of IPM may accelerate its application.

Among incentives to adopt IPM systems in Wearing's work, most surveys first perceived the cost advantage, followed by the development of pesticide resistance in local pest populations, the hazard to the grower from using pesticides, and environmental issues. The surveys also examined the major constraints for IPM implementation. The importance of obstacles for faster and wider application of IPM varied from one region to another. Whereas in USA over the 50% of respondents ranked social/market obstacles first, in Australia–New Zealand organizational obstacles were the first ranked, and technical obstacles were signaled in Europe as the least important to implement IPM.

In Europe much has been done in labeling agricultural products issued from IPM technology, particularly from regional administrations: IPM labels and integrated production (IP) labels have proliferated in the second half of the twentieth century in northern and southern Europe as well. The International Organization for Biological and Integrated Control (IOBC/WPRS) soon established the bases of IP and later developed guidelines in specific crop groups (see the organization Web site www.iobc-wprs.org). Food retailers and marketing food chains more recently have developed auditing procedures, in part inspirited in IPM principles which have pressed growers to progress more rapidly to more integrated production techniques. The impact of labeling and certification initiatives on IPM adoption has been quite variable in each country and commodity but the initiatives probably have contributed to publicize IP and IPM techniques among consumers.

A common question among policy makers is how to measure IPM adoption. Most likely, data on acquisition and use of tools for implementing IPM in the field (for instance, monitoring devices, meteorological receptors, users of warning systems and significant Web sites, and varied software for decision making among others) in combination with data related to pesticide usage (amount and economic value of pesticides sold, commodity rejection because of high residue levels, inspection of pesticide residues in food trading, and significant habitat and ecosystem elements) may give an approximate idea of the progress made by the implementation of IPM. The number and size of companies (including small local firms) devoted to selling IPM products (e.g., natural enemies for biological control) may be another realistic way to monitor IPM adoption in world agriculture. Data on all these indicators are very disperse but perhaps they allow moderate optimism for faster IPM adoption in developed and emerging countries. Additionally, more strict legislation on pesticide use and the "disappearance" of most insecticides in the coming years may accelerate this process.

Future Directions

Most elements of IPM are among the factors that contribute greatly to the sustainability of agriculture. Beyond IPM, integrated control of insect pests, diseases, and weeds should progress toward the integration of all elements of agroecosystems to produce a balanced and harmonized growth of plants through true integrated production techniques. Exploitation of local natural resources and energy saving are common benefits of implementing novel integrated management systems. Additionally, most insecticides are being prohibited by western legislations. This should be the main focus of IPM progress to accelerate the transition of classical pest control based on chemicals to more integrated approaches.

Review of the vast literature on IPM confirms that success has come from a fundamental understanding of the processes acting in agroecosystems, rarely from a revolutionarily new control tactic. However, faster adoption of IPM strategies and tactics should also come from a more intense linkage among research, development, education, extension, and production. It is well documented that much of the scientific progress issued from R&D is not applied in practice or it takes too long to do it. Analysis of surveys conducted to identify the major incentives for the adoption of IPM systems by growers shows that an innovation is not adopted unless it contributes to producers' economic goals and meets the requisites for acceptance by the whole society.

Irrigation Management for Efficient Crop Production

Elías Fereres, Margarita García-Vila
Institute for Sustainable Agriculture, IAS-CSIC and University of Cordoba, Cordoba, Spain

Article Outline

Glossary

Application efficiency Relationship between the target irrigation depth (depth of water stored in the root zone to be used by the crop) and the depth of water applied to meet this target during a single irrigation event.

Conservation agriculture (CA) An agricultural production system aimed at achieving a sustainable and profitable agriculture through the application of three principles: minimal soil disturbance, permanent organic soil cover, and diversification of crop species in rotations or associations.

Decision support systems (DSS) Interactive information systems (not limited to computerized systems) that aid decision makers to identify and solve problems, and make decisions, which may be rapidly changing and are not easily specified in advance.

Deficit irrigation (DI) An irrigation strategy based on applying irrigation depths that are less than the full crop water requirements (ET), either throughout the crop life cycle (continuous or sustained deficit irrigation) or during specific stages that are insensitive to water stress (regulated deficit irrigation).

Distribution uniformity A measure of the spatial evenness with which irrigation water is distributed across a field.

Evapotranspiration (ET) The combination of two separate evaporation processes whereby water is lost to the atmosphere, on the one hand from the soil surface and crop surfaces (canopy interception) and on the other hand, from inside the leaves and other organs through pores called stomata, a process termed "transpiration."

Irrigation return flows The combination of surface and subsurface water flows resulting from the runoff and drainage following the application of irrigation water which may be available for subsequent appropriation from either a stream or an aquifer downstream of the original use.

Leaching requirements The depth of water needed to displace the excess salt accumulation in the soil profile resulting from irrigation, and aimed to maintain the salt balance in the crop root zone.

Soil water balance The state of soil water in the crop root zone resulting from the balance between water inputs from precipitation and irrigation and the water losses to evapotranspiration, runoff, and drainage below the root zone.

Water use efficiency (WUE) The ratio between the water volume used for a specific purpose and the water volume derived from a source to accomplish that purpose.

Definition of the Subject

The anticipated population growth in the coming decades will place large worldwide demands to increase the global production of food, animal/fish protein, livestock feed, fiber, and biofuels. Such an increase must come primarily from enhancing productivity, given the constraints in further land expansion for agriculture. Irrigated agriculture currently produces more than 40% of total production on 17% of the land. It is therefore imperative that irrigated agriculture not only sustains its current rates of productivity but that they be increased in the future. Irrigation

expansion has taken place over the last 60 years, and is currently under pressure from other sectors to reduce its share of the freshwater resources. Efficient crop production under irrigation in the future would be essential to produce more food with less water than is used today. This goal is a challenge that will not be easy to achieve without new and innovative approaches in irrigation management and in crop productivity. These innovations would also have to address the problems created by the return flows from irrigation which will threaten its sustainability, unless solutions are found to resolve permanently the environmental impacts of irrigation.

Introduction: Background on the Sustainability of Irrigation

The practice of irrigation started soon after agriculture was discovered thousands of years ago. Near the main rivers in the arid zones, water was diverted to the fields where crops were grown in areas and times of lack of rainfall, in an attempt to obtain a stable food supply. The Sumerian civilization that inhabited the Mesopotamia plains is believed to be among the first that used irrigation for crop production. Other locations where major irrigation developments took place early in the history of modern agriculture include the Yellow River basin of China, the Indus River Valley in Pakistan, and the Nile River Valley of Egypt. Many civilizations developed successfully in the past centuries, their food security heavily dependent on irrigation. History is filled with cases, however, where irrigated agriculture failed after some time, leading to the decline and even the disappearance of civilizations (e.g., Mesopotamian civilizations). The causes for failure included technical as well as economical, social, and political factors, but all combined suggest that irrigated agriculture may not be sustainable indefinitely. On the contrary, cases where irrigation has been practiced successfully for millennia, such as the Nile River basin in Africa and many areas of Southeast Asia, prove that it is possible to sustain irrigated agriculture in the long run [1].

Nowadays, irrigation is by far the largest consumer of developed freshwater on a global basis. It is estimated that irrigated agriculture currently uses about two thirds of water diversions, while industry and urban diversions amount to around 20 and less than 10%, respectively [2]. Such a high level of consumption in agriculture is due to the fact that crop plants require a continuous supply of water to replace the water transpired from their leaves and other aerial organs. The water demand arises because the crop is exposed to strong evaporative demand (due to the fluxes of solar and thermal radiation and warm, dry air). For carbon dioxide to enter the leaves, the microscopic leaf pores (stomata) must be open. But when the pores are open, water vapor freely escapes from the interior of the leaves which are nearly saturated with water. Because of the differences in concentration of carbon dioxide and water vapor between the interior of the leaf and the air, 50–100 molecules of water are lost for every molecule of carbon dioxide taken up. Crop water consumptive use is thus an unavoidable consequence of wet crop surfaces being exposed to dry air. Nevertheless, despite the large amounts of water that are transported through the plants, if they are not capable of taking up soil water to replace the losses, water deficits develop which can be detrimental to yield [3]. Therefore, if irrigated agriculture is to be sustainable, it needs sufficient water to meet its requirements at present and in the future.

Presently, more than 260 million ha of irrigated lands exist, representing 17% of the cultivated area but more than 40% of food production worldwide [2]. Future increases in population combined with changes in dietary habits toward the consumption of more animal protein will require sustained increases in crop production in the next decades well above present levels. Additionally, there may be demands on agricultural products for uses other than food production, such as energy from biomass. The increase in production cannot come from a significant expansion of the area devoted to agriculture for at least two reasons. On one hand, the area best suited for agricultural use is already under production, and only in a number of regions in the American and African continents there is additional land that has not been put under cultivation. Furthermore, that expansion would alter further the balance between agricultural and natural ecosystems, which much of the world population would oppose, arguing for the environmental preservation of the remaining areas that are not in cultivation.

If land expansion will not be possible, the goal would then be to increase productivity, the production

per unit of cultivated land. Crop productivity of the main cereals has been increasing steadily since the 1960s, albeit at rates that are apparently declining in recent years [4]. Given that the average productivity of irrigated lands is more than twice that of rainfed areas, it appears that preserving irrigated agriculture would be essential for future food security. The issue is whether it would be possible to expand irrigated agriculture beyond its present level by transforming rainfed into irrigated areas. While some expansion may be possible in the foreseeable future, it is difficult to see how a major world expansion of irrigation would occur, given the present commitments of freshwater (supplies already overcommitted in many arid and semiarid areas), the perceived strong opposition from urban societies, and the uncertainties that climate change brings to future water supplies. It is therefore essential that the productivity of irrigated lands be increased to cope with future demands, and this will have to be done at efficiency levels higher than those achieved at present. The reduction in water used in irrigation per unit production emerges then as a critical issue in the area of crop production in the future.

Irrigated agriculture has to manage large amounts of water that must be utilized with a high level of efficiency. This is not the only requisite of good management, however. All irrigation waters contain salts, and crops transpire pure water; thus, the irrigation process concentrates the salts in the soil profile at a rate which mostly depends on the salt content of the irrigation water. In this respect, the salinity that develops under irrigation would make cropping unsustainable unless the salts are evacuated to prevent the salinization of the crop root zone. In many areas, natural rainfall is sufficient to leach out the salts from the potential root zone. However, when waters of high salinity are used for irrigation in arid areas of limited rainfall, salt leaching must be performed by applying irrigation in excess of the crop needs. The control of salinity is one important requisite of a sustainable irrigated agriculture. However, the water applied in excess of the consumptive use must be disposed of, and this creates a whole host of potential environmental problems associated with water pollution [5]. Many of the problems caused by the return flows from irrigation occur outside the farms, at the level of the irrigation district or at the basin level, and are discussed below.

The Process of Irrigation at Different Scales: From the Field to the Basin

When a field is irrigated, the water applied may be lost via surface runoff or by deep percolation, or may be stored in the crop root zone for subsequent uptake by the crop and lost as ET. However, the focus of irrigation management for efficient crop production extends well beyond a field, up to the farm, the irrigation district, and the watershed. The water balance is the unifying concept that connects the water disposition in the different scales. In any field, farm, or watershed, it is possible to quantify a water balance in which the incoming water in the form of rain or irrigation must be balanced by the water lost as evapotranspiration (ET), runoff, deep percolation, and that stored in the soil profile.

When scaling up from an irrigated field, one needs to consider the situation upstream and downstream of that field. Irrigation water originates from storage reservoirs, flowing streams, or from the groundwater. In all cases it must be conveyed and distributed among the different areas, their farms, and individual fields. The process of distribution entails a number of losses due to direct evaporation from reservoirs and open conduits, leakages from canals, and management losses in the handling of distribution networks that deliver the water to individual farms [6]. Farmers on collective networks do not always have access to water when they need it, and that may cause imbalances between the supply of irrigation water and the crop demand. Those that pump directly from the groundwater have greater flexibility at the expense of additional energy usage. At any rate, by the time the water is delivered to a particular field, there have been distribution and management losses upstream that are often substantial. The classical work of Bos and Nugteren [7] quantified the efficiency of irrigation along the path from the source of water to the field and found very low values, of the order of 40–50%. Hsiao et al. [8] have also analyzed the efficiency losses in the network, from the dam to the crop, and have highlighted the dramatic differences between good and bad situations, given the multiplicative effects of the chain of efficiencies from the source of water until it is transpired to the atmosphere [8].

At the field scale, water may be used beneficially for ET and for salinity control or may not have a beneficial

use when it is lost through runoff or drainage. However, at higher scales, water that evaporates from a watershed is considered a loss or consumption, while water running off a field can be recovered downstream and may not be lost to the system. Equally, water that percolates below the root zone may reach the groundwater from which it can be pumped and recovered. Thus, there are consumptive and nonconsumptive uses of irrigation water. Water applied as irrigation may be used consumptively in the ET process, while the network and runoff losses may be recovered downstream and used by others within the basin. Water used in one farm within a basin is not always consumed in that basin and can be used severa1 times before it leaves the basin.

The difference between water use and consumption is important to understand whether water conservation efforts will result in net water savings [9]. If *all* the water lost outside the ET can be recovered, then efficiency improvements via reducing runoff or percolation losses would not lead to net water savings. On the contrary, if the losses are partially or not recoverable at all, because either the water quality is deteriorated or the losses end in a saline sink, then the water saved at the field scale also represents (partial) savings at the basin scale. Thus, knowing the fate of water all along its path, it is critical to determine whether the water saved on the farm may be part of the recoverable or of the unrecoverable losses.

The basin perspective of water conservation could change the emphasis on where to act when irrigation improvements are sought, and whether such improvements are really needed. Nevertheless, the picture would not be complete if two other issues are not included in the overall assessment of basin irrigation management. One is the fact that field and farm losses, while they could be recovered downstream, often have negative environmental consequences. Surface runoff may carry sediments and chemicals that act as pollutants in streams, lakes, and dams. Drainage waters pick up salts, fertilizers, and other chemicals in the soil profile and may contaminate the groundwater. The other issue is the energy requirements for recovering the losses. Whether is surface runoff recovered at the end of a field or groundwater pumped from the aquifers, additional energy is always needed to recover the losses. Needless to say, the water quality of these return flows would always be worse than that of the original irrigation water.

Irrigation Management Goals for the Improvement of Sustainability

An agriculture that aims toward sustainability should be economically viable, efficient in the use of the natural resource base, socially equitable, and must have a minimal environmental impact. These requisites are essential when defining the goals of irrigation management for efficient crop production. Economic viability in irrigated agriculture is usually associated with *high production levels,* because the investments needed for irrigation development would not be justified under low levels of production. Thus, irrigation must be managed in such a way as to avoid water deficits that reduce economic yield. Not only high production should be sought but also, *high productivity* in relation to the use of production inputs, including water, should be an important goal. Contrary to the common belief, de Wit [10] demonstrated that production inputs are used at their highest efficiency when yields approach the maximum potential. Therefore, it is possible to combine both goals with judicious management.

Equity is an important goal in irrigated agriculture because, first of all, irrigation development represents a quantum leap in terms of increased income relative to rainfed agriculture. Also, sometimes water supplies are managed rigidly by water authorities or are insufficient relative to the potential demand; thus, *equitable distribution* of the available water supply is definitely an important goal of sustainable irrigation management. How this goal is pursued would depend on a number of socioeconomic, political, and cultural factors discussed below. Finally, irrigation can have a number of detrimental effects on the environment that must be minimized. Firstly, without *control of salinity* agriculture cannot be sustainable [11]. However, the leaching of salts and other chemicals from the soil profile end up as part of the return flows and contribute to the nonpoint pollution generated by irrigated agriculture. To minimize these negative effects on the environment, irrigation must be managed in such a way as to *avoid runoff* and *minimize deep percolation.* To achieve this goal, the engineering of irrigation systems (to distribute water uniformly) and the scheduling of irrigations (correct timing and application amounts) are the main instruments to be optimized when walking the fine line

of achieving high production and productivity while reducing the environmental impact of irrigation.

Management Options: Strategic, Tactical, and Operational

In this entry, we are assuming that farmers have already made a choice among the different irrigation methods, basing their decision on their access to capital, the availability of water and its distribution mode, their management skills, and the labor and energy costs. There are frequent interactions between engineering and management in irrigation that are frequently ignored but are covered here, even though the focus is on management.

The temporal scale determines the nature of irrigation management decisions. Operational decisions are those that must be made in the short term, within days; for instance, the advancing or delaying of one irrigation application. Tactical decisions are those that are taken within the irrigation season once it has started, and have a time scale of days to weeks. One example would be the adjustment of the number of irrigation applications within the season, if the water supply has been reduced after planting. Strategic decisions have a time scale of months to years, and are normally taken before the season starts. The preseason decisions pertaining to the allocation of water to the different fields and crops are examples of strategic decisions.

Crop and Cultivar Selection

Farmers' choice of crops in commercial agriculture is a complex decision that is, above all, based on factors related to production economics and marketing, while other socioeconomic and biophysical factors are considered afterward. The water-related factors such as crop water usage are most important when the supply available is less than the anticipated demand. Crop consumptive use depends primarily on the evaporative demand, the length of season, and the fraction of incoming radiation intercepted by the crop canopy. There are ample differences among the crop ET of different species. These differences are also modulated by the type of climate in which crops are grown. In that respect, there are major differences between tropical and temperate climates. In tropical climates, reference ET (the ET from a standard grass surface: ETo) is relatively constant throughout the year and irrigation is used during the dry season; here, the critical issue is the duration of the growing season, with the goal of producing multiple crops in 1 year. Production per day is the best indicator of efficiency in tropical climates, where crops must follow a sequence that uses best the land and water available.

In temperate climates, evaporative demand during winter is a small fraction than that in the summer. For instance, in Mediterranean-type climates, ETo oscillates between 1–2 mm/day in winter and 6–8 mm/day in summer. Thus, winter crops require much less water than summer crops per unit time. Additionally, seasonal rainfall occurs primarily from fall to spring in those climates, thus reducing the irrigation needs of winter and spring crops. One environmental factor that indirectly affects the crop water requirements in temperate climates is air temperature. Temperatures in winter are low in such climates and that slows down the rate of crop growth and development, thus lengthening crop duration. For instance, the season of winter cereals may last 6–7 months while maize, a summer crop, may be grown in 4 months. These differences in season length balance out some of differences in ETo between winter and summer, but still winter crops generally use less water than summer crops. As an example in some interior valleys of Mediterranean climate, wheat ET is between 350 and 400 mm while maize ET ranges between 600 and 650 mm. Perennial crops have higher ET rates, alfalfa ranging between 800 and 1,200 mm, and deciduous trees between 700 and 1,000 mm. Evergreen tree crops should have the highest ET, however, both citrus and olive have strong stomatal control of transpiration and their seasonal ET does not exceed values that range between 700 and 1,000 mm, depending on the specific climate.

Crop choice is therefore the most important factor in determining irrigation water requirements. Cultivar differences in water use are considerably smaller than the differences among crops, and are directly related to season length. Early cultivars of maize in temperate climates may use 10–20% less water than late-maturing cultivars. Similar differences have been observed in other crops. Even though such differences are relatively small, they can be important when the crop sequence is such that only short-season cultivars fit in the rotation or when the water supply available is limited. Genetic

improvement of the intrinsic transpiration efficiency (TE, g CO_2/g H_2O) [12] has not been successful until now. The limited variability encountered within crop species has not led to cultivars that have higher productivity in irrigated agriculture, although some yield advantage (of the order of 10% at around 1 t/ha yield levels) has been achieved when selecting wheat cultivars for high TE in rainfed environments [13]. The use of genetic engineering in the future [14] may offer new opportunities for enhancing other basic responses that can indirectly improve crop WUE (e.g., maintenance of harvest index under water stress).

Planting dates also have some effects on crop ET in temperate climates. Early plantings of spring or summer crops have lower ET by avoiding the times of peak ETo. One example is that of winter plantings of sunflower in Mediterrranean climates. By planting early, the growing season is displaced away from the summer and the seasonal ET is less, even though the season may be longer due to the slow growth and development in the early crop stages. The irrigation requirements may even be lower because of the higher rainfall probabilities in early spring. In general, plantings of summer crops have been moved as early as feasible to reduce irrigation requirements; this is the case of maize in many areas where the optimal planting dates have moved more than 40 days over the last 30 years. To displace the growing season any further the temperature limitation to growth and development must be overcome. Progress has already been made in crop improvement; for example, maize has expanded significantly into colder areas in the last decades, but more breeding efforts are needed to achieve higher growth rates under low temperatures in the principal irrigated crops.

Contrary to the measurable effects of varying planting dates on crop ET, the variation in planting density within commercial practices has little influence on the ET of annual crops. This is because the differences in radiation interception among different planting densities are small and restricted to the short period of early canopy development. It is important, however, in the case of perennials, as tree or vine densities have a strong influence in the intercepted radiation for several years after the initial planting, and may be carried over the entire life of the orchard or vineyard. Biomass production and thus yield of most crops is directly related to the seasonal intercepted radiation. Any agronomic practice that favors quick canopy development and complete radiation interception should increase production and will have a smaller effect on crop ET, thus increasing the efficiency of water use.

Optimal Use of Rainfall and of Stored Soil Water

The goal of irrigated crop production is to use all sources of water supply as effectively as possible. Soil water storage from rainfall or from preplanting irrigation is an effective way of using the water resource. To maximize stored soil water, infiltration should be enhanced so that surface runoff is minimized. Low infiltration rates decrease the effectiveness of rainfall to the point that only a small fraction of it may be stored in the potential crop root zone for subsequent use by the crop. Many irrigated soils have problems of slow infiltration, either inherent to their physical makeup or caused by the application of irrigation water for a long time that alters negatively the surface infiltration properties of the soil [15].

Excessive tillage of some irrigated soils and, more importantly, the traffic required in crop intensification under irrigation has exacerbated the problems related to low infiltration, which not only reduces the effectiveness of rainfall but also affects the distribution of irrigation water. The use of minimum tillage, no-tillage, surface residues, permanent beds, and of controlled traffic is all being incorporated into what is now known as conservation agriculture [16]. These soil management systems have been used successfully in many world areas for sometime now, primarily under rainfed agriculture, but they are now increasingly being adopted for irrigated agriculture as well. The benefits of conservation agriculture (CA) include soil surface protection by the crop residues, the maintenance of soil organic matter, increased infiltration, and better distribution uniformity. The limitation of CA is that it needs to be tailored to the specific situation thus requiring field experimentation before it is introduced in a new area or system. The widespread expansion of CA in the main agricultural areas of the world [17] suggests that it will be adapted to many irrigated systems in the near future.

The critical role of rainfall, while being obvious in rainfed agriculture, is nearly as important in irrigated

agriculture because it leads to a reduction in irrigation demand. The best strategy for optimal use of stored soil water is the conjunctive use of both, the applied irrigation water and the soil reserve. It is desirable that the soil is partially depleted to allow the storage of anticipated rainfall in the root zone, although such depletion has to be managed to avoid yield-reducing water deficits (See below). As the crop approaches maturity, it is recommended to rely more on the stored reserve and use as much of it as possible, thus reducing irrigation water use. Ideally, the soil reserve should be almost totally depleted when the crop is harvested, assuming it will be replenished by rainfall. Obviously, to manage the soil reserve, it must be quantified from planting to harvest. Growers need to know the level of soil water at planting and the rate of water use (ET) relative to the depths of irrigation and rainfall. Therefore, making best use of the rainfall and of the water reserve requires carrying out a seasonal water budget for each crop. It is also important to evaluate the risk of basing a limited irrigation strategy on using a large fraction of the stored rainfall, because in the event of a drought, irrigation would be insufficient to meet the crop demand and this strategy may not be sustainable.

Technical Irrigation Scheduling

Decisions on when to irrigate and how much water to apply – the irrigation scheduling process – are commonly made by irrigators around the world solely based on experience. There are, however, a collection of technical procedures and tools developed to forecast the timing and amount of irrigation applications. Some sort of irrigation on demand is a prerequisite for the application of these technical procedures, because when the delivery method of the network is on rotation, the farmers have no flexibility to vary the irrigation interval and they tend to use all the water they receive as insurance for uncertain conditions.

Among water-sensing devices, soil water sensors were perhaps the first instruments that were introduced for irrigation scheduling in the 1950s, and it is remarkable that they have enjoyed a certain degree of success until recently. There is now a new generation of soil water sensors that track soil water status continuously, rather than providing point measurements as the traditional instruments such as the tensiometer offer. Unfortunately, the new developments have not resolved the quantification of volumetric soil water content with depth, a parameter that is still most reliably measured with the neutron probe since the early 1970s. The regulatory constraints on this nuclear instrument have limited its use even for research in many countries, with the result that reliable data on soil water balance and crop ET are difficult to obtain with soil water measurement methods. The information from current sensors is treated as trends and these tendencies, often observed at more than one depth, are the basis for making decisions, rather than using a threshold value of soil water at a given depth as the indicator of irrigation timing. Protocols have been developed to automate irrigation scheduling on the basis of soil water status [18].

The use of plant water sensors for irrigation management lagged behind that of soil water sensors by about 2 decades. The pressure chamber was the first portable instrument that was rugged enough to be used under field conditions, although it is manually operated and its readings cannot be automated. It is now used commercially in some areas for irrigation scheduling of tree crops and vines. Other plant sensors have not been as successful for their use in practical scheduling, although they have been around for sometime. The most notable example is that of dendrometers, sensors that detect the variations in stem diameter, which were used since the 1950s and have today the same degree of precision they have had since the 1970s, but they became popular for research 20 years later. Protocols to be used with trunk diameter sensors have also been proposed [19] although its use, while attractive, has been mostly limited for research purposes. One of the most promising plant-based indicators is the canopy temperature as measured by infrared thermometry. Jackson and coworkers (summarized in [20]) developed several indicators based on canopy temperature, the Crop Water Stress Index (CWSI) being the most popular. Threshold values of CWSI have been found for several crops and its use as a water stress indicator is gaining acceptance. Plant-based parameters are best used as pre-visual indicators of water stress, rather than being indicative of irrigation timing and amount. Their strength resides in providing a specific, crop-based calibration for other methods

that use either soil water sensors or the water balance procedure. One important limitation of all soil- and plant-based sensors is the variability in the measurements, as discussed in Coping with Spatial Variability: Precision Irrigation.

The most robust technique for wide use in irrigation scheduling is the one using the soil water budget. Here, irrigation timing is computed by adding the crop ET losses minus effective rainfall until a soil water level termed "the allowable depletion" is reached. The basic information in this method is that of crop ET, computed as the product of a crop coefficient times ETo. After a method for computing ETo has been standarized and widely accepted [21], agrometeorological weather stations provide the information needed for calculating ETo from meteorological variables. In some developed countries, networks of weather stations now provide the ETo information routinely. The pan evaporation is a viable alternative for estimating ETo to the more sophisticated automated weather stations. Computer programs have been developed for calculating the water balance of fields, and irrigation scheduling services have been developed, mostly by public agencies and by consultants as well. These services have been around for several decades now but most farmers have been reluctant to pay for them. Nevertheless, irrigation advisory services are becoming more popular in areas of scarce or expensive water. One pattern that has been observed is that farmers subscribe to these technical procedures or services for a few years and then, they no longer use them. Perhaps they perceive that they have acquired sufficient knowledge during that time period, a reason that may also explain why the use of sensors is discontinued after some time by many growers.

Interactions Between Irrigation Methods and Their Management

Irrigation has been practiced for thousands of years by flooding the soil surface and keeping the water standing until it infiltrates. This method is named surface irrigation and it is still the most popular method worldwide. In surface irrigation, the soil intake rate determines the depth of water that infiltrates and if its properties are spatially variable, the farmer will not have good control of the amount of water applied. Pressurized irrigation methods (sprinkler and microirrigation) were invented much more recently, about 70 years ago. Since then, they have enjoyed increasing popularity in areas where farmers have access to sufficient capital to shift from surface to pressurized systems. In other, newly developed areas where topography and/or water infiltration properties made the use of surface methods impractical, pressurized methods have been preferred over surface irrigation. One advantage of pressurized systems is that the depth of applied water does not depend on soil properties but is determined directly by the run time. Farmers' preferences for pressurized systems are based on the need for better control and the greater skills needed for effective surface irrigation management. The higher capital and energy requirements are two limitations of pressurized systems relative to surface irrigation.

The key feature of irrigation systems in relation to their management is the degree of uniformity of water distribution. Regardless of the method, high distribution uniformity prevents excessive percolation losses in some areas of the field and the development of water deficits in others. To emphasize the importance of high distribution uniformity suffices here to summarize an example in which the performance of two systems with low (70%) and high (90%) distribution uniformity (DU) were compared for maize irrigation [22]. The additional depth of water needed under low uniformity to achieve maximum yields amounted to 400 mm, or 70% of the net irrigation requirements. The requisites for high DU include an appropriate design, good maintenance, and correct operations. Nowadays, efficient irrigation cannot be practiced unless high to very high DU values are achieved.

All irrigation methods have potentially high performance that can eliminate or minimize runoff and percolation losses, but they seldom achieve their potential due primarily to lack of maintenance or to mismanagement. To optimize the operation of existing surface irrigation systems the water delivery procedures often need to be changed. There are needs relating to adjusting the flow rates delivered to fields, altering the operation of delivery networks, and sometimes land consolidation is also needed. Such changes not only require capital investments but agreements among

various users as well. The introduction of pressurized systems (sprinkler and drip) in collective irrigation networks also requires changes in the physical infrastructure (e.g., reservoirs). Thus, there must be economic incentives for the farmers and access to capital to introduce the improvements needed to increase the potentia1 application efficiency and distribution uniformity at the system level.

Control of Salinity and of Return Flows

Irrigated agriculture cannot be sustainable unless salinity is properly managed. Salts that accumulate in the root zone must be leached but the amount of leaching must be kept to the minimum if the environmental impacts of drainage waters and the return flows are to be controlled. Determining the leaching fraction (proportion of the ET that must be added for salt leaching) should be based not only on the quality of irrigation and drainage waters but on the need to avoid excessive percolation. Here again, high DU is essential when the target leaching fraction is of the order of 5–10%, which is only achievable under very high DU values.

The use of salt-tolerant crops is often proposed as a means of controlling salinity. It is true that there is an ample range of salinity tolerance among crop plants and that it is possible to exploit waters of low quality for irrigation of salt-tolerant crops. However, because the process of salt concentration in the profile in the absence of leaching is inexorable, the use of salt-tolerant crops should be considered as a temporary measure until excess salts can be leached out of the potential root zone. Sometimes, tolerant crops have been used for some years in the event of a drought that limits the irrigation supply available for leaching. Their long-term use in dry areas should not be considered sustainable, given the progressive salinization of irrigated soils. After some environmental problems related to toxicity caused by the selenium content of the return flows, the drainage from a large area in California, San Joaquin Valley, was interrupted in 1989 [23]. The rainfall in the area is negligible, thus salt leaching depends on artificial drainage. As of 2010, the area is still under irrigation; irrigation systems installed have high DU values and there is an extensive monitoring program of soil salinity. Perhaps long-term control of salinity would be feasible with systems that have very high DU, and where irrigations are scheduled with precision, keeping most of the salts near the bottom of the root zone, as it was first proposed by Hoffman et al. [24].

At scales beyond that of a field or farm, the concerns shift toward the quality of return flows, its reuse, and the environmental impacts of irrigation. The decline in water quality after the water has gone through the irrigation process has an associated cost that needs to be quantified. The concept that water lost to a farm is recovered downstream needs to have associated an economic analysis of the energy costs and the quality deterioration costs of recovering the return flows. If minimum leaching is practiced at the field scale, the amount of return flows is also reduced but that increases the concentration of salts and other contaminants in the drainage waters. Eventually, it may be possible to reduce the quantity of return flows so much so that they can be disposed of in evaporation ponds that become salt sinks. It would then be possible to either accumulate or export the salts and make the agriculture of that region fully sustainable.

Coping with Spatial Variability: Precision Irrigation

The major challenge that technical farm irrigation management has faced and continues to face is how to cope with variability. Under field conditions, both spatial and temporal variabilities are the norm rather than the exception. The strong spatial heterogeneity of soil water properties even in what are considered uniform soils, combined with the variations in the distribution of irrigation water applications, and the uncertainties of rooting depth and densities, all contribute to create a heterogeneous environment that farmers have to manage as accurately as feasible. The problem has increased in magnitude over the last decades due to the increase in size of the management units, in an attempt to reduce production costs by managing uniformly larger and larger field units. The complexities involved in dealing with the variability problem are such that, until very recently, the common solution chosen by irrigators was to apply water in excess so that the risk of inducing water deficits in some parts of the field is minimized. Because of the difficulties that farmers and technicians have had in characterizing the variability,

significant uncertainty is introduced and often the irrigation management decisions may be in error.

To advance solutions for coping with the variability problem in irrigation management what is needed is to be able to characterize the variation across a field, and also to have the option of applying variable amounts of water within that field. The objective would then be to apply variable water depths under non-uniform crop growing conditions to match the requirements of every area of the field, while minimizing the environmental consequences that uniform irrigation over a variable field would have. The technologies for variable water application are already available in self-propelled sprinkler systems and can lead to significant water conservation [25]. Significant efforts in the engineering of irrigation systems have been undertaken recently to offer the flexibility of applying spatially variable amounts of water (and agrochemicals) for the different pressurized methods, including microirrigation [26]. These new capabilities should enable growers to increase productivity and minimize environmental impacts of irrigation.

While the engineering solutions for precision irrigation are underway, there is still the need, not only to characterize and monitor the variability but to interpret the causes of the variations in crop growth and development. The characterization of irrigation performance through remote sensing [27] is a promising area, as it enables performance evaluation in a fast and an inexpensive way, and can also identify the areas in need of improvement. Interpreting the underlying causes of variations among and within fields is much more difficult, however. The use of remote sensing techniques has progressed substantially in recent years by developing capabilities for detecting a number of vegetation properties with very high resolution (e.g., [28]). High-resolution imagery cannot be acquired from current satellites, and a number of initiatives to obtain them from aerial vehicles flying closer to the ground have been launched recently. As an example that is relevant for irrigation management, Berni et al. [29] applied models based on canopy temperature estimated from high-resolution airborne imagery, obtained with an unmanned aerial vehicle, to calculate tree canopy conductance and the CWSI of heterogeneous canopies, such as those of tree crops.

Use of Simulation Models and of Decision Support Systems

Decision-making in crop production has been the focus of numerous studies, mainly on the description of the decision-making process and decision outcomes [30]. The numerous decisions dealing with irrigation management include, not only the scheduling and application of the available water to different crops over the irrigation season, but also strategic decisions related to crop choices and seasonal water allocation. Irrigation is a complex operation, based on technical and agronomic knowledge, and on sociological factors which may include a negotiating process among irrigators [31]. Recent advances in information and telecommunication technologies allow farmers to acquire vast amounts of site-specific data for their farms, with the ultimate goal of *reducing uncertainty* in decision-making. However, farmers face many difficulties in efficiently managing, analyzing, and interpreting the vast amount of data collected, while considering both the costs and value of the information [30].

The tactical decisions related to irrigation scheduling have been discussed above; however, strategic decisions that must take into account the complex nature of agricultural systems and changes in environmental conditions are difficult to make without tools that assist the farmer in the decision-making process. Among the tools available in the area of water management are the Decision Support Systems (DSS), which were first used in the early 1970s as a radical alternative to large-scale management information systems [32]. There are different types of DSS; many of them are expert systems [33], which have the problem of handling multiple experts to evolve decisions and uncertainty. Linear programming, dynamic programming, and non-linear programming are the most popular modeling techniques; while recently, genetic algorithms [34] have been used to generate optimal solutions more efficiently [35] than dynamic programming (e.g., [36]). Also, DSS have been shown to help decision-making at different scales: at the field level, considering only one crop (e.g., [37]); and at the farm scale, with multiple crops (e.g., [38]).

Because irrigation decisions include many factors, the DSS combine crop simulation models with econometric models to assist farmers in optimizing irrigation

management, according to environmental, socioeconomic, and political prospects [39]. The yield response to different irrigation levels is one of the inputs of DSS that traditionally has been quantified as empirical crop-water production functions [40–42]. Even though these functions have been used profusely, they are site-specific and difficult to extrapolate without costly, empirical calibration. An alternative to crop-water production functions is the use of dynamic crop simulation models [43]. Among the simulation models usable for irrigation decision-making are CropSyst [44], EPIC [45], CROPWAT [46], APSIM [47], and CERES [48]. However, most of these models require detailed information (difficult to obtain) about parameters that describe plant behavior (APSIM, CERES), or make use of simple empirical functions (CROPWAT). The models must be calibrated, validated, and be sufficiently robust to provide reliable predictions. For this reason, detailed models may be less practical than simpler but robust models [49] such as the recently published FAO water productivity model, AquaCrop [50]. AquaCrop is a model focused on simulating attainable yield in response to the water available, and it is thought to have an optimum balance between accuracy, simplicity, and robustness [50]. In water-limited situations, these models can be helpful in determining the optimal level of irrigation water that leads to maximizing income (e.g., [51]).

To make informed decisions that will enhance the efficiency of irrigation, farmers need to be able to assess how agricultural systems respond to internal (e.g., new technology) and external changes (such as those in the economic and political context, water constraints, or climate change). Therefore, DSS may be used for scenario analyses, showing the effects of alternative scenarios on irrigation management for efficient crop production [39]. The possibility of DSS implementation to assist farmers on irrigation management creates opportunities to establish a relationship that leads to the solution of problems and research feedback, redirecting the paths of research to better solve problems. Until now DSS are not commonly used directly by farmers as they are considered complex tools, which usually lack a user-friendly interface that permits easy access by the users. Irrigation advisory services of the irrigator's communities may be the right platform for the introduction of DSS, being potentially a major breakthrough in improving the use and management of irrigation water.

Management Under Water Scarcity

At present and more so in the future, irrigated agriculture will take place under water scarcity. Insufficient water supply for irrigation will be the norm rather than the exception, and irrigation management will shift from emphasizing production per unit area toward maximizing the production per unit of water consumed, the water productivity (WP).

Water Allocation Constraints and Their Impact on Management

While irrigation is an ancient technique, its expansion is very recent. The world area under irrigation has more than doubled in the last 60 years [4], in response to the increase in food demand. This expansion has required the development of additional water supply through the construction of dams for storing surface waters and exploitation of the groundwater resource. The sustainability of supply depends on the long-term rainfall and on the rate of groundwater recharge. As the irrigated areas expanded, the pressures on the finite water resources in some areas increased and the balance between supply and demand was altered (e.g., [52]). Two issues cause the imbalances; first, periodic drought cycles reduce the availability of water supply, some times during several years. Then, the increases in the demands from other sectors of society, notably the environment that has been neglected in the past, compete with irrigation demands, which are often considered the lowest in priority. The expansion of groundwater use is also a cause of concern; it is possible that the abstraction exceeds the rate of recharge, causing a decline in the water table depth with time. In fact, groundwater may be considered a reservoir of supply that may be overexploited during drought years, when surface supplies are scarce. However, when the aquifers are depleted in the long run and do not recover after years of high rainfall, the groundwater overdraft is unsustainable and the abstraction must be reduced to sustainable levels.

Regardless of the causes for water scarcity, knowing the degree of supply reduction is essential for farmers to make rational decisions regarding how to manage

the limited supplies. Preseason decisions are centered on crop choice and/or to land abandonment. Matching demand to supply is achieved by selecting low-water-use crops or by leaving some land in fallow, if the supplies are insufficient to irrigate all the developed land. Once the season starts it is much more difficult to make adjustments, if the reduction in supply is significant. Changes in the irrigation system to reduce percolation and other operational losses, changes in scheduling to reduce the number of applications thus reducing E losses, and the use of deficit irrigation (see below) are the only options left to growers once the season has started and the crops have been planted.

Water scarcity does not occur overnight, and water authorities and farmers have conservative attitudes to avoid risks. Predictions of big cuts in supply that do not materialize reduce economic opportunities, but the reverse may be even more catastrophic. Thus, planning in advance by water authorities and by irrigation districts, and knowing precisely the expected level of reduction are the two key elements to manage successfully the anticipated scarcity. Seasonal predictions of rainfall would be very useful to anticipate droughts and consequently, irrigation supply reductions. One paradox is the enormous investment in climate change research relative to that devoted to medium range weather predictions, and the apparent lack of connections between two areas that should be closely related.

Deficit Irrigation

Deficit irrigation (DI) is defined as the application of water below the crop ET requirements. Therefore, water demand for irrigation can be decreased relative to full irrigation and the water saved can be diverted for alternative uses. Even though DI is simply a technique aimed at the optimization of economic output when water is limited [53], the reduction of irrigation supply to an area imposes many adjustments in the agricultural system. Thus, DI practices are multifaceted, inducing changes at the technical, socioeconomical, and institutional levels.

In the humid and subhumid zones, irrigation supplements the rainfall as a tactical measure during drought spells to stabilize production. This practice has been called supplemental irrigation [54] and, although it uses limited amounts of water due to the relatively high rainfall levels, the goal is to achieve maximum yields and to eliminate yield fluctuations caused by water deficits. Supplementing rainfall in arid areas with one or more irrigation applications is a form of DI as maximum yields are not sought. When irrigation is applied at rates below the ET under DI, the crop extracts water from the soil reservoir to compensate for the deficit. Two situations may then develop. In one case, if sufficient water is stored in the soil and transpiration is not limited by soil water, even though the volume of irrigation water is reduced, the consumptive use (ET) is unaffected. However, if the soil water supply is insufficient to meet the crop demand, growth and transpiration are reduced and DI induces an ET reduction below its maximum potential. The difference between the two situations has important implications at the basin scale [55]. In the first case, DI does not induce net water savings and yields should not be affected. If the stored soil water that was extracted is replenished by seasonal rainfall, the DI practice is sustainable and has the advantage of reducing irrigation water use. In the second case, both water use and consumption (ET) are reduced by DI but yields may be negatively affected in cases where yields are directly related to ET [56].

There are several strategies to impose the water deficits under DI, but basically there are two alternatives [56]. One is to impose the same level of deficit over the entire irrigation season (continuous or sustained DI), while the other concentrates the deficits in certain crop growth stages believed to be the least sensitive to water stress (Regulated DI, RDI). Deficit irrigation, by reducing irrigation water use, can aid in coping with situations where supply is constrained. In field crops, a well-designed DI regime can optimize WP over an area when full irrigation is not possible. It will reduce yield to a certain extent because of the linear relations between ET and the yield of the major field crops [40]. In many horticultural crops, such as fruit trees and vines, RDI has been shown to improve not only WP but farmers net income as well. Because of the differential responses among the different crops to water deficits it would be important to investigate the basis for the positive responses to water deficits in the cases where water deficits are not detrimental to yield. While DI can be used as a tactical measure to reduce irrigation water use when supplies are limited by droughts or other factors, it is not known whether it

can be used over long time periods, given that the reduction in applied water could lead to greater accumulation of salts in the profile. It is imperative to investigate the sustainability of DI via long-term experiments and modeling efforts to determine to what extent it can contribute to the permanent reduction of irrigation water use.

Future Directions

Farmers in irrigated agriculture are confronted, at the start of every season with a critical question: How much water would be available this season, and how should I distribute it among the different crops and fields? There are many procedures and tools to answer those questions in such a way that the water allocation will be used efficiently. In fact efficiency of water use in irrigated agriculture has been steadily increasing with the improvements in science and technology, and as pressures from other sectors of society mount. Irrigation management encompasses several scales, from the network down to the individual field. One of the primary management targets at the field level is, once the amount of water needed is precisely determined, to distribute it over the field as uniformly as possible. Elimination of surface runoff and minimal percolation losses are prerequisites for optimizing irrigation water use and for limiting the environmental impacts of irrigation.

Monitoring, evaluation, and real-time feedbacks for benchmarking and to assess irrigation performance is essential for efficient water use. In the future, performance evaluation will be done routinely and at low cost with the use of remote sensing techniques. These surveys will allow the identification of areas within irrigation networks in need of improvement, and farmers will have the information to modify practices or to change methods, thus achieving greater productivities. Incentives are needed, however, for farmers to adopt new technologies for more efficient water use when water supplies are abundant and/or inexpensive.

The recent expansion of irrigation combined with increased water supply limitations will lead to water scarcity in many areas. In those situations, efficient use of water will be critical for the sustainability of irrigated agriculture. Deficit irrigation will be used more, and other socioeconomic measures, such as water markets, will play a more important role in water scarce situations [57]. Planning ahead in water-limited situations would be critical to achieve optimal use of water, and it is envisaged that robust DSS that include economic models will be used to allocate the limited irrigation water available among different users in networks and among crops in farms.

Finally, bridging the yield gap between potential and actual yields offers another avenue for improving the efficiency of water use in irrigated agriculture. Crops that are limited only by solar radiation and temperatures have potential yields that are several times the current world average yields. For instance, wheat world averages are reaching 3 t/ha, while the potential yield approaches 14 t/ha. In the case of maize, average world yield is about 5 t/ha while the potential yield exceeds 18 t/ha. The yield gap is not only important in rainfed conditions [58], but under irrigated conditions as well. Differences that exist between actual and potential yields are caused by many factors, water being just one of them. Therefore, it is most important to optimize crop agronomy in all of its facets, from soil to crop management, and from pest and disease management to weed control. Most of the time, yield improvement by better agronomy does not increase crop ET significantly, and it has proven over and over again to be a very effective path for enhancing the efficiency of water use now and in the near future.

Article Outline

Glossary

Aquaculture The farming of aquatic organisms, including fish, mollusks, crustaceans, and aquatic plants. Farming implies some form of intervention in the rearing process to enhance production, such as regular stocking, feeding, and protection from predators. Farming also implies individual or corporate ownership of the stock being cultivated.

Co-product allocation Partitioning the input or output flows of a process or a product system between the product system under study and one or more other product systems.

Functional unit The quantified function provided by the product system(s) under study, for use as a reference basis in an LCA, e.g., 1,000 h of light.

Life cycle assessment (LCA) An ISO-standardized analytical tool developed to evaluate environmental performance of products and processes. It constitutes a compilation and evaluation of the inputs, outputs, and potential environmental impacts of a product system throughout its life cycle; the term may refer to either a procedural method or a specific study.

System boundary Defines the inputs and outputs that are included in the study. System boundaries should be set depending on what will be relevant to the aim of the study.

Definition of the Subject

Aquaculture production has grown three times faster than the livestock sector since the 1970s, becoming a major source of edible seafood and other products. This rapid expansion has, however, had a combination of positive and negative environmental, social, and economic effects. A variety of tools are available to evaluate these impacts in an attempt to identify the most sustainable practices. One of the more recent tools that has been applied to the evaluation of aquaculture production is Life Cycle Assessment (LCA), an ISO-standardized biophysical accounting framework that allows for multi-criteria environmental performance assessments. This chapter reviews studies that have applied LCA to studying the environmental dimensions of aquaculture production to date. Methodological differences and alternative approaches are discussed, along with their influence on research outcomes. There is little homogeneity between the studies when it comes to the choice of functional unit, system boundaries, and basis for allocation. However, several clear trends do emerge that point toward imperatives for sustainable practices in aquaculture and considerations for sustainable development of the industry moving forward. Recommendations for further methodological development of LCA for application to seafood sustainability research are advanced.

Introduction

Society is increasingly aware of both the drivers and consequences of natural resource depletion and environmental degradation. Various analytical frameworks

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

have therefore been developed for the purpose of evaluating the environmental performance of products and processes. Finding a suitable tool for assessing sustainability in the rapidly developing aquaculture sector has gained increasing profile over the past 2 decades. What has emerged is the need for a tool that can incorporate multiple environmental performance criteria in the evaluation of diverse aquaculture production technologies. For this reason, there is increasing interest in, and application of, life cycle assessment (LCA) as a research framework to better understand environmental performance in this sector. The interest has, however, not been coming from within the aquaculture industry itself, but rather outside. LCA is a versatile methodology that is well suited to address a broad suite of resource use and emissions-related issues. Over the last decade, it has become an increasingly common tool for characterizing an important subset of environmental impacts in aquaculture and elsewhere.

Aquaculture Development

Even though global capture fisheries landings have declined since the late 1980s, total production of marine fisheries products has increased 67% between 1970 and 2007 (including brackish water fish). This has only been possible through a large increase in aquaculture production over the last 4 decades. Aquaculture currently provides half of all finfish destined for human consumption. Seafood from all sources accounts for about 20% of all animal proteins consumed by humans, and demand continues to grow [1]. The aquaculture industry is the fastest growing animal products' sector, with an average annual growth rate of 6.9%. At present, it provides almost 8 kg of seafood per capita year^{-1} globally [1]. In 2006, aquaculture accounted for more than 70% of global shrimp and prawn production, 47% of total food fish production, and 36% of total fish production. Mariculture of finfish dominates production in developed countries [2]. By mass, however, the majority of global production is accounted for by carp farmed in extensive and semi-intensive farms in Asia.

Aquaculture comprises an enormous diversity of farming technologies, culture settings, and species. From monoculture to polyculture systems operated in ponds, raceways, land-based tanks, along with cages, pens, poles, rafts, and longlines in open water settings, well over 250 species are currently in culture. Production technologies may also reflect traditional farming methodologies or more modern systems [3–5]. In turn, post-production processing yields a diverse range of products, including salted, dried, smoked, and various kinds of preserved fish. About 37% of all fish and fishery products are traded internationally, with the major importers being Japan, the USA, and Spain [1].

Aquaculture and the Environment

It has been proposed that aquaculture represents the most viable option for meeting future demands for fish, as well as providing economic and nutritional benefits to millions [1]. The recent rapid expansion of this sector has, however, been accompanied by a range of environmental and social concerns, including localized nutrient enrichment or depletion, chemical pollution, genetic pollution, introduction of non-indigenous species, habitat destruction, greenhouse gas (GHG) emissions, depletion of wild fish stocks, inefficient energy and biotic resource usage, and spread/amplification of diseases and parasites [2, 3, 6–9]. Of these, local-scale interactions have traditionally attracted the most attention. However, global scale interactions such as greenhouse gas emissions associated with intensive production strategies are of increasing interest. What has become clear is that each production strategy is characterized by a unique suite of environmental interactions at local, regional, and global scales. Informed decision making for improved environmental management in aquaculture, therefore, requires tools, which can provide multi-criteria environmental performance assessments and make clear the environmental trade-offs associated with specific aquaculture technologies and products.

Sustainability Tools in Aquaculture

Increasing aquaculture production to meet future demands is clearly attractive from a policy and development perspective. However, a number of critical questions related to growth in this sector must be addressed. These questions encompass complex issues associated with sustainability objectives at local, regional, and international scales. For example, a spectrum of negative ecological and social

externalities associated with aquaculture and other food production systems bear careful scrutiny and must be weighed against anticipated benefits [10]. Such comparisons need to extend beyond short-term gains and localized impacts and incorporate a long-term social-ecological resilience perspective. This requires tools to identify the most sustainable aquaculture practices, drawing knowledge from both new and traditional culture systems [5].

A wide range of tools/frameworks for assessing various aspects of environmental performance have been advanced [11], some focusing especially on food production. These include techniques such as Risk Assessment, Ecological Footprint, and Energy Analysis. Frameworks more specific to assessing seafood production systems are Fishprint and the Global Aquaculture Performance Index (GAPI) [10, 12, 13]. Most of these, however, encompass a limited range of the environmental concerns associated with aquaculture and some suffer from a lack of methodological standardization [10]. Moreover, the degree of scientific rigor in both the methods and their application is also variable. Data limitations and analytical scope have, therefore, often led to misrepresentation of the environmental consequences of specific management decisions.

LCA – The Method and Its Applicability in Aquaculture

History of LCA

LCA has, since its emergence in the 1970s, evolved from a tool whose primary application was waste management and energy efficiency management to a more general eco-efficiency measurement framework. It has close links to energy analysis, but is unique among biophysical accountancy-type tools in that it has been internationally standardized (ISO 14040-14044) [14, 15]. An LCA typically begins at the "cradle" of a product or service life cycle (i.e., at the point of primary resource extraction), and extends along the supply chain to encompass all life cycle stages of interest to a particular analysis. Single or multiple impact assessment methods may be applied. Estimation of the cumulative environmental impacts along supply chains permits attention to spatially and temporally discrete impacts not typically considered in more traditional environmental impact analyses. Impact categories range from highly quantifiable effects, such as greenhouse gas emissions or energy use, to (less frequently) more diverse social consequences, such as human health effects [16].

The outcome of a LCA is highly influenced by the ambition, skill, and objectives of the practitioner. Modern software with built-in inventory databases and impact assessment methods has simplified the LCA process, to the extent that an aquaculture system may be modeled in hours. However, the rigor of such models is to a large extent dependent on data quality. While use of generic data available in many public and commercial life cycle inventory databases may provide a starting point for scoping analyses, more context-specific data is required for robust modeling of specific production systems and technologies. Unfortunately, the former (simplified analyses) are increasingly common in the peer-reviewed literature, providing what may be misleading signals and eroding the credibility of the research framework, generally.

Software Tools and ISO

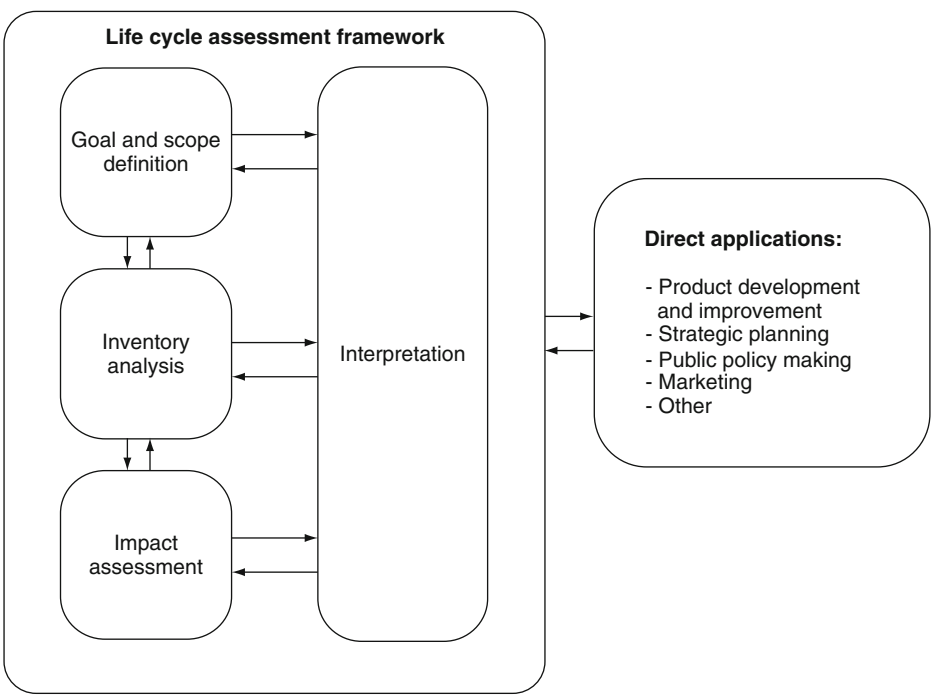
The rapid evolution and adoption of LCA have been accompanied by the creation of a variety of guidelines, manuals, and dedicated software [17]. The most commonly used LCA software platforms are GaBi and SimaPro, which are commercial products. Others, such as CMLCA and openLCA, are available free of charge. There are also several life cycle inventory databases, which have been developed, with the most extensive being the EcoInvent database (www.ecoinvent.ch). Such databases provide inventory data for materials and processes common to most product systems – for example, the production of materials such as concrete, steel, and plastic; the provision of energy carriers such as diesel or regionally specific electricity mixes; or transportation modes like air freight, rail freight, or private automobile transport. As these "background" data are often premised on different methods, assumptions, and rigor, sourcing data should be done with care as different databases apply different methodologies. It is therefore recommended to be consistent when choosing sources of background systems data and also to be aware of the methodology used before making comparisons between studies. ISO compliance does not require that studies are comparable, only that

they follow the same requirements. Individual studies also often differ in functional unit (the unit of output against which impacts are quantified), system boundaries, and allocation criteria.

A LCA study is, in accordance to ISO standards, carried out methodically through four phases (Fig. 1). As an initial phase, the goal and scope definition will specify the main characteristics of the study. Goal is specified as the application, audience, and reason for the study, while scope outlines the product system to be studied, functional unit, system boundaries, allocation procedures, impact categories, data requirements, assumptions, limitations, data quality, and format of the report. System boundaries specify the processes that are to be included in the product system and are in turn set by the cutoff criteria. This is followed by a Life Cycle Inventory Analysis (LCI), which involves the collection and calculation of data as well as allocation of burdens, in cases where input or output flows involve more products or processes than the defined unit. The impacts of these results are then, in the third phase (Life cycle impact assessment, LCIA), assessed according to their contribution to the impact categories defined in the goal and scope phase. Finally, the three previous phases are interpreted and communicated to the anticipated audience.

Functional Unit

Seafood commodities are farmed for different purposes, which complicates the choice of functional unit. Most LCA studies to date have used live weight mass at the farmgate or mass of processed product as the functional unit. Variable protein contents and edible portions between aquatic animals therefore may complicate direct comparisons. For example, the edible portion of an oyster is only about 18% of its wet weight, a number that in turn is subject to local variation [18] while the edible yield from an Atlantic salmon (*Salmo salar*) typically exceeds 50%. Local customs may further confound the decision as certain parts of the fish that may be discarded as inedible in one region are considered good for human consumption in another region. Two such examples are herring roe and catfish



Life Cycle Assessments and Their Applications to Aquaculture Production Systems. Figure 1
The general methodological framework for LCA studies according to ISO 14040 (2006) and its four comprised phases

stomachs; both of which are considered offal in the western world but are prized in parts of Asia [19, 20]. Ideally, the functional unit should reflect the function of the product system. For aquaculture products intended for consumption as food, such functions might include the provision of caloric energy, protein, or omega fatty acids, etc.

Setting System Boundaries

System boundaries delineate those processes formally included in an analysis from those that are excluded. There are only general requirements on how to set these boundaries, though they should be decided relative to the research objectives and include all elements having a non-trivial influence on research results. Most LCA studies in aquaculture limit their system boundary to the farmgate, whereas some include processing, packaging, marketing, and consumption phases [21–23]. Thrane [24] evaluated the effects of post-harvest stages of the life cycle of seafood products and concluded that they have a significant impact on the overall environmental performance of most seafood products. For example, inclusion of the processing phase contributed an additional 10% to life cycle energy use, while inclusion of the consumption phase resulted in an average 25% increase in cumulative energy demand [24].

Allocation

A common issue faced by many LCA practitioners is how to allocate environmental burdens to products and materials that are co-produced with other products [25]. Examples in aquaculture include the allocation of environmental burdens between targeted catch and bycatch used in fishmeal production, the multiple products derived from corn and other commodity crops used in feeds, and alternative uses of fish by-products or aquaculture wastewater used to fertilize other crops. The ISO standards for LCA do provide guidelines for an allocation decision hierarchy, but leave considerable room for interpretation. According to the standard, environmental burdens are primarily to be allocated according to an underlying physical relationship, if subdivision is unavoidable. The standard further states that where such relationships cannot be established, the allocation should reflect other relationships between the input system and output system. In reality, the final choice of allocation basis will likely reflect the goals of the study, as well as the worldview of the practitioner. Some of the more common bases for allocation in aquaculture and their characteristics are summarized in Table 1. Accessibility of the different allocation factors differs depending on location and situation, where regional differences will play a large role in making generalizations. Time and spatial scales will also have a great influence on the allocation factors that do not represent physical relationships, as these will not remain static.

There are several things to keep in mind when choosing a basis for allocation. The first is that nothing limits a study to only one allocation factor; each allocation scenario may be treated differently depending on the circumstances. Results may also be presented using several of the allocation factors, thus enabling readers to interpret results according to their own perspective or worldview. No matter how the allocation problem is approached, it is very important to be clear in the supporting text about which methods have been used. It is, however, important to keep in mind

Life Cycle Assessments and Their Applications to Aquaculture Production Systems. Table 1 The most commonly used bases for allocation and their characteristics

Allocation factor	Accessibility	Physical relationship	Static	Market oriented
Mass	Good	Yes	Yes	No
Value	Average	No	No	Yes
Nutritional energy content	Average	Yes	Yes	No
System expansion	Poor	Sometimes	Sometimes	Sometimes

that the basis of allocation can influence the allocated burden by as an order of magnitude [26].

Impact Categories and Impact Assessment

Any quantifiable performance measure can be included within the LCA methodology, from emissions to the well-being of workers, as long as: (a) a causal relationship between the variable of interest and the provision of the functional unit can be established and (b) a defensible impact assessment methodology is available [27]. A wide variety of impact assessment methods are available for use in LCA, most of which have been applied to assessments of seafood production systems [27]. These methods may describe environmental interactions that have relevance at local (e.g., eutrophication), regional (e.g., acidification), or global (e.g., greenhouse gas emissions) scales. Generally, impact assessment methods are based on peer-reviewed, internationally accepted environmental accounting protocols. Some of these continue to evolve, and novel methods emerge in response to newly identified issues [27, 28].

Labor

Labor is rarely accounted for in LCA due to the difficulty of establishing defensible system boundaries and quantifying associated environmental impacts. It can also be debatable if the number of employees should be considered as a negative or positive input. It is, however, important to keep labor in mind when comparing traditional and modern production systems. Labor can be presented in a number of different ways, either separately or incorporated into the individual impact categories [28, 29]. Several methods have been suggested on how to quantify the environmental impacts of labor. Suggested reference units include metabolic energy, calorific content of food consumed, national fuel share, or other more complex equations [29].

LCA in Food Production

Working with non-Static Systems

The adaptation of LCA from the characterization of static industrial systems to food production systems typified by significant variability has brought with it new challenges. Annual fluctuations occur both on the farm, as productivity will depend on water temperature, extreme weather events, algae blooms, etc., as well as on indirect variables such as oil prices and public demand. Fisheries providing fishmeal and fish oil for use in aquafeeds offer a good example of such variability, as fuel inputs per tonne of fish landed will fluctuate with season, stock status, gear type, and skipper [30, 31]. The aquaculture sector is particularly dependant on annual production of the anchoveta fishery off South America for both of these commodities, which in turn is strongly influenced by El Niño-Southern Oscillation (ENSO) events [32]. Increased use of compound feeds and higher oil prices have also boosted prices of both fishmeal and oil over the last decade [1]. Such fluctuations not only affect economic allocation but also catch per unit effort. It can therefore be hard to set average fuel consumption for fishing fleets, especially since the species and status of the stocks used for fishmeal production often are unknown [33]. The situation is further complicated in certain parts of the world where low value fish are used directly as fish feed [33].

Agricultural crops – the other major source of aquafeed inputs – may also experience significant annual fluctuations, with larger variability in developed countries, for crops such as maize and wheat [1, 34]. Farmgate prices will further affect the LCA as many feed formulators and aquaculturists quickly adjust to price trends in their choice of feed inputs or cultured species in efforts to maximize profits [20, 35]. One such example is the constant push toward higher stocking densities of shrimp in SE Asian polyculture systems, where the large profits that are to be made often outweigh the risk of white-spot disease [36]. Farming practices, as for feed composition, are also under constant change, which emphasizes the importance of considering the time scales used in LCA studies. Ultimately, a balance must be struck between feasibility and the goals of the study in pursuing representative data and models.

The relevance of such variability will, in part, be determined by the scope of the analysis and specific research questions of interest. Variability might be accommodated when modeling at regional scales by applying average data over specified spatial and temporal horizons. It is increasingly common to account for and report such variability in published outcomes. In other cases, quantifying variability might comprise

research foci – for example, understanding the influence of variable field-level nitrous oxide emissions on the overall greenhouse gas intensity of crop production at local scales.

LCA in Aquaculture

The first LCA studies focusing on aquaculture systems were conducted in the beginning of the new millennium, with an increasing application of the methodology to aquaculture issues toward the end of its first decade [37–39]. As the number of studies increased, so too did the seeming detail of analysis and possibly also the accuracy of the results. Most have focused on production systems in developed countries (see Table 2). The methodological detail used between studies does, however, vary widely and makes broad comparisons between studies difficult. This includes differences in functional unit, system boundaries, data sources and quality, and choice of allocation criteria.

A common theme that has emerged from LCA research of intensive, finfish aquaculture production systems is the importance of feed provision in supply chain environmental impacts [21, 22, 42–44]. For example, Pelletier et al. (2009) found that feed provision accounted for, on average, 92% of quantified impacts in global salmon farming systems. Of particular importance are fisheries and livestock products, which typically have higher impacts per unit mass relative to crop-derived feed inputs (Fig. 2). Also of note is that on-site processes have only made a substantial contribution in highly mechanized systems, where industrial energy inputs are required to maintain water quality [3, 20, 21, 40, 44].

Although animal-derived feed ingredients usually have a higher impact per unit mass compared to crop-derived inputs [22, 43, 45, 46], their inclusion may support more rapid growth of the cultured organisms and, in some cases, result in a higher quality product [47]. By including a larger portion of agriculturally sourced materials in feeds, environmental burdens may be reduced. In this light, it might be anticipated that rearing herbivorous or omnivorous species is environmentally preferable. However, both feed composition and feed conversion efficiency must be considered in determining and comparing impacts between cultured organisms [44].

The choice of impact categories in aquaculture LCAs varies widely (Table 2). These include resource depletion and emissions-related environmental concerns, as well as toxicological potentials. The only categories almost consistently applied are global warming potential, acidification, and eutrophication, while cumulative energy demand is also very commonly evaluated. There is an expected but imperfect correlation of cumulative energy demand and global warming potential (Table 3), since much of the feed-related emissions for agricultural inputs do not arise from fossil fuel combustion. Rather emissions of nitrous oxide and methane are typically as or more important. It is only in systems where ecosystem services have been replaced to a large extent by anthropogenic processes that on-farm energy demand has a significant impact on the total energy consumption.

Guiding the Way for More Sustainable Aquaculture and Alternative Farming Methods

Feed Production

Improvements of feed conversion ratios (FCRs) for piscivorous fish in addition to an increased inclusion of non-fish ingredients has led to great environmental improvements over the last decades [46]. Additional improvements are to be made by identifying and sourcing for the least-environmental-cost feed formulations; especially for sources of fishmeal and oil [22]. In reduction fisheries, effective management will play a major role in reducing fuel consumption along with associated environmental impacts while sustaining output from the industry [30, 50]. In many fisheries, boats today have to travel further to find productive fishing grounds and invest more fishing effort to maintain catches. This has resulted in a sixfold increase in energy consumption for some capture fisheries over the last two decades [51]. A collapse of one of the large reduction fisheries, of the scale that occurred to the anchoveta fishery in the 1970s, would further drive up the energy intensity of aquafeeds and culture products as well as have devastating effects on the aquaculture industry as supply of fishmeal and oil supplies already are outpaced by demand [1, 52].

Decreasing fishmeal inclusion has, to a large extent, been driven by increasing public awareness about "fish-in to fish-out" ratios, as a result of labeling and

Life Cycle Assessments and Their Applications to Aquaculture Production Systems. Table 2 Overview of species, functional unit, system boundary, allocation factor, and impact categories applied for a selection of published LCA studies on aquaculture systems. One ton at farmgate is the most prominent functional unit while global warming potential, acidification, and eutrophication are the only impact categories that are included in all studies

Life Cycle Assessments and Their Applications to Aquaculture Production Systems. Figure 2
Cumulative Energy Use and Greenhouse gas emissions from salmon production. Feed production is by far the largest contributor to environmental concerns, constituting 93% of the energy use and 94% of the GHG emissions. The feed represents an average from farms in Norway, UK, Canada, and Chile with 41.8% of the ingredients derived from crops, 49.4% from fish, and 8.8% from livestock. Data from: Pelletier et al. [22]

certification initiatives [9, 46]. It has also been strongly influenced by rising prices for these commodities, due to increased competition from the aquaculture sector [1]. The overall demand for fishmeal and oil in aquaculture has, despite this, increased due to a larger share of farmers using compound feeds and increasing aquaculture production over time [46, 53]. At present, in most aquaculture LCAs, the amount of fishmeal and oil used is only reported as life cycle inventory data. Beyond the standard impact categories, methods to account for the ecological impacts of producing these products are underdeveloped. To date, only a few researchers have, e.g., applied a measure of biotic resource use in life cycle assessment, following the methods originally advanced by Pauly and Christensen [54]. This method quantifies the net primary productivity, as measured in carbon, required to support the provision of a specified amount of fish-derived material, taking into account trophic level and species-specific meal and oil yield rates. Biotic resources used can differ by as much as an order of magnitude between different sources of fishmeal and oil [22]. Alternative sources of proteins that could in part replace fishmeal include soy meal, wheat gluten, bone, feathers, blood, livestock co-product meal, and seafood processing materials [46, 55]. A variety of vegetables oils may also be partially substitutable for fish oils. The environmental performance of systems using, e.g., agriculture alternatives for fishmeal and oil needs, however, to be carefully analyzed as such substitution does not guarantee improved performance. Switching to the culture of low-trophic species is often described as a solution for more sustainable aquaculture [6]. While this would allow for great reductions in fish inclusion rates, the higher FCRs associated with lower quality feeds may result in only marginal improvements in GHG and related life cycle impacts [44]. In contrast, a switch to more energy and climate-friendly fertilizer production either through efficiency improvements in existing fertilizer plants or the use of biological nitrogen fixation in place of conventional N fertilizers could, however, offset some of the impacts associated with crop production [56, 57].

Improvements of feeding practices on farms can both reduce costs, emissions, and FCR [58]. The amount of feed added is often calculated according to feeding charts or as a percentage of the fish biomass. These generalizations often result in inefficient feed

Life Cycle Assessments and Their Applications to Aquaculture Production Systems. Table 3 Summary of the different results for 1 t of seafood product at farmgate

Species	Country	Source	CED (MJ) t^{-1}	GWP kg CO_2-e t^{-1}

Tilapia, Pond	Indonesia	Pelletier and Tyedmers [44]	26,500	2,100

Energy use in Norwegian salmon farming reported by Ellingsen and Aanondsen [39] was calculated by assuming that 15% of total reported energy use was used in the processing and distribution phases

utilization as it does not take factors such as species, genetic stock, feed composition, water temperature, or growth rate into account [58]. In addition, feeding efficiency is also influenced by the type of farming facility as confined bodies of water, such as raceways or bags, allow for more efficient feeding practices and effluent management [59].

Replacing Ecosystem Services with Anthropogenic Processes at Farm Site

Traditional extensive aquaculture systems depend, to a large extent, on labor and natural energy inputs [3]. Solar energy inputs promote in-situ production utilizable by some farmed animals while tidal energy or other natural watercourse flows provide means for water exchange.

As for energy consumed in highly mechanized production systems, such as most intensive land-based systems, the energy for farm-site activities often originates from fuel as farm-sites typically lack access to alternative sources of energy. It is therefore recommended to consider the location characteristics of the farm-site before implementing artificial services. Farms situated in areas with high water turnover, i.e., in streams, tidal zones, or exposed coasts, may cause little or no impact on the local ecosystem. Farms situated in areas without such hydrodynamic conditions need to treat their wastewater to avoid negative impact on the environment or run as closed systems. It is, however, important to acknowledge that environmental impacts from farm release need to be analyzed from an ecosystem perspective, which implies considering additional pollution sources and more regional scale effects and thresholds.

LCA has limited capacity to predict the actual consequences of many of the estimated impact potentials [60]. It may be justifiable to have such an approach for the impact categories that are operational on a global scale, such as global warming potential or ozone depletion. For more regional consequences, however, it can be highly misleading to make comparisons of the impacts between two localities. To address this in a more justifiable manner, several country-specific factors, such as RECIPE, TRACI, EDIP2003, and LUCAS [61], have been developed and arguments have been raised for similar factors on regional scales [62].

Transmission of disease and parasites between wild and farmed stock and introduction of non-indigenous species are both major concerns associated with aquaculture that have yet have not been addressed by LCA methodology [63, 64]. Nor is the framework necessarily conducive to accommodating such interactions since it is necessary to be able to link the impact to the production of a functional unit following a clear and quantifiable cause-effect pathway. Both of these types of impacts have attracted much public attention and have been major incentives for closed farming facilities. Transmission of sea lice has, apart from having potentially detrimental effects on wild fish stocks, been estimated to account for 6% of the product cost in salmon farming [64]. Floating cages and net cultures allow for free movement of pathogens from farmed to wild stocks [64]. They also run an increased risk of large escape events of domesticated fish due to their vulnerability to extreme weather events, marine mammal interactions, failing infrastructure, and management errors. Such events can lead to the introduction of non-indigenous species as well as undermining the genetic fitness of wild stocks. It has been estimated that aquaculture is responsible for 16% of all introductions of non-indigenous species to European coastal waters, and further introductions are to be expected with changing climate [63].

The use of chemicals and antibiotics on farm sites is still only generally covered by existing impact categories. These practices can result in long-term effects such as antibiotic-resistant bacteria or other public health risks [10]. They may also lead to contaminated water sources and loss of biodiversity [10]. Shrimp farms are implicated most frequently for using large amounts of antibiotics to reduce stock losses. On several occasions, this has resulted in product recalls and import bans by the EU, Canada, and the USA [10]. The social consequences of this might be direct (e.g., lower water quality) or indirect, as import bans can seriously affect the financial viability of many farmers [65]. Even if LCA has the potential to account for such social and economic consequences, there is a lack of metrics to describe how to include socioeconomic indicators [28]. Overcoming the hurdles associated with the development of such impact categories would allow for better estimations of overall sustainability, including environmental, social, and economic variables [28]. However, it should be recognized that LCA is not necessarily conducive to accounting for the full spectrum of sustainability concerns. As such, it should be considered a complement to, rather than a replacement for, other metrics.

Discussion

As the number of LCA studies describing aquaculture systems increases, so too does our understanding of a broader suite of the environmental costs of aquaculture production. In some cases, it would appear that aquaculture may indeed provide an inexpensive and sustainable source of food and other products; however, this will depend on numerous factors including cultured species, production technology, and socioeconomic characteristics. To date, LCA research has helped to identify those aspects of the life cycle that contribute disproportionately to environmental degradation, allowing for the

identification of improvements opportunities. There is, however, always the danger of oversimplification where results get misinterpreted as a result of inaccurate data or where results are not put into their relevant context. LCA should therefore not be seen as an all-encompassing tool, but rather as a screening tool, which allows for the mapping of good practices. Additional environmental and socioeconomic analyses can thereafter be applied to strengthen assessment of sustainability.

As for advancements that can be made within the sector, the major challenge will be to find good sources of low impact feed inputs for fed aquaculture systems, especially for fish oil that currently drives the demand for wild marine resources [46]. This would, of course, ideally be combined with further advances in feed utilization by fish in culture. A shift toward organically produced crop inputs may also reduce the impacts of fed aquaculture, while bringing other benefits such as biodiversity improvements and superior soil quality [57, 66]. However, the choice of some resource intensive "organic" inputs can negate much of the life cycle environmental benefits associated with organic crop production [57]. Another alternative protein source is offal meal from fish processing. Tilapia, for example, has an offal yield of about 67% of live weight [59]. This does, however, increase the risk of disease transmission and/or recycling of environmental contaminants [53]. Moreover, the environmental costs of producing these materials from a life cycle perspective may be high [22]. Recently, there has been increased interest in the use of fish processing co-products for biofuel feedstock [67]. Conversion of high-quality protein into biofuels appears rather wasteful when the environmental burdens associated with producing certain high protein feed inputs are taken into account. It is clearly desirable to identify and implement optimal uses of high-quality protein toward the overarching sustainability objective. This must include, among other things, attention to the environmental dimensions of alternative protein production and use strategies. Since our ability to make informed decisions will be strongly influenced by the robustness of our models and the extent to which they actually reflect the environmental impacts associated with the products and systems of interest, methodological decisions such as choice of allocation criterion should be clearly communicated and defended in the context of each analysis.

Increasing trade flows of aquatic products from developing to developed countries highlights the need for more LCA work beyond production systems in the developed world. It also indicates that there are substantial opportunities for expansion of aquaculture in developed countries. Tyedmers et al. [2] points out that the USA only accounts for 1% of global aquaculture production, half of which is made up by channel catfish. Future developments may also to be expected within mariculture, as much recent effort has focused on the development of marine fin-fish hatcheries and offshore cages.

Impacts involved with on-site activities can more easily be avoided by selecting for better farm locations, use of renewable energy, improved utilization of ecosystem services, and farming of more tolerant species. One example of such a species is Pangasius catfish, which has reached high production levels in Vietnam over the last decade. This fish does not require aeration as it can utilize aerial respiration when the oxygen level drops. The farms also often utilize tidal floods for water exchange [20]. As for tilapia, the tolerance toward hypoxia and changes in pH is much higher than other species normally found in western aquaculture. This would, again, lower the inputs needed for maintaining water quality. Wastewater quality can also be improved by the use of settlement ponds and/or plant production to remove nutrients. Cultivation of plants such as *Azolla* spp. and duckweed within ponds can also enhance carbon fixation and be used as feed inputs [48, 68]. Duckweed may further reduce GHG emissions as it will shade the pond and thereby limit the ammonia volatilization rate [49]. Some of these feed inputs may, however, negatively influence the color and the taste of the final product, which makes them less suitable as feed inputs [48].

Converting to energy conserving practices will not only have environmental benefits, it can also improve the economic profitability of farms and reduce vulnerability to peaks in the price of oil. Lower intensity systems are also less sensitive to mechanical or infrastructure failures, such a black outs, which otherwise can cause mass mortality. This is especially important in developing countries where there is less access to spare parts and power failures are recurring events. Open systems are, on the other hand, more vulnerable to other events such as algae blooms, pollution, and

extreme weather events, which may cause the loss of an entire crop. Areas ravaged by extreme storm events, such as typhoons, may suffer from weeks of poor water quality as large quantities of sediments may lead to high turbidity for long periods of time.

More knowledge on the true carbon emissions associated with aquaculture is needed as there is increasing interest in its potential as a climate-friendly source for food and biofuels [68, 69]. LCA can play an essential part in the screening for sustainable farming practices and also provide information for the implementation of carbon credit schemes. This need is especially critical for developing countries, as this is where the majority of production occurs and exports are increasing. This will, however, pose a challenge as farming methods are highly diverse and data on farm practices are usually limited.

Also, some important environmental impacts from aquaculture are at present not quantifiable using the LCA framework, such as spread of diseases and parasites. These impacts have been attracting widespread public concerns and have influenced development of farming methods in many countries. The associated consequences could, for example, be accounted for as biotic resource use. Concerns associated with deforestation to produce agricultural land should also be further discussed, as it is only partially covered in current LCA practice and literature.

Future Directions

LCA provides a robust tool for dealing with an important subset of sustainability concerns, many of which have historically been overlooked in discussions of environmental management in aquaculture. However, it must be kept firmly in mind that decisions made during the analytical process strongly influence research outcomes.

It is, therefore, important to continue the discussion about such methodological decisions, including the kind of LCA framework applied (i.e., attributional versus consequential LCA), systems boundaries, and choice of allocation methods for LCAs of aquaculture production. In the least, it would be constructive for all practitioners to clearly communicate and defend all methodological choices, as they may ultimately send different signals to the industry and policy makers working with sustainability issues.

A more standardized methodology within the sector would certainly facilitate the advancement of the field. This could be achieved by better communications between major practitioners or by the development of a manual to guide the community toward one common framework. Even still, there will always be deviations from common practice as each study serves a unique purpose, stressing the need for more transparency.

Even though ongoing initiatives for developing the LCA framework exist, it is important to acknowledge that the present framework has limited ability to accommodate the other two pillars of sustainability, namely, social and economic impacts [28]. Thus, even if LCA provides a tool with great potential to guide the aquaculture industry toward more sustainable production, its framework needs to be reinforced by other analytical tools to capture a wider range of sustainability concerns. The need to include other tools alongside LCA has already been recognized and recent projects, such as the SEAT project (www.seatglobal.eu), include complementary tools to give a more holistic measurement of sustainability. Limitations aside, however, the rapid development of this sector, coupled with the diverse range of possible culture species and technologies, demands careful attention to environmental effects at all relevant scales. LCA can and should play an important role in guiding decisions oriented toward sustainability in aquaculture.

Article Outline

Glossary

Aneuploid An unbalanced number of chromosomes.

Blastocyst A stage of early development where the embryo contains a fluid-filled cavity and two cell populations: an inner cell mass and an outer layer of trophectoderm cells.

Cell cycle The period between the birth of a cell and its division. During a single cell cycle, the cell must duplicate all of its components, including DNA, to form two equal daughter cells.

Chromatin The combination of DNA and proteins, mostly histones.

Cytoplast An enucleated cell used as a recipient for a donor nucleus. Generally in SCNT, the recipient cytoplast is an enucleated oocyte.

Diploid The cell or nucleus contains two complete copies of the genome or a complete complement of chromosomes (2n), in general, a single maternal and a single paternal.

Donor cell The cell that provides the genetic material (nucleus) for SCNT. The resulting animal will be a genomic copy of the animal from which this cell was collected.

Haploid The cell or nucleus contains only a single copy of the genome or half of the chromosome complement (n). Pronuclei are, in general, haploid, containing either a single maternal genome or a single paternal genome.

Karyoplast A cell or a membrane-bound portion of a cell containing the donor nucleus enclosed. In livestock SCNT, the karyoplast is generally an intact cell.

Meiosis The process of reduction in the number of chromosomes that occurs during germ cell formation. Following a round of DNA synthesis, a single cell undergoes two rounds of division resulting in four cells, each containing a haploid genome. During division, independent assortment of parental chromosomes and homologous recombination generate a unique haploid genotype in each of the germ cells.

Metaphase II (MII) Stage during the second meiotic division where the chromosomes are aligned at the metaphase plate prior to segregation of sister chromatids to opposite poles. In most mammalian species, mature oocytes arrest at MII and meiosis is reinitiated and completed upon fertilization.

Parthenote An unfertilized zygote produced by activation of an oocyte. A parthenote may be haploid or diploid for maternal DNA, a gynogenote, or following enucleation and replacement with paternal DNA, an androgenote.

Tetraploid The cell or nucleus contains four haploid copies of the genome (4n).

Zygote The 1-cell stage of development of a fertilized embryo. During most of the first cell cycle, the zygote will contain two pronuclei containing the maternal and paternal DNA.

Definition of Cloning and SCNT

Cloning is the production of genetically identical individuals by the process of asexual reproduction. In animals, the term has been applied to offspring that are produced by the technique of nuclear transfer (NT). The process of nuclear transfer involves the production of an embryo by transferring nuclear genetic material from a donor cell (karyoplast) into a recipient cell from which the genetic material has been removed (cytoplast). Two factors determine the clonality of the resultant offspring. One is the recipient cell, generally an oocyte or unfertilized egg obtained from an unrelated animal.

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

The second is the donor cell, which can be obtained from a variety of sources including embryos, germ line, and somatic tissues of fetuses and adult organisms. When cells from somatic tissues are used, the procedure is termed somatic cell nuclear transfer (SCNT). In most species, transfer of the donor nucleus is primarily carried out by cell fusion with fewer reports of direct injection. In the case of fusion, the complete contents of the donor cell are introduced into the recipient cell, while in the case of injection, the donor nucleus might be accompanied with a proportion of the donor cytoplasm.

While SCNT became publicly known with the creation of Dolly the sheep in 1997, NT was already in the realm of science since 1928, with the first successful SCNT experiments carried out in frogs in the late 1950s. By creating a genetic copy of a known animal, SCNT opens many opportunities in several fields including biomedical research and agriculture.

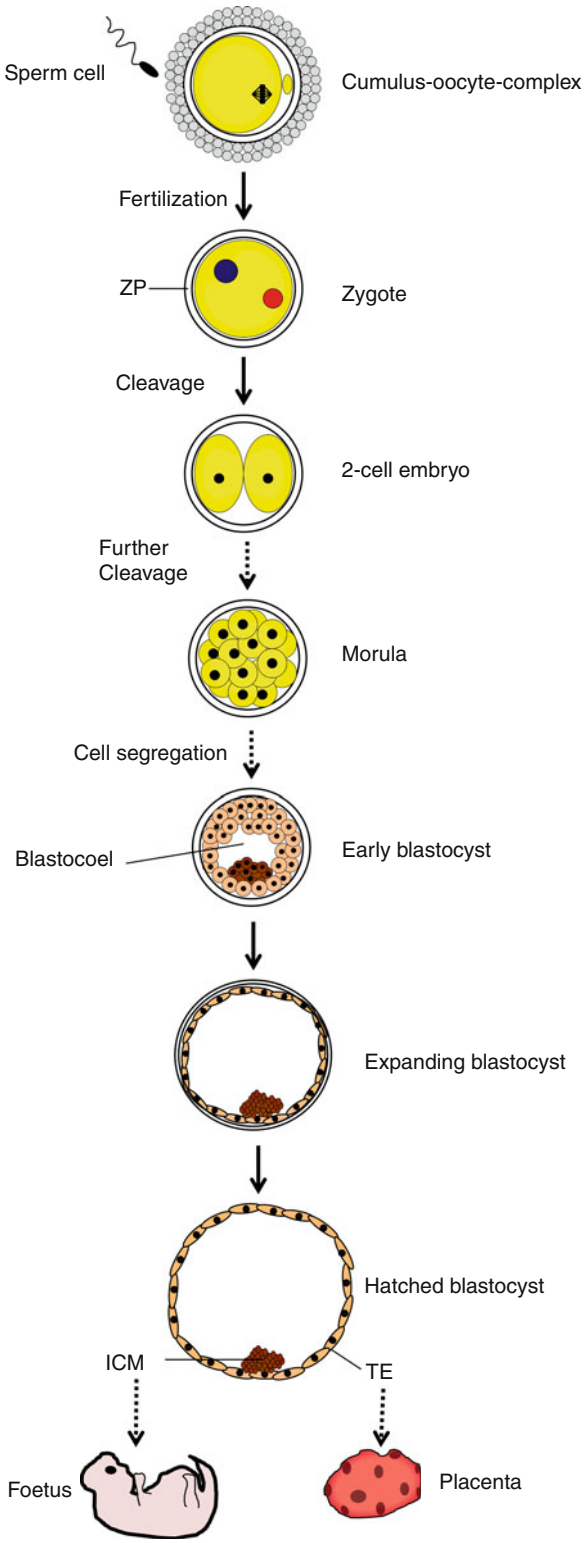
Introduction: Embryo Development and Highlights of NT

In animals, reproduction occurs primarily by sexual means, resulting in the creation of a new individual that contains genetic material (DNA) from two contributing parents of different sexes, each parent contributing half of the genetic material. Conception of a new individual occurs by the fusion of specialized cells or gametes, sperm in males and ova in females. Sperm are haploid (n) and contain a single copy of the genome, meanwhile ova, in most species, at the time of fertilization are arrested in metaphase of the second meiotic division and are diploid (2n). After fusion, however, the ovum completes meiosis to become haploid, and the resultant zygote is diploid (2n), containing a full set of chromosomes derived from both parents. The ovum is a large cell that contains sufficient maternally derived proteins and mRNAs to control early development. Following fertilization, during the early stages of development, no net growth occurs (Fig. 1); transcription from the embryonic genome is low but subsequently increases rapidly at a particular stage termed maternal to zygotic transition (MZT) [1]. The timing of the MZT is species dependent, for example, in mice, it occurs at the 1–2-cell stage; in pigs and humans at the 4–8-cell stage; in cattle and sheep at the 8–16-cell stage; while in the amphibian *Xenopus laevis*, it occurs approximately at the 4,000-cell stage [2]. After this transition, the embryonic genome orchestrates its own development. The embryo continues to increase in cell number within the confines of the zona pellucida (ZP), which acts as a protective shell. By the blastocyst stage, a fluid-filled cavity, called blastocoel, has formed and two distinct cell populations have emerged: the inner cell mass (ICM) and the trophectoderm (TE). As the blastocyst expands, build-up pressure together with the secretion of enzymes causes the ZP to break, enabling the blastocyst to hatch. Now the blastocyst is ready to interact with the endometrium and eventually to implant. By cell proliferation and differentiation, the ICM will form the fetus and some extraembryonic tissues while the TE will give rise to most of the placenta (Fig. 1).

The zygote is a totipotent cell, having the capacity to produce the fetus and the placenta. In contrast, sperm and ova are specialized cells. How do they acquire totipotency? Following fertilization, unknown factors present in the ovum's cytoplasm reprogram the paternal and maternal genomes so that their specialized gamete functions are erased to give way to an embryonic totipotent genome. This capacity to reset a specialized genome into a less specialized or totipotent genome is termed nuclear reprogramming. It is this nuclear reprogramming ability of the ovum that is harnessed in NT technology.

The first rudimentary NT experiments were performed by Hans Spemann in 1928. He used a donor nucleus from a 16-cell embryo and a presumptive zygotic cytoplast, resulting in a normal salamander [3]. Interestingly, Spemann had already predicted the possibility of cloning an adult animal by doing NT with an adult donor nucleus in what he termed the "fantastical experiment" [3].

In 1952, Briggs and King used NT to address the question of nuclear equivalence, that is, whether or not the different cells of a multicellular organism have the same genome. They developed the NT procedure by transplanting nuclei from frog blastula cells into enucleated oocytes [4]. Later on, Briggs and King tested the nuclear equivalence of more developmentally advanced frog cells and found that the developmental potential of reconstructed embryos gradually declined with increased donor cell differentiation [5]. However, John Gurdon pushed the field further by generating



Livestock Somatic Cell Nuclear Transfer. Figure 1 (Continued)

cloned adult frogs from differentiated epithelial somatic cells at the tadpole stage [6, 7], providing strong evidence for nuclear equivalence. Thus, the first successful SCNT had been achieved, but attempts to clone adult frogs failed [8].

Nuclear transfer in mammals lagged behind, with the first attempt in 1975 using morula-stage blastomere donors and unfertilized rabbit eggs. Even though the extent of reprogramming required for a blastomere, compared with a fully differentiated cell, is quite reduced, the reconstructed cloned embryos did not develop beyond the early cleavage stages [9]. In 1983, McGrath and Solter transplanted zygotic nuclei into enucleated zygotes resulting in mice developing to term, showing that the technique of nuclear transfer in mammals was feasible [10]. However, such a zygotic nuclei-replacement experiment did not involve any nuclear reprogramming, and when the same approach used more developmentally advanced blastomere nuclei as donors, it failed [11]. This failure in mice NT was followed by several breakthroughs in which enucleated oocytes were used as recipients of blastomere nuclei, leading to the production of cloned animals in sheep [12], cattle [13], and pigs [14]. In contrast to McGrath and Solter's failure in cloning mice, these results suggested that the enucleated oocyte is a better recipient than the enucleated zygote for reprogramming the donor blastomere nucleus.

Ten years passed until another breakthrough advanced the field of mammalian nuclear transfer: Keith Campbell and colleagues at the Roslin Institute succeeded in cloning a lamb by NT using donor nuclei from an established cell line derived from embryos [15]. In this study, cell cycle coordination between the donor cell and recipient oocyte was carried out

Livestock Somatic Cell Nuclear Transfer. Figure 1
Flow diagram illustrating mammalian development. Following fertilization of the MII oocyte by sperm, a zygote with the two parental pronuclei is formed. By cleavage, the embryo develops sequentially through the 2-cell, 4-cell, 8-cell, 16-cell, morula, and blastocyst stages. By the blastocyst stage, the first differentiation event has formed the inner cell mass (ICM) and the trophectoderm (TE). These two cell populations will form the foetus and placenta, respectively

prior to NT in order to improve the development of reconstructed embryos as previously determined by this group [16, 17]. One year later, this same group, led by Ian Wilmut, used a similar approach and shook the world's news with the creation of "Dolly" the sheep, the first mammal to be cloned from an adult somatic cell [18]. This study showed that an adult somatic cell retains all the information necessary to generate a new organism. After the creation of Dolly, much research has been done in SCNT and several species have been cloned from adult cells. Despite advances in the field, the frequency of development of embryos produced by SCNT remains low, with only 1–10% reaching term, depending on the species. Moreover, many cloned animals are born with abnormalities.

Applications of Livestock SCNT

Soon after the arrival of Dolly came the realization that SCNT had several potential applications. For instance, derivation of embryonic stem (ES) cells from human blastocysts was eagerly sought for regenerative medicine research. The rationale was that cells from a patient could be used for SCNT to derive ES cells, which in turn could be induced to differentiate into a specific tissue. Since such a tissue would be genetically identical to the patient, it could replace a damaged tissue in the same patient without the risk of immune rejection. Due to the ethical concerns of destroying human embryos, SCNT for regenerative medicine has been fiercely opposed. Fortunately, this problem seems mostly circumvented with the revolutionary creation of induced pluripotent stem (iPS) cells [19]. These cells have similar properties to ES cells and can also be derived from the somatic cells of a patient without the use of human oocytes or embryos. Since then, much of the field of regenerative medicine research has shifted from SCNT to iPS cell technology. However, recent studies have found genetic and epigenetic abnormalities in iPS cells [20–22], making them potentially unsafe for medical uses. Whether or not iPS cells are inferior to ES cells is currently the focus of heated debate. Since some of the problems found with iPS cells have not been reported with ES cells derived from SCNT embryos [23, 24], the process of nuclear reprogramming occurring in the oocyte appears to be of better quality than the one taking place during the derivation of iPS cells. Very little is known about the mechanism of nuclear reprogramming and the factors present in the oocyte responsible for triggering or carrying out such process. If these factors are found, they could potentially contribute to generate safer iPS cells for regenerative medicine. Thus, further research in the mechanism of nuclear reprogramming following SCNT is needed.

Apart from being a useful tool for basic research with potential indirect applications in regenerative medicine, SCNT has wide applications in agriculture. For instance, an animal of exceptional productivity can be multiplied by SCNT to increase commercial output or to reduce environmental impact. However, caution must be taken with such approach. First, consumption of products derived from cloned animals is not yet widely accepted by the public, and in some countries, there are regulations forbidding their entry into the human food chain. Second, the SCNT technology is so inefficient at present that its application for livestock multiplication might not be economically justified. Finally, it is important to keep in mind that clones are not necessarily true copies of their donor because of epigenetic differences, which result from faulty nuclear reprogramming following SCNT (discussed later). Slight epigenetic differences can affect the physiology of the cloned animal and thus its productivity. Such consideration should especially warn breeders of race-winner horses, as a cloned horse is unlikely to be a winner again.

A more realistic agricultural application of SCNT is to reproduce animals of high genetic value for breeding purposes. For instance, a prizewinning bull could be cloned and subsequently produce thousands of offspring by artificial insemination. To a lower extent, the genetic value of a cow could also be disseminated by SCNT followed by artificial reproductive technologies. While there might be risks associated with consumption of products from cloned animals due to potential epigenetic errors originated during nuclear reprogramming, their offspring should be safe since epigenetic and imprinting errors are normally erased during gametogenesis.

More importantly, SCNT has represented a great technical advance in the production of transgenic animals (this is discussed in detail in the entry ► Nuclear Transfer to Produce Transgenic Mammals,

this volume). In turn, transgenic animals have a myriad of other applications, which are discussed throughout this volume. Furthermore, transgenic animals producing pharmaceutical or novel proteins are good candidates for multiplication by SCNT since the cost of using this technology would be relatively small compared to the product harvested from the cloned animals.

SCNT can also be used for cloning individuals from an endangered species population. Examples of this application include the cloning of wild cattle (Gaur and Banteng) and wild sheep (European Mouflon) [25]. These examples resorted to interspecies SCNT in which a close-related species is used as cytoplasmic recipients and surrogates for the donor. Therefore, the resultant offspring will be a hybrid containing a genomic copy of the endangered donor and most mitochondrial DNA (mtDNA) from the close-related recipient. While the physiological consequences for this are unclear, it certainly raises ethical issues. Besides, other efforts such as restoration of the natural habitat and assisted breeding programs are likely to be more effective at helping an endangered population.

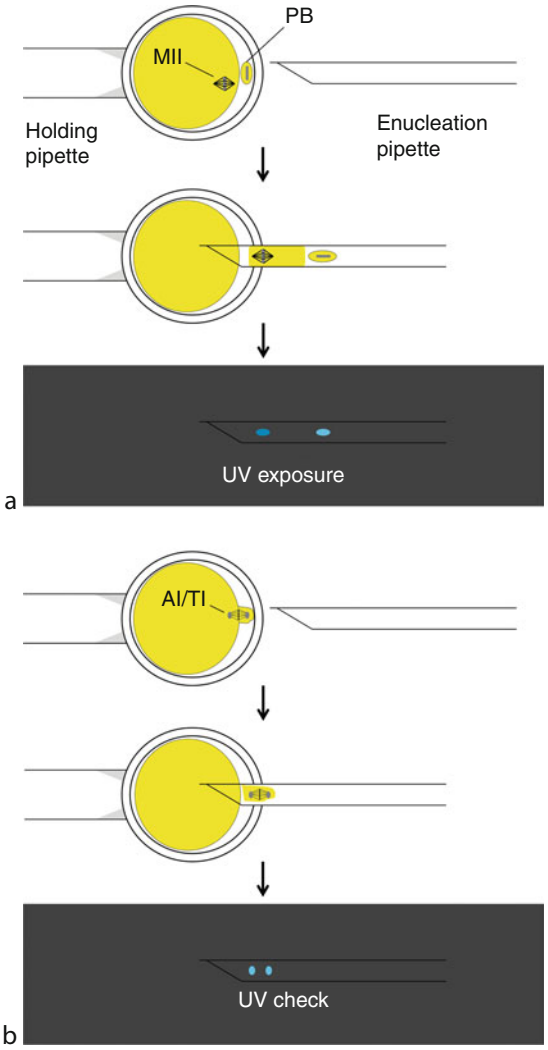
Taken together, SCNT has some interesting applications, but the ethical implications surrounding this technology must be fully considered before rushing into implementing SCNT in the field. Rather than an end, SCNT is especially useful when used as a tool in research, production of transgenic animals, and in cloning of prizewinning animals for breeding purposes in agriculture.

NT Techniques

NT is a complex multistep procedure, with several alternatives at some steps, which include oocyte maturation, cumulus cell removal, enucleation, nuclear transfer, activation, and embryo culture. Culture of the donor cells is important and usually accompanied with cell-cycle synchronization prior to NT. Enucleation and nuclear transfer are the most important and difficult steps. To carry out these steps, most laboratories use micromanipulators. A micromanipulator is a relatively complex instrument composed of a microscope, micromanipulators at both sides to hold the holding and injection micropipettes, micromanipulator joysticks to precisely maneuver the micropipettes in three dimensions, and microinjectors to precisely aspirate and expel fluid and cellular material from the micropipettes. For mice cloning, microinjectors are usually equipped with piezoelectric devices to prevent lysis of the fragile mouse oocyte during enucleation and nuclear transfer. An alternative to micromanipulators is a technique called handmade cloning (HMC) and seems equally efficient as micromanipulator-based NT (for a review of HMC, see [26]). Following is a brief discussion of the different steps involved in the entire NT procedure with focus on livestock species unless stated otherwise.

Oocyte maturation is usually required in livestock cloning as immature oocytes are commonly obtained from ovaries collected from slaughterhouses. Alternatively, in vivo–matured oocytes can be obtained by stimulating superovulation, which is followed by oviduct flushing after slaughtering the animal. In vitro maturation (IVM) entails mimicking to some extent the in vivo environmental conditions found in the ovary at the time of the LH (luteinizing hormone) surge. Thus, three key hormones, LH, FSH (follicular stimulating hormone), and estradiol, are added to the IVM medium to stimulate maturation. Oocytes are surrounded by cumulus cells, forming a cumulus-oocyte complex (COC); cumulus cells aid oocyte maturation. COCs are incubated at about 39°C in livestock species and for 24 h (e.g., cow and sheep). Following the required maturation period, oocytes are denuded from the cumulus cells using hyaluronidase to digest the extracellular matrix that holds cumulus cells together. Removal of cumulus cells is necessary to allow visualization of the oocyte's chromatin during enucleation and to prevent inserting a cumulus cell accidentally inside the oocyte during enucleation and cell/nuclear transfer procedures. Now the denuded oocytes are ready for enucleation.

A few enucleation methods exist. The most commonly employed method uses micromanipulators to aspirate the chromatin. In this method, the oocyte is held steady at one side with the holding pipette while the enucleation pipette is inserted from the opposite side to remove, depending on the maturation state, the extruding spindle or first polar body together with the metaphase plate (Fig. 2). In order to confirm enucleation, it is desirable to visualize the chromosomal material. In mice and human oocytes, which have a clear cytoplasm, chromatin can be readily observed under bright



Livestock Somatic Cell Nuclear Transfer. Figure 2
Diagram illustrating enucleation of livestock oocytes. (**a**) When enucleation is carried out at metaphase II (*M*II), the polar body (*PB*) and a portion of cytoplasm is blindly aspirated to remove the underlying MII plate. Chromatin cannot be observed under bright field illumination, thus UV light exposure (*dark field*) is essential to confirm enucleation of the pre-stained chromosomes. (**b**) When enucleation is carried out earlier at anaphase I/telophase I (AI/TI), the extruding spindle is aspirated. In contrast to MII enucleation, the AI/TI spindle can often be observed directly inside the enucleation pipette. However, enucleation of pre-stained DNA can be checked with UV light. In both enucleation methods, the oocyte is removed from the field of view to avoid damage by direct UV irradiation when exposing the enucleation pipette

field illumination. However, the oocytes of livestock species have high lipid contents that hamper chromatin visualization, and therefore, enucleations must be made "blind" (Fig. 2a). Generally, to aid enucleation of livestock oocytes, they are briefly preincubated with the vital DNA stain Hoechst. The stained karyoplast is confirmed in the enucleation pipette by UV light following enucleation. Although this procedure does not expose the oocyte to direct UV irradiation, conflicting evidence exist whether Hoechst diminishes the developmental competence of the oocyte.

Alternatively, a blind-enucleation method without DNA staining uses the first polar body as a point of reference to subsequently remove the underlying metaphase II (MII) plate. Unfortunately, the MII plate can shift away from the polar body, rendering its removal inaccurate. However, when blind enucleation is performed earlier at anaphase I/telophase I (AI/TI) stages of the cell cycle, removal of the complete spindle is close to 100% accurate (Fig. 2b) [27]. A newer microscopy technology based on birefringence, the PolScope, allows noninvasive visualization of spindles not only in human oocytes but in other species as well. Probably due to the high cost of the PolScope, this enucleation method has not gained much popularity.

Direct enucleation by aspiration can be chemically assisted with cytoskeleton-relaxing agents, resulting in a protrusion cone containing the oocyte's chromosomes. Drugs used for this purpose include demecolcine and nocodazole, both interfering with microtubule polymerization. Other enucleation methods that have been attempted are centrifugation and laser ablation. In HMC, the zona pellucida is digested, and one third of the oocyte containing the extruding polar body and metaphase plate is manually bisected with a microblade under a stereomicroscope.

Donor cells are usually cultured in vitro and synchronized in a specific phase of the cell cycle prior to NT in order to ensure a known ploidy content. In livestock species, donor cells are preferentially used in G_0 and, to a lower extent, in G_1. Quiescent G_0 cells are arrested in the G_1 phase of cell cycle by either serum starvation or cell-contact inhibition. The advantage of these two methods is that they are drug independent, while methods to arrest cells at G_1 usually require the use of pharmacological agents. Alternatively, actively dividing presumptive G_1 cells can be selected by

collecting small-sized cells. A more accurate drug-free method to select for G_1 cells from actively dividing cultures involves using the eukaryotic "baby machine", which briefly consists of an effluent that collects newly divided and floating daughter G_1 cells from the culture medium (this methodology is described in [28]). Such a methodology would be especially useful when it is desirable to clone ES cells in G_1 (discussed further in the section Coordination of Donor and Recipient Cell Cycles). In mice cloning, ES cells are often arrested in metaphase by nocodazole or colcemid treatments.

A few alternatives exist for inserting the donor nuclear material into the enucleated oocyte (Fig. 3). In livestock species, the most common method is to insert the whole donor cell (cell transfer) into the perivitelline space to achieve contact between the membranes of donor and recipient cells. The donor DNA is then incorporated into the enucleated oocyte by cell fusion (Fig. 3a) (discussed below). Another method is to directly insert the nucleus (nuclear microinjection) into the enucleated oocyte, a common practice in mice cloning (Fig. 3b). The advantage of this method is that it bypasses the need for fusion. Nuclei are isolated using a micropipette with an inner diameter smaller than the donor cell. Pipetting the cell in and out breaks the membrane and releases the nucleus. Interestingly, it is also possible to microinject the whole cell into the enucleated oocyte cytoplasm, thus bypassing the need for nuclear isolation or fusion (Fig. 3c). Although it is unclear how the donor plasma membrane is degraded, high blastocyst development has been reported with this technique [29]. Another alternative method is to directly microinject a broken cell containing mitotic chromatin and cytoplasm, known as chromosome transfer (Fig. 3d). In HMC, phytohemagglutinin is used to glue the donor cell to the enucleated oocyte, followed by fusion.

When cell transfer is employed, the recipient-donor couplet must be fused to deliver the donor chromatin into the recipient oocyte. This is commonly achieved by electrofusion. In this method, the couplet is placed between two electrodes and short electric pulses are applied to fuse the recipient-donor membranes together. A second method involves the use of inactivated sendai virus (SV). Donor cells are briefly incubated in a solution containing SV prior to cell transfer, achieving oocyte-cell fusion by viral particles. SV-mediated fusion is less laborious and might be less stressful to the reconstructed embryo than electrofusion [30].

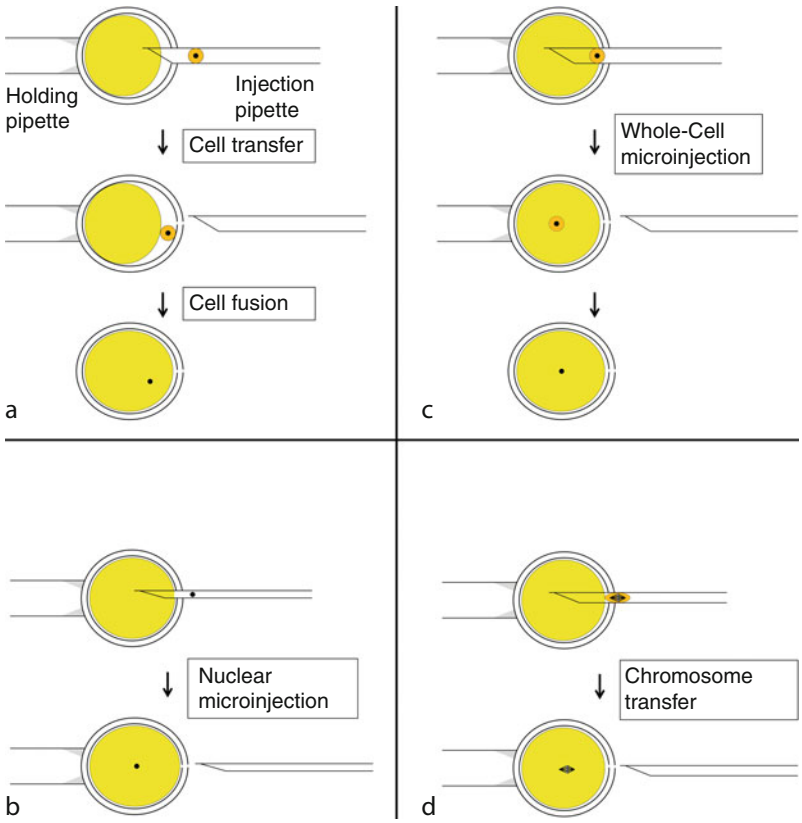
Once the donor chromatin has been incorporated into the enucleated oocyte, the reconstructed embryo is activated to begin development. The reconstructed embryo is then ready for embryo culture. Different methods of activation and embryo culture are discussed later in this entry in relation to how they affect NT outcomes. When cloned embryos reach the blastocyst stage in vitro, they are transferred to surrogate females to carry the pregnancy.

Hormonal treatments must be administered to the surrogate so that the "uterine cycle" is synchronized with the developmental stage of the transferred embryo. If this is not properly planned, the uterus will be "out of phase" compared to the blastocyst and implantation will likely fail. To achieve synchrony, in farm animals, the surrogate must be induced to enter estrus on the day of NT. Following transfer to surrogates, care of the embryos is shifted to the hands of the veterinarian. Management of pregnancy includes ultrasonography, to check pregnancy status, as well as measuring maternal levels of pregnancy proteins to assess placental development.

Problems of Cloning

Despite advances in the field, the efficiency of SCNT technology remains very low, with only 1–10% of transferred embryos reaching term, depending on the species. More than 50% of pregnancies are lost in the first trimester, and in contrast to IVF pregnancies, losses of clone pregnancies continue throughout gestation (e.g., [31]). Additionally, developmental abnormalities are commonly observed in cloned fetuses and in their placentas.

During mammalian embryogenesis, the fetus is derived exclusively from the inner cell mass (ICM) while extraembryonic tissues, including the placenta, are mostly derived from the trophectoderm (TE). It is thought that the extraembryonic membranes are the most negatively affected by SCNT, including the placentas of full-term clones. Although cloned fetuses and offspring can present abnormalities as well as large offspring syndrome (LOS), these seem to be secondary to placental dysfunction, which leads

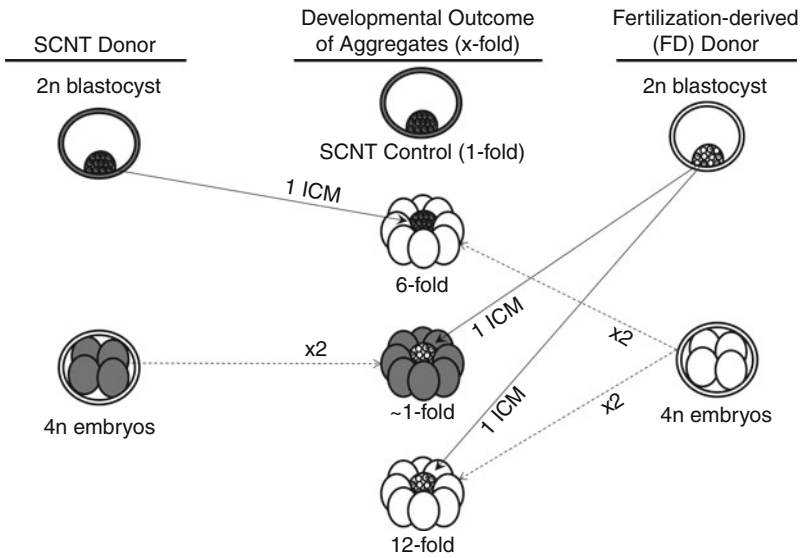


Livestock Somatic Cell Nuclear Transfer. Figure 3

Diagram illustrating different methods for donor genome transfer into recipient enucleated oocytes. (**a**) In cell transfer, an intact donor cell is transferred into the perivitelline space and the genome is then incorporated into the recipient by cell fusion. (**b**) In nuclear microinjection, nuclei are previously isolated and a single nucleus is then microinjected into the recipient. (**c**) In whole-cell microinjection, the whole cell is injected into the recipient. Eventually, incorporation of the genome into the recipient occurs by spontaneous degradation of the donor plasma membrane. (**d**) In chromosome transfer, a broken mitotic cell is microinjected into the recipient to transfer the mitotic spindle

to imbalances in placental fluid and in kidney function [32]. In sheep, placental abnormalities include a hypotrophic trophoblastic epithelium, reduced vascularization, and thickening of the trophoblast basement membrane [33]. Placentomegaly (enlarged placenta) is a common occurrence in mice and cattle cloning. Other placental abnormalities in bovine cloning include edema and hydroallantois. Developmental failure can account for fetal losses, stillbirth, and even postnatal mortality of mice, cattle, and sheep. Postnatal mortality is particularly pronounced in cloned sheep [34].

A recent study showed that indeed defects in the trophectoderm lineages rather than in the ICM are the main cause of low cloning efficiencies, at least in mice [35]. This experiment used chimeric aggregates of diploid and tetraploid embryos (Fig. 4). Tetraploid embryos are obtained by fusing the two blastomeres of a two-cell embryo. NT-ICMs were aggregated with tetraploid fertilization-derived (4nFD) early-cleavage-stage embryos. In this diploid/tetraploid "chimera," the 2n NT-ICM cells can only develop into the fetus while the 4n cells can only give rise to the extraembryonic tissues (although minimal cross-contribution was observed). By this approach, a sixfold increase in development to term was obtained compared with the nonaggregated NT control. Moreover, when ICMs from normally fertilized embryos were



Livestock Somatic Cell Nuclear Transfer. Figure 4

Experimental evidence shows that the trophectoderm lineage is severely affected in mice cloning. A diploid (2n) ICM and two tetraploid (4n) 4-cell embryos were aggregated from cloned and fertilized embryos in different combinations. The ICM forms the embryo while tetraploid blastomeres can only give rise to extraembryonic tissues. Development to term demonstrated that replacing the trophectoderm lineage in cloned embryos dramatically improves development

aggregated with tetraploid NT embryos, the birth rate was similar to that of the NT control, indicating that a normal ICM does not rescue the developmental potential of the reconstructed embryo. However, FD-ICM/4nFD aggregates showed twice the developmental rate than NT-ICM/4nFD. Thus, while trophectoderm defects are mainly responsible for low cloning efficiencies in mice, the ICM has a minor contribution as well.

It is generally thought that the low cloning efficiencies and developmental problems arise from an incomplete reprogramming of the donor nucleus.

Nuclear Reprogramming

Successful NT experiments demonstrated that differentiated cells (with a few exceptions) retain the same intact genome (i.e., nuclear equivalence) within an organism. In other words, these experiments supported that cell differentiation is not achieved through genetic changes or deletions but rather through epigenetic changes. Epigenetics regulates cell identity through chromatin modifications that are heritable through cell divisions, without altering the DNA sequence. Thus, chromatin modifications establish an epigenetic "code" that results in different gene expression programs between cell types.

Chromatin is formed by DNA associated with histone and nonhistone proteins. The chromatin template is epigenetically modified at the DNA and histone levels. DNA modification is limited to methylation (or demethylation), while histone modifications are numerous, including methylation, acetylation, phosphorylation, ubiquitination, ADP-ribosylation, biotinylation, and sumoylation. In turn, such modifications affect gene expression and the overall chromatin structure, which can be described as open or compact. During normal development, global changes in DNA methylation and histone modifications take place; much effort is being dedicated in understanding how these changes are altered or preserved in cloned embryos.

For SCNT to be successful, it is essential that the chromatin of the donor somatic nucleus is remodeled so that it becomes compatible not only with the totipotent gene expression program of development but

also with the rapid cell-cycle dynamics of early embryo cleavage.

Nuclear reprogramming, either following fertilization or SCNT, is the result of active and passive processes. For instance, in most mammals after fertilization, the sperm compact chromatin undergoes active remodeling in which protamines are exchanged by ooplasmic histones followed by global loss of DNA methylation. The sperm pronucleus also acquires distinct histone marks such as histone hyperacetylation. However, it is not clear whether such modification is acquired actively through the action of enzymes or it is the result of passive acquisition from the ooplasmic histone pool already rich in acetylation marks [36].

The timing required for completing nuclear reprogramming is unclear. Some researchers have suggested that the donor nucleus should be reprogrammed upon reaching embryonic genome activation. Such a restrictive reprogramming timing would be consistent with the lower cloning efficiencies usually observed in mice compared to bovine, two of the most cloned animals, the latter having more time for reprogramming the differentiated donor nucleus before genome activation. However, it has also been suggested that reprogramming continues up to the blastocyst stage.

To better understand the nuclear reprogramming process, the dynamics of the most important epigenetic marks and of gene expression during early embryogenesis in fertilized and cloned embryos are discussed next.

Reprogramming of DNA Methylation

DNA methylation is a reversible modification of the chromatin template at the DNA level in which a methyl group is predominantly added to cytosine of the dinucleotide sequence CpG. DNA methylation is a widely used mechanism of epigenetic regulation commonly associated with stable heritable gene silencing, heterochromatin, chromosome stability, genomic imprinting, X-chromosome inactivation, and inactivation of retroviral sequences. It has been shown that DNA methylation is essential for embryonic development, especially at postimplantation stages [37]. DNA methylation is carried out by DNA methyltransferases (DNMTs). DNMT1 maintains DNA methylation patterns after DNA replication by using the old strand as a template to methylate the new strand. De novo DNA methylation is carried out by DNMT3a and DNMT3b.

DNA methylation is dynamically regulated. Removal of methyl groups can be an active process when specific DNA demethylases are involved to remove the methyl groups, or it can be a passive process when failure to copy the methylation marks on the newly synthesized DNA leads to erasure of those marks during cell divisions. In contrast to DNA demethylation of the sperm pronucleus, which is thought to be an active process [38], passive DNA demethylation of the embryonic genome takes place following the zygotic stage.

After SCNT, DNA methylation reprogramming is usually inefficient. Mice and bovine cloned embryos have aberrantly hypermethylated DNA [39]. In sheep, SCNT embryos also tend to be significantly hypermethylated compared to fertilized embryos [40]. Such abnormal hypermethylation was observed from the 1-cell to the 8-cell stage and then at the blastocyst stage, in which the trophectoderm was hypermethylated relative to the fertilized control.

Interestingly, the rate of demethylation is similar in both SCNT and fertilized embryos, suggesting that the hypermethylated DNA pattern of SCNT embryos is probably inherited from the hypermethylated donor cell [38]. Alternatively, it has been suggested that cloned embryos undergo precocious DNA methylation due to the presence of DNMT1 associated with the donor nucleus, thus preventing passive demethylation [39].

DNA methylation reprogramming appears to be an indicator of developmental potential. In sheep, the proportion of SCNT embryos that were normally methylated at the 2-cell stage coincided with the proportion of surviving embryos reaching the 16-cell stage [38]. Similarly in mice, aberrant methylation of early-cleavage cloned embryos was proportionally associated to developmental failure to the blastocyst stage [41].

Reprogramming of Histone Modifications

The tails of the histone subunits H3 and H4 are targets for chromatin modifier enzymes, with histone methylation and acetylation modifications the most extensively studied. These modifications set epigenetic "marks" associated with either gene silencing or gene activity.

Histone acetylation is associated with open chromatin and gene activity. This modification neutralizes positive charges on histone tails and thus increases the overall repulsive negative charge of DNA on the chromatin structure. In turn, an open chromatin favors the binding of transcription factors to DNA.

In contrast, histone methylation can be either repressive or activating, depending in the lysine residue modified. These modifications act as signals that are "read" by proteins, which in turn can trigger downstream chromatin-modulating events. Together with methylated DNA, methylation of lysine 9 of histone 3 (H3K9), H3K27, and H4K20 has been implicated with heterochromatin and gene repression, while methylation of H3K4, H3K36, and H3K79 is associated with active gene expression.

In addition to abnormal DNA methylation, embryos produced by SCNT show aberrant reprogramming of histone modifications. Asymmetry of H3K9me3 fails to be established between ICM and TE in bovine cloned blastocysts compared with fertilized controls [42]. When histone acetylation marks are compared, however, cloned and normal blastocysts look similar [43, 44], suggesting that these marks are well reprogrammed. Yet, at earlier embryonic stages, the same histone acetylation marks show significant differences, with cloned embryos being hyperacetylated [42, 43].

Deregulation of DNA methylation and H3K9 methylation might be major problems during nuclear reprogramming [38, 42]. Their aberrant reprogramming leads to hypermethylated trophectoderm and extraembryonic tissues. As these epigenetic marks promote inactive chromatin, they are likely to cause downregulation of a substantial number of placental genes, explaining the placental abnormalities frequently reported in cloned embryos.

Reprogramming of Gene Expression

After fertilization or SCNT, the ooplasm induces global remodeling of chromatin, genome silencing, erasure of permissive epigenetic marks of differentiation-associated genes, and resetting the genome to an embryonic state [45–47]. Four classes of genes play an essential role to ensure normal embryogenesis following NT: (1) pluripotency-associated genes, (2) trophectoderm genes, (3) imprinted genes, and (4) differentiation-associated genes. Reactivation of pluripotent and trophectoderm genes must take place, whereas differentiation-associated genes must be silenced. Imprinted genes should be reactivated without altering the normal imprinting of somatic cells.

Pluripotent Genes Pluripotency is the capacity to differentiate into all embryonic cells. The cells of the ICM are pluripotent because they form the embryo. To recognize the state of pluripotency, landmarks of the ICM have been sought, such as stage-specific gene expression or antigens. These landmarks should be associated only with those stages and tissues known to have pluripotent potential such as the cleavage-stage embryo and ICM of the blastocyst. They should not be expressed in differentiated tissues of later development. Key genes associated with the ICM vary with species.

In mice, Oct4 is highly expressed and restricted to the ICM. It plays an essential role in early development as Oct4-depleted mouse embryos fail to form the ICM and are developmentally incompetent [48, 49]. Inducing overexpression of Oct4 is key to revert the gene expression profile of an adult differentiated somatic cell to one of embryonic and pluripotent characteristics [19]. Thus, in the mouse, Oct4 appears to be an ICM-specific marker that can be used to assess pluripotency.

Also in mice, other important pluripotent factors restricted to the ICM are Nanog and Fgf4 [50, 51]. Nanog is involved in maintenance of the pluripotent state of ES cells, for instance, by repressing differentiation into primitive endoderm [50]. Fgf4, a target gene of Oct4 [52], is necessary for proliferation and differentiation of both the ICM into embryonic tissues [53] and the TE into placental tissues [54].

In mouse SCNT blastocysts, Oct4 and Oct4-related genes often fail to be reactivated [55, 56]. Frequently, when Oct4 is expressed, aberrant spatial expression in the trophectoderm indicates faulty reprogramming [55]. Interestingly, when ES cells are used as donors, instead of adult somatic cells, Oct4 and related genes were always expressed in cloned blastocysts [56]. Since pluripotent genes are already active in ES cells, these genes do not need to be reactivated in ES-cloned embryos.

In human and large ungulate mammals, however, it is less clear what master regulatory factors are involved in the segregation of the ICM. For instance, Oct4 is expressed in both ICM and TE of bovine, goat, and human blastocysts [57–60]. Thus, for nonmurine species, we are left with less information to assess the extent of ICM-lineage reprogramming. Yet, Nanog does seem to be restricted to the ICM in bovine [61] and goats [59]. Similarly, Fgf4 is restricted to the ICM of bovine blastocysts [57]. Therefore, Nanog and Fgf4 are preferred ICM markers to Oct4 depending on the species.

To assess reprogramming of ICM, expression of Nanog and Fgf4 has been measured in bovine cloned blastocysts. Differences between studies were found, with similar [62, 63] and lower levels [57, 64] compared with fertilized controls. The disparity of results may reflect differences in nuclear transfer procedures leading to variable success in reprogramming.

Trophectoderm Genes In mice, the transition from morula to blastocyst that results in the segregation of ICM and TE is regulated by the antagonistic activity of Oct4 and Cdx2, respectively [65]. Together with Cdx2, Taed4, Eomes, and Gata3 are required for specification and development of the TE lineage [66, 67]. Tead4 appears to be a master factor in TE-lineage induction since it activates Cdx2 and Gata3 [67, 68].

Less is known about the mechanism of segregation of the trophectoderm lineage in other mammals. Although CDX2 protein seems to be a conserved TE-restricted marker, as observed in bovine and porcine blastocysts [61], transcripts levels of Cdx2 were also found in the ICM [57]. It is possible that a posttranscriptional regulation mechanism accounts for the difference between gene expression and gene product levels. Thus, to assess reprogramming of Cdx2, it might be more appropriate to look at the protein level. In contrast to mice, Cdx2 does not repress Oct4 expression in bovine [69], explaining why OCT4 is detected in the bovine TE [58]. Another difference between these two species is the expression of Tead4 and Gata3 transcripts, which are found in both ICM and TE of bovine blastocysts, and thus, their role in TE lineage segregation is not clear [57]. Further evidence that bovine TE formation is quite different to mice is the observation that Eomes is not detected in trophoblast tissue [70]. Surprisingly, although bovine TE cells will only contribute to the trophectoderm lineage, they are not committed to it before pregastrulation stages since they were observed to contribute to ICM in aggregation assays [69]. Taken together, these observations suggest that differences in expression of lineage markers between species might be the result of different implantation requirements. For instance, while mouse blastocysts implant readily at this stage, domestic blastocysts undergo elongation and have delayed implantations. Indeed, while OCT4 is expressed in both the ICM and TE of the bovine blastocyst, it is restricted to the ICM lineage at a later elongated stage [71].

Few studies have assessed reprogramming of the TE lineage in cloned embryos. In mice, CDX2 protein was frequently expressed normally at the blastocyst stage [72]. A similar result was found in the bovine [57]. Although reprogramming of Taed4 and Gata3 was faulty in bovine cloned blastocysts [57], these are not specific markers of the TE lineage in the bovine. Therefore, in nonmurine species, assessing reprogramming outcome of the TE lineage is currently limited to measuring CDX2 protein.

Imprinted Genes Imprinted genes are genes expressed either from the paternal or maternal chromosomes, but not both. Gene imprinting plays an essential role in development. When androgenetic (two paternal pronuclei) or gynogenetic (two maternal pronuclei) embryos are produced, embryogenesis is arrested shortly after implantation [73]. Thus, the paternal and maternal genomes have different contributions and must complement each other at fertilization for normal development to occur. Imprinting marks originate during gametogenesis and are generally protected from genome-wide reprogramming, such as DNA demethylation/methylation, during embryonic development [36].

Many imprinted genes regulate development, growth, and function of embryonic and extraembryonic tissues. Following SCNT, many imprinting errors can occur during reprogramming of the somatic chromatin. For an imprinted gene, simultaneous expression from the paternal and maternal alleles or lack of expression is the result of aberrant reprogramming. Because

of their regulatory growth function, deregulation of imprinted genes might explain several placental abnormalities and "large offspring syndrome" often observed in cloned animals.

Some researchers have proposed that long-term culture of donor cells, the usual scenario for embryonic stem (ES) cells, is an additional source for imprinting errors, and thus, it has been suggested that ES cells are a poor choice for NT [74]. However, using microarray technologies, Humpherys et al. [75] found no significant difference between ES-NT and noncultured cumulus cell-NT clones in terms of gene expression abnormalities including imprinted genes. Therefore, it is not clear whether extensive in vitro culture is a major problem for NT in terms of imprinting deregulation. Moreover, mammals seem rather tolerant to imprinting errors [76].

Differentiation-Associated Genes Following SCNT, silencing of differentiation-associated genes is often incomplete. For instance, cloned embryos produced with myoblast nuclei still expressed the myoblast marker GLUT4 [77]. Similar somatic epigenetic memory was also observed in Xenopus cloned embryos, which overexpressed endoderm or ectoderm markers according to the origin of the donor cells [78]. While insufficient silencing of differentiation-associated genes may alter metabolic demands, the functional consequences of retaining expression of somatic genes on the developmental potential of cloned embryos are unclear [46].

Several studies have compared global gene expression profiles between cloned and fertilized embryos. At the 1-cell stage of murine embryos, most transcripts (~98%) were similarly abundant between clones and IVF groups [45], although such similarity might be the result of maternal transcripts abundantly present in the oocyte. Nonetheless, similar expression profiles were obtained between cloned and fertilized blastocysts in bovine (e.g., [63, 79]). Thus, overall gene expression of cloned embryos appears normal. However, it is possible that small alterations in gene expression are amplified during postimplantation stages, which would contribute to the low developmental potential of cloned embryos [79].

In summary, perfect gene expression reprogramming may be unlikely following SCNT. Cell-type-specific genes may be incompletely silenced while imprinted genes are subject to deregulation. Reactivation of ICM- or TE-lineage genes might be problematic depending on the species. The mechanism of nuclear reprogramming is still a black box, and much further research is needed to understand where the bottleneck of NT is.

Factors Affecting Development of Embryos Produced by SCNT

Frequently, reports have shown that there is ample room for optimization in NT technology. Major investigated factors affecting NT success include quality of recipient oocyte, time of enucleation, nuclear donor source, cell-cycle coordination of donor and recipient cells, alterations in the timing and inducer of oocyte activation, and culture of reconstructed embryos.

Sources of Recipient Oocytes

Mammal females produce mature oocytes (oogenesis) during the ovarian cycle. The earliest stage of oogenesis is the primary oocyte within the primordial follicle. Primary oocytes are arrested at the first meiotic prophase in a quiescent state. Some of these are regularly recruited for further growth since puberty and thereafter. As primary oocytes resume growth, they increase in size and undergo cytoplasmic maturation. An oocyte must undergo cytoplasmic and nuclear maturation to be developmentally competent. Cytoplasmic maturation involves mRNA synthesis, translation into protein, and posttranslational modifications. Many mRNA and protein molecules are stored in the cytoplasm to function later during early embryo cleavage, before embryonic-genome activation. Some of the proteins produced, such as maturation promoting factor (MPF), are necessary for meiotic progression during nuclear maturation. Within the follicle, oocyte growth is accompanied with follicular growth. Indeed, oocytes obtained from medium- and large-sized follicles are developmentally better than those obtained from small-sized follicles. It seems that oocytes from the latter group have not completed cytoplasmic maturation [80]. Oocytes are surrounded by cumulus cells, and mutual communication is required for complete oocyte maturation.

Oocytes can be matured in vivo or in vitro. In vivo maturation involves collecting oocytes that have

naturally matured within the ovary of a live animal. In contrast, in vitro maturation involves aspirating immature oocytes from the ovaries of slaughtered animals and placing them on favorable culture conditions to complete the maturation process in the incubator. Although much understanding has been gained in oocyte maturation, in vitro maturation is still suboptimal at best. In vitro–matured oocytes have altered energy metabolism [80], higher chromosomal abnormalities [81], and lower developmental competence than in vivo–matured oocytes [82, 83].

For convenience, in livestock cloning, in vitro maturation is widely used as very large numbers of immature oocytes can be obtained from slaughterhouses at low cost. However, the poorer quality of these oocytes is likely to contribute to the low frequency of development usually observed in cloned embryos.

Enucleation of Recipient Oocytes

Nuclear maturation is resumed at the time of the LH surge in vivo or during in vitro conditions. The oocyte continues meiosis to progress from the arrested prophase I to metaphase I, anaphase I, telophase I, and cytokinesis with unequal cytoplasmic distribution, when half of the chromosomes are discarded in the first polar body. The oocyte progresses to meiosis II and is arrested at metaphase II. Following fertilization or artificial activation, the metaphase II–arrested oocyte resumes meiotic progression once more to complete metaphase II, anaphase II, and telophase II, discarding again half the number of chromosomes in a second polar body, achieving a haploid number of chromosomes. Enucleation can be carried out at any of these meiotic stages, although with possible different consequences (discussed later). Table 1 provides some

Livestock Somatic Cell Nuclear Transfer. Table 1 Examples of cloning experiments using recipients at different meiotic and mitotic stages of the cell cycle

Recipient cytoplast	Donor cell type	Species	Offspring	References
Enucleated GV oocytes (subsequently matured)	ES cells	Mouse	No	[84]
Enucleated Pro-MI oocyte (subsequently matured)	ES cells	Mouse	Nd	[84]

examples of cloning experiments carried out using recipients enucleated at different stages of meiosis or mitosis.

For NT, it is most important that the oocyte undergoes cytoplasmic maturation to construct a developmentally competent embryo, while nuclear maturation is less important because the oocyte DNA is eliminated at enucleation and does not form part of the embryo. Enucleation of prophase I oocytes, also known as germinal vesicle (GV) stage, has been attempted in the mouse, and the resultant recipients were capable of reprogramming donor nuclei [84, 92]. However, the reconstructed embryos are developmentally incompetent even when recipients are further matured in vitro prior to NT [84]. It is possible that GV oocytes are poor recipients because removal of their transcriptionally active chromatin [93] prevents synthesis of new mRNA necessary for completing cytoplasmic maturation. Similarly, enucleation of pro-metaphase I (pro-MI) oocytes also results in poor recipients [84]. Beyond interfering with mRNA synthesis, it is also likely that enucleated GV and pro-MI oocytes are poor recipients because enucleation disaggregates the cumulus-oocyte complex, thus depriving the oocyte of the beneficial communication with cumulus cells for completing cytoplasmic maturation during in vitro maturation.

Enucleation of metaphase II–arrested oocytes is the most common practice in cloning experiments. The rationale of using such recipients is evident as the COC is left undisturbed during the entire in vitro maturation period, thus maximizing the probability of cytoplasmic maturation. However, a practical alternative is to enucleate at anaphase I/telophase I (AI/TI). By doing so, the spindle is more efficiently removed along with less cytoplasm compared to MII enucleation [27]. AI/TI cytoplasts are further cultured to complete the maturation period and have produced lambs after SCNT [85].

Other recipients have been used for NT. Activation of MII oocytes with subsequent enucleation at anaphase II/telophase II has been done for practical reasons similar to those of AI/TI enucleation [89, 94]. Zygotes and two-cell embryos have also been enucleated and used as recipients for NT. These will be better discussed below in relation to the "potential loss of reprogramming factors" during enucleation and later in relation to the "coordination of donor and recipient cell cycles."

Potential Loss of Ooplasmic Reprogramming Factors

Enucleation involves removing the DNA material from the unfertilized or fertilized oocyte plus an unavoidable volume of ooplasm. It has been speculated that loss of ooplasmic volume is accompanied with a reduction of developmental potential, possibly due to the removal of cytoplasmic reprogramming factors. However, fusion of two or more cytoplasts prior to NT did not improve the frequency of development in mice [95]. Apparently, the amount of cytoplasmic factors in the oocyte is not critical for cloning success.

However, the above discussion does not take into account that the content of reprogramming factors in the cytoplast is dependent on the cell-cycle phase. The genome can be removed as interphase pronuclei in zygotes or with the spindle if recipients are mitotic zygotes or meiotic oocytes. In the latter case, the components of the nucleoplasm stay in the recipient as they are diluted in the cytoplasm following nuclear envelope breakdown. Recipient zygotes enucleated at interphase can only support development of nuclei obtained from 1-cell or 2-cell embryos [11] but fail consistently when more differentiated donor nuclei are transferred [11, 96, 97]. Kevin Eggan and colleagues have shown that zygotes and 2-cell embryos at the mitotic phase regain the reprogramming ability [90, 91]. These authors have proposed that reprogramming factors are sequestered in the nucleus during interphase but then redistributed throughout the cytoplasm during M phase [98]. Therefore, reprogramming factors would be lost when enucleation is carried out during interphase [99]. Indeed, Brg1, a component of the Swi/SNF chromatin remodeling complex necessary for embryonic genome activation, was absent in 2-cell cloned embryos when using enucleated interphase zygotes as recipients [99]. Further proof of this idea is supported by the observation that oocyte recipients at the germinal vesicle (GV) stage fail to develop after NT [84]. A possible contributing factor for the low developmental potential of enucleated GV oocytes and interphase zygotes is the low levels of maturation promoting factor (MPF) in these recipients (discussed below). Taken together, while the mechanism of

reprogramming remains largely unknown, essential reprogramming factors are present in the recipient's cytoplasm during M phase, but absent during interphase, at least in the mouse model [99].

It is still possible that some unknown factors beneficial for reprogramming might be stably associated with chromatin and lost during enucleation. It is well known that spindle factors are associated with the meiotic chromosomes, and therefore, enucleation could impair spindle function. Indeed, in human SCNT, it is apparently necessary to leave the recipient genome to achieve development to the blastocyst stage, at the cost of producing a triploid embryo [100]. How spindle function is affected by SCNT in livestock species will be discussed later in this entry.

Coordination of Donor and Recipient Cell Cycles

During a single cell cycle, a cell must double all of its components, segregate its genetic material equally to the two daughter cells, and undergo cell division. One exception occurs during the first few cell cycles of early embryo development where no net growth occurs. However, cell-cycle events associated with duplication and segregation of the nuclear DNA still occur. Another exception to the mitotic cell cycle is meiosis, which results in halving the chromosome number. Only germ cells undergo meiosis, while somatic cells only mitosis.

The mitotic cell cycle has four sequential phases: G_1, S, G_2, and M. During S phase (S for DNA synthesis), replication of DNA takes place. During M phase (M for *mitosis*), the cell divides all its components equally into two daughter cells. Cell growth occurs only during interphase, which constitutes G_1, S, and G_2. In a typical in vitro–cultured mammalian cell, interphase lasts about 23 hours (of a 24-hour cell cycle) while M phase is very short, lasting about one hour. S phase takes about half of the cell-cycle time (reviewed in [101]). The gap phases G_1 and G_2 are designed to provide extra time for the cell to grow and checkpoints for favorable growth conditions as well as for DNA damage.

At fertilization, the oocyte is arrested at MII, in a diploid state, while the sperm cell has completed meiosis and is haploid. Following oocyte activation by the sperm cell, the oocyte resumes meiosis to become haploid, thus matching the chromosome content and forming a viable diploid embryo. In NT, of course, it is not important that the donor chromosome content matches the recipient's since the oocyte chromatin is removed. Rather, the donor's cell-cycle phase should be compatible with the recipient cytoplasmic reprogramming content, which in turn depends on the recipient's cell-cycle phase. An important cytoplasmic reprogramming factor that has been extensively studied and has a profound effect on the donor nucleus is maturation promoting factor (MPF).

Campbell and colleagues, at the Roslin Institute (Scotland), carried out pioneer work in cell-cycle coordination between the donor cell (karyoplast) and recipient cytoplast prior to NT [16, 17, 102]. Their work suggests that cell-cycle coordination is a very important factor that should be taken into account prior to NT experiments to avoid damage of the donor chromatin.

For NT, mature MII cytoplasts are the recipients most frequently used. These contain high levels of MPF (also known as M-Cdk). MPF is a complex of two factors, protein kinase $p34^{cdc2}$ and cyclin B. MPF activity is regulated through synthesis and degradation of cyclin B and through phosphorylation of $p34^{cdc2}$. MPF activity is responsible for nuclear envelope breakdown (NEBD) and premature chromosome condensation (PCC) of the donor nucleus following activation of reconstructed embryos. MPF declines progressively after activation or fertilization and remains low during interphase. Declining MPF levels are followed by nuclear membrane reformation and DNA synthesis. NEBD and PCC occur independent of the cell-cycle stage of the donor nucleus in MII-arrested oocytes. In contrast, when activation precedes NT for a few hours, MPF activity is low and nuclear envelope integrity is maintained because NEBD and PCC do not occur.

An intact nuclear membrane prevents replication of previously replicated DNA [16, 103]. Transferring donor nuclei in S or G_2 phases into MII cytoplasts followed by activation leads to NEBD and eventually to DNA rereplication, likely resulting in ploidy abnormalities. In addition, PCC could also cause chromosomal damage of S-phase nuclear donors. These early observations suggested that only G_1 embryonic donor nuclei should be transferred into unactivated MII cytoplasts. In contrast to unactivated MII oocytes, activated oocytes serve as "universal recipients" since MPF activity is low and NEBD/PCC do not occur, allowing

the transfer of any nuclear donor without the risk of DNA rereplication. In these reconstructed embryos, coordinated replication of nuclear DNA should occur. Indeed, unsynchronized sheep blastomere donors developed to the blastocyst stage more frequently when using activated cytoplasts (low MPF) compared with cytoplasts activated following NT (high MPF) [17].

For differentiated cells, however, activated oocytes might be poor recipients because NEBD and PCC are thought to be beneficial for reprogramming the donor nucleus. In bovine, for instance, when activated enucleated MII oocytes were used as recipients for somatic donors at different stages of the cell cycle (except S phase), development did not proceed to the 8-cell stage. However, unactivated MII oocyte recipients resulted in successful in vitro development to blastocyst [104]. Similarly, activated oocytes were shown in mice to be ineffective for development to term when using cumulus cells as donors [105]. These results suggest that activated oocytes, with low levels of MPF, fail to reprogram somatic donor nuclei. Blastomeres, on the other hand, probably require little or no reprogramming and thus can be cloned successfully with activated recipients as in Campbell et al. [17]. Not surprisingly, for somatic nuclei donors, the most common recipient is the unactivated enucleated MII oocyte.

Later research showed that donor genomes at G_0, G_1, and M phases of the cell cycle can be transferred into unactivated oocytes and produce offspring. For instance, embryonic stem (ES) cells arrested at metaphase produced live mice [106]. Metaphase-arrested chromatin donors are ready to segregate and form a pseudo-second polar body, thus eliminating the extra set of chromatin. However, G_2 donors were observed to fail at extruding the pseudo-second polar body resulting in tetraploidy [104], probably because they are "out of phase" with the meiotic cytoplast. This, combined with the rereplication event, could explain the consistent failure to produce viable offspring with G_2 donors (reviewed in [107]). For G_0 and G_1 donors, spindle function inhibitors are required to prevent pseudo-polar body formation and loss of chromosomes.

There is no apparent advantage between nuclei at G_0, G_1, or M phases for NT. Somatic cell donors are routinely synchronized at the G_0 phase of the cell cycle prior to NT. However, synchronized G_0 or G_1 fetal fibroblasts were compared and no clear superiority for either donor was found. Their relative cloning efficiencies were cell-line dependent in cattle [107]. Synchronization of ES cells at G_0 or G_1 might be problematic since they have a very short G_1 phase, and if induced to become quiescent (G_0), they likely differentiate. The most successful studies in cloning mice with ES cells used unsynchronized cell populations [108, 109], but others were less successful [110, 111]. ES cells at presumptive G_1 (by selecting small cells) were used with cloning success [112] and without success [113]. ES cells were also synchronized at M phase with moderate success in several occasions [106, 114, 115].

Taken together, enucleated MII oocytes seem to be the best recipients. However, the cell cycle of the donor nuclei might be less important since cloning success is achieved with G_0, G_1, and M donors, adapting the NT protocol accordingly.

Sources of Nuclear Donor Cells

Donor cells of different ages including embryonic, ES, fetal, and adult cells have been used for NT. It has been suggested that the age of an adult somatic donor cell could be transmitted to the clone. Such belief originated from a study showing that Dolly and other cloned sheep had shorter telomeres compared to age-matched controls [116]. The belief was later emphasized by the premature death of Dolly. However, several studies in cattle and mice showed that telomere length was normal in clones; telomerase activity was found to be reactivated in cloned bovine preimplantation embryos at similar levels to fertilized controls. Yet, further studies in sheep showed that indeed clones have shorter telomeres [117], suggesting that the mechanism of telomerase reactivation differs in this species. Nonetheless, studies have not observed premature aging in clones produced by SCNT.

Beyond age, a more interesting discussion relies on the epigenetic differences between donor cells. Differentiated somatic cell types diverge in their gene expression programs but have similar global chromatin configurations and modifications, or epigenomes. However, the epigenome of differentiated cells contrasts with that of undifferentiated pluripotent cells.

It is probably the epigenome features that render one cell more amenable to reprogramming following NT rather than the cell's specific gene expression program.

Epigenomes Differentiated cells are different to pluripotent cells in several epigenetic features. Compared to pluripotent cells, differentiated cells show expansion of repressive domains marked by H3K9me3 and H3K27me3 [118]. Similarly, differentiated cells show hypermethylated DNA compared to ES cells [119] and have lower levels of histone acetylation, consistent with heterochromatin configurations [120]. In agreement, electron microscopy showed that ES cells have dispersed global chromatin architecture, while the chromatin of the differentiated cells is more compact [121].

The epigenome of a differentiated cell can be reverted to that of an ES cell by overexpression of master-regulatory genes of pluripotency, thus forming iPS cells [19]. It has been shown that iPS and ES cells have similar global DNA methylation [20, 119] and similar global levels of the histone modifications H3K4me3, H3K9me3, and H3K27me3 [118, 119, 122].

Differentiated Versus Undifferentiated Donors It is generally postulated that an inverse relationship exists between the differentiated state of a donor cell and its "reprogrammability." This hypothesis is based on NT efficiencies obtained with different types of donor nuclei ranging in their differentiation status from the totipotent zygote to the terminally differentiated cell.

It has been suggested that a small proportion of somatic stem cells are present in a tissue sample, and these cells, rather than differentiated cells, account for the successful cases of SCNT. Studies were performed to test whether terminally differentiated cells are "clonable." First attempts to clone mice with donor lymphocyte cells failed [123]. Thus, a two-step NT procedure, in which ES cells are derived from cloned embryos and used for embryo tetraploid complementation, was later adopted for lymphocyte and olfactory neurons, resulting in viable mice offspring [124, 125]. Later on, cloned mice were produced by direct NT of T lymphocyte cells, albeit with a very low efficiency [126]. These results show that terminally differentiated cells can be cloned, but does not reject the possibility that less differentiated cells might be better donors.

In contrast to terminally differentiated cells, blastomeres give high frequencies of development after NT. Yet, the developmental potential of donor blastomeres decreases as the cleavage stage of the embryo increases. In mice, a gradual decline is observed from the 1- to the 4-cell-stage embryo followed by a steep decline from the 4- to the 8-cell stage, remaining low thereafter (reviewed in [127]). In cattle, such a significant decline in developmental potential is observed after the 8-cell stage (e.g., [13]). Apparently, the greatest decline in developmental potential after blastomere NT occurs following embryonic genome activation.

Literature reviews on NT generally support that ES cells are better than somatic cells in terms of the developmental potential of the reconstructed embryos. This view is based on experimental evidence gathered from a few early studies in mice, where good outcomes were achieved using ES cells as donors [108, 109, 112]. In these studies, the cloning efficiency (here defined as development to term after blastocyst transfer to surrogate females) ranges from 8% to 21%. These values are much higher than those obtained previously with SCNT by Wakayama and colleagues, where cloning efficiencies ranged from 0.4% to 1.6% using cumulus cells [128] and fibroblasts [129], respectively. Other studies also found similarly low mice cloning efficiencies (0–2.5%) with fibroblast cells (e.g., [130]).

However, lower efficiencies (0–5.4%) were also reported with ES cell donors (e.g., [111, 113–115]). These studies question whether ES cells have indeed better developmental potential than somatic cells following NT and suggest that major reviews are relying too heavily on positive results while overlooking the negative ones. In a critical review, Oback and Wells [127] argue that postimplantation sample sizes are generally small in animal cloning and thus insufficient to draw robust conclusions. Furthermore, they claim that many confounding factors exist in nuclear transfer experiments, rendering comparisons difficult. These factors include cell line and sex, confluency of donor cell culture, cell-cycle, passage number, and nuclear transfer procedure. Oback and Wells conclude that to determine whether ES cells have a better developmental potential than differentiated cells, it is necessary to carry out large NT experiments in which ES cells and the same cells induced to differentiate prior to NT are directly compared while keeping other parameters

constant. Taken together, the published data are inconclusive but suggest that ES cells give better cloning efficiencies than somatic cells. Indeed, only one study directly compared the developmental potential of ES cells to somatic cells, resulting in a cloning efficiency of about four times greater with ES cells [112].

According to Jaenisch's group, the cloning efficiencies with ES cells are 10- to 20-fold higher than with somatic cells after embryo transfer [76]. These authors have proposed that ES cells have better developmental potential following NT because they are undifferentiated and thus require less reprogramming than differentiated cells [76]. For instance, ES cells already express pluripotency-associated genes such as Oct4, Nanog, and Sox2, needed for early embryogenesis. In contrast, these genes need to be reactivated in differentiated cells. A second hypothesis could be that ES cells can be more easily reprogrammed as they have overall open chromatin configurations compared to differentiated cells, which typically have compact heterochromatin. The open and accessible chromatin of ES cells might facilitate the binding of nuclear remodeling factors found in the oocyte's cytoplasm.

Unfortunately, ES cells cannot be stably derived in livestock species yet. However, it is probably a matter of time until the mechanism and factors that govern pluripotency are discovered in these species. When derivation of ES cells in farm animals becomes possible, it would be of interest to further test their developmental potential compared to that of somatic cells following NT.

Differential Organelle Contribution

During fertilization, the oocyte and sperm each contribute a haploid set of chromosomes to form a diploid zygote. However, most of the cytoplasm and organelles are inherited from the oocyte. Among these are mitochondria, with their own genetic material. An exception to this is the centrosome, which is partly contributed by sperm. The differential contribution of the centrosome and mitochondria can affect NT outcomes. These contributions can be altered by the method used to transfer the donor chromatin.

Centrosome Inheritance The centrosome is the main microtubule-organizing center (MTOC) of animal cells involved, among other functions, in assembly of the mitotic spindle for cell division. This organelle is composed of two centrioles surrounded by abundant centrosomal proteins, which are often referred to as pericentriolar material (PCM). The centrosome is replicated during the S phase of the cell cycle from material stored in the cytoplasm. Mammalian oocytes have no centrioles but contain PCM that is recruited by the sperm centriole after fertilization, restoring a functional centrosome. Mice, however, are acentriolar until late preimplantation stages, achieving embryo cleavage by using maternal MTOCs.

In SCNT, the MTOCs associated with the oocyte meiotic spindle are removed while the centrosome from the donor cell is introduced [131]. It is not well understood the composition of the donor centrosome once within the recipient. Also, it is unclear whether the donor centrosome recruits leftover PCM from the recipient oocyte [131]. Nevertheless, it is thought that the donor centrosome needs to be remodeled into a zygotic centrosome for normal embryonic cleavage [131].

Centrosomes from donor cells at S phase might be reduplicated following oocyte activation in the subsequent S phase [132]. This would lead to the formation of extra spindles followed by aberrant segregation of chromosomes, a phenomenon frequently observed with S-phase donors. Even when using G_0 donors, 35% of bovine reconstructed embryos had abnormal cleavage correlated with abnormal centrosome number and distribution [133]. This suggests that providing only one centrosome does not guarantee normal centrosome function following NT.

An early NT study in monkeys suggested that removing the MII meiotic spindle depletes the oocyte of spindle proteins NuMA and HSET [134]. These proteins closely associate with maternal chromosomes and are required for mitotic spindle function. This study showed disorganized spindles with misaligned chromosomes in all reconstructed embryos, which were unable to produce pregnancies. However, in a later study using a different nuclear transfer procedure, NuMA location and spindle formation were normal in most reconstructed monkey embryos [135]. Taken together, these results suggest that different parameters of the NT procedure can affect centrosome function.

Mitochondrial Inheritance The mitochondrion is a special organelle, having a double membrane and containing its own genome (mtDNA). The main function of mitochondria is to produce energy in the form of ATP. Other functions include production of reactive oxygen species (ROS), calcium signaling, and apoptosis. mtDNA encodes for 13 mitochondrial proteins involved in ATP synthesis, for 22 tRNAs, and for 2 rRNA molecules involved in translating mitochondrial proteins [136]. Replication and expression of mtDNA are regulated by the nuclear genome through the expression of transcription and replication factors that translocate into mitochondria.

Mitochondria are maternally inherited because sperm mitochondria are targeted for destruction upon fertilization [137]. In SCNT, the donor cell mitochondria can persist and contribute to the reconstructed embryo, thus resulting in heteroplasmy (two different populations of mtDNA). Donor mitochondrial contribution is quite variable, ranging from 0% to 59% (reviewed in [138]). A bovine oocyte contains about 250,000 mitochondria, a 100-fold compared to a somatic cell [139]. Therefore, high heteroplasmy probably results from preferential amplification of donor mitochondria.

Compatibility between nuclear and the recipient's mtDNA seems to play an important role in SCNT. It has been shown that autologous SCNT (a female donor cell is transferred to its own enucleated oocyte) improves the frequency of pre- and postimplantation development when compared with heterologous SCNT [140]. Likewise, bovine reconstructed embryos developed more frequently as the similarity between the mtDNA haplotype of the donor and of the recipient cell increased [141]. Moreover, it is thought that the developmental block commonly observed in interspecies-SCNT embryos is due to genomic-mitochondrial incompatibilities [142].

Transfer of Donor Nuclei From the above discussion, it is apparent that the method chosen to deliver the donor chromatin into the cytoplast can have implications in terms of organelle inheritance of the reconstructed embryo. By whole-cell fusion, the donor cell contributes the nuclear and cytoplasmic material including mitochondria and centrosome, while nuclear microinjection does not. This would not seem to be problematic in mice since maternal MTOCs suffice to form the spindle-chromosome complex during cell division. In livestock species, however, centrioles function in spindle formation during early embryo cleavage. Nonetheless, pigs have been cloned by nuclear microinjection (e.g., [83]), suggesting that the presence of a centriole is not necessary for embryo cleavage in pigs. While cell fusion contributes mitochondria and cytoplasm, there is no evidence that either heteroplasmy or the amount of somatic cytoplasm contributed by a single donor cell is enough to reduce the developmental potential of the reconstructed embryo.

Cell fusion has been directly compared to nuclear microinjection in cloning experiments. In pigs and cattle, greater preimplantation development with the cell fusion method has been reported [143, 144]. Unless centrioles are often transferred along with residual cytoplasm during nuclear microinjection, these results suggest that centrioles are not strictly necessary for embryo cleavage, although their presence enhance preimplantation development. In mice, conflicting data have been reported when comparing the two methods. These mixed results are consistent with the exception that centrioles are dispensable in mice during preimplantation stages. Interestingly, it has been reported that the quality of blastocyst produced by cell fusion was better; analysis showed that piezo-assisted microinjection can cause DNA damage by shear forces [145].

Activation of Reconstructed Embryos

In mammals, egg activation is achieved when summation of intracellular Ca^{2+} oscillations reach a minimum threshold. Egg activation leading to Ca^{2+} oscillations is thought to be triggered by a sperm-specific isoform of PLC, known as PLC zeta (PLCζ), introduced into the oocyte following fertilization [146]. It has been suggested that summation of these Ca^{2+} oscillations encodes information for directing later development. For instance, few Ca^{2+} oscillations lead to decreased implantation, while excess Ca^{2+} oscillations, to increased postimplantation failure in mice [147].

Maturation promoting factor (MPF) also plays an important role in MII arrest and in regulating Ca^{2+} oscillations (reviewed in [148]). Inhibiting MPF activity enhances oocyte activation. Inhibition of protein synthesis (by cyclohexamide) or inhibition of

phosphatases (by 6-dimethylaminopurine [6-DMAP]) can decrease the activity of MPF and induce meiotic progression. These inhibitors are usually combined with stimulation of Ca^{2+} oscillations to efficiently activate reconstructed embryos. However, it is important to bear in mind that these chemicals have broad spectrum actions and can interfere with other cellular processes [148].

In the absence of the natural inducer of egg activation, several artificial methods exist to trigger activation of reconstructed SCNT embryos, including electrical pulses, ethanol, calcium ionophore A23187, ionomycin, strontium, and thimerosal (Thi)/dithiothreitol (DTT). With the exceptions of strontium and Thi/DTT, the other treatments induce a single Ca^{2+} oscillation [149]. Comparisons of several activation methods in mice cloning could not found a preferred method [95].

To mimic more physiological activation events, sperm-mediated activation methods have been used. Fertilized oocytes were used as recipients, but such approach has not produced any significant improvement in developmental potential to term in mice or bovine cloning [150, 151]. To avoid the added complication of removing the sperm chromatin, an alternative activation protocol involved directly injecting the sperm activating factor PLCζ, in the form of mRNA, resulting in long-term Ca^{2+} oscillations [152]. This approach improved gene expression patterns of several genes and reprogramming of the repressive histone mark H3K27me3 [153]. Therefore, mimmicking sperm-activation events might improve reprogramming of the donor nucleus.

Another factor that can be controlled in activation protocols is the timing of activation following embryo reconstruction. It is common practice to delay activation for 1–3 h to extend the time for nuclear remodeling after nuclear envelope breakdown. This "nuclear exposure" has been shown to be beneficial in bovine [104]. However, the effectiveness of this approach likely varies between species since in monkeys, it was shown that development improves by immediate activation [154].

Culture of Reconstructed Embryos

For animal cloning, the reconstructed embryos can be directly transferred to a surrogate female or cultured in vitro to the blastocyst stage followed by transfer. Since in vitro culture functions as a first filter to select growing embryos with exclusion of the developmentally arrested ones, it allows transferring fewer embryos to surrogates and is, therefore, widely used. Many factors can be manipulated in an in vitro culture system to affect the developmental outcome of cloned embryos. These factors include incubation temperature, media composition and osmolarity, oxygen tension, culture substrate, communal or individual culture, embryo concentration, cocultures, medium renewal, and embryo stress. Analyzing each of these factors is outside the scope of this entry, but the reader is encouraged to read Vajta et al. [155] for a comprehensive review on embryo culture. Instead, an eccentric culture preference of cloned embryos will be highlighted.

Usually, NT experiments culture cloned embryos in conditions designed for normal embryos. However, as discussed during *nuclear reprogramming*, a cloned embryo is usually not a normal one. Several reports support that reconstructed embryos have altered metabolism and culture requirements compared to normal embryos (e.g., [77, 156]). For instance, due to incomplete reprogramming of the donor chromatin, mice cloned embryos produced with muscle nuclei overexpress the glucose transporter GLUT4 and thus exhibit enhanced rates of glucose uptake and benefit from somatic cell culture media instead of standard embryo culture media [77]. The benefits of using somatic cell culture media included improved blastocyst formation rate and increased total cell numbers in the resultant blastocysts. These results suggest that normal embryo culture conditions might subject cloned embryos to a harsh selection process, while somatic-like culture media seem to maintain the viability of reconstructed embryos, allowing them more time to complete nuclear reprogramming. Nonetheless, sequential use of different embryo culture media has been shown to dramatically improve blastocyst development of mice reconstructed embryos [156]. Taken together, culture media for reconstructed embryos should be optimized to match the donor cell preferences.

Perinatal/Neonatal Care

Once cloned blastocysts have been transferred to surrogate animals, work is usually limited to monitoring

the progress of pregnant surrogates of livestock species. However, it is important to bear in mind that cloned animals are prone to suffer health problems arising from epigenetic errors caused by incomplete nuclear reprogramming of the donor chromatin. Respiratory difficulties seem to be the main problem in cloned neonates. Other health problems include myoarthroskeletal malformations and metabolic abnormalities. It is advisable that cloned neonates are regarded as being at high risk [157], and thus, intensive care should be provided to increase survival. Some studies suggest that veterinary intervention during the perinatal and neonatal periods can improve the survival rates of cloned livestock animals (for a review, see [158]).

Perinatal care involves monitoring readiness for birth, induced parturition, and induction of final pulmonary maturation. For yet unclear reasons, pregnancies of cloned fetuses often extend beyond the normal gestation period [157]. While this might indicate that cloned fetuses require more time in utero to complete maturation, prolonged gestations are associated with increased birth weight, dystocia, and increased morbidity and mortality [157]. To prevent these problems, induction of parturition is commonly carried out. In parallel, to aid pulmonary maturation, pharmaceutical drugs are often administered to promote production of lung surfactant necessary for alveoli inflation. Due to respiratory deficiencies, cloned neonates can quickly become hypoxic and acidotic. Lack of vigor and weak suckling reflexes are other common symptoms of cloned neonates. Thus, intensive care of the cloned neonate is crucial, even for preventative measures. Good care practice includes providing oxygen for at least one hour, heat, mechanical ventilation for more severe cases, and monitoring blood parameters [158].

Improving Development

From the above discussion, it is clear that veterinary science can play an important role in the management of pregnancy and neonatal care to improve the survival rate of cloned animals. In the laboratory, researchers have attempted many things to improve cloning efficiencies. The two most promising areas that have yielded the best results are chromatin remodeling treatments and embryo aggregation.

Chromatin Remodeling Treatments

Relaxation of the donor chromatin could enhance the reprogramming of the donor nucleus. To this end, a few different approaches have been implemented to treat donor nuclei or SCNT embryos. Well-defined chemical treatments include trichostatin A (TSA) and 5-azacytidine (5-Aza).

Early in the mouse zygote, both parental genomes are rich in histone acetylations, suggesting that these epigenetic marks are important for reprogramming. Treatment of donor cells with TSA, a histone deacetylase inhibitor, has been used to increase histone acetylation and promote opening of the chromatin. Such treatment led to increased development to blastocyst stage in bovine [159]. Later on, optimized TSA treatments resulted in significant increases (up to tenfold) in development to term compared to untreated groups in mice cloning (e.g., [160]). Remodeling of the donor chromatin with TSA has been the single most important innovation for improving consistently the efficiency of SCNT [95, 161].

DNA methylation patterns have been observed to be abnormally high in cloned embryos [36], and therefore, some researchers have attempted to correct this epigenetic abnormality by treating the donor cells with 5-Aza, a DNA demethylating drug. Such treatment, however, has led to poor blastocyst development [159]. A similar decrease in developmental potential was also observed when using 5-Aza in cloned embryos at the 2-cell stage [162]. It is thought that such failure is due to the effects of 5-Aza on massive DNA demethylation and subsequent DNA rearrangements and formation of pronuclei [163]. Chromosomal abnormalities resulting from 5-Aza treatment would be consistent with the regulatory function of DNA methylation on chromosome stability. These unsuccessful results also suggest that following fertilization, active global demethylation of the sperm chromatin must be well regulated to prevent chromosomal damage. Indeed, the sperm genome retains some methylated regions including centromeres, which contribute to chromosomal stability. When 5-Aza and TSA are used together, however, a synergistic effect has been observed in cloned bovine preimplantation development compared to TSA treatment alone [164].

Another approach to induce chromatin relaxation involves using cell extracts from Xenopus eggs to treat

differentiated donor cells prior to NT. The rationale is that many of the reprogramming factors present in the mammalian oocyte might also be present in the frog egg. This approach showed a significant increase in development to term in sheep [165]. Treated cells had lower global levels of the heterochromatic epigenetic mark H3K9me3, thus probably contributing to more relaxed chromatin configurations and to improved cloning efficiencies.

Notoriously, somatic cells have even been preheated at nonphysiological temperatures prior to NT in order to relax higher order chromatin; however, development to term was not significantly higher than nontreated control [166].

Overall, when the "right" treatment is used (such as TSA), remodeling of donor chromatin appears to improve development of cloned embryos. A better understanding of chromatin remodeling following fertilization or NT might help design a "cocktail" of drugs to efficiently remodel the differentiated chromatin of somatic donor cells.

Embryo Aggregation

Two hypotheses exist supporting the rationale of embryo aggregation. One involves the *community effect* in which the ability of a cell to take a specific differentiation pathway is enhanced when more neighboring cells are differentiating in the same way [167]. Since cloned embryos tend to have lower cell numbers than fertilized controls, at least in mice [168], the *community effect* obtained by aggregation might enhance the formation of the ICM and/or TE lineage [169]. The second hypothesis involves *epigenetic embryo complementation* [168, 170]. While the aggregated embryos are genetically identical, reprogramming defects of one embryo can be compensated by another embryo, and vice versa. Although embryo complementation is largely unknown, it is thought that cell-cell communication between blastomeres, by permeable gap junctions or by autocrine and paracrine factors, compensates for deficiencies between blastomeres [170]. It is possible that both hypotheses work together since greater cell numbers will increase the opportunities for epigenetic embryo complementation.

Aggregation of four-cell cloned embryos improved developmental potential and gene expression. In mice, expression of Oct4 increased to normal levels, the number of cells was higher at the blastocyst stage, and development to term was increased eightfold compared to single-clone embryos [168]. In bovine, embryo aggregation resulted in blastocysts with double the number of cells and in upregulation of a subset of differentially expressed genes involved in transcription, biosynthesis, and signaling compared with single-clone embryos [170]. Overall, embryo aggregation is an interesting approach to improve the quality of a cloned blastocyst.

RNA interference

While this entry was in production, an article was published in which mice cloning efficiencies were increased tenfold and the gene expression of the resultant offspring was similar to IVF controls [171]. Such impressive outcome was simply achieved by knockdown of a single gene, Xist, by RNA interference. This study showed that cloned mouse embryos usually undergo permature overexpression of Xist as well as aberrant X chromosome inactivation. Although regulation of X chromosome inactivation differs between mammals [172], cloned bovine embryos were also observed to overexpress Xist [173]. Therefore, the next logical step would be to try the same Xist knockdown approach in livestock species.

Summary Points

- SCNT involves using a somatic donor nucleus and an enucleated oocyte to produce an animal genetically identical to the donor.
- The first NT experiments were carried out in 1928, the first successful SCNTs in the late 1950s, and the first cloned adult mammal (Dolly) in 1996.
- Basic research in the nuclear reprogramming mechanism following SCNT could yield transferable knowledge to produce iPS cells safer for regenerative medicine. Realistic pharmaceutical/agricultural applications of SCNT include production of transgenic animals and cloning prizewinning animals for breeding purposes.
- NT is commonly carried out with micromanipulators, although micromanipulator-free NT is possible and effective. NT steps include oocyte maturation, enucleation, nuclear transfer, fusion, activation, embryo culture, and embryo transfer.

- Common problems in SCNT include low cloning efficiencies and developmental abnormalities. The placenta is mostly affected by the technique.
- Problems in SCNT probably originate from incomplete reprogramming of the donor chromatin. Faulty chromatin reprogramming in cloned embryos includes hypermethylated DNA and increased H3K9me3, especially in the TE.
- Gene expression reprogramming is usually aberrant in cloned embryos, with differences between species. Pluripotent genes often fail to be reactivated in mice, although reactivation is normal when ES cells are used as donors. Fewer markers exist to assess reprogramming of pluripotency and TE lineage in livestock species, and the existing data are rather conflicting. Imprinted genes are often deregulated and differentiation-associated genes incompletely silenced.
- MII oocytes are the best recipients as they have high MPF levels. Reprogramming factors are lost when enucleating interphase recipients, which also have low MPF levels.
- Donor nuclei can be in G_0, G_1, or M phase of the cell cycle. No specific cell type has been found to be advantageous for NT; however, inconclusive data suggest that ES cells are superior donors than somatic cells.
- Centrosomal structures are recovered by introduction of centrioles along with donor cell in livestock species, although normal spindle function is not always observed in reconstructed embryos.
- Increased compatibility between genomic DNA and mtDNA is beneficial for SCNT.
- In livestock species, cell fusion appears to result in better development than nuclear microinjection, consistent with centrosomal function recovery.
- There is no preferred method for oocyte activation.
- Normal embryo culture media are not optimal for reconstructed embryos.
- Cloned neonates are at high risk, and thus, intensive care should be provided to improve survival.
- Remodeling of the donor chromatin with TSA has been the single most successful innovation for improving consistently the efficiency of SCNT.
- Aggregation of cloned embryos seems to improve embryo quality by two working models: community effect and epigenetic embryo complementation.
- X chromosome inactivation appears to be deregulated in cloned embryos and correcting this by Xist knockdown can dramatically improve development.

Future Directions

Although efforts are being made toward dissecting the mechanism and the factors that bring about nuclear reprogramming of the donor chromatin, scientists are still quite far away from gaining a clear understanding. Even if there is general consensus that the low efficiency of SCNT originates from faulty nuclear reprogramming, there is no common agreement in where the bottleneck is. Does it lie in the reprogramming of the trophectodermal lineage or is the pluripotent lineage to blame? Is deregulation of imprinted genes the culprit of low cloning efficiencies or is it the incomplete silencing of differentiation-associated genes? Is incomplete remodeling of the overall chromatin structure preventing the SCNT technology from thriving? Does the bottleneck lie in the misregulation of X chromosome inactivation? Perhaps all these are contributing factors responsible for the low SCNT outcomes. Unless much further efforts are dedicated toward understanding the mechanism of nuclear reprogramming inside the oocyte, scientists will not have clear answers to such questions. The great improvement in cloning efficiencies observed with TSA treatment and Xist knockdown gives much hope and emphasizes that innovations can radically improve the technology.

In basic science, SCNT is not limited to nuclear reprogramming. For instance, SCNT interferes with centrosomal function in livestock species, and more research is needed to understand donor centrosome behavior, spindle formation, and embryo cleavage following NT in these species. SCNT can also provide insight into genomic-mitochondrial interactions, the effects of heteroplasmy, and preferential mitochondrial amplification. Such studies might warrant a change in technique such as the method by which the donor chromatin is delivered into the cytoplast.

As the science behind SCNT will be better understood through years of research, it is likely that the outcomes of this technology will closely match those

of IVF. When that day comes, widespread use of SCNT technology in livestock species would be feasible. However, being an artificial reproductive technology, SCNT is surrounded by ethical issues and regulations that should be fully contemplated to ensure good use of the technology for the benefit of society.

Lodging Resistance in Cereals

Pete M. Berry
Sustainable Crop Management, ADAS UK Ltd, Malton, North Yorkshire, UK

Article Outline

Glossary

Anchorage failure moment Anchorage failure at the point of failure. Also described as anchorage strength.

Base bending moment Wind-induced force acting on the base of the shoot or the anchorage system. Also described as leverage force.

Brackling Lodging resulting from buckling of the upper half of the stems.

Crop management Agronomic methods of growing crops.

Failure wind speed Wind speed at which a plant will lodge.

Hagberg falling number (HFN) Measure of bread making quality.

Lodging Permanent displacement of cereal stems from their vertical position.

Lodging-proof ideotype Plant dimensions required to achieve a lodging-return period of 25 years.

Necking Lodging resulting from buckling of the stem just below the ear.

Plant growth regulators – (PGRs) Chemical growth regulators that reduce the rate of stem extensions.

Root lodging Lodging resulting from failure of the anchorage system.

Stem failure moment Stem strength at the point of failure. Also described as stem strength.

Stem lodging Lodging resulting from buckling of the lower stems.

Definition of the Subject

Lodging is the process by which the shoots of small grained cereals are permanently displaced from their vertical stance. Lodging limits yield potential and reduces grower profits, but it is difficult to control because it is a complex process that is influenced by many factors including wind, rain, topography, soil type, previous crop, crop management, and disease. Significant progress was made during the 1950s, 1960s, and 1970s to reduce lodging risk by the introduction of semi-dwarf varieties. The reduced lodging risk of these shorter varieties enabled them to respond to greater amounts of fertilizers and this was a significant reason for the steady improvement in global cereal grain yields starting in the late 1960s. However lodging is still a major problem in many countries and there is an urgent need to improve lodging resistance to further increase the yield of cereal species.

Introduction

Lodging is the permanent displacement of cereal stems from their vertical position (Fig. 1) and usually only occurs after the ear or panicle has emerged. This can reduce yield by up to 80% and causes several knock-on effects including reduced grain quality, greater drying costs, and slower harvest. It is a problem that limits cereal productivity in both developed and developing countries.

Lodging is a complicated phenomenon that is influenced by many factors including wind, rain, topography, soil type, previous crop, husbandry, and disease. It is frequently associated with conditions that promote plant growth such as an abundant supply of nutrients. Significant progress was made during the 1950s, 1960s, and 1970s to reduce lodging risk by the introduction of semi-dwarf varieties. These shorter varieties had a greater lodging resistance and could respond to greater amounts of fertilizers. For these reasons the introduction of semi-dwarf varieties was one of the most significant reasons for the steady improvement in grain yields starting in the late 1960s, which has resulted in cereal yields increasing by as much as 1 t ha^{-1} per decade in western Europe and 0.5 t ha^{-1} in many American and Asian countries [1]. The continued improvement in yields in some

Lodging Resistance in Cereals. Figure 1
Lodging in wheat

countries has been significantly aided by the use of plant growth regulators (PGRs) that further reduce crop height making cereals even more resistant to lodging. Four major types of PGRs have been introduced including chlormequat chloride during the mid-1960s, ethephon during the late 1980s, trinexapac-ethyl during the mid-1990s, and prohexadione-calcium in the 2000s. In France, Germany, and the UK, which have among the highest cereal yields in the world, PGRs are now applied to more than 70% of wheat area (W. Rademacher 2004, personal communication).

Dwarfing genes and PGRs have been very effective tools for reducing lodging risk and maintaining steady improvements in yield. However, they have not eradicated lodging and there is evidence that farmers will not be able to rely on these tools for further reductions in lodging risk in order to counter the escalating lodging risk resulting from continued yield increases. Several studies have shown that yield is reduced when crops are shortened too much [2–7]. The reduction in yield appears to be exacerbated by high temperatures or drought stress. Several of these studies indicate that the minimum crop height for optimum yield lies between 0.7 m and 1.0 m. Many modern varieties are already within this height range. While there is scope for further shortening with PGRs through sequential applications, pressure may be brought to bear to reduce their use because some PGRs leave residues in the grain [8]. It is therefore clear that new methods of improving lodging resistance in cereals must be developed.

During the 1990s and 2000s collaborative studies by biologists and engineers have elucidated the mechanisms of lodging in cereals [9]. Crucially it has been demonstrated that lodging may occur by two mechanisms: stem lodging and root lodging. These studies have culminated in models of the lodging process which help to understand how the plant interacts with its environment during the lodging process and identifies the most important plant traits that must be targeted to improve lodging resistance. Several studies have also explained how variety, sowing date, seed rate, nitrogen fertilizer, and PGRs affect lodging. This improved understanding offers the prospect of designing a lodging proof ideotype for cereals which may be achieved through a combination of crop management and plant breeding. This entry on lodging resistance in cereals describes (1) the impact that lodging in different cereal species has on crop yield and grain quality, (2) the mechanisms of the lodging process, (3) the effect of cultivar choice and crop management on lodging resistance, and (4) prospects for improving lodging resistance. This entry is intended to be a concise summary of the most important aspects of lodging resistance in cereals, and for a more comprehensive review readers are directed to Berry et al. [10].

Impact of Lodging on Grain Yield and Quality

Grain Yield

Lodging can reduce cereal yield by reducing the grain size and number or through reducing the amount of crop that can be recovered at harvest. This section deals only with physiological reductions in yield associated with lodging. The greatest lodging-induced reductions in grain yield occur when crops are lodged flat at anthesis or early on in grain filling. Yield reductions from this type of lodging have been reported to reduce yields of wheat by [11] 31–80% [12], barley by 28–65% [13–15], oats by 37% [16], and rice by 38% [17]. All of the above studies, apart from Easson et al. [12], artificially lodged the plants. This was achieved by growing the plants through wire netting and then moving the wires to effect lodging. This method has the advantage of lodging the crops at specific dates and at different angles, but may induce damage not normally incurred with natural lodging. Easson et al. [12] compared the yields of crops grown at high seed rate, which lodged

naturally, with those at low seed rate, which experienced negligible lodging.

Smaller yield losses have been observed when the angle of lodging is less than 90° from the vertical. Lodging at 45° causes between one quarter and one half of the yield losses incurred from 80° lodging in wheat [18], barley [14], and oats [16]. Smaller yield losses also occur when lodging occurs at a later stage of development. Artificial lodging at the ear emergence, milk, soft dough, and hard dough stages reduced yield by 31%, 25%, 20%, and 12%, respectively [11]. Stapper and Fischer [19] supported these observations by showing that about 0.5% of the potential yield was lost for each day of the grain filling period that a crop was lodged flat. Crops that lodge before anthesis often have smaller yield losses than crops that lodge soon after anthesis [18]. This appears to be associated with the upper one of two internodes bending upward to partially re-erect the crop. Crops that lodge after anthesis have completed stem extension and are unable to re-erect themselves. In natural situations, the re-erected crops are very unstable and are usually re-lodged by unexceptional weather conditions [12].

Grain Quality

Artificial lodging has been observed to cause significant reductions in grain quality in terms of the bread making quality (measured as the Hagberg falling number [HFN]), individual grain weight, and the specific weight of the grain [10]. Lodging increases the likelihood of grain sprouting in the ear due to the more moist environment (Fig. 2) and this reduces HFN. Lodging induced during early grain filling reduced grain quality by reducing the HFN from 289 s to 114 s, reducing individual grain weight from 42.2 mg to 37.2 mg, and reducing specific weight from 70.3 kg/hl to 65.8 kg/hl. Lodging after early grain filling caused smaller effects on quality. A HFN of at least 250 s is required to produce good quality bread. Similar effects on grain weight and specific weight have also been observed in wheat [11, 20], barley [13, 21], and oats [22]. In the UK, the harvest year of 1992 was a severe lodging year with 16% of the wheat area lodged [23]. In this year the national average HFN fell from a 5-year average of 287 s to 254 s, thus significantly reducing the amount of bread making grain produced in this year.

Lodging Resistance in Cereals. Figure 2
Sprouting in a lodged wheat crop

Also in this year, the specific weight of wheat grains fell from 77 kg hl^{-1} to 73 kg hl^{-1} and the number of small grains (<2.0 mm) increased from 1.9% to 2.6% [24]. It is likely that at least a proportion of these effects were caused by the greater than usual lodging experienced in this country during this year.

Mechanisms of Lodging

Lodging can either occur through stem buckling (stem lodging) or displacement of the roots within the soil (root lodging) (Fig. 3). During stem lodging the roots are held firmly in a strong soil and the wind force buckles the stem. Stem lodging can occur due to buckling of the lower internodes. Buckling of the middle internodes is commonly known as "brackling" and is often observed in barley (Fig. 4) [25] and oats. Buckling of the peduncle just below the ear is known as "necking" and occurs most frequently in barley [26]. Root lodging becomes more likely when the anchorage strength is reduced by weak soil or poorly developed anchorage roots. Rainfall can reduce soil strength by several fold and has an important influence on the anchorage strength of cereals.

Very few observations have been reported of the lodging process as it occurs and conjecture exists as to whether stem lodging or root lodging predominates in cereals. Wheat and barley have been observed to root lodge [27, 28] and to stem lodge [25]. However, recently a quantitative understanding of root and shoot

Lodging Resistance in Cereals. Figure 3
Wheat plants leaning as a result of root lodging

Lodging Resistance in Cereals. Figure 4
Brackling in barley

lodging has been developed for wheat and barley showing that both types of lodging are possible depending on the circumstances of a particular crop [29, 30]. This has been confirmed in wheat by direct observations of both mechanisms occurring during wind-tunnel experiments on field-grown winter wheat [31].

The lodging models described by Baker et al. [29] and Berry et al. [30] calculate the wind-induced base bending moment of a shoot from plant characteristics and meteorological data. The base bending moment is then compared to the failure moments (strength at the point of failure) of the stem base and of the anchorage system. Stem lodging is assumed to occur when the base bending moment of a single shoot exceeds the failure moment of the stem base. Root lodging is assumed when the base bending moment of all the shoots belonging to a single plant exceeds the failure moment of the anchorage system. The following sections describe current understanding about how the components of lodging (base bending moment, stem failure moment, and anchorage failure moment) may be calculated and what factors influence them.

Base Bending Moment

The wind-induced force acting on the upper sections of a shoot or plant results in a bending moment at the plant's base. This can be described as the shoot leverage. The coherent waving of cereal shoots, apparent even in light winds, provides evidence that cereal shoots are subjected to varying forces and illustrates the importance of including the shoot's motion in any calculation of the applied base bending moment. Baker [32] attempted to account for the dynamic nature of shoot movement by considering the forces that act on an idealized shoot and assuming that the shoot's movement could be modeled as damped harmonic oscillator. The theoretical modeling work described in [32] and [29], which was later validated in wind-tunnel experiments using field crops [31], showed that the wind-induced base bending moment of wheat could be calculated from a range of environmental and plant inputs. These include: the wind speed at crop height, the natural frequency of the shoot (rate at which it oscillates), the damping ratio of the shoot (which describes the rate at which oscillations die out), the height at center of gravity of the shoot, and the projected area and drag coefficient of the ear. These parameters can be used to estimate the bending moment at the base of the shoot for a shoot with a stiff stem such as wheat. Additional parameters are required to estimate the bending moment of more flexible stems such as for barley and include the flexural rigidity of the stem and its fresh weight. A method for calculating the bending moment of flexible stems is described in [30].

Anchorage Failure Moment

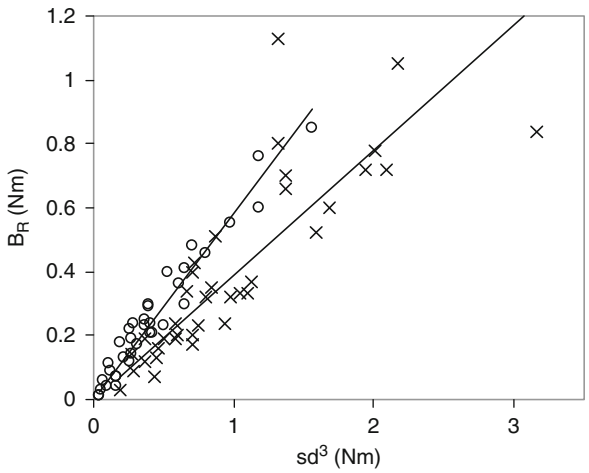
There is uncertainty about the exact mechanism of anchorage failure in cereals due to the obvious difficulty associated with observing the process in field conditions. Ennos [33] showed that anchorage failure of spring wheat involved bending of the crown roots and resistance to axial movement through the soil. Crook and Ennos [27] showed that the upper portions of the crown root system of winter wheat form a cone (Fig. 5) and anchorage failure occurred when the root-soil cone rotated at its windward edge, the soil inside the cone moved as a block and compressed the soil beneath. This idea supported earlier observations by Pinthus [34], who showed that a wider angle of root spread was related to greater resistance to root lodging. Easson et al. [35] suggested that winter wheat roots acted like ropes to withstand root lodging and that anchorage strength would therefore be a function of the tensile strength of the roots on the windward side of the plant.

The model developed by Crook and Ennos [27] has been tested and calibrated with field experiments on wheat [29] and on barley [30] (Fig. 6). These experiments showed that the anchorage strength was linearly related to the product of the diameter of the root cone cubed, the shear strength of the surrounding soil, and a constant specific to wheat or barley. The size of the root plate is identified by the parts of the crown roots that are surrounded by a rhizosheath. The rhizosheath is a dense mat of hairs that cover the upper sections of crown roots. These sections of roots have been shown to have an outer ring of lignified tissue in addition to the lignified central stele [27], which is why the rhizosheath can be used to estimate the length of root that provides anchorage.

The observation that anchorage strength was linearly related to the spread of the diameter of the root cone for both wheat and barley strongly suggests that both species have the same mechanism of anchorage failure first described by Crook and Ennos [27]. However, it was apparent that the constant factor was different between species with a value of 0.39–0.43 for wheat [29, 30] compared with 0.58 for barley demonstrating a greater anchorage strength for a given root plate spread for barley. This may have been caused by the greater number of stems per mm of root plate for barley compared with wheat. Up to 20 mm of the stem base is below ground, so it seems likely that a greater number of stems will increase the rotational resistance of the anchorage system.

A model of soil strength developed by Baker et al. [29] showed that variation in clay content, moisture content, and compaction that is normally found within farmer's fields could each be expected to alter the soil

Lodging Resistance in Cereals. Figure 5
Upper portions of the root system of winter wheat



Lodging Resistance in Cereals. Figure 6
The product of soil shear strength (s) and root plate spread cubed (d^3) plotted against failure moment (B_R) for winter barley (o; y = 0.58x, R^2 = 0.95) and for winter wheat (5; y = 0.39x, R^2 = 0.69) (Adapted from [30])

shear strength by several fold. This indicates that the state of the soil is likely to be of paramount importance for determining lodging given that it has been predicted in the anchorage model described above to be directly proportional to anchorage strength.

Stem Failure Moment Assuming that a typical stem can be considered to be analogous to a cylinder, Baker [32] showed that the stem failure moment (B_S) can be expressed as:

$$B_S = \frac{\sigma \pi a^3}{4}\left(1 - \left(\frac{a-t}{a}\right)^4\right)$$

where σ is the stem failure yield stress (material strength), a is the external radius of the stem, and t is the wall thickness. This formula assumes that the pith in the center of the stem does not contribute to the structural properties of the stem. Experiments by Neenan and Spencer-Smith [25] have shown that the stems of wheat and barley buckle at a certain critical ratio of radius of curvature to the outside diameter of the stem. Buckling was shown to occur suddenly with negligible amounts of plastic deformation. The Young's modulus of wheat and barley was shown to remain reasonably constant for a range of stem curvatures which indicates that negligible plastic deformation occurs and that the limit of proportionality between the applied stress and corresponding strain is seldom exceeded. It may therefore be concluded that stem lodging occurs abruptly and will result in complete structural failure of the stem.

Influence of Crop and Environmental Characteristics on Lodging Risk

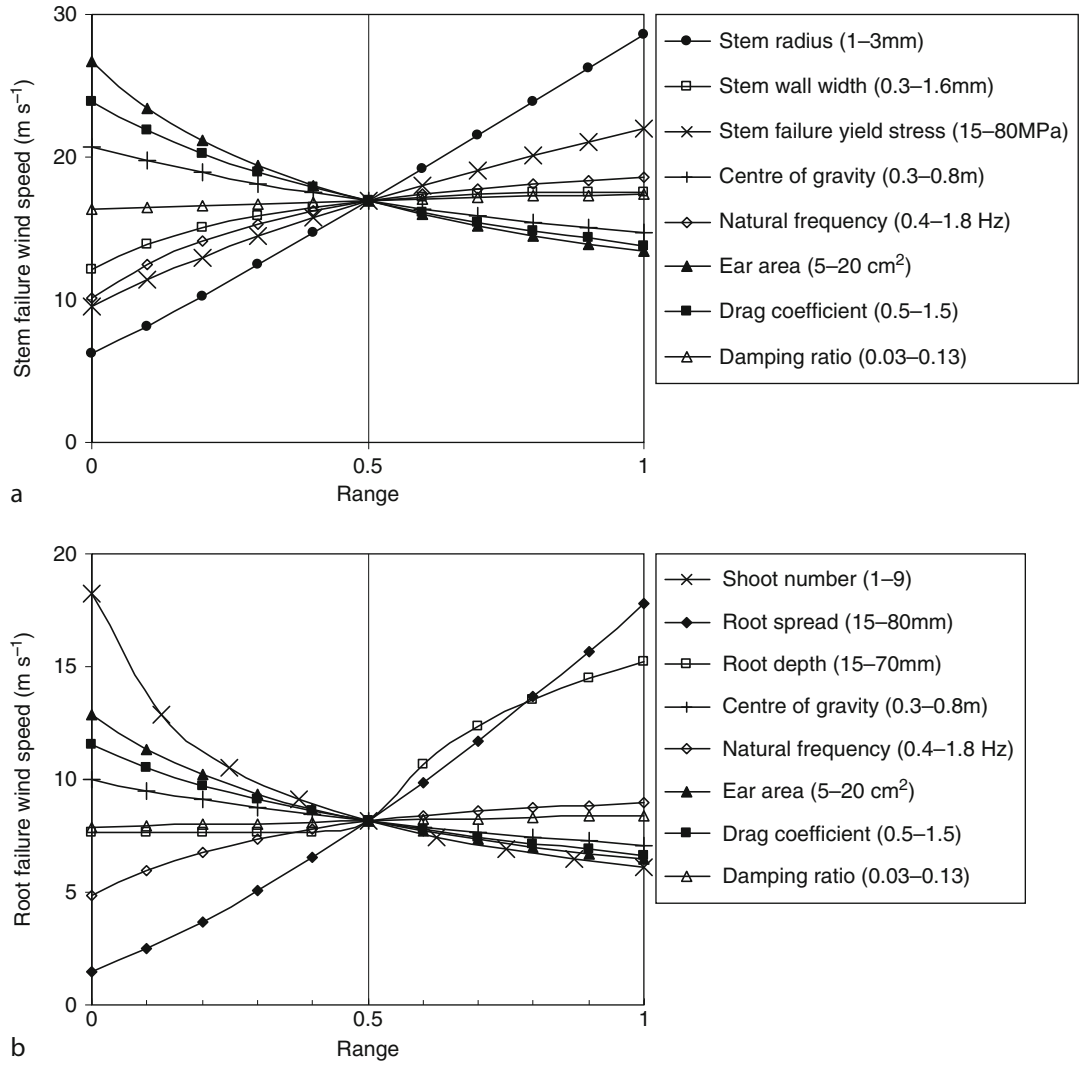
Lodging is a complex process that involves several environmental and plant characteristics. Any assessment of the effect of individual characteristics on lodging risk must account for interrelationships between characteristics. To date the only study to have achieved this involves a sensitivity analysis of the lodging model of Baker et al. [29] and this is described in [9]. This study further developed the model of Baker et al. [29] to account for spatial non-uniformity between plants and temporal changes in plant structure during the growing season. A sensitivity analysis using this model showed that the risk of stem lodging is influenced most by changes in stem diameter and the risk of root lodging is affected most by changes to the diameter of the root cone (also referred to as the spread of the root plate) (Fig. 7). In these analyses, the risk of lodging is measured in terms of the wind speed required to cause lodging, which is termed the "stem" or "root" "failure wind speed." The large effect on the chance of lodging caused by small changes in the failure wind speed is illustrated by the probabilities of experiencing different wind speeds above a UK wheat crop (Fig. 8).

Methods for Controlling Lodging Risk

Crop Management

Cultivations The use of minimal cultivations or direct drilling to prepare seed beds have been shown to reduce lodging compared with more traditional methods which usually involve plowing to about 20 cm depth [36]. It seems likely that observations for direct drilling or minimal cultivations to reduce lodging are mainly caused directly by increased soil strength resulting from greater bulk density [37, 38]. The common observations for high bulk density to impede root extension and increase root thickness [39, 40] appear to be restricted to sections of the cereal root system that play little part in anchorage, namely, the seminal roots or the distal sections of the crown roots.

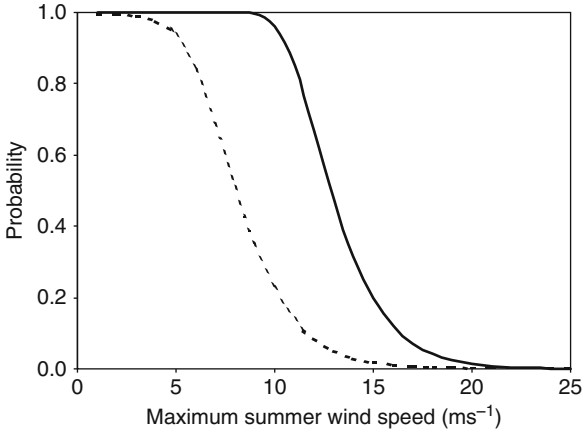
Rolling to consolidate the soil is another management practice that has been shown to reduce lodging [34, 41–43]. This can be done immediately after the primary cultivations or can be done in spring to re-consolidate the top-soil after it has been loosened by cycles of freezing and thawing. Berry et al. [43] showed that rolling a sandy loam in the spring increased shear strength in the top 5 cm by 25% and this effect persisted until harvest. No effects were observed on the biomechanical properties of the wheat roots. This study also showed that rolling before growth stage (GS) 30 [44] reduced lodging, but rolling after GS31 had no effect on lodging. It was hypothesized that this treatment damaged the extending stems, which encouraged extra tillering, and these extra shoots countered the effects of the stronger soil. This theory was supported by rolling experiments to break cereal stems by Peltonen and Peltonen-Sainio [45].



Lodging Resistance in Cereals. Figure 7

Failure wind speeds after 7 mm rain for (**a**) internode 1 and (**b**) anchorage. The ranges (0–1) are judged to represent the combined genetic and environmental range of each parameter within a high yielding wheat crop (Adapted from [9]). Stem radius – radius at the mid-point of the lowest internode; stem wall width – wall width at the mid-point of the lowest internode; stem failure yield stress – material strength of the stem wall of the bottom internode; center of gravity – height at center of gravity of the main shoot; natural frequency – rate at which the shoot oscillates; ear area – projected area of the ear; drag coefficient – resistance offered by the ear to wind; damping ratio – rate at which the shoot's oscillations stop; shoot number – number of fertile shoots per plant; root spread – diameter of the root plate defined by the thickened regions of the crown roots; root depth – depth of the root plate defined by the thickened regions of the crown roots

Sowing Date and Seed Rate The lodging risk of wheat is almost always reduced by delaying sowing [19, 46–49]. Pinthus [50] cites two studies that show reduced lodging in barley when it is sown later, but [47] observed that early sowings could reduce or increase lodging in barley. Reducing the number of plants established also causes a large reduction in the lodging risk of wheat [12, 19, 48, 51–53], and of barley [54].



Lodging Resistance in Cereals. Figure 8
Probabilities of experiencing wind gusts independent of rainfall (—) and wind gusts with $\geq$ 7 mm daily rain (---) between mid-June and mid-August within the main wheat-growing regions of the UK (Adapted from [9])

The sowing date and seed rate effects described above are caused by changes to the structure of the crop. Berry et al. [48] showed that sowing winter wheat 6 weeks earlier increased both root and stem lodging risk by increasing the base bending moment of the shoot by about 30% and by reducing the strength of the stem base and the strength of the anchorage system by about 50%. Stapper and Fischer [19] have shown that early sowing results in a greater number of extended internodes, and this probably caused the longer stems which gave rise to the greater base bending moment. Establishing 200 plants m^{-2} compared with 400 plants m^{-2} reduced lodging risk by increasing the strength of the anchorage system by more than 50% and the strength of the stem base by 15% [48]. The increase in anchorage strength more than compensated for the increase in shoot number on these plants. The greater anchorage strength has been attributed to several morphological changes including more roots per plant [12], stronger and thicker roots [55], and a wider and deeper root cone [48].

Sowing earlier or establishing more plants resulted in weaker stems because the stems were narrower and had thinner walls [48]. The mechanism by which weak stems develop is thought to be due to a greater number of shoots competing for limited photo-assimilate during early stem extension, which reduces the dry matter per unit length of the lower internodes [56]. Sparsely populated plants have many tillers [57] each of which develops up to four crown roots from each of their subterranean nodes. Therefore, it should be of no surprise that establishing fewer plants results in plants with more crown roots. Thicker and stronger roots may be caused by the absence of a strong shade avoidance response by the plant, which stimulates a greater proportion of assimilate to be partitioned to the roots [58]. Similar effects on anchorage strength were observed after later sowing as a result of fewer plants established.

Drilling Depth and Seed Treatment Deeper sowing has also been found to reduce lodging in barley [50], but in general published evidence for sowing depth effects is scarce. This is probably caused by the plants ability to adjust its crown depth to about 40 mm for sowing depths of between 40 and 70 mm [59]. This means that sowing depths over this range are unlikely to affect the depth of the structural roots. However, drilling more shallowly than 40 mm may be expected to raise the crown and its structural roots, thus weakening anchorage.

Evidence that altering crown depth can affect lodging can be found from the effect of seed treatments: fluquinconazole [60] and triadimenol [61]. Studies on fluquinconazole showed that it shortened the sub-crown internode linking the seed to the crown (the part of the plant where the crown roots and tillers emerge). This deepened the crown and the depth of the root plate, which in turn increased anchorage strength and the resistance to root lodging. Observed natural root lodging also showed that the plots treated with the triazole seed treatment were less susceptible to root lodging [60].

Disease Scott and Hollins [62] showed that wheat crops with a greater incidence of sharp eyespot (*Rhizoctonia*), brought about through inoculation, had more lodging. It has been shown that severe levels of either disease can reduce the failure moment of the lower internodes by between 30% and 40%, thus increasing the likelihood of stem lodging [10]. Interestingly, slight or medium levels of disease did not appear to weaken the stems. There is no evidence that take-all root disease increases the risk of lodging.

Nutrition An increased supply of available nitrogen from either mineralization of organic matter or from inorganic fertilizer has frequently been shown to increase lodging in wheat [48, 63, 64], barley [26, 65], and oats [66]. In wheat, the greatest increase in lodging is usually observed in response to early applications of nitrogen fertilizer before the onset of stem elongation [22, 23, 67], with applications after anthesis having no effect [52]. Contrary to this, Chalmers et al. [66] found that lodging in winter oats was reduced by applications of nitrogen before the onset of stem extension compared with later applications at GS30/31.

Both Crook and Ennos [68] and Berry et al. [48] showed that increasing the nitrogen supply to winter wheat, through either greater amounts of soil residual nitrogen at sowing or through larger applications of fertilizer in the spring, reduced the strength of the stem base and, to a lesser extent, reduced the strength of the anchorage system. Increases in crop height were generally small. Reductions in stem strength could be as much as 50% when high levels of residual nitrogen were combined with applications of fertilizer early in the spring [48]. Greater nitrogen supply almost always decreases the dry weight per unit length of the basal internodes of wheat [27, 48], barley [26], oats, and rye [22]. In relation to this, stem diameter and stem wall width are also frequently reduced. Berry et al. [48] showed that high levels of residual nitrogen reduced the strength of the stem wall material. These findings were supported by Crook and Ennos [27], who showed that a component of material strength, Young's modulus (which approximates to the stiffness of the stem), was also reduced by more fertilizer in spring. The cause of these effects may have resulted from a reduced amount of lignified tissue within the sclerenchyma zone and the thickness of the sclerenchyma cell walls [22]. Reductions in anchorage strength in response to more nitrogen can be linked with fewer roots, which are thinner with smaller bending and tensile strengths [55, 68]. Mulder [22] showed that the crown roots of oat plants supplied with large amounts of nitrogen were practically free from lignified cells beneath the epidermis, in contrast with plants supplied with moderate amounts of nitrogen.

In the consideration of nutrition, there should be a differentiation between the effects that result from repairing a deficiency and effects resulting from super-optimal supply. For example, it appears that an increase in nitrogen will increase lodging risk, but the mechanism by which this occurs will depend on the level of nitrogen supply. If a nitrogen deficiency is being repaired then lodging risk increases because the leverage of the shoot and ear increases. It seems likely that the stem strength, and possibly the anchorage strength, will be increased by correcting the deficiency but these effects are outweighed by the greater leverage. Additional nitrogen increases the shoot leverage by progressively smaller amounts, but lodging risk continues to rise because the strength of the stem base and root system begins to decrease as a result of the indirect effects of shading. It is possible that phosphorus behaves in a similar way to nitrogen [67]. However, potassium might be different as the evidence [22, 50, 69] indicates that it can reduce lodging when repairing a deficiency and additional amounts have no effect. This may be due to the important role that this element plays in regulating the turgor of plant tissues.

Plant Growth Regulators Plant growth regulators (PGRs) are synthetic compounds that can be used to reduce lodging in cereal species. They are most commonly used for this purpose in north and western European countries and in North America. In the UK, 89% of the winter wheat is treated with PGRs [70]. PGRs can be classified into two main groups: inhibitors of gibberellic acid biosynthesis and ethylene-releasing compounds. The most commonly used inhibitors of gibberellic acid biosynthesis in cereal crops are chlormequat chloride, mepiquat chloride, trinexapac-ethyl and prohexadione-calcium [71]. Ethephon is the most commonly used ethylene-releasing compound used on cereals [72].

Plant growth regulators have been shown to be a cost-effective method of reducing the incidence of lodging. PGRs applied before the emergence of the ear reduced lodging in almost all of the vast number of published experiments that have studied their effect and in which lodging occurred, with reductions in the percentage area lodged of anything up to 70% [10]. The primary mechanism by which PGRs have been shown to reduce lodging risk is by reducing crop height, with height reductions of up to 40% [10]. The variation on plant height reduction is probably caused by interactions between the type of active ingredient, the cereal

species together with the stage of plant development, and the environmental conditions when the chemical is applied. No evidence has been found for PGRs to increase the strength of the stem or of the anchorage system [48, 68], although it must be recognized that only two studies have investigated the effects of PGRs by directly measuring stem and anchorage strength. Chlormequat has been shown to be effective at reducing lodging in winter and spring wheat, oats, and rye, but less effective on barley [73, 74]. Barley undergoes large height reductions in response to a mixture of ethephon and mepiquat chloride [13, 75].

Summary of Crop Management Effects Many crop management practices result in large changes in lodging risk by either affecting the wind-induced leverage of the shoot, the strength of the stem base, the strength of the anchorage system, or a combination of all three mechanisms. Furthermore, the strengths of the stem base and anchorage system are often changed by different amounts for any change in crop management. This means that certain types of crop management would be expected to reduce one type of lodging (stem or root) more than the other. The effects of several crop management practices on the risk of stem and root lodging have been summarized by Berry et al. [76] in terms of changes to the failure wind speed (Table 1). This shows that stem lodging is best reduced by sowing on soils with less residual nitrogen and by reducing and delaying the amount of fertilizer applied in the spring. Root lodging is best reduced by establishing fewer plants, using a seed treatment with growth regulatory properties and by rolling in the spring to consolidate the soil. Delayed sowing and growth regulators were estimated to reduce stem and root lodging by equal amounts.

Plant Breeding

The *Rht* (Reduced height) alleles began to be introduced into wheat varieties during the 1960s and 1970s and are now part of the germplasm of most high yielding semi-dwarf varieties. In UK and German wheats, *Rht*1 and *Rht*2 alleles can reduce height by 14–17% independently of each other and by 42% when in combination [2]. *Rht*3 can reduce height by 59%, but has not yet been used in commercial varieties. In the UK, the *Rht*1 and *Rht*2 alleles have helped to reduce the height of wheat cultivars from over 1 m to about 0.7–0.9 m between the early 1970s and the mid-1990s. This reduction in height and consequent reduction in leverage has enabled the amount of nitrogen fertilizer applied to wheat to be increased from less than 100 kg ha^{-1} in the early 1970s to nearly 200 kg ha^{-1} in the 1990s [77] without a dramatic increase in the incidence of lodging. Pleiotropic effects have further added to the yield improvements associated with these *Rht* genes in wheat. Reduced stem growth rates allow

Lodging Resistance in Cereals. Table 1 Effect of crop management on the wind speed required to cause stem or root lodging (Adapted from [60, 76]

Factor	Increase in stem failure wind speed ms^{-1}	Increase in root failure wind speed ms^{-1}
Less soil residual N (116–71 kg N ha^{-1})	2.3 (3.9 [a])	1.3
Seed treatment with PGR activity (e.g., Fluquinconazole [60])	0	0.7
Delayed sowing (per week, between 20 September and 1 November)	0.5	0.5
Less plants established (per 100 plants m^{-2}, between 400 and 200 plants m^{-2})	0.8	1.8
PGRs (split chlormequat @ GS30/31)	1.4	1.4
Delayed and less fertilizer N (Target GAI of 5)	1.4	0.8
Spring rolling (pre-GS30)	0	0.8

[a]At 400 plants m^{-2}

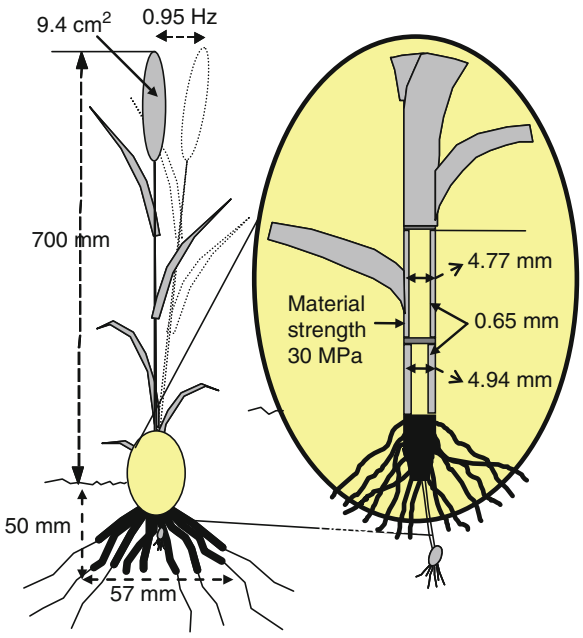
more resources to be allocated to the developing ear which results in a greater number of fertile florets and grains per year.

In oats, the variety S172, released in 1939, has been reported to be Europe's first dwarf cereal variety [78]. However, dwarfness in this and several derived varieties was associated with small grains and a yield penalty. Recently varieties have been released that contain the *DW-6* dwarfing gene which was discovered in a mutation program in Canada [79] and has been shown to shorten the peduncle [80]. This gene has been shown to reduce height by 20–75 cm, have thicker stems, and to reduce lodging by large amounts [81]. Major dwarfing genes are common in spring barley. The *ari-eGP* dwarfing gene was found in cvs Golden Promise and Midas, which comprised over 70% of the Scottish barley crop from the mid-1970s to early 1980s. The *ari-eGP* gene was then superseded by the *sdw1* dwarfing gene, such that by 1989 the percentages of certified seed carrying the sdw1 and ari-eGP genes were 74 and 8, respectively [82].

There is great potential to continue increasing lodging resistance through further height reductions via the introduction of more extreme dwarfing genes such as *Rht3* in wheat. However, several studies have shown that yield is reduced when crops are shortened too much [2–7]. The reduction in yield appears to be exacerbated by high temperatures or drought stress. Several of these studies indicate that the minimum crop height for optimum yield lies between 0.7 m and 1.0 m, a height which many modern varieties have already achieved. There is evidence that the same problem could occur in oats because the *DW-6* dwarfing gene has been associated with small grains, low kernel content and poor extrusion of the panicles from the flag leaves in some genetic backgrounds [81]. It therefore seems unlikely that much further improvement in lodging resistance can be made by continuing to shorten wheat crops and there may be only limited further shortening possible in other cereal species. As a result breeders must target other plant traits, namely, stem strength and anchorage strength, to improve lodging resistance and counter greater yields.

The lodging model of Baker et al. [29] has been used with preliminary datasets describing the dry matter costs of improving traits associated with stem strength and anchorage strength to estimate the dimensions of a wheat plant to make it lodging-proof for the least investment of biomass in the supporting stem and root system [83]. The characteristics required to give a crop yielding 8 t ha^{-1} with 500 shoots m^{-2} and 200 plants m^{-2} a lodging return period of 25 years in a UK environment include a height of 0.7 m, a root plate spread of 57 mm, and for the bottom internode a wall width of 0.65 mm, a stem diameter of 4.94 mm, and a material strength of 30 Mpa (Fig. 9). Observations of a range of varieties grown in the UK showed that the root plate of the best variety was 7 mm less than the ideotype target, the widest stem was 0.5 mm below the ideotype target, other stem character targets were achieved but not all in one variety, and the height target was achievable with the use of plant growth regulators.

It is possible that the lodging-proof ideotype traits could be achieved because large differences among wheat varieties have been observed for the traits that determine stem strength and anchorage strength [42, 76, 84]. The latter study showed that anchorage strength could vary from 206 Nmm to 587 Nmm and stem strength could vary from 122 Nmm to 175 Nmm



Lodging Resistance in Cereals. Figure 9
Description of a lodging-proof ideotype for wheat grown in a UK environment as defined in [83]

between varieties. These differences were caused by a combination of wider, deeper root plates and stiffer roots for anchorage strength, and wider, thicker walled stems with a greater material strength for overall stem strength. Subsequent studies using more varieties and breeding lines showed even greater genetic variation in the traits which determine stem strength and anchorage strength [83, 85]. In barley, differences in culm wall thickness have frequently been positively correlated with varietal differences in lodging resistance [86–88]. If oats and barley have a similar level of genetic variation in stem and anchorage strength as has been observed in wheat then there appears to be significant scope for breeders to improve the strength of the stems and anchorage systems of cereals. However, these traits are time-consuming to measure; therefore, new technologies will be required to help plant breeders to rapidly select them.

Future Directions

The majority of lodging research has concentrated on wheat. This has enabled models of the lodging mechanism to be developed, which have been used to identify the critical plant characters, to quantify the effects of factors on lodging and to elucidate the mechanisms by which these effects are caused. A rudimentary model of lodging has been developed for barley, but further work is required to fully validate this model, particularly the way in which flexural rigidity of the stem is considered. Understanding about lodging in other cereals, such as rice, maize, and oats, lags far behind wheat. In order to replicate the advances made in wheat the next step must be to model the lodging mechanisms in these cereals. This may require fundamentally different types of lodging model due to the different plant structures of these species.

Historically reducing crop height has been the main avenue by which the lodging risk of wheat has been reduced. However, several studies on wheat indicate that the minimum height compatible with high yields is around 0.7 m. This height has been achieved by many wheat varieties. Crop height also has a major impact on the structural dry matter requirements for lodging resistance with each additional centimeter in height increasing the stem dry matter required by 0.23 t/ha [83]. Further work must investigate why there appears to be a minimum height for high yield, whether this barrier can be overcome and whether the minimum height for high yield varies between environments.

Preliminary studies with wheat have indicated that increasing stem strength has a significant dry matter cost which could compete with the formation of grain yield [83]. Further work must quantify the dry matter cost of increasing stem strength, understand the optimum combination of stem diameter, wall width, and material that is required to minimize the dry matter cost of increasing stem strength, and quantify the extent to which this competes with yield formation.

It has been predicted that breeders must increase the stem strength and anchorage strength of wheat in order to achieve a lodging-proof ideotype for wheat. These traits are time-consuming to measure; therefore methods must be developed for rapidly assessing these traits. Berry et al. [89] and Keller et al. [90] have identified more than one quantitative trait loci associated with these traits and indicated that they are controlled by several genes. Further work will be required to better understand the genetic control of the traits associated with lodging and to investigate whether reliable genetic markers can be identified which work across a range of genotypes and environments. Phenotypic screens must also be investigated to assess whether they can offer an alternative method to genetic markers for selecting germplasm.

Recent work has shown that although a wide genetic variation for the key lodging traits is present within UK wheat breeding material [85], few of the target traits required for complete lodging proof have been identified. This indicates that a wider range of germplasm must be assessed to find the target traits.

Currently there is not a reliable method predicting the likelihood of lodging from earlier stages of crop development, when growers can alter lodging risk through their crop management (PGRs, fertilizer, rolling). Therefore, further research must study the development of the lodging-associated plant characters with the objective of predicting lodging from early assessments of the crop. Any prediction scheme must predict lodging risk before, or soon after, the onset of stem elongation to enable growers to alter their crop management accordingly.

PGRs reduce lodging risk by shortening crops, but there is little published evidence that they can

strengthen the stems and anchorage system. Further research should investigate the effect of existing PGRs on stem and anchorage strength as well as focusing on discovering new chemicals that strengthen these traits.

Article Outline

Glossary

Detritivores (also known as *saprophages*) They are heterotrophs that obtain nutrients by consuming detritus (decomposing organic matter).

Halophyte Salt-loving plants that can be grown at higher salinities than most traditional crop plants.

IMTA The Integrated Multi-Trophic Aquaculture System (IMTA) is an aquaculture practice in which excretions of one or more organisms are utilized by other cultured organisms from different trophic (nutritional) levels within the system.

Land-based and offshore mariculture systems Two methods of seawater aquaculture (mariculture); the former on land and the latter in the ocean.

Polyculture An aquaculture practice which involves culture of two or more species from the same or different trophic levels in the same water reservoir.

RAS Recirculated Aquaculture System (RAS) is an aquaculture practice for the rearing of aquatic organisms wherein 90% or more of the water is recycled within the system.

Sludge Solid/particulate waste that includes, among other components, feces, uneaten feed, algae and bacteria, which sinks to the bottom of aquaculture water reservoirs.

Definition of Subject

The Integrated Multi-Trophic Aquaculture System (IMTA) is an aquaculture practice in which excretions of one or more organisms are utilized by other cultured organisms from different trophic (nutritional) levels. IMTA systems are distinct from polyculture systems, which involve two or more species from the same or different trophic levels in the same water reservoir. In a typical IMTA, the various species are cultured in separate spatial entities, permitting intensification and optimization of production. The IMTA concept has been increasingly adopted in modern day aquaculture, including land-based (Fig. 1) [1–5] and offshore mariculture [6, 7].

In land-based IMTA systems, seawater is pumped from the sea to fish or shrimp ponds. A pelleted diet is the only source of nutrients for the animals in the system. Nutrient-rich effluent water from these ponds can take three directions: microalgae ponds, macroalgae ponds, and constructed wetlands with halophyte plants. The microalgae can be utilized by filter feeders such as *Artemia* or/and bivalves. The macroalgae can be utilized by macroalgivores such as abalone or sea urchins, and detritus can be utilized by detritivores such as mullets, sea cucumbers, or polychaete worms (Fig. 1).

Introduction

The concept of polyculture and IMTA systems is not new. Such systems of different species of fish, or combinations of invertebrates and fish, have been existing in ancient Egypt and China for thousands of years. Artificial enclosures or natural ponds in tidal zones were generally used. Extensive traditional IMTA and polyculture systems are still practiced today in various parts of Asia in fresh and salt water. Rice and fish are cultured together in China. Earthen ponds, in association with wild or agricultural plants, are used on a wide scale in fish and shrimp farming in China, Indonesia, Taiwan, Thailand, Japan, Vietnam, India, the Philippines, and Ecuador. In Europe, ducks, fish, and crayfish have been raised together in freshwater ponds. This type of extensive production has proven sustainable, because it utilizes organisms that feed on different levels of the food web, and maintains a clean environment.

Mariculture Systems, Integrated Land-Based. Figure 1
Schematic design of land-based IMTA systems (con. = constructed)

The traditional IMTA and polyculture systems are more environmentally friendly than modern intensive mono-aquaculture systems. These systems utilize fewer resources and do not pollute surrounding waters with waste products, because they generally sustain relatively low stocking densities and do not employ fertilizers. Most of them rely on natural production of food. This concept has increasingly been adopted for modern aquaculture, including land-based and sea-cage mariculture. With dramatic increases in global human population, food demand, and overfishing problems, traditional extensive aquaculture cannot satisfy present demand, and much less so the projected future demand, for sea products.

Modern intensive monoculture systems require high levels of resources and produce undesirable wastes. They are dedicated to a few expensive species and do not generate a large amount of food. Intensive aquaculture uses extensive amounts of resources such as water, feeds, fertilizers, chemicals, and energy, while discharging fecal material, uneaten feed, excretions, and drugs into the environment. In turn, this creates eutrophication of the water, has deleterious effects on marine life, increases the risks of antibiotic resistance in organisms, has an adverse effect on biodiversity, and contributes to habitat destruction. The economic success of intensive monoculture in sea cages or land-based facilities has much to do with the fact that, even today, pollution of the environment involves little or no monetary outlay or penalty for the growers. In most countries, aquaculture does not yet include the cost of effluent treatment. However, in the industrialized nations, this age is coming to a timely end and in Europe, there are already laws and regulations requiring effluent treatment and imposing fines for noncompliance. In some countries, this cost can be as high as €0.5–1 kg^{-1} feed, resulting in an expense of €250,000–350,000 per annum for medium-scale RAS (Recirculating Aquaculture System) farms (250 t/year). Awareness is growing among scientists, industry, the public, and politicians that technologies disregarding environmental impact are neither sustainable nor acceptable.

History

The development of modern land-based IMTA using extractive organisms such as shellfish, microalgae, and seaweeds began in the 1970s with the pioneer work of Goldman et al. [1] and Ryther et al. [2] in the treatment of household effluents. Phytoplankton was cultured in a mixture of domestic wastewater effluent and seawater, fed to suspension-feeder molluscs, and the dissolved remnants of nutrients in the final effluent were assimilated by seaweeds. As the food value of organisms grown on human waste effluents was questionable, adaptations of this principle to the treatment of intensive aquaculture effluents in both inland and coastal areas were proposed [8] and were followed by the integration into a system of carnivorous fish and abalone (e.g., [9]). The first practical and quantitative integrated land-based cultures of marine fish and shellfish, with phytoplankton as biofilter and food for shellfish, were constructed in Israel by Hughes-Games [10] and Gordin et al. [11]. A semi-intensive seabream and gray mullet pond system with silicate-rich green water, located on the coast of the Gulf of Eilat (Red Sea), supported dense populations of diatoms, excellent for feeding oysters [12, 13]. Later, the development of a practical intensive culture of bivalves in phytoplankton-rich effluents was described in a series of articles [3, 14–18]. Lefebvre et al. [19] showed that detritical waste from intensive fish farming can contribute to the growth of bivalves and reduce particulate matter in the water. Jones et al. [20], using the Sydney rock oyster *Saccostrea commercialis*, significantly reduced the concentration of suspended particulates including algae, bacteria, and inorganic particles in integrated systems.

Studies showing the performance of seaweed in land-based IMTA, initially at laboratory scale and later expanded to outdoor pilot scale, began to appear in the 1970s [21, 22]. The theoretical and practical principles of intensive large-scale land-based seaweed culture were studied and developed first at Woods Hole and later at Harbor Branch Oceanographic Institution in Florida – U.S.A. [8, 23–25]. The quantitative aspects of their functioning have been described [14, 16, 26–29]. Fish, abalone, and seaweed IMTA systems were studied by Shpigel et al. [30], Butterworth [31], and Nobre et al. [32]. The aspects of bioeconomics of land-based IMTA are described by Nobre et al. [32], Neori et al. [33], and Bunting and Shpigel [34].

Offshore IMTA system is a relatively new concept that started in the late nineties and is a modification of the land-based IMTA. In coastal integrated mariculture, shellfish and seaweed are cultured in proximity to cage fish culture [6, 7]. Kelp (brown algae) [35, 36] and red algae [37, 38] efficiently take up dissolved inorganic nitrogen excreted by the fish [39], so that seaweed production and quality are often higher in areas surrounding fish cages than elsewhere [6, 40–42]. However, nutrient removal efficiency in offshore IMTA is still relatively low, ranging between 15% and 25% [43].

The concept of IMTA systems is generic and can be applied to cold, warm, and temperate waters, in intensive, semi-intensive, and extensive systems, in sea cages or land-based facilities, in fresh water in land-based facilities or lakes, and all of the above in closed, semi-closed, or flow-through systems.

In recent years, several enterprises and research facilities have begun setting up land-based IMTA; most of the systems are pilot scale or R&D facilities. The IMTA typically include two or three species. In most of the studies, seaweed and microalgae are used as biofilters for the dissolved nutrients (review by Neori et al. [33] and Soto [44]). A broad spectrum list of selected organisms being used in farms and in R&D is presented in Fig. 2. Key species in cold water are salmon, mussels, and the seaweeds *Gracilaria, Laminaria*, and *Porphyra*. For temperate and warm seawater, sea bream, sea bass, oysters, clams, and *Ulva lactuca* are the predominant cultured species (Fig. 2).

Over 200 species are currently the object of R&D projects and in commercial farms and research institutes around the world, in various climate conditions. A significant number of fish and shellfish are cultured in temperate water, and a relatively low number of fish and large number of seaweeds in cold-water climates (Fig. 3).

Nutrient Budget in Land-Based IMTA

Protein in fish or shrimp feed is the most expensive component of nitrogen input into the IMTA systems. In conventional cages or ponds, fish or shrimps assimilate only 20–30% of the nitrogen, while the rest

KEY SPECIES CULTURED IN POLYCULTURE AND MULTI-TROPHIC SYSTEMS

Cold Seawater	Temperate Seawater	Warm Seawater
Oncorhynchus sp.	*Pagrus major*	*Sparus aurata*
Crassostrea sp.	*Sparus aurata*	*Lates calcarifer*
Mytilus edulis	*Dicentrarchus labrax*	*Mugil cephalus*

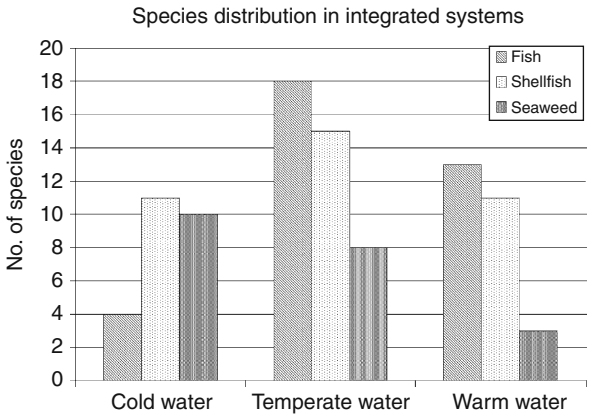
Penaeus monodon		*Penaeus* sp.

Mariculture Systems, Integrated Land-Based. Figure 2
Key species cultured in IMTA and polyculture systems for marine and freshwater environment

is excreted into the water, mainly as dissolved ammonia, feces, and uneaten feed.

Two main practical approaches are emerging for handling the organic and nitrogenous wastes: bacterial dissimilation into gasses in "Recirculating Aquaculture Systems" (RAS), or plant assimilation into biomass (IMTA). Bacterial biofilters are dissimilative. Through a process of nitrification followed by denitrification, bacteria break down the organic pollutants into N_2 and CO_2 gasses. Bacterial biofilters are technically rather effective for aquaculture and allow significant water recirculation. However, the technology is relatively expensive, and not simple. Bacterial biofilter technologies are suitable for relatively small intensive land-based culture of lucrative organisms. There are no suggestions as to how such technologies can be integrated with large-scale, low cost fish or shrimp production. In addition, this system wastes expensive nitrogen by converting this valuable resource into gas, which is lost into the atmosphere.



Mariculture Systems, Integrated Land-Based. Figure 3
Fish, shellfish, and seaweed species combination in IMTA systems in different bio-geographical regions around the world

Nutrient assimilation by other organisms is a more promising method of water treatment. In land-based IMTA ponds, seawater is pumped from the "nuclear species" (fish or shrimp) into the ponds/tanks of secondary organisms or macro-/microalgae. A pellet diet is the only source of nutrients for the primary animals in the system. Nutrient-rich effluent water from these ponds can take three directions: microalgae ponds, macroalgae ponds, or to irrigate halophyte crops (e.g., *Salicornia* sp.). The microalgae can be utilized by filter

feeders such as artemia or bivalves. The macroalgae can be utilized by macroalgivores such as abalone, sea urchins, or herbivorous fish. Halophytes such as *Salicornia* can be used as a food product. The remaining detritus can be fed to detritivores such as mullets, sea cucumbers, or polychaete worms, singly or in combination.

Optimization of the IMTA is typically based on the highest value "nuclear" product at any given time. This "nuclear" product may be shifted according to climatic conditions and economic considerations. For example, in a fish-abalone-seaweed integrated system, abalone is the most valuable species, and the entire system is centered around this species. Abalone will be the first organism to receive the incoming water. From the abalone, the water will drain to the ammonia producers and from there to the biofilters.

The biological and chemical processes in the IMTA system should be balanced between nutrient production by the main organism and nutrient uptake capacity of the micro- and/or macroalgae and downstream by the micro- and macroalgivores. In such systems evaluated in Eilat, Israel, macro-and microalgae were able to assimilate 1–5 g N m^{-2} day^{-1}, while algivores and filter feeders assimilated 0.5–1 g N kg $(WW)^{-1}$ day^{-1} (Table 1 and references therein). However, there will be variation in nutrient uptake depending on season and climate, as algal biomass is influenced by day length (i.e., light hours), water temperature, and the nutrient levels in the water.

For example, in a fish-bivalve-seaweed IMTA system in Eilat, 63% of the nitrogen from the feed was assimilated by edible organisms, 32% sank to the bottom as biodeposit (sludge), and only 4.1% was discharged back to the sea (Fig. 4) [3].

Nitrogen, phosphate, and silicate ratios can vary according to local farm conditions.

Nutrient composition is also affected by additional biochemical processes in the effluent water such as nitrification, denitrification, and ammonification which occurs in the sedimentation pond as well in the pond walls and in the water pipes. These processes can be accelerated or affected by water temperature, nutrient loads, flow rates, and fish feed biochemical composition. Local natural microfauna in the ponds (e.g., zooplankton) and microflora, as well as bloom and crash phenomena, can affect the water quality as well. In most cases, effluent water from fishponds is characterized by a mixture of ammonia, nitrate, and nitrite.

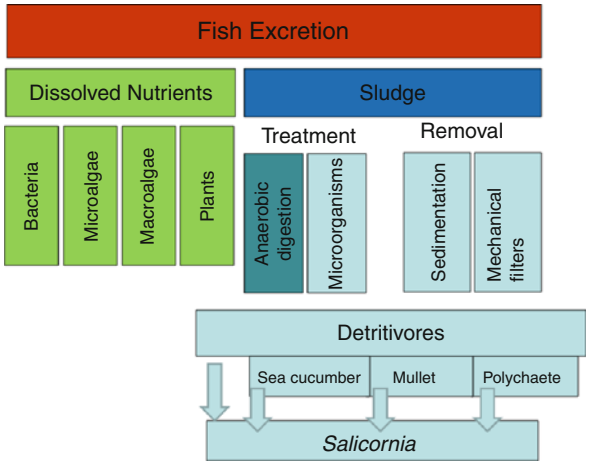
While macro- and microalgae have proven effective components in land-based systems, neither removes 100% of the dissolved matter and they do not remove particulate matter at all. The remaining waste that includes, among other components, feces, uneaten feed, algae and bacteria, sinks to the bottom and becomes what is known as sludge. This sludge contains valuable ingredients, but can also be toxic to the cultured organisms. It can increase stress and



Mariculture Systems, Integrated Land-Based. Figure 4 Different pathways to treat sludge from fishponds

disease risk, and reduce the quality of the water both in situ and for reuse. Ignoring the negative effects of the sludge can thus create serious problems and cause financial losses to the farmers. Removing and dumping sludge into the environment would similarly cause damage, even if moderated by dilution, and "foul the fish farmer's own nest" should he use seawater pumped in from the same area. Using detritivores is a novel option for land-based IMTA. Detritivore organisms such as mullets, cockles, and sea cucumbers will assimilate the waste into their bodies, thereby generating a significant saving in treatment costs, while additionally serving as valuable products in their own right, without requiring the purchase of feed for their culture.

The halophyte *Salicornia* sp. as a biofilter in constructed wetlands was evaluated in the "Genesis" and "Envirophyte" EU projects [34, 45, 46]. Using constructed wetlands (CW) planted with halophytes, which would take up the nutrient-rich wastewater and convert it into valuable plant biomass, is a new option for land-based IMTA. This system was developed to a practical stage for cold (UK) and warm (Israel) water. It was found that CW is efficient in clearing water of nutrients and suspended solids, some materials being purified through incorporation into the plants' biomass and others attaching to the substrate or being broken down by bacteria living therein. CW has the benefit of being low cost, is simple to operate, and can be given an aesthetically pleasing appearance. These plants have commercial value as a health food and are potential candidates for the health, beauty, and nutraceutical industries.

Pilot Scale Systems

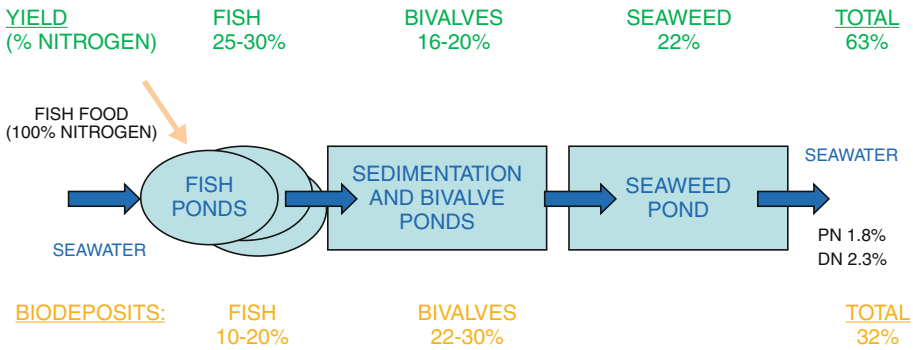
In R&D projects in Eilat, Israel, three different types of IMTA systems were developed:

1. Fish (seabream *Sparus aurata*) – seaweed (*Ulva lactuca*)
2. Fish (seabream *Sparus aurata*) – abalone (*Haliotis discus hannai*)/sea urchin (*Paracentrotus lividus*) (macroalgivores) – seaweed (*Ulva lactuca*)
3. Fish (seabream *Sparus aurata*) – bivalve (*Crassostrea gigas* and *Tapes philippinarum*) – seaweed (*Ulva lactuca*)

In the seabream-*Ulva* system, a daily ration of 1.3 t of feed supported 250 t of fish. This amount of food is equivalent to 64 kg of nitrogen. The fish assimilate around 16 kg of nitrogen. About 9.6 kg of the nitrogen is drained as particulate nitrogen, and 38.4 kg is drained as dissolved nitrogen. One hectare (ha) of macroalgae (*Ulva lactuca*) is required to remove most of the dissolved nitrogen from the water. This system using 500 t of food per year would require an area of 3.4 ha, at a ratio of 1 ha fish to 2.5 ha *Ulva*. Expected yield is approximately 220 t of fish and 1,600 t of *Ulva* (modified from [5] and [47]) (Table 2).

In the seabream-*Ulva*-macroalgivores (sea urchins/abalone) IMTA system, 1 ha of macroalgae produces 1,600 t of *Ulva* annually. This *Ulva* supports 133 t (WW) of abalone (*Haliotis discus hannai*) or 200 t of sea urchins (*Paracentrotus lividus*). A seabream-*Ulva*-sea urchins/abalone IMTA system in Eilat, Israel, using 500 t of food per year will need an area of 5.3 ha, at a ratio of 1 ha for fish, 2.5 ha for *Ulva*, and 1.8 ha for the macroalgivores (modified from [5] and [47]) (Table 2).

In the seabream, microalgae, and bivalves (*Crassostrea gigas* and *Tapes philippinarum*) IMTA system, a daily ration of 1.3 t of feed supports 250 t of fish. The fish assimilate around 16 kg of nitrogen; 38.4 kg of nitrogen is drained as dissolved nitrogen. This system using 500 t of food per year would need an area of 2 ha of phytoplankton pond (with assimilation efficiency of 1–2 g N m^{-2} day^{-1}) to support



Mariculture Systems, Integrated Land-Based. Figure 5
Nitrogen budget of fish-bivalve-seaweed IMTA system in Eilat, Israel

Mariculture Systems, Integrated Land-Based. Table 2 Expected performance of land-based IMTA (WW = wet weight)

IMTA system	Organism	Pond size Ratio/ha	Yield (WW t year^{-1})	Yield (kg WW m^{-2} year^{-1})
Fish-*Ulva* (500 t feed y^{-1})	Seabream	1	220	22
	Ulva	2.5	1,600	64
	Total		1,820	86
Fish-*Ulva* abalone/sea urchin (500 t feed y^{-1})	Seabream	1	220	22
	Ulva	2.5	1,600	64
	Abalone	1.8	185	10
	Sea urchins	1.8	140	8
	Total		1960–2005	94
Fish-*Ulva*-clam/oyster (500 t feed y^{-1})	Seabream	1	220	20
	Clams/*oysters*	4	140	8
	Ulva	0.5	70	64
	Total		430	92

production of 140 t bivalves and 70 t of seaweed (modified from [5] and [47]) (Table 2).

The economics of these types of land-based IMTA systems were summarized in [5]. However, the economics of a land-based IMTA are site specific since they depend on variables including local construction and operating costs and market prices for the farm's products at any given time [34].

Additional anticipated parameters based on the same model of using 500 t feed per year in each of the three IMTA systems tested in Eilat, Israel, with the projected yields as depicted in Table 2, can be seen in Table 3.

Future Directions: Challenges and Constraints

Although considerable information is already available for putting land-based IMTA systems into practice, much of it is designed around commercial exploitation of a few high value species that are not affordable for the masses. The challenge for the future is to produce a large quantity of aquaculture products that will be cost-effective for producers, at a reasonable price for consumers, and ecologically sustainable.

Additional studies are required to overcome further constraints, including biological, engineering, and economical aspects:

Mariculture Systems, Integrated Land-Based. Table 3 Anticipated parameters for organisms in the three IMTA systems tested in Eilat, Israel, based on 500 t feed per year

Seabream
FCR = 1.9; Feed protein content = 49%
Fish stocking density = 200 t ha^{-1}; Annual fish yield −300 t ha^{-1}
Seabream farm gate price = €4 kg^{-1}
Seaweed
Ammonia uptake rate –4 g m^{-2} day^{-1}; ammonia uptake efficiency = 85%
Annual Ulva yield = 900 t ha^{-1}
Seaweed (WW) price = €0.5 kg^{-1}
Abalone
FCR = 12; stocking density = 25 kg m^{-2}
Annual yield = 10 kg m^{-2};
Farm gate price = €35 kg^{-1}
Sea urchins
FCR = 8 t *Ulva* 1 t of production; stocking density = 10 kg m^{-2}
Annual yield = 8 kg m^{-2}
Farm gate price = €10 kg^{-1}
Clams/Oysters
Clam annual yield = 6–8 kg m^{-2}
Clams farm gate price = €4.5 kg^{-1}
Oyster annual yield = 25 kg m^{-3}
Oyster farm gate price = €3.5 kg^{-1}

Biological Aspects

- To acquire the knowledge necessary to maintain the correct balance between nutrient production by the system's core organism, nutrient uptake capacity of microalgae and macroalgae, shellfish filtering efficiency, and macroalgivores' activity in the system
- To acquire the knowledge necessary to maintain steady populations of microalgae (mainly diatoms) for the filter feeders and of macroalgae for the macroalgivores within the system in order to avoid blooms and crashes
- To acquire the knowledge necessary for the efficient regeneration of the biodeposit (sludge) from the bottom back to dissolved nutrients for the macro- and microalgae
- To effectively control diseases of the cultured organisms in IMTA systems and transmission of pathogens between components of the system

Engineering Aspects

- To reduce construction and operating costs by engineering improvements
- To minimize heat loss or gain in downstream components of the system
- To increase the use of greenhouse-covered modular systems, gravitation, low head upwelling, water semi-recirculation and other promising energy-saving methods

Economical Aspects

- To render cost effective the use of the extensive areas required for cultivating micro- and macroalgae which cannot be done in a fully recirculating system and for which the facilities must thus be located not too far from the sea
- To develop and diversify the market of seaweed for human consumption from IMTA in Europe and North America
- To develop new markets and consumer acceptance of IMTA products

With the dramatic increase in population and food requirements, traditional extensive production systems cannot satisfy present and future market needs. Modern intensive monoculture systems are not ideal for mass production because they focus on few and expensive species, require high levels of resources, and produce undesirable wastes. To achieve high production rates and environmental conservation, food production using land-based IMTA systems is one of the most promising routes. The IMTA method assimilates expensive nitrogen waste into a valuable product that will increase profit for the farmer, improve FCR, diversify the mariculture products, create additional jobs, and, most importantly, reduce environmental pollution.

Article Outline

Glossary

Bioassay (BIOlogical ASSAY) A procedure to test the effect of a substance on living organisms, e.g., the effect of plant nutrients on plant growth rate.

Chemotherapeutants The use of chemicals to treat disease.

Dead zones Coastal areas that undergo seasonal hypoxia (low-oxygen), generally related to eutrophication events, whereafter many of the local (mainly benthic) animals die.

Exotic species An introduced or alien species living outside its natural range, which has been introduced by deliberate or accidental human activity.

FCR (feed conversion ratio) The efficiency at which an animal converts its food into biomass (body mass); FCR = mass of food eaten/increase in biomass.

Immunostimulants Chemicals used to stimulate the immune system by inducing activation or increasing activity of any of its components.

Marine protected areas Areas that restrict human activity (e.g., fishing, boating, coastal development) to protect living, nonliving, cultural, and/or historic resources.

NIMBYism "Not In My Back Yard"-ism; the practice of objecting to a human activity (generally commercial or industrial) that will take place near one's home.

Oligotrophic Waters that have low levels of nutrients and algae, high level of dissolved oxygen, and deep light penetration (i.e., clarity).

Prebiotics Food ingredients (e.g., soluble fiber) that stimulate the growth and/or activity of bacteria in the digestive system which are beneficial to the health of the body.

Probiont Living bacteria added to the environment and feed of reared animals and thought to benefit them by improving intestinal microbial balance, thereby inhibiting pathogenic bacteria.

Protista Unicellular (single-cell) eukaryotic organisms, e.g., foraminifera.

Definition of the Subject

Fisheries and aquaculture play an important role in the economies of many countries; yet this fact is often overlooked as the focus, in many nations, is on provision of food primarily, if not exclusively, from terrestrial agriculture. The value of seafood products as a source of foreign currency is especially important in developing countries and in many cases may exceed the profits from certain agricultural products [1], though this fact also tends to evade common knowledge. The Mediterranean aquaculture sector continues to grow at a rate of close to 9% per year (since 1970) as compared to 3% per year for farmed meat production systems. If the growth of the aquaculture sector can be sustained, it is likely to fulfill the demand for aquatic food supplies by supplying >50% of the total aquatic food consumption within the next 5 years! Therefore, the emphasis here is on the review of the sustainable growth of a commercial activity within an enclosed sea with many conflicting multinational interests. Aquaculture includes the cultivation of finfish, shellfish, crustaceans, and algae; however, this review will focus primarily on Mediterranean finfish farming since many of the sustainability issues revolve around fish farms. There are many different facets (e.g., ecological, social, political, economic) to sustainable commercial activities and this review will touch on several, though not all, of the issues related to aquaculture and its sustainable development in the Mediterranean Sea region.

Introduction

The Mediterranean Sea Environment

Although the term "environment" is often used to mean "ecology," the following description embraces the more holistic meaning, which includes the socio-economic aspects as well. The Mediterranean is a large, semi-enclosed sea bordered by 22 countries, with two distinct basins divided by a narrow, relatively shallow channel between Sicily in the north and Tunisia in the south. The areal division of the sea between the western and eastern basin is roughly 1/3:2/3. The eastern basin is somewhat more saline than the western basin, especially in the vicinity of the Suez Canal. The Mediterranean Sea has a wide range of seawater temperatures, from as low as 5°C in the Gulf of Trieste in the winter to 31°C off the coast of Libya in the summer [2]. The sea is oligotrophic and phosphorus limited [3] though some limited areas (such as parts of the northern Adriatic) may be eutrophic and it is warmer and more oligotrophic in its southern and eastern areas. Whereas the Mediterranean Sea accounts for only 1% of the world's ocean, it contains 6% of the world's marine species, including >400 endemic species of plants and animals [4]. Despite this impressive biodiversity, biomass is relatively low, mainly due to low primary production.

There are approximately 82 million people in the Mediterranean coastal zone: most in coastal cities and 32% of the population is in North Africa. Levels of development vary widely over the region. Tourism brings >100 million visitors to coastal areas annually, serving as a major source of seasonal population pressure and income and is thus a major competing sector with aquaculture. The Mediterranean Sea is a major shipping route, bridging between Europe and the Middle East and is a base for capture fisheries and mariculture. There are 75 marine protected areas (MPA) in the region, designed to protect unique and threatened resources and habitats such as the seagrass *Posidonia oceanica*, and breeding and nesting sites for endangered species, such as the loggerhead sea turtle (*Caretta caretta*). MPAs were also designated to encourage specific uses, such as sustainable tourism and regenerating fish stocks [5].

A Brief History of Mediterranean Aquaculture

The earliest evidence of aquaculture activity in the Middle East is from the ancient Egyptians. An Egyptian frieze, dated from 2500 B.C., depicted men gathering fish from a pond in what may be the earliest record of such activities in this region [6, 7]. In the sixth and fifth centuries B.C., the Etruscans reared fish in marine farms and the Greeks grew mollusks [8]. Throughout the Roman empire, marine fish (mainly sea bass, sea bream, and mullets) and oysters were reared in special enclosures (e.g., piscines) along the coast [9–11], but this practice seems to have died out with the collapse of the empire and did not appear in the Mediterranean until the middle ages. It is not clear precisely when it began, but there are records of extensive aquaculture in lagoons in Italy, also known as valliculture, starting from around the fifteenth century. Europeans traditionally collected shellfish along the shores, but since the eighteenth century the French oyster industry added a more reliable source – shellfish reared in specialized gear in the intertidal zone. Shellfish aquaculture expanded in the nineteenth century and coastal cultivation spread throughout the Western Mediterranean and the northern Adriatic Sea.

In the second half of the twentieth century, aquaculture developed rapidly, mainly as a result of successful research into the life cycle of the farmed animals (reproduction and larval rearing), as well as physiology, nutrition, and engineering of farming systems [8].

Main Forms of Mariculture (Culture Types and Species) in the Mediterranean

On a global scale, aquaculture production in the Mediterranean Sea is small, but not insignificant – especially with regard to the European demand for fresh seafood. Total aquaculture production in the Mediterranean Sea in 2006 was about 370,000 t [1] with 14% growth from 2000 to 2006, outpacing the growth of capture fisheries. It is noteworthy that the interannual variability in aquaculture production is lower than in capture fisheries (these have reached a plateau in terms of annual harvest), which may be a consideration of prime significance for business and decision-makers concerned with food security, coastal communities, and development.

Within the Mediterranean aquaculture sector, the most striking feature of production is the rate at which finfish have overtaken mussels as the dominant product. In 1990, finfish production accounted for less than 10,000 t as compared to approximately 90,000 t of mussels. In 2003, 180,000 t finfish and 150,000 t mussels were produced (49% and 40% of total production, respectively). Clam and oyster production were only 7% and 2%, respectively, and the remainder of production (∼2%) was crustaceans and seaweed. The main cultivated finfish species in the region are gilthead sea bream (*Sparus aurata*), European sea bass (*Dicentrarchus labrax*), and flathead gray mullet (*Mugil cephalus*). Greece, Turkey, Spain, and Italy were the four largest producers of sea bream and bass in 2006, comprising >90% of total Mediterranean production. Sea bream and bass are predominantly reared in net cages in coastal waters, whereas mullets are generally reared in ponds. The major producers of mullets are Egypt and Italy with Egypt generating more than 90% of global mullet production.

A fairly recent development is the farming of bluefin tuna in the Mediterranean, which mainly serves the Japanese sushi market. Tuna farming falls in between the definitions of a standard fishery, which is defined as "capture of wild stock" and aquaculture where fish are both bred and reared in captivity. Because tuna farming is a "postharvest" practice, it is not governed by the regulations of GFCM or ICCAT [12] and as a result there was unregulated growth in this sector, putting heavy pressure on the endangered Mediterranean wild stocks. Concerted efforts are being made to create brood stocks and hatcheries to enable the cultivation of bluefin tuna by the traditional aquaculture methods to release pressure on the endangered Mediterranean wild stocks.

Sustainable Marine Aquaculture in the Mediterranean

One of the features of marine aquaculture in the Mediterranean is that it is developing rapidly in response to a large and ever-growing demand for seafood. This demand was traditionally supplied by fisheries, but the drop in landings in recent decades as a result of overfishing has opened the path for sustainable alternatives to provision of seafood, namely aquaculture. That said, mariculture needs to operate in a manner that will minimize negative impacts on the marine environment, on wild stocks, and on other uses of the seas. Thus, sustainable aquaculture must ensure "*economic viability, social equity and acceptable environmental impacts*" [13].

It is obvious that aquaculture activity must be profitable to succeed, but there are many criteria to profitability and *economic viability* and these may vary considerably in countries that are at different stages of economic development (the process whereby an economic activity develops the technology and experience needed to operate successfully) or that have different interests in mind. In some developing countries, aquaculture may serve as a much needed food and protein source for local consumption, whereas other developing countries may prefer to export their aquaculture production for economic benefit.

Another component of sustainability is *social equity*. Societal equity depends on cultural norms and tendencies of society and varies considerably among the Mediterranean countries. It is probably the most difficult aspect of sustainability to consider because of its intrinsic variability.

Environmental "*acceptability*" is also a difficult issue because of the obvious question: "acceptable by whom?" In order to address this, one needs to consider where the aquaculture activity takes place, who are the stakeholders and how this activity may be conducted in such a manner that it will be acceptable by as many stakeholders as possible. The first aspect of sustainability, discussed below, is the public perception of aquaculture since public opinion may play an important role in the success or failure of the industry. In addition to the various social ramifications, "environmental acceptability" includes the effects of aquaculture on its surroundings and on the ecosystem. The following sections list several of the environmental issues that affect or are affected by Mediterranean aquaculture and a discussion of what is being done about them to enhance the sustainability of this sector.

Public Perception of Aquaculture

The *image* of fish farming varies considerably among different countries and can have a strong effect on the

sustainability of the industry. In some northern European countries, the public considers aquaculture in a positive light as a means to enhance food safety and security. In comparison, many southern European countries have a generally negative attitude toward farmed fish as these are considered inferior in taste and health value in comparison to wild-caught ("natural") fish [14, 15]. Numerous negative connotations are associated with marine aquaculture, including: "pollution causing eutrophication," "discharge of antibiotics and harmful chemicals into the environment," "genetic dilution/pollution of wild fish stocks," and "negative visual impact on the coasts."

The public perception is very important for both producers and coastal zone managers since there are many factors that are stacked against the aquaculture sector [16, 17]. These include lack of knowledge on many aspects of the coastal environment, the weakness of a small industry, competition with tourism and other coastal stakeholders, and increasing political power of local environmental lobbies and associations. These lead to non-sustainable situations, including loss of licenses, leases and markets, and reduced diversity in the coastal economy.

The social acceptability of aquaculture was examined at two Greek islands [18] and revealed that residents were more likely to be opposed to aquaculture if they thought that the fish farms would pollute the environment. A study conducted in Israel [19] evaluated public attitudes toward aquaculture and concluded that although most citizens were not terribly well informed in the implications of aquaculture on tourism and environmental issues, the majority are in favor of marine aquaculture. It is noteworthy that this lack of familiarity with aquaculture and aquaculture implications was also observed among the public surveyed in such countries as Scotland [20], Australia [16], and Germany (Schultz, unpublished).

Although the above focuses on the attitudes of the lay public toward aquaculture, it is possible that the opinion of stakeholders is equally (or more) important, despite the fact that the number of stakeholders is usually smaller. Competition over the coastal zone is one of the major sustainability issues that Mediterranean aquaculture faces on a regular and large-scale basis. The competition is especially severe between aquaculture and tourism since the Mediterranean attracts about 30% of the volume of global tourism annually and this is expected to increase over time. There are many examples of such competition, and one of the more recent clashes between the tourism and aquaculture sectors occurred in Turkey in 2008–2009, resulting in a major shift in legislation and in aquaculture lease requirements.

Measures to Improve the Public Attitudes Toward Aquaculture The negative attitudes toward aquaculture are largely a result of ignorance. The media often presents NGO views and opinions in their description of the fish-farming industry, and many of the facts presented are incorrect. The way to correct some of the misconceptions surrounding aquaculture is by preparing a well-planned outreach and educational program geared to reach as many households as possible. There are myths and misconceptions regarding such things as how fish are reared and the densities at which they are stocked, the safety of the feed used, the quality and healthiness of farmed versus wild fish, etc. Preparation of an aquaculture "module" to be taught at schools is an effective way to reach and educate future stakeholders and decision-makers. Another measure that could reduce conflict between aquaculture and other coastal stakeholders is a search for synergies among the stakeholders that would enable multiple use of the coastal zone [21]. Promotion of organic and other types of certification programs to increase public confidence in aquaculture practices and products would also improve public attitude toward this sector.

Benthic Impacts

In the 1990s, the study of the interactions of Mediterranean marine aquaculture with the environment focused on the negative impacts of the industry since most of the early research on salmon farms documented heavy benthic loading, which caused serious damage to underlying seafloor communities and in some cases to the water column as well [22–26]. Benthic organic enrichment that often occurs under intensive finfish farms rapidly leads to hypoxia and anoxia in the sediments. Anoxic sediments support bacterial sulfate reduction, generally leading to an increase in sediment hydrogen sulfide [27]; conditions that are

noxious, at best and often lethal to macro- and meiofauna [28]. Although abundances of macrofauna in Mediterranean sediments are considerably lower than the abundances found in temperate regions [29–31], defaunation under fish farms strongly reduces benthic bioturbation (i.e., aeration of the sediments) and leads to accumulation of reduced compounds and organic matter therein. If the farm is situated at a site with limited flushing and circulation, the depth and aerial extent of the impacted sediments may grow with time, creating localized "dead zones." Moreover, when methane accumulates in and bubbles out of anoxic sediments, noxious chemicals such as ammonia and hydrogen sulfide may affect the cultivated fish in the overlying cages.

Because the Mediterranean Sea is largely oligotrophic, and fish farming is generally not practiced at sites with poor flushing, the phenomena described above are not common. At a few sites with limited water circulation, for example, some farms in Croatia and Greece, organic enrichment of the seafloor and local impacts were observed, but these were exceptional and sediment conditions under Mediterranean fish farms are generally less impacted.

At those sites that showed evidence of impacted sediments, the visible effects generally did not extend beyond tens of meters from the edge of the perimeter of the farm [32], though the situation at each farm is different as a result of site-specific currents, depth, bathymetry, etc. The determination of the extent of impacted sediments and benthos (distance from the farm) is subjective and may be strongly affected by the method used. Organic matter determinations, visual inspection, and macrofauna indices are often the methods used to assess the state of the sediments and these clearly show a local effect that diminishes with increasing distance from the point source. However, more sophisticated analyses involving stable isotope signatures of farm effluents indicate that the aquaculture effluents may be detected as far away as 1–2 km from the farms [33–35]. It is very important to qualify the meaning of these measurements because they may be used to make a point about the extent of fish farm effects, but the real issue at hand is the extent of "significant impact." The distribution of small suspended particles over great distances will only constitute a significant impact if the flux of these particles is large and in the case of Mediterranean fish farms, the flux of very small suspended particles is small [36]. Therefore – it is essential to emphasize the difference between qualitative and quantitative effects.

Measures to Reduce Benthic Impacts Despite the fact that benthic loading is generally not a major issue in the Mediterranean, a number of different approaches are employed to increase feeding efficiency and reduce benthic loading. Feeding efficiency is not only an environmental issue, but also a major economic consideration since one of the greatest cost factors in intensive fish farming is the formulated feed. Feeding efficiency includes optimizing the composition of the feed (optimal digestibility) to maximize growth and minimize waste at the lowest possible cost, as well as feed delivery. Considerable efforts are invested by feed companies and fish nutritionists to optimize feed for the various strains of cultivated Mediterranean finfish [37, 38] and during recent years, sea bream and sea bass feed conversion ratios (FCR) have been substantially improved, largely (though not exclusively) due to improved diets and feed delivery. Feed delivery includes the optimal feeding regime whereby feed is provided to the caged fish in suitable portions and at the correct intervals to both maximize growth and health and minimize loss to the surrounding waters. Low-tech feeding involves delivery of pelleted feed to fish either manually by hand, or with the aid of a compressor and regulating the amount according to the response of the fish. High-tech systems include feeding programs that are computerized and customized to each individual cage to optimize delivery of feed to the stock. Another sophistication is the use of submerged Doppler systems (e.g., Doppler Pellet Sensor) that detect when fish stop feeding (increase in the flux of pellets to the bottom of the cages), and send signals to cause the automated feeders to cease feeding (http://www.akvagroup.com/). Many of the above are technologies that were developed outside of the Mediterranean, but as they are also applicable to sea bream and bass production, they are widely used by this sector. One of the more recent developments in Mediterranean aquaculture was the tuna-fattening process, which offered large profits to the farmers. Although it is arguable whether this process should actually be

qualified as aquaculture, the environmental ramifications were clear. The penned fish are fed freshly caught or frozen fish rather than pelleted feed and release large amounts of waste (greater than would be released from pelleted food) to the seafloor and have rather high feed conversion ratios (FCRs) 10:1–20:1 as compared to the FCR of sea bream (2:1) or salmon (1:1). Research is currently ongoing to develop artificial diets to create a better FCR for the tuna and to reduce the reliance and fishing pressure on small pelagic fish (e.g., [39]).

Water Quality

The sustainability of any human activity is a function of the nature of the receiving or host environment and in the case of aquaculture this is the basis for estimating the assimilative, holding, or carrying capacity [40]. At a few sites with restricted water exchange, for example, lagoons, there were reports of eutrophication problems [41–43] as the loading of organic and inorganic nutrients clearly exceeded the capacity of the environment to assimilate these [44]. Sites where such self-pollution problems emerge suggest that the preliminary environmental impact assessment and site selection procedures were not carried out properly. In the oligotrophic waters of the eastern Mediterranean, there are generally no reports of eutrophication or degraded water quality related to finfish or shellfish farms [45–47] and this was interpreted as the ability of the oligotrophic system to successfully assimilate the nutrients released by the farms. In an effort to understand whether nutrient release from aquaculture might have large-scale effects on the Mediterranean ecosystem, Karakassis et al. [48] employed a model to examine various production scenarios. They concluded that if aquaculture continues to grow and expand at present rates, farm wastes may increase overall nutrient (mainly N and P) levels by 1%, however, this is a general assessment and does not take into account localized effects. As suggested by Pitta et al. [49] in a study of three different Greek farms, it is likely that dispersion and dilution of the nutrients, combined with efficient herbivore grazing of algae (that develop from the released nutrients) were the reason for the absence of eutrophication around fish farms.

Although water quality is generally not affected, fish farms that operated over or near seagrass beds (especially *Posidonia oceanica*) exerted a clear effect on these [50, 51] and it was proposed that this may be related to the enhanced flux of dissolved and particulate nutrients from aquaculture. In an attempt to identify the effect of the plume of nutrients released from fish farms on water quality, Dalsgaard et al. [52] devised an innovative "bioassay" to measure the effect of dissolved nutrients released from fish farms on micro- and macro-algal production. They determined that primary productivity decreased with distance from the fish farms, yet by comparing bioassays with and without grazer exclusion, Pitta et al. [53] found that planktonic grazers (probably protista) play a key role in transferring nutrients up the food web.

Measures to Reduce Effects on the Water Column

One of the primary considerations when evaluating the suitability of sites for aquaculture is how they will interact with the surrounding marine system [54]. It does not pay, for example, to place net cage farms in shallow, poorly flushed waters (e.g., lagoons) because the organic and inorganic enrichment may affect both the marine ecosystem and the farmed organisms. Nevertheless, some farms have been deployed in unsuitable locations and these need to be relocated to allow the environment to recover and to enable the healthy growth of farmed finfish.

One of the early water quality problems associated with Mediterranean fish farms was the presence of an oily film around the cages. This was generally related to the large percentage of dust (pulverized feed pellets) in the pelleted food, which is not available to the farmed fish. Because this causes considerable loss to the farmers, and reduced water quality (stimulated bacterial growth also depletes the water of essential dissolved oxygen), the problem was rapidly addressed and most of the pelleted feeds are now extruded to improve pellet integrity and reduce feed loss and feed dust is collected and recycled.

A similar problem was identified in the tuna-penning industry. Unlike sea bream and bass that feed on formulated pellets, tuna are fed whole (preferably oily) fish such as sardine, anchovy, and mackerel. When these fish are offered to the tuna, the water around the pens often has an oily film and emits a strong smell. Moreover, in some cases, divers have complained of poor visibility near the pens. As described above,

research is ongoing to develop artificial diets for tuna [55] that will address not only the problems related to feeding with fresh fish but also the water quality problems.

Disease

Intensive aquaculture systems are very susceptible to disasters such as loss of the farmed stock. Among the various causes of such disasters, disease outbreaks rank highest [56] and may lead to great losses within a very short period of time.

Most finfish cage farms in the Mediterranean are intensive, that is, they have high stocking density in order to be economically profitable and to compensate for the low profit margin of sea bream and sea bass, the main species reared in this region. Although cage stocking densities are usually <25 kg m^{-3}, in some farms stocking densities are higher and such conditions may cause a reduction in fish growth rates, suppression of immune mechanisms [57–59], and ultimately greater susceptibly to disease agents, including opportunistic bacterial and viral pathogens and eukaryotic parasites [60]. Current estimates of average mortalities for farmed sea bream and sea bass as a result of disease are 10% and 20%, respectively, for growth from juvenile to market size (350 g) fish. In many cases, the profit margin for these fish is not much higher than 10–20%, which has therefore obliged the aquaculture sector to consider various options to address this problem. Moreover, there is concern regarding the potential transmission of disease from the farmed stock to wild fish, based on studies of disease transfer among Atlantic salmon (e.g., [61]). It is noteworthy that although there are numerous examples of disease exchange between caged and wild fish (e.g., [62–64]) in the Mediterranean, and other seas, most of these are not clearly understood [65, 66] and their effect on native stocks is unclear.

Measures to Reduce Disease Outbreaks Numerous antibiotics have been tested against the common farmed fish diseases and there are currently treatments available for most bacterial fish pathogens [67]. However, the routine use of antibiotics in marine aquaculture is problematic and has declined for a number of reasons. First, as specified above, there are concerns related to human and environmental health and safety. Second, although many of these drugs work well in freshwater, some of the major antibiotics, such as quinolones and tetracyclines interact with the divalent cations that are abundant in seawater (mostly Mg^{2+} and Ca^{2+}) which massively reduces their function and efficacy [68, 69]. Moreover, there is no "harmonization" regarding antibiotics use among Mediterranean countries and the list of pharmaceuticals licensed for fish varies from country to country, complicating international trade and marketing.

In addition to bacterial pathogens, there are several parasitic diseases that may stunt growth rates, cause loss of fecundity, and even mortality in Mediterranean fish. These include various protozoa and metazoa, which are classified as ecto- and endoparasites according to their distribution on/in the fish. Pathologists consider the myxosporeans *Myxidium leei*, *Polysporoplasma sparis*, and *Ceratomyxa* sp., isopods, copepods, and monogenean infections among the more problematic parasites.

Athanassopoulou et al. [70] reviewed the drugs used against a variety of parasites and found that amprolium and sanilomycin were the most effective against myxosporans in cultivated breams. Moreover, extracts from oregano revealed anti-myxosporan as well as antibacterial properties. Ivermectin and deltamethrin – drugs used to combat sea lice, have also been tested against copepod and isopod infections in sea bass and were fairly effective, but they tend to become toxic to the fish at fairly low levels.

In order to limit the use of antibiotics and other chemotherapeutants, the European Union established the "Maximum Residue Limit" (MRL) regulation, which monitors the presence of these drugs in all agriculture and aquaculture products and this has had a dramatic effect on the use of therapeutants. Because the MRL differs among countries insofar as which compounds are regulated and which are not, there is a lot of work ahead, but despite this, the trend looks very promising.

Vaccines are one of the preferred measures for prevention of disease outbreaks, however because the Mediterranean finfish market is still fairly small, only a limited number of vaccines have been developed for commercial use. Moreover, consumer concerns and increasing restrictions regarding their use have led the

industry to consider other alternatives to disease "management" [71, 72].

There are other alternatives to the use of chemotherapeutants and vaccines against disease. One of the key factors in the prevention of disease is good husbandry, which focuses on minimizing stress to the farmed stock. This includes proper stocking densities, optimal nutrition, sanitary practices, use of vaccines, and probiotics [66, 73]. The practice of good husbandry ensures fish are healthy and able to resist various disease agents naturally found in their environment. When they become stressed, the dietary requirements of fish for nutrients and vitamins change and a diet that compensates for such needs may optimize the growth of fish in captivity.

In recent years, it has become clear that the integrity of the gastrointestinal tract is essential in defense against pathogen attack as well as in proper endocrine and osmoregulatory activity. In recognition of this, Dimitroglou et al. [74] added the mannan oligosaccharide, Bio-Mos® (Alltech Inc, USA) to the diet of several marine fish including gilthead sea bream and found that this improved the gut morphology.

It is assumed that one of the roles that the mannan plays in protection of the fish is agglutination of pathogenic bacteria, which prevents their colonization of the gut. Indeed, the application of Bio-Mos significantly reduced the bacterial load in fish guts by reducing the biomass of aerobically cultivated bacteria [74]. Torrecillas et al. [75, 76] applied Bio-Mos to sea bass juvenile diets and found that it improved growth rates by 10%. Moreover, challenge trials using *Vibrio alginolyticus* showed that Bio-Mos fed sea bass had fewer of the pathogenic vibrio in their gut.

In recognition of the essential role of healthy gut flora in fish, especially in young fish, the use of immunostimulants, prebiotic, and/or probiotic bacteria have been proposed as a means to reduce gut colonization by pathogens [77], thereby improving the survival of cultured fish. Probiotics involves the addition of nonpathogenic bacteria to the diet and water of fish with the aim of loading the gut with bacteria that will prevent colonization by competing pathogens. The use of prebiotics and immunostimulants focuses on boosting the fish immune system so that the fish may more readily recognize and repel pathogen gut colonization. Although research has been conducted on the use of probiotics in Mediterranean aquaculture, (e.g., [78–80]), this approach has not successfully replaced the use of antibiotics to combat disease. One of the problems related to the use of probiotic bacteria is concern that these may not be as safe as they are supposed to be and their use may lead to other problems rather than a sustainable solution in the battle against disease.

Immunostimulants are commonly used in finfish farming to reduce the risk of disease by stimulating the protective activity of the immune system. The common forms of immunostimulants used in sea bream and sea bass aquaculture include ascorbic acid, a-tocopherol, and glucans [81, 82], which are added to the feed. Their presence appears to enhance antibacterial lysozyme activity and other indicators of disease resistance, but there is considerable discussion about their effectiveness due to the inherently wide range in concentrations and activities of the disease resistance molecules in fish serum.

Another approach to reduce the risk of disease is by means of classical selection/breeding for disease resistance by means of selective breeding programs [83]. The understanding of immune regulatory genes responsible for resistance to finfish pathogens is still in its infancy in Mediterranean aquaculture, but this field is rapidly expanding and it is anticipated that genetically superior lines will dominate the populations of fish reared in intensive aquaculture [84].

Escapes

In addition to problems related to disease and fluctuating profitability of aquaculture operations, fish farmers are also concerned with keeping their fish within the cages so that these can be marketed at the end of the growth cycle. There are many factors that may lead to loss of the farmed stock, including storms that may physically damage the net cages, predators (e.g., sharks, dolphins, bluefish, seals) that may bite the nets in their attempt to eat the enclosed fish, human error (e.g., during replacement of net cages or during harvest), poachers that cut the nets to catch fish, collision of ships with cage farms, etc. All of these generally result in the release of farmed fish to the surrounding environment, involving financial loss to the farmer and potential environmental problems related to genetic and ecological interactions of the escapees with the wild fish. At present, there are an

estimated >1 billion fish; mostly sea bream and sea bass in net cage farms throughout the Mediterranean as compared to much smaller stocks of the wild populations of these species [85], so the potential impact of escapees is considerable. Because many Mediterranean countries do not require farmers to report escapes, there are no reliable data on the frequency of escapes, however, it is assumed that the percentages of escapees are similar to those reported in Norway [86], ranging between 0% and 6%. In addition to genetic "pollution" of the wild-stock gene pool, and potential competition between escapees and wild fish over the same habitat and food resources, there is also concern regarding the spread of disease from farmed fish to wild fish populations [87].

Measures to Reduce Escapes and Damage due to Escapes As the volume of aquaculture production increases in the Mediterranean to match demand, and with the anticipated addition of North Africa to the fish-producing countries, there is a growing need for regulation in order to minimize problems related to escapes. In order to appreciate the scale of escapes from Mediterranean aquaculture, there is a need to legislate reporting of escape events, as is currently done in other parts of the world. Moreover, several new finfish species have been domesticated and their potential effect, as escapees, on wild populations and on the ecosystem need to be assessed. In addition, in order to assess escape impacts, it is useful to be able to track the escaped fish, as described by Triantaphyllidis [88].

There are many measures that may be employed to reduce the risk of escapes from fish cages. Storm damage to farm systems is one of the major causes of escapes and employment of a reliable standard, as practiced in Norway (NS 9415 – requirements for design and operation of marine fish farms) is a promising approach to reduce such risks. Even sturdy, reliable cages are occasionally damaged by especially strong storms, but most of the surface wave energy is concentrated in the upper 10 or 15 m of the water column [85]. Submersible cage systems designed for open sea conditions, such as the Sub-flex system (www.subflex.org) and the Ocean-Spar system (www.oceanspar.com/) are an option to reduce mechanical stress to net cages in high-energy environments. Added advantages of submersible cage systems include the reduced risk of collisions with maritime vessels and the reduced visibility following the "out of sight–out of mind" solution to NIMBYism. Human poachers are a problem that may be reduced by vigilance and by cooperation with the local police or security forces. Marine predators that bite net cages from the outside may be deterred by using stronger materials, though this has financial consequences, or by embedding chemical deterrents in the net material. Several farmed species tend to bite the net material from the inside and this may create holes enabling escapes. The biting may be prevented by using taste deterrents, as described for predators, or stronger material that will be more bite resistant. Moe et al. [86] suggest making the cage environment more "appealing" or stimulating to reduce gnawing on the net mesh which they attribute to boredom.

In addition to reducing the risk and frequency of escapes, there is also a need to reduce the impacts caused by the escaped fish. One direction that is being tested is the development of sterile triploid sea bream and sea bass that will not be able to pass on their genes to wild fish. Another possibility is the recapture of the escaped fish, but this direction is still in early developmental stages. The location of fish farms relative to areas of high ecological sensitivity or to spawning grounds should be one of the major considerations in light of the possibility that some of the stocked fish may escape.

Introduced Exotic Species

Invasive species are probably the cause of the greatest ecological problems identified over the past century, not only in terrestrial but also in aquatic and marine systems [4]. This problem has intensified over the past 20–30 years, as the volume of intercontinental traffic has increased. Aquatic invasive species are a major threat to marine biodiversity and impact human health and the economy [89]. There are numerous examples of the impacts of invasives on human welfare and environmental health, for example, the invasion of the Black Sea by the exotic ctenophore *Mnemiopsis leydi*, which caused the collapse of most of the local fisheries [90]; invasion of the eastern Mediterranean by the Red Sea medusa, *Rhopilema nomadica*, which has

heavily impacted Israeli and Turkish fisheries, tourism and coastal facilities [91].

In the eastern Mediterranean, exotic introductions are mainly channeled through the Suez Canal whereas most of the successful invaders in the western Mediterranean have been introduced by ships and via aquaculture [92].

Species introductions via aquaculture activities may be intentional or accidental, though the consequences are generally similar. Intentional introductions generally include the import of an exotic species and its release into the environment, without the intention that it spreads and dominates its new habitat. Examples include shellfish such as the Japanese oyster that was brought to France and spread rapidly throughout French coastal waters and certain species of sport fish that were intentionally released in northwestern US waters. The majority of introductions are not intentional but rather accidental and may occur in a number of ways. One common example of an accidental introduction is the transfer of a local species of oyster from a hatchery to the coast in a restocking program and the accidental release of an associated seaweed with the oysters. In another case, recreational boaters did not thoroughly wash the bottom of their boat after a holiday in a given bay and when they transported the boat back to their own shore, they brought with them a cryptic gastropod which subsequently invaded the new environment and decimated the local clam population.

Measures to Reduce the Invasion of Exotic Aquatic Species and Associated Damages In order to avoid the various risks involved in the use of exotic species, it is essential to rear/grow native species, as a rule. In many cases, the commercially attractive species are not native and farmers prefer to culture nonnative species. Introduced species may only be considered after taking all required precautions as specified in the ICES *Code of Practices on the Introductions and Transfers of Marine Organisms* [93] and the report on *Alien Species in Aquaculture* by Hewitt et al. [94]. Because the introduced species may escape and invade either local or neighboring environments, with implications for marine biodiversity, there is a need for both regional and international collaboration to address transboundary introductions and invasion issues, as discussed in UNEP [92].

The Mediterranean Aquaculture Market

The dominant species currently reared in the Mediterranean Sea are sea bream and sea bass [95]. These are native species that have been traditionally fished and eaten for centuries in many of the Mediterranean countries. Aquaculture has greatly increased the availability of these fish to the public and as production has increased, the price of the farmed fish has dropped dramatically so that in many cases its profitability is questionable. One of the important elements of a sector's sustainability is its economic performance yet the current trend in the Mediterranean is a plateau in profitability, that is, stagnation due to a glut in production of the two main species and a concurrent drop in their market value.

Alternative Aquaculture Species In order to survive and grow, the Mediterranean aquaculture sector needs to diversify its marine finfish production and include species with high market value. There are many native Mediterranean species that have a market because they are caught and sold by fishers and are suitable for cage culture. These include several species that have already been successfully reared in the eastern Mediterranean, such as Grey mullet (*Mugil cephalus*), Dover sole (*Solea solea*), Meagre (*Argyrosomus regius*), Sharp snout sea bream (*Diplodus puntazzo*), White bream (*Diplodus sargus*), Red porgy (*Pagrus pagrus*), Shi drum (*Umbrina Cirossa*), Striped sea bream (*Lithognathus mormyrus*), Pandora (*Pagellus erythrinus*). Although these fish are commercially available for aquaculture, there are several bottlenecks that prevent large-scale production. These include lack of knowledge regarding their nutritional requirements, lack of farm facilities for production, slow growth rates (may be related to nutrition or other problems), sensitivity to certain pathogens.

Ecosystem Effects

It has been shown that Mediterranean fish farms generally have a local effect, primarily on the underlying benthos, as described above, yet within a short distance from the cages, this effect rapidly dissipates. It has been suggested that the large load of nutrients that pass via the farmed fish into the marine environment are rapidly processed by the biota, yet may exert some

ecosystem effects. This hypothesis was tested by comparing the biological/chemical composition of seawater from fish-farming zones (within 2–3 nautical miles of fish farms) versus nonfarm zones (20 nautical miles of fish farms) in three parts of the Aegean sea in May and in September [49]. The data indicate that there is rapid transfer of nutrients up the food web, from the primary producers, via herbivores [53] to fish [96, 97]. These findings may be interpreted in a number of ways and their ramifications are debatable. If the precautionary approach is adopted, it is not clear what sort of implications these ecosystem-level changes may have and so they should be regarded with caution. On the other hand, if fish farms increase the size of natural fisheries, providing fishermen with an increased catch, this may be regarded as a positive externality of aquaculture (positive socioeconomic impact), which should be encouraged.

Seagrasses

One of the unique features in the Mediterranean Sea is the seagrass meadows of *Posidonia oceanica*. This slow-growing seagrass species occurs exclusively in the Mediterranean and grows best in clear, oligotrophic waters [98]. *P. oceanica* provides many ecosystem services, such as seabed stabilization, provision of a complex habitat to many larval and juvenile animals, oxygen production/release and long-term storage of CO_2 as plant tissue. Due to their slow growth rates, there is concern that these seagrass beds will not manage to recover if damaged and this important ecosystem and the services it provides may be lost. Marine botanists have calculated that some clonal colonies of *P. oceanica* may be 100,000 years old, that is, these are probably the largest and oldest-known living "organisms" on earth (http://en.wikipedia.org/wiki/Posidonia_oceanica). Because of their unique features, important ecological role and relatively low resilience to damage there is a strong movement in many Mediterranean countries to conserve and protect seagrass meadows from pollution, coastal development, trawling, and aquaculture. Recent work indicates that *P. oceanica* meadows located near or under fish farms have sustained considerable loss, including reduced meadow density, high shoot mortality rates (50-Diaz-Almela et al. 2008), increased epiphyte cover [99, 100] and very slow recovery rates following farm removal [101]. An analysis of several variables that may cause the observed damage to *P. oceanica*, in the context of the *MedVeg* project, has identified the deposition of particulate organic matter from the farms onto the seagrasses as the main factor leading to seagrass decline [102].

Measures to Protect Seagrass Meadows A set of recommendations were published by Pergent-Martini et al. [103] for the protection of Posidonia from fish farms, guided by the precautionary principle. These specified that: (a) Fish farms should not be situated directly over *P. oceanica* and *Cymodocea nodosa* (another important seagrass) meadows. (b) If seagrasses grow where a farm is planned, cages should be located at least 200 m from the nearest meadow. (c) Because these seagrasses generally occur at depths shallower than 45 m, farms should be set up at depths of 45–50 m where possible. (d) Environmental Impact Studies that relate to all seagrasses in the region should precede all lease requests to set up a fish farm. (e) If there are *P. oceanica* meadows near fish farms, these should be examined every 4 years to assure they have not been affected by the farming activity. On the basis of more recent findings, Holmer et al. [102] recommended to increase the distance between seagrass beds and fish farms to 400 m and to establish permanent seagrass plots to enable annual monitoring and sampling for seagrass health.

Future Directions

In the early 1990s, finfish aquaculture was generally a novelty in most parts of the Mediterranean, but this has changed radically during the past 20 years, as cage culture has spread throughout the region. Aquaculture is one of the fastest growing sectors worldwide and in the Mediterranean and it has many advantages over other food production industries, but in order to maintain a "green" image, aquaculture production and development must be sustainable. Progress has been made in many aspects of aquaculture technology but there are several areas that require attention and improvements in order to make this industry more environmentally and socioeconomically sustainable. Although numerous projects have focused on understanding the environmental interactions of aquaculture, the calculation of a reliable "carrying capacity" for aquaculture in a given water body is still generally

beyond our means, that is, there is a need for further study of ecological processes on a variety of different scales with respect to fish farms. Because there are so many different types of habitats and ecosystems within the Mediterranean Sea (e.g., hard vs. soft seafloors, Adriatic vs. Levant, etc.), it is essential that the ecological and socioeconomic research address region-specific issues [45].

As aquaculture expands into new areas and new species, there is added urgency to improve the understanding of fish pathology in Mediterranean systems. In addition to bacterial diseases, there is a need for research into antihelminthic treatments, and better understanding of life cycles and early diagnostics for many of the Mediterranean parasites. In view of EU policies concerning reduction of chemical use in the aquatic environment, the prudent and effective use of chemotherapeutants is essential. This may be achieved by combining therapeutic treatments with such health management strategies as breeding of tolerant fish, improving water quality, and vaccination.

Escaped fish may impact wild fish through competition, predation, habitat displacement, gene pool dilution, etc. In an attempt to reduce the numbers of escapees, progress is being made (e.g., in the EU project "Prevent Escape," which includes several partners from Mediterranean countries) in the design of cages that should be more damage resistant and in devising strategies to track the escapees and to reduce migration away from the breeched cages.

A Need for Legislation

One of the areas that urgently requires attention to enable development of the sector is legislation since this aspect is inadequately addressed in many Mediterranean countries. Moreover, in many countries that are active in aquaculture, there is a policy vacuum with regard to this sector. There is a need for clear rules and standards for licensing, planning, environmental impact assessment (EIA), administrative organization, and coordination. In the absence of clarity and transparency in such matters, investors and entrepreneurs will not take the risks involved in establishing aquaculture operations and the development of the industry will be retarded and sluggish. In a review of the legal obstacles to aquaculture, Van Houtte [104] included: (a) the legal status of water used (public or privately owned), the nature of water used (marine, brackish, or freshwater); (b) the legal status and nature of the land used (coastal vs. inland; private vs. public); and (c) the need for government regulation of aquaculture, and related activities. Moreover, the lack of coordination among public and regulatory agencies with regard to the EIA process, planning, etc. complicates the aquaculture application process. To further complicate matters, the permit application process is complex, cumbersome and very time consuming. The number of laws, regulations, rules, and procedures involved in the application process is large and many different authorities are involved at several levels. On top of that, the application requirements vary widely from country to country and in some countries, aquaculture legislation may vary internally on a provincial or regional basis.

One of the most problematic policy issues has to do with site selection and site allocation for aquaculture. As an economic activity that takes place, and has an effect on the littoral, aquaculture competes with many other uses of the coastal zone and needs to be included in Mediterranean coastal planning and management schemes. In recognition of the rapidly growing sector, in 2002 the European Union acknowledged that planning and coastal management would be among the major challenges facing European aquaculture. This was reinforced by the recent EU [105] communication, which emphasizes that "area choice is crucial and spatial planning has a key role to play in providing guidance and reliable data for the location of an economic activity, giving certainty to investors, avoiding conflicts and finding synergies between activities and environments with the ultimate aim of sustainable development" and invites all Member States to "develop marine spatial planning systems, in which they fully recognize the strategic importance of aquaculture."

One of the options chosen by some Mediterranean countries is zoning, that is, allocating a specific area for aquaculture as a means to reduce conflicts between coastal activities. In principle, this sort of approach simplifies things, provided: (a) the criteria used for selection of the aquaculture zones were appropriate and (b) the decisions regarding zoning involved the stakeholders and their interests. It is noteworthy that although there is aquaculture zoning in some

countries, aquaculture jurisdiction generally falls under regional governance, that is, there are no national zoning plans in the Mediterranean [54]. Although zoning is probably one of the better options for site selection, the lack of national coordination regarding the allocation of space for aquaculture will probably increase conflicts with time, thereby jeapordizing the sustainability of the industry. It would therefore be prudent to promote national zoning policy for aquaculture in the Mediterranean.

The conflict over space is fierce in the coastal zone as there are many competing stakeholders and one of the solutions to this is to go offshore [95, 106]. There have been many initiatives over the past few decades promoting offshore or open-ocean aquaculture, including several international conferences in the Mediterranean; however, a number of obstacles have prevented the realization of this concept. These obstacles include (a) economic feasibility of such ventures; (b) engineering and technological solutions for aquaculture in sites exposed to oceanic conditions; (c) international and national (government) support for an offshore aquaculture industry; (d) investors willing to take the risks involved in offshore aquaculture; (e) lack of understanding of the ecological ramifications (water column and benthos; local and regional effects) of large-scale aquaculture in exposed sites; and (f) the biological effects of cultivation in exposed conditions (storms, currents, predators, etc.) on the farmed stock, and other similar issues. At present, there are a few Mediterranean fish farms situated in exposed, offshore sites, but these are the exception rather than the rule, and most farms are situated in protected or semi-sheltered sites. A move away from the coastal zone into offshore waters will probably become a reality rather than an option in the near future and the aquaculture sector stands to benefit if it can accept this and help establish the scientific basis and technology in advance.

Integrated Aquaculture

Another option that makes considerable ecological and economic sense is an integration of different forms of aquaculture within the same farm. By arranging systems for rearing finfish (a form of "fed" aquaculture) adjacent to systems for growing shellfish and/or seaweeds (extractive aquaculture), it may be possible to increase farm sustainability on a number of levels. On the ecological level, shellfish and algae are called "extractive" because they extract their nutrients or food from within the system (autochthonous), and can therefore help reduce the nutrient loads from fish farms. Finfish are usually "fed" with feed that is manufactured from materials that come from outside the system (allochthonous) and the release of wastes and uneaten feed from the farms may affect water and sediment quality and even cause eutrophication. On the social level, cultivation of different products as compared to monoculture will require greater manpower and expertise and create the opportunity for greater employment, both within the farms and in the form of support services. On the economic level, additional crops should increase farm profitability, provided the filtering organisms are able to absorb the nutrients efficiently and they fetch a good price at market. Moreover, by diversifying the cultured stock, the farmer protects himself from risks related to market fluctuations, storms, and disease. Integrated aquaculture is currently practiced in Canada and in China on pilot to commercial scales but it is not clear how this approach will develop with time. In the Mediterranean Sea, there are no commercial integrated aquaculture farms [21] and this is due to the fact that either the secondary crop is a low-value (not profitable) product or the secondary (extractive) crop is not able to grow in the oligotrophic conditions that characterize Mediterranean waters. The potential for integrated Mediterranean aquaculture exists, but it must be both ecologically and economically viable to work.

Herbivorous Fish

One of the major challenges for both global and Mediterranean aquaculture is the limited supply of essential fish oil and fish meal [107]. The artificial diets of many farmed fish, including salmon, sea bream, and sea bass rely heavily on fish meal and fish oil, which places considerable pressure on wild fisheries (the source of fish meal and oil), severely jeapordizing the sustainability of the sector [108]. Several strategies have been proposed to address this problem, including the extraction of oils from fish-processing wastes [109, 110] and from fishery by-catch discards (the noncommercial fish

and animals that are caught by fishermen and subsequently thrown back to sea), and feeding fish with plant oils. There has been some success in the replacement of fish oils with plant oils [107], but many fish species have reduced survival and growth rates when reared without fish oils.

Another solution that has been proposed to address this problem is the rearing of herbivorous fish that do not require fish oils. Although these are generally not the highest value fish, they are nonetheless commercial species that are profitable to rear. The most common farmed herbivore in the Mediterranean is the diadromous gray mullet, *Mugil cephalus* (www.fao.org/fishery/culturedspecies/Mugil_cephalus/en). A lot of the pond rearing technology of this species was developed in Israel [111] and included polyculture. Egypt, the world leader in mullet production, has recently exceeded 1 million t/y. Although this fish is common in some of the southern Mediterranean countries, it does not have a large market in southern Europe and this is a challenge that needs to be overcome to promote herbivores as more sustainable species for aquaculture. Another problem that exists for *M. cephalus* is the absence of commercial hatcheries. Despite recent breakthroughs in spawning induction [112, 113], juvenile mullets are still collected from river mouths for aquaculture purposes thereby jeapordizing natural populations. These problems need to be addressed if this species is to be seriously considered a sustainable alternative to the common Mediterranean carnivores.

Indicators for Sustainable Aquaculture

The Water Framework Directive establishes the Environmental Quality Standards for European waters, and all activities that may affect environmental quality, for example, aquaculture must comply with these standards. Aquaculture lease applications generally include Environmental Impact Assessments (EIA), which assess risks and predict the impacts of aquaculture. Monitoring is an approach to test if EIA predictions were correct, and to establish a feedback system to protect both the environment and the fish farmer. The Modeling-Ongrowing fish farms-Monitoring (MOM) system [114, 115] was developed for salmon farming in Scandinavia, and includes a feedback process of EIA – monitoring – farm adjustment. Although the MOM concept was developed for Scandinavian farms, this approach has been adopted by the operators of several farms in the Mediterranean Sea to monitor their performance and environmental status. Monitoring generally includes measurement of: (a) physical variables, such as hydrography, weather, water temperature, sediment type, etc.; (b) chemical variables, including dissolved oxygen, nutrients, suspended solids, dissolved and particulate organic matter, etc.; and (c) biological attributes, for example, algal pigments, biomass, productivity, macrofauna abundance, diversity, etc. Fernandes et al. [116] reviewed the science underlying aquaculture monitoring in Europe and found that it was generally motivated by research interests rather than by clear environmental objectives. Whereas comprehensive monitoring of marine environments improves the understanding of the functioning of these systems [117], and thus the ability to predict the response of these waters to anthropogenic perturbations, it is often not necessary to include many of the variables that are monitored [102].

The CONSENSUS project recently established a set of 18 indicators (www.euraquaculture.info/index.php?option%20=%20com_content&task%20=%20view&id%20=%20149&Itemid%20=%20118) to promote "European Best Aquaculture Practice." These indicators are currently being evaluated to examine their practicality and suitability for the sector. In a separate project entitled *ECASA* (www.ecasa.org.uk/), a set of indicators to assess aquaculture–environment interactions were evaluated in order to streamline the farm monitoring process. This was done for aquaculture in both northern European and several Mediterranean countries (e.g., [118]) yet despite the advances made in that project, there is still a need to further streamline the list of indicators. The main criteria that should be used as a guideline in the quest for optimal indicators have been described in UNESCO [119] and include: (a) relevance, (b) feasibility (amount of effort, expertise, and cost required to obtain the data), (c) sensitivity (to inform on how the environment is responding), and (d) clarity (how easy it is for stakeholders to understand). Although progress has been made toward developing the final list of such indicators for aquaculture, this work is only partially done and further work is needed to achieve this.

Marine Fisheries Enhancement, Coming of Age in the New Millennium

Kenneth M. Leber
Center for Fisheries Enhancement, Mote Marine Laboratory, Sarasota, FL, USA

Article Outline

Glossary

Anadromous Species that spawn in freshwater, then their offspring gradually make their way into estuaries or the sea, where they remain during much of the subadult and adult stages of the life cycle, before returning to rivers and streams to spawn.

Catadromous Species whose females release their eggs at sea, then the offspring move as larvae or early juveniles into estuaries, rivers, and streams where they spend the juvenile stage of the life cycle.

Marine Species that spawn in sea water, including those that spend most of their lives at sea and catadromous fishes, which spawn in seawater, then enter freshwater nursery habitats.

Marine fisheries enhancement Release of aquacultured marine organisms into seas and estuaries to increase or restore abundance and fishery yields in the wild.

Outbreeding depression Caused when offspring from crosses between individuals from different populations or subpopulations (stocks) have lower fitness than progeny from crosses between individuals from the same population/stock.

Recruitment The process of joining an existing population. Species *recruit* to the juvenile stages in nursery habitats; juveniles subsequently *recruit* to adult stages in adult habitats. Species *recruit* to a fishery when they reach the minimum size fished.

Reintroduction Temporary release of cultured organisms with the aim of reestablishing a locally extinct population.

Restocking Release of cultured juveniles into wild population(s) to restore severely depleted spawning biomass to a level where it can once again provide regular, substantial yields.

Sea ranching Release of cultured juveniles into unenclosed marine and estuarine environments for harvest at a larger size in "put, grow, and take" operations.

Stock enhancement The release of cultured juveniles into wild populations to augment the natural supply of juveniles and optimize harvests by overcoming limitations in juvenile recruitment.

Supplementation Moderate release of cultured fish into very small and declining populations, with the aim of reducing extinction risk and conserving genetic diversity. Supplementation serves primarily conservation aims and specifically addresses sustainability issues and genetic threats in small and declining populations.

Definition of the Subject

Marine fisheries enhancement (aka "stock enhancement") is the use of hatchery-reared saltwater organisms to increase abundance and fishery yields in the wild. "Conservation hatcheries" also produce and stock depleted, threatened, or endangered organisms – to help preserve species in decline. The practice began in the latter part of the nineteenth century when fish hatcheries were first developed but understanding of the ecology and management of wild stocks into which the hatchery-reared organisms where released was very limited. Early stock enhancement thus has gone through a series of fits and starts and misfires. In the century after its birth, the technologies required for scientific inquiry of the effects and effectiveness of stocking hatchery-reared organisms were lacking. The science needed to guide reliable use of cultured

aquatic organisms in conservation and resource management remained undeveloped. Then, at the close of the twentieth century, new mariculture, tagging, and genetic technologies surfaced and rapid advances were made in the science underpinning marine stock enhancement.

As growth in human population size approaches the carrying capacity of the planet in this century, and the world increasingly turns to the oceans to farm and harvest food [1], sustainable fishery yields and conservation of natural resources face unparalleled challenges. Over the past two decades, marine fisheries enhancement has been transformed from a tentative, poorly developed management tool to a maturing science. Some believe research funding for this field would be better spent on traditional fishery management. But today's seafood producers, fishery managers, and "...conservationists need all the tools that biology, ecology, diplomacy and politics can muster if endangered species are to survive beyond the next century," [2] and fisheries are to continue to support a viable seafood industry and sport pastime. This entry traces the emergence and progress of marine fisheries enhancement, and offers a prescription for future direction.

The term *stock enhancement* is originally derived from efforts to augment wild fish sub-populations, or "stocks," by releasing cultured fishes into aquatic environments. Stocking cultured organisms is one of the tools available for managing aquatic natural resources. It has been used with varying degrees of success to help increase abundance of habitat- or recruitment-limited stocks to help restore depleted populations, augment fisheries and help recover threatened or endangered species. There has been much debate over the effectiveness of stock enhancement as a fisheries management tool. However, most of the scientific evaluation of stocking is quite recent [3], as is a code of responsible practices that help guide effective application [4–6], and marine fisheries enhancement is finally poised for effective use.

In the USA, from the 1880s through the early 1950s, stocking hatchery-reared marine fishes was a principal approach used by the US Fish Commission (renamed Bureau of Fisheries in 1903, Bureau of Commercial fisheries in 1956, and later the National Marine Fisheries Service) for maintaining fishery stocks. But by the 1950s the practice of stocking marine fishes to manage US fisheries was curtailed for lack of evidence of its effectiveness in fisheries management [7]. Stocking was replaced by harvest management to control total catch and sustain fisheries. Stocking of freshwater habitats continued (particularly with salmonids into rivers), although the scientific basis for many of the management decisions needed for stocking salmonids was clearly lacking and did not begin to be addressed until the mid-1970s.

In the decade following 1975, scientists began to evaluate survival and fishery contributions of stocked salmon enabled by advances in fish tagging technology [8, 9]. Quantitative evaluation of marine fish stocking began in earnest in the 1980s and 1990s. The science underlying fisheries enhancement has since evolved to the point where, in some situations, stocking can be a useful fishery management tool to help restore depleted stocks and increase abundance in recruitment-limited fisheries [6]. Effective use of enhancement, though, requires full integration with harvest and habitat management, and a good understanding by stakeholders and resource managers of the opportunities where enhancement can be used successfully as well as its limitations [5, 6]. Principles for guiding the successful use of marine fisheries enhancement to help sustain aquatic resources are now being employed to design new enhancements and reform existing efforts. What follows is a brief overview of those principles and progress made in using hatchery-reared organisms to help sustain marine resources.

Introduction

Marine fisheries enhancement is happening around the world and in some countries on a massive scale (e.g., China). However, in many countries the careful assessment of genetic and ecological risks is lagging behind implementation, putting wild stocks, the seafood supply, and sport fisheries at risk. The science of marine enhancement is still in its infancy compared to other fields of fisheries science, but now shows good potential to (1) increase fishery yield beyond that achievable by exploitation of the wild stock alone, (2) help restore depleted stocks, (3) provide protection for endangered species, and (4) provide critical information on the natural ecology, life history and environmental requirements of valuable marine species.

Stock enhancement has often been used as a generic term referring to all forms of hatchery-based fisheries enhancement. Bell et al. [3] and Lorenzen et al. [6] classified the intent of stocking cultured organisms in aquatic ecosystems into various basic objectives. Together, they considered five basic types, listed here from the most production-oriented to the most conservation-oriented:

1. Sea ranching – *recurring release of cultured juveniles into unenclosed marine and estuarine environments for harvest at a larger size in "put, grow, and take" operations*. The intent here is to maximize production for commercial or recreational fisheries. Note that the released animals are not expected to contribute to spawning biomass, although this can occur when harvest size exceeds size at first maturity or when not all the released animals are harvested.
2. Stock enhancement – *recurring release of cultured juveniles into wild population(s) to augment the natural supply of juveniles and optimize harvests by overcoming recruitment limitation in the face of intensive exploitation and/or habitat degradation*. Stock enhancements can increase abundance and fisheries yield, supporting greater total catch than could be sustained by the wild stock alone [10]. However, such increases may be offset, at least in part, by negative ecological, genetic, or harvesting impacts on the wild stock component. Stock enhancements tend to attract greater numbers of fishers, which can offset expected increase in each individual's catch-per-unit-effort (CPUE) [5, 11].
3. Restocking – *time-limited release of cultured juveniles into wild population(s) to restore severely depleted spawning biomass to a level where it can once again provide regular, substantial yields* [12]. Restocking requires release number to be substantial relative to the abundance of the remaining wild stock, and close ecological and genetic integration of wild and cultured stocks, combined with very restricted harvesting [6].
4. Supplementation – *moderate releases of cultured fish into very small and declining populations, with the aim of reducing extinction risk and conserving genetic diversity* [13, 14]. Supplementation serves primarily conservation aims and specifically addresses sustainability issues and genetic threats in small and declining populations [6].
5. Reintroduction – *involves temporary releases with the aim of reestablishing a locally extinct population* [15]. Continued releases should not occur, as they could interfere with natural selection in the newly established population. Fishing should also be restricted to allow the population to increase in abundance rapidly [6].

Scientific development of marine fisheries enhancement was lacking throughout most of the twentieth century. Although stocking cultured marine fishes began in the nineteenth century, the technology was limited to stocking only eggs and larvae. There were no published accounts of the fate of released fish until empirical studies of anadromous salmonids began to be published in the mid-1970s [16, 17], followed by the first studies (published in English) of stocked marine invertebrates in 1983 [18, 19] and marine fishes in 1989 [20].

During the past two decades, the field of marine fisheries enhancement has advanced considerably. Science in this field is rapidly growing, in part because of critical examination and debate about the efficacy of enhancement and the need for quantitative evaluation (e.g., [21, 22]), and in part because of advances made in aquaculture, genetics, tagging, and fishery modeling technologies, which have enabled quantitative studies and predictions of stocking effects. A clear process has emerged for developing, evaluating, and using enhancement [4–6]. Together, this process and the rapid growth of knowledge about enhancement effects should enable responsible and effective use of enhancement in marine fisheries management and ocean conservation.

Scientific Development of Marine Fisheries Enhancement

Scientific and Strategic Development

Since 1989, progress in marine fisheries enhancement has occurred at two levels – scientific advances and adoption of a careful and responsible approach to planning and organizing enhancement programs and manipulating abundance of marine species using aquacultured stocks. Much of the progress made in the 1990s was scientific and involved an expansion of field studies to evaluate survival of released fish

and improve the effectiveness of release strategies. The earliest studies on effectiveness of stocking *marine* fishes, published in English in the scientific literature, were in Japan [20, 23–26] and Norway [27–31], followed by studies in the USA [32–39], and Australia [40]. Progress made with invertebrates is well covered by Bell et al. [12].

Following the initial publications of scientific studies of marine fish enhancement, the number of peer-reviewed publications and symposia in this field began to escalate ([41–52], and see abstracts in [53]). It is now clear that stocking marine organisms can be an effective addition to fishery management strategies, but only when certain conditions are met. For stocking to be productive and economical, and help ensure sustainability of wild stocks, careful attention must be given to several key factors and stocking must be thoroughly integrated with fisheries management [6]. It is clear that stocking can be harmful to wild stocks if not used carefully and responsibly.

Aside from scientific gains in this field, the other level of progress made in the past two decades has been the evolution of a strategic "blueprint" for enhancements, such as the principles discussed in "a responsible approach to marine stock enhancement" [4, 6]. By the early 1990s, salmon enhancement in the US Pacific Northwest, which had been underway for a century, was beginning to incorporate reforms that were needed to improve efficiencies and protect wild stocks from genetic hazards that can lead to loss of genetic diversity and fitness. Concerns had been mounting over uncertainty about the actual effectiveness of salmon hatcheries and impacts on wild stocks. Concerns about wild stock impacts were twofold, including ecological effects of hatchery fish, such as competitive displacement, and genetic issues, such as translocation of salmon stocks, domestication and inbreeding in the hatchery and associated outbreeding depression, and loss of genetic diversity related to hatchery breeding practices (e.g., [54, 55]). Meanwhile, special sessions on marine stock enhancement began appearing at major fisheries and mariculture conferences in the early 1990s [41–44]. These sessions took a sharp turn from past approaches, where the principal focus in conference presentations about stock enhancement had been mainly on Mariculture research topics alone. The conveners of the special sessions on stock enhancement in the 1990s recruited presenters who worked on evaluating the effects and effectiveness of stocking hatchery organisms into the sea and interactions of hatchery and wild stocks. The special sessions focused on the "questions of the day" in marine enhancement and fostered debate in the marine enhancement research community about many of the reform issues being considered in salmon enhancement. The early 1990s was a period of rapid developments in enhancements, characterized by engagement of multiple scientific disciplines in a field that had previously been guided largely by a single discipline – aquaculture.

The salmon experience and reforms underway in salmon enhancement made it clear that a careful and multidisciplinary approach was needed in the development and use of marine enhancement. Many involved in developing new marine fisheries enhancement projects were paying close attention to the debate that had emerged over salmon hatcheries. Following the 1993 special session on "fisheries and aquaculture interactions" held at a mariculture conference in Torremolinos, Spain [44], several of the presenters (including scientists from Japan, Norway, the USA, and Italy [United Nations Food and Agriculture Organization, FAO]) met and formed an "International Working Group on Stock Enhancement," and affiliated the workgroup with the World Aquaculture Society. At that inaugural working group meeting, a decision was made to publish a platform paper to frame the question, "what is a responsible approach to marine stock enhancement?" This paper was presented at the 1994 American Fisheries Society symposium, "Uses and Effects of Cultured Fishes in Aquatic Ecosystems," and published in the 1995 peer-reviewed symposium proceedings [4]. The paper recommended ten principles for developing, evaluating, and managing marine stock enhancement programs. The Responsible Approach paper afforded a model for developing and managing new enhancement programs and refining existing ones. It has also helped frame research questions in the emerging science of marine fisheries enhancement.

The International Working Group on Stock Enhancement (IWGSE) was instrumental in advancing the science of marine fisheries enhancement in the 1990s. The working group focused primarily on

highlighting ongoing stock enhancement research around the world and fostering awareness of the Responsible Approach in their publications and presentations. International awareness and new research in the field was aided by the broad international makeup of the working group. Membership grew and soon included scientists from Australia, Canada, China, Denmark, Ecuador, Italy, Japan, Norway, Philippines, Solomon Islands, Spain, the UK, and the USA. Initially, the primary communication vehicle used by the working group was the special sessions on stock enhancement, which it planned and convened annually in various countries at the international conference of the World Aquaculture Society. The working group promoted a synergy among its members and the influence of the group expanded as members planned additional workshops and symposiums in their own countries and brought IWGSE scientists into the planning process.

The period 1990–1997 was a fertile time that gave birth to a rapid expansion of science in marine fisheries enhancement, which continues to this day, aided since 1997 in large part by the International Symposium on Stock Enhancement and Sea Ranching (ISSESR). The first ISSESR, held in 1997 in Bergen, Norway, was the brainchild of the Norwegian PUSH program (Program for Development and Encouragement of Sea Ranching) and the Norwegian Institute of Marine Research (IMR). In 1995, IMR scientists invited IWGSE scientists to become involved in the International Scientific Committee charged with planning the program for the first ISSESR. The first ISSESR, and the series of follow-up symposia that it launched (see www.SeaRanching.org), have encouraged and brought about fundamental advancements in the field of marine enhancement – by networking the scientists working in this specialized field, highlighting their work at the ISSESR, and publishing their peer-reviewed articles in the symposium proceedings. The 3–5 day ISSESR has now become a regular scientific symposium event, hosted by a different country every 4–5 years. Following the first ISSESR in Bergen [47], subsequent symposiums in the series were held in Kobe, Japan in 2002 [49], in Seattle, USA in 2006 [52], and in Shanghai, China in 2011 [53]. The fifth ISSESR will be held in Sydney, Australia in 2015 or 2016. Inquiries from scientists in different countries interested in hosting the sixth one are already being received by the organizing group. Following the first ISSESR, the IWGSE scientists continued the efforts they started in the working group through their involvement in the International Scientific Committees for the ISSESR and steering committees for other stock enhancement symposia (e.g., [46, 48, 51]). In 2010, a refined and updated version of the Responsible Approach was published [6] and presented at the fourth ISSESR.

As in any new science, lack of a paradigm and consensus on the key issues retard progress. The ISSESR and other marine enhancement symposia and working groups have helped to place scientific focus on critical uncertainties and communicate results of new science in this field at symposiums and in the scientific literature. They have also provided a forum for debate on the issues, and increased networking of scientists, resource managers, students, and educators working in this field worldwide. The focus on key issues is nurturing this new field of science.

Technological and Tactical Constraints

Although marine enhancements do show promise as an important tool in fisheries management, why has this field taken so long to develop and why have marine enhancement programs often failed to achieve their objectives? The scientific development of marine fisheries enhancement has long been impeded by lack of the technologies needed to evaluate effects of stocking cultured fish. Although marine enhancements began in the 1880s, until the advent of the coded-wire tag in the mid-1960s [8], there was no way to identify treatment groups and replicates in experimental releases of juvenile cultured fish [56]; and quantitative marking methods for multiple experimental groups of postlarvae and very small juveniles (<50 mm in length) came much later (e.g., [57]). To make matters worse, scientific development of marine enhancement was also stymied by lack of adequate technology for culturing marine fishes. Rearing methods for larval and juvenile marine fishes, many of which require live feeds during the larval stage, remained undeveloped until the mid- to late 1970s, when breakthroughs finally began to be achieved in rearing a few marine species past metamorphosis [58]. By the mid-1980s mass production of juveniles had been achieved for several

species of marine fishes. Even today, though, many marine fishes cannot yet be cultivated to the juvenile stage in the quantities needed for stocking. Without the availability of juveniles grown to a wide range of sizes, fundamental questions about density dependence, hatchery-wild fish interactions and cost-yield efficiency of size-at-release and other release variables cannot be addressed in field experiments. Thus, even the basic technologies needed to develop and understand the potential of marine enhancement have been unavailable until relatively recent times for some fishes and have yet to be developed for others.

Technology has not been the only constraint to successful development of marine fisheries enhancement. The effective use of stocking cultured marine organisms in fisheries management has been hindered by lack of understanding of the effect of releases on fish population dynamics and a lack of related, quantitative assessment tools [10]. Moreover, there has been a lack of essential governance and fisheries management considerations in planning, designing, implementing, and evaluating enhancement programs [6, 59]. A symptom of this is the relentless concern among stakeholders and hatchery managers alike about the numerical magnitude of fish released, rather than on the effective contribution of the hatchery program to fisheries management goals. Certainly, a hatchery needs to meet some release quotas, but the numbers of fish released is a misleading statistic for gauging success or comparing effectiveness among enhancement programs. Yet, from the very beginning, progress has been judged by the number of eggs, yolk-sac larvae or juveniles stocked, rather than by the number of fish added to the catch or to spawning stock biomass. The thinking behind this approach apparently is "grow and release lots of hatchery fish and of course they'll survive and add to the catch," without realizing the need to optimize release strategies (e.g., [39, 60, 61]) (e.g., to know what size-at-release, release habitat and release magnitude combination has the greatest impact on population size, fishery yields, and economics), or that the impact from stocking could in fact be a negative one on wild stocks (such as replacement of wild fish by hatchery fish) if certain precautions are not taken. This attitude has been pervasive and exists even today among many stakeholders and enhancement administrators. In fact, research now shows that survival and recruitment to the fishery following hatchery releases is a complex issue that requires much greater understanding about the fishery, hatchery fish performance, and biological and ecological factors in the wild than simply "the catch is down, thus releasing large numbers of fish will bring it back up." And quite often large release magnitudes are achieved by releasing millions of postlarvae, rather than fewer but larger juveniles. But releases of postlarvae alone may be effective, yet can also be totally ineffective, depending on conditions at the release site [62].

The key to successful use of stocking is to plan enhancement programs from a fisheries/resource management perspective, using a broad framework and scientific approach [6, 59]. The probability of achieving effective results is greatly increased when stakeholders are engaged from the outset in planning *new* programs, using a framework that is structured, multilayered, participatory, and makes good use of science, to design, implement, and analyze enhancement fisheries systems [6]. Incorporating the key principles in the Responsible Approach into the frameworks of *existing* programs as well is likely to improve performance.

Responsible Approach to Marine Fishery Enhancement

In retrospect, the slow development of marine fish culture (a century behind salmonid aquaculture) has helped marine stock enhancement programs avoid some of the mistakes of the past made with salmon stock enhancement, where lack of understanding of genetic issues during most of the twentieth century led to inadvertent domestication and inbreeding in salmon hatchery populations, leading to reduced fitness in wild stocks. Marine finfish juvenile production technology lagged behind freshwater and anadromous fish culture by a century. Thus, mass release into the sea of juvenile marine fishes large enough to survive and enter the breeding population did not begin until the 1980s. The relatively recent capabilities to conduct marine fisheries enhancement emerged at about the same time that geneticists realized that hatchery practices with salmonids (1) could reduce genetic diversity in the hatchery and ultimately, enhanced wild stocks, owing to inadequate broodstock management, (2) have caused translocations of salmon genes into

environments where they are less fit, and (3) have contributed to loss of local adaptations in the wild population. Today, population genetics is much better understood and broodstock genetics and hatchery practices can be better managed to address these concerns (e.g., [63–65]). Thus, marine enhancement programs need careful guidance from qualified geneticists. The Puget Sound and Coastal Washington Hatchery Reform Project in the USA has been instrumental in reforming salmon enhancements [66]. This group affords a model for managing enhancement hatcheries in the twenty-first century.

As progress was being made in the early 1990s to better understand the genetic structure of stocks and how to manage genetics in hatcheries, realizing the need for reform in approaches to enhancing non-salmonids was just beginning. In the mid-1990s, Cowx [67], for enhancements in freshwater systems, and Blankenship and Leber [4], for enhancements in marine and estuarine systems, published papers calling for a broader, more systematic, reliable, and accountable approach to planning stock enhancement programs. Prompted both by the salmonid hatchery reform movement and by the WAS IWGSE, the ten principles presented in Blankenship and Leber ([4] Table 1) gained widespread acceptance as the "Responsible Approach" to stocking marine organisms and provided a platform for subsequent discussions on planning, conducting, and evaluating marine enhancements (e.g., [6, 12, 22, 51, 52, 68–70]). Since 1995, the awareness of the Responsible Approach has steadily increased and has helped guide hatchery and reform processes for marine enhancements worldwide [11, 36, 37, 39, 60, 62, 69–90].

The Responsible Approach provides a conceptual framework and logical strategy for using aquaculture technology to help conserve and increase natural resources. The approach prescribes several key components as integral parts of developing, evaluating and managing marine fisheries enhancement programs. Each principle is considered essential to manage enhancements in a sustainable fashion and optimize the results obtained [4, 6].

A major development since the publication of the original "Responsible Approach" has been increasing interest from fisheries ecologists in understanding and quantifying the effects of hatchery releases from a fisheries management perspective. This has led to the development of fisheries assessment models that can be used to evaluate stocking as a management option alongside fishing regulations [5, 10]. At the same time, approaches to fisheries governance underwent major changes that allow enhancements to become more integrated into the management framework and in some cases, were driven by interest in enhancement approaches [59].

Walters and Martell [5] discuss four main ways that a marine enhancement program can end up causing more harm than good: (1) the replacement of wild with hatchery recruits, with no net increase in the total stock available for harvest (competition/predation effects); (2) unregulated fishing-effort responses to the

Marine Fisheries Enhancement, Coming of Age in the New Millennium. Table 1 The ten principles of a responsible approach to marine stock enhancement [4]

1	Prioritize and select target species for enhancement by ranking and applying criteria for species selection
2	Develop a management plan that identifies how stock enhancement fits with the regional plan for managing stocks
3	Define quantitative measures of success to track progress over time
4	Use genetic resource management to avoid deleterious genetic effects on wild stocks
5	Implement a disease and health management plan
6	Consider ecological, biological, and life history patterns in forming enhancement objectives and tactics; seek to understand behavioral, biological, and ecological requirements of released and wild fish
7	Identify released hatchery fish and assess stocking effects on the fishery and on wild stock abundance
8	Use an empirical process for defining optimal release strategies
9	Identify economic objectives and policy guidelines, and educate stakeholders about the need for a responsible approach and the time frame required to develop a successful enhancement program
10	Use adaptive management to refine production and stocking plans and to control the effectiveness of stocking

Marine Fisheries Enhancement, Coming of Age in the New Millennium. Table 2 Code of responsible conduct for marine stock enhancement [5]

• Make certain that management priorities and acceptable trade-offs are absolutely clear
• Do careful stock assessments to show that the target stock is recruitment overfished or can no longer rear successfully in the wild
• Show that enhanced fish can recruit successfully in the wild
• Show that total abundance is at least initially increased by the hatchery fish contribution
• Show that fishery regulations are adequate to prevent continued overfishing of the wild population, unless there has been an explicit decision to "write off" the wild population
• Show that the hatchery production system is actually sustainable over the long run, when it is to be a permanent component of the production system

presence of hatchery fish that cause overfishing of the wild stock; (3) "overexploitation" of the forage resource base for the stocked species, with attendant ecosystem-scale impacts; and (4) genetic impacts on the long-term viability of the wild stock. They stress that it is critical to monitor the impacts of enhancement as the program develops to have evidence in hand if debate about the efficacy of the program does surface. To help guide developing programs, they provide and discuss a "Code of Responsible Conduct" as critical steps in marine fisheries enhancement program design (Table 2).

In 2010, Lorenzen, Leber, and Blankenship [6] published an updated version of the Responsible Approach to refine the original key principles and include five additional ones (Table 3). The key principles added in the updated version bring stakeholders more firmly into the planning process; place much stronger emphasis on a-priori evaluation of the potential impact of enhancements using quantitative models; place marine fishery enhancements more firmly within the context of fishery management systems; emphasize design of appropriate aquaculture rearing systems and practices; and incorporate institutional arrangements for managing enhancements. Lorenzen et al. [6] provide comprehensive discussions for each of the 15 key

Marine Fisheries Enhancement, Coming of Age in the New Millennium. Table 3 The updated responsible approach (From [6])

Stage I: Initial appraisal and goal setting	
1	Understand the role of enhancement within the fishery system [*new*]
2	Engage stakeholders and develop a rigorous and accountable decision making process [*new*]
3	Quantitatively assess contributions of enhancement to fisheries management goals
4	Prioritize and select target species and stocks for enhancement
5	Assess economic and social benefits and costs of enhancement
Stage II: Research and technology development including pilot studies	
6	Define enhancement system designs suitable for the fishery and management objectives [*new*]
7	Design appropriate aquaculture systems and rearing practices [*new*]
8	Use genetic resource management to maximize effectiveness of enhancement and avoid deleterious effects on wild populations.
9	Use disease and health management
10	Ensure that released hatchery fish can be identified
11	Use an empirical process for defining optimal release strategies
Stage III: Operational implementation and adaptive management	
12	Devise effective governance arrangements [*new*]
13	Define a management plan with clear goals, measures of success, and decision rules
14	Assess and manage ecological impacts
15	Use adaptive management

principles listed in Table 3. Readers are urged to consult Lorenzen et al. [6] for additional detail, as it is beyond the scope, here, to repeat their discussions of each principle.

The 15 principles in the updated Responsible Approach include the broad range of issues that need to be addressed if enhancements are to be developed or reformed responsibly [6]. Clearly, marine

• Statistics and experimental design
• Tagging technology
• Communications and outreach

enhancement programs are multidisciplinary and their effective use requires specialist knowledge and skills from diverse fields (Table 4). Forming interdisciplinary teams of the various specialists required is an important factor in employing the Responsible Approach in developing, reforming, and executing marine enhancements. For effective design of enhancement programs, specialists in each area of expertise listed in Table 4 should be included in the planning teams.

It should be clear that without a careful monitoring system in place, marine enhancements simply cannot be managed. Monitoring is essential to understand the impacts of enhancement, to manage release strategies so that they are efficient and designed well enough to achieve the goals of the program, to protect against misuse of stocking (as discussed in 5 and 6), resulting in harm to wild stocks, and to document success or failure in meeting enhancement program objectives. Walters and Martel [5] list several key monitoring requirements for managing fishery enhancements well: (1) mark all (or at least a high and known proportion of) fish released from hatcheries; (2) mark as many wild juveniles as possible at the same sizes/locations as hatchery fish are being released; (3) experimentally vary hatchery releases over a wide range from year to year and from area to area, probably in on/off alternation (temporal blocking) so as to break up the confounding of competition/predation effects with shared environmental effects; (4) monitor changes in total recruitment to, production of, and fishing effort in impacted fisheries, not just the percentage contribution of hatchery fish to production; (5) monitor changes in the fishing mortality rates of both wild and hatchery fish directly, through carefully conducted tagging programs that measure short-term probabilities of capture; and (6) monitor reproductive performance of hatchery-origin fish and hatchery-wild hybrid crosses in the wild. Sound management-action design and monitoring is the essence of adaptive management [91] and adaptive management enables refinements, progress, and success in marine enhancement programs [4, 6, 11, 92].

Marine fisheries enhancement is a powerful tool that requires careful and interdisciplinary planning to control its effects. The process of transforming marine enhancement from an idea before its time into an effective resource management and sea ranching tool involves adopting a clear prescription for responsible use. As marine enhancement comes of age in this new millennium, agencies and stakeholders have a growing library of protocols for enhancement at their disposal and the responsibility to use them. The Responsible Approach and Code of Responsible Conduct provide healthy prescriptions for controlling the outcome of enhancements. These principles need to be adopted and used well, in order to increase and ensure the readiness of this tool to aid in conservation and to increase fishery yields when it is needed. Growth in human population size is fast approaching a critical level, and much greater attention will be placed in this century on obtaining food from the sea [1]. It is unwise to not be ready with marine enhancement to help sustain depleted, threatened, and endangered species, help maintain wild stocks in the face of increasing fishing pressure, help sustain sports fisheries, and help increase fishery yields.

Legacy from the Past

Allure of a Quick Fix

Marine enhancement programs are often seen as a "quick fix" for a wide variety of problems in marine

resource management. At best, they may be an important new component of marine ecosystem management; if not implemented responsibly, though, they may lull fishery managers into false confidence and thus lead to inaction and delay in the development of other fisheries management and restoration programs [5, 6].

Although marine fisheries enhancement is certainly not a quick fix, it can be a powerful tool for resource management when conditions warrant the use of this tool and if the time and care needed are taken to develop enhancement programs well. Unfortunately, the allure of a quick fix has often prompted stakeholders and managers to skip or ignore several elements needed to allow those programs to succeed, leading to wholesale failure of such efforts. The field of marine fisheries enhancement is littered with examples of enhancement projects that failed to achieve their potential for lack of a careful enough or quantitative approach (e.g., see accounts discussed in [7, 21, 62, 72, 93–95]). Most of the failures can be traced back to attempts to use enhancements when they were not warranted or failure to consider several, if not most, of the principles now incorporated in the "Responsible Approach" and "Code of Responsible Conduct" for marine fisheries enhancement.

Isolation from the Fisheries Science Community

Historically, marine fisheries enhancements have been conducted more or less isolated from other forms of fisheries management. Enhancement hatcheries have often been promoted by stakeholders and government mandates without the necessary funding or authorization behind them to do much more than produce and release fish without funds for monitoring impacts and adaptive management needed to increase the effectiveness of enhancements. Such programs are often built and implemented from a vantage point within resource management agencies that has little or no connectivity with the existing fishery management process. This has stymied development of this field in two ways – first, by compelling hatcheries to operate within resource management agencies largely independent from stock assessment and fisheries monitoring programs, or even worse, within different agencies altogether. Second, such isolation has fostered development of a production-oriented operational mode, and thwarted development of an enhancement-oriented mode [92].

Part of this isolation from fishery management also stems from the poor track record of the early marine hatcheries as an effective way to recover depleted fish stocks, coupled with the lack of scientific development of marine fisheries enhancement for so long into the twentieth century. This has understandably led to bias against fishery enhancements. Many of today's fishery scientists have been schooled to understand that stock enhancement has not worked, based in part on the lingering legacy from past failures and in part on lack of awareness of new marine fisheries enhancement science, as few citations have yet appeared in fisheries science textbooks. With many of the scientific achievements in fisheries enhancement having occurred only over the past decade or so, this is understandable. But in light of the need to couple fisheries enhancement with fisheries management systems, lack of awareness of progress in this field is an obstacle that may be resolved only by compilation of more and more success stories over time. Thus, it is imperative that existing and developing enhancement programs alike incorporate modern concepts about how to plan and conduct enhancements so they are enabled for success.

Progress in Marine Fisheries Enhancement

Lessons Learned from Marine Enhancement Programs

Much progress has now been made in understanding how to manage enhancement more effectively. Bartley and Bell [96] considered progress made from three decades of stocking initiatives and summarized and discussed lessons learned. These are listed here, below [96], with a brief clarification or caveat on each.

Deciding When and How to Apply the Release of Cultured Juveniles

1. Objective assessment of the need for releases is crucial – and requires an evaluation of the status of the fishery, modeling of stocking impact to determine if stocking can help achieve the goals, coupled with consideration of whether there are recruitment limitations and adequate habitat available for stocking.

2. Releases of cultured juveniles for restocking and stock enhancement need to be made at the scale of self-replenishing populations – releases will not be effective unless the spatial extent of target populations has been identified; thus prior to conducting releases of hatchery organisms, clear identification of genetically discrete stocks should be determined.
3. There are no generic methods for restocking and stock enhancement – largely because of wide variation in life history among different species and variation in ecological conditions among release sites.
4. Very large numbers of juveniles are often needed for effective stock enhancement – this is particularly so for offshore stocks, which can be comprised of a huge number of individuals; more modest releases may suffice for localized enhancement of inshore stocks or those comprised of multiple stocks that occur on relatively small scales.
5. Large areas are needed for stock enhancement of some species – and this can result in user conflict, particularly for sea ranching, where large areas are leased and protected by the enhancement program (e.g., [97]); in other cases, limited dispersal of adults and larvae indicates stocking in smaller areas can be effective, for example, common snook along Florida's Gulf Coast [98].
6. Invertebrates offer good opportunities for restocking and stock enhancement – because invertebrates are often comprised of self-recruiting populations that occur at small scales.

Integrating Interventions with Other Management Measures

7. Problems that caused lower production must be addressed before release of juveniles – particularly in the case of degraded, lost, or insufficient habitat. With better management of the wild resources, the scope for augmentation of total production declines; enhancement becomes a very site specific tool when habitat has been lost, or something needs rebuilding, or there are species of particularly high value [94].
8. Biotechnical research must be integrated with institutional and socio-economic issues – ownership rights and control and use of enhanced stocks need to be well understood by the greater institutional, social, economic, and political environment [99].
9. Successful stock enhancement programs are often run by cooperatives and the private sector – where there is increased incentive in sharing the costs of fisheries enhancement.
10. The costs and time frames involved in restocking programs can be prohibitive – hatchery costs, which can be considerable, are particularly difficult to bear in smaller countries and developing countries.

Monitoring and Evaluation

11. Development of cost-effective tagging methods is critical to efficient evaluation of stock enhancement – refining and monitoring the effects and effectiveness of marine enhancements cannot be done without a way to distinguish hatchery from wild stocks and distinct release groups.
12. Large-scale releases of hatchery-reared juveniles can affect genetic [fitness] of wild populations – genetic hazards can be caused by hatchery-wild fish interactions and these need to be minimized.

Reducing the Cost of Juveniles

13. Costs of stocking programs can be reduced by "piggybacking" production of juveniles for release on existing aquaculture – this could reduce or eliminate the need for expensive new hatchery construction for enhancement programs, as long as appropriate broodstock management protocols are in place for conserving wild-stock genetics.
14. Wild [postlarvae] can provide an abundant, low-cost source of juveniles for stock enhancement programs – this can sometimes be an effective way to reduce costs and eliminate genetic issues; successful scallop enhancement in Japan is based on collection of wild seed stock.
15. The costs of restocking can be reduced greatly for some species by relocating adults to form a viable spawning biomass – rebuilding spawning aggregations by concentrating broodstock can be effective for depleted stocks with limited larval dispersal, but care must be taken to avoid comingling different stocks (i.e., avoid translocation of exogenous genes).

Improving Survival in the Wild

16. Predation is the greatest hurdle to survival of released juveniles – care must be taken to understand ecology of the species and ecosystem at the release site and pilot experiments are needed to develop optimal release strategies to maximize survival.
17. Excessive releases of juveniles cause density-dependent mortality – density has a strong effect on growth and survival in the wild; planning release magnitude must take into account the carrying capacity at release locations. This requires adaptive management and an experimental framework for releases.
18. Small-scale experiments to test methods for releasing juveniles can give misleading results – "commercial scale" releases are needed to test assumptions made from small-scale release experiments.
19. Good survival of released juveniles at one site is no guarantee that the methods can be transferred to other sites – stocking effectiveness will vary with release location and what works at one site may not be effective at another.

Other Manipulations to Increase Abundances

20. Artificial habitats can be used to increase the carrying capacity for target species – and may enable increased production at release sites where there are resource (food, refuge, space) limitations.
21. Yields of some species can be increased by providing suitable settlement habitat and redistributing juveniles from areas of heavy settlement – for example, redistribution can be used to reduce density effects and increase probability of successful recruitment when moved to a location with greater availability of food, refuge, or settlement habitats. But care must be taken to avoid genetic hazards associated with comingling stocks.

Examples of Progress Made in Marine Enhancement

As science and constructive debate have advanced in this field, there are many signs of progress. Some explicit examples of progress made in marine enhancement over the past couple of decades are presented below, ranging in scale from local experimental investigations of release strategies and density-dependent effects on hatchery and wild stocks (e.g., [100]) to documented replenishment impact in large-scale enhancement efforts (e.g., [101, 102]). This is but a sample of examples and is by no means a comprehensive list. There are many more examples in the peer-reviewed proceedings from the ISSESR and other stock enhancement conferences [41–53] and other journal articles.

1. Adoption of a science-based responsible approach to marine stock enhancement has now become widespread, resulting in a much more assessment-driven and precautionary approach than ever before (a few examples include Refs. [4, 6, 10, 12, 20, 22, 27–29, 33, 37–39, 59–61, 68, 69, 72, 75, 84, 86, 87, 89, 96, 103–106]). This has been enabled, in part, by advances in tagging technology (e.g., [8] and see examples in [9, 56]) and in development of new marine aquaculture technologies that can now provide juvenile fishes for marine enhancement research.
2. Networking of Scientists involved in this rapidly advancing field has been fostered by various symposia and working groups, for example, the World Aquaculture Society Working Group on Stock Enhancement and the scientific committees for the International Symposium on Stock Enhancement and Sea Ranching (www.SeaRanching.org).
3. There is a much better appreciation of the importance of managing marine fishery enhancements from a fisheries management perspective (e.g., [6, 59, 107]).
4. New tools are available for modeling stock enhancement effects and effectiveness [10, 82, 108–110].
5. At least two experimental field studies have now been conducted to evaluate density-dependent interactions of stocked hatchery and wild fish; these provide evidence that increased production can be achieved in juvenile nursery habitats without displacing wild fish, but not necessarily without displacing some of the hatchery fish [33, 100].
6. There is now clear evidence and a prescription of techniques for improving post-release survival (often with a doubling effect or more) of stocked marine fishes, and optimizing release strategies to maximize stocking efficiency and control impacts

(e.g., [26, 36, 37, 39, 60–62, 70, 72, 100–115]). There is also ample evidence that in habitats with limited carrying capacity or intense predation, regardless of release strategy used, little can be done to improve survival of hatchery fish and stocking simply cannot increase production [106, 116, 117].

7. It is now fairly clear that marine enhancements may be cost effective only if (a) the supply of recruits is generally limiting, (b) there is adequate habitat to support an increased supply of juveniles, (c) cultured juveniles represent a large portion of recruitment, (d) fishing is regulated appropriately, and (e) other management measures (catch regulations and habitat restoration) are insufficient to restore catch rates [96].
8. Stock enhancement of some species of marine finfish has been successful at the scale of large bays, for example, Hirame flounder and red sea bream in Japan [72, 106] when there is sufficient carrying capacity at release sites. Carrying capacity varies considerably among release sites, and thus must be evaluated and taken into account using monitoring and adaptive management for each release site.
9. Scallop sea ranching has been a large success in Japan, New Zealand, and China, where property rights and large ocean leases have created strong incentives for careful management by fishermen and owners of the sea ranching operations [72, 101, 102, 118]. For example, near Dalian, China, Zhangzidao Fishery Group leases 2,000 km^2 of ocean-bottom-to-ocean-surface for sea ranching. In 2010, Zhangzidao harvested an average of 150 t/day of ocean scallops from their sea ranching operations (over 50,000 t/year) (Wang Qing-yin, personal communication 2011).
10. Property rights have also provided incentives for bivalve culture in the State of Washington, USA, where clam sea ranching operations have remained economically and environmentally sustainable for over three decades [119].
11. Pilot experiments with black bream in an Australian estuary have documented quite good survival and recruitment to the fishery. The latest phase of this project reveals strong rationale for long-term monitoring of enhancement impact [87, 120].
12. Restocking success with red drum in a South Carolina estuary [77, 121]. Pilot experiments revealed surplus productive capacity in the Ashley River in South Carolina, where fishery landings of red drum were doubled over a few years.
13. Pilot experiments to evaluate blue crab enhancement potential in Maryland and Virginia led to improvements in traditional fishery management, with information learned through stocking research [70, 114]. Pilot experiments can be used to provide critical information on the natural ecology, life history, and environmental requirements of valuable marine species [122].
14. Perhaps the largest scale enhancement success for fishes is Japanese chum salmon restocking – a special tool for a circumstance in which the habitat had almost totally been lost [94].

Future Directions

Over the past two decades, there has been a rapid expansion of knowledge about marine fisheries enhancement systems and the effects and effectiveness of stocking a wide variety of marine organisms for sea ranching, stock enhancement and restocking. Many gaps in knowledge have now been filled. Well thought out approaches now provide a roadmap for effective use of enhancements. When models show potential for stocking, efforts to deploy marine enhancements can be successful if the principles in the roadmap are carefully employed. The basic reason that marine enhancement programs do not have more of a track record of success stories yet is that implementing them well is a complex endeavor that demands attention to multiple factors spanning many disciplines. Rarely have these been pulled together in an enhancement program. The Hatchery Reform Project in the Pacific Northwest USA, which includes an independent scientific review panel ("Hatchery Scientific Review Group") is a good example [123]. Because of their efforts, salmonid hatchery reforms now underway are bringing many of the principles of the Responsible Approach into play. The Norwegian PUSH program is another good example. In that case, information gained from quantitative assessments of enhancement showed that stocking would not be an economical way to enhance cod in Norway, thus saving years of wasteful

spending that could have occurred there, had monitoring and adaptive management not been a central part of the enhancement system.

Successful examples of fisheries enhancement are truly group efforts, involving stakeholders, agency officials, and individuals with expertise in the principal sub-disciplines needed. Suffice to say that at this point in time few, if any, marine fisheries enhancement programs have enlisted all of the key elements of the Responsible Approach and Code of Responsible Conduct. But these principles are now well described and laid out in a systematic manner. It is reasonable to expect that if the Responsible Approach is used as the blueprint for planning and executing enhancements, and if the initial appraisal and goal setting stage indicates moving ahead, then there is ample opportunity for success in applying marine fisheries enhancements, as long as dedicated attention is focused on applying each of the key elements.

So how will marine enhancement advance to the next level – emergence of a rapidly growing body of success stories in restocking, stock enhancement, and sea ranching? Listed below are a few factors that are now needed to transition this field to the next level, where marine enhancements are well integrated into resource management systems and used wisely and appropriately.

Enabling Factors for Increasing Successful Marine Enhancements

1. *Greater awareness is needed among all stakeholders of the issues, pitfalls, progress, and opportunities in this field.* The concepts underlying effective enhancements need to be translated into lay language and used to inform stakeholders. This will help all stakeholders recognize the various issues and parameters needed for effective enhancements. Pivotal among stakeholders are public officials who fund enhancement programs, as they need to understand what it takes to develop an effective program or reform existing ones. New enhancement programs that may not be funded well enough to implement all of the key principles in the Responsible Approach would do well to use the results of Stage 1 in Table 3 to document the potential for success, but not proceed beyond Stage 1 until adequate funding is available.
2. *Use of Adaptive management is one of the most important principles for guiding successful enhancement programs.* Active adaptive management [91] is critical for gauging the effectiveness of, improving, and managing fisheries systems in the face of uncertainty. However, it is often dismissed by enhancement programs or given low priority for lack of funding or when enhancement is viewed as a quick fix. But, this important principle is used to optimize release strategies, to identify and deal with ecological or genetic impacts on wild stocks, to refine the enhancement process and identify the results of improvements, to evaluate and improve progress towards goals and objectives, and to monitor and improve economic impact. Active adaptive-management is an essential component of managing enhancement programs; it empowers management teams to understand and control the impacts of enhancements well. Without it, enhancement programs at best rely on hope to achieve their potential (but cannot) and at worst are doomed to failure. Australia is employing active adaptive management principles early in the development stage as part of ongoing work to evaluate enhancement potential for a wide range of species [124].
3. *Adapt the Responsible Approach to local circumstances.* The Responsible Approach is purposely vague on how to implement it. This is partly because not all elements are needed under all situations, but most will be. Fitting the process to particular circumstances is in itself a key part of implementing the Responsible Approach by engaging the various stakeholders in planning [6]. As progress continues in this field, additional principles will emerge that need to be included, for example, to account for needs of regional fishery management plans in response to climate change.
4. *Seek assistance from established workers in the field.* For new and developing enhancement programs, or existing ones seeking to design and implement reforms, there is a broad and expanding network of workers in this field who could be queried for advice on various enhancement issues. The ISSESR website is a good source for identifying individuals with specific kinds of expertise, by perusing presentation abstracts or locating published proceedings from past ISSESR conferences [125]. If researchers

or workers in the field are contacted, but do not have time to provide advice, they usually will help identify others who can.

This entry may help expand awareness among fishery stakeholders, other natural-resource stakeholders, scientists, and fishery managers alike about the pitfalls, challenges, and progress made in using marine hatchery releases as one of the tools in resource management and seafood production. Readers are referred to the articles and symposium proceedings cited herein to gain a better understanding of the issues, lessons learned, and progress.

The debate focused on enhancement is a healthy one, for it is fostering steady improvements and reforms in existing programs, and careful planning and design in new ones. With each advance made, the potential seen by our forefathers to use hatcheries as a tool for recovering depleted stocks, increasing abundance in recruitment-limited stocks, and producing seafood by sea ranching is coming closer to fruition. One of the greatest lessons learned from the past is that the emphasis on expanding hatchery fish production for marine enhancement should not be allowed to take the focus off of the objective – increasing yields in fisheries and recovering stocks in restoration programs. Clearly, marine fisheries enhancement is a strong tool to add to the fishery management toolbox. But only careful analysis of conditions of the wild stock and the fishery will guide when and where it is appropriate to use enhancements in addition to other management options, and when to stop. As Albert Einstein once said, "a perfection of means, and confusion of aims, seems to be our main problem." With the focus shifted to outcomes in marine enhancement programs, the appropriate means should fall into place, aided by healthy debate and prescriptions for a responsible approach to marine fisheries enhancement.

Marker-Assisted Breeding in Crops

Roberto Tuberosa
Department of Agroenvironmental Science and Technology, University of Bologna, Bologna, Italy

Article Outline

Glossary

Backcross Procedure used by plant breeders to introgress an allele at a locus of interest (e.g., disease resistance) from a donor parent to a recurrent parent, usually a successful cultivar. The recurrent parent is crossed several times to the original cross and selection is performed at each cycle to recover the plants with the desired allele and the largest portion of the genome of the recurrent parent.

Candidate gene A coding sequence that is supposed to be causally related to the trait under selection. The candidate-gene approach is best applied with simple biochemical traits when a clear cause-effect relationship can be established between the gene function and the target trait.

Epistasis The interaction between two or more genes to control a single phenotype. Interaction between two or more loci that control the same trait. The presence of epistatic loci makes it more difficult to predict the phenotypic value of progeny derived either from crosses or from selfing.

Forward genetics Approaches to dissect the genetic makeup of traits starting from the observation of the phenotype. QTL mapping and positional cloning are examples of forward genetics to investigate quantitative traits.

Haplotype Chromosome fragment of varying length carrying a common set of marker alleles in close linkage at adjacent loci. When using haplotypes in association mapping studies, the information of several linked bi-allelic markers is combined as a single, multi-locus informative marker.

Heritability The portion (from 0% to 100%) of phenotypic variability that is genetically determined. The additive portion (i.e., not due to dominance) of variability is inherited from one generation to the next and is the main determinant of the gain from selection. Heritability is specific to a particular population in a particular environment.

Introgression library lines (ILLs) A collection of lines (ca. 80–100) obtained by subsequent backcrosses of a recurrent parent (usually an elite cultivar) with a donor parent, usually a line highly diversified from the recurrent parent for one or more traits. Each ILL carries a fragment (from ca. 20 to 40 cM) of the donor genome different from that carried by the other lines. Collectively, the fragments of all ILLs cover the entire genome with partial overlap. ILLs are ideal for the fine mapping and cloning of major loci and to investigate epistatic interactions.

Linkage disequilibrium (LD) The level of nonrandom assortment of alleles at different loci. The level of LD varies greatly according to the species and the mode of reproduction.

Linkage drag The negative phenotypic effects (e.g., lower yield) on the recurrent parent associated with the loci of the donor parent tightly linked to the locus of interest being backcrossed.

Logarithm of the odds ratio (LOD) A logarithmic value (base 10) of the ratio between the probability of the presence of a QTL vs. its absence. A LOD value of 3.0 indicates that the probability of the presence of the QTL is 1,000-fold higher than its absence.

Metanalysis A comprehensive analysis based on the data of several mapping populations of the same species. The objective is to obtain a better resolution of the LOD profile of the QTLs for the traits of interest.

Near isogenic lines (NILs) A set of two or more inbred lines that share most of the genome except for a small portion that contains functionally different alleles at the target locus. NILs are commonly used for the positional cloning of a locus of interest.

Phenotypic selection Selection based on the observation of the phenotype at different levels of functional organization based on the target trait(s). If the selected trait is highly influenced by environmental conditions and has low heritability, the effectiveness of phenotypic selection quickly decreases.

Pleiotropy Condition where a single locus controls more than one trait. It is more common for biochemical traits.

Positional cloning A series of procedures to clone a locus of interest. Positional cloning is based on the joint analysis of phenotypic data and genotyping profiles of near isogenic material with recombination events at the target region.

Quantitative trait locus A portion of DNA that influences the expression of a quantitative trait. The presence of QTLs is determined through appropriate statistical analysis of phenotypic and molecular data of a mapping population (e.g., linkage mapping) or a collection of unrelated genotypes (e.g., association mapping).

Recombinant inbred lines A collection of homozygous lines (usually from 150 up to 400) obtained following subsequent selfings (usually four or five) of an equivalent number of randomly chosen F_2 plants.

Reverse genetics An approach for discovering the function of a locus by analyzing the phenotypic effects of specific sequences obtained by DNA sequencing. Reverse genetics attempts to connect a given genetic sequence with specific effects on the organism.

Synteny The physical colocalization of linked loci on the same chromosome among different species. Study of synteny can show how the genome of phylogenetically related species has evolved from a common ancestor (e.g., rice for cereals) through rearrangements of the genome (e.g., translocations, inversions, duplications, etc.) in the course of evolution.

Definition of the Subject

Attaining global food security by means of increased crop productivity will require an increase in gains from selection achieved through conventional breeding. To this end, the identification of molecular markers associated with loci controlling traits of agronomic interest coupled with the exploitation of marker-assisted breeding (MAB) approaches provides the opportunity to accelerate gain from selection. In particular, marker-assisted selection (MAS) and marker-assisted backcrossing have been widely adopted to improve resistance to diseases and other relatively simple traits. Notwithstanding these remarkable achievements, the improvement of yield and other complex quantitative traits via MAB has been marginal, mainly due to the difficulty in identifying major quantitative trait loci (QTLs) with an adequately stable effect across environments and genetic backgrounds. Additionally, the effect of most QTLs affecting yield is too small to be detected with either biparental mapping or association mapping. Genomic selection (GS) circumvents this problem by using an index for the selection of unmapped QTLs of small individual effects but with otherwise sizable effect at the whole plant level when selected together. GS is already having a positive impact on the improvement of crop yield, mainly in the private sector where high-throughput infrastructures allow breeders to handle the large number of molecular datapoints that are required for effectively deploying GS. Ultimately, an effective exploitation of MAB to enhance crop performance will rely on a closer integration between molecular approaches and conventional breeding.

Introduction: Global Food Security and Plant Genomics

During the past century, plant breeders have been very successful in constantly raising crop yields to a level sufficient to meet the global demand in food, feed, and fiber. For wheat and rice, the two most important staples of humankind, the so-called Green Revolution spearheaded by Norman Borlaug, awarded the Nobel Peace Prize in 1970, provides the most spectacular example of the contribution of science toward an improved food security [1, 2]. Similar progress has been achieved also in maize, particularly following the

introduction of hybrids [3]. This notwithstanding, during the past decade, the rate of increase in yield in cereals, especially wheat and rice, has not met the global demand [4] as shown by the substantial decrease in the amount of global cereal reserves. Additionally, during the past two decades the number of chronically hungry people has increased and is fast approaching one billion. A number of reasons have contributed to this worrisome scenario that has already sparked food riots (e.g., during the 2007–2008 food crisis and also in 2009) and social unrest in a number of less-developed countries. An even bleaker picture looms on the horizon, when mankind will reach a projected nine billion in 2050. Consequently, an acceleration in the rate of gain in crop yields is a must in order to keep up with the need of a burgeoning population that increasingly seeks a protein-enriched, nutritionally balanced diet. The challenge faced by modern breeders is even more daunting in view of (1) global warming and the consequent increased frequency of drought, floods, high temperatures, etc., (2) the decreased availability of natural resources (e.g., water, fertilizers, arable land, etc.), (3) the increasing cost of fuels, (4) the necessity to safeguard the remaining biodiversity, and (5) the increased societal awareness of the critical need to improve the long-term sustainability of agricultural practices and decrease its impact on the environment. More simply, agriculture will need to produce more with fewer resources and more sustainably.

In this daunting scenario, genomics has ushered in a new breeding paradigm based on molecular approaches and platforms that in some cases have already contributed to accelerate the yield gain commonly achieved through conventional breeding practices [5–13]. However, a more widespread adoption of genomics-assisted selection will require the definition of new strategies based on a more effective integration of conventional and nonconventional breeding approaches as well as agronomic practices [14]. Clearly, a better knowledge of the genetic factors that determine yield and its variability from season to season will be instrumental in devising effective marker-assisted breeding (MAB) strategies for enhancing crop performance under a broad range of environmental conditions. As compared to conventional breeding approaches, MAB approaches offer unprecedented opportunities to dissect the genetic control of traits, particularly those that are quantitatively inherited, such as biomass production, yield, and many other agronomic traits selected by breeders.

Molecular Dissection of the Genetic Control of Traits Governing Crop Performance

The first step for the dissection of the genetic control of traits that govern crop performance is the assembly of a linkage (genetic) map based upon the data of the molecular profiles of the marker loci – from as few as 100 up to several thousand – surveyed in a mapping population, usually comprised of ca. 150–200 genotypes such as F_2 plants, F_3 families, recombinant inbred lines (RILs), doubled haploids (DHs), etc., usually derived from the cross of two parental lines differing for the trait(s) of interest. The assembly of a genetic map is based on the level of linkage disequilibrium (LD, i.e., the level of nonrandom assortment of alleles at different loci) among adjacent marker loci on the same chromosome. Accordingly, mapping the loci that control the target trait is also based on the LD between the locus and nearby markers.

The estimated genetic distance between loci (markers or genes) is a function of the average number of recombination events (i.e., crossing-overs) between them at meiosis. The measuring unit used for expressing the distances among loci along a genetic map is the centimorgan (cM), which defines the interval along which one recombination event is expected to occur per 100 gametes produced at each meiotic cycle (i.e., at each sexually reproduced generation). Because a density of one marker per ca. 10–15 cM is usually sufficient to detect the presence of a functionally polymorphic locus with a major effect on the phenotypic variability of a mapping population, the number of well-spaced markers required to adequately sample the targeted species varies from as little as 100–120 as in the case of rice – one of the crops with the smallest genome size (ca. 0.45 billion bp) – to well over 300 for large genomes such as in bread wheat (ca. 16 billion bp). The desired level of genetic resolution will depend on the objective being pursued and the type of genetic materials being used.

For breeding purposes, a density of one marker every 5–10 cM is sufficient for most applications when dealing with elite cultivars. Nonetheless, for the

introgression of a particular gene (e.g., a locus for disease resistance) from a wild relative of the crop to the crop itself, a high resolution is desirable in order to avoid the negative effects of the so-called linkage drag caused by negative effects of wild alleles at the loci closely linked to the one being targeted for introgression. A much higher genetic resolution is required when the goal is the cloning of the sequence that affects the target trait. In this case, the screening of several thousands of individuals is required to reach the desired level of resolution.

Cloning the loci that govern a particular trait can be achieved via either forward- or reverse-genetics approaches, or their combination. While forward genetics focuses on the phenotype as starting point, reverse-genetics approaches rely on sequence and functional information of candidate sequences (e.g., expressed sequence tags: ESTs) that are postulated to play a role in the expression of the target trait [15]. Although most results in the dissection of the genetic basis of crop performance and agronomic traits have been obtained via forward genetics, the use of reverse-genetics approaches in *Arabidopsis* and other model species (e.g., resurrection plants, rice, *Brachypodium*, etc.) has been instrumental to elucidate the genetic networks of the signaling pathways that regulate the adaptive response of plants to abiotic and biotic constraints [16–18]. Notably, the spectacular decrease in sequencing costs [19] and the increased availability of sequence information in public databases make the reverse-genetics approach increasingly attractive and feasible.

Following the assembly of the first genetic maps based on the molecular profiling of RFLPs (restriction fragment length polymorphisms; [20, 21]), the introduction of AFLPs (amplified fragment length polymorphisms; [22]), SSRs (simple sequence repeats; [23]), and DArT (diversity array technology; [24]) markers improved substantially the assembly of genetic maps. More recently, high-throughput platforms based on SNPs (single nucleotide polymorphisms), the most frequent polymorphism in living organisms, have enabled a quantum leap in saturating maps with thousands of markers [25–29]. Notably, the spectacular advances obtained with next-generation sequencing (NGS) technology will soon allow for the resequencing of entire mapping populations and association mapping panels of species for which a template sequence is available, thus providing an almost endless supply of markers [30–34].

Once all the molecular and phenotypic data are available, statistical tests will be applied to verify whether the means of the trait values of the genotypes carrying different alleles at a particular marker are significantly different. A test statistic larger than a threshold value rejects the "null hypothesis" (i.e., the mean is independent of the genotype at a specific marker locus) and implies a significant association between the investigated marker and a linked locus that affects the phenotypic value of the target trait. The exploitation of syntenic relationships among phylogenetically related crops has greatly contributed to the identification of additional markers at target regions [35–37] and, most importantly, candidates for the investigated traits, particularly when the genome sequence of one or more of the syntenic species becomes available. This is the case of cereals, where the annotated sequence for rice, *Brachypodium*, sorghum, and maize has allowed for the identification of conserved orthologous set (COS) markers from ESTs that have maintained their microlinearity throughout evolution and speciation [37]. These markers are particularly valuable to assess the possible role of candidate genes in species not yet sequenced (e.g., wheat) and to identify orthologous sequences that have maintained their functions and colinearity across species. Thus, a good understanding of the syntenic relationships at regions underlining a QTL for rather simple traits can provide excellent clues to pinpoint the most likely candidate.

Notably, mapping loci controlling the target traits allows breeders to implement marker-assisted selection (MAS) on the basis of the polymorphic molecular markers flanking the relevant loci. Traits are usually categorized as monogenic (qualitative or Mendelian traits controlled by a single locus) and polygenic (or quantitative; controlled by many loci), the latter being highly influenced by environmental conditions and considerably more difficult to improve consequent to their lower heritability, [38]. Quantitative traits (e.g., flowering time, plant height, biomass production, yield, etc.) are particularly important for breeding purposes. Although the genetic dissection of both qualitative and quantitative traits relies on similar principles, the latter requires more extensive phenotyping and much larger mapping populations.

The prevailing assumption in the field of quantitative genetics has been that continuous variation in trait performance is caused by the segregation and action of multiple genes with a rather similar effect on the phenotype, together with a major influence of the environment which acts like some sort of "statistical fog" that blurs and limits our capacity to identify the genes that control the target trait. These genes, also referred to as polygenes, are known as quantitative trait loci (QTLs; [39]). Although the original concept – but not the acronym – of QTL mapping was first suggested in 1923 [40], the dissection of quantitative traits became eventually possible in the 1980s and the 1990s with the introduction of molecular marker platforms that allowed for genome profiling with the needed level of genetic resolution [41–45]. Two decades of dedicated experiments indicate that most QTL effects are of small magnitude as originally predicted by the so-called infinitesimal model [38, 46, 47]. This notwithstanding, a limited number of so-called major QTLs have shown a rather large effect and, in a number of cases, have been cloned [48, 49]. Once a QTL has been cloned, both genomics and genetic engineering offer additional opportunities for tailoring improved cultivars and crossing reproductive barriers among species, thus expanding the repertoire of genes available to breeders. In view of the importance of quantitative traits in breeding activities and crop performance, particular attention should be devoted to QTL mapping and the implementation of MAB for this category of traits.

Biparental Linkage Mapping

The early studies in QTL mapping were conducted based on the analysis of the means at single markers using simple test statistics, such as linear regression, *t*-test, and analysis of variance. Because a genome-wide survey typically involves a large number of markers, the probability of detecting one or more false positives at the whole-genome level quickly increases unless the threshold of significance is adequately readjusted according to the number of tested markers [50]. Typically, a threshold level of $P_{0.05}$ entails a false-positive discovery rate (i.e., declaring the presence of a locus able to affect the target trait when actually there is no locus) of approximately 5%. Consequently, a mapping experiment based on 100 markers tested at $P_{0.05}$ will identify, on average, five markers putatively associated with loci even when no real locus segregates in the population. In order to avoid this problem, the significance threshold is corrected accordingly through a multiple test adjustment (e.g., Bonferroni's or Tukey's) that will adjust the *P* level according to the number of independent statistical tests that are performed. This notwithstanding, a much more critical shortcoming of this single-marker approach is that no information is provided on the most likely position of the locus and its effects on the phenotype. Due to these major limitations, single-marker analysis was quickly replaced by interval mapping and similar methods based on the estimated linear order of markers on a genetic map. In comparison to single-marker analysis, interval mapping provides a much more accurate estimate of the position and genetic effects of each locus [51–53]. In interval mapping, statistical methods are applied to test for the likelihood of the presence of a QTL. The result of the likelihood tests carried out at regular intervals across the ordered markers is expressed as LOD (Logarithm of the ODds ratio) scores, computed as the $\log_{10}$ of the ratio between the chance of a real QTL being present given the phenotypic effect measured at that position, divided by the chance of having a similar effect when no QTL is present. Thus, LOD values of 2.0 and 3.0 indicate that the presence of the QTL is 100- and 1,000-fold more likely than its absence, respectively. The graphical output is an LOD profile that allows one to compute an empirical confidence interval (usually computed as LOD – 1) around the QTL peak. In order to avoid declaring false-positive QTLs (i.e., declaring the presence of a QTL when the QTL is actually absent), a reasonably high threshold value for the LOD score should be set (usually > 2.5). Iterative software based upon resampling procedures provides a more accurate estimate of threshold values according to the size of the mapping population and the number of markers [54].

Epistasis can greatly influence the outcome of interval mapping. This problem can be partially overcome with the use of composite interval mapping, a statistical procedure that can account for the effects of other QTLs inherited independently from the interval (i.e., chromosome region) being considered, thus reducing the possibility of detecting "ghost" (i.e., false) QTLs. Compared to single-QTL interval mapping, statistical

approaches for locating multiple QTLs are more powerful because they can differentiate between linked and/or interacting QTLs that will otherwise go undetected when using single QTL interval mapping. Given the potential impact of epistasis on the response to selection, quantifying its influence on target traits is an important component for designing and organizing any MAS strategy [55]. It is likely that the incorporation of epistatic interactions into more properly devised statistical models will play a relevant role in explaining complex regulatory networks governing the expression of quantitative traits.

A major shortcoming of QTL studies is the low accuracy in detecting the real number of QTLs affecting the genetic variation of the investigated traits, particularly with populations of less than 150–200 families, which is the case in the majority of QTL studies reported so far. A simulation study applied to experimental data showed that with populations of ca. 100–200 families only a modest fraction of QTLs was identified; furthermore, the effect of each single QTL was usually overestimated [56]. Another study showed that detection of QTLs of small effect is very difficult with mapping populations with less than 500 families [44]. These predictions were supported in experiments carried out with maize mapping populations large enough (>400 families) to allow for a meaningful subsampling [57, 58]. Therefore, the chance of detecting a QTL in several environments is small even in the absence of QTL × Environment (QTL × E) interaction. Accordingly, inconsistency of QTL detection across environments has been repeatedly reported [59, 60].

Association Mapping

In the past decade, as an alternative to linkage mapping with biparental populations, association mapping based on the evaluation of panels of unrelated accessions (ca. 150 or more) has been adopted as an additional option for trait dissection [61–65]. The assumption underlying the use of association mapping to detect the presence of loci influencing the target trait is that alleles at two closely linked loci share a historical ancestor, and this original co-occurrence will gradually decay in the population due to recombination events during subsequent meioses. Consequently, the relative allele distributions of an unknown gene and that of a closely linked marker will be nonrandom because the two are in LD. A major factor to be considered for a correct application of association mapping is the presence of population structure, which will significantly bias the results and inflate spurious marker-trait associations (i.e., declaring false positives). Algorithms and methods are being developed to correct for these effects. An important advantage of association mapping is that the linkage is evaluated over the large number of historic meiosis, which in turn entails a much lower LD and higher genetic resolution as compared to linkage mapping with biparental populations. Another advantage is that the genetic variability explored by a large panel of unrelated accessions is much larger than that present in a segregating population derived from two parental lines. Conversely, a major shortcoming of association mapping is that it does not allow for the detection of the effect that a rare, but otherwise agronomically valuable, allele may have on the target trait. In fact, the statistical procedures used for revealing the effects associated to a particular locus/haplotype consider only alleles with a frequency higher than 10% over the entire population; alleles with a frequency lower than 10% are considered rare and as such, are discarded. The cutoff threshold of 10% has been introduced to reduce the ascertainment bias that a small sample (i.e., less than 10%) of accessions would inevitably introduce, being unable to correctly represent the effect of that particular allele at the level of the entire population [62]. Clearly, this is not an issue when dealing with mapping populations where allelic frequencies are expected to be equal to ca. 50%, barring the presence of genetic factors that might influence the transmission of gametes carrying the different parental alleles. In association mapping, the procedure of discarding the individuals carrying rare alleles inevitably reduces the statistical power to identify the role of such loci in controlling the variability measured for the target trait. An example of this has recently been reported in durum wheat, where a locus with a large effect on yield in a biparental cross [162] showed no appreciable effect in a parallel association mapping study where only one of the parental alleles was considered, due to the fact that the other parental allele was present in low frequency [65].

The main factors to be carefully considered for optimizing the effectiveness of association mapping are the level of LD among the investigated accessions and the presence of population structure that could greatly increase the false-discovery rate (i.e., type-I error). Closely related to the concept of LD is the concept of "haplotype," which can be defined as the chromosome fragment carrying a common set of marker alleles in close linkage at adjacent loci [66]. When using haplotypes in association studies, the information of several linked bi-allelic markers is combined as a single, multi-locus informative marker. Haplotypes can be generated *in silico* from sequences deposited in the database, by resequencing target loci (sequence haplotypes) or genetic maps (marker haplotypes). Therefore, haplotypes will extend according to the level of LD, the value of which varies greatly (up to 100-fold or even more) not only among species, but also within a single species according to the frequency of crossing-over events in each chromosome region. As an example, centromeric regions are characterized by very low recombination if compared to subtelomeric, gene-rich regions. Populations characterized by high LD (i.e., extending for $>$ 1 cM, corresponding to several million base pairs (bp) depending on the ratio of the genetic and physical distance) are best suited for a genome-wide search [65]. Alternatively, the utilization of panels with a low LD (i.e., extending $<$ 10,000 bp, typically a small fraction of 1 cM), a condition that is typical of allogamous species like maize [67], allows for a much higher level of genetic resolution and for the validation of a candidate sequence. Clearly, the level of LD influences the number of markers/cM required to obtain meaningful information. As compared to a low LD condition, a high LD level is associated with a proportionally longer haplotype, hence requiring a lower number of markers to conduct meaningful genome-wide surveys. This feature is more prominent in elite materials that have undergone high selection pressure as a result of modern breeding practices, which in most cases has led to a reduction of haplotype diversity as compared to locally grown landraces and, more notably, wild relatives of crops that have not gone through the domestication bottleneck. As an example, LD in wheat – a selfing species that has undergone a very stringent selection mostly due to the importance of quality parameters required by the food industry – extends up to 5–10 cM [65], while in outcrossing species like maize LD is usually below a fraction of cM or even less than 10,000 bp [68]. An example of the high level of genetic resolution made possible through association mapping is shown by the fine mapping and, in one case, positional cloning of QTLs for flowering time in maize [67, 68]. In particular, association mapping revealed that the most important QTL for flowering time per se (i.e., independently from photoperiod sensitivity) in maize corresponds to a 2.3 kb, noncoding, long-distance enhancer region located 70 kb upstream of a gene known to regulate flowering time also in *Arabidopsis* [49]. Another remarkable example in which the functional polymorphism responsible for phenotypic variability was assigned to a noncoding region far (ca. 5,000 bp) from the structural gene has been reported in sorghum through the cloning of a major QTL for aluminum tolerance [69]. Clearly, only a positional cloning approach is able to unequivocally highlight the role of noncoding regions in controlling the level of expression of a particular gene and the resulting phenotype. To what extent noncoding, long-distance enhancers might be involved in regulating the expression of quantitative traits is presently unknown. Notwithstanding the importance of this issue for a more complete understanding of the regulation of gene expression, this level of genetic dissection is certainly not required from a breeding standpoint, since both MAS and genetic engineering would still allow breeders to fully exploit the beneficial effects linked to either natural allelic variation or the ectopic expression of the structural locus encoding for the target trait.

Despite the clear advantages of association mapping on biparental linkage mapping (e.g., multiallelism, higher genetic variability and genetic resolution, no need to assemble a mapping population, shorter time required to identify relevant loci, etc.), a major limitation of the former is represented by the high rate of false positives (i.e., Type-I error rate), hence spurious association, due to the presence of hidden population structure among the accessions being evaluated [62]. An additional constraint to a more widespread utilization of association mapping for the dissection of physiologically complex traits may derive from factors other than statistical issues.

For highly integrative and functionally complex traits such as yield, particularly under adverse conditions, association mapping may quickly lose its effectiveness as the level of functional complexity of the target trait increases. In this case, similar phenotypic values in different genotypes can result from the action of different gene networks and/or trait compensation (e.g., yield components), thus undermining the identification of significant marker-trait association across a broad range of genotypes such are those usually present in the panels used for association mapping. Although a similar limitation also pertains to a mapping population developed from the cross of two divergent lines, its relevance in the case of association mapping for complex traits is greatly increased by the much wider functional variability explored with association mapping. This is particularly the case whenever the investigated trait (e.g., yield under drought conditions) is strongly influenced by differences in phenology, mainly flowering time and/or plant height; in this case, the overwhelming effects on yield of phenological traits will inevitably overshadow the effects due to the action of loci controlling yield per se, i.e., irrespectively of flowering time and plant height.

Comparative QTL Mapping and Metanalysis

A major shortcoming in QTL mapping is the limited accuracy in identifying the most likely position of each single QTL on the chromosome. Unless highly isogenic materials are evaluated, the confidence interval in assigning a QTL is rarely shorter than 10 cM, an interval likely to contain several hundred genes. The availability of QTL data for two or more mapping populations of the same species allows for the comparison of the position of QTLs by means of a metanalysis carried out with dedicated software [70]. This, in turn, provides a better genetic resolution of the QTL interval and reduces the confidence interval around the peak of the LOD profile. This exercise is particularly useful when a reference map with hundreds of well-spaced markers is available and contains "anchor markers" (usually RFLPs, SSRs, and/or SNPs) also used to investigate other mapping populations of the same species. An additional advantage of a reference map is that it allows one to compare the map position of QTLs with that of mutants for the same trait, thus contributing relevant information for the identification of possible candidate genes causally affecting the investigated trait. Accordingly, Robertson [71] suggested that a mutant phenotype may be caused by an allele with a much more drastic effect in comparison to that of QTL alleles at the same locus, a hypothesis that has been validated in maize for a QTL for plant height colocalized with the mutant *dwarf3* [72]. These results indicate that no real boundary exists between Mendelian and quantitative genetics, while suggesting that loci can be classified in either category based upon the magnitude and heritability of the effect of the alleles being considered. It follows that the information provided by mutants is of great value for QTL studies and breeding applications.

Isogenic Materials for Mapping and Cloning QTLs

A valuable opportunity for investigating the effects of a particular QTL and eventually isolate the functionally polymorphic sequence responsible for its effects is offered by the analysis of pairs of isogenic materials (e.g., near isogenic lines: NILs) contrasted for the parental chromosome regions (usually ca. 10–30 cM long) present at the target QTL. NILs can be obtained through repeated selfings of F_3-F_5 individuals heterozygous at the QTL region prior to isolating the homozygotes for each one of the two parental segments carrying the functionally contrasting QTL alleles [73]. Alternatively, each parental line of the mapping population originally evaluated for discovering the QTL can be used as recurrent parent in a backcross scheme in which a single genotype heterozygous at the QTL in question is utilized as donor of the alternative QTL alleles; in this case, the congenic lines are identified as backcrossed-derived lines [74]. With NILs, it is thus possible to "mendelize" major QTLs characterized by a sizable additive effect. Unlike genome-wide QTL studies where more than 100–150 genotypes are usually screened, experiments conducted with NILs involve few genotypes (two as a minimum), thus allowing for a much more refined and detailed phenotypic evaluation of the effects of the QTL [74, 75]. However, it should always be appreciated that the results of NIL-based studies could to a certain extent be biased by the action of one or more closely linked genes affecting the investigated traits, a particularly likely event when the region flanking the QTL extends for several cM.

A more systematic search of QTLs is made possible with the use of a series of isogenic lines obtained through the introgression, via backcrossing, of a small portion (ca. 20–30 cM) of the genome of a donor line into a common recurrent line, usually an elite cultivar [76]. The final objective is to assemble a collection of so-called introgression library lines (ILLs; at least 70–80 or more lines for each cross), basically a collection of NILs, each one differing for the introgressed chromosome portion and collectively representing the entire donor genome [76]. A major advantage of ILLs is the rapid progress that they allow for the fine mapping and positional cloning of major QTLs [48, 77]. Besides the well-documented effectiveness of ILLs for the mapping and cloning of QTLs in tomato [77, 78], ILLs have been instrumental for mapping drought-adaptive QTLs in rice [79] and maize [163]. Once ILLs are made available and major loci for the target traits are identified, testing for epistasis becomes particularly feasible using a small number of genotypes, unlike with mapping populations, where an accurate testing for epistasis will require the evaluation of at least 200 families.

The availability of NILs for a major QTL is an important prerequisite for undertaking the cloning of the sequence underlying the trait being targeted. Besides contributing to a better understanding of the functional basis of quantitative traits [68, 80], QTL cloning provides an essential opportunity for more effectively mining and exploiting the allelic diversity present in germplasm collections [49, 82]. Recent advances in high-throughput profiling and sequencing of both the genome and transcriptome coupled with reverse-genetics approaches/platforms (e.g., collections of knockout mutants, TILLING, RNAi, etc.) have streamlined the procedures and markedly reduced the time required to identify the sequences governing variation in quantitative traits. Until now, the molecular dissection of a candidate locus has been prevailingly achieved through positional cloning and association mapping. Both approaches exploit LD to identify the most promising candidate gene(s) and benefit from the map information of candidate genes and mutants in the species under investigation and in closely related ones. As sequence information accumulates and our understanding of biochemical pathways improves, QTL cloning via the candidate-gene approach becomes an attractive alternative to positional cloning, particularly for traits underlined by a known metabolic pathway [83, 84].

Modeling QTL Effects

QTL-based modeling holds promise to allow for a more effective design of "molecular ideotypes" on the basis of estimated QTL effects for growth parameters of response curves to environmental factors revealed by exposing mapping populations to such environmental factors [85–87]. Additionally, crop modeling provides useful clues to unravel the genetic basis of G × E interactions and toward a better understanding of traits' plasticity [88], a feature of increasing importance in view of the effects on crop growth and yield due to the enhanced vagaries in weather conditions consequent to global warming. An accurate estimate of the consistency of QTL effects in a particular genetic background can be obtained through extensive testing of the genetic materials under different environmental conditions as to level of irrigation, nutrients, temperature, etc.

In maize, an ecophysiological model and QTL analysis have been integrated to investigate the genetic basis of leaf growth in response to drought and predict leaf elongation rate as a function of estimated QTL effects at varying air humidity, temperature, and soil water status (Tardieu 2003). QTLs with a limited QTL × E interaction and with a linear response to a particular environmental factor will provide more predictable opportunities to improve crops' performance through MAS. An important issue rarely addressed in view of the inherent difficulty in doing so from an experimental standpoint under field conditions is that crop performance is often constrained by more than one environmental factor (e.g., drought and heat) occurring simultaneously, a condition which greatly undermines the prediction of QTL effects, particularly when considering multiple QTLs.

Marker-Assisted Breeding to Improve Crop Performance

The improvement of crop performance through conventional breeding has for the most part been achieved with little or no knowledge of the genetic basis of the selected traits, particularly yield and its underlying

morphophysiological determinants. The main obstacle to raising crop yield via conventional breeding by means of phenotypic selection is represented by the low heritability of yield, particularly under marginal conditions and low-input agriculture (e.g., low supply of nutrients and/or water). As an alternative to phenotypic selection, MAB can be applied to more effectively improve crop performance. The ultimate goal of MAB is to increase the cost-effectiveness of the selection gain per unit time. Although the costs entailed by MAB are still quite high when compared to conventional breeding practices, the sizable reduction in the time required to release an improved cultivar made possible through MAB can justify its application once agronomically valuable alleles at target loci (genes or QTLs) are identified. The convenience of adopting MAB to improve the efficiency of the selection process should be carefully evaluated on a case-by-case basis. The success of MAB will depend on the identification of the agronomically beneficial alleles at target loci, their effect in the different elite genetic backgrounds prevalently grown by farmers and their pyramiding in the correct combinations. MAB could thus be regarded as an extension and evolution of the so-called ideotype breeding, an approach based on phenotypic selection for an ideotype characterized by those morphophysiological features deemed necessary to maximize yield. As compared to ideotype breeding, MAB allows us to dissect the genetic basis of key traits and to piece back together the best alleles in a sort of molecular jigsaw puzzle, the main limitation being that only a very small number of the jigsaw tassels (i.e., genes and QTLs) have been identified. This approach, referred to as "breeding by design" [89], extends the concept of "graphical genotypes" first introduced by Young and Tanksley [90] to portray the parental origin and allelic contribution of each genotype on a genome-wide basis. Although a breeding-by-design approach is technically applicable to all major crops, its impact has been much more tangible for traits with a simple genetic control (e.g., quality, disease resistance; [91–95]) as compared to more complex quantitative traits, such as yield under adverse environmental conditions [60], a result mainly due to our rudimental understanding of the genetic basis of the latter category of traits, their interaction with environmental factors and, most importantly, the difficulty in predicting the phenotypic value of a new genotype tailored through MAB for several QTLs. Along this line, it should be underlined that the effects of QTL alleles for complex traits (e.g., yield) characterized by a large G × E interaction can drastically change according to the conditions (e.g., water availability along the crop life cycle) present in the environment being targeted.

The molecular profiles obtained with molecular markers provide the basic information required to identify the haplotype of each individual plant at a target locus. Haplotype profiling of collections of elite cultivars released during the past decades and derived from a limited number of founders (i.e., genotypes that in view of their positive features have been frequently used by breeders as parental lines) provides a means to identify the chromosome regions that have been preferentially retained throughout the breeding activities carried out during such time period. It is plausible to hypothesize that these chromosomal regions harbor loci (genes or QTLs) important for the selection of improved cultivars.

The strategies deployed to improve crop performance based on molecular information can be categorized according to the level of knowledge and understanding of the loci that underline the phenotypic traits under selection. While MAS and marker-assisted recurrent selection (MARS) during the past two decades have deployed allelic variation at mapped loci often characterized by a rather large effect on the phenotype, the new paradigm ushered in by genomic selection (GS) via high-throughput profiling has emphasized the selection of unmapped, uncharacterized loci with rather limited individual effects but with otherwise sizable effects when selected together. The next sections will critically analyze some of the main features of these rather different approaches that should not be regarded as antagonistic, but rather complementary.

Marker-Assisted Selection

Once loci are mapped and their effects characterized, the two most common applications of MAS in crop breeding are to (1) accelerate the backcross (BC) procedures required to transfer beneficial alleles at one or more loci into an elite cultivar and (2) facilitate the selection of one or more target traits within

a segregating population. The former application is the one that so far has been most frequently adopted in breeding programs and is usually referred to as marker-assisted backcross (MABC). MAS has also been deployed frequently to create isogenic lines (e.g., NILs, introgression libraries, etc.). These materials are used to identify and map genes/QTLs and, as such, usually do not impact directly on the outcome of breeding practices and the release of improved cultivars.

As compared to the conventional BC procedure, MABC based on the use of markers uniformly spaced along the genome (ca. 20–25 cM apart) can save three to four BCs in recovering most of the genome of the recurrent parent, thus reducing the time required for the release via BC of the improved version of the recurrent parent [96]. The advantage is greater for the incorporation via BC of recessive resistance genes, the phenotypic detection of which is only possible for the homozygous individuals carrying recessive alleles at both loci. In this case, phenotypic selection takes twice longer as compared to dominant alleles, since a selfing generation is required after each BC for the phenotypic identification of the homozygous recessive resistant plants to be used for the next BC. The utilization of codominant markers (e.g., SSRs) allows for the identification of heterozygous plants carrying the resistance-encoding allele directly in F_1, thereby saving one generation for each BC cycle. During the past two decades, MABC has been routinely deployed by seed companies to introgress beneficial alleles from unadapted accessions (e.g., landraces or wild, sexually compatible relatives of crops) and particularly to introgress transgenes into elite materials [9, 97, 98]. At each generation, individuals heterozygous at the region flanking the target locus are identified based on the results of molecular profiling. In comparison to conventional BC, MABC provides additional, distinct advantages such as (1) avoiding the vagaries in phenotyping when the conditions do not allow an accurate classification of the progeny segregating for the target trait (e.g., absence of the pathogen when backcrossing an allele for resistance to the disease), (2) reducing the number of plants to be screened in each selection cycle, and (3) identifying plants with the shortest possible chromosome segment introgressed from the donor line. The latter factor is particularly important when the donor is a wild accession of the recurrent, elite line being backcrossed. In this case, the introgressed chromosome segment flanking the target locus is likely to contain many alleles with a detrimental effect on quality and yield. Therefore, it is necessary to select individuals with the shortest possible chromosomal fragment contributed by the donor parent. An additional benefit is when the phenotyping of the trait under transfer is expensive and/or cumbersome like in the case of genes affecting tolerance to diseases/pests that require artificial inoculation in order to correctly identify those plants carrying the tolerant alleles (e.g., resistance to nematodes; [99]). Other cases where MABC provides a distinct temporal advantage as compared to conventional procedures is when the phenotypic evaluation of the target trait is destructive or when the trait is expressed after flowering. Selection before flowering greatly reduces the number of plants to be selfed or crossed, thus reducing the operating costs, particularly with species with a long life cycle.

During backcrossing, different rates of recovery of the recipient genome are expected at the target region and the nontarget chromosomes. Because each BC reduces by half the percentage of the donor genome at nontarget regions, at least six or seven BCs are required for a satisfactory recovery (ca. 99%) of the recipient genome. However, the number of BCs is frequently higher due to residual linkage drag around the target locus and it is not uncommon that up to nine or ten BCs are implemented before the improved cultivar is finally released. Clearly, the longer the time required to complete the BC procedures, the lower the probability of success of the new cultivar, since other improved, competing cultivars will be released in the meantime. Simulation and practice have both shown that in a moderately sized population of a species with a relatively small genome (<500 million bp, such as rice) using more than two to three well-spaced markers per chromosome arm hardly brings any additional benefit. For a species with large chromosomes (e.g., wheat, ca. 16 billion bp), a larger number of markers in each chromosome are beneficial. With an increasing genome size, more independent recombination events are needed to reduce the contribution of the donor parent, which in turn requires a larger population size. To what extent the contribution of the donor

parent should be reduced will depend on the type of alleles carried by such fragments and, most importantly, the genetic distance between the donor parent and the recurrent parent. Nowadays, the availability of large number of SNPs in most of the major crops facilitates the screening of the BC individuals to verify in great detail to what extent the genome of the donor parent has been retained.

Formulas are available to compute the level of concordance between the allelic state at the target locus and the flanking markers during the BC procedures [81]. These formulas values indicate that the level of control made possible with only one marker is insufficient to keep the risk of losing the target allele below 5% throughout five cycles of BC. Conversely, the level of control possible with two flanking markers is considerably higher even when the markers are not tightly linked to the target locus. If the BC procedure targets a QTL instead of a Mendelian locus, the uncertainty about the exact position of the sequence underlining the QTL introduces further complexity. Because the quantity of donor genes on the carrier chromosomes decreases much more slowly in comparison to the noncarrier chromosomes, after six BCs the majority of heterozygous loci with undesirable donor alleles will be on the carrier chromosome, with the vast majority included in the intact fragment flanking the target locus.

At the chromosomes not targeted by the BC procedure, it is expected that after "n" BCs, the probability that any locus remains heterozygous between the donor and the recipient is $(0.5)^n$, which means that each BC halves the residual level of heterozygosity. Consequently, six BCs ensure a level of similarity with the recurrent parent above 99%. Results in different species have shown that there may be a significant deviation from the 75% genomic portion of the recurrent parent expected in the BC_1 generation [100, 101], thus demonstrating the usefulness of genotype-based selection to identify plants with the highest possible portion of the genome from the recurrent parent.

Pyramiding Beneficial Alleles at Multiple Loci

The possibility to rapidly introgress and pyramid into existing cultivars a suite of beneficial alleles allows breeders to more quickly release improved cultivars to farmers. The best examples are in the area of disease resistance. Monogenic (Mendelian) resistance based on a single major gene is usually nondurable due to the high mutation rate in plant pathogens, which can lead to the selection of new virulent strains able to overcome the physiological barrier of an individual resistance gene. Consequently, the durability of disease resistance can be increased by screening for new sources of resistance followed by marker tagging of the relevant genes and their incorporation in elite cultivars. Pyramiding identifies the procedure for stacking the beneficial resistance alleles in a single line or cultivar, which provides a more durable resistance to pathogens as compared to monogenic resistance based on a single major gene. The advantage of pyramiding multiple alleles for resistance is particularly evident with diseases that require repeated inoculation and when phenotypic selection alone is too cumbersome and fails altogether to detect and combine multiple resistance genes in a single genotype.

Direct disease screening based on phenotypic observations is not always desirable due to a number of factors: quarantine restrictions, lack of routine screening methods and informative pathogen races for discriminating specific resistance genes, host escapes, and/or the inability to identify specific genes or gene combinations due to the occurrence of race or pathogen mixtures in the field. In these cases, MAS of race-specific genes offers a viable alternative for stacking beneficial alleles in improved genotypes which will eventually turn into novel cultivars characterized by more durable resistance to rapidly changing pathogen populations. Along this line, the constant changes in pathogen populations in different environments underline the potential value of previously defeated resistance genes. In this case, MAS offers the only practical solution to maintain such genes in current cultivars since they are masked by the epistatic effects of other resistance genes that are still effective.

In all major crops, the availability of markers tightly linked to resistance loci now allows breeders to tailor new cultivars with a suite of resistance genes able to enhance durable disease resistance to highly variable pathogens [102]. In broader terms, pyramiding is also implemented for combining beneficial alleles at loci (Mendelian or QTLs) that control traits other than disease resistance. In wheat, alleles at major loci that

influence quality (e.g., semolina color, protein content, micronutrient concentration, etc.) and tolerance to abiotic stress (e.g., aluminum, boron, salinity, etc.) are routinely introgressed via MABC [94].

When multiple loci are targeted in a BC program, the minimum population size to be considered increases considerably and rapidly becomes a major limiting factor when more than three or four loci are targeted, a number that can be increased to five or six when Mendelian loci are considered. When the targeted loci are QTLs, the uncertainty of the exact location of each selected QTL adds further constraints and reduces the number of loci that can be selected with a population of manageable size. When different lines contribute the beneficial alleles, the easiest strategy is to cross them to produce recombinant progenies and select the desired individuals. Multiple crosses might be required to pyramid all the desired alleles in one single genotype. A more general framework and the underlying theory to optimize breeding schemes for gene pyramiding have been described [103].

Marker-Assisted Selection in a Segregating Population

MAS has been extensively used for the selection of single genes conferring tolerance to diseases/pests [91, 94, 102, 104–106]. Although early simulation studies suggested the effectiveness of MAS for the improvement of biparental populations segregating for moderately complex traits [107], the first applications of MAS in maize were disappointing [57, 108]. Sweet corn is the only exception, the main reason being its much narrower genetic basis as compared to maize used for feed production, a feature that increases the reliability of predicted gains from selection and extrapolation of the effects of different loci to different populations [109]. Another feature that makes the application of MAS particularly attractive in sweet corn is the high costs associated to conventional phenotyping, in view of the large amount of grain that needs to be processed in order to obtain an accurate estimate of the phenotypic values of the progeny to be selected. MAS applications have been more widespread in the private sector as compared to public institutions, most likely owing to a lack in the latter of the infrastructure required for an effective exploitation of MAS.

Notwithstanding the remarkable progress in identifying and in some cases cloning major loci regulating agronomically valuable traits [48, 49], more limited success has been reported for MAS of quantitative traits [110], mainly due to the difficulty in identifying major QTLs with a sufficiently large and stable effect for justifying their deployment via MAS. While true QTL $\times$ E interaction due to variable expression of a trait may cause lack of consistency in QTL detection particularly with traits characterized by low to moderate heritability, the interaction between a mapping population of small size – hence with limited power in QTL detection – with variable environments is probably an equally important factor causing inconsistency in QTL detection. This is particularly evident for the improvement of crop yield under drought conditions, one of the most difficult traits to improve not only via MAS [14, 60, 111–113] but also through conventional breeding.

Marker-Assisted Recurrent Selection

Although marker-assisted recurrent selection (MARS) was first proposed in the early 1990s [114], only recently its adoption has provided a tangible contribution to crop improvement, mostly due the difficulty in identifying multiple loci characterized by limited G $\times$ E interaction and reasonably consistent effects in different genetic backgrounds other than that in which they were originally identified. The goal of MARS is pretty much similar to that pursued in pyramiding alleles at multiple loci, i.e., accumulating the beneficial alleles at as many as possible, preferably all, loci being targeted. Pyramiding alleles at many loci (e.g., >10) is best achieved with a recurrent selection strategy [115]. In this case, simulation showed that with 50 QTLs and a population of 200 plants the frequency of favorable alleles reached 100% after ten cycles when markers cosegregated with the QTL (i.e., they coincided), but only 92% when the marker-QTL interval was equal to 5 cM, hence increasing the possibility of losing the desired QTL allele due to recombination. In practice, with a higher number of loci under selection the occurrence of plants carrying the desired ideal combination becomes increasingly unlikely and basically impossible when more than 20 loci are targeted simultaneously. This problem can be partially mitigated through

successive cycles of crossing individuals carrying complementary combinations of the desired alleles [89]. This concept can be extrapolated to crosses with multiple parents.

MARS can start irrespectively of knowing the map position of the desired loci, which instead can be identified during the selection process. Simulation has clearly shown the superiority of MARS over phenotypic selection (from 5% to 20%), particularly when the selected population is highly heterozygous [116]. In maize, MARS has been applied rather extensively for improving relatively complex traits such as disease resistance, tolerance to abiotic stress, and also grain yield [111, 117–119].

The outcome of both MAS and MARS within a segregating population can be influenced by the genetic makeup of the targeted genetic background in terms of alleles present at other loci that interact epistatically with the target locus, an aspect which becomes particularly relevant for quantitative traits in view of the high number of loci involved in their control. Accordingly, since most evaluations of QTL effects and MAS strategies assume that QTLs act independently [55], it has been argued that MAS has little if any power over traditional phenotypic selection [46]. With maize as a model species, computer simulation showed that gene information is most useful in selection when few loci (<10) control the trait, while with many loci (>50) the least squares estimates of gene effects become imprecise. Based on these results, the typical reductionist approach pursued through QTL discovery strongly limits the outcome of MAS carried out for traits controlled by many QTLs [46].

Genomic Selection

In genomic selection (GS), genetic markers in number sufficient to cover the entire genome according to the level of LD are used so that most QTLs controlling the trait being selected are in LD with at least one neighboring marker. Unlike in MAS, in GS the individual plants are chosen without mapping the underlying QTLs that remain unknown along the entire process. Originally devised for animal breeding, only recently has GS been adopted for improving crop performance [120–122]. This was due to the fact that only in the past few years its application has become technically feasible in plants thanks to the introduction of SNP profiling with a level of genome saturation sufficient to detect the cumulative effects of the plethora of minor QTLs affecting quantitative traits which, on a single basis, will inevitably remain undetected in a biparental mapping population.

In GS, the breeding values of all the markers distributed across the genome are fitted as random effects in a linear model. The trait values are then predicted as the sum of the breeding values of each individual genotype across all the profiled markers and selection is based on these genome-wide predictions. A simulation study showed that across different numbers of QTLs (from 20 to 100) and levels of heritability, the response to GS was from 18% to 43% higher as compared to MARS. The number of markers that are used to predict the breeding values usually varies from a minimum of ca. 200 up to 500. A higher number of markers are required as the functional complexity of the targeted trait increases and LD decreases. Notably, GS is most effective for complex, low-heritable traits controlled by a large number of QTLs.

Implementation of GS is already having a major impact on the improvement of yield and other complex traits, mainly in the private sector where high-throughput infrastructures and robots allow for the routine creation and handling of millions of datapoints. Clearly, GS is not antagonistic to either MAS or MARS. Rather, they should be deployed in a complementary fashion on a case-by-case basis and according to the availability of mapped major QTLs, the accurate evaluation of their effect, and the frequency of the agronomically desirable alleles in the germplasm under selection.

Integrating Marker-Assisted Breeding in Conventional Breeding Projects

Among other factors, a broader application of MAB in conventional breeding projects will depend on the cost of molecular profiling [123, 124]. SNP markers are ideally suited for this role. In maize, the cost-effectiveness of MAS for the introgression of a single dominant allele into an elite line was compared with that of conventional breeding [125]. In this particular case, neither method showed clear superiority in terms of both cost and speed: Conventional breeding schemes

were found to be less expensive while MAS-based breeding schemes were shown to be faster. High-throughput genotyping based on the scoring of markers that do not need the use of gels [126–128] coupled with quick DNA extraction protocols are needed to streamline MAS and lower its cost.

An important factor to be carefully considered prior to embarking in any MAS activity targeting specific loci is the robustness of the marker-locus association and their genetic distance. Clearly, the level of LD of the genetic materials used to investigate the genetic makeup of the target traits plays a pivotal role in determining the level of genetic resolution. Accordingly, biparental F_2 populations have the maximum amount of LD, hence the lowest level of genetic resolution. Although this feature is advantageous for the initial QTL mapping studies in view of the limited number of markers that are required, it clearly limits the accuracy of MAS and usually does not allow us to resolve tightly linked QTLs from pleiotropic ones [129]. This problem can be circumvented by deploying genetic materials that capture a higher recombinational level, either historically (e.g., panels of unrelated genotypes suitable for association mapping; [67, 130]) or through subsequent random matings of the individuals of the original mapping population [131]. Increasing the genetic resolution not only enhances the reliability of MAS but also reduces the list of the possible candidates, an important prerequisite in identifying the sequence responsible for the phenotype of interest. Therefore, prior to undertaking an association mapping study, it is important to acquire a good understanding of the LD patterns in the set of genetic materials to be evaluated. In fact, LD can be caused by factors other than linkage. Spurious associations in a collection of germplasm accessions can be due to LD between unlinked genomic regions (i.e., >50 cM apart) on the same chromosome and/or between genomic regions located on different chromosomes. Dedicated softwares are available to reduce the frequency of false-positive associations due to the bias introduced by preexisting population structure.

One of the most critical steps in any breeding program is the choice of suitable parental lines to create the new segregating populations that will undergo selection. Ideally, such parental lines will contribute beneficial alleles at the loci most critical for the target traits and, more in general, crop performance and its quality. Molecular profiling can contribute in two major ways to expedite the selection process and increase the response to selection. In autogamous crops, MAS is applied to choose the parental lines that are crossed to generate new mapping populations (mostly biparental) and then to select during the subsequent generations the recombinant progeny that carry the desired alleles at the targeted loci. In wheat, MAS is being deployed in a number of breeding programs both in the public and private sectors [94]. In particular, more than 30 traits have been targeted, mainly for disease resistance, quality, and abiotic stress tolerance. In allogamous crops (e.g., maize) where the populations used to extract new parental lines routinely undergo recurrent selection, MARS can be applied at each selection cycle to increase the frequency of the beneficial alleles within the population until the best performing alleles are fixed within the population and, as such, no longer require selection. By increasing the frequency of beneficial alleles in a breeding population, the probability of recovering a genotype with the combination of desired alleles is increased. As an example, increasing the favorable allele frequency from 0.50 to 0.96 will increase the probability of recovering the ideal genotype for 20 independent regions from one in a trillion to one in five [9]. This change in allele frequency will improve the mean performance for the selected trait of the population and any line derived from it. Breeders can deploy different MARS schemes depending on the selection model and the desired genetic structure (e.g., inbreeding level) of the population obtained after MARS. The MARS schemes require optimization for best managing field and laboratory resources, hence containing the costs, as well as for expediting the selection process, hence the accumulation of favorable allele frequency. When several traits and loci are targeted simultaneously, a multiple trait index is used to combine the values of each individual trait into a single index and different weights are assigned according to the perceived importance of each trait. The output of this process is an estimated genotypic value calculated for each progeny being considered for selection. MARS can also be applied to autogamous crops (e.g., soybean) in order to enhance the performance of the breeding populations used to select improved genotypes that will hopefully outperform the existing cultivars.

As compared to conventional breeding practices, the outcome of MARS has clearly indicated its superiority for improving yield in maize, sunflower, and soybean [9]. Of utmost importance for the successful implementation of MARS is that breeders perform phenotypic selection on the lines per se that will be utilized for MARS. Additionally, phenotypic evaluation and selection among and within derived lines should continue after MARS.

Systematic profiling of parental lines is now routinely applied with a different level of genetic resolution, hence according to the level of LD of the target species. SSR profiling is rapidly being replaced by SNP profiling, much more effective than the former to define haplotype structure and much cheaper and amenable to high-throughput profiling. SNP platforms are particularly suited to the high-throughput profiling required by GS.

Once the template sequence of a crop becomes available, resequencing of lines can be used to obtain a far deeper understanding of their genomic architecture, allelic composition, and ultimate haplotype [132–134]. The spectacular reduction in cost that followed the introduction of second-generation sequencers makes resequencing of single genotypes a rather attractive and affordable option [135–137]. Additional progress in sequencing will further reduce the costs in as much direct resequencing of entire mapping populations may soon become more affordable than SNP profiling.

Mining Beneficial Alleles in Wild Relatives of Crops

As compared to their wild counterparts, the domestication bottleneck that all crops went through coupled with the strong selection first empirically practiced by farmers and then more systematically by modern breeders have markedly reduced the level of genetic variability within cultivated species, an aspect even more relevant for traits playing a substantial role in survival under natural conditions [82]. This limitation can be overcome through the implementation of advanced backcross QTL (AB-QTL) analysis [138], an approach that allows breeders to quickly discover and exploit beneficial QTL alleles present in wild germplasm but otherwise absent from elite germplasm. The AB-QTL approach relies on the evaluation of BC_2 families between an elite cultivar utilized as recurrent parent and a donor accession, usually a wild species that is sexually compatible with the crop. Usually, QTL analysis is delayed until the BC_2 generation and after selection in BC_1 against features known to affect negatively yield (e.g., ear shattering in small-grain cereals). The effectiveness of the AB-QTL approach has been proven in tomato [138, 139], rice [140], and barley [141]. These results are encouraging for using AB-QTL as a germplasm enhancement strategy for identifying wild alleles capable of improving the yield of the related crop, particularly under low-input agriculture and marginal environments where wild alleles may prove more beneficial, particularly for yield per se and disease resistance. An essential prerequisite is that the introgression of such beneficial alleles should bear no negative consequences when crops are grown under more favorable and high-yielding conditions.

Wild relatives of crop species can contribute to the identification of novel alleles for agronomically relevant traits by focusing on those loci that molecular evidence indicates as having been targeted by selection during both domestication and modern breeding [142]. To this end, the comparison of the allelic diversity present in elite accessions, landraces, and the undomesticated wild relatives of each crop allows for the identification of loci devoid of genetic variation within the elite germplasm, most likely as a result of domestication and subsequent man-made selection. The underlying assumption is that the loss of genetic diversity observed from the wild parent to the cultivated crop highlights the strong man-made selection at loci that control the expression of agronomically important traits, particularly those relevant for adaptation to abiotic stress. Therefore, both this "diversity screen" approach and the AB-QTL approach allow for the identification of valuable loci which would otherwise go undetected due to a lack of allelic diversity in the cultivated gene pool. An additional advantage of the diversity screen approach is that it allows for the identification of candidate genes of potential agronomic importance even without prior knowledge of gene function.

Leveraging the "-Omics" Platforms

During the past decade, a number of technologically sophisticated platforms have become available to

collect a large amount of data on the dynamics of the transcriptome, proteome, and metabolome. The availability of these "-omics" profiling data facilitates the identification of candidate genes and provides us with a more holistic picture of the molecular events characterizing functions at the cellular, organ, and plant levels and how these are influenced by environmental cues [84, 143–146].

Unlike from the classical QTL positional cloning approach in which an adequately large mapping population is basically "interrogated" in order to identify the genetic determinants of QTLs, the candidate-gene approach capitalizes on gathering experimental evidence to support and validate the causal role of a coding sequence (e.g., glutamine synthetase gene) in governing variation for the putative target trait (e.g., nitrogen-use efficiency). The major advantage of the candidate-gene approach is that it bypasses the tedious and expensive procedures required by positional cloning. Identifying suitable candidate genes and elucidating their function can be expedited by combining different approaches and high-throughput -omics platforms applied to target crops and/or to model species. From a technical standpoint, combining laser-capture microdissection with the -omics platforms offers an unprecedented level of functional resolution at the tissue level, down to a single-cell layer [145]. Among the different platforms available for the mass-scale profiling of the transcriptome, microarrays have been more frequently utilized to investigate the changes in gene expression, particularly in plants exposed to adverse conditions [147–150]. Nonetheless, microarray platforms are quickly being replaced by high-throughput transcriptome sequencing by means of second-generation sequencing platforms [151].

Additional information on the changes in cellular metabolism is provided by the profiling of the proteome [152] and metabolome [153, 154] that, as compared to the transcriptome, are functionally closer to the phenotype, thus reporting also on variability due to posttranscriptional and posttranslational regulation. However, it should be appreciated that both proteomics and metabolomics report changes for a rather limited portion (ca. 5%) of the expressed genes; additionally, proteomics is often unable to detect the changes in gene products (e.g., transcription factors) that despite their low level are more likely to play an important role in pivotal functions (e.g., signal transduction in response to biotic and abiotic stress) and consequently, to underline QTLs.

Metabolome profiling can also be used to identify loci regulating the level of a particular metabolite and verify its coincidence with QTLs for yield and/or genes involved in metabolic pathways. With the present technology, up to ca. 2,000 different metabolites can be profiled in a single sample [155]. In maize, QTLs for invertase activity have been identified in a population subjected to drought stress [156]. The number of QTLs for invertase activity detected under drought was more than twice the number detected under well-watered conditions, an indirect indication of the important role of this enzyme under drought conditions. One QTL common to both treatments was located near *Ivr2*, an invertase-encoding gene. The colocation reported between the activities of three enzymes (invertase, sucrose-P synthase, and ADP-glucose pyrophosphorylase) involved in sucrose and starch metabolism and a corresponding structural gene suggests its role as a candidate gene for explaining part of the variability in enzyme activity [157]. These studies indicate that invertase activity is an important limiting factor for grain yield in maize exposed to drought during the reproductive phase [158].

The candidate-gene approach is particularly effective when a clear cause-effect relationship can be unequivocally established between the gene product and the target trait. An example of this approach is the cloning of a QTL for cell-wall beta-glucans in barley grains based on a synteny analysis between barley and rice that revealed the presence in the syntenic portion of the rice genome of a cellulose synthase-like *CslF* gene that genetic engineering unequivocally showed to influence beta-glucans content in barley grains as well as in other species, including also *Arabidopsis* [83]. This notwithstanding, identifying suitable candidates for functionally complex traits such as yield and yield components is a much more daunting undertaking given the large number of genes that influence these traits.

Future Directions

The first comprehensive report of DNA-based markers (RFLPs; [20]) in a crop species was published in 1986.

Since then, an almost countless number of studies have shed light on the genetic control of plant growth and functions, and, most importantly crop yield. One clear take-home message that has emerged from these studies is the existence of a continuum between Mendelian and quantitative traits that will eventually help in identifying the functional polymorphisms, either of genetic or epigenetic origin that underlie quantitative trait variation. In this respect, QTL cloning will become a more routine and easier practice thanks also to the massive resequencing of mutant collections. This, in turn, will facilitate the identification of the best performing QTL alleles, their pyramiding through MAS, and the identification of novel alleles via TILLING [159] or by means of site-directed mutagenesis at the key functional domains of the encoded proteins. It is under this QTL cloning paradigm that the molecular basis of quantitative traits will be dissected in order to advance our understanding of the genetic makeup of this category of traits and to more accurately tailor crop morphology and productivity with beneficial alleles.

From an applicative standpoint, although conventional selection based on phenotypic evaluation will likely remain the mainstay for most breeding programs, particularly in the public domain, MAB and its applications will increasingly be adopted and will in some cases become prevalent as compared to conventional practices. As the twenty-first century unfolds, a multitude of genomics and postgenomics platforms are at hand to expand our understanding of the genetic basis of crop performance and to improve the efficiency of selection procedures for the release of new, improved cultivars. Resequencing will revolutionize the way breeders deal with their germplasm and will provide unsurpassed opportunities for a deeper mining of allelic diversity and harnessing its full potential. Nonetheless, our understanding of the functional basis of yield and other quantitative traits is likely to remain rudimental. The elusive nature of the QTLs that govern yield and yield stability is a formidable hurdle toward a more effective selection targeting specific loci and a better understanding of quantitative traits. Notably, GS can and will be applied irrespective of our degree of understanding of the genetic architecture of quantitative traits. Importantly, MAS and GS should be considered as complementary rather than alternative approaches, the utilization of which should be determined on a case-by-case basis. Bioinformatics and user-friendly databases will play a pivotal role for handling and managing the deluge of data produced by the molecular and phenotypic platforms.

In terms of experimental materials utilized for QTL studies, a growing attention will be devoted to the exploitation of multiparental crosses and mini-core collections of germplasm accessions with varying LD levels. In the mapping populations so far utilized for QTL discovery, most QTLs go undetected owing to the small size of the population, the presence of functionally monomorphic alleles and the small effects of many of such QTLs. Along this line, nested-association mapping (NAM) populations provide an interesting option to take advantage of both biparental (linkage) mapping and association mapping [160]. On a finer scale, high-throughput proteome and metabolome profiling will accelerate the identification of the causative mechanisms contributing to adaptive responses to adverse environmental conditions (e.g., drought, flooding, heat, etc.) whose frequency and intensity are expected to increase due to global warming. Nonetheless, the deluge of information originated through the molecular approaches and the -omics platforms will not automatically translate into novel cultivars. A "systems biology"-like approach will be instrumental for optimizing the accurate integration and exploitation in breeding terms of all the -omics information.

From an applicative standpoint, accurate phenotyping often remains the main limiting factor for identifying novel loci [161]. Semiautomated, high-throughput phenotyping under both controlled conditions and in the field promises to streamline gene discovery and narrowing the genotype-phenotype gap that hampers a more widespread deployment of MAB in crop improvement [87]. Along this line, it is important to emphasize that any molecular approach aiming to discover genes/QTLs and test their effects should preferably be carried out in an experimental context whose results are as relevant as possible and readily applicable to the conditions prevailing in farmers' fields [150]. An effective exploitation of genomics approaches to enhance crop performance will depend on their integration with conventional breeding. Although it is not possible to predict to what extent and how quickly the latter will be replaced by MAB, the

future release of improved cultivars will be expedited and made more cost effective through a systematic marker-based manipulation of the loci that govern crop performance and the desired features targeted by breeders.

Article Outline

Glossary

Bioreactor A fermentor in which plant cell cultures can be cultivated in sterile, controlled, and contained condition for biotechnological production of cell biomass and/or particular protein or small molecule.

Medicinal plants Plants that are used for medicinal purposes; whole plants or specific plant organs or compounds derived thereof can be utilized.

Metabolic engineering A process to understand metabolic pathways; a targeted alteration of metabolic pathways with the aim of improved yield, quality, and/or spectrum of produced metabolites.

Plant cell culture Process where plant cells are cultivated under controlled conditions; may consist of differentiated tissues or organs (e.g., shoots, roots, embryos, stems) or undifferentiated cells (e.g., callus, suspension cultures).

Secondary metabolites Low molecular weight compounds with enormous chemical diversity often found in plants in small amounts essential for plants' defense system; many secondary metabolites are used as pharmaceuticals, dyes, flavors, and fragrances by humans.

Transgene A gene that has been transferred from one organism to another.

Definition of the Subject

Plants are the most excellent designers and producers of a variety of small compounds that are beneficial to mankind as foods, medicines, and industrial raw materials. The use of medicinal plants for human health dates back to ancient history of mankind. The first written document of the use of medicinal plants can be found in Papyrus Ebers (1800 BC). Even if the use of certain medicinal plants was known to treat certain diseases – often using the trial-and-error approach – it is only less than 200 years ago the isolation of the first active chemical constituent (secondary metabolite) responsible for its pharmacological effect occurred. Today, many plant-derived compounds are used in pharmaceutical industry, and plants also serve as an important source for new lead compounds.

Many plants containing high-value secondary metabolites are difficult to cultivate or are becoming endangered because of the overharvesting. Furthermore, the chemical synthesis of plant-derived compounds is often not economically feasible due to their highly complex structures and the specific stereochemical requirements of the compounds. The biotechnological production of valuable secondary metabolites in plant cell or organ cultures is an attractive alternative to the extraction of whole plant material. However, the use of plant cell or organ cultures has had only limited commercial success so far. This is explained by the empirical nature of selecting high-yielding, stable cultures and the lack of understanding of how secondary metabolites are synthesized or how their synthesis is regulated.

Introduction

It has been estimated that there are at least 400,000 higher plant species in the world of which only about 10% are characterized chemically to certain extent [1]. There is no doubt that the chemical diversity of plants is much greater than any chemical library made by humans, and thus the plant kingdom represents an enormous reservoir of pharmacologically valuable molecules waiting to be discovered. Plants are thus excellent organic chemists in nature and constantly respond to environmental changes by adjusting their capacity to produce natural products. Functional genomics may open entirely new avenues to screen

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

unexplored medicinal plant species for their pharmacological value. Many pharmaceutical companies have now renewed their interest on plant-derived compounds due to too high expectations on combinatorial chemistry or computational drug design to obtain new drug leads during the past decades [2, 3].

Many secondary metabolites of industrial value are complex in their structures making chemical synthesis very challenging and expensive. Moreover, plants contain usually very low contents of these compounds, and therefore other production processes are essential to be developed. Biotechnological production using plant cells as real green factories is a very promising technology, but currently there are still many limiting factors, mainly related to our poor understanding how the plants synthesize these high-value compounds and how the synthesis is regulated.

In the following sections, an overview is given how secondary metabolites are produced in plant and tissue cultures, how the production can be enhanced by classical optimization methods, and what metabolic engineering has to offer today and in the future. Spectacular advances in plant genomics and metabolite profiling offer unprecedented possibilities to explore the extraordinary complexity of the plant biochemical capacity. State-of-the-art genomics tools can be used to engineer the enhanced production of known target metabolites or to synthesize entire novel compounds by the so-called combinatorial biochemistry in cultivated plant cells. Finally, some future perspectives are given for novel techniques and tools that are just now emerging.

High-Value Products from Medicinal Plants

Medicinal Plants

Many plants such as crops play a central role in our everyday diet. The nutritional value of edible plants and their constituents has been studied for decades. Besides the edible plants, there is a huge variety of toxic plants in the plant kingdom. These include, for example, many alkaloid or terpene containing medicinal plants such as *Atropa belladonna*, *Camptotheca acuminata*, *Capsicum annuum*, *Catharanthus roseus*, *Erythroxylum coca*, *Papaver somniferum*, *Cannabis sativa*, *Artemisia annua*, and *Taxus* species – just to name a couple of them. These plants have been and still are an important source of pharmaceuticals. Molecules derived from medicinal plants make up a sizable proportion of known drugs currently available on the market. These include compounds such as morphine, codeine, and several anticancer drugs such as paclitaxel, vincristine, and vinblastine, the monetary value of which is very high. In Western medicine, over 25% of prescription drugs sold in pharmacies contain at least one active principle which is directly or indirectly (via semi-synthesis) a natural product. This number does not include the over-the-counter sold drugs or pure phytopharmaceuticals.

According to WHO, 11% of the current 252 drugs considered essential for humans are exclusively derived from flowering plants. Furthermore, plants are also important source of new drug lead compounds. During the past 25 years, 1,010 new drug entities (NDEs) were introduced to the market; 27% of them were either natural products or derived from natural products as semi-synthetic derivatives [3]. In addition, 15% of the drugs were synthesized after the molecule was first discovered from natural resources. Table 1 shows the origin of the 458 NDEs representing the four major therapy groups with anti-infectives (antibacterial, antiviral, antifungal, and antiparasitic), anticancer, antihypertensive, or anti-inflammatory activities discovered between 1981 and 2006. It is remarkable that over 68% of all antibacterial compounds and 51% of all anticancer drugs were directly or indirectly derived from natural resources. Natural sources will undoubtedly continue to play a prominent role in the discovery of pharmaceuticals in the future.

Secondary Metabolism in Plants

Secondary metabolites are low molecular weight compounds found in small quantities throughout the whole plant kingdom. They exhibit many biological functions vital for the survival of the plant such as responding to stress, mediating pollination, or acting as defense compounds. In plant cell, they are accumulated often in the vacuoles. Besides the importance for the plant itself, secondary metabolites have always been of interest to humans as flavors, fragrances, dyes, pesticides, and pharmaceuticals. However, for most of the secondary metabolites, the exact function in plants still remains unknown.

Medicinal Plants, Engineering of Secondary Metabolites in Cell Cultures. Table 1 Number of new drug entities (NDEs) discovered during 1981–2006 belonging to the four most important therapy groups (modified from [3])

Therapy group	Total	N	ND	NS	B	S	V	N+D+NS	%
Antimicrobial	230	12	74	34	13	60	37	120	52.2
Anti-bacterial	109	10	64	1	0	23	11	75	68.8
Anti-fungal	29	0	3	0	1	25	0	3	10.3
Anti-viral	78	0	2	31	12	8	25	33	42.3
Anti-parasitic	14	2	5	2	0	4	1	9	64.3
Anti-cancer	100	9	25	17	17	30	2	51	51.0
Anti-hypertensive	77	0	2	34	0	41	0	36	46.8
Anti-inflammatory	51	0	13	0	1	37	0	13	25.5
Total	458	21	114	85	31	168	39	220	48.0

N natural product, *ND* natural product derivative, *NS* product is synthesized but the original molecule is discovered from natural sources, *B* biotechnologically produced compound (often a large molecule, protein), *S* synthetic molecule, *V* vaccine

More than 200,000 secondary metabolites have hitherto been discovered from the plant kingdom, but only half of them are structurally fully elucidated [4–6]. They are characterized by an enormous chemical diversity, and every plant has its own characteristic set of secondary metabolites. The production of specific alkaloids is often strongly restricted to certain plant families, whereas, for example, flavonoids are abundant in many plant species. Based on their biosynthetic origins, plant secondary metabolites can be structurally divided into five major groups: polyketides, isoprenoids (e.g., terpenoids), alkaloids, phenylpropanoids, and flavonoids [7]. The polyketides are produced via the acetate-mevalonate pathway; the isoprenoids (terpenoids and steroids) are derived from the five-carbon precursor, isopentenyl diphosphate (IPP) produced via the classical mevalonate pathway, or the novel MEP pathway (see the details in section "Targeting the Metabolic Enzymes"); the alkaloids are synthesized from various amino acids; phenylpropanoids are derived from aromatic amino acids phenylalanine or tyrosine; and the flavonoids are synthesized by the combination of phenylpropanoids and polyketides [8].

Since the discovery of the opium alkaloid morphine almost two centuries ago, alkaloids are still one of the most studied groups of plant secondary metabolites although terpenoids are the largest chemical family of secondary metabolites. It is somehow surprising that such an extensive array of different nitrogen-containing organic molecules are known in higher plants even though only 2% of the plant dry weight is composed of the element nitrogen. The largest requirement of nitrogen is the synthesis of amino acids which function as building blocks of proteins as well as precursors to many secondary metabolites. Alkaloids are thus the most prominent nitrogenous compounds with diverse, complex structures and often possessing strong physiological properties leading their wide use as pharmaceuticals. Human use of them dates back to more than 3,000 years. Currently, more than 12,000 alkaloids are known and they are classified into several subclasses based on the amino acids from which they are derived and according to their chemical structures [9].

At the present time, small amounts of plant compounds including alkaloids, for example, morphine, scopolamine, and vincristine are isolated with often some difficulties from natural vegetation or cultivated plants which explain the high price of the raw material. Numerous secondary metabolites have also served as models for modern synthetic pharmaceuticals [3]. However, the biosynthetic pathways leading to their formation in plants are often long, complex multistep events catalyzed by various enzymes, and are still largely unknown in enzymatic and genetic level.

The best characterized pathways after the decades' intensive classical biochemical research are the biosynthesis of opium and terpenoid indole alkaloids.

Besides the low quantities of the compounds in plants, the production rates may vary from year to year and secondary metabolites often accumulate in specific plant organs in particular time of the vegetative stage of the plant. Some substances can only be isolated from extremely rare plants which is not a choice for sustainable production. Therefore, alternative production systems for plant-derived compounds are needed. The biotechnological production, that is, producing the plant secondary metabolites in cultured plant cells in large bioreactors may offer an attractive alternative approach.

Biotechnological Production Options

The production of a secondary metabolite of interest for industrial needs is often a challenge. As explained above, these compounds accumulate in plants in small quantities. The biotechnological production of high-value plant secondary metabolites therefore is a viable option to isolation processes from the intact plants or to the total chemical synthesis.

Biotechnology focuses on the exploitation of metabolic properties of living organisms for the production of valuable products of a very different structural and organizational level for the benefit of humans. The organisms vary from microbes (bacteria, fungi, yeast) to plants and animals. Over the decades, many laboratories all over the world have studied the possibilities to produce desired secondary metabolites using plant cell or tissue cultures. Cell cultures have been established from many plants, but often they do not produce sufficient amounts of the required secondary metabolites or the production is unstable. Various classical optimization tools have been applied (see in detail section "Enhancing the Production by Classical Optimization"), but very few success stories exist contrary to many good examples using microbial production systems.

Molecular biology of plants has emerged enormously during the past decades, but still the plant metabolic engineering has met only limited success, again in sharp contrast to microorganisms. This is due to our limited knowledge on complex biosynthesis of secondary metabolites. Despite the rapid development of not only plant genomics but also of analytical tools, genetic maps of biosynthetic pathways are far from complete. Furthermore, regulation of the individual steps leading to the desired end product is poorly understood (section "Metabolic Engineering").

Plant Cell Cultures Plant cell culture is a method where plant cells are cultivated under sterile conditions *in vitro*. Commonly, cell cultures are established from callus tissues by cultivating callus in liquid medium, and cell aggregates are broken by either mechanically or by orbital shaking in the cultivation vessel. Plant cells are biosynthetically totipotent, which means that each cell in culture retains its complete genetic information and thus is able to produce the same metabolites as the parent plant. Plant cell cultures have been extensively exploited for various biotechnological applications as an alternative to the traditional agricultural cultivation of plants. The use of cell culture systems offers advantages to produce metabolites in a controlled environment, independent of climatic conditions and under conditions in which the different production parameters can be optimized. Plant cell cultures can be categorized in two main classes, differentiated and undifferentiated cell cultures. The former consists of, for example, organs like shoots, roots, or embryos, whereas callus and cell suspension cultures are referred to as undifferentiated cell cultures. Since the first gene transfers in plants in 1983, achieved by four independently working groups [10–13], a number of efficient gene transfer techniques have been developed for genetic engineering of plants. In addition to so-called direct gene transfer techniques (e.g., particle bombardment, electroporation, microinjection), *Agrobacterium*-mediated gene transfer has been the most commonly used method for gene delivery to plants.

Hairy Root Cultures *Agrobacterium* (Rhizobiaceae) is a soil bacterium, which is able to deliver its own plasmid-DNA into the nuclear genome of the plant cell. The bacterium attaches into the wound site of the plant tissue and recognizes certain wound substances, for example, acetosyringone, secreted by the plant [14]. As a result, the *vir* (virulence) region of the plasmid becomes activated and processing of the T-DNA (transferred DNA) for the gene transfer starts [14, 15].

After successful integration of the bacterial DNA into the host plant genome, the tumor formation in the wound site begins as well as the production of low molecular weight tumor substances called opines. The opines are used as a nutrient for the bacterium [16]. The host range of *Agrobacterium* is perhaps broader than that of any other plant pathogenic bacterium, although a number of cultivated monocotyledonous plants and legumes are not natural hosts for this bacterium. The molecular mechanism of the resistance to *Agrobacterium* is not known, although the production of antimicrobial metabolites [17], a lack of *vir* gene inducers [18], inefficient T-DNA integration [19], and *Agrobacterium*-induced programmed cell death [20] have all been suggested. Successful gene transfer in monocot plants via *Agrobacterium* has been performed with maize, rice, wheat, and barley [21].

Hairy root is a plant disease caused by the infection of *Agrobacterium rhizogenes* carrying Ri (root-inducing) plasmid. During infection of the plant, the T-DNA of the Ri-plasmid is transferred and integrated in the nuclear genome of the host. As a result of the transformation, hairy roots appear at the infection site [22]. In the T-DNA, there are four genetic loci, called *rol*A, *rol*B, *rol*C, and *rol*D, which are responsible for the hairy root phenotype. These genes were shown to positively affect the secondary metabolite production in *Nicotiana* [23] and in *Atropa* [24]. Hairy roots are able to grow without externally supplied auxins, and certain *aux* genes from *Agrobacterium* have been shown to provide transformed cells with an additional source of auxin [25]. This is a clear advantage when considering the costs for large-scale cultivation. Hairy roots characteristically lack geotropism and have a high degree of lateral branching. In addition, hairy root cultures have demonstrated their ability to rapidly produce biomass as well as high contents of secondary metabolites, for example, tropane alkaloids [26, 27]. In Table 2, some pharmaceutical compounds produced by hairy root cultures are presented. Unlike crown gall tumors, hairy roots are capable of spontaneously regenerating into plants [57].

Bioreactors The selection of a suitable bioreactor type for the specific process depends on the desired product and the production material, for example, whether the production involves growing undifferentiated cells, hairy roots, or plantlets. Plants cells are larger in size than those of microbial cells, making them more sensitive to shear forces. For this reason, bioreactors have been designed where conventional mechanical impeller stirring have been replaced by bubble or wave-type agitation. Most widely used bioreactors are stirred tanks [58], but also airlift and bubble column reactors have been used in cultivation of plant cells. The classical production of shikonin is performed in airlift type of bioreactors. A balloon-type bubble bioreactor has been successfully used for the cultivation of, for example, ginseng roots [59].

One of the more recent developments in bioreactor design for plant cell applications has been the use of disposable bioreactors, usually plastic bags. Major advantages in these are that the capital costs are much lower than that of common stainless steel tanks. The production of glucocerobrosidase used for treating the enzyme deficiency cased in Gaucher's disease is performed in carrot cells grown in disposable bioreactors by Israeli company Protalix Biotherapeutics (www.protalix.com). The only secondary metabolite of pharmaceutical value, paclitaxel (Taxol®), is commercially produced in *Taxus* cells by German company Phyton Biotech (www.phytonbiotech.com). Moreover, lower expenses allow multiple parallel units to be employed, and high sterility requirements are met when there is no need for costly cleaning processes between runs. Disposable bioreactors may consist of a rigid cultivation container (tube, plate, flask, cylindrical vessel) or a flexible container (bag) [60]. Issues restricting the use of disposable bioreactors arise from a limited experience in their usage, insufficient strength of a plastic material, limited applicability of advanced automatization, and lack of suitable disposable sensors. Wave-mixed bioreactors [61], such as BioWave®, are well suited for small- to middle-scale processes for the production (Fig. 1) of, for example, plant-based secondary metabolites and therapeutic proteins, as well as cultivation of hairy roots [62, 63]. One of the highest productivities reported to date for paclitaxel production in *Taxus baccata* cell suspension cultures was achieved with immobilized cells cultivated in BioWave® system [64, 65].

Important factors when designing the cultivation of plant cell suspension cultures in bioreactors include

Medicinal Plants, Engineering of Secondary Metabolites in Cell Cultures. Table 2 Examples of metabolites produced by transformed hairy root cultures (adopted mainly from [28, 29])

Metabolite	Species	Activity	Reference
Ajmalicine, ajmaline	*Rauvolfia micrantha*	Antihypertensive	[30]
Artemisinin	*A. annua*	Antimalarial	[31]
Benzylisoquinoline alkaloids	*P. somniferum; E. californica*	Analgesic, antibiotic	[32]
Betalains	*Beta vulgaris*	Antioxidant, colorant	[33]
Camptothecin	*Ophiorrhiza pumila; Camptotheca acuminata*	Antitumor	[34, 35]
Iridoid glycosides	*Harpagophytum procumbens*	Anti-inflammatory, analgesic, and antidiabetic	[36]
3,4-Dihydroxy-L-phenylalanine	*Stizolobium hassjoo*	Therapeutic agent against Parkinson's disease	[37]
Rutin, hispidulin and syringin	*Saussurea involucrata*	Anti-inflammatory, antifungal	[38]
Scopolamine, hyoscyamine and atropine	*A. belladonna*	Anticholinergic	[24, 39]
Scopolamine and hyoscyamine	*Datura innoxia*	Anticholinergic	[40]
Scopolamine and hyoscyamine	*Datura quercifolia*	Anticholinergic	[41]
Scopolamine	*Duboisia leichhardtii*	Anticholinergic	[42]
Scopolamine and hyoscyamine	*Datura candida*	Anticholinergic	[43]
Scopolamine and hyoscyamine	*Datura innoxia*	Anticholinergic	[44]
Scopolamine and hyoscyamine	*H. niger*	Anticholinergic	[40]
Scopolamine and hyoscyamine	*H. muticus*	Anticholinergic	[26]
Scopolamine and hyoscyamine	*H. muticus, Nicotiana tabacum*	Anticholinergic	[45]
Scopolamine	*H. niger*	Anticholinergic	[46]
Solasodine	*Solanum khasianum*	Steroid hormone precursor	[47]
Paclitaxel	*Taxus brevifolia*	Anticancer	[48]
Terpenoid indole alkaloids	*C. roseus*	Antitumor	[49]
Thiarubrine A	*Ambrosia artemisiifolia*	Antifungal, antibacterail, antiviral	[50]
6-Methoxy-podophyllotoxin	*Linum album; Linum persicum*	Anticancer	[51]
Quinine, quinidine	*Cinchona ledgeriana*	Antimalarial	[52]
(+) catechin, (−) epicatechin-3-O-gallate, procyanidin B_2-3′-O-gallate	*Fagopyrun esculentum*	Antioxidant	[53]
Anthraquinone	*Rubia tinctoria*	Antimalarial, antineoplastic	[54]
Thiophene	*Tagetes patula*	Anti-inflammatory precursor	[55]
Valpotriates	*Valeriana officinalis*	Tranquilizing	[56]

Medicinal Plants, Engineering of Secondary Metabolites in Cell Cultures. Figure 1
Wave bioreactor is used to culture various types of plant cells. This is a 2-L disposable bag in a Wave® reactor containing tobacco hairy roots

guaranteed sterility through the whole process and low-shear mixing allowing still efficient nutrient transport without causing sedimentation or a loss in viability of the cells. In addition, the possibility for application of light induction for heterotrophic, photomixotrophic, and photoautotrophic cultures might be relevant [62]. Major physical process parameters regarding cultivation of plant cell and tissue cultures are temperature, viscosity, gas flow rates, and foaming.

Sometimes the lack of end-product formation may be due to the feedback inhibition, degradation of the product in the culture medium, or due to volatility of the substrates or end products. In such cases, adding of extra phase as a site for product accumulation might lead to increased production of the desired substance [66]. For example, addition of amberlite resin and charcoal resulted in increased accumulation of anthraquinones and vanilla, and coniferyl aldehyde, respectively [67–69]. On the other hand, bioconversion of water-insoluble substrates in cell culture systems can be aided by using cyclodextrins. They form inclusion bodies in their cyclodextrin cavity and by this way increase the water solubility of the substrates [70].

Enhancing the Production by Classical Optimization

Selection of High-Producing Lines

Selection of individual plants with desired traits has been a traditional approach in plant breeding. Similarly, high producers have been selected for further use, for example, for cloning and as a starting material for cell cultures. However, cell clones from the same origin may vary considerably in their metabolite production capacities. Selecting high producers is thus a very empirical approach, requiring a huge amount of screening work before good producing individuals are found [71, 72]. In order to obtain good producing cells, mutation strategies or application of various selective agents, such as *p*-fluorophenylalanine [73], 5-methyltryptophan [74], or biotin [75], have been used. Although undifferentiated plant cells can be maintained in an undifferentiated state using

phytohormones, they are not genetically or epigenetically stable. The concept of somaclonal variation was introduced by Larkin and Scowcroft in the beginning of 1980s, standing for the genetic variability in tissue culture–derived plants or cell culture clones [76]. These changes causing the variation can occur as large rearrangements in chromosomal level, for example, changes in chromosome number, karyotype modifications, or changes in gene level.

Somaclonal variation can be exploited when searching for high secondary metabolite producers or high producers of biomass, although a clear disadvantage is that these changes cannot be predicted or controlled and moreover, they are not always stable or heritable. The effect of culture age on growth rates were observed with *Nicotiana plumbaginifolia*, which showed higher growth rates with older cultures compared to newer cultures [77]. These differences were thought to appear as a cause of higher proportion of cells in older cultures exhibiting mutations which elevate cyclin-dependent kinases. Changes in ploidy levels are reported to affect regeneration capacity [78], gene silencing [79], and secondary metabolite production [80, 81]. After choosing good-producing cell lines, cultivation over time requires usually continuous selection in order to maintain high production levels. However, a gradual loss of secondary metabolite productivity over time is an obstacle in the development of commercial plant cell culture production systems [82, 83].

Optimization of Culture Medium

One of the major advantages in using plant cell cultures is the possibility of controlled and contained production systems. When attempting to reach high production levels, key roles are played by the composition of nutrient medium and other cultivation parameters, such as temperature, light, phytohormones, and gas exchange.

Because the plant cell is a production factory, the first requirement for obtaining high levels of products is the generation of high amounts of biomass or at least enough biomass for economic product yields. Plant cell cultures are usually grown heterotrophically using simple sugars as carbon source, sucrose being the most commonly used. Carbon source effects mainly on primary metabolism and by this way affects the overall productivity with either increased or decreased biomass production. Sucrose level may also have an indirect impact on secondary metabolite production, as inverse correlation between sucrose and hyoscyamine production was observed in *Hyoscyamus muticus* hairy root cultures [84]. This was probably due to the increased glycolysis and respiration rate with simultaneous overriding of secondary metabolite production. Sucrose is commonly applied in approximately 3% (w/v) concentration, but levels as high as 8% (w/v) have shown to increase the accumulation of indole and benzophenanthridine alkaloids in cell cultures of *Catharanthus roseus* and *Eschscholtzia californica*, respectively [85, 86].

Phosphate and nitrogen levels are perhaps the most important macronutrient factors effecting the secondary metabolite formation. Phosphate usually promotes cell growth, but often has been accompanied by lower secondary product formation. In fact, very often cell proliferation has been accompanied by decrease in secondary product formation and vice versa. For this reason, a two-stage cultivation system could be considered, where the cells are first cultivated in the medium optimized for cell multiplication and then transferred into medium limiting the biomass growth whereas enabling maximum product formation. As an example, shikonin produced by *Lithospermum erythrorhizon* in commercial scale by this type of two-phase system [87]. Low phosphate levels often have been correlated with high secondary metabolite formation, for example, in case of alkaloids in *Datura stramonium* [88], *Nicotiana tabacum* [89], and *C. roseus* [90]. Nitrogen is an important building block of amino acids, nucleic acids, proteins, and vitamins. Generally, nitrogen is added in the form of nitrate or ammonium, and the ratio of these salts plays an important role in secondary metabolite production of the plant cells. Reducing the levels of nitrogen generally leads to lower biomass production and thus leads to higher secondary metabolite production, as in the case of anthocyanin production by *Vitis vinifera* [91].

Phytohormones have an extensive effect not only on growth of plant cells, but also on differentiation and secondary metabolite production. Both the type and concentration of auxin and cytokinin as well as their ratio alter the growth and metabolite production dramatically in cultured plant cells. High auxin levels are known to inhibit the formation of secondary

metabolites in a large number of cases, for example, tobacco alkaloids [92] with the simultaneous activation of polyamine conjugate biosynthesis [93]. Sometimes, replacement of synthetic auxin 2,4-D (2,4-dichlorophenoxy acetic acid) by NAA (naphthalene acetic acid) or natural auxin IAA (indole acetic acid) has shown to enhance the production of anthraquinones, shikonin, or anthocyanins [94–96].

Commonly understanding of cell culture behavior has been relied on the measurements of culture average parameters, such as cell density and metabolite profiles. However, due to the nature of plant cell division, in which daughter cells often remain attached through cell wall, aggregates of various sizes in cell suspension culture are formed. Thus, each aggregate is exposed to different microenvironmental conditions with respect to nutrient and oxygen availability between inner and outer regions of the aggregate [97]. Understanding such subpopulation dynamics and cellular variability using tools such as flow cytometry is important in order to control the culture as a whole.

Effect of Elicitors

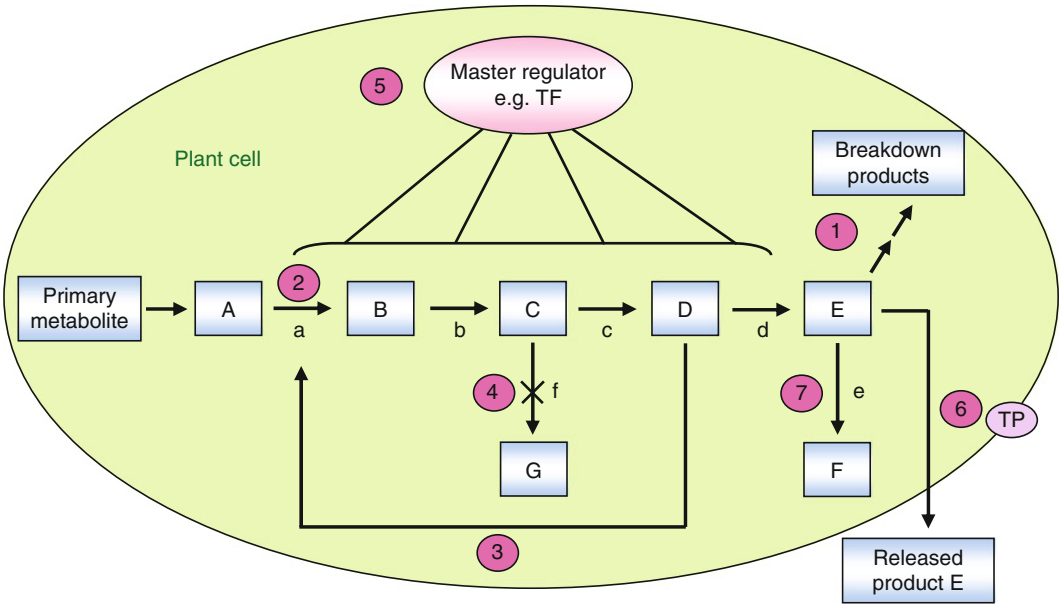
The enhanced production of secondary metabolites from plant cell and tissue cultures through elicitation has opened up a new area of research which could have beneficial influences for pharmaceutical industry. Elicitors are compounds, biotic or abiotic, or even physical factors, which can trigger various defense-related reactions, and thereby induce secondary metabolite formation in plant cells. The mechanisms of how elicitors activate the respective genes and the whole biosynthetic machinery in a plant cell are under active investigation. However, it is evident that the gene expression occurs very quickly after the elicitor contact and many hours before the secondary metabolites are accumulated in a plant cell [98].

In general, elicitors can be categorized based on their molecular structure and origin. Biotic elicitors include compounds such as chitosan, alginate, pectin, chitin or they may contain complex mixtures of compounds like those of fungal or yeast extracts [99]. Abiotic elicitors are chemical compounds of nonbiological origin, for example, heavy metals and vanadate derivatives, or physical factors such as thermal or osmotic stress, UV-irradiation, or wounding. In particular, widely used elicitors for plant cell culture systems are jasmonates and jasmonic acid derivatives, which are naturally occurring hormones involved in the regulation of defence-related genes and act as signaling compounds in these reactions [100]. Application of jasmonates can result in large alterations in desired metabolites in *Catharanthus* [101, 102], in *Taxus* [103], and in *Nicotiana* [98]. Even though plant cells accumulate secondary metabolites typical for species in question independent of the type of elicitor used, the accumulation kinetics may vary greatly with different elicitors. Moreover, elicitors can effect on the release of desired secondary metabolite from the cell to the cultivation medium [104]. This is beneficial when considering the biotechnological production facilitating thus the downstream processing.

Generally, both the elicitor concentration and the length of elicitor application have to be determined for each cell culture individually [104]. Commonly it is thought that the best growth phase for the start of the elicitation is during the exponential growth phase when the enzymatic machinery for elicitor response is most active [105]. In addition, the composition of the culture medium, especially phytohormones, has a major impact on elicitor response. For example, divergent regulation by auxins on the biosynthesis of different metabolites in terpenoid indole alkaloid pathway was observed by *C. roseus* cell cultures [102]. This regulation by auxins was shown to be partly dependent on the presence of methyl jasmonate. Production of various plant-derived medicinal compounds has been successfully induced by using elicitors [106]. Unfortunately, many elicitors also cause a loss of viability of the producing cells, thus a thorough optimization of the whole production process is required when using elicitation.

Metabolic Engineering

Functional genomics tools offer now huge potential to engineer plant metabolic pathways toward the targeted end product or alternatively to form entirely novel structures through combinatorial biochemistry. However, rational engineering of secondary metabolite pathways requires a thorough knowledge of the whole biosynthetic pathway and detailed understanding of the regulatory mechanisms controlling the flux of the pathway (Fig. 2) [7]. Such information is not



Medicinal Plants, Engineering of Secondary Metabolites in Cell Cultures. Figure 2
The hypothetic scheme how the secondary metabolite E could be formed from primary metabolites via different enzymatic steps and how the biosynthesis could be regulated in a plant cell [7]. Engineering of secondary metabolite pathways is a series of complex events. The following strategies could be used to modify the production of hypothetical plant metabolite E: (1) decrease the catabolism of the desired compound, (2) enhance the expression/activity of a rate limiting enzyme, (3) prevent feedback inhibition of a key enzyme, (4) decrease the flux through competitive pathways, (5) enhance expression/activity of all genes involved in the pathway, (6) compartmentalize the desired compound, and (7) convert an existing product into a new product. *TF* transcription factor, *TP* transporter gene

available for vast majority of secondary metabolites, explaining why only limited success has been obtained by metabolic engineering. New genome-wide transcript profiling techniques combined with up-to-date metabolomics allow us now to establish novel gene-to-gene and gene-to-metabolite networks which facilitate the gene discovery also in non-model plants that include most medicinal plants [102]. The ability to switch on entire pathways by ectopic expression of transcription factors suggests new possibilities for engineering secondary metabolite pathways (Fig. 2). Consequently, the utilization of plant cell cultures for biotechnological production of high-value alkaloids would thus become a true viable alternative.

Gene Discovery

Since the sequencing of *Arabidopsis* genome in 2,000 several other plants are being sequenced but still today very limited information exists for any medicinal plant. Therefore, also the biosynthetic pathways in these plants are largely unknown at the gene level. Several approaches have been developed to identify enzymes and the corresponding genes that are responsible for different biosynthetic pathway steps. One of the classical methods is the identification and isolation of intermediates and enzymes *via* precursor feeding [107]. The other very basic approach is to use cDNA libraries to identify genes by PCR amplification with primers designed to recognize conserved regions on the basis of enzyme homology from other plants with already known sequences [108]. More recently, methods based on differential display comparing mRNA transcripts of elicited and non-elicited cell culture samples have shown their potential in gene discovery. Goossens and coworkers [98] and Rischer and coworkers [102] utilized cDNA-AFLP technique for genome-wide gene hunt, whereas [109] supplemented their search with

homology-based analysis of a cDNA library of elicited cells. In addition, the use of random sequencing of elicited cDNA library can lead to identification of clones involved in the biosynthetic route in question as proven in case of *Taxus* biosynthesis [110].

The use of microarrays as widely used for model plants such as *Arabidopsis* is usually not applicable to medicinal plants simply because none has been sequenced with the very recent exception of tobacco http://www.pngg.org/tgi/index.html. The rapid advance of deep sequencing, however, will soon result in many important species being investigated at genome scale. The 454 pyrosequencing technique is currently perhaps the most widely used so-called next-generation sequencing technique for the *de novo* sequencing and analysis of transcriptomes in non-model organisms like medicinal plants are. For example, the GS FLX Titanium can generate one million reads with an average length of 400 bases at 99.5% accuracy. This technology was successfully used to discover putative genes involved in ginsenoside biosynthesis [111].

Once the candidate genes are discovered, they are functionally tested alone or in combination to find out their real mode of action, for example, improving or altering the production of desired metabolite. This is time consuming, and therefore new high-throughput systems have been developed, for example, miniaturized cell culture formats and multigene transformations.

Controlling the Expression of Transgenes

In order to be able to modify the metabolite profile of a respective medicinal plant or cell culture, the gene expression of target proteins and enzymes needs to be fine-tuned in an appropriate manner. For that purpose, the elements involved in transcriptional regulation of gene expression should be well characterized and evaluated to ensure correct spatial and temporal display. This also minimizes the potential adverse effects, and the outcome will be as wanted. Specific DNA sequences upstream of the encoding region of a gene that are recognized by proteins (transcription factors) involved in the initiation of transcription are determined as promoters. It is noteworthy that the promoter sequence itself is present in all tissues and cells, and thus the activity is controlled via transcription factors and their abundance. This opens the possibility to boost a cascade of enzymes and influence in the whole biosynthetic pathway in question by overexpressing transcription factors [112].

Promoters used for the metabolic engineering purposes can be divided into three classes:

1. Constitutive, that is, promoters that are continuously on in most or all of the tissues
2. Organ- or stage-specific, that is, promoters controlling spatiotemporal activity of the transgene
3. Inducible that are regulated by an external trigger of chemical or physical nature [113, 114].

As an example of the constitutive promoters and also the most used one in plant genetic engineering is the *Cauliflower mosaic virus 35S* promoter [115, 116]. The CaMV 35S promoter has been very thoroughly characterized and currently a typical CaMV 35S promoter in plant vectors consists of a bit more than one third of the full-length sequence [117]. It has also been observed that a partial duplication from −343 to −90 amplifies expression up to tenfold [118]. This promoter is also the most used one in metabolic engineering of plant cell cultures [119]. For the secondary metabolite production, the hairy root cultures have shown most potent, and little promise has been found with undifferentiated suspension cultures [120]. Actually there exist no studies for trying to find most suitable callus or suspension culture–specific promoters for efficient expression of target genes. This might be one factor why the success in using undifferentiated plant cell cultures for the production of valuable secondary metabolites has been so poor. However, the main blame for this is the current limited understanding of how the metabolic pathways and fluxes of secondary metabolites work in general.

Nowadays that the multigene transformations [121] are paving the way for more accurate and complex engineering of phenotypes, there is also more need to apply different promoter deployment strategies to reach the wanted goals. The delivery of 10–20 genes at the time is already very demanding, and thus there is no space for failure in running their expression. Roughly, two ways of proceeding can be drawn for promoter choice: utilization of the same promoter to run all the genes or combination of promoters to run different target genes in the generated multigene transformants.

The use of same promoter carries the risk of triggering gene silencing. It is very important to increase the promoter diversity via promoter discovery and generation of synthetic sequences to run the expression. Perhaps one of the most interesting ways is to apply bidirectional sequences which allow simultaneous expression of two genes, and thus halves the number of required promoters for multigene engineering [122].

Targeting the Metabolic Enzymes

From the genetic engineering perspective of medicinal plants, one of the key elements is to express the genes in question in right tissues, and even more importantly target the respective enzymes to correct, specific subcellular compartments. A good example of compartmentalization is the biosynthesis of terpenoids that are synthesized from universal five-carbon precursors isopentenyl diphosphate (IPP) and dimethylallyl diphosphate (DMAPP), which in turn are formed via two alternate biosynthetic pathways localized in different subcellular compartments. The cytosolic mevalonic acid (MVA) pathway starts with condensation of two molecules of acetyl-CoA into acetoacetyl-CoA and finally gives rise to IPP. The methylerythritol phosphate (MEP) pathway takes place in plastids and leads to the formation of IPP and DMAPP from pyruvate and glyceraldehyde phosphate. The IPP and DMAPP precursors are then processed with prenyl diphosphate synthases in different compartments giving rise to intermediates that serve as substrates to a large group of terpene synthases resulting in construction of the final terpenoids [123, 124]. However, the picture is never black and white, and the subcellular localization studies as well as the genetic engineering experiments have shown that such a thing as a general rule does not apply to all tissues and species. From the rational genetic engineering point of view, this makes things even far more complex and we still need to reveal several aspects of biosynthetic pathways.

Targeting the biosynthetic enzymes to non-original compartment can also lead to interesting results. Precursors can be available in other compartments, and introduction of the respective enzyme can lead to increased accumulation of target compounds. For example, Wu and coworkers [125] showed that redirecting the sesquiterpene pathway from its natural cytosolic location to chloroplasts increased patchoulol accumulation even up to 10,000-fold when compared to native situation. Another example was given by introducing three different targeting modes: cytosolic, plastid, and ER of limonene synthase in transgenic tobacco plants [126]. Both the cytosolic and plastid targeting resulted in limonene formation, whereas ER targeting gave no response probably due to false folding or instability of the protein.

There has also been discussion on so-called metabolic channeling, which means that enzymes from the same pathway, especially the ones committing successive steps, form a protein complex resulting in efficient reactions and regulation of the pathway [127–129]. Aharoni and coworkers [130] interpreted that this might be a cause why some pathways do not seem to proceed even though substantial amount of substrate seem to be available. As a solution, an artificial channeling is suggested with the help of fusion constructs to be applied in the metabolic engineering. These studies also highlight the need for fluxomics and thorough understanding of metabolic pathways (see Sect. "Controlling the Expression of Transgenes").

Multigene Transformation

The first multigene-carrying transgenic plants were created either with several rounds of crossings between transgenic lines or by transforming transgenic plants with a new set of genes [131, 132]. The current multigene delivery systems are co-transformations with either linked or unlinked genes, that is, genes within a same vector or different vectors, respectively. The transfer itself is carried out either via *Agrobacterium*-mediated or direct transformation techniques. These systems have been developed mainly with crop plants, and the target pathways have been on nutritional composition like in engineering of the carotenoid pathway [133, 134]. These pioneer works have opened the possibility to engineer metabolic pathways of medicinal plants, and the potential in these can be seen almost as limitless. The future aim is the creation of a SMART locus (stable multiple arrays of transgenes), that is, a transgenic locus containing multiple genes, thus avoiding segregation in meiosis and possibly also minimizing rearrangements and silencing [121]. For medicinal plants, the possibility to modify entire

metabolic pathways, to introduce completely new pathways, and to study complex metabolic control circuits and regulations are perhaps the main future goals.

New Compounds by Engineered Enzymes/Proteins

In most common approaches, the intention of metabolic engineering is to either overexpress or repress genes leading to the accumulation of certain compounds (Fig. 2). The first successful genetic engineering approach to the medicinal plant was performed already almost 20 years ago. Yun and coworkers [135] introduced the gene-encoding hyoscyamine-6β-hydroxylase (H6H) from *Hyoscyamus niger* to the medicinal plant *A. belladonna*. As a result of the overexpression of *h6h*, the plants produced almost exclusively scopolamine, whereas in the control plants the production of hyoscyamine (precursor of scopolamine) was dominant. Later, the function of the same gene was demonstrated to be different in hairy roots of *Hyoscyamus muticus* [26]. The overexpression of *h6h* caused 100-fold increase in scopolamine production, whereas the hyoscyamine contents were not reduced.

There are also examples where genetic engineering can lead to formation of entirely new metabolites. Classically, this can, for example, be achieved by generating somatic hybrids, that is, by exposing enzymes and regulators derived from different genomes to new environments. A good example is the production of demissidine in somatic *Solanum* hybrids neither parent of which contained this specific metabolite but only a set of different precursors [136].

More recently, the combinatorial biochemistry concept which is based on the fact that enzymes often show relaxed substrate specificity, that is, that they can under certain conditions process substrates which differ from the preferred one is exploited in a stricter sense. Usually, native genes are modified with the aim of creating modified enzymes catalyzing new reactions. Initially, attempts to alter the substrate specificity of plant-derived terpenoid synthases by rather unspecific methods such as mutagenesis or truncation were quite unpredictable [137]. Meanwhile, however, it could be shown that preselection of a mutant strictosidine synthase with a specific point mutation according to substrate acceptance results in quite predictable events. *C. roseus* hairy roots expressing the gene formed unnatural terpenoid indole alkaloids when were fed with derivatized precursors in contrast to the wild type [138].

Future Directions

Different omics in techniques have opened totally new avenues to discover genes, to learn about their functions, for example, transcription, and to finally map the biosynthetic pathways leading to the formation of important secondary metabolites. Metabolomics, which deals with all cellular metabolites, was first defined in microbiology but has also been recognized as an important sector of post-genome plant science [139]. Even in the absence of any visible change in a cell or individual plant, metabolomics, which allows phenotyping by exhaustive metabolic profiling, can show how cells respond as a system. Plant metabolomics is of particular importance because of the huge chemical diversity in plants compared to microorganisms and animals [140]. The number of metabolites from the plant kingdom has been estimated at 200,000 or even more [6], and each plant has its own complex set of metabolites. By integrating transcriptome and metabolome data, one can build networks and get insight on how particular metabolites are formed in plants [102, 140]. This in turn helps us to identify the key genes that could be engineered for the production of improved medicinal plants.

Since cell physiology involves dynamic rather than static processes, the investigation of fluxes is needed to complement phenotyping by metabolomics which only allows inventory, although time-resolved snapshots. However, in contrast to mammalian and microbial cells, flux quantification in plants is much less advanced. This is mainly due to the high degree of subcellular compartmentation and the complexity which arises from intercompartmental transport. Labeling experiments have been very successfully used already in the past for the elucidation of biosynthetic pathways in plants [141], but flux determination has only recently gained pace due to the fast development of analytical and computational technology. Analytical techniques of choice are nuclear magnetic resonance (NMR) spectrometry and mass spectrometry (MS) [142]. Generally, there are two fundamentally different methods

available facilitating flux measurement – steady-state and dynamic analysis – both of which have certain restrictions and benefits [143]. The latter, that is, kinetic approach is particularly interesting in the sense that it potentially could lead to predictive modeling in regard to secondary metabolism, while steady-state analysis is mainly used to measure carbon flux in well-defined pathways of primary metabolism [144].

In conclusion, modern genomic tools allow for mass gene discovery from plants although many biosynthetic pathways are incompletely resolved and medicinal plants have rarely been sequenced. Nevertheless, predictive metabolic engineering remains a goal of the future. This is because transgene integration in higher plants occurs through illegitimate rather than homologous recombination. DNA integration is random with a preference for gene-rich regions. Gene disruptions, sequence changes, and the production of new proteins constitute common consequences resulting in either predictable or unpredictable effects [145]. In this situation, the power of functional genomics tools allowing the comprehensive investigation of biological systems cannot be overemphasized. Genomics identifies all genes of a plant, while transcriptomics and proteomics provide information about their activities in cells or organs under certain conditions, and finally metabolomics and fluxomics account for the accumulation and kinetics of metabolites, that is, the phenotype. The individual techniques as such are thus invaluable to assign functions, but the real advantage lays in their combination, that is, the systems biology approach [140]. Interestingly at the same time, these tools allow not only the investigation of artificial situations generated by man but also for the first time broad assessment of natural variation.

Molecular Breeding Platforms in World Agriculture

Jean-Marcel Ribaut, Xavier Delannay, Graham McLaren, Frederick Okono
Integrated Breeding Platform, Consultative Group on International Agricultural Research, Generation Challenge Programme, c/o CIMMYT, Texcoco, Edo. Mexico

Article Outline

Glossary

Analytical pipeline A sequence of data management and statistical analysis algorithms which can be applied to one or more data sets to produce a result which can be interpreted and applied in decision making.

Capacity building Assistance that is provided to entities, usually institutions in developing countries, which have a need to develop a certain skill or competence, or for general upgrading of capability.

Cyberinfrastructure (CI) Computer-based research environments that support advanced data acquisition, data storage, data management, data integration, data mining, data visualization, and other computing and information processing services over the Internet. In scientific usage, CI is a technological solution to the problem of efficiently connecting data, computers, and people with the goal of enabling derivation of novel scientific theories and knowledge.

Gene Segment of DNA specifying a unit of genetic information; an ordered sequence of nucleotide base pairs that produce a certain product that has a specific function.

Information system (IS) An integrated set of computing components and human activities for collecting, storing, processing, and communicating information.

Integrated breeding platform (IBP) Term to describe a Molecular Breeding Platform (see below) in a broader sense including the availability of tools and services suitable for conventional breeding based on phenotypic selection only.

Molecular breeding (MB) Identification, evaluation, and stacking of useful alleles for agronomic traits of importance using molecular markers (MMs) in breeding programs. MB encompasses several modern breeding strategies, such as marker-assisted selection (MAS), marker-assisted backcrossing (MABC), marker-assisted recurrent selection (MARS), and genome-wide selection (GWS).

Molecular breeding platform (MBP) A term that has come to indicate a virtual platform driven by modern information and communication technologies through which MB programs can access genomic resources, advanced laboratory services, and analytical and data management tools to accelerate variety development using marker technologies.

Plant breeding The science of improving the genetic makeup of plants in order to increase their value. Increased crop yield is the primary aim of most plant breeding programs; benefits of the hybrids and new varieties developed include adaptation to new agricultural areas, greater resistance to disease and insects, greater yield of useful parts, better nutritional content of edible parts, and greater physiological efficiency especially under abiotic stress conditions.

Quantitative trait locus (QTL) A region of the genome that contains genes affecting a quantitative trait. Though not necessarily genes themselves, QTLs are stretches of DNA that are closely linked to the genes that underlie the corresponding trait.

Definition of the Subject

In the last decade, private seed companies have benefitted immensely from molecular breeding (MB) [1]. A private sector-led "gene revolution" has boosted crop adaptation and productivity in developed countries, by applying and combining the latest advances in molecular biology with cutting-edge information and communication technologies combined with accurate plant phenotyping.

MB allows the stacking of favorable alleles, or genomic regions, for target traits in a desired genetic background thanks to the use of polymorphic molecular markers (MMs) that monitor differences in genomic composition among cultivars, or genotypes, at specific genomic regions, or genes, involved in the expression of those target traits. The use of MMs generally increases the genetic gain per crop cycle compared to selection based on plant phenotyping only, and therefore reduces the number of needed selection cycles, hastening the delivery of improved crop varieties to the farmers.

In contrast to the private sector, MB adoption is still limited in the public sector, and is hardly used at all in developing countries. This is the result of several factors, among which are the following: (1) scientists from the academic world are more interested in discovering new genes or QTLs to be published than in applied biology; (2) until recently access to genomic resources was limited in the public sector, especially for less-studied crops; (3) public access to large-scale genotyping facilities was not easily available; and (4) although a broad set of stand-alone tools are available to conduct the multiple types of analyses necessitated by MB, no single analytical pipeline is available today in the public sector allowing integrated analysis in a user-friendly mode.

The situation is even more critical in developing countries as additional limitations include shortage of well-trained personnel, inadequate laboratory and field infrastructure, lack of ISs with applicable and flexible analysis tools, as well as inappropriate funding – simply put, resource-limited breeding programs. As a result, the developing world has yet to benefit from the MB revolution, and most of the countries indeed lack the fundamental prerequisites for a move to informatics powered breeding.

Under those circumstances, developing and deploying a sustainable web-based Molecular Breeding Platform (MBP) as a one-stop shop for information, analytical tools, and related services to help design and conduct marker-assisted breeding experiments in the most efficient way will alleviate many of the bottlenecks mentioned earlier. Such a platform will enable breeding programs in the public and private sectors in developing countries to accelerate variety development using marker technologies for different breeding purposes: major genes or transgene introgression via marker-assisted backcrossing (MABC), gene pyramiding via marker-assisted selection (MAS), marker-assisted recurrent selection (MARS) and, in a not too distant future, genome-wide selection (GWS).

Introduction

Since the dawn of agriculture, mankind has sought to improve crops by selecting individual plants with the most desirable characteristics or traits. Agricultural productivity has been progressively enhanced by constant innovation, including improved crop varieties to increase production in specific environments [2]. The major objective of crop improvement is to identify within heterogeneous materials those individuals for which favorable alleles are present at the highest proportion of loci involved in the expression of key traits [3]. The classical plant breeding method is based on increasing the probability of selecting such individuals from populations generated from sexual matings. Selection has traditionally been carried out at the whole-plant level (i.e., phenotype), which represents the net result of genotype and environment (and their interactions). Phenotypic selection has delivered tremendous genetic gains in most cultivated crop species, but is severely limited when faced with traits that are heavily modulated by the environment [4]. In addition, the nature of some traits can make the phenotypic testing procedure itself complex, unreliable, or expensive (or a combination of these).

The recent remarkable development of molecular genetics and associated technologies represents a quantum leap in our understanding of the underlying genetics of important traits for crop improvement. The ongoing revolutions in molecular biology and information technology offer tremendous and

unprecedented opportunities for enhancing the effectiveness and efficiency of MB programs. Indirect selection, based on genetic markers, presents an efficient complementary breeding tool to phenotypic selection. Individual genes or QTLs having an impact upon target traits can be identified and linked with one or more markers, and then the marker loci can be used as a surrogate for the trait, resulting in greatly enhanced breeding efficiency [5–8].

Molecular techniques can have an impact upon every stage of the breeding process from parental selection and cross prediction [9], to introgression of known genes [10] and population enhancement. Selection of beneficial alleles of known genes can be done through marker-assisted selection (MAS) – the selection of specific alleles for traits conditioned by a few loci [10] – or through marker-assisted backcrossing (MABC) – transferring specific alleles of a limited number of loci from one genetic background to another, including transgenes [11, 12]. For marker-assisted population improvement, individuals selected from a segregating population based on their marker genotype are intermated at random to produce the following generation, at which point the same process can be repeated a number of times [13]. A second approach aims at direct recombination between selected individuals as part of a breeding scheme, seeking to generate an ideal genotype or ideotype [14]. The ideotype is predefined on the basis of QTL mapping within the segregating population, combined with the use of multi-trait selection indices that can also consider historical QTL data. This variety development approach is commonly referred to as marker-assisted recurrent selection (MARS) [15–17], or genotype construction. An alternative is to infer a predictive function using all available markers jointly, without significant testing and without identifying a priori a subset of markers associated with the traits of interest. This more recent approach coming from genomic medicine [18, 19], and then applied successfully in animal breeding [20] named genome-wide selection (GWS), also appears to be quite promising in crop improvement [7].

Concomitantly with the evolution of marker technologies becoming increasingly "data rich," the amount of data produced by plant breeding programs has increased dramatically in recent years. Increasingly, the critical factor determining the rate of progress in plant breeding programs is their capacity to manage large amounts of data efficiently and subsequently maximize the timely extraction of meaningful information from that data for use in selection decisions. If genotyping has become less of an issue, the efficient management of genotyping data in a broad sense, including sequence information, is increasingly becoming a major challenge in modern plant breeding. This was recognized early on in the private sector where the establishment of platforms or pipelines integrating field and laboratory processes with powerful data management systems (DMS) that merged and analyzed the data collected at every step and guided the process of crop improvement toward the release of improved cultivars has been the key to successful adoption of MB.

A few initiatives have taken place in the public sector to establish efficient data management or ISs [21, 22]. One of these has been led by several centers of the Consultative Group on International Agricultural Research (CGIAR) which have worked over the past decade, along with advanced research institutes (ARIs) and national agricultural research systems (NARS) in developing countries, to develop an open-source generic IS, the International Crop Information System (ICIS), to handle pedigree information, genetic resource, and crop improvement information [23]. Based on some elements of ICIS, the CGIAR Generation Challenge Programme (GCP, http://www.generationcp.org) has invested in integrating crop information with genomic and genetic information and in using existing or developing new public decision-support tools to access and analyze information resources in an integrated and user-friendly way [24]. Another initiative has been led by Primary Industries and Fisheries (PI&F) of the Queensland Government Department of Employment, Economic Development and Innovation in Australia, which recognized that effective data management is an essential element in obtaining maximum benefit from their investment in plant breeding. In conjunction with the New South Wales Department of Primary Industries (NSW DPI) and more recently Dart Pty Ltd (http://www.diversityarrays.com/) they are in the process of developing a linked IS for plant breeding (Katmandoo) that includes applications for capturing field data using hand-held computers, barcode-based seed management systems, and databases to store and link field

trial data, laboratory data, genealogical data, and marker data [25].

Although an IS involves far more than a database, the development and implementation of a suitable database system alone remains a real challenge because of the fast turnover in technologies, the need to manage and integrate increasingly diverse and complex data types, and the exponential increase in data volume. Previous solutions, such as central databases, journal-based publication, and manually intensive data curation, are now being enhanced with new systems for federated databases, database publication, and more automated management of data flows and quality control. Along with emerging technologies that enhance connectivity and data retrieval, these advances should help create a powerful knowledge environment for genotype–phenotype information [26].

In addition to efficient data management, advances in statistical methodology [27–29], graphical visualization tools, and simulation modeling [9, 30–32] have greatly enhanced these ISs. The availability of molecular data linked to computable pedigrees [33] and phenotypic evaluation now makes genotype–phenotype analysis a practical reality [34].

In order to realize the full potential of marker technologies and bioinformatics in plant breeding, tools for molecular characterization, accurate phenotyping, efficient ISs, and effective data analysis must be integrated with breeding workflows managing pedigree, phenotypic, genotypic, and adaptation data. The goals of this integration of technologies are to (1) create genotype–phenotype trait knowledge for breeding objectives, and (2) use that knowledge in product development and deployment [4].

This entry generally explores the pace of innovation in world agriculture and the rise of MB. It particularly illustrates the accelerating application of information and communication technologies to the information management challenges of MB and, as a result, the emergence of virtual molecular breeding platforms (MBPs) as a vital tool for accelerating genetic gains and rapidly developing more resilient and more productive cultivars.

This entry reviews the rationale for access to MB technology and services and the status of existing public analytical pipelines and ISs for MB, and offers a detailed case study for the CGIAR GCP Integrated Breeding Platform (IBP) – the pioneer public sector MBP specifically targeting developing country breeding programs. It explores the gaps between countries and between crops in the application of informatics-powered MB approaches, and the potential for adopting MBPs to close these gaps; and it reviews institutional, governmental, and public support for these approaches. The entry discusses the challenges and opportunities inherent in MBPs, and the potential economic impact of MB. Finally, the entry explores the future directions and perspectives of MBPs.

Marker Technologies and Service Laboratories

Markers are "characters" whose pattern of inheritance can be followed at the morphological (e.g., flower color), biochemical (e.g., proteins and/or isozymes), or molecular (DNA) levels. They are so called because they can be used to elicit, albeit indirectly, information concerning the inheritance of "real" traits. The major advantages of molecular over other classes of markers are that their number is potentially unlimited, their dispersion across the genome is complete, their expression is unaffected by the environment and their assessment is independent of the stage of plant development [35]. During the past two decades, DNA technology has been exploited to advance the identification, mapping, and isolation of genes in a wide range of crop species. The first generation of DNA markers, restriction fragment length polymorphisms (RFLPs), was used to construct the earliest genome-wide linkage maps [36] and identify the first QTLs [37, 38]. During the 1990s, emphasis switched to assays based on the polymerase chain reaction (PCR), which are much easier to use and potentially automatable [39]. The development of simple sequence repeats (SSRs) [40], amplified fragment length polymorphisms (AFLPs) [41], and single nucleotide polymorphism (SNP) [42] opened the door for large-scale deployment of marker technology in genomics and progeny screening.

SNPs are amenable to very high throughput and a wide range of detection techniques has been developed for them, from singleplex systems to high-density arrays. They can be used in fully integrated robotic systems going from automated DNA extraction to automated scoring in high-throughput detection platforms. The combination of increase in throughput and lowering in costs makes SNPs highly suitable to

intensive marker applications in plant breeding such as MARS and the emerging approach of GWS. Based on SNP technology, production of molecular marker (MM) data expanded more than 40-fold between 2000 and 2006 at Monsanto, while cost per data point decreased to one sixth of the original cost [43].

With the transition from SSRs to SNPs and the concomitant large increase in the demand for genotyping as markers get more and more widely used in a broad range of applications from medicine to plant breeding, marker genotyping laboratories have evolved from relatively low-tech operations to highly automated, high-throughput laboratories using an array of sophisticated equipment (pipetting robots, high-density PCR, high-throughput SNP detection machines, high-level informatics). Although large private seed companies have had the need and the resources to put in place large-scale genotyping laboratories for their own uses, smaller programs, especially in the public sector, have typically not had the resources or the justification to establish such large operations to respond to their increasing need for SNP genotyping data. In response to this need, a few private marker service laboratories have sprung up over the past few years, which can provide complete genotyping services for their customers, from DNA extraction to generation of large numbers of SNP or other datapoints. Due to their broad customer base (from medical research laboratories to animal and plant breeding operations, both public and private), these laboratories can have a large volume of datapoint production which may lead to low costs for the customer and high throughput. They are able to invest in the most advanced equipment to keep up with the constant evolution of genotyping technologies and are able to pass on the resulting benefits to their customers. Processes have now been put in place for rapid shipment of leaf samples from any location (field or laboratory) around the world without any restrictions. Examples of such companies that can service breeding programs from around the world are DNA LandMarks, Inc. of Saint-Jean-sur-Richelieu, Quebec, Canada (http://www.dnalandmarks.ca/english/) and KBioscience Ltd. of Hoddesdon Herts, UK (http://www.kbioscience.co.uk/). For many public breeding programs and small companies, especially in developing countries, it is now more efficient to use those types of contract genotyping services than to try to support their growing MB needs through the establishment of an in-house laboratory. Functional and reliable SNP laboratories are especially difficult to establish in many developing countries due to the unreliability of the power supply, difficulties in shipping and storing and a low level of resources for the purchase and maintenance of sophisticated equipment. The GCP is facilitating the linkage between users and service laboratories through its marker services, a component of the breeding services offered through the GCP's IBP.

Analytical Tools, Software, and Pipelines

One of the achievements of the plant biotechnology revolution of the last two decades has been the development of molecular genetics and associated technologies, which have led to the development of an improved understanding of the basis of inheritance of agronomic traits. The genomic segments or QTLs involved in the determination of phenotype can be identified from the analysis of phenotypic data in conjunction with allelic segregation at loci distributed throughout the genome. Because of this, the mode of inheritance, as well as the gene action underlying the QTL, can be deduced [44]. As with the improvement in marker technologies, the statistical tools needed for QTL mapping have evolved from a rudimentary to a very sophisticated level [45]. Previous approaches based on multiple regression methods, using least squares or generalized least squares estimation methods [46, 47], have evolved to composite interval mapping [9], mixed model approaches using maximum likelihood or restricted maximum likelihood (REML) [48], and Markov Chain Monte Carlo (MCMC) algorithms [49, 50], which use Bayesian statistics to estimate posterior probabilities by sampling from the data. In parallel, with progress in the characterization of genetic effects at QTLs and refinement of QTL peak position through meta-analysis [51], advances have also been made in understanding the impact of the environment on plant phenotype. The mapping of QTLs for multiple traits has allowed the quantification of QTL by environment interaction (QEI) [52] and, more recently, approaches using factorial regression mixed models have been applied to model both genotype by environment interaction [53] and QEI [48, 54, 55]. Recent approaches are now

implemented to evaluate gene networking [56] and epistasis, based on Bayesian approaches [57, 58] or through stepwise regression by considering all marker information simultaneously [59, 60]. Epistasis and balanced polymorphism influence complex trait variation [61, 62], and classical generation means analyses, estimates of variance components, and QTL mapping indicated an important role of digenic and/or higher-order epistatic effects for all biomass-related traits in model plants [63] and in crops [64–66]. It will be critical to implement the most efficient MB strategies in order to evaluate and include these genetic effects in breeding schemes [60].

All tools necessary to run MB projects, from the simplest to the most complicated approaches, are available today in the public domain. They are based on different algorithms and statistical approaches, from the very simple to the more complex. One challenge is the diversity of tools available for a given analytical function or along the different steps of an analytical pathway, making the choice of the "right" tool difficult and the move from one analytical step to the next very tedious due to the complete lack of common standards and formatting across tools. The number of applications available for QTL analysis illustrates well the multiplicity and diversity of tools that are available for a given analysis. The following software packages have been developed over the past 20 years:

- Mapmaker/QTL [67]
- MapQTL [68, 69]
- QTL Cartographer [9, 70]
- PLABQTL [71]
- QGene [72, 73]
- Map Manager QT [74]
- iCIM [59, 60]

For most of these applications, the first versions were already available 15 years ago and the multiplicity and possible duplication generated by the independent development of these tools were already identified at the Gordon Research Conference on Quantitative Genetics and Biotechnology held in February 1997 in Ventura, California. A main objective of that workshop was to survey participants on the attributes of several software packages for QTL mapping and to define their analytical needs which were not presently met by the existing software packages. The workshop covered software for QTL mapping in inbred and outcrossed populations and the conclusions are available at: http://www.stat.wisc.edu/~yandell/statgen/software/biosci/qtl.html. In those conclusions one can read that "[a] consensus was reached that there is considerable overlap in the kinds of matings handled and statistics produced by the various QTL mapping software packages," clearly identifying the need for better coordinated efforts. Such coordination never took place, as is often the case in public research. As a result, most of those QTL packages are still available today, although in more sophisticated versions. They are all suitable for QTL mapping but use different statistical algorithms, present a different user interface, and necessitate different input and output file formats.

Some specialists in the field realized that the public software packages are usually too specialized and too technical in statistics to permit a thorough understanding by the many experimental geneticists and molecular biologists who would want to use them. In addition, the fast methodological advances, coupled with a range of stand-alone software, make it difficult for expert as well as non-expert users to decide on the best tools when designing and analyzing their genetic studies. Based on this rationale, a few commercial analytical pipelines emerged about a decade ago that include some of the QTL packages mentioned above. Two of them are Kyazma and GenStat®. These applications assist plant scientists by providing easy access to statistical packages for phenotypic and genotypic data. Kyazma was founded in the spring of 2003 (http://www.kyazma.nl/), and offers powerful methods for genetic linkage mapping and QTL analysis. Since 2003 Kyazma has taken over the development of the software packages JoinMap® and MapQTL® from Biometris of Plant Research International. Kyazma handles the distribution and support of JoinMap and MapQTL and, in collaboration with the statistical geneticists of Biometris, Kyazma provides introductory courses on genetic linkage mapping and QTL analysis in order to make the use of the software even more accessible. GenStat encompasses statistical data analysis software for biological and life science markets worldwide. GenStat includes the ASReml algorithm (average information algorithm for REML) to undertake very efficient meta-analyses of data with linear mixed models. The development of GenStat at Rothamsted

began in 1968, when John Nelder took over from Frank Yates as Head of Statistics. Roger Payne took over leadership of the GenStat activity when John Nelder retired in 1985 (http://www.vsni.co.uk/). An important feature of GenStat is that it has been developed in (and now in collaboration with) a Statistics Department whose members have been responsible for many of the most widely used methods in applied statistics. Examples include analysis of variance, design of experiments, maximum likelihood, generalized linear models, canonical variates analysis, and recent developments in the analysis of mixed models by REML.

These commercial analytical pipelines offer a set of quality tools to researchers in plant science. However, they cover only a part of the configurable workflow system that is required for integrated breeding activities. In addition, there is a need to have tools and analytical pipelines that are freely available and, if possible, based on open source code to avoid dependence on private companies that might discontinue support and ensure access to the tools even with limited financial resources, which is a critical constraint in the arena of research for development, of which breeding programs of developing countries are key partners. It is important to underline that a version of GenStat that does not include the most advanced version of the different tools but allows users to run most basic analyses is available for breeding programs in developing countries. The web site for the GenStat Discovery Edition is http://www.vsni.co.uk/software/genstat-discovery/, but this version of the pipeline does not include QTL selection based on the mixed model approach, which is available in the commercial version.

The issue of open source code is an important one as, even for freely-available tools, the lack of availability of the source code limits the further expansion and customization of the tools. It also reduces the opportunity of researchers in developing countries to participate in methodology development. Over the last decade, a programming language and software environment for statistical computing and graphics, R, is becoming the reference in open source code for a broad range of biological applications, including genetic analysis (http://www.r-project.org/). Its source code is freely available under the *GNU General Public License* (http://en.wikipedia.org/wiki/GNU_General_Public_License). The R language has become a de facto standard among statisticians for the development of statistical software. It compiles and runs on a wide variety of UNIX, Windows, and MacOS platforms. R is similar to other programming languages, such as C, Java, and Perl, in that it helps people perform a wide variety of computing tasks by giving them access to various commands. For statisticians, however, R is particularly useful because it contains a number of built-in modules for organizing data, running calculations on the information, and creating graphical representations of the data sets. R provides a wide variety of statistical (linear and nonlinear modeling, classical statistical tests, time-series analysis, classification, clustering, etc.) [29] and graphical techniques, and is highly extensible. Close to 1,600 different packages reside on just one of the many web sites devoted to R, and the number of packages has grown exponentially. However, R is difficult to use directly and procedures based on R must be wrapped in user-friendly menu systems if field biologists are to use them.

Information Systems

A functional IS involves far more than an analytical pipeline; it is a complete system that should include:

- A project planning module
- A germplasm management module
- A robust relational database
- Analytical standards
- Data collection and cleaning tools
- Analytical and decision support tools
- Query tools
- A cyber infrastructure (CI) that links the different tools in a cohesive and user-friendly way

Key elements of an IS are obviously the CI and the DMS as described in the following section. The value of an IS does not only reside in the quality of the individual tools or modules that are part of it, but rather in the CI or middleware that ensures cohesion across tools and efficient communication with databases.

There are not many examples of breeding ISs in the public domain. One example is the ICIS (http://www.icis.cgiar.org, [23]). ICIS is an open source IS for managing genetic resource and breeding information for any crop species. It has been developed over the last 10 years through collaboration between centers of the

CGIAR, some NARS, and private companies. The ICIS system is Windows-based, and distributable on CD-ROM or via the Internet. It contains a genealogy management system (GMS, [33]) to capture and process historical genealogies as well as to maintain evolving pedigrees and to provide the basis for unique identification using internationally accepted nomenclature conventions for each crop; a seed inventory management system (IMS); a DMS [75] for genetic, phenotypic, and environmental data generated through evaluation and testing, as well as for providing links to genomic maps; links to geographic ISs that can manipulate all data associated with latitude and longitude (e.g., international, regional, and national testing programs); applications for maintaining, updating, and correcting genealogy records and tracking changes and updates; applications for producing field books and managing sets of breeding material, and for diagnostics such as coefficients of parentage and genetic profiles for planning crosses; tools to add new breeding methods, new data fields, and new traits; and tools for submitting data to crop curators and for distributing data updates via CD-ROM and electronic networks. The community of ICIS collaborators communicates via the ICIS Wiki (http://www.icis.cgiar.org), where all design and development decisions are documented. Feature requests and bug reports are made through the ICIS Communications project and the source code is published through various other ICIS projects on CropForge (http://cropforge.org). A commercial company, Phenome-Networks, has implemented a Web-based IS based on ICIS (http://phnserver.phenome-networks.com/).

Another system available is the Katmandoo Biosciences Data Management System (http://www.katmandoo.org/, [25]), which is a freely available, open source DMS for plant breeders developed by PI&F, NSW DPI, and DArT Pty. Ltd. It comprises linked ISs for plant breeding including applications for capturing field data using hand-held computers, barcode-based seed management systems, and databases to store and link field trial data, laboratory data, genealogical data, and marker data. A particular focus is on the use of whole-genome MM information to create graphical genotypes, track the ancestral origin of chromosomal regions, validate pedigrees, and infer missing data. It includes the applications of the Pedigree-Based Marker-Assisted Selection System (PBMASS) developed by PI&F as well as a seed management system, a digital field book for hand-held computers, and a system for directly recording weights of barcoded samples.

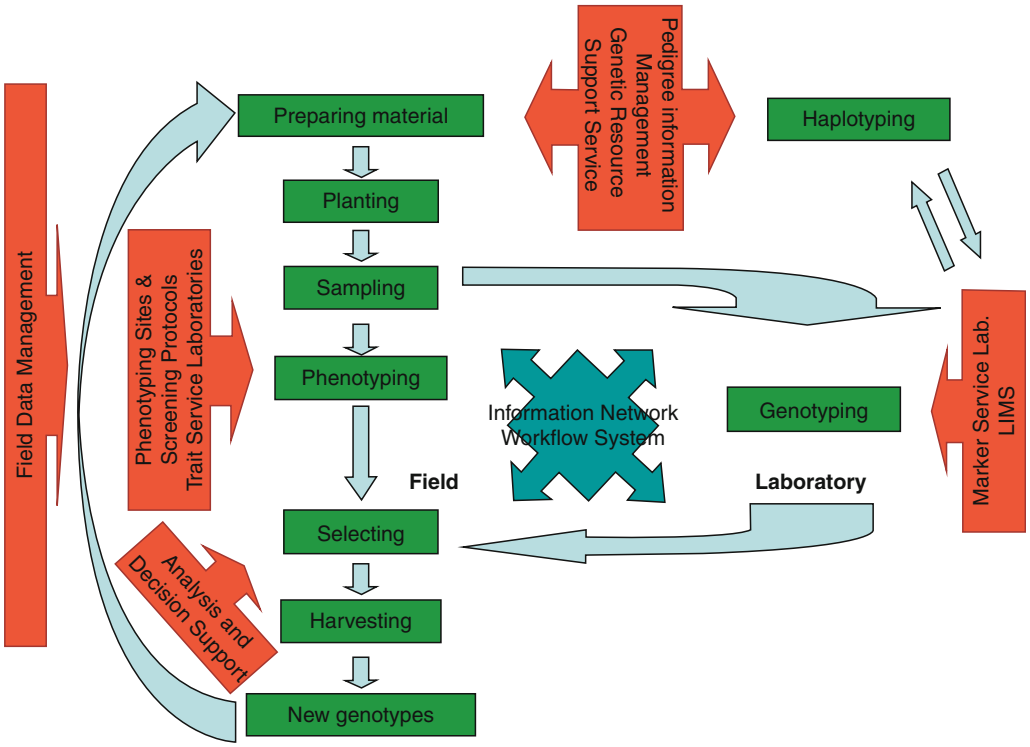
Both ISs struggle with the problem of integrating the different components into a single configurable system which matches the workflows of different breeding projects. Such a workflow should provide the user all tools and analytical means required to run a crop cycle: from germplasm preparation and planting, through the collection of phenotypic and the production of the genotypic data and their analysis, to the identification of genotypes to be crossed or the selection of suitable genotypes to be planted in the next cycle (Fig. 1).

In order to do this effectively, a CI is required which allows syntactic linkage between different data resources and applications.

Cyberinfrastructure and Data Management

We have referred to the revolution in Information and Communication Technology and the opportunities it presents for improving the efficiency of plant breeding. However, plant breeding is not the only area of biology being affected by this revolution and, in fact, the successful deployment of MB depends on other fields of information-intensive biology delivering knowledge (markers and methodology) to plant breeding. Even more is expected of the information and communications technology (ICT) revolution in the developing world, as it offers an opportunity for scientists there to overcome some of the constraints of isolation, the "brain drain," and the lack of infrastructure which have prevented them from fully participating in science for development in the past [76].

It is generally recognized that upstream biology is increasingly reliant on networks of integrated information and on applications for analyzing and visualizing that information. Discipline-specific (sequence and protein databases) and model organism ISs such as Graingenes (http://wheat.pw.usda.gov/GG2/index.shtml), Gramene (http://www.gramene.org/), MaizeGDB (http://www.maizegdb.org/), and Soybase (http://www.soybase.org/) have been developed to facilitate exchanges in molecular biology and functional genomics. As noted above, plant breeding



Molecular Breeding Platforms in World Agriculture. Figure 1
Different activities conducted during the crop cycle of an MB experiment presented in a generic way

depends on these upstream sciences of molecular biology, functional genomics, and comparative biology to deliver the knowledge needed to deploy MB. The bottleneck in the overall network has been the technology needed to integrate diverse and distributed information resources, and many information scientists have been working on this problem [24, 26, 77].

One constraint to integration of scientific information is the necessity to have a standard terminology for biological concepts across species and disciplines. A successful example of such standardization is the Gene Ontology (GO) initiative (http://www.geneontology.org, [78]). Another more specialized ontology initiative, especially pertinent to agriculture, is the Plant Ontology Consortium (POC: http://www.plantontology.org, [79–81]). However, these formal descriptions remain somewhat limited to biology of model plants and controlled environments. A key challenge will be to extend such standards to describe characteristics of plants growing in the unique, stress-prone environments found within the developing world to ensure a wider impact of such standards on international agriculture. The GCP has been working with POC to expand these ontologies to economic traits and farming environments so that they can be used in the field of plant breeding [82].

Another constraint to the efficient utilization of genomic information is the sheer volume of sequence data that can now be generated very cheaply across numerous genotypes. ISs to handle this volume of information are struggling to keep up. In plant biology, some examples of systems aiming to handle these torrents of data are the Germinate database ([83], http://bioinf.scri.ac.uk/public/?page_id=159) and the Genomic Diversity and Phenotype Connection (GDPC, http://www.maizegenetics.net/gdpc/). The primary goal of Germinate is to develop a robust database which may be used for the storage and retrieval of a wide variety of data types for a broad range of plant species. Germinate focuses on genotypic, phenotypic, and passport data, but has been designed to potentially handle a much wider range of data including, but not

limited to, ecogeographic, genetic diversity, pedigree, and trait data, and will permit users to query across these different types of data. The developers have aimed to provide a versatile database structure, which can be simple, requires little maintenance, may be run on a desktop computer, and yet has the potential to be scaled to a large, well-curated database running on a server. The design of Germinate provides a generic database framework from which interfaces ranging from simple to complex may be used as a gateway to the data. The data tables are structured in a way that they are able to hold information ranging from simple data associated with a single accession or plant, to complex data sets, images, and detailed text information. Features of the Germinate database structure include its ability to access any information associated with a group of accessions and to relate different types of information through their association with an accession. The GDPC database was designed as a research database to support association genetics applications such as Tassel (http://www.maizegenetics.net/index.php?option=com_content&task=view&id=89&Itemid=119) and is being extended to handle higher and higher densities of genotyping and sequence data. The second version of Germinate seems quite similar to GDPC and if new databases are developed to handle the large data files to be generated soon through high-throughput sequencing, some conversion tools should be easily developed to migrate data from one system to another.

Finally, the problem of integrating all these diverse and widely-distributed information resources is a major informatics challenge, which is being tackled on several fronts at several levels of complexity. The BioMOBY project ([84], http://www.biomoby.org, [85]) and the Semantic Web seek to define standards that will allow computer programs to interpret requests for information or services, find informatics resources capable of fulfilling those requests, and return the results without the authors of the interacting software having specifically collaborated. In the private sector, solutions have been more pragmatic and Enterprise Software solutions have been developed to link data resources and applications with specific services. The iPlant Collaborative (http://www.iplantcollaborative.org/) is a National Science Foundation (NSF)-funded initiative designed to bring these Enterprise Software solutions to the biological sciences in the form of CI which can support any biological data resource and analytical application. iPlant and the GCP are collaborating on integrating plant breeding information resources and applications into the infrastructure. This will automatically link these resources to upstream biological applications using the same infrastructure such as that used by the Systems Biology Knowledgebase initiative (http://genomicscience.energy.gov/compbio/#page=news) of the US Department of Energy which will be producing knowledge needed for crop improvement.

With all the progress achieved in marker technology, software development, analytical pipelines, and DMS, it is time to provide an IS, available through a public platform, that will offer breeding programs in developed and developing countries access to modern breeding technologies, in an integrated and configurable way, to boost crop quality and productivity.

Case Study: GCP's Integrated Breeding Platform

To fill this gap in the public sector and in particular in the arena of research for development, the GCP has been coordinating the development of the IBP (www.generationcp.org/ibp) in collaboration with scientists from ARIs, CGIAR centers, and national research programs since mid-2009. In a first phase the IBP aims at serving the needs of a set of 14 pioneer "user cases" – MB projects for eight crops in 16 developing countries in Africa and Asia. Leading scientists of those user cases help in testing the prototypes developed for the different tools of the analytical pipeline and contribute to the monitoring and evaluation of the platform development. This ensures that IBP development is driven by real breeding needs and its interface is user-friendly.

Objective of the IBP

The overall objective of the IBP project is to provide access to modern breeding technologies, breeding material, and related information and services in a centralized and functional manner to improve plant breeding efficiency in developing countries and hence

facilitate the adoption of MB approaches. The short-term objective of the project (the initial phase) is to establish – through a client-centered approach – a minimum set of tools, data management infrastructure, and services to meet the needs and enhance the efficiency of the 14 user cases.

To achieve the overall objective, GCP is developing and deploying a sustainable IBP as a one-stop shop for information, analytical tools, and related services to design, implement, and analyze MB experiments. This platform should enable breeding programs in the public and private sectors to accelerate variety development for developing countries using marker technologies – from simple gene or transgene introgression to gene pyramiding and complex MARS and GWS projects. Hence IBP aims at bringing cutting-edge breeding technologies to breeding programs that are too resource-restricted to invest in the requisite genotyping and data management infrastructure and capacity on their own.

The IBP Partnerships

The primary stakeholders of the platform are plant scientists – at this time specifically breeders leading the selected MB projects of the 14 pioneer user cases. These pioneer user cases are all recently initiated marker-assisted breeding projects with specific budgets, objectives, and work plans. The needs of the projects are defining the user requirements, and hence the design and development prioritization of the different elements of the platform. In selecting the user cases, crop diversity was a primary consideration, since the platform is supposed to address the needs of a broad variety of crops. The platform's reciprocal contribution to these breeding projects is in helping them overcome bottlenecks that would compromise final product delivery and in enhancing their overall efficiency and chances of success by providing appropriate tools and support.

The developmental phase of the IBP brings together highly regarded public research teams – institutes and individuals who have been working on the challenges of crop information management and analysis, biometrics, and quantitative genetics. This team of bioinformaticians, statisticians, and developers aims to design and develop the different elements of the platform, based on needs and priorities defined by the user cases.

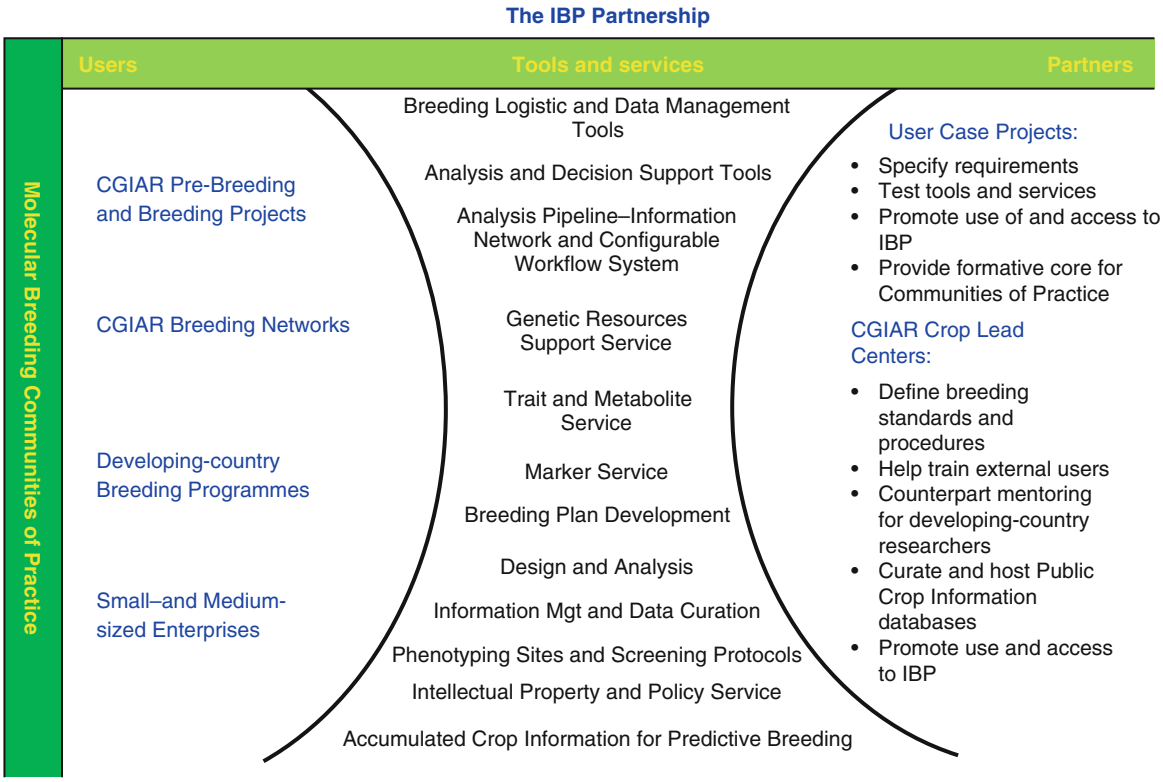
A continuous dialogue between users, developers, and service providers ensures a healthy balance between having a user-driven platform on the one hand, with a reasonable degree of "technology push" on the other hand, to ensure that users are kept abreast of technological solutions they may not be aware of but that would facilitate and accelerate breeding work.

The private sector has led the application of MB approaches and utilization of MBPs. The IBP is the first public sector effort of this magnitude aimed at developing and deploying an MBP. Given that MB for complex polygenic traits, and more so MARS, is still in its infancy in the public sector, it is recognized that efficient partnerships with the major private sector transnational seed companies is a strong prerequisite for the success of the IBP project. Consultations are ongoing with leaders in MB at Limagrain, Monsanto, Pioneer-DuPont, and Syngenta. Partnership with the private sector includes mainly some technology transfer, especially for stand-alone tools, and access to human resources to advise on the development of the platform and contribute to developing new tools or implement data management. The users, tools and services, and partnership of the platform are presented in Fig. 2.

The Platform

The IBP has three broad components (see Fig. 3): a Web-based portal and helpdesk, an open-source IS incorporating an adaptable breeding workflow system, and breeding and support services.

The stepwise development of the breeding workflow includes: (1) access to existing tools, (2) development of stand-alone new tools or adapted versions of existing tools to address the needs of the user cases, and (3) the integration of those tools into a CI (collaboration with the iPlant initiative) or through a thin middleware linking with local database to form a user-friendly configurable workflow system (CWS). A first version of the CWS, including an adequate set of tools, should be available by mid-2012, with full unfettered access scheduled for 2014.



Molecular Breeding Platforms in World Agriculture. Figure 2
The IBP partnership

Component 1: The Integrated Breeding Portal and Helpdesk

Inaugurated by mid-2011, the portal is the online gateway through which users access all the tools and services of the IBP. Through the portal, users will select and download tools and instructions, order materials, and procure laboratory services.

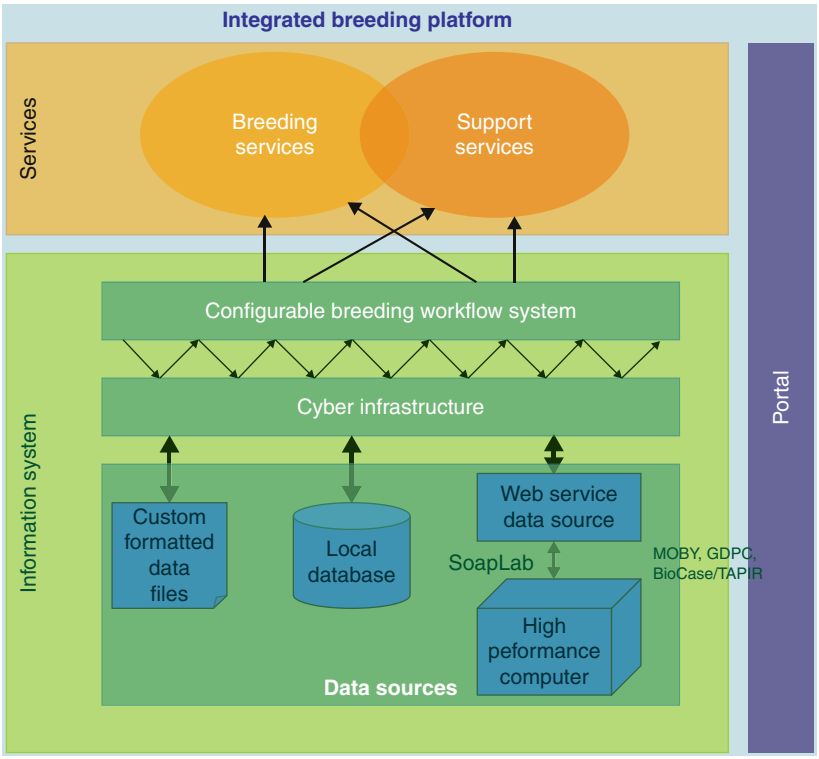
The portal's helpdesk facilitates its use and ensures access for users who cannot efficiently use the Web interface by providing the elements they need via email, compact disc, and other offline media.

Through their user-friendly networking components, the Portal and Helpdesk will stimulate the development of collaborative crop-based and discipline-based communities of practice (CoPs). The CoPs are expected to promote the application of MB techniques and the utilization of facilitative information management technologies, enhance data and germplasm sharing, and generally advance modern breeding capacity by linking CGIAR Centers and ARIs with developing-country breeding programs and research organizations. There is a strong hope that CoPs will facilitate and accelerate a paradigm shift to a more collaborative, outward-looking, technology-enhanced approach to breeding.

Component 2: The Information System

The IBP IS is structured as a CWS, with access to both local databases and distributed resources, such as central crop databases, molecular databases from GCP partner sites and from public initiatives such as Gramene and GrainGenes.

The Configurable Workflow System This CWS is the operational representation of the IS and will be implemented by assembling informatics tools into applications configured to match specific breeding workflows (e.g., for MAS, MABC, or MARS; Fig. 4). The tools are organized in a series of functional modules comprising



Molecular Breeding Platforms in World Agriculture. Figure 3
The IBP and its three main components

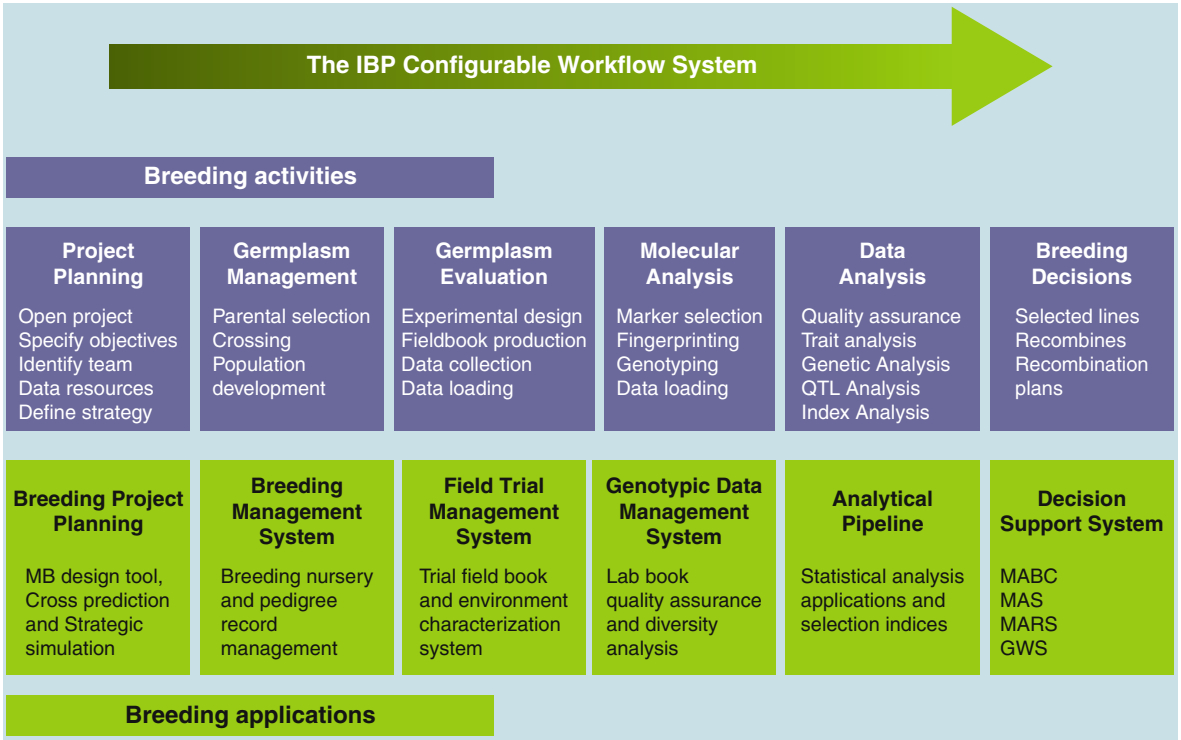
the Integrated Breeding Workbench, which is really the background structure that implements the CWS.

The IBP CWS drives the users through the different practical steps or activities of an MB project. The setup of the experiment and the germplasm management are the first steps of any project, to be followed by a set of activities that can be repeated during subsequent crop cycles, depending on the breeding objective of the experiment:

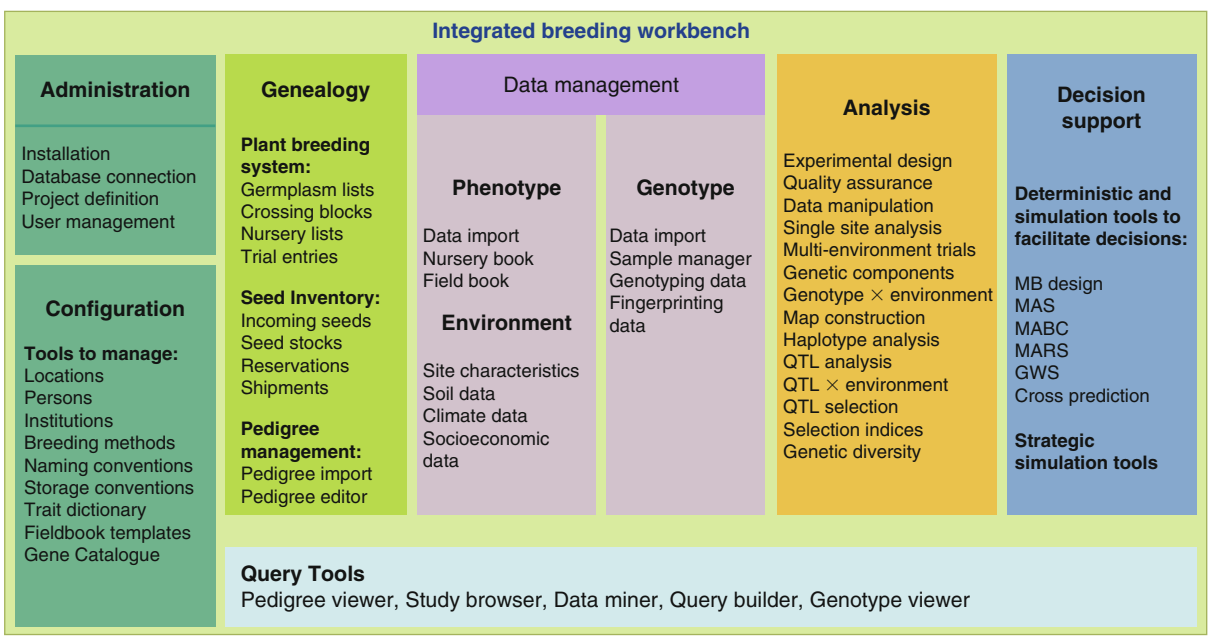
- Germplasm evaluation
- Genetic analysis
- Data management
- Data analysis, and
- Breeding decisions

The Integrated Breeding Workbench The workbench starts as a blank slate and the first task for the user is to open or create a project. A project manages a breeding workflow for a particular crop and a specified user. The initial sets of tools which should be available are grouped in seven modules: Administration Tools, Configuration Tools, Query Tools, and Workflow Initialization Tools (genealogy, data management, analysis, and decision support; Fig. 5).

The administration module of the workbench specifies the crop, which identifies the central (public) data resources that will be accessible to the project. This includes a central genealogy database, a central phenotype database, a public gene management database, and a central genotype database. Each installation provides access to local (private) data resources. These data resources include a private or local database for the above data types as well as a seed inventory management system. Each installation has at least one user with administrative privileges. Users are identified by authentication codes (username and password) for access to specific private data resources. ("Private" simply means "requiring authentication for access" and several users may have access to the same private data.)



Molecular Breeding Platforms in World Agriculture. Figure 4
The IBP configurable workflow system



Molecular Breeding Platforms in World Agriculture. Figure 5
The integrated breeding workbench

The first functionality of the workbench asks the user to open a project by selecting from a list of available project configuration "files." Once the configuration is selected, the availability of the public data resources should be checked, the user authentication codes verified, and the local data resources checked. Next, the list of modules should be reviewed and checked for availability and, depending on the state of the workflow, icons or menus should be made available for modules and tools.

The configuration tools allow users to:

- Select or specify naming conventions for germplasm, germplasm lists, studies, etc.
- Use and update ontologies such as germplasm methods and the trait dictionary
- Update breeding, testing, or collection locations
- Create and modify study templates

The query tools will depend on the data resources specified in the project configuration, and examples are:

- A germplasm and pedigree viewer
- A study browser to view phenotype or genotype data
- A data miner for identifying data patterns
- A cross-study query builder for linking different data sets
- A gene catalog viewer for viewing genetic diversity
- A genotype and trait viewer for visualizing graphical genotypes and trait markers

The workflow initialization tools comprise a set of modules (genealogy, data management, analysis, and decision support tools) that provide the user with a choice of different tools to achieve precise breeding objectives. Users might construct different breeding workflows to match their project activities. The user will only see the workbench tools and settings for those tools required to execute the steps in a particular breeding workflow, and at the appropriate step in that workflow.

The development of each tool is overseen by a team of IBP researchers, developers, and users who design, mock up, and prototype the tools of the breeding application and pass the specifications to a software engineering team. They will then monitor the development and test and support the application. For each application, the team develops a description of the application, functional specifications of all the tools, workflow specifications for the application, and an interface mockup. A workflow for a MARS project is shown in Fig. 6.

Component 3: IBP Services

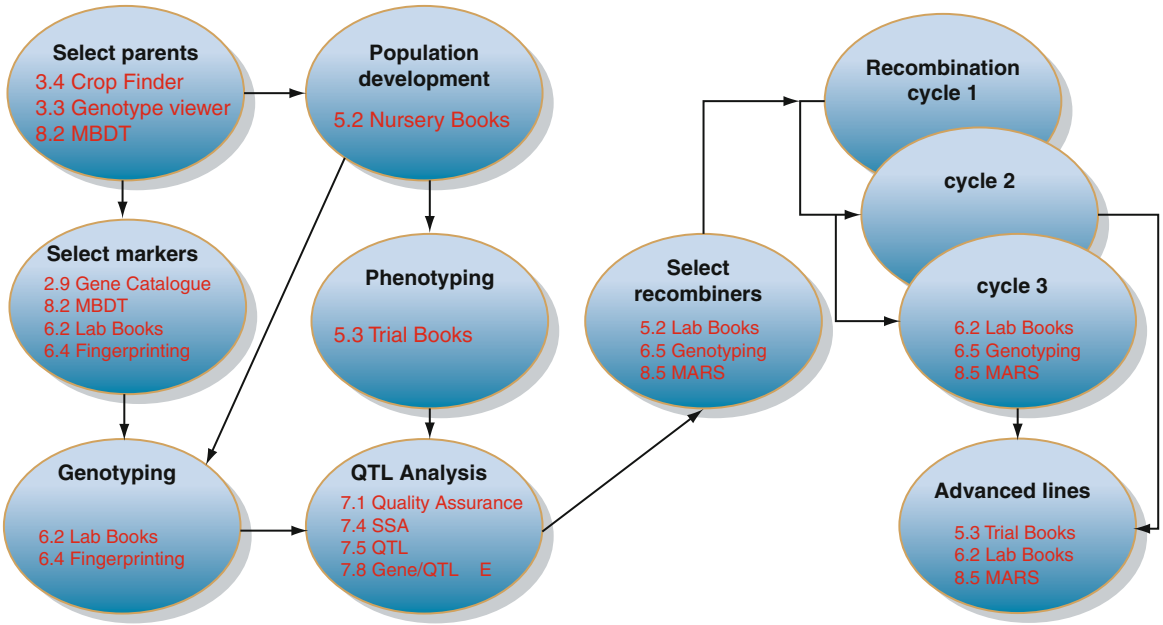
The Services component comprises two modules. The first module, Breeding Services, provides services to conduct MB projects. The second module, Support Services, deals with training and capacity-building, aiming to provide support and improve capacity of NARS breeders to deliver improved germplasm through marker approaches – essential for the adoption of MB approaches and the MBP.

Breeding Services These services provide access to specific germplasm, and assist with contracting a service laboratory to conduct the marker work or to quantify specific traits, such as metabolite profiles or grain quality parameters. The module has three elements (Fig. 7):

Genetic Resource Support Service: Access to suitable germplasm and related information from the different partners is a critical element of the portal. To address this, a Genetic Resource Support Service (GRSS) plans to tap into the CGIAR System-wide Genetic Resources Program (SGRP), a collaborative effort between GCP and existing gene banks in the CGIAR and NARS. The GRSS should ensure quality control, maintenance, and distribution of genetic resources, including reference sets and segregating populations acquired or generated through projects supported by GCP, and material generated from other sources and deposited with the GRSS (e.g., maize introgression lines from Syngenta).

Marker Service: The portal provides a set of online options for users to access different high-throughput marker service laboratories in the public and private sectors with clear contractual conditions. Service Laboratories have been selected on the basis of competitive cost, compliance with quality control requirements, and expeditious delivery, but are currently accessible by offline processes pending deployment of the IBP portal.

Trait and Metabolite Service: The portal provides a set of options for users to access laboratories



Molecular Breeding Platforms in World Agriculture. Figure 6
Breeding workflow for an MARS experiment

specialized in the evaluation and analysis of specific traits, such as quality traits, pathology screening, or metabolite quantification. Analyses of certain secondary traits and metabolites that are indicative of plant stress tolerance can potentially provide valuable information to be used in breeding. Such analyses are generally prohibitively expensive if done locally, as it is difficult to maintain assay quality and devote the necessary resources for expertise, quality control, and specialized facilities.

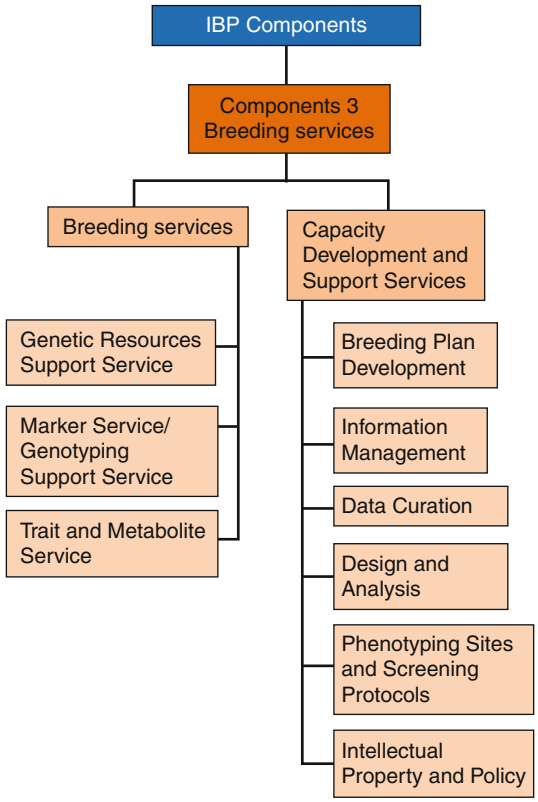
Capacity Development and Support Services
Capacity development is an integral part of the project, encompassing training and support in using MB techniques and markers, designing breeding strategies, quality data management, information analysis and decision modeling, phenotyping protocols, and protection of intellectual property (IP).

The main objective of this set of services is therefore to provide backstopping and training in a broad set of disciplines, to complement the elements of the breeding services and address specific technical and logistical bottlenecks. Such expert assistance is essential for the adoption and proper use of new technologies. Services that will be available include:

Breeding plan development: It is essential to develop a breeding plan with a cost–benefit analysis before conducting a multi-cycle MB project. Depending on the nature of the experiment, such a plan may be quite simple or very elaborate, from the transfer of a single region (e.g., transgene) to complex selection that can consider the simultaneous transfer of dozens of regions. The critical factor is that the plan must detail all the activities over time, and the costs and benefits of the project to determine if it is worthwhile conducting the experiment. The platform provides templates and associated cost calculation sheets for different breeding schemes.

Information management: Under this service, assistance is provided in installing and parameterizing the platform IS for use by specific breeding projects.

Data curation: This service assists with capturing and curating current data for particular breeding projects, and in entering them into the integrated IS. This step is absolutely critical for quality control and further sharing of the information, and a contact person for each of the pioneer user cases has been identified to ensure good communication between the platform and the users.



Molecular Breeding Platforms in World Agriculture.
Figure 7
Organogram of the services provided by the IBP

Design and analysis: This service provides support on statistics, bioinformatics, quantitative genetics, and molecular biology. It includes training in data generation, handling, processing, and interpretation, as well as experimental design from field planting to MAS and MABC schemes. It provides assistance with the "translation" of the molecular context to the breeding context, and it will ensure that the methodology developed for the design and analysis of breeding trials is rapidly available to the users.

Phenotyping sites and screening protocols: Through this service, users can access information on phenotyping sites, protocols, and potential collaborators to ensure that selection is carried out under appropriate biotic and abiotic stresses and that the adaptation of germplasm is well characterized. Characterization of phenotypic sites includes geographical information, meteorological historical data, soil composition, and field infrastructure.

Genotyping Support Service (GSS): The GSS aims to facilitate access by developing country national agricultural research institutes to genotyping technologies, and bridge the gap between lab and field research. This service provides financial and technical support for NARS breeders to access cost-efficient genotyping services worldwide and supports training activities in experimental design and data analysis for MB projects.

Intellectual property (IP) and policy: This service provides support on IP rights and freedom to operate in the arena of biotechnology and germplasm use. The service is currently being provided on an experimental basis through a virtual IP Helpdesk hosted by the GCP web site at http://www.generationcp.org/iphelpdesk.php.

Integrated Breeding Hubs

If today few question the usefulness of local basic laboratories, it is also generally accepted that large-scale genotyping activities are best outsourced to cost-effective, high-throughput service laboratories, irrespective of location. Following that rationale, the IBP provides access to marker service laboratories as the main avenue to generate the large amount of genotyping data that will be necessary to support the extensive MABC programs of the future, starting with the user cases, but the GCP also recognizes the need to provide breeders in developing countries with access to some regional hubs. At the beginning of the project four regional hubs are envisioned, covering the needs of the Americas – Centro Internacional de Agricultura Tropical (CIAT, www.ciat.cigiar.org); Africa – BioSciences eastern and central Africa (BecA, http://hub.africabiosciences.org); South Asia – International Crops Research Institute for the Semi-Arid Tropics (ICRISAT, www.icrisat.org); and South East Asia – International Rice Research Institute (IRRI, www.irri.org).

These regional hubs are expected to provide the following services:

- In-house hands-on training (different formats are possible from short- to medium-length periods), with the objective of exposing scientists to new technologies and their applications to breeding.
- Training courses for selected groups of researchers, targeting basic knowledge of marker technologies and their applications, as well as data analysis.

These courses can be used for the testing and validation of learning materials, which will then be continuously upgraded.

- Facilitation of small genomic and genotyping projects led by national programs, academia, and small and medium enterprises (SMEs).
- Marker services for "small" and "orphan" crops that do not have mass demand from breeding programs and would therefore not benefit from large service providers, due to the lack of availability of SNP markers and the need to use lower-throughput SSR or other markers that can more easily be handled in lower-tech laboratories.

The Genomics and Molecular Breeding Hubs should help raise the visibility of the IBP and thus help promote the adoption of MB. Collaboration between the IBP and the regional hubs is anticipated to occur through sharing information, guiding users to apply for the appropriate service, organizing training events, and planning other developments of common interest.

Scope and Potential for Molecular Breeding Platforms

Gaps Across Countries and Crops

The application of MB approaches is now routine in developed countries, as is the integration of facilitative information and communication technologies, which are critical given the immense volumes of data necessary for, and generated by, these breeding processes. However, the situation is very different in developing countries, where MB is still far from routine in its application in breeding programs, particularly in Africa. This is especially critical due to the monumental and urgent imperative to rapidly achieve food security and improve livelihoods for a rapidly growing population through breeding for biotic stresses (including weeds, pests, and diseases) and abiotic stresses (including physical soil degradation, nitrogen deficiency, drought, heat, cold, and salinity) – conditions that make accurate phenotyping challenging. Fortunately, the history of modern breeding in developing countries is comparatively short, allowing a larger potential for crop improvement relative to the genetic gains that can be obtained at this time in developed countries, in which extensive breeding has been applied to crops for a longer time.

To address these issues, the capacity of national research institutions in terms of funds, infrastructure and expertise is directly related to the strength of their national economies [86]. This is reflected in the sharp differences in the capacity to conduct and apply biotechnology research as observed across developing countries (FAOBioDeC, http://www.fao.org/biotech/inventory_admin/dep/default.asp), and by the same token in their capacity to establish and/or utilize MBPs. The result is a three-tier typology of developing countries, directly attributable to the level of each country's investment in agricultural R&D [87].

Tier-1 countries, comprising newly industrialized countries (NICs) such as Brazil, China, India, Mexico, South Africa, and Thailand, substantially invest in technology and R&D and are self-reliant in most aspects of marker technologies [88, 89]. These countries have the simultaneous potential to effectively adopt, adapt, and apply information and communication technologies to enhance research efficiency and outputs. They are therefore naturally at the vanguard in adopting MBPs.

Mid-level developing world economies (tier-2) such as Colombia, Indonesia, Kenya, Morocco, Uruguay, and Vietnam are well aware of MB's importance, and some effectively apply marker technologies for germplasm characterization [90–93] and selection of major genes [94–99]. These countries have a matching potential for a limited utilization of MBPs, a potential that can be enhanced fairly rapidly in the medium to long term.

Low-level developing world economies (tier-3 countries) are struggling to sustain even basic conventional breeding. They have very limited or no application of MB approaches and are unlikely to adopt MBPs except in the long term.

Especially for tier-3 countries, resource-limited breeding programs in many developing countries are severely hampered by a shortage of well-trained personnel, low level of research funding, inadequate access to high-throughput genotyping capacity, poor and inadequate phenotyping infrastructure, lack of ISs and appropriate analysis tools, and by the logistical difficulty of integrating new approaches with traditional breeding methodologies – including problems of scale when scaling up from small to large breeding programs.

Until recently, the scarcity of available genomic resources for clonally propagated crops, for some neglected cereals such as millet, and for less-studied crops such as most tropical legumes, which are all very important crops in developing countries, represented a further constraint to agricultural research for development [100], thereby limiting the application of molecular approaches and hence the potential for MBPs. However, the recent emergence of affordable large-scale marker technologies (e.g., DArT [101]), the sharp decline of sequencing costs boosting marker development based on sequence information [102], and the explicit efforts of national agricultural research programs (e.g., India [103]) and international initiatives such as GCP [104]) have all resulted in a significant increase in the number of genomic resources available for less-studied crops. As a result, most key crops in developing countries now have adequate genomic resources for meaningful genetic studies and most MB applications.

Similarly, international efforts such as GCP's IBP are designed to help overcome the challenges of developing-country breeders – exploiting economies of scale by making available convenient and cost-effective collective access to cutting-edge breeding technologies and informatics hitherto unavailable to them, including genomic resources, advanced laboratory services, and robust analytical and data management tools. Together, this increasing availability of genomic resources and tools for previously neglected but important crops and the access to initiatives targeting the resource-challenged NARS of the developing world will hasten the adoption of MBPs for these countries.

Institutional, Governmental, and Public Support

While corporate and other proprietary MBPs need only meet the specific requirements of a particular corporation or of specific paying clients, the development of platforms targeted at breeding programs in the developing world require a broad consensus among the parties that would use them and support them from multiple overseeing organizations. This is because these platforms are built on the premise of minimizing costs and maximizing benefits through economies of scale generated through collective access by multiple partners.

The public-access MBPs would therefore be critically dependent on well-structured MB programs, which may not be a reality in many developing countries. A good structure would entail compliance with common or compatible:

- Good field infrastructure, including meteo station
- Good agronomical practices at experimental stations
- Crop ontology information system
- Data collection, management, and analysis protocols
- Breeding plan design
- Information and communication technology infrastructure
- Informatics tools for analysis, decision support purposes, and eventually modeling and simulation

Traditionally, developing world breeding programs have largely been poorly funded and poorly supported, and have been primarily driven by donor organizations [105, 106]. The lack of in-country support has often limited the dependent breeding activities to no more than a basic level. Under such circumstances, it was unrealistic to anticipate the adoption of new biotechnologies – including the utilization of MBPs. Fortunately, this scenario is changing. In 2003, through the Comprehensive Africa Agriculture Development Programme (CAADP, http://www.caadp.net/implementingcaadp-agenda.php), African governments committed to invest more in food security and in agriculture-led growth. Since then, many countries in Africa and elsewhere have developed comprehensive agricultural development strategies.

There is also a growing participation by foundations and nongovernmental organizations, and more recently the emergence of public–private sector partnerships (e.g., US Global Food Security Plan, http://www.state.gov/s/globalfoodsecurity/129952.htm). This governmental and institutional commitment is critical for the adoption of biotechnologies in general [8, 107] and for MB adoption in tier-2 countries in particular, with the attendant establishment and utilization of MBPs.

Challenges, Risks, and Opportunities

Challenges hampering the potential of MBPs in developing countries include both factors applicable generally to MB and those specific to MBPs. These

factors encompass infrastructure capacity, human resource, and operational and policy issues. But amidst the challenges there are also actual and potential opportunities.

Human Capacity Human capacity for MB technologies in developing countries is a challenge, and limitations include substandard agriculture programs at universities; difficulties in keeping up to date with relevant developments, including failures by others; poor technical skills in core disciplines; isolation as a result of insufficient peer critical mass in the workplace; and poor incentives to attract and retain scientists, resulting in brain drain and staff turnover [108].

To partially offset the undesirable trend of losing the "champions" and to "generate" more "champions," novel international initiatives like Alliance for a Green Revolution in Africa (AGRA) support high-quality education in the South. Examples include the African Centre for Crop Improvement (ACCI, http://www.acci.org.za/) based at the University of KwaZulu–Natal in South Africa and the University of Ghana-based West African Centre for Crop Improvement (WACCI, http://www.wacci.edu.gh/). Both institutes offer doctorate degrees in modern breeding to African students, with the fieldwork component being carried out in the students' home countries.

While obtaining their Ph.D. in plant breeding, these scientists study the principles of marker technologies, equipping them to undertake MB activities. To retain this much-needed expertise in Africa, the WACCI and ACCI programs also provide post-Ph.D. funds for these scientists to conduct research in their home countries and, in some cases, provide matching funds for their career advancement.

Precise Phenotyping There can be no successful MB program without precise phenotyping of the target traits. Reliable phenotypic data is a must for good genetic studies [109] and most developing countries lack suitable field infrastructure for good trials and collection of accurate phenotypic data. As part of the services of a good MBP, guidelines on best practice must be provided on how to design and run a trial and conduct precise phenotyping for genetic studies under different target environments. Improving access to homogeneous field areas, and paying attention to good soil preparation and homogeneous sowing are critical. The development of new geographic IS tools [102, 110], experimental designs, phenotyping methodologies [111, 112], and advanced statistical methods [113] will facilitate the understanding of the genetic basis of complex traits [114] and of genotype-by-environment (G×E) interactions [48, 115]. Improving phenotyping infrastructure in developing countries must thus be a top priority to promote modern breeding and utilization of MBPs [106].

Laboratories for Markers Services Genotyping can be expensive when it is performed in small laboratories using labor-intensive and low-throughput markers such as SSRs. This has traditionally limited the use of MMs in developing countries beyond the fingerprinting of germplasm with a small number of markers or the use of MAS for a few key traits. Operational efficiency is also vital, because fundamental timelines must be respected to ensure that no crop cycle is lost. Indeed, at every selection cycle, a service laboratory may have only a few weeks (time between DNA being extracted from leaves harvested on plantlets and the flowering time) to conduct the analysis and return the data to the breeders to enable them to conduct appropriate crosses among selected genotypes.

There is general agreement today that basic local laboratories at national and regional levels can be useful at least to service small local needs such as fingerprinting of limited number of accessions, GMO detection or MAS for specific traits, or for teaching and training purposes. It is also generally accepted that large-scale genotyping activities are best outsourced to advanced, modern, cost-effective high-throughput service laboratories, irrespective of the original location of the needs. This outsourcing is driven by the evolution in marker technologies. The advent of SNP genotyping led the shift from the low-throughput, primarily manual world of SSRs to high-throughput platforms powered by robotics and automated scoring, better handled by dedicated service laboratories [102, 116, 117]. As a result, genotyping costs have decreased by up to tenfold while data throughput has increased by the same magnitude. An example for MARS is provided in Fig. 6. SNP markers are increasingly available for most mainstream crops

and for several less-studied crops [118, 119], which are important in developing countries.

A particular effort will be needed to ensure an easy and reliable way to track samples from the field to the laboratory, and back to the field – it will hence be vital to carefully identify DNA samples from material collected in the field. Such documentation should optimally be through bar-coding, and all information pertaining to management of field trials or experiments should be recorded in electronic field books. Marker work would of necessity be subcontracted to a service lab with a good and preferably platform-compatible laboratory information management system (LIMS).

Data Management For breeders to efficiently access relevant information generated by themselves and by other researchers, reliable data management (including sample tracking, data collection and storage, and modern analytical methodologies and tools for accurate decision making, among others) is critical both within a given MB program and across programs. In view of this, it is essential that breeders manage pedigree, phenotypic, and genotypic information through common or mutually compatible crop databases, in keeping with the collective access principle of a public MBP. The format of databases would need to be user-friendly and compatible with field data collection devices and applications to encourage both adoption and compliance. Ultimately, data collection and management processes would need to seamlessly link with a platform-resident analysis, modeling, simulation, and a decision support workbench for full utility of the breeding platform.

Paradigm Shift: Collaborative Work and Data Sharing Access to information and products generated by fellow users is a potentially critical incentive for breeders to use the platform and share their own data with other users. However, this would require a fundamental paradigm shift from the present data-hoarding, inward-looking approach to research common to breeders. This may, however, only be achievable if it is a clear requirement in the terms of engagement for membership of a "platform community," or if distinct financial and other incentives are offered for such sharing.

Technology-Push Versus Demand-Driven An MBP is by nature a high-level technological solution. It carries with it the inherent risk of failing to address fundamental practical problems of developing-world breeding programs, which will often by nature be technology-deficient. Such platforms therefore face the challenge of ensuring that they meet targeted user objectives and address practical constraints.

However, with this challenge comes an opportunity to introduce advanced MB methodologies to developing world breeders, by encouraging change that will enable them to take advantage of the efficiencies and economies of scale offered by the MBP. This opportunity would be particularly reachable with bottom-up platform design and development that actively engages and involves the breeders – including elements of human resource capacity development and support in usage.

Adoption and Use by Breeders An MBP would only make a difference if it is adopted and widely used by the breeders. The most important element influencing this would be credibility – a function of the quality of the technology, the awareness of potential users, the ease of access, and initial incentives. There is a need for successful public sector developing-country examples to demonstrate that the platform can effectively enhance the efficiency of breeders through the use of modern approaches – a clear demonstration of the added value of using the platform.

Sustainability of the Platform Sustainability would be a challenge for MBPs targeting developing world breeding programs, given their resource limitations. These programs may not be able to meet the full cost of platform usage, and the cost of maintaining and updating the different elements of the platform on a regular basis – particularly tools and facilities that must keep abreast with evolving information and communication technologies.

Of course, platform sustainability is directly linked to its adoption by breeders, and sustainability strategies must be adapted to the diversity and financial resources of the potential clients, from developing-world national agricultural research institutes with limited resources to SMEs. Service costs might also be adjusted

if clients are willing to share data and release germplasm through the platform.

Platform managers may also have to consider other innovative options like on-platform advertising by agriculture-related commercial enterprises. However, ongoing donor support would most likely still be required in the medium to long term.

Communities of Practice The development of platform-based MB communities of practice, to connect groups of crop researchers, mainly breeders, willing to share experiences and information on modern breeding methods, best field practices, and development of improved varieties, and to practice peer-to-peer mentoring, are an additional potential avenue for platform adoption and sustainability, besides providing means to quickly and efficiently resolve recurring breeding problems. Partnerships between developed and developing-country institutions, and between the private and public sectors, are also an opportunity for realizing the full potential of MB [87, 108].

Many other hurdles limit successful public sector utilization of MB opportunities [120, 121]. However, the potential of virtual MBPs made possible by the revolution in information and communication technologies provides opportunities to counter and overcome many of those shortcomings.

Potential Economic Impact of Molecular Breeding Platforms

By its nature, MB improves the efficiency of crop breeding – progressively increasing genetic gains by selecting and stacking favorable alleles at target loci. The utilization of MBPs accelerates and amplifies the advantages of MB by introducing significant efficiencies in resource and time usage. Predictive or designer breeding, which would be the ultimate result of information-rich MB, attainable through the use of MBPs by numerous different breeding programs that freely share data and germplasm, would particularly bring about these savings in resources and time.

However, a direct comparison of the cost-effectiveness of MB with phenotypic selection is not straightforward. Firstly, factors other than cost – such as trade-offs between time and money – play an important role in determining the selection method. Secondly, this choice is further complicated by the fact that the two methods are rarely mutually exclusive or direct substitutes for each other [122]. On the contrary, under most breeding schemes, they are in fact complementary. Where operating capital is not a limitation, MB maximizes the net present value, especially when strengthened through MBPs [123]. With the increasing ease of accessing marker service laboratories and the declining cost per marker data point, MB costs are shrinking, making it extremely attractive from a purely economic perspective.

However, once the technological hurdles are overcome, the ultimate impact of new technologies (such as MBPs) is often limited by the lack of, or ineffective, seed distribution systems or by distant markets. SMEs are critical in promoting access to, and distribution of, improved seeds, thus helping alleviate a major bottleneck to the impact of improved breeding on smallholder farmers [124, 125].

Few economic analyses have been conducted to objectively assess the potential impacts of MB in the public sector, and none for MBPs that are just now emerging as a tool for breeding in the public sector.

Of the few analyses done to date, one evaluates the economic benefits of MABC using preexisting MMs in developing rice varieties tolerant to salinity and P-deficiency [126] in Bangladesh, India, Indonesia, and the Philippines. Encompassing a broad set of economic parameters, the study concluded that MABC saves an estimated minimum of 2–3 years, resulting in significant incremental benefits in the range of USD 300–800 million depending on the country, the extent of abiotic stress encountered, and the lag for conventional breeding [127].

Future studies are likely to confirm the positive economic benefits of MB and, given that MBPs amplify the benefits of MB, it can be reasonably inferred that the emerging platforms would indeed further enhance those economic benefits.

Future Directions

MBPs will inevitably have a significant impact on crop breeding in developing countries in the medium to long term because of:

- The needs-driven demand for improved crop varieties to counter the global food crisis

- The exponential development of genomic resources
- The ever-declining cost of marker technologies
- The increasing occurrence of public–private partnerships, where the public sector can learn from private companies about best practices for integrating MB into their breeding programs
- The need for innovative solutions to the challenges of resource and operational limitations

The first challenge of MBPs will be to meet the immediate needs of the breeders in developing-country public and private programs. The first step will be to provide them with the tools for enhancement of their current breeding programs, through the implementation of field books, pedigree management, and basic statistical analytical tools necessary to optimally conduct their current breeding efforts. In close succession with these first applications, tools will need to be made available to facilitate the integration of MB into their breeding programs. Databases will need to be developed for storing genotypic and phenotypic data, integrated analytical tools will need to be made available to breeders for analysis of this accumulated data and for the identification of important simple trait loci or QTLs to monitor and recombine in their breeding programs, and decision support tools will need to be developed to help breeders decide on the next steps to engage in based on the data they generated from their MB activities.

In the near future, more complex tools will need to be developed for the storage and analysis of the large amounts of genotypic data that will be generated by new next-generation sequencing technologies and for their application in GWS. A tight linkage will also have to be established with the wealth of information that is being generated and will continue to be generated even faster in the genomics area, leading to the dissection of the genome and to the discovery of the location and function of major genes having an impact upon the performance of crops in environments relevant to developing-country programs.

Eventually, the accumulation of large amounts of genetic information linked to specific haplotypes will lead to the increasing use of predictive breeding in combination with traditional MB usage and appropriate tools will also need to be developed to support those efforts.

Although it is critical for a platform to anticipate all the new possible features of MB, ensuring that new technologies and ISs will find their way in a flexible infrastructure, it is also quite probable that most of the breeding programs in developing countries will work at the short- and mid-term mainly with simple MB approaches as they will never reach the critical size of crosses and germplasm evaluation requested to maximize complex approaches.

Conclusion and Prospective Scenarios

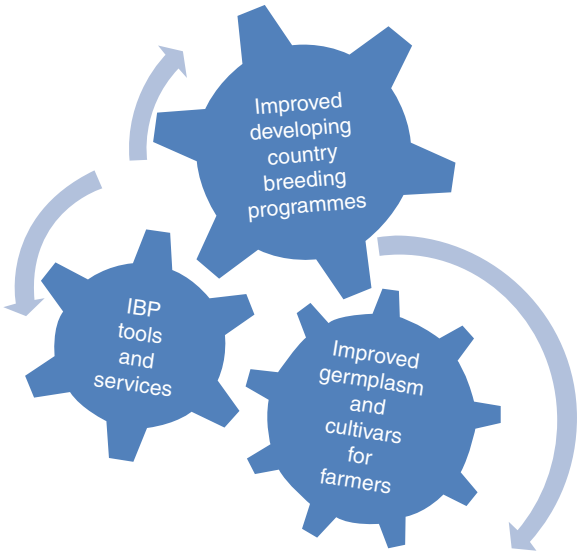
Through international initiatives like the ones coordinated by the CGIAR centers and programs, several notable developing-world MB successes have already been reported.

A well-known example is the development of submergence-tolerant rice cultivars through MABC led by IRRI [128]. The introgression of the Sub1 gene from FR13A (the world's most flood-tolerant variety) into widely grown varieties like Swarna improved yields in more than 15 million hectares of rain-fed lowland rice in South and Southeast Asia.

MB in general and the use of MBPs in particular have definitely been shown to be an efficient approach for reducing the number of required selection cycles and for increasing the genetic gain per crop cycle to a point where the required human and operational resources can be kept to a minimum.

However, for sustainable adoption, the use of modern breeding strategies requires a breeder-led bottom-up approach. As a start, simple MB approaches adapted to local environments should be tested first by individual breeders to evaluate their success and impact under those breeders' conditions. Once proven, these approaches can then be implemented more widely or integrated to an MBP for enhanced efficiency. In case of individual success the adoption of MB by those breeders should be quite straightforward.

It is clear that the extent, speed, and scope of adoption of MB approaches and of utilization of MBPs will vary somewhat across tier-1, tier-2, and tier-3 countries, depending on the local priorities and on the resources available in given breeding programs. It is unrealistic to expect that large-scale MB breeding activities, including utilization of MBPs, will be widely implemented across the board in developing



Molecular Breeding Platforms in World Agriculture. Figure 8
IBP as a key component to boost NARS breeding capacities and therefore crop productivity in developing countries

countries in the near term. However, the prospects are bright for individual breeders in these countries (particularly in tiers 1 and 2) to access germplasm, data, tools, and methodology that will allow them to conduct efficient MB projects by taking advantage of large international initiatives specifically targeting developing-country breeding programs. This will, however, happen in different ways and on different timelines for each tier.

For tier-1 countries, the impact would be evident in the shorter term – say in 3–6 years. These countries will benefit from new tools and platforms by increasing the rate of MB adoption. The biggest change is likely to occur in tier-2 countries, as these countries would be starting MB from scratch, but the impact would realistically be measurable only in the medium term, meaning in about a decade from now. For countries currently in tier-3 to advance to tier-2, basic breeding programs must first be established, which is highly dependent on governmental priorities and on subsequent resource allocation.

All in all, implementing MB (and catalyzing and accelerating its impact through MBPs) will boost crop production, which will translate into higher farm productivity per unit of land, better nutrition, higher incomes, poverty alleviation, and ultimately improved livelihoods in developing countries (Fig. 8). These gains will be amplified by sustained use, by continuously improving expertise, and by growth and development of homegrown capacity for the application of advanced breeding approaches.

Mussel Culture, Open Ocean Innovations

Richard Langan
Atlantic Mariner Aquaculture Center, University of New Hampshire, Durham, NH, USA

Article Outline

Glossary

Suspension culture A production method for mussels and other shellfish that employs ropes, cages, or nets suspended in the water column from either rafts or longlines.

Surface longline An anchored structure consisting of surface floatation supporting one or more horizontal lines from which ropes, cages, or nets can be suspended in the water column.

Open ocean farming Refers to aquaculture production of marine organisms in open ocean or offshore waters that are removed from any significant influence of land masses.

Submerged longline Subsurface structure consisting of anchors and submerged floatation from which ropes, cages, or nets can be suspended.

Site selection The process for selecting farming sites based on specified parameters such as depth, current and wave climate, temperature, and primary productivity.

Environmental effects The effects of farming activities on the physical, biological, and chemical properties of the marine environment *and* the effects of the environment on cultured organisms and consumers of cultured food products.

Seston Particulate material suspended in the water column of water bodies consisting of both living and dead organic material and inorganic particles.

Pseudofeces Suspended particles that have been rejected as food by filter feeding bivalve mollusks. The rejected particles are wrapped in mucus and expelled without being passed through the digestive tract.

Definition of the Subject

Aquaculture production of several species of mussels in sheltered marine waters is well established and occurs in many countries worldwide. The primary method of production of high quality mussels is suspension of ropes with attached mussels from floating rafts or surface longlines that are anchored to the seafloor. While demand for fresh, frozen, and canned mussel products continues to increase, growth in production is hampered by a lack of suitable space for expansion in sheltered waters. For more than a decade, there has been interest in developing production methods suitable for open ocean environments where wind and wave conditions preclude the use of either rafts or surface longlines. Recent advances in the use of longlines that can be submerged below the sea surface and therefore avoid the upper portion of the water column that is most affected by wave energy indicate that open ocean production is feasible. However, additional development in technology and methods to improve production efficiency and insure worker safety, as well as changes to political and regulatory frameworks are needed in order to achieve large-scale production.

Introduction

Population growth and consumer preference have resulted in a growing demand for seafood, a trend that is projected to continue into the future [1]. Production from capture fisheries has leveled off, and by most projections will remain stagnant or decline, depending on management and regulatory measures implemented by fishing nations [2, 3]. In contrast,

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

Originally published in
Robert A. Meyers (ed.) Encyclopedia of Sustainability Science and Technology, © 2012, DOI 10.1007/978-1-4419-0851-3

aquaculture production has increased by nearly 10% each year since 1980, and has played an important role in filling the gap between seafood supply and demand. Only a few decades ago, wild-caught fish and shellfish supplied nearly all edible seafood, though with essentially flat growth since 1980 and the rise of aquaculture over the same time period, capture fishing now accounts for only about half of the total [1]. In the most optimistic scenarios, wild-caught fisheries production will remain stagnant [2]; therefore, growth in the global seafood supply will continue to rely on aquaculture production.

There are signs, however, that the rate of growth for global aquaculture may have peaked for land-based and nearshore marine culture due to political, environmental, economic, and resource constraints [1]. Expansion of land-based culture is limited primarily by economics, particularly in developed countries where costs associated with land, capital equipment, and energy required to pump and treat water are prohibitive. In addition, very few marine species are appropriate for land-based culture. For example, the space and volume of phytoplankton required to produce large quantities of filter feeding mollusks in land-based systems would be enormous, and therefore not economically viable.

For nearshore marine farming, available and suitable space is the primary limiting factor as sheltered coastal waters are for most countries quite constrained to begin with and are already used for a multitude of commercial and recreational activities with which aquaculture must compete for space [4]. Expansion of large-scale finfish farming in coastal waters is also limited by environmental concerns. While there are also concerns about potential environmental effects of bivalve mollusk culture, they are minor in comparison to net pen culture of finfish and are balanced by recognition of the ecosystem services such as enhanced habitat complexity and filtration capacity provided by mollusks [5]. It is rather the effect of environmental conditions on mollusk culture, and specifically the effects of pollution on product safety that is limiting expansion in nearshore waters. Rapid coastal development and population growth and the resulting increase in human sources of pollution have affected the sanitary quality of nearshore waters, rendering shellfish grown there unsafe for consumption. As a consequence, many otherwise suitable sheltered sites for mollusk culture are off limits due to public health restrictions.

In developed countries, conflict with coastal residents and tourist-related businesses over aesthetic values, primarily over water views from shorefront property, have also affected the establishment of new farming sites. As the demographic of coastal communities continues to change and new residents place more value on views and recreation than food production, these conflicts are likely to increase. Given the constraints on expansion of current methods of production, it is clear that alternative approaches are needed in order for the marine aquaculture sector to make a meaningful contribution to the world's seafood supply.

Farming in open ocean waters has been identified as one potential option for increasing production and has been a focus of international attention for more than a decade. Despite the global interest in open ocean farming, development to date has been measured, primarily due to the significant technical and operational challenges posed by wind and wave conditions in most of the world's oceans [4]. Farming in fully exposed open ocean waters requires a different engineering approach since equipment and methods currently used in sheltered nearshore sites are largely unsuitable for the open ocean. In addition, the scale of investment required to develop and demonstrate new technologies and methods for offshore farming is yet to be determined, though most engaged in this endeavor would agree that it will likely be substantial.

Despite these challenges, there is sufficient rationale for pursuing the development of open ocean farming. Favorable features of open ocean waters include ample space for expansion, tremendous carrying capacity, less conflict with many user groups, reduced exposure to human sources of pollution, the potential to moderate some of the negative environmental and aesthetic impacts of high density coastal farming [6–8], and optimal environmental conditions for some bivalve mollusk species [9, 10]. For many countries, where cost, environmental concerns, limited space, and competing uses have restricted growth of land-based and nearshore marine farming, few other options for significant expansion exist.

Of the many species of finfish and shellfish that have been considered for open ocean farming, several

species of mussels have emerged as attractive candidates. There are several reasons for this. Like all filter-feeding mollusks, mussels derive all their nutritional needs from naturally occurring phytoplankton and organic particulates. Therefore, daily visits to deliver formulated feed by service vessels and farm personnel, which may be prohibited for extended periods by sea conditions, are not needed, nor is on-site infrastructure for automated feeding, which is both costly and vulnerable to damage from storms. Unlike many cultured species that have gradually transitioned from wild capture to aquaculture, farming has been the primary means of production for mussels for many decades; therefore, methods used in sheltered waters are well developed, highly automated, and very efficient [11]. Mussels are also relatively fast growers, with production cycles ranging from 12 to 18 months [9, 12].

Production methods in sheltered nearshore waters include bottom culture, which is practiced in some locations such as the Netherlands, Scandinavia, and the USA (Maine), and pole or "bouchot" culture, which is practiced in France; however, suspension culture, because of superior product quality, accelerated growth, and opportunities for mechanization, has emerged as the leading method of production [11]. Techniques and materials used for suspension culture may vary somewhat from place to place; however, in general, culture methodology consists of suspending mussel ropes or "droppers" from either rafts or longlines [13]. Raft culture was pioneered in Spain and from there became established in Scotland and more recently in Maine USA and in the Pacific Northwest coast of North America [11]. While rafts can be highly productive, they are suitable for use only in very sheltered embayments. Longline technology, which was developed in Japan, consists of either surface or submerged longlines, held in place with anchors and supported by buoys or floats. As with raft culture, surface longlines are only suitable for use in sheltered waters [13]; therefore, in locations where adverse sea conditions or drift ice occur, submerged longlines are the only option. Submerged longlines have been used primarily in locations (e.g., Atlantic Canada) where winter ice would impact buoys and lines [14]. It is only in recent years that the technology has been used in fully exposed open ocean locations [9].

Characterization and Selection of Open Ocean Farming Sites

Before discussing approaches to the development of open ocean mussel culture, it is important to first define what is meant by the term "open ocean." For most engaged in this sector, it is used synonymously with "offshore" and is generally accepted to mean farming in locations that are subjected to ocean waves and currents and removed from any significant influence of land masses rather than a set distance from shore. Clearly, a wide range of sea conditions falls under this broad definition. Ryan [4] reported on a site classification system for marine waters developed in Norway that is based on significant wave height exposure (Table 1).

While this classification method is instructive, knowledge of the full range of conditions at a particular site is needed to develop appropriate technologies and safe and efficient operating procedures.

There are a number of criteria that determine the suitability of open ocean sites for farming, many of which are also considerations for sheltered waters. These include proximity to infrastructure such as ports, processing and distribution centers, as well as physical and biological criteria such as bathymetry, seabed characteristics and contour, current velocities, temperature profiles, dissolved oxygen, turbidity, the quantity of quality of phytoplankton, and the frequency of occurrence of harmful algal blooms. The most important additional feature of offshore sites is wave climate. Significant wave heights, wave periods, the frequency and duration of high energy storm

Mussel Culture, Open Ocean Innovations. Table 1 Norwegian classification of offshore waters based on significant wave heights (From Ryan [4])

Site Class	Significant wave height (m)	Degree of exposure
1	<0.5	Small
2	0.5–1.0	Moderate
3	1.0–2.0	Medium
4	2.0–3.0	High
5	>3.0	Extreme

conditions, and the combined forcing of waves and currents must be known in order to determine whether a site is suitable, accessible by service vessels and personnel with reasonable frequency, and if so, what type of technology is required for farming.

It is imperative that a thorough evaluation of the parameters described above be conducted before proceeding with development of a site for farming. The requirements for data and subsequent analysis can be substantial; however, the use of advanced oceanographic technologies can greatly facilitate this task [8]. Multibeam sonar and three-dimensional visualization can generate a wealth of data on seafloor contours and texture to inform mooring system design and placement. Collection of time intensive data on temperature, salinity, dissolved oxygen, turbidity, and fluorescence can be greatly facilitated by strategic deployment of in situ instrumentation at appropriate depth intervals in the water column. Additional instrumentation should include Acoustic Doppler Current Profilers (ADCP) that can measure and record current velocity and direction throughout the water column, wave sensors that can give precise data on wave height, direction, steepness, and period, and meteorological sensors to measure air temperature and wind speed and direction. Many countries have buoy arrays in coastal waters that can provide long-term data on regional climatology to aid site evaluation; however, collection of site-specific data is critical. Assessment of the potential for the effects of global climate change on critical parameters such as water temperature should also be considered.

The data collection period required for site evaluation will vary, depending on local and regional environmental and meteorological conditions. Good baselines for some parameters can be established in a relatively short time frame (1 year), others such as the frequency, duration, and severity of storms or blooms of toxic algae are less predictable and it may take longer to determine the suitability of a particular site.

While most of the focus on open ocean development has been on cage culture of finfish, there has also been growing interest in offshore culture of bivalve mollusks. Some of the same drivers such as ample space and the opportunity to avoid user conflicts are identical to those for finfish culture, though perhaps more importantly, reduced risk of exposure to human sewage and industrial pollution presents a major advantage of open ocean waters over coastal locations.

There are, however, possible limitations as well as advantages. Open ocean waters in many areas of the world are nutrient deficient, so careful attention must be paid during site selection to the quantity, quality, and seasonality of phytoplankton available to dense arrays of filter feeding mollusks. Macroscale information on primary productivity can be obtained from ocean color satellite data generated by instruments such as Sea-viewing Wide Field-of-view Sensor (SeaWiFS) and Moderate Resolution Imaging Spectroradiometer (MODIS). Site-specific data on concentration and composition can be generated by in situ fluorometry and microscopic analysis of the plankton community. Phytoplankton concentration at different depths is also an important factor, as farmers will wish to maximize the use of vertical space for production in deep ocean waters. The frequency and duration of harmful algal blooms (HABs) is also a critical consideration for offshore mollusk farming. In some locations, blooms of toxic algae originate and persist in offshore waters (e.g., *Alexandrium sp.* In the Gulf of Maine, USA) and can result in extended public health closures with severe economic impact on producers.

In addition to physical, chemical, and biological characteristics of a site, other human uses in the vicinity such as shipping, fishing, and mining must be identified in order to avoid conflicts. Involvement of the appropriate permitting authorities in the early stages of development of an open ocean farming site is also critical [15]. Other factors such as use of the area by marine mammals, proximity to foraging areas of predators (e.g., diving ducks), location of sensitive biological communities, presence of parasitic organisms (e.g., pea crabs, trematodes, and copepods), and sediments contaminated by toxic substances must also be considered [16].

Technologies for and Methods Open Ocean Mussel Farming

Technologies for open ocean mussel farming are essentially adaptations of suspension culture methods employed in sheltered marine waters. Designs and prototypes for submersible rafts have

been developed [17, 18]; however, submerged longlines are the most commonly used method. This technology was developed in Japan and has been in use there for several decades for deep water suspended scallop culture, though not in fully exposed open ocean conditions. The technology has been successfully adapted for sheltered water mussel culture in Atlantic Canada where winter and spring drift ice can damage surface longlines [14]. More recently, the technology has been shown to be effective for mussel production in very high-energy open ocean conditions (e.g., significant wave heights >10 m) in the northeast USA [9] and at a test site in the German Bight with significant wave heights >8 m, and current velocity up to 1 ms^{-1} [19]. The technology is quite simple and it consists of relatively inexpensive materials. A design currently in use in North America is presented in Fig. 1.

The structural stability of a submerged longline is maintained by the opposing forces of submerged flotation at the ends of a single horizontal backbone, connected by lines set at a 45° angle to seafloor anchors. The most commonly used anchors are large (3–6 tons) deadweight concrete anchors, though both plow type and screw anchors have been used in some locations. Submergence depth of the backbone is dictated by site-specific wave climate and can range from 3 to 15 m. Surface floatation is minimized to prevent the transfer of wave-induced motion the backbone, and consists of nonstructural marker buoys for the anchor lines and a mid-backbone pick-up line that provides access to the crop from a service vessel. Anchors are generally spaced from 100 to 200 m apart, and depending upon the depth of the water and desired depth of submergence, the backbone length can range from 70 to 130 m. Ropes or "droppers" of mussels are suspended from the backbone, and additional submerged floatation is added as the crop gains mass during growout (Fig. 2).

At some of the open ocean farms that have been established, converted fishing vessels are currently used to tend offshore longlines. The deck equipment required for tending lines to seed growout ropes and to inspect and harvest crops is similar to that in use for sheltered sites and includes rail mounted starwheels (Fig. 3) and an articulating crane (Fig. 4).

In addition, equipment common to many fishing vessels such as a lobster or crab trap hauler or a rotating boom is needed for lifting the submerged line to the surface. If there is sufficient deck space, bulk processing equipment such as declumping and debyssing machines can be used during harvest operations to reduce the need for extensive processing at shore-based facilities. Though converted fishing vessels may be used as this sector develops, it is likely that large, seaworthy, specialized vessels that can carry the harvesting and primary processing gear, provide a stable platform for lifting operations and a large load capacity for the harvest will be required to support large-scale operations. Vessels of this nature are in use in France and New Zealand [20].

In addition to submerged longlines, some experimental efforts have employed a submersible ring-like structure attached to a wind turbine tower, which has

A forward looking view of the starboard side of a service vessel showing the backbone of a submerged longline set into aft (foreground) and forward starwheels. Growing ropes with seed mussels are attached to the backbone for the growout cycle

Mussel Culture, Open Ocean Innovations. Figure 4
A hydraulic articulating crane on a service vessel, shown here being used to unload equipment, is used extensively in mussel farming operations

been used for offshore macroalgae growout [21]. This device could potentially be used for mussel cultivation; however, there may be scaling issues in reaching the desired biomass.

Mussel Species in Open Ocean Cultivation

There are several species of mussels that are cultivated in open ocean waters; however, regardless of species or location, production is currently minor by comparison with well-established nearshore production sites. In North America, small quantities of blue mussels (*Mytilus edulis)* are produced in offshore farms in New England (USA) and Atlantic Canada and Mediterranean mussels (*M. galloprovincialis*) are being grown at an offshore farm off the southern California (USA) coast [22]. In Europe, *M. galloprovincialis* are grown on submerged longlines at exposed locations in the Mediterranean coast of France [23] and in the Turkish Black Sea. Culture trials have been initiated for *M. edulis* in the North Sea off the coast of Germany, [19] and in the Belgian North Sea [24]. Other European

countries, including Portugal, Spain, Italy, and Ireland are developing strategies for offshore mussel production.

In New Zealand, where the nearshore greenshell mussel (*Perna canaliculus*) industry is well developed and highly mechanized, there is a great deal of interest in developing large-scale ocean farms, as lease sites in sheltered nearshore waters have become difficult to obtain [25]. Initial efforts at open ocean mussel farming involved moving the double longline surface technology into more exposed sites and some success was achieved in wave conditions up to 2.5 m [26]. However, failure of surface longline systems in higher energy sites has led to the development of submerged technologies and a small number of open ocean mussel farms are operating in New Zealand offshore waters, with many new farms proposed [27]. This scale of expansion is projected to provide a threefold increase in production and export earnings by 2020 [28].

While data is limited to a few locations in North America and France, there are indications that production cycles and product quality for mussels grown in open ocean waters are highly favorable. Open ocean farms off the New Hampshire coast in the northeast USA have consistently produced market-sized (55 mm) blue mussels in 12–14 months from spat settlement with meat yields ranging from 42% to 58% [9]. Similar data has been reported for blue mussels at sites off the coast of Martha's Vineyard [29]. By comparison, rope-grown blue mussels from nearby estuaries and bays can take up to 18 months to reach market size [30]. Mediterranean mussels produced at an open ocean site in California have also demonstrated excellent growth and quality, reaching market size in 6–8 months and nearly 50% meat yield [22]. Trials in the North Sea have shown that the growth conditions in the German Bight are very favorable for mussel cultivation. Market-size (50–55 mm) can be reached by 12–15 months and infestation by parasites is much lower than in nearshore sites [10]. Faster growth at offshore sites may to be due to a more stable temperature and salinity conditions and therefore lower stress, reduced turbidity, and better water exchange [20].

Open Ocean Mussel Farming in Multiuse Facilities

Open ocean mussel farming can be practiced in isolation of other activities; however, there may be economic or environmental advantages to combining mussel culture with offshore fish farming or energy production. At a nearshore marine farming site in New Brunswick, Canada, Lander et al. [31] demonstrated better growth rates for raft-cultured mussels 100 m down current of a salmon farm than at reference sites, and was able to document that organic wastes, primarily fine particulates from feed emanating from the salmon farm contributed to the diet of the mussels. In open ocean sites, creating mussel culture "zones" in proximity to finfish farms may offset the effects of organic loading to the environment [32].

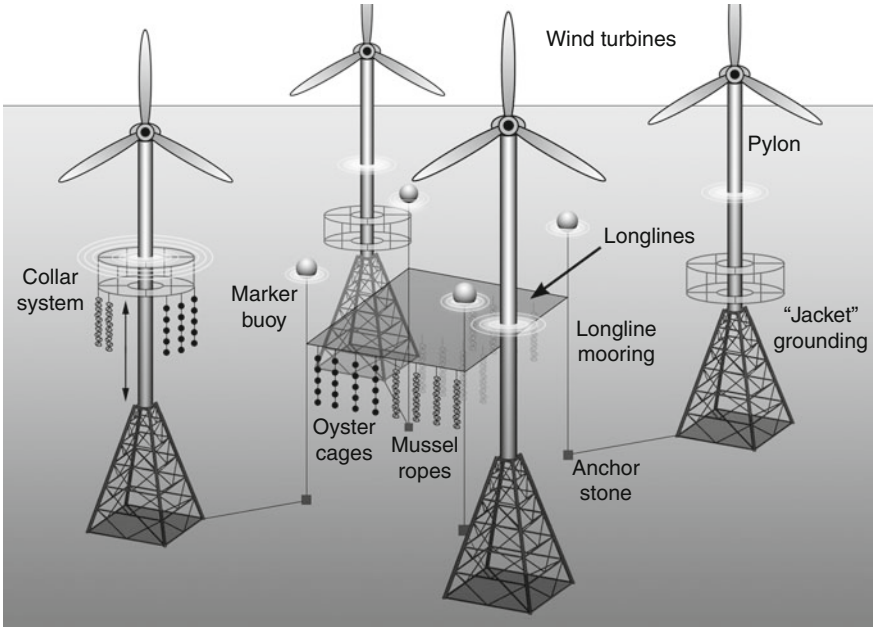
Energy installations may also provide structure for deployment of mussel culture systems. Mussels (*M. galloprovincialis*) have been harvested from oil platforms in California, USA for many years [33], and there is interest in using decommissioned offshore oil platforms as attachment points for mussel culture infrastructure.

Buck et al. [34] investigated the possibility of integrating suspension culture of oysters and mussels at existing offshore wind energy platforms in the North Sea (Fig. 5).

There are a number of advantages for conducting mussel cultivation activities within the footprint offshore wind farms. The placement of aquaculture production facilities in defined corridors between wind farm turbines eliminates the need for a separately permitted facility and reduces the space required if the two facilities were located separately [34]. Also, infrastructure for regular servicing may be shared. As both industries need a multifunctional service vessel, preferably with lifting capacities to install and change plant components and execute farming operations, and sufficient deck space to carry equipment and stock, the opportunity to share high-priced infrastructure exists [35]. Further, a combined environmental impact assessment for both users may reduce costs.

Environmental Considerations for Open Ocean Mussel Farming

Like all forms of food production, the culture of marine species, whether practiced in land-based, nearshore, or open ocean locations will have some effect on the environment. The effect can be both negative and positive and can vary depending upon the species,



Mussel Culture, Open Ocean Innovations. Figure 5
A schematic of shellfish growing systems associated with wind turbine towers (from Buck et al. [34])

location, and farming practices. In the past 3 decades of marine farming in sheltered marine waters, adverse impacts from aquaculture of both molluskan shellfish and finfish have been documented, though most of the concerns and controversy are centered on finfish. Mollusk culture is generally perceived as environmentally benign or even beneficial [5]; however, there have been documented environmental impacts from nearshore mussel farming that merit consideration for development of the offshore sector.

Though mussels feed on naturally occurring seston and no external feed is provided to the organisms, deposition of feces and pseudofeces can enrich bottom sediments beneath culture systems and impact benthic communities [36, 37]. Occurrences of sediment impacts have been associated with very dense culture in shallow embayments; therefore, if offshore farms are sited in locations with sufficient depth and adequate water circulation to disperse wastes, enrichment of bottom sediments should not be an issue [7]. High-density mussel culture can also deplete the water column of planktonic food, affecting both the growth and fitness of the cultured organisms as well as naturally occurring filter feeders in the system [38]. This too, is an impact that has been observed in sheltered embayments with limited circulation and is unlikely to be an environmental issue in open ocean waters [8]. However, in very large, high-density offshore farms, depletion of food within the farm and reduced growth and condition of the stock may be an issue for producers.

Hydrodynamic alteration is another environmental effect that has been documented in sheltered embayments with high-density shellfish culture [39] and has recently been an issue of concern in New Zealand where large-scale open ocean mussel farming is in development. Plew et al. [28] reported significant current and wave attenuation and strong water column stratification at a large (230 longline) mussel farm in Golden Bay, New Zealand. The farm was located in relatively shallow water (10–12 m) and the culture organisms were suspended from the surface to a depth of 8 m, therefore, occupying nearly the entire water column. As it is likely that open ocean development will use submerged culture in much deeper water (30–100 m) with ample space above and below the culture arrays, the severity of flow modifications as observed in this study are improbable.

Mussel Culture, Open Ocean Innovations. Figure 6
Seed collecting rope (*black*) is attached to the backbone of a submerged longline

A legitimate environmental concern for open ocean mussel culture is entanglement of whales and other marine life in seed collection lines [40]. These collectors are either discrete lengths of line or one continuous length of rope suspended from the backbone to provide substrate for settlement of mussel larvae (Fig. 6). As this sector develops, it is important to avoid deployment of seed collection lines in the migratory pathways of endangered marine mammals or to use weak links and electronic alert systems in the farming infrastructure [41].

Future Directions

Developments over the past 2 decades indicate that aquaculture production of mussels in open ocean environments is feasible and that opportunities exist for large-scale production [9, 10]. Conflicts with other uses can be significantly reduced, though they are not totally eliminated [34]. There is also evidence to support the premise that environmental impacts can be reduced by farming in open ocean environments [8, 36]. There is also strong indication that if sites are chosen properly, faster growth and excellent product quality can be achieved [9].

Though some technical challenges remain such as the development of large, purpose built, and highly seaworthy service vessels, obstacles to development of open ocean mussel farming are primarily economic, social, and political in nature. The scale of investment needed to establish and operate large-scale open ocean mussel farms is not well known, though it is assumed that production costs will be higher than for nearshore farming. The additional costs could be partially offset if ocean grown mussels, due to superior quality and greater consumer confidence in product safety can command a higher price [9], however, market prices are subjected to many economic externalities that are difficult to forecast. Space conflicts with the fishing industry may be an issue in some locations, therefore, involvement of local capture fishermen in industry development may be needed to gain acceptance of an alternative use of ocean space. As many countries move toward spatial planning of their territorial ocean waters, it is important to include a future vision of the potential for open ocean mussel farming in the planning process and give due consideration to compatibilities and possible synergies with other uses. Many countries also currently lack the regulatory framework for permitting open ocean farming sites. Until economic and regulatory uncertainties are resolved, entrepreneurs will be reluctant to make the level of investment needed to move this sector forward.

Ideally, development of open ocean farming should take place within the context of overall ocean management and marine spatial planning in order to assure compatibility with other uses and consistency with broader goals to restore and sustain the health, productivity, and biological diversity of the oceans.

Nuclear Transfer to Produce Transgenic Mammals

Alexander Kind, Angelika Schnieke
Chair of Livestock Biotechnology, Technical University of Munich, Freising, Germany

Article Outline

Glossary

Cell cycle The sequence of stages between one cell division and the next. These are: gap 1 (G1) DNA synthesis (S), gap 2 (G2), and mitosis (M).

Chimera An organism composed of a mixture of genetically distinct cells that originate from two individuals.

Chromatin The natural form of genomic DNA within the nucleus. A highly structured multi-coiled fiber composed of a complex of DNA, RNA and proteins.

Clone (a) Molecular clone, an isolated DNA fragment propagated artificially in bacteria. (b) Cell clone, a group of genetically identical cells descended from a single individual. (c) Animal clone, an animal produced by embryo splitting or nuclear transfer.

Cytoplasm The portion of a eukaryotic cell outside the nucleus.

Differentiation A process by which a cell takes on a more specialized role or function.

Epigenetic regulation Regulation of gene expression by modification of chromatin not involving changes to the DNA sequence, e.g., by methylation of cytosine bases.

Locus A defined position in the genome.

Metaphase A stage of cell division when chromosome pairs are condensed and ready to be divided between the daughter cells.

Pluripotent The ability of a single cell to generate all cell types of the body. Pluripotent cells are distinct from totipotent cells in that they cannot make extraembryonic structures, such as the amniotic sac or the placenta.

Promoter trap A method of enriching gene-targeted cell clones against a background of random integrants. Expression of a selectable marker is conditional on integration at the desired location and driven by the promoter of the target gene.

Pronuclei Two structures formed from the sperm and oocyte genetic material following fertilization. Pronuclei later fuse to form the nucleus of the zygote.

Reprogramming A general term describing a radical change in the pattern of gene expression by a nucleus. This may be in response to a change in cytoplasmic factors, for example, after transfer of a nucleus from a somatic cell into an oocyte.

Somatic cell Cells of an organism other than the germ line.

Transcription The first stage in the expression of a gene, in which an RNA copy, or transcript, is made from a DNA template.

Transfection Term covering a variety of chemical, electrical and mechanical methods of introducing nucleic acids into cells.

Undifferentiated Relating to a cell that is capable of differentiation but has not generated specialized characteristics.

Zygote The one-cell embryo formed after fusion of the male and female pronuclei.

Definition of the Subject

Over the last 3 decades, researchers in molecular genetics and developmental biology have generated a repertoire of powerful biological techniques that allow genes to be isolated, analyzed, modified at will, then transferred and studied in cultured cells and live animals. This technology has revealed the functions of thousands of genes and dramatically advanced the knowledge of normal and disease states, providing the basis for numerous practical benefits especially in biomedicine. This entry tracks one strand within this interconnected and ever-broadening field: the use of nuclear transfer to generate transgenic mammals.

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

Originally published in
Robert A. Meyers (ed.) Encyclopedia of Sustainability Science and Technology, © 2012, DOI 10.1007/978-1-4419-0851-3

Transgenic animals were originally defined as those that contain additional DNA, such as a gene introduced from another species. The term "transgenic" is now commonly used to encompass a range of experimentally engineered genetic modifications including DNA deletion, rearrangement, and replacement. Here the word is used in this broader sense.

Nuclear transfer is the replacement of the nuclear genetic material of an oocyte or zygote with the nucleus of another cell. The technique has been applied in three main areas:

1. Therapeutic cloning – the generation of embryos and stem cells from differentiated cells.
2. Reproductive cloning – the replication of animals from cells, for example, where sexual reproduction is difficult or impossible, or to preserve valuable genetic material.
3. Cell-mediated transgenesis – the production of transgenic animals from genetically modified cultured cells.

The production of transgenic animals was a principal motivation for the development of nuclear transfer in mammals and is the focus of this entry.

This entry is structured as follows: Section "History and Introduction" gives some historical background to the conception and development of nuclear transfer. Section "Nuclear Transfer" outlines the current state-of-the-art and related transgenic technologies. Section "Future Directions" describes possible developments in the near future. This entry can however provide only an overview of this diverse and expanding subject. Interested readers can gain more detailed information by accessing the key papers, reviews, and books cited.

History and Introduction

Cloning animals by nuclear transfer is not a new idea. The first recorded reference is attributed to Yves Delage, a French marine biologist who wrote in 1895: "if, without any deterioration, the egg nucleus could be replaced by the nucleus of an ordinary embryonic cell, we should probably see this egg developing without changes" [1]. There is however no evidence that Delage actually carried out such an experiment. Hans Spemann described the first nuclear transfer in 1928 [2]. In a remarkable piece of microsurgery using micro-tweezers and a loop of hair from his baby daughter, he constricted a single-cell salamander embryo into two parts, one of which contained the cell nucleus. Left to develop, the portion with the nucleus divided and formed an embryo, while the other side remained a pouch of clear cytoplasm. As the embryo developed further, Spemann allowed a single nucleus to pass back into the empty cytoplasm; this reconstructed single cell then developed into another normal embryo.

In the early 1950s, Robert Briggs and Thomas King performed a series of nuclear transfer experiments with frogs. They removed the nucleus from an activated frog oocyte using a glass needle. A single cell dissected from a later stage embryo was then drawn up into a fine glass pipette connected by rubber tubing to a syringe. The cell broke open as it was squeezed within the pipette, and the free nucleus was then injected into the enucleated egg. Culturing the reconstructed embryos further, they found that cell nuclei from blastula stage embryos could support normal development to tadpoles. But nuclei from later stage embryos, in which the major embryonic cell lineages were already established, were unable to do so.

Transfer of nuclei following this basic scheme was continued by various researchers for several decades. The work was at first restricted to the large eggs of amphibians, but in the late 1970s, embryo culture and micromanipulation techniques improved sufficiently to use the far smaller and more vulnerable eggs of mammals. The overwhelming finding was that the developmental capacity of transplanted nuclei decreased with the age and extent of differentiation of the donor cell. Nuclei of very early embryonic cells had equivalent potential, but at some stage in development, it seemed that the fate of different cells became determined, "hard wired" in some way. The mechanism was unknown, but some form of irreversible modification or loss of nuclear DNA was viewed as a likely explanation. The concept of cell determination thus became widely accepted among developmental biologists. In 1984, James McGrath and Davor Solter seemed to put an end to the possibility of nuclear transfer in mammals. They systematically transferred nuclei from one-, two-, four-, eight-cell and blastocyst stage mouse embryos into enucleated one-cell stage embryos, zygotes. Nuclei from one-cell embryos supported

development to blastocysts, but success dropped off sharply using two-cell stage nuclei and failed entirely with later stages. They interpreted this as a rapid loss of nuclear capability during development and concluded their paper with the categorical statement: "the cloning of mammals by simple nuclear transfer is biologically impossible" [3].

However, strict cell determination remained difficult to reconcile with the well-known capacity for organ regeneration shown by various vertebrates, including most fish and some types of amphibian. If for example a newt loses a limb, cells from surrounding tissues migrate into the wound and undergo a process of reverse development, changing their identity to form a mass of rapidly dividing undifferentiated cells termed a blastema. Cells within the blastema then organize and undergo processes similar to those in embryo development to form a replacement limb [4]. This was good evidence that some adult differentiated cells are not determined in their fate and can radically change their identity. So, despite the repeated failure of experimental nuclear transfer, there remained the tantalizing possibility that the limitations were essentially technical rather than biological. This provided sufficient motivation for some researchers to continue testing.

In retrospect, it was unfortunate that early efforts focused on mice, because they are now known to be one of the more difficult species to clone by nuclear transfer. So, somewhat unusually, the major breakthroughs were made with livestock. The first indication that nuclear transfer from later stage cells might be possible came ironically just a few months before McGrath and Solter's paper was published. Steen Willadsen produced three Suffolk sheep by merging single cells from eight-cell embryos with enucleated unfertilized eggs [5]. It later emerged that the reason for the discrepancy with the mouse work was because McGrath and Solter had used enucleated zygotes for nuclear transfer, because mouse oocytes are too fragile to survive nuclear transfer. Willadsen had been able to use unfertilized oocytes, which are more robust in sheep. Years of work have subsequently shown that unfertilized oocytes are successful recipients for nuclear transfer in numerous species, while zygotes can only be used at a very particular stage.

In the decade that followed Willadsen's achievement, nuclear transfer remained restricted to cells of the very early embryo. While this was potentially useful in increasing the number of embryos of valuable animals such as prize cattle, there were few other practical applications. However, developments in transgenic technologies over the same period led to increasing pressure to improve nuclear transfer.

In 1980, it was reported that naked DNA microinjected into the pronuclei of fertilized mouse eggs could stably integrate into the host genome [6]. Microinjection by the same procedure was extended to livestock 5 years later [7]. A host of practical applications for transgenic livestock species were soon envisaged, including enhanced production characteristics, disease resistance, and the production of pharmaceutical proteins. However as time went on, it became apparent that DNA microinjection suffered numerous drawbacks. The process was inefficient and offered no control over where a transgene would integrate in the host genome. Randomly integrated transgenes exhibited a very wide range of expression, and this was a major problem for biotechnology companies seeking to make useful transgenic products, such as pharmaceuticals.

A quite different means of generating genetically modified animals, based on the use of cultured cells, was also developed during the 1980s. In 1981, Martin Evans and Gail Martin independently isolated embryonic stem (ES) cells from early mouse embryos [8, 9]. ES cells can be grown indefinitely in culture and then be incorporated back into a developing embryo. In 1984, it was found that these cells could also contribute to the germ line and produce functional sperm or oocytes [10]. This provided a means of establishing mouse strains derived from the ES cell genotype, including any experimental modifications. In 1987, a method of introducing predefined alterations into genes in situ, originally developed in tumor cell lines [11], was applied to ES cells by Thomas and Capecchi [12]. This technique, termed gene targeting, made it possible to engineer and study precise genetic alterations in whole animals. The phenomenal power of gene targeting in ES cells has provided an abundance of knowledge about the function of genes in mammals, and was recognized by the 2007 Nobel Prize for Medicine, awarded jointly to Mario Capecchi, Martin Evans, and Oliver Smithies.

Mice are vital for basic research, but by the late 1980s, it was apparent that many practical applications

in areas such as biomedicine and animal agriculture required ES technology or a functional equivalent in other species, particularly livestock. Despite considerable efforts, fully functional ES cells had not (and still have not) been derived from livestock. Despite the difficulties, transfer of nuclei from "ordinary" somatic cells was seen as a possible alternative means of transferring engineered genetic modifications from cells to whole animals. However, this would not be possible if nuclear transfer was restricted to cells obtained directly from early embryos. Genetic modification and powerful techniques like gene targeting require cells to be cultured for several weeks.

The breakthrough in nuclear transfer came in the 1990s, when it became clear that the cell-cycle stage of the nuclear donor cell must be correctly matched to the state of the recipient cytoplasm. Keith Campbell and Ian Wilmut of the Roslin Institute near Edinburgh made the key insight that only nuclei in G1 phase (prior to DNA replication) would support normal development in unfertilized oocytes. Transfer of nuclei at other stages in the cell cycle leads to aberrant chromosomal replication and inviable embryos. The method they developed and which is still widely used is to block cycling in the donor cells before DNA replication by reducing the amount of serum in the culture medium.

In 1995, two live lambs, Megan and Morag, were produced by transfer of nuclei from cells that were derived from a day 9 sheep embryo and then grown in culture for 6–13 passages [13]. The following year a similar experiment was performed that also included cultured adult sheep mammary cells. On 5 July 1996, a lamb was born from these cells and named Dolly [14]. Her birth showed that previous difficulties with nuclear transfer had indeed been technical. Adult cell nuclei were not irreversibly determined in their developmental potential and could be radically reprogrammed to adopt a new fate. Shortly after, transgenic and gene-targeted animals were produced, demonstrating that nuclear transfer from somatic cells was a practical means of generating genetically modified animals [15, 16].

Nuclear Transfer

Choice of Transgenic Methods

As mentioned in the introduction, the development of nuclear transfer in livestock mammals was largely inspired by the power of ES cell–mediated transgenesis in mice. The aim was to gain more precision and control over the type of genetic modifications that could be carried out. This section reviews nuclear transfer within the overall context of transgenic technology.

Methods of producing transgenic mammals can broadly be divided into two categories:

1. Direct transgenesis – the transfer of transgene DNA directly into embryos. Methods include DNA microinjection, viral transduction, transposon-mediated transgenesis, and sperm-mediated DNA transfer.
2. Cell-mediated transgenesis – the engineering of genetic alterations in cultured cells that are then converted to whole animals. Nuclear transfer falls within this category. The other major method is the incorporation of ES, or induced pluripotent stem cells, into developing embryos to produce chimeric animals.

Methods of direct transgenesis are more straightforward than cell-mediated transgenesis. However, at present these allow only transgene addition. Earlier techniques, such as DNA microinjection, are also very inefficient. Although not a significant drawback in mice, this is an important factor in livestock because gestation and maturation times are longer and maintenance costs far higher. For example, cattle have a generation interval between 2 and 3 years and each cow bears either one or two calves, while the generation time of mice is 3 months and litter size is between 6 and 12 pups. There has therefore been a strong incentive in livestock programs to reduce the number of animals gestating non-transgenic fetuses. Transgenic fetuses can be identified in utero by analysis of cells shed by the developing fetus and obtained by amniocentesis or allantocentesis. However, these procedures carry a significant risk of inducing abortion. Some efforts have also been made to detect and analyze fetal cells or DNA in the maternal circulation, but with little success. Definitive analysis of the integrated transgene must therefore be carried out in animals shortly after birth using small samples taken from blood, tail, or ear tips.

Methods of cell-mediated transgenesis share the important feature that genetic manipulation and analysis of the transgenic genotype are carried out in cells in the laboratory, rather than in animals "on the farm." These cells are then used to transfer the modified

genotype to whole animals. While cell-mediated transgenesis is more labor intensive than direct transgenesis, it offers significant advantages. Cells can be analyzed in detail so that only those with the desired genotype are converted to whole animals. Far larger numbers of independent transgene integration or other events can be screened and investigated in cells than in whole animals. This allows the selection and isolation of cells carrying rare integration events resulting from homologous recombination, the basis of gene targeting.

Nuclear transfer is currently the only practical form of cell-mediated transgenesis in mammals other than mice.

Nuclear Transfer Basics

The standard nuclear transfer procedure is to prepare a recipient cytoplast by removing the genomic DNA from an unfertilized oocyte. This is usually carried out by microsurgical withdrawal of a portion of cytoplasm containing the second metaphase plate using a micromanipulator. A low-tech option is to split the oocyte under a microscope using a thin blade, dye is then used to identify the half containing the metaphase chromosomes, a procedure termed "hand made cloning." The donor nucleus, or a whole cell, is then introduced into the enucleated oocyte by microinjection or electrofusion. Reconstructed embryos are activated with an electrical pulse to simulate fertilization, cultured if possible to identify viable embryos, and then transferred to the oviduct of foster mothers to complete gestation. Readers interested in detailed protocols are referred to a book by Verma and Trounson [17].

As mentioned in the introduction, the key insight that led to the success of nuclear transfer from a wide variety of cells was recognizing the importance of matching the cell-cycle stage of the donor nucleus and the oocyte cytoplasm. Oocytes of most mammalian species pause twice during the meiotic cell divisions that form the gametes: once before the first meiotic metaphase, and again at the second metaphase, at which stage the oocyte is mature and can be fertilized. Oocyte maturation and arrest are induced by a high level of a protein complex termed maturation-promoting factor (MPF). Fertilization causes a chain of events that result in proteolytic cleavage of MPF, breaking the arrested state and allowing the fertilized oocyte to complete meiotic division.

The level of MPF in the oocyte has a profound effect on the outcome of nuclear transfer. If a nucleus is transferred into oocyte cytoplasm with high MPF, the nuclear envelope breaks down and chromatin undergoes chromosome condensation, followed by nuclear reformation and DNA replication. A nucleus from a cell in G1 phase of the cell cycle will undergo normal DNA replication and can support normal development. However, a donor nucleus in S, or G2, phase undergoes aberrant re-replication of DNA, causing chromosomal damage or an abnormal chromosome number with consequent failure of development. Nuclear transfer into unfertilized oocytes can therefore be improved by synchronizing donor nuclei in G1 phase. This can be achieved by depriving donor cells of serum, blocking the cell cycle before DNA replication.

It has been proposed that the key to successful reprogramming of a transferred nucleus is the free availability in the recipient cytoplasm of factors necessary for regulating the program of gene transcription [18]. These are normally associated with DNA within the nucleus, but dissociate from the genome during cell division, and are released into the cytoplasm when the nucleus breaks down, ready to be distributed with the chromosomes into the new daughter nuclei. These factors reassociate with the DNA in G1 phase to reestablish the transcriptional program. Unfertilized oocytes have an abundance of such free factors, being paused part way through meiotic metaphase. Consistent with this model, if the genome of a zygote is removed during cell division, the resulting cytoplast can successfully reprogram an incoming cell nucleus to embryonic gene expression, but if the zygote nucleus is removed during interphase, it cannot [18].

Nuclear transfer from somatic cells opened a new route to produce transgenic livestock, and lifted the requirement for ES cells for cell-mediated transgenesis. Cells such as primary fetal fibroblasts can be obtained in large quantities, manipulated in culture, and then converted into whole animals by nuclear transfer. The initial work carried out in Edinburgh was inspired by the possibility of producing large numbers of genetically modified animals without conventional breeding,

termed "instant flocks," for applications such as biopharmaceutical production in milk [19]. The first large animal produced in this way was a Poll Dorset sheep "Polly" that carried a human clotting factor IX transgene, randomly introduced into the genome by in vitro transfection of fetal fibroblasts [15]. Shortly after, an α1-antitrypsin transgene was placed by gene targeting into a site chosen as likely to favor expression [16]. Somatic cell nuclear transfer has since been used to generate transgenic and gene-targeted animals in several other species.

From the outset, comparative data indicated that nuclear transfer requires fewer experimental animals than DNA microinjection to produce a useful transgenic animal [15], reducing costs and benefiting animal welfare. Techniques continue to improve gradually; for example, bovine nuclear transfer data from 1998 to 1999 showed an efficiency of 6.3% calves born per reconstructed embryo, while in 2003–2004 this increased to 15% [20].

Fetal and perinatal mortality and morbidity are the most serious issues that face nuclear transfer. The severity of the problem varies between species, cell types, and experimental regimes and is unrelated to genetic manipulation of the cultured cells. Rather, it is believed to be a consequence of defective epigenetic reprogramming of the donor nucleus and possibly incompatibility between the cell-derived nuclear genome and the oocyte-derived mitochondria. Cumulative data for cattle collected up to 2005 indicate that more than 1,500 cloned calves were born, of these, 60–70% survived normally to adulthood. The performance of these, including reproduction, was similar to non-cloned animals. Evidence is also accumulating that ill effects are limited to the first generation. Offspring, including those from two nuclear transfer parents, exhibit no increased morbidity or mortality.

Nuclear Transfer with Differentiated Cells

Transgenesis by nuclear transfer began with the use of abundantly available somatic cells such as fetal fibroblasts, mainly as a matter of convenience [15]. It is desirable to characterize as fully as possible cell clones used to generate whole animals. However, most primary cell types have a short lifespan in culture, allowing little time for transfection, selection, and the expansion of individual cell clones. Furthermore, prolonged growth in culture risks genetic and epigenetic alterations that may reduce their ability to support normal development.

A number of precautions can be taken to minimize the total time cells spend in culture. Genetic manipulation should ideally be carried out using primary cells at very early passage. Samples of each cell clone can be cryopreserved and retained as a frozen stock for nuclear transfer, while a replicate sample is expanded for further analysis. Determination of the modal chromosome number of cell clones is also useful because it allows those that have undergone gross changes in chromosome complement to be excluded. Frozen samples of cell clones identified as most suitable as nuclear donors can be thawed and used to generate whole animals. The viability and lifespan of primary cells can vary considerably between different isolates and are affected by factors such as the age of the donor animal and the method of preparation. It is therefore important to identify a suitable cell isolate before commencing a transgenic project.

The problem of short lifespan can also be overcome by "rejuvenating" cells by nuclear transfer and re-derivation from resulting fetuses. This allows successive rounds of in vitro genetic manipulation to be carried out relatively quickly, but does introduce a possible risk that genetic aberrations occur in the cultured cells, but remain undetected until animals are born. Serial nuclear transfer has been used to carry out multiple genetic manipulations in large animals. Three successive rounds of cloning were used to inactivate both alleles of the α1,3-GT gene in pigs [21]. In cattle, serial nuclear transfer has been used to inactivate immunoglobulin genes and the prion protein gene PrP [22, 23]. Some researchers have described a progressive decrease in the efficiency of development over successive clonal generations (e.g., [24]). However, there has been a recent report of 15 successive generations of recloned mice produced with no decrease in success rate using a chromatin-modifying reagent trichostatin A [25], suggesting that animal cloning can in principle be repeated indefinitely.

Nuclear Transfer and Gene Targeting

As mentioned in Section "History and Introduction," a major motivation for the development of nuclear

transfer in mammals was to circumvent the need for embryonic stem cells and enable gene targeting in species other than mice [16] In brief, gene targeting exploits the ability of a cell to support recombination between an exogenous DNA molecule and chromosomal DNA at regions of shared homology, as part of the DNA repair process. It can be used to inactivate individual endogenous genes by insertion or deletion, replace whole genes, precisely place transgenes in the host genome, introduce subtle gene modifications, and carry out large-scale modifications such as the deletion of megabase-sized DNA fragments. There are many variations and technical refinements, and the reader is referred to a review by Capecchi [26] for further details. Typically, cells are transfected with a DNA construct carrying an engineered modification flanked by DNA "arms" homologous to the target locus. At a certain frequency, homologous recombination occurs between the construct and the target gene and the engineered modification is seamlessly incorporated. The frequency of homologous recombination events varies by locus, vector, and the cell type used. Identifying cell clones carrying a targeted event among a large background of random integrants is key to success. Various methods have been devised to aid their isolation, the most powerful of which is to use a drug resistance marker gene that is expressed only if the vector recombines correctly at the chosen target site. Variations of this technique are referred to as "promoter trap," "intron trap," or "polyA trap" selection.

Nuclear transfer is currently the only practical method of producing gene-targeted livestock; however, it has become clear that gene targeting in somatic cells is considerably more difficult than targeting in mouse ES cells, and relatively few gene-targeted large animals have been generated. Genes so far targeted in livestock are: *COL1A1* in sheep [16], *PRNP* in cattle, sheep and goats [22, 27, 28], *GGTA1* in pigs [29, 30], *IGH* in cattle [22], and *CFTR* in pigs [31]. The main problems are the short lifespan of primary somatic cells in culture, as discussed above; the overall lower frequency of homologous recombination relative to random integration events in somatic cells; and the difficulty of targeting genes not expressed in the host cells.

Although direct comparisons are hard to find, it is generally understood that homologous recombination events are less frequent in somatic cells than in mouse ES cells [32]. Methods such as promoter trapping can enrich rare cell clones bearing targeted events, but lack of transcriptional activity in the host cell precludes their use. There is also evidence that spontaneous homologous recombination events are particularly rare for non-expressed genes [33]. This has made targeting of many potentially important genes difficult. There are however promising strategies to enhance the proportion of homologous recombination events in somatic cells, such as the synchronization of cells in late S phase so that vector transfection can be optimally timed [34], but these have yet to be fully evaluated. Current progress and a review of the field are provided by Laible and Alonso-González [35].

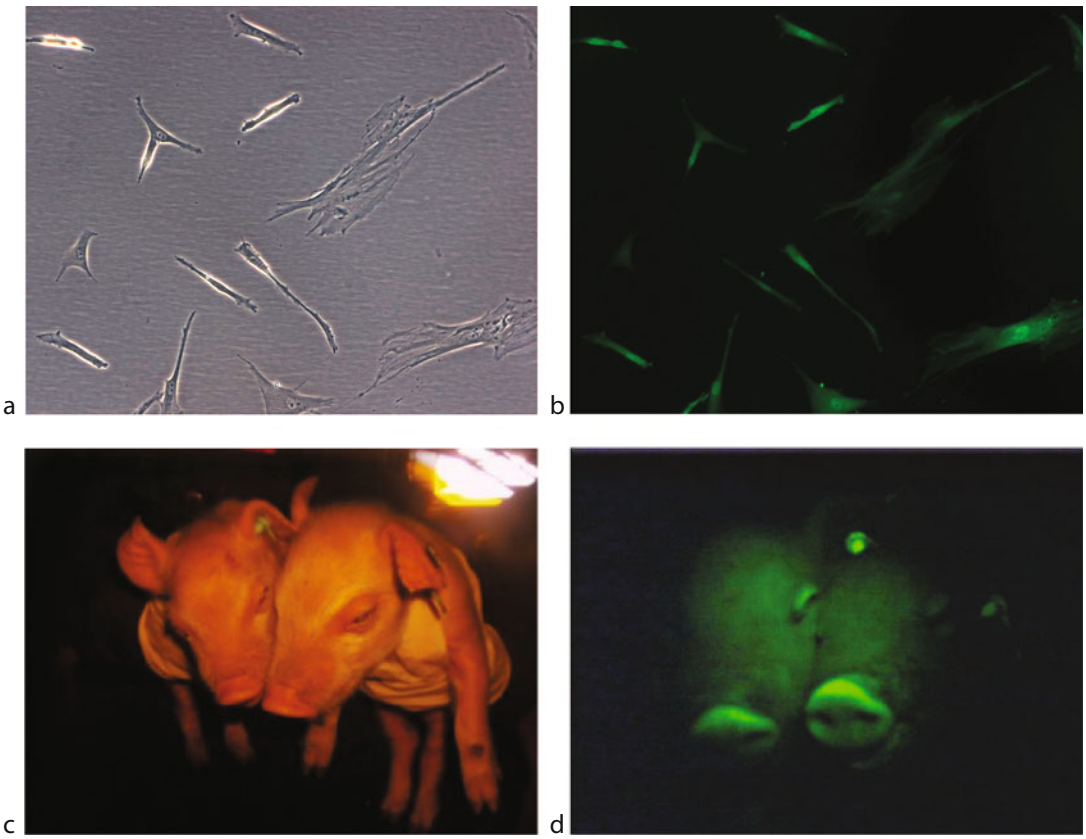
An entirely new approach to mammalian gene targeting is now emerging, based on the use of highly specific nuclease enzymes. This promises to overcome many of these problems and possibly supplant nuclear transfer for some applications, as discussed in Section "Beyond Nuclear Transfer – Direct Manipulation of Early Embryos."

Multipotent and Pluripotent Stem Cells as Nuclear Donors

The main advantage of multipotent cells, such as mesenchymal stem cells (MSCs), and pluripotent cells, such as ES cells, over more differentiated cell types is their longer lifespan and greater stability in culture. This facilitates genetic manipulation procedures and the isolation of cell clones for the generation of transgenic animals.

One of the defining characteristics of ES cells is that they can grow indefinitely as undifferentiated cells in culture while retaining the ability to form all tissues of the body. However, experience gained in mice is not always applicable to other species. From the few species investigated, it is clear that not all ES cells are as easy to handle as those from mouse. For example, human ES cells survive electroporation and dissociation to single cells poorly and this has made derivation of stable transfected human ES cell clones difficult [36]. Despite considerable efforts over more than a decade, few gene-targeted human ES lines have been reported [37].

However, the main problem is that ES cells are simply not available for most mammals. Artificial induction of pluripotency by the expression of key transcription factors [38, 39] offers an alternative to



Nuclear Transfer to Produce Transgenic Mammals. Figure 1
Legend (**a**) gfp-transfected porcine MSCs; (**b**) gfp-transfected porcine MSCs under UV light; (**c**) nuclear transfer piglets generated from gfp MSCs; (**d**) nuclear transfer piglets under UV light

classical ES cells that is rapidly being extended to other species. Induced pluripotent stem (iPS) cells can be cultured for long periods, and mouse iPS cells have already been used for nuclear transfer [40]. At the time of writing, the detailed characteristics of iPS cells from most species however remain unknown. It is perhaps cautionary to note that although candidate pig iPS cells have been reported by several authors, in each case, the reprogrammed pluripotent state was not stable in culture and relied on continued expression of exogenous transcription factors.

Multipotent mesenchymal stem cells (MSCs) are attractive alternatives to ES cells for generating transgenic animals. MSCs can be readily derived from bone marrow or adipose tissue. They proliferate well for long periods in culture and have been used successfully for nuclear transfer in cattle and pigs [41–44]. MSCs can be transfected and retain their multipotent identity and support preimplantation development of nuclear transfer embryos at rates similar to non-manipulated MSCs [42, 43]. Figure 1 shows an illustrative transgenic experiment in which a green fluorescent protein reporter gene was introduced into pig MSCs and whole animals derived by nuclear transfer.

Studies of reconstructed embryos produced by nuclear transfer indicate that an important cause of developmental failure is incomplete reprogramming of the transferred nucleus. This leads to deficient expression of early embryonic genes and failure to establish a normal embryonic pattern of epigenetic regulation and chromatin structure. It has been suggested that the epigenetic state of the donor nucleus influences reprogramming efficiency, and cells with a high degree of developmental plasticity, such as

multipotent and pluripotent stem cells should be more successful nuclear donors than differentiated cell types (e.g., [45]). In mice, a higher fraction of embryos derived from ES cells were found to develop to term than those from differentiated donor cells [46]. Evidence from other species is however less clear, although some studies in pigs describe higher rates of development to blastocyst with bone marrow MSCs than fetal fibroblasts [47, 48]. These findings were supported by analysis of gene expression, which revealed that porcine MSC-derived cloned embryos resembled normal embryos more closely than did those from fetal fibroblasts [48].

As mentioned in the previous section, another advantage of stem cells is that they may support homologous recombination more efficiently than other cell types, enabling gene targeting. There is insufficient data regarding MSCs, but evidence from mice indicates that iPS cells support homologous recombination at rates similar to ES cells [49]. Human ES cells also seem to support homologous recombination at a rate similar to mouse ES cells [50].

Beyond Nuclear Transfer: Direct Manipulation of Early Embryos

Sequence-specific DNA endonuclease enzymes that recognize long target sequences are new tools that promise to revolutionize genetic manipulation in many species. Enzymes of this type include naturally occurring homing endonucleases, often termed meganucleases, and artificially engineered enzymes such as zinc finger nucleases (ZFN), please see review by Cathomen and Joung [51]. Recent years have seen particular interest in the use of ZFNs in mammals.

ZFNs are artificial enzymes produced by fusing the cleavage domain of the FokI restriction endonuclease with a series of DNA-binding domains known as zinc finger motifs. Each ZFN is a heterodimer that can be produced to recognize a specific DNA target sequence of 18–24 base pairs. An appropriately designed ZFN can create a double-strand break at a single predetermined site in the genomic DNA. In eukaryotes, the error-prone non-homologous end-joining DNA repair pathway is often mutagenic, creating small insertions and deletions at the break site. Thus, careful choice of break site provides a means of inactivating a chosen gene, an alternative to gene knockout by classical gene targeting. ZFNs must be designed and custom made for each individual target site. A critical goal of enzyme design is to ensure that it does not produce double-strand breaks at sites other than that intended. Such off-target activity is likely to be toxic or mutagenic.

Perhaps the most important feature of this technology is that the frequency of gene inactivation can be so high that selection or enrichment of cells carrying the targeted event is unnecessary, effectively removing the need for cell culture. In 2008, ZFN-mediated gene inactivation was achieved directly in vertebrate embryos. Viable gene-targeted zebra fish were created by injecting mRNAs encoding ZFNs directly into one-cell embryos [52, 53]. This approach has now been extended to mammals, with the report of rats carrying inactivated IgM and Rab38 genes produced by ZFN targeting in embryos [54].

At present, ZFNs are expensive and have yet to be widely tested, but on present evidence, it seems likely that this approach could replace somatic cell nuclear transfer as a means of generating knock out animals in many mammal species. The exception being mice, where ES cells already provide a simple means of producing gene-targeted animals. ZFNs also promise to facilitate gene-targeted insertion or substitution of defined sequences in cultured somatic cells. As mentioned in Section "Nuclear Transfer and Gene Targeting," the low frequency of homologous recombination is a problem, and some genes have been difficult to target. Evidence indicates that a double-strand break at the target site dramatically increases the frequency of targeting events [55]. It has recently been shown that ZFNs facilitate gene targeting by homologous recombination in human ES and iPS cells, which had proved difficult [56]. It remains to be seen whether gene-targeted insertions or substitutions can also be achieved directly in embryos, this is a fascinating possibility that will undoubtedly be explored in the near future.

Future Directions

Science can be very unpredictable, and history is littered with authoritative, but inaccurate forecasts of future progress. So these comments are necessarily tentative.

What is already clear is the attention that nuclear transfer has brought to questions of cell identity and fate. The year 1997 marked a radical change in experimental biology; the concept of cell determination was

overturned and replaced by the possibility of complete reprogramming of cell identity. This inspired many talented people to embark on projects that were previously inconceivable, with perhaps the most notable outcome being the derivation of induced pluripotent stem cells. The production of primitive stem cells essentially at will, coupled with increasing knowledge of the normal development of many cell types, is fuelling intense research activity in regenerative medicine and will undoubtedly bring significant advances in medicine and benefit to human health.

The efficiency of nuclear transfer has improved, but advances have been incremental rather than dramatic. There is still considerable mortality during gestation and around birth. First generation nuclear transfer animals sometimes face health difficulties, probably as a consequence of epigenetic defects. These may be resolved or mitigated by the use of pluripotent stem cells as nuclear donors, but supporting evidence has so far been restricted to mice. At least for a while, somatic cell nuclear transfer remains the preferred option for the production of genetically modified livestock, and the next decade will likely see gene-targeted animals of many kinds being generated, especially for biomedicine. However, while nuclear transfer remains technically difficult and inefficient, alternative methods will continually be sought. It is possible that efficient methods of embryo incorporation such as laser-assisted injection [57] could supersede nuclear transfer, with iPS cells used to generate 100% chimeras.

Another notable new technology is the use of zinc finger nucleases in early embryos. It already seems likely that this approach might take over from nuclear transfer for the production of gene knockout animals. There is also the promise that the use of ZFNs in combination with gene replacement vectors in cultured cells will significantly improve the efficiency of conventional gene targeting and give access to more difficult genes.

The availability of an enabling technology is in itself insufficient reason to produce genetically modified animals. Any transgenic project requires an objective risk to benefit analysis in which the well-being of the animal is given a high priority. But, where there are real long-term benefits to the environment, or for animal or human health, then nuclear transfer and its successor technologies can offer powerful and precise tools.

Ocean Farming and Sustainable Aquaculture Science and Technology, An Introduction to

Barry A. Costa-Pierce
University of New England, Marine Science Center, Biddeford, ME, USA

Aquaculture is closely tied to enhanced fisheries; indeed, marine fisheries enhancement by using the "aquaculture toolbox" is happening around the world and in some countries on a massive scale, e.g., in China. The science of marine enhancement is still in its infancy compared to other fields of fisheries science, but now shows potential to (1) increase fishery yield beyond that achievable by exploitation of the wild stock alone, (2) help restore depleted stocks, (3) provide protection for endangered species, and (4) provide critical information on the natural ecology, life history, and environmental requirements of valuable marine species (► Marine Fisheries Enhancement, Coming of Age in the New Millennium). The key to successful use of stocking is to plan enhancement programs from a fisheries/resource management perspective, using a broad framework and a transdisciplinary scientific approach where stakeholders are engaged from the outset in planning new programs.

Marine fisheries enhancement is a powerful tool that requires careful and interdisciplinary planning to control its effects. Marine enhancement will come of age in this new millennium as agencies and stakeholders align in truly group efforts. Few marine fisheries enhancement programs have enlisted all of the key elements of the Responsible Approach to Marine Stock Enhancement and the Code of Responsible Conduct for Marine Stock Enhancement. But these principles are now well described and laid out in a systematic manner. It is reasonable to expect that future, more sustainable fisheries enhanced by aquaculture will be successful as long as dedicated attention is focused on applying each of the key elements of the Approach and Code.

Polyculture is a sophisticated ecological precept illustrating the "niche concept." In aquaculture, it is ancient practice originating in China where the production of two or more noncompetitive species are cultured in the same physical space at the same time, often with the objective of producing multiple products from one system, and thus multiplying production and adding value. Polyculture is used primarily to enhance total production within an aquaculture facility while maintaining, and in many cases, enhancing water quality. Species used may be a combination of animals and plants, or aquatic and terrestrial species. In the modern context, polyculture systems have evolved to incorporate hydroponic systems (aquaponics).

Aquaculture may be an ancient practice, but until recently, the field has developed mainly on a trial and error basis. Modern aquaculture developments are organized principally in a traditional, compartmentalized manner designed to maximize financial returns. However, macroeconomic factors are not the sole drivers of success in aquaculture. Advancing sustainable aquaculture science and technology requires innovation in multiple fields, plus must incorporate innovative participatory processes that engage scientists, extension professionals, policy-makers, and the public. Aquaculture has advanced rapidly in many economically developing countries due to the formation of multidisciplinary teams that have worked together over 10–20-year periods not only to incorporate the latest biophysical and engineering advances but also to evolve innovative, socioecological, and ecosystem governance approaches to management and civil society (► Aquaculture, Sustainability Science in). In the twenty-first century, the environmental and social costs of aquatic food production cannot be externalized, and "social profit" is as important as economic. It is well recognized that the development of sustainable aquaculture is dependent not only on the technical needs for hatcheries to produce seed and feed mills to produce feeds but also on markets, equipment, and the overall capabilities of the entire "seafood infrastructure." Aquaculture is evolving rapidly and has a real chance to be a shining example of sustainable foods production for millions of people both rich and poor. A new development paradigm is needed, one that uses the principles and practices of ecology to break through disciplinary bounds and tie together real-world

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

knowledge, combining the findings of disparate, applied research disciplines in the ecological and social sciences in order to create a new, knowledge-based infrastructure and social-ecological support system (► Aquaculture, Ecological). FAO has developed guidelines for an ecosystems approach to aquaculture which can be used to design "aquaculture ecosystems" at many scales. Until recently, there were few commercial examples of successful models of these advanced aquatic food ecosystems, especially in marine waters, but the basis and content of two commercial operations are described here (► Aquaculture, Integrated Multi-trophic (IMTA), and ► Sustainable Ecological Aquaculture).

IMTA and SEA systems incorporate innovative engineering and ecological design components that demonstrate a clear transition from single to multiple species aquaculture production in the ocean. The concept is simple, but the practices are elegant. The farming of aquatic species from different trophic levels in proximity allows one species' uncontaminated (no toxicants used), uneaten feed and nutrient wastes to be recaptured and converted into fertilizers, feeds, and energy for other aquatic crops. IMTA and SEA systems combine "fed aquaculture" (e.g., finfish) with "extractive aquaculture," which utilizes inorganic waste nutrients (absorbed by seaweeds) and organic waste nutrients (filtered by shellfish) from the fed aquaculture system. The aim is to design and operate a balanced farming ecosystem for improved environmental sustainability, greater economic profit (improved outputs, lower costs, product diversification, reduction of risks, value added, ecolabeled products), and societal acceptability (job creation, improved governance, safe products, no contaminants).

Production of finfish species from coastal aquaculture systems has been limited until recently to the use of open, net pen cage systems. These systems are the most available (inexpensive in terms of cost/volume) and, thus, have proliferated where the regulatory environment has allowed their use inshore. Surface gravity cage systems are also the most controversial of all engineered aquaculture systems. They can be more easily destroyed in storms. And they are capital and labor intensive, requiring large and expensive hydraulic and feeding equipment for management, maintenance, net handling, washing, and cleaning.

In the Mediterranean, coastal finfish aquaculture in surface gravity cages has spread throughout the region. Progress has been made, but there is still a poor understanding of the environmental interactions of aquaculture in such a unique sea. Scientists remain unable to calculate the carrying capacity of areas of the sea for aquaculture (► Marine Aquaculture in the Mediterranean). There are many different types of habitats and ecosystems within the Mediterranean Sea so that it is essential that ecological and socioeconomic research address regionally specific issues. There is a special urgency to improve the understanding of fish pathology in Mediterranean aquaculture systems, especially in view of EU policies concerning the reduction of chemical use in the aquatic environment. Sustainable aquaculture within the Mediterranean Sea may be achieved by combining therapeutic treatments with health management strategies as breeding of tolerant fish, improving water quality, and vaccination.

Aquaculture in the open ocean or in high-energy coastal areas is predicted to grow rapidly in the twenty-first century due to space and resource conflicts in crowded coastal areas where most of the world's population resides. There are few commercial examples of successful models of well-studied commercial finfish cage operations in marine waters off islands, so the example of 5 years experience at the Kona Blue farm site, the evaluation of actual data, and observations recorded there are globally important (► Environmental Impacts of an Open Ocean Mariculture Operation in Kona, Hawaii). Baselines and evaluation of impacts of commercial aquaculture at such sites, their context, and their interpretations give invaluable insights into the future trajectory of sustainable open ocean aquaculture for many tropical nations.

Escaped fish may impact wild fish through competition, predation, habitat displacement, gene pool dilution, etc. In an attempt to reduce the numbers of escapees, rapid progress is being made throughout the world in the design of new, submersible containment cages that are easier to manage in difficult environments and are more storm resistant. One globally important aquaculture engineering innovation is the development of a modular "Aquapod™ cage system" which utilizes individual triangular net panels fastened

together to construct a rigid sphere as a secure enclosure. The Aquapod™ panels are made of simple structural members (plastic lumber from mainly recycled bottles) and wire mesh netting. Some individual panels or groups of panels have other functions, such as access, feeding, fish transfer and grading, harvest, mooring, and mortality recovery. Other individual panels may have pneumatically controlled flotation devices which allow an almost infinite orientation of the Aquapod™ in the water (► Aquapod Systems for Sustainable Ocean Aquaculture).

The rationale placement of aquaculture systems in the ocean is now being considered as an essential part of coastal and marine spatial planning (CMSP) efforts, and for some countries, the movement toward development of offshore renewable energy systems (wind, tidal, wave) has been viewed as a opportunity to examine closely the opportunity to site multiple, compatible uses in the ocean, such as the integration of offshore aquaculture with renewable energy systems. Analyses and field experiments have been conducted that merge submerged finfish cages and shellfish growing structures with offshore wind energy structures, and some important logistical, economic, and environmental advantages have emerged (► Aquaculture and Renewable Energy Systems, Integration of). Offshore windmills use the wind above the surface to produce energy, and their fixed pylons, concrete foundations, metal jackets, tripods, or tripiles offer excellent potential for a wide range of aquaculture systems. Pioneering studies conducted in Germany have examined the colocation of offshore wind farms and off-bottom offshore aquaculture for shellfish and algae. In addition, a broad-based stakeholder process involving all concerned in the multifunctional uses of offshore wind farms for aquaculture has been conducted which has helped dispel the many mistaken perceptions, concerns, and doubts about these ideas.

Engineering advances for open ocean shellfish aquaculture worldwide, initially adapted from deep water suspended scallop culture systems in Japan, push the frontier of shellfish production away from the multiple user conflicts of the world's coast and offer enormous potential for the production of low trophic level grazing shellfish species that could provide massive amounts of new, high protein, and fatty acid rich seafood for humanity. Advances have not been limited to new types of lines, moorings, buoys, but also in shellfish management and innovative extension methods to move capture fishermen into shellfish aquaculture (► Mussel Culture, Open Ocean Innovations). Offshore deepwater shellfish farming technologies have been shown to be effective for mussel production in very high-energy open ocean conditions (e.g., significant wave heights >10 m) in the northeast USA, and at a test site in the German Bight with significant wave heights >8 m and current velocities up to 1 ms^{-1}.

Shellfish and seaweed aquaculture are considered by many marine stakeholders to be best choices due to the elimination of many of the environmental concerns over feeds plus their beneficial impacts on particulate and nutrient pollution (► Seaweed Aquaculture for Human Foods in Land-Based and IMTA Systems). The sustainable expansion of seaweed aquaculture is also being driven by the needs for additional sources of high quality, nutrient-dense human foods (sea vegetables with high levels of omega-3's). Expansion of seaweed aquaculture is being considered in offshore and coastal areas but also in land-based systems. Land-based cultivation of seaweeds reduces the pressure on wild harvests, particularly those which are unsustainable and ecologically damaging, assists in the evaluation of numerous species that are unsuitable candidates for traditional, open water systems, and allows for increased environmental and input controls. High levels of control in land-based settings provide the necessary traceability, security of supply, high quality standards, and safety standards required not just for human consumption but also for nutraceutical and pharmacological applications (► Mariculture Systems, Integrated Land-based).

Shellfish aquaculture is one of the fastest growing sectors of the food industry, raising concerns about the influence of the activity on the environment. The sustainability of shellfish aquaculture and assessments on its trajectory toward sustainability involve a detailed review of the ecological impacts – both positive and negative – on nutrients, particles (filtration), exotic species, biodiversity, structure (habitats), and opportunities for incorporating best practices and developing innovative culture systems (► Shellfish Aquaculture, Methods of Sustainable). The concept of "acceptability" of impacts is critical to determining the

sustainability of shellfish aquaculture in the marine environment. Since the term "acceptable" is governed primarily by social values, the social carrying capacity of aquaculture should be the basis of a sustainability program to assess the sum of activities, not only including aquaculture, within a defined area. The mechanism toward identifying sustainable activities in the marine environment will progress when clear policies are elucidated and an inclusive approach is adopted reflecting legislative requirements and the views of all stakeholders.

Sustainable shellfish aquaculture will depend upon a strong but reasonable regulatory system, responsible farmers adhering to best management practices so that they raise do not deplete resources in a given area to such an extent that bivalve production is decreased, and a society that judges if shellfish aquaculture has an acceptable impact on the environment and is sustainable. Since there is intense competition for space and use in many coastal zones, the siting of shellfish aquaculture farms can be contentious. Thus, many organizations have stressed the importance of determining the carrying capacity of different areas for shellfish aquaculture. There are a number of ways that "carrying capacity" may be defined, including physical, production, ecological, and social, and the first three categories are to lesser or greater degrees related to social expectations and standards. A number of methods have been developed to calculate these different categories of carrying capacity for bivalve culture. Advances to estimate the different categories of carrying capacity have been made (► Carrying Capacity for Sustainable Bivalve Aquaculture). Scientific advances in modeling for shellfish aquaculture have encouraged the rapid development of a sustainable shellfish aquaculture industry, with excellent case studies from throughout the world (► Carrying Capacity for Aquaculture, Modeling Frameworks for Determination of).

There have been concerns that aquaculture has been moving away from its global responsibility to be more sustainable and to realize its altruistic goals of providing net benefits (additional foods) for a protein-hungry planet. Whether the word sustainability has become overused or not, it has catalyzed a forum for oversight of the growth and development of sustainable aquaculture on a global scale. The challenges to aquaculture sustainability are numerous from the biological, environmental, economic, technological, engineering, regulatory, and societal perspectives. Appropriate species need to be selected based on their biology, growth, and harvesting technologies, all adapted to local environmental conditions. Cost-effective, safe, and full containment engineering innovations will be required. Growing multiple species in an ecosystem sense will require aquatic farmers to develop additional "skill sets" since multiple farming practices are oftentimes completely different activities. There is one view that high value markets will have to be found for these additional "janitorial" species to justify their culture. There are also issues with permitting and regulatory authorities and not so trivial opposition from coastal and riparian land owners.

Sustainable aquaculture will also have to incorporate at the outset, and not as an afterthought, planning for not only the sustainable production of aquatic foods but also for innovative participatory social processes, community development, and the wider social, economic, and environmental contexts of aquaculture at diverse scales, both large and small. To judge the sustainability of new models of ecological aquaculture will require the development and use of new, more comprehensive models for decision-making for the evaluation of aquaculture production, such as life cycle assessments, an ISO-standardized accounting framework that allows for multicriteria environmental and social performance assessments. Such comprehensive methods will help a new cadre of innovators see the opportunities to evolve the next generation of sustainable practices in aquaculture. With an increase in ecological innovations coming to aquaculture, a higher level of sustainable intensification could be achieved. Important flows of natural resources will be increasingly understood, measured, used, and allocated more efficiently globally, regionally, and locally, which could result in the reallocation of resources more consciously into the most efficient animal and plant production systems for humanity. Such a sustainable intensification of ecological aquaculture will be essential in order to maintain and preserve aquatic ecosystems while providing additional high-energy aquatic foods for people by 2050.

Pig Breeding for Increased Sustainability

Pieter W. Knap
PIC International Group, Schleswig, Germany

Article Outline

Glossary

Allele Allele is one of the several possible forms of the DNA sequence at a particular locus.

BLUP (best linear unbiased prediction) BLUP is a method to estimate breeding values by taking account of the pedigree relationships among the individuals instead of assuming uncorrelated residuals as in ordinary least squares methodology.

Corticosteroids Corticosteroids are steroid hormones such as cortisol, produced in the adrenal cortex. They are involved in energy metabolism, immune response, stress response, and many other functions.

Cryoconservation Cryoconservation is the conservation of living material by freezing.

Effective population size Effective population size is a measure of the genetic variability of a population. It is defined as the number of breeding individuals in a stable population with a 1:1 sex ratio, no overlapping generations, and random mating and reproduction, that would lead to the same rate of inbreeding as what occurs in the population under study.

Fitness constraint Fitness constraint is a reduction of the health and strength of an individual.

Microsatellite Microsatellite is a repeating sequence of a few DNA base pairs, highly variable and therefore used as molecular markers in genetic analyses. Typically neutral, i.e., not associated with functional genes. The alleles differ in terms of the number of repeats, so there can be many.

SNP (single nucleotide polymorphism) SNP is a mutation of a single DNA base pair at a specific locus, possibly in a functional gene. SNPs are used as molecular markers in genetic analyses. They usually carry two alleles.

Stereotypy Stereotypy is a repetitive, apparently purposeless, behavior such as pacing, rocking, chewing, and licking during psychological distress. This behavior is seen in captive animals, often caused by the lack of options to exercise *other* instinctive behavior patterns because their required substrate (e.g., space or companions) is not available.

Definition of the Subject

The sustainability of farm animal production depends largely on strategies for animal management, health care, and nutrition, and on strategies for processing and marketing the products (e.g., meat, eggs, milk, and manure). Strategies for animal *breeding* exploit genetic and reproductive technology to better match the next generation of production animals to what the market requires. Breeding creates gradual changes in the animal species, providing a way to support sustainable development: better match the next generation of production animals to what enhanced sustainability requires. The technological challenge is to consider the balance among the various sustainability elements (profitability, human nutrition, environmental load, resource management, animal welfare), and to design genetic strategies to support that balance.

Introduction

Gamborg and Sandøe [1, 2] write about "applying the notion of sustainability" in animal breeding. They first explain why this is relevant at all: "animal breeding [. . .] is a largely unnoticed, yet economically vital part of the agriculture and food sector. But despite remarkable advances in productivity [it has] negative impacts: for example, on animal health and welfare, and on genetic diversity. This raises the question of what limits

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

Originally published in
Robert A. Meyers (ed.) Encyclopedia of Sustainability Science and Technology, © 2012, DOI 10.1007/978-1-4419-0851-3

to acceptable practice we should set in this area." This is about societal regulation of industry practice: about a *license to breed*.

These authors notice that "discussions of sustainability may open up dialogue on ethical issues and [may] help to set an agenda," and describe projects where "breeders were required [...] to develop a definition of sustainable farm animal breeding [...]. They were asked to identify their key concerns and priorities, to characterize any resulting dilemmas, and to suggest ways towards a meaningful operationalization.

The [...] breeders [could describe and clarify] the concerns they considered relevant [...]. But they found it harder to identify the concerns they had chosen to *exclude* [...] Most difficult [...] was the prioritization of potentially conflicting concerns. Roughly speaking, there are two ways to overcome conflict here:

1. technological solutions, in which relevant conflict is resolved through technological changes in breeding practice
2. increased transparency, in which clear statements about the relative priorities [...] are essential."

The rest of the above text focuses on point (2).

By contrast, the present chapter deals mainly with point (1), focusing on pig breeding while borrowing from poultry and cattle breeding where relevant. Prioritization of the relevant, and potentially conflicting, concerns is indeed difficult, but essential in any concrete case. Such a prioritization cannot be attempted here, as it will always depend on that concrete case.

The classical "triple bottom line" of Elkington [3] is extended here with a fourth element, leading to the sustainability targets

People — Pigs — Planet — Profit

The possible contribution of the technology of pig breeding and genetics to two of these targets is discussed here: *Pigs* is about animal welfare, *Planet* deals with biodiversity and pollution.

People is about social justice, with little connection to pig breeding technology. A possible case would be biopiracy which is more a political and economic issue than a technological one, and more relevant in the plant breeding sector – but see [4] for a case study of the immigration of Meishan into western pig populations, a commercial failure due to unforeseen technological developments. Influencing *Profit* by pig breeding has been covered intensely since selection indexes were designed – there is no need to repeat that here.

It must be borne in mind throughout that "sustainability will always be a matter of more or less: it can never be an absolute goal" [2].

Biodiversity

FAO's *State of the world's animal genetic resources for food and agriculture* [5] mentions 140 known extinct and 599 non-extinct pig breeds. Of the 599, 90% are *local breeds* (LB, occurring in one country only) and 6% are *international transboundary breeds* (ITB). Of these 599 breeds, 22% are "at risk" based on population size: roughly, populations with less than 1,000 breeding females or 20 breeding males are considered to be at risk, genetic survival being endangered. The risk status of 38% of the breeds is unknown, 40% are "not at risk."

Livestock breeds become endangered in many ways. FAO [5] gives three categories: (1) emergencies: drought, flooding, earthquakes, famine, war; (2) epidemics and zoonosis eradication campaigns; (3) most important: livestock sector trends, described earlier [6–8] in terms of displacement by other breeds, indiscriminate crossbreeding with exotic germplasm, overfocus on a single trait, no sustained breeding program, changes in production systems or producer preferences, and technology development. To this can be added the reduction of demand for the breed's products – for pigs, since about 1950, such a product would typically be fat. Most pig breeds have evolved as an intrinsic part of a production system, catering for demands for particular products. When the production system (or the demand for its products) disappears, its associated breeds (e.g., lard-type pigs) will disappear with it – unless they find an alternative niche.

Extinction of a livestock breed can be undesirable for several reasons. A pressing one is (A) when it contributes to "maintaining the identity of human communities" [9], e.g., pigs in the South Pacific, or even more when the livelihood of a human group depends on it; this typically involves ruminant breeds. Simianer [10] gives two other categories: (B) "the insurance

argument": "genetic diversity can be seen as an insurance against future changes, [with] the objective [. . .] to maintain sufficient genetic diversity to be able to adapt to the challenges that are ahead" – bearing in mind that those challenges are increasingly unpredictable in times of global climatic change and intensifying global trade; and (C) cultural arguments: "farm animal breeds must be seen as a man-made good with a long history, often parallel with [human] cultural development [. . .] and therefore similar arguments for conservation apply as for other cultural assets [such as historical] buildings or artwork".

All these arguments call for genetic conservation, most pressingly with regard to category (A). With regard to category (C), the question is how to objectivize the cultural *value* of a livestock breed [11], which will be necessary when the costs of its conservation are being budgeted.

With regard to category (B), the main question is what kind of future challenges might require the breeding sector to exploit genetic material that previously has been unsatisfactory enough to become endangered; why [12] "preserve animals that farmers have abandoned"? The interest must then be in traits that were not important in mainstream breeding, e.g., meat quality traits (covering unexpected changes in consumer preferences) or robustness traits that facilitate adaptation to previously uncommon conditions, covering unexpected changes in options for health or climate control, or nutrition.

There is serious doubt among geneticists whether this insurance argument for breed conservation is realistic at all. To quote [13, 14], rearranged for consistency: "little use is made of conserved populations in mainstream commercial production of livestock; modern populations [. . .] are so far ahead of conserved strains in production traits, that adaptation of [the modern populations] offers far more opportunity than crossing back to far out of date stocks; even in countries where highly adapted breeds have evolved, typically these breeds are not perceived as having sufficient immediate utility to make them commercially viable; there are no present-day commercial animal-improvement companies or organizations that feel the need to invest in conservation as an insurance; the main perceived insurance benefit [. . .] is the conservation of adapted [sets of] alleles that are confined to one or a few breeds; there is [. . .] no reason to assume that there is [. . .] little variation in fitness associated traits in livestock populations simply due to selection; another important justification for conservation [. . .] is the value [. . .] for the increasingly powerful genomics analyses that have the potential to shed much light on the basic biology of adaptive traits; with moves towards genomic selection [. . .] the emphasis moves more towards best utilization of the large amounts of variation present in [. . .] commercial populations." Much earlier, Dempfle [15] wrote "only in very exceptional cases would a geneticist interested in improving [a leading] breed consider going to another breed to exploit interbreed variation, since most likely this would result in lowering of the mean. This is not likely to change very much, even with future technology."

Despite such skeptical points of view, endangered breed conservation is a current political commitment and an actively promoted reality, so it is valid to consider its technical issues.

Category (B) above centers around disappearance of (possibly) useful alleles – emphasizing within-species genetic diversity rather than particular breeds. From a technological point of view, in vitro cryoconservation would be adequate. So, allowing for the 38% "unknown" risk status breeds mentioned above, the technological challenge is to conserve the useful alleles carried by 130–360 pig breeds. Most of these are LBs.

Conservation of animal genetic resources is expensive, logistically complicated, and its worldwide funding is limited and fragmentary. Conservation of all genetic diversity is therefore not feasible and choices will have to be made with regard to funding the conservation of particular breeds, and not other ones: *global genetic resource management*. FAO [5] presents criteria (the breed's status, value, and potential for improvement) to support decision-making around conservation and genetic improvement actions, see Fig. 1. It holds several items where animal breeding and genetics technology can usefully contribute: (1) genetic distinctiveness; (2) population size and structure; (3) utility for food and agriculture, including adaptive traits. On a higher level, the balance between distinctiveness, risk status, and utility: (4) the ultimate priority level of the breed. Further elements are (5) target traits for genetic improvement and (6) genetic

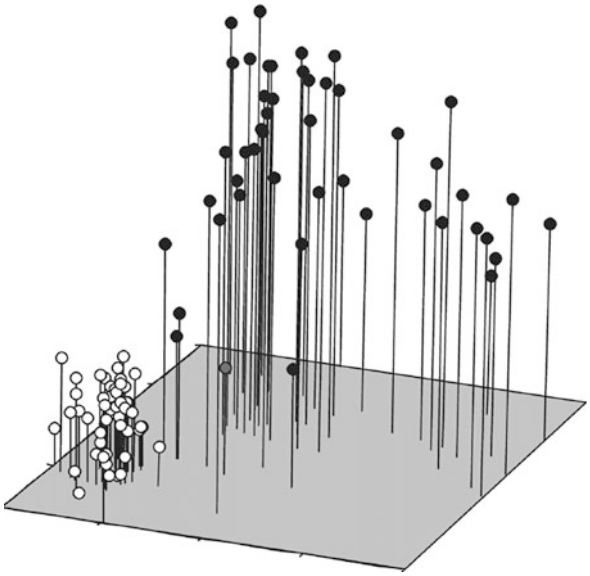
Information required to design strategies for global genetic resource management (Modified from [5])

improvement programs. Sections "Genetic Distinctiveness" to "Genetic Improvement Programs" deal with these items in this order.

Genetic Distinctiveness

Megens et al. [16] describe the genetic diversity among 46 Chinese and 51 European pig breeds. Microsatellite marker genotypes were converted to genetic distance estimates among breeds, which can be worked into phylogenetic trees (dendrograms) and other cluster representations; see [17] for background information about various techniques. The results of this analysis are in Fig. 2, which shows genetic distance estimates among these breeds through three-dimensional scaling. This reveals a marked difference between the Chinese breeds (strongly diverse in all three dimensions, falling apart into five geographic clusters) versus the European breeds which form a separate cluster, much tighter when compared on the same scale. The European dendrogram (not shown here) gives more detail, suggesting distinct groups of English and south-European LBs. The authors relate their results in beautiful detail to the domestication history of the breeds.

An earlier study of roughly these same European DNA samples [18, 19] measured the *allelic richness* of these breeds, in terms of the mean effective number of alleles per marker (2.3–3.5 in the ITBs, 1.9–4.0 in the LBs, for microsatellites), and the number of *private alleles* (found in one breed only) – zero to five, with an outlier at 15.



Pig Breeding for Increased Sustainability. Figure 2 Estimated genetic distances among 46 Chinese (*black circles*) and 51 European (*white circles*) pig breeds, and one Sino-European synthetic (*gray circle*). The genetic distance between two breeds is quantified here by the physical distance between their two circles (From [16])

Many similar analyses have been reported since 1995 ([20]; four Belgian breeds). Recent ones involve three Brazilian LBs, one ITB and an industrial synthetic [21], and twelve North and South American LBs, three ITBs, and three wild varieties [22].

Obviously, the accuracy of such analyses depends on the number of markers per breed. Alves et al. [23] show a diminishing-returns pattern for the accuracy of clustering six pig breeds and wild boar, as a function of numbers of microsatellites analyzed – with ~24 markers required for 95% overall clustering accuracy, and ~35 to cluster the "less divergent populations." The accuracy of clustering parameter estimates is commonly quantified by bootstrapping. Felsenstein [24] notices that such resampling techniques are particularly valuable when the function to be estimated (e.g., a dendrogram) is algebraically complicated so that its variance cannot be derived analytically. An example of analytical derivation is in [25] where the standard error of the genetic distance estimate was obtained from observed allele frequencies. Contrary to data-specific procedures such as the bootstrap, analytical forms allow for algebraic rearrangement of terms so that data volume and structure required for a particular accuracy level can be obtained – as done empirically in [23].

To support the decision-making process of Fig. 1, quantification of genetic distinctiveness of a breed must consider within-breed and between-breeds diversity. The breed's (possibly unique) alleles will be of future interest more likely (1) when it shows a clear genetic distance to other breeds in the between-breeds diversity as in Fig. 2, and (2) when it shows a larger within-breed diversity (carries a larger number of different alleles). Also, a successful breeding program will be easier to implement for breeds with larger within-breed diversity, see the section on "Genetic Improvement Programs". Therefore a breed's genetic distinctiveness should be quantified by some combination of (1) genetic distance to other breeds and (2) within-breed genetic variability. Their relative weighting will depend on the value of parameters such as the proportion of total diversity due to diversity between breeds (Wright's F_{ST}, estimated at <0.3 in the above studies, naturally dependent on the sample's breed composition); the "standard" approach [26] is to weight item (1) by F_{ST} and (2) by $(1 - F_{ST})$. It will also depend on strategic issues like the breed's intended purpose. For example, the between-breeds component would count more if the breed must play a role in a terminal crossbreeding program [27] and less if the breed must be merged into a synthetic for subsequent genetic improvement. Approaches are described, discussed, and/or illustrated by [28–31] and sources referenced therein. A practical suggestion [32] is "to consider how much diversity the breed adds to a core set constituted by commercial lines or breeds that are already subject to successful conservation."

All the above presumes a random approach: no specific traits are targeted and genetic diversity is valued as a neutral entity. Neutral markers like microsatellites are appropriate if future needs are indeed unknown: "since we need to maintain the genetic capacity to cope with challenges not even known today, this can be best accomplished by maintaining neutral genetic diversity" [10].

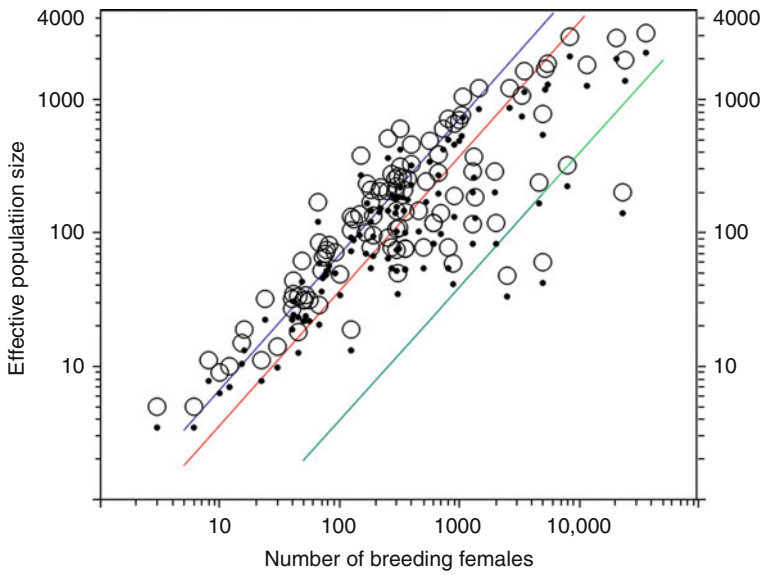
Nevertheless, some studies have deliberately used markers associated with specific traits. Ciobanu et al. [33] argue that "the relationship between variability at

neutral marker loci [. . .] and adaptation or individual fitness is still unclear" and "to characterize a breed not only in terms of genetic distance [. . .] but also in terms of variation at interesting loci associated with phenotypes, [. . .] will give more opportunity to elaborate an efficient strategy for conservation of breeds, maintaining their 'useful' genetic diversity and providing important resources for possible new unique traits." Likewise, half of the markers typed by Iannuccelli et al. [34] were SNPs "chosen for their position close to interesting QTLs." They mention that in addition to comparisons between breeds, they have "focused on the diversity within genomic regions containing genes that influence economically important traits, the variability of which is supposed to have evolved under the influence of artificial selection. [This has] allowed us to reveal regions where artificial selection favored certain alleles. For some SNPs where both alleles were found in all breeds, the frequencies were very different between breeds, suggesting different selection histories" (translated). A method to combine neutral diversity and diversity due to selection into a single criterion is presented in [35].

Population Size and Structure

There are three ways to estimate effective population size (N_e). Two make use of quantitative genetics theory [36].

First, from census counts of breeding males and females (N_m, N_f), typically through approximations developed for scenarios without selection, such as $N_e \approx 4\times(N_m\times N_f)/(N_m+N_f)$, possibly expanded with information on variation in family structures. This method has been applied to Romanian, Japanese, and Croatian pig breeds [37–39]. The European Farm Animal Biodiversity Information System (EFABIS; http://efabis.tzv.fal.de) holds data on livestock breeds, including N_e derived this way. Figure 3 shows its estimated N_e values for 111 pig breeds, in relation to their N_f values. These datapoints are not on a straight line because of variation in the (N_f/N_m) ratio; the reference lines indicate where N_f equals 5 (*top*), 10, or 100 (*bottom*) times N_m. Therefore, datapoints above the two highest reference lines represent situations with less than five (or ten) recorded breeding females per recorded breeding male – not very feasible scenarios in pig breeding,



Pig Breeding for Increased Sustainability. Figure 3
Reported numbers of breeding females (N_f) in 111 European pig breeds, and the associated N_e values from $4\times(N_m\times N_f)/(N_m+N_f)$; N_m is the number of breeding males. The reference lines indicate where N_f equals 5 (*top*), 10, or 100 (*bottom*) times N_m. Open circles, raw data; small dots, multiplied by 0.7 in an attempt to adjust for the effects of selection (Data from EFABIS, December 2009)

certainly at N_f values above 100. This only illustrates the difficulty of obtaining consistent census counts, and the limitations to deriving credible N_e estimates from them.

Second, through the rate of inbreeding (ΔF) as calculated from pedigree analysis, exploring the fact that $N_e = 1/(2\,\Delta F)$ under random mating. The main resource required here is a complete pedigree. This method has been applied to Japanese, American, German, and Finnish pig breeds [38, 40–42]. The approach can be taken an important step further by focusing on its across-breeds distribution characteristics [43].

A third approach makes use of molecular genetics technology, with various ways of analyzing marker data – for an overview see [44]. Álvarez et al. [45] analyzed the full pedigree of a small fragmented sheep population and genotyped microsatellites. They conclude that co-ancestry coefficients as estimated from pedigree data and from molecular data become rapidly correlated when pedigree depth increases, so that the expense of recording "molecular information in well established conservation programs may not be justified"; on the other hand, for small populations with a shallow pedigree "neither [pedigree] nor molecular information by themselves are sufficient [...]; each available parameter offers partial information."

For the correlation between pedigree-based and molecular measures of diversity "to be substantial, a considerable number of loci is required and, more importantly, a high variance of the [pedigree-based] inbreeding values should be present; [...] it should be preferable to use pedigree information whenever available, and limiting the use of markers to verify, correct, complete or even implement pedigree recording" [32].

Of course, in livestock breeds, deep and complete pedigrees are almost as scarce as dense DNA marker data, so "markers could be most useful in cases where little information on population history is available" [46]. Toro et al. [47] give a beautiful example of two LB varieties with complete 20-generation pedigree data, but these were maintained on an experimental farm – not a common situation.

Therefore, the molecular approach is widely seen as potentially more powerful than classical quantitative methods. Aspi et al. [48] write: "Owing to variation in family size and overlapping generations [...] N_e is [...] difficult to estimate from demographic field surveys. [...] Genetic methods may provide more effective ways for estimating N_e." They genotyped microsatellites and estimated N_e at ~40. Moreover, from those same data "large genetic variation was found in the population despite a recent demographic bottleneck. No spatial population subdivision was found, even though a significant negative relationship between genetic relatedness and geographic distance suggested isolation by distance." This is about a wolf population; similar quantification of N_e, demography, and subdivision would be very useful in livestock genetic resource management.

An effective population size of 40 would be regarded as dangerously low. Meuwissen [49] mentions a "critical effective size" (below which fitness steadily decreases) of 50–100, at least in populations not selected for traits negatively correlated to fitness. Ollivier et al. [50] transform N_e into the *extinction probability* P_{ext}, operationally defined as the expected level of inbreeding (accumulating deleterious mutations, which eventually leads to extinction) after 50 generations: $P_{ext} = 1 - e^{-50/(2N_e)}$. With a pig generation interval of 1 year, this goes back to [51] where risk of extinction is based on cumulative inbreeding over 50 years. The above $N_e = 40$ works out as a dangerous 46% probability that the population will not survive 50 generations. A slightly different approach is the *degree of endangerment* described by [52]. The relationships among P_{ext}, N_e, and ΔF are described in more detail in [53–55], at different levels of complication. The latter source also considers the estimate's accuracy, which will be useful once such estimates are to be used in practice.

Effective population size influences the extent of genetic drift, which affects the development of linkage disequilibrium (LD), i.e., the correlation between genotypes at different loci. Loci that are closer together are less often separated by recombination – so they are more strongly correlated, with higher LD values. In terms of data analysis of biallelic loci, the relevant relationships can be generalized [56] in terms of what is actually happening (due to N_e) and of what can be observed (due to sample size) as

$$E(r^2) \approx \frac{1}{\alpha + kcN_e} + \frac{1}{n} \qquad (1)$$

$E(r^2)$ is the expectation of the square of the abovementioned correlation, a common parameter to

quantify LD. Parameter α equals 1 in the absence of mutation, and 2 if mutation is accounted for; k equals 4 for autosomes, and 2 for the X chromosome; c is the recombination rate between the markers being analyzed (their genetic distance from each other, in Morgan); n is sample size.

For an analysis of many autosomal markers, ignoring mutation, this works out as

$$N_e \approx \frac{1-r^2}{4cr^2} + \frac{1}{4cr^2(nr^2-1)} \quad (2)$$

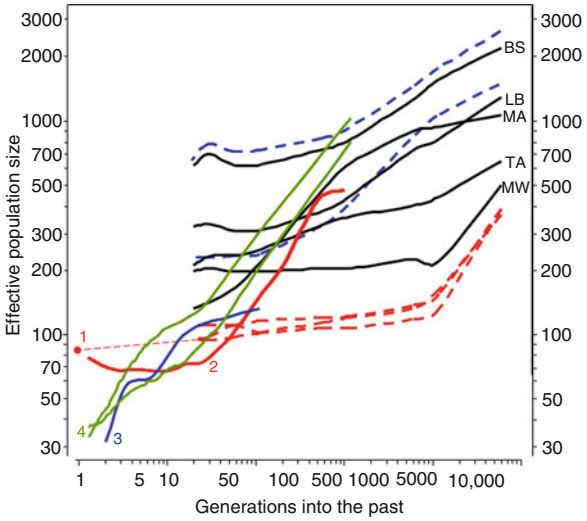
Hayes et al. [57] introduced *chromosome segment homozygosity* (CSH), an alternative parameter to r^2 for quantifying LD. CSH has a smaller sampling variance than r^2, but the same approximate expectation (Eq. 1). When population size changes linearly over time, the effective population size of 1/(2 c) generations ago can be approximated as (1 – CSH)/(4 c CSH), the same form as Eq. 2 when n is large.

Accordingly, when many individuals are genotyped for many biallelec DNA markers varying widely in their mutual distance c, then the (supposedly linear) history of N_e can be traced by plotting $\frac{1-CSH}{4cCSH}$ against $\frac{1}{2c}$.

Amaral et al. [58] estimated LD decay (reduction of r^2 with increasing c) on SNP markers in ten European and ten Chinese pig breeds (subsets of the breeds in Fig. 1). Figure 4 shows those data reworked into Hayes's relationship, using r^2 instead of CSH, for the European breeds ($N_e \geq 10{,}000$ for the Chinese breeds). Comparable data on commercial pig lines [59, 60, 226] has been added.

Figure 4 illustrates that this method can reveal interesting information about a population's demography. Such information would be most relevant to livestock genetic resource management when it covers recent generations, as [59, 60, 226] do. This requires large c values: from the equation above, the situation of two and five generations ago is represented by LD among markers 0.25 and 0.10 Morgan apart. The maximum distance between Amaral's markers was 0.03 Morgan.

This methodology is statistically demanding. England et al. [61] report on "simulations to show that [the most widely used LD] estimator is strongly biased when sample size is small [...] and below true N_e. This is probably due to [LD] generated by the sampling process itself." They also proposed



Pig Breeding for Increased Sustainability. Figure 4
Time trends in effective population size for 14 European pig breeds, estimated from linkage disequilibrium decay patterns according to [57]. Blue dashed line, transboundary breeds; black solid line, local breeds (British Saddleback, Large Black, Tamworth, Middle White, Mangalica); Others, commercial lines: "1" from [67]; "2" from [59]; "3" from [60]; "4" from [226] (All other data from [58])

"a way to determine whether a given sample size exceeds population N_e and can therefore be used for computation of an unbiased estimate." Waples [62] confirmed this by describing how Eq. 1 above is inappropriate for low values of n and N_e, particularly when $n < N_e$.

The accuracy of the N_e estimator of Eq. 2 depends not only on the numbers of individuals and markers involved, but also on N_e and c. Based on [44], for a system with n individuals genotyped for m pairs of markers, each with a within-pair distance of c Morgan, an approximation of the standard error of estimated N_e is

$$\mathrm{stderr}(N_e) \approx \left(N_e + \frac{2c(2-c)}{(1-c)^2+c^2} \times \frac{N_e^2}{n} \right) \times \sqrt{\frac{2}{m}} \quad (3)$$

From this equation, estimates of $N_e = 100$ or $N_e = 200$ for five generations into the past (c = 0.1 Morgan) would require n = 100 individuals genotyped for

m = 400 or m = 750 marker pairs to achieve a standard error of 10% of the estimate (i.e., 100 ± 10 or 200 ± 20). Similar accuracies for one generation into the past (c = 0.5 Morgan) would require m = 3,000 or m = 10,000 marker pairs. N_e estimates for more recent situations require more data for a given proportional accuracy. However, high accuracies (low standard errors) are easier achieved for lower N_e levels – often the more interesting ones from a resource management point of view.

Other molecular approaches to estimate N_e trace changes in allele frequencies over time (the *temporal* method), or derive (small) population size from (large) sampling errors of observed heterozygote proportions deviated from Hardy–Weinberg proportions (the *heterozygote excess* method). Schwartz et al. [63] give a review; further developments are described in [64–66]. The latter paper introduces the immigration rate into the equation – a useful issue in livestock scenarios with their common introgression of extraneous germplasm. Abdallah et al. [67] also take immigration into account when analyzing 12 of the breeds of Fig. 2. One of these was also analyzed by Amaral [58]; Fig. 4 gives Abdallah's estimate as the end point of the Hayes approach to Amaral's data.

Relative Utility

Comparisons of pig lines are difficult to organize and expensive to run: (semi)-governmental versions of such tests have run for several decades as *commercial product evaluation* in western Europe, focusing on growth and carcass traits. Reproductive traits are sometimes included by across-farm analysis of routine field data, with its inevitable and unpredictable bias. Robustness traits are very rarely included, not surprisingly given the demanding nature of categorical trait analysis. Such a test was designed [68] for growth and carcass traits to detect differences between genotypes of 0.25 trait standard deviations at 95% significance, with a statistical power of 75%; this led to a scheme with, on average, 67 sires per genotype, 2.6 litters per sire, and 1.8 tested pigs per litter. Subsequent tests also covered reproduction and longevity traits; these schemes specify 65 sires, 3 litters per sire, and 2.7 tested daughters per litter [69]. The statistical significance of breed differences must be tested against the variation among sires within breed, which requires inconvenient sampling schemes.

Gibson et al. [70] (condensed here) discuss characterization for production and robustness traits: this can only be genetically meaningful when the production environment is properly accounted for; environmental factors are so complex that records from different locations or times cannot be validly compared; valid breed comparisons are possible, first, when breeds are recorded simultaneously at the same location under identical management [as in the previous paragraph]; second, through meta-analyses linking records from different locations or times through overlapping breeds, statistically adjusting for environmental effects; such meta-analyses are powerful, but only valid when genotype×environment interactions are negligible (as in controlled confinement conditions); it will remain problematic that lifetime productivity traits are extremely difficult to record.

These authors stress that the functionality of information systems "must be greatly increased to allow extraction and customized analysis of phenotype and molecular genetic data within and between data sources; [. . .] breed information can be linked to [. . .] environment and production system mapping, allowing [. . .] disease resistance and adaptation traits to be predicted from past and current breed distribution and use." They conclude that "these are substantial but fully achievable functions."

Tixier-Boichard et al. [46] emphasize characterization for robustness: "local breeds survive in harsh environments and this needs to be better understood; epidemics are major threats for all animal genetic resources across the world; climatic change is likely to increase the spread of tropical diseases to temperate areas. [Scientific evidence] that local breeds are adapted and resistant [. . .] has been obtained in several instances [. . .], well documented for parasitic diseases [. . .], with local breeds maintaining a better performance in the presence of parasites and/or exhibiting lower levels of parasite infestation [tolerance]". These authors take a utilitarian position: "data on production systems, phenotypes and molecular markers should be used altogether in an integrated approach to characterization. [. . .] Decisions regarding conservation should incorporate all descriptors. Conserving without documenting would be useless."

In summary, a livestock breed's direct-use utility value should be assessed in terms of production traits and robustness traits like disease resistance/tolerance, adaptation to unfavorable conditions, and lifetime productivity. This assessment must use any available phenotypic and molecular data (the latter element comes back to the work of Ciobanu [33] and Iannuccelli [34], section "Genetic Distinctiveness"). All this will require extensive information systems, difficult to achieve but not impossible. Without such functionality, utility-directed breed conservation is not feasible.

Of course, phenotypic and molecular characterization can only focus on known characteristics. The main drawback is that the traits of true future interest (covering unexpected changes in consumer preferences, or in options for health or climate control or nutrition) cannot, by definition, be defined or measured. This makes it difficult to combine the utility issue with the insurance argument for conservation: it calls for option values. Viral diseases (e.g., PRRS, PMWS, influenza) are expected to break out on a wide scale every few years [71, 72], and any breed that happens to carry full resistance would suddenly have a very high utility value. This would require fast and widespread testing, and challenging logistics to distribute the relevant alleles throughout the worldwide pig industry – which may well become feasible with further development of genomics and reproductive technologies. But that particular breed's utility is likely to drop dramatically again, as soon as the next outbreak (of a different virus) occurs.

Urgency, Importance, and Feasibility: Priority Level of the Breed

To quote Wikipedia, Covey et al. [73] introduced "a framework for prioritizing work that is aimed at long-term goals, at the expense of tasks that appear to be urgent but are in fact less important." This is about time management, but the same is relevant in global genetic resource management. Sections "Genetic Distinctiveness" to "Relative Utility" describe different features that might make a livestock breed a candidate for conservation – but limited funding requires prioritization. Obviously, highest conservation priority should be given to breeds that (1) have a great utility, (2) are strongly distinct from other breeds with much within-breed variation, and (3) are strongly endangered due to inadequate population size or structure. Items (1) and (2) are about *importance*; item (3) is about *urgency*. This requires integration of these issues, preferably quantitatively so that priority levels can be ranked and funding allocated. Another element to include is then (4) the cost of conservation – introducing the issue of *feasibility*: "identified benefits could be quantified so that society has some sense of how much the conservation is worth. Society can then determine how much they would want to spend on a conservation effort" [74].

A comprehensive way to deal with the above elements [75] defines the genetic distinctiveness of a breed (calculated with the relevant emphasis on between-breeds and within-breed diversity) as D, its utility value (for all relevant purposes) as U, recalls its extinction probability P_{ext} (based on its N_e and possibly on additional parameters) and defines the cost of reducing it (through any relevant conservation action) by ΔP_{ext} units as C. Then the priority ranking R for such a conservation action would simply be

$$R = \frac{(D + U) \times \Delta P_{ext}}{C} \quad (4)$$

This would be calculated for every breed in the conservation portfolio, assuming that all their D, U, P_{ext}, and C values can be directly compared – which requires D and U to be expressed in the same unit, and everything to be calculated using the same algorithm and parameter definitions across breeds. Breeds with higher R values get a higher priority for conservation – because their conservation is more important (D, U), more urgent (P_{ext}), and/or more feasible (C). The probability P_{ext} takes values from 0 to 1, and ΔP_{ext} from 0 to P_{ext}: reducing the extinction probability by its full value (i.e., $\Delta P_{ext} = P_{ext}$) comes down to safeguarding the breed entirely.

These authors notice that the costs of the most complicated in vivo, in situ conservation schemes would likely be proportional to conservation effort, i.e., $\Delta P_{ext}/C$ is roughly constant and ranking is based on D and U. By contrast, the costs of the simplest in vitro cryoconservation schemes might vary only little, i.e., C is roughly constant and ranking for complete safeguarding is based on the *cryoconservation potential* $(D+U) \times P_{ext}$. Real-life conservation programs would fall between these extremes.

Simianer et al. [76] compared three forms of the actual relationship between C and ΔP_{ext}, applied these to a set of breeds characterized in terms of genetic distances and extinction probabilities, and found that "conservation funds should be spent on only three to nine of the 23 breeds, depending on the model used." This approach was further formalized [77] into a comparison of *maximum-risk*, *maximum-diversity*, and *maximum-utility* strategies to determine the optimum set of breeds to conserve, which favors the latter strategy which combines diversity and utility – although it obviously requires the quantification of U, which makes it difficult to implement in practice. The latter two approaches quantify the *expected conserved diversity* or the *expected conserved utility* of possible sets of breeds that may be successfully conserved at some point in the future, and then calculate the *marginal diversity* or *marginal utility* of each breed by differentiating with respect to the breed's P_{ext}. These are then multiplied by P_{ext} to obtain the breed's conservation potential, similar to the term $(D+U)\times P_{ext}$ of Eq. 4.

As argued at the end of the section on "Relative Utility," utility is the weakest element here: conservation aims at the future, and future utility cannot be predicted. All the other elements can in principle be dealt with by a complete pedigree and/or dense DNA samples from ~100 individuals. One of the options would be to drop U from the equation and rank conservation priorities on D only (the *maximum-diversity* option of above). This reasoning is taken to its logical extreme by suggesting to "devote the majority of present conservation budgets to freezing [...] samples from existing breeds [...] concentrate on ova and sperm from abattoir material, and somatic cells, e.g., ear clips (the latter in anticipation of the increasing effectiveness of somatic cloning)," because future "genomic tools will open up completely novel means of exploiting genetic resources" [14]. In line with this, the USA has "invested in the establishment of an in vitro conservation program and a genebank [covering 18 local pig breeds and one ITB at the time of reporting]. Collections are being built up very quickly, in close collaboration with the industry. Breeding companies use the genebank as a backup of their breeding work. In Canada, a program for in vitro conservation [...] will be implemented in the near future" [5], as later documented by www.ushrl.saa.ars.usda.gov/SP2UserFiles/Place/54020500/documents/update%208-10-02.pdf and dsp-psd.pwgsc.gc.ca/collection_2008/agr/A52-88-2008E.pdf.

Target Traits for Genetic Improvement

Livestock breed improvement requires a breeding goal and a selection strategy best suited to the needs of the production system and the market that it supplies – this is one of the elements of *population-level genetic resource management*. Animal breeding technology has a long tradition in this field, but improvement of an endangered breed may require substantially different goals and strategies than in mainstream industry breeding programs. FAO [5] write: "the most appropriate strategies for managing these breeds may involve only limited genetic change [...] to maintain adaptation to the local environment and disease challenges, and [...] to maintain the level of a production trait [...] if this is currently [near] an optimum level." Of course, the insurance argument for breed conservation assumes that the breed may, at some time, support a different production system than its original one, because it happens to carry alleles (likely adaptive ones) of large utility, then and there. This adaptive utility must be balanced with production utility, which will likely be much lower than in commercial lines. The actual uptake of the breed as a source of adaptive alleles will be much easier when the production-related lag is limited. So for the insurance argument, genetic improvement of production traits is desirable – but not at the expense of adaptive quality: possible genetic antagonisms between production traits and anything else require specific attention. "The genetic basis of population differentiation for fitness traits will be non-additive, with different adaptive gene complexes evolved in each breed. Genetic improvement programs therefore should start with an adapted population, with selection then for production traits" [78].

Another argument in favor of improvement of production traits is that many endangered breeds are endangered precisely because they lag behind other breeds in terms of production traits. The common idea that improvement of production traits inevitably leads to a reduction of robustness is false – it just requires a sensible breeding program, see the section on "Robustness."

Genetic Improvement Programs

As argued above, any livestock breed with a future must support an agricultural production system. Rege [79] writes: "the most rational and sustainable way to conserve animal genetic resources is to ensure that indigenous breeds remain functional parts of production systems, that is, *conservation through use*. This is possible only if economically important attributes of indigenous breeds are identified, studied and incorporated in breed improvement programmes." Genetic improvement will always be required – unless the production system is completely static, without any interactions with the world around it. A useful concrete example is from [80]: "during the past few years the Limousin pig, endangered and neglected during the 1970s and 1980s in favor of the better-performing large breeds, has become popular with consumers looking for quality. Today it is victim to its own success with supply being lower than demand, so that it has become necessary to develop its productivity" (translated).

This requires a breeding goal and a selection strategy best suited to the needs of the production system and the market that it supplies, as discussed in the Section on "Target Traits for Genetic Improvement." A checklist of items that play a role here, from definition of the product and the market to evaluation of the breeding program's profitability, is in [81].

The breed also has to be *maintained* – preserving as much of its genetic variation as is feasible. And its qualities must be *exploited* in an optimal way, making efficient use of other resources.

Livestock breed *maintenance* requires strategies and tools to keep N_e sufficiently high. This comes down to keeping inbreeding under control, usually by minimizing co-ancestry in the breeding population. There is a possible antagonism with the previous point: selection in a population reduces N_e, so a balance will have to be found and maintained. There are many rules-of-thumb to delay inbreeding (e.g., *keep one son from every sire* or *maximize generation intervals*); an example of implementation in commercial lines is in [82]. Many of these rules perform well on the short term but have unexpected long-term effects, and they usually reduce genetic improvement unpredictably, leading to uncertain genetic resource management. N_e can be affected by age at first breeding and culling policy in quite counterintuitive ways [83], so that "the general tendency is contrary to the expectation that [N_e] would increase with increasing [longevity]." High longevity increases generation length but reduces genetic drift; the combined effect favors a short productive lifetime, so that N_e can actually be increased by early culling.

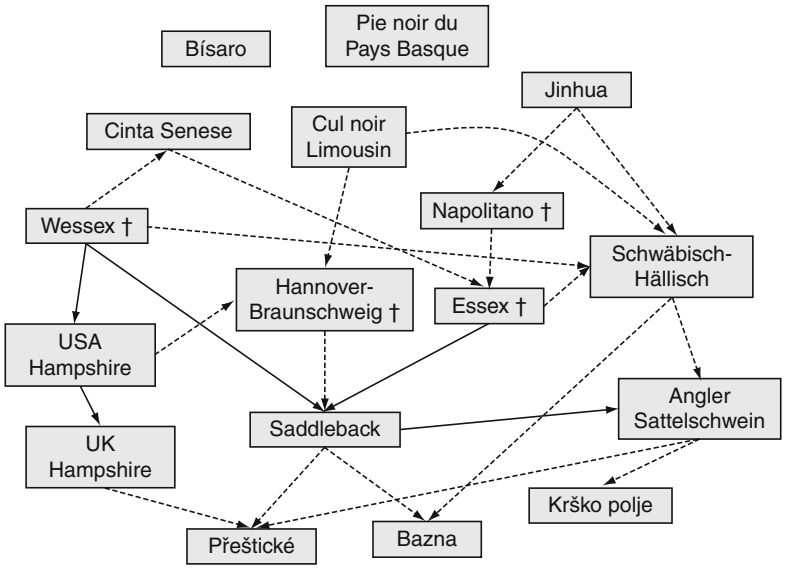
A better solution is to apply co-ancestry management and mate selection based on optimum contribution theory or similar frameworks. The principles are covered in detail in [49, 84, 85]. The latter source's *mate selection index* (MSI) is an optimized criterion, based on an objective function such as [86]:

$$\mathrm{MSI} = \mathrm{EBV} - \lambda_1 \mathbf{x}' \mathbf{A}\mathbf{x} - \lambda_2 \overline{F} \qquad (5)$$

Here, (1) EBV holds estimated breeding values; (2) $\mathbf{x}' \mathbf{A}\mathbf{x}$ represents average co-ancestry in the system: A holds the additive relationships among all animals, weighted by their contributions x (numbers of progeny) to the next generation; (3) $\overline{F}$ is their average inbreeding coefficient, calculated from A; λ_1 and λ_2 are positive weighting factors. This is a cost-benefit equation, with element (1) representing the benefit and (2) and (3) representing the (genetic) cost: EBV, A, and $\overline{F}$ are known, so the system can be solved to deliver the contributions x that give the best (genetic) cost-benefit for particular values of λ_1 and λ_2. The result of this is a list, based on x, with animals to select and animals to mate to each other (the optimum selections and optimum matings that lead to optimum contributions).

Proper genetic resource management can lift populations much smaller than the FAO threshold of 1,000 breeding females to the "not at risk" level. Many industrial pig lines are maintained at far less than that population size (e.g., see Fig. 4) with a secure genetic future. Careful immigration and admixture is regular practice in the breeding industry, but it is often avoided by breed societies and similar structures for chauvinistic reasons.

For example, Fig. 5 shows an intensive network of historical genetic connections among the European black-belted and saddled pig breeds, with a genetically useful loop with Hampshire (an ITB). Many of these populations have a herd size far lower than 1,000 sows, and most of those focus on the same set of



Pig Breeding for Increased Sustainability. Figure 5
Genetic connections from ~1,770 (Jinhua) to present, among black-belted and saddled pig breeds. Consecutive series of arrows do not imply any chronological development. Solid arrows represent the main source of a breed; dashed arrows imply the existence of other sources not included here. (Data from [16, 37, 222–225]; Lenoir H, 2010, IFIP Institute du Porc, Le Rheu, France, Personal communication; www.elbarn.org; www.besh.de; efabis.tzv.fal.de; dad-training.fao.org/cgi-bin/EfabisWeb.cgi; www.thepigsite.com/info/swinebreeds.php)

characteristics (meat quality and robustness, and of course coat color) when describing their distinctiveness in the associated Web sites. This would suggest a clear case for the quantification of the various elements of Eq. 4 above, followed by regular and careful genetic exchange to make resource management easier.

Exploitation: A common negative term in the literature on genetic resource management is *indiscriminate crossbreeding*. For example, "very often, crossbreeding has been indiscriminate and the local breeds that underpin the crossbreeding program have been lost because of a lack of understanding [...] that these pure breeds must be maintained to support the system" [87]. This is clearly a management issue. On the other hand, these authors mention systems where crossbreeding is "used for gradual breed replacement with [...] the controlled [...] formation of composites [...] for specific production systems," as "a rapid method of introducing desirable traits into local well-adapted breeds," and "as a way out of a narrowed genetic base in commercial breeds." The logical way of making use of exotic germplasm without any risk of endangering the LBs is "structured cross-breeding systems, such as 'terminal crossing' where [F_1] animals are slaughtered or where specialized crossbred dam lines are used." Pig examples are from Germany where Angler Sattelschwein, Schwäbisch-Hällisch, and Bunte Bentheimer are crossed with Pietrain; and from Spain where various Iberico strains are crossed with Duroc, all to optimize meat quality versus meat quantity in the terminal F_1 product.

This chapter is about science and technology. But "logistics, not science, is the underpinning of a successful breeding policy. Without a system for handling the details of livestock identification, classification and movement, the science is of little avail" [88]. This certainly holds for endangered populations, typically managed by fragmented groups of independent-thinking people. Nimbkar et al. [87] stress the importance of "structures to organize the keepers of animals and help motivate communal efforts [...] allowing livestock keepers better access to information, [...] extension services, facilitating the organization of training, and improving [...] marketing. In Europe,

there are strong farmer cooperatives and breeding organizations that go back a century." Indeed, successful breeding programs were founded on equally fragmented conditions in many European countries and also in Canada, starting out with breeds with similar production performance as the ones from that same area that are now endangered or extinct. Apart from the clear need for incentive and for institutional backing, there are two prerequisites for such development. First, technically: an efficient system for ensuring genetic connections among farms, e.g., through regular exchange of males or across-farm AI – everything else of a technical nature will have to build upon that. Second, organizationally [89]: employment of professional genetic expertise by the breeders' organization – so that the system does not have to rely on fragmented and unstable governmental service, and can arrange for effective feedback between breeders' objectives and technological options.

Pollution

FAO's *Livestock's long shadow: environmental issues and options* report [90] gives an overview of the amount of nitrous oxide (N_2O) released from livestock manure and urine, worldwide, in 2004. Of the total emission of 3.69×10^9 kg, 12% was due to pigs – just over half of that from Asia. N_2O is an effective greenhouse gas (GHG), also involved in the depletion of the ozone layer. Other nitrogen compounds that enter the environment from livestock excreta are ammonia (NH_3) and nitrogen oxides (NO and NO_2), involved in acidification or, indirectly, in global warming.

Technology

The FAO report [90] devotes much text to options for reduction of nitrogen emission, most of which involve manure management and improved animal nutrition. For example (p. 122): "An important mitigation pathway lies in raising the low animal nitrogen assimilation efficiency [...] through more balanced feeding (i.e., by optimizing proteins or amino acids to match the exact requirements of individual animals or animal groups). Improved feeding practices also include [...] improving the feed conversion ratio [FCR] by tailoring feed to physiological requirements. However, even when good management practices are used to minimize nitrogen excretion, large quantities still remain in the manure." This is quantified in another table in the report (p. 137) with typical values for nitrogen intake, retention, and excretion in cattle, pigs, and poultry. According to these numbers (which go back to [91]), across these species, only about 19% of nitrogen ingested in "less productive situations" is retained in meat, eggs, and/or milk – in "highly productive situations," this goes up to 30%. Likewise nitrogen retention rates (N_{ret}) of about 34% for pigs were reported for the 1995 "highly productive situations" of France, Denmark, and the Netherlands [92].

These retention rates are indeed low, but the difference between the above productivity levels is considerable, suggesting scope for increase by "improved feeding practices". Dourmad et al. [93] state that "the ultimate reduction of N excretion can be reached when multi-phase feeding is combined with a perfect balance of essential amino acids and [...] optimization of the supply of non-essential amino acids" – ideally on a daily basis. They refer to a 1995 experiment [94] where the use of a single diet over a growing period from 26 to 101 kg body weight was compared to such an optimized multiphase feeding strategy, and where N_{ret} values at 34% (single diet) and 50% (optimized regime) of the ingested nitrogen were found.

Later studies in laboratory conditions have achieved higher retention rates. De Lange et al. [95] studied the effect of dietary amino acid levels on protein deposition rate in pigs from 39 to 77 kg liveweight, and present results that lead to $N_{ret} = 61\%$ at complete amino acid availability – "at a more typical protein digestibility, this would become 56%" (cf. de Lange, personal communication, 2010). Similarly, Buraczewska et al. [96] measured N_{ret} of up to 57% in 35-kg and 45-kg pigs of a "high lean gain potential" genotype, after optimization of the dietary amino acid composition. In more practical conditions, Pomar et al. [97] fed pigs from 25 to 105 kg liveweight according to a "traditional three-phase feeding program" or with "individually tailored diets," obtaining $N_{ret} = 37\%$ and 48%, respectively.

Curiously, the FAO report [90] pays no attention to a logical alternative to "improving [FCR] by tailoring feed to physiological requirements," i.e., improving it by tailoring these physiological requirements

themselves, through animal breeding [98]. When nitrogen excretion data of growing (Landrace × Large White) and (Hampshire × Duroc) pigs were adjusted for body weight and feed intake, significantly different values were obtained between the genotypes – which reveals genetic variation so that "genetic selection may be an effective method for altering nutrient utilization and output" [98]. Heritabilities for laying-hen excretion traits such as dry excreta weight, excreta humidity rate, and the ratios of dry excreta and nitrogen excreta to feed intake (0.25–0.46) and for dairy cow methane production (0.12) were reported in [99, 100].

Improvement of traits like litter size, sow feed intake, growth rate, and FCR reduces nitrogen excretion (N_{excr}) from sows and growing pigs [101]. The 1988–2007 genetic trends for growth rate (+8.5 g/day/year), FCR (−0.02 kg/kg/year), and litter size (0.16 pigs/litter/year) in the UK pig sector were estimated to cause 0.8% annual reduction of the associated global warming potential of GHG emission [102]. In that study, the genetic reduction of FCR explains about 70% of the reduction in N_2O emission; the genetic increase of growth rate explains about 70% of the reduction in NH_3 and methane emission. The genetic increase of litter size (which reduces the sow herd with its emission, for a fixed number of slaughter pigs) explains about 20% of all three elements. The future scope for emission reduction is underestimated in that study, for two reasons. First: genetic trend of lean content (which was substantial in the UK during this period, probably about 0.5%/year) was not taken into account. Second: future trends in all these traits may be expected to be stronger than the historic values, due to further development of genetic technology and of the "uptake rate of improved genetics by the commercial level" [102].

The reduction of N_{excr} due to genetic improvement of production traits is quantified by the simulation results in Fig. 6, obtained with the model of [103]. The time trends of model parameters such as maximum protein deposition rate (PD_{max}) that were described for six pig sire lines [104] can be used to model N_{ret} and N_{excr} at the nucleus level throughout the 1969–2004 period. The simulations involve these six progressively advanced genotypes, grown from 20 to 120 kg body weight. Each of these genotypes was fed ad libitum on each of seven three-phase (20–50, 50–80, and 80–120 kg) diet specifications, targeting overall lean tissue growth rates (LTGR) from 275 to 425 g/day in steps of 25 g/day [105]. This involves diets with a fixed digestible energy content (DE = 14.2 MJ/kg) and varying levels of crude protein (e.g., from 12.2% to 15.5% in phase 3) and essential amino acids (e.g., lysine from 0.525 to 0.765% in the diet, ditto).

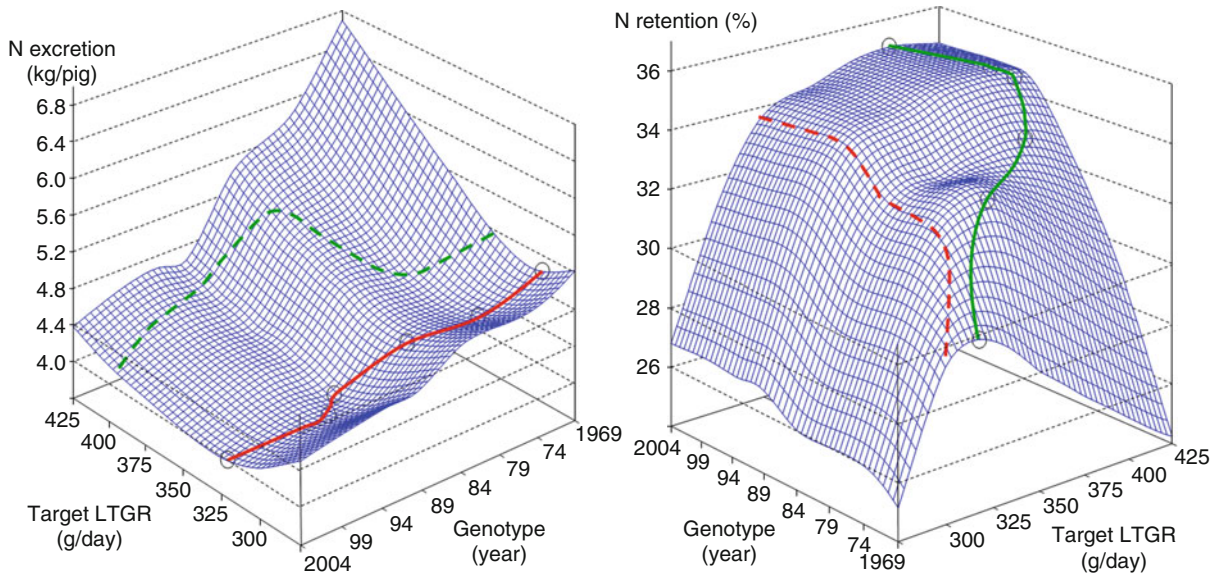
The older genotypes in this simulation do not have the potential to achieve the higher LTGR targets, with the consequence of low N_{ret} and high N_{excr} levels. Low LTGR targets obviously lead to low N_{ret} as well, more so in the older genotypes. Figure 6 shows clear optimum trajectories across genotypes and feeding strategies, for both N_{ret} and N_{excr}. It also shows that these optimum trajectories follow different paths for both characteristics, particularly in the more advanced genotypes.

Along these optimum trajectories (i.e., when fed to achieve maximum N_{ret}, or minimum N_{excr}, within the limits of the three-phase feeding program) the 2004 genotype shows a proportionally 19% higher N_{ret} or, alternatively, a 20% lower N_{excr} than the 1969 genotype. Deviations from these optimum diet composition settings have much stronger effects in the older genotypes than in the more advanced ones.

The more advanced genotypes in this simulation show a clear diminishing-returns pattern for N_{ret} with a very flat asymptote around N_{ret} = 35%. But the simulated PD_{max} levels (i.e., genetic potential for N_{ret}) increase progressively throughout the 1969–2004 period covered here – so the expression of that potential must be constrained by the three-phase fixed-diet program employed here. This comes back to the real-life results of Pomar et al. ([97]; above) who obtained N_{ret} = 37% with a three-phase fixed-diet program and N_{ret} = 48% with "individually tailored diets." The latter strategy involved a daily analysis of the performance-to-date of each pig, to predict today's individual body weight, growth rate, nutrient requirements, and ad libitum feed intake. Each pig was then fed a mixture of basic rations via automated feeders to match these predictions.

It follows that the more advanced genotypes require more advanced feeding strategies to bring their more sustainable performance potential to expression.

This was further explored by Morel and Wood [106], who used simulation modeling to quantify nitrogen flux in growing pigs of low, medium, and



Pig Breeding for Increased Sustainability. Figure 6

Nitrogen excretion (*left*) and retention rate (*right*) in simulated growing pigs of six genotypes (representing sire lines from 1969, 1976, 1984, 1990, 1993, and 2004; From [104]). Each genotype was fed from 20 to 120 kg liveweight on three-phase diet specifications targeting [275, 300,. . .,400, 425] g/day lean tissue growth rate (LTGR), according to [105] – the higher LTGR targets are beyond the potential of the older genotypes, and the more advanced genotypes do not realize their potential due to inadequate nutrient supply. The blue response surfaces are spline interpolation plots through the 6×7=42 simulated datapoints. The red and green trend lines represent minimum excretion and maximum retention, respectively, for each genotype. Each broken trend line mirrors the solid one of the same color (with its datapoints as black circles) in the other graph, approximately

high LTGR genotypes, on a variety of dietary regimes. Their simulated high LTGR genotype achieved N_{ret} = 57% when fed daily individually tailored diets (similar to Pomar et al.'s [97] diets mentioned above) with a strong focus on the minimization of N_{excr}. By contrast, the simulated low LTGR genotype achieved N_{ret} = 29% on a three-phase fixed-diet program with all focus on gross margin (i.e., carcass return minus feed costs). So the various N_{ret} results of these simulations (see Fig. 7) span the relevant range of commercial and high-tech conditions described above.

These authors conclude that although "a reduction in nitrogen excretion is mainly achieved through a reduction in nitrogen intake" (as in Fig. 6), "genotypes with a high lean growth potential can be more profitable [in terms of gross margin] *and* have improved nitrogen excretion." A simple ANOVA of their results of gross margin and N_{ret} across the simulated scenarios (supplementary data from Morel PCH, 2010, personal communication) quantifies this. The low versus high LTGR genotypes show least-square means for simulated gross margin at 102.0 versus 150.0 CHF per pig, and for N_{ret} at 34.1% versus 46.8%, respectively. Their "three-phase fixed-diet" versus "individually tailored" feeding regimes show least-square means for gross margin at 116.3 versus 138.6 CHF, and for N_{ret} at 36.7% versus 45.0%, respectively. So Morel's genetic scenarios [106] are *more* effective (because further apart) than his feeding regimes, for improving both gross margin and N_{ret}. With some generalization, this can be put into perspective as follows.

With the 1969–2004 trend of PD_{max} in pig sire lines from [104] (above), the PD_{max} input values of Morel's simulated genotypes (120, 160, and 200 g/day) can be located in time at 1970, 1987, and 1997, respectively – so his low and high LTGR genotypes are 27 years of sire line genetic improvement apart. The simulated gross

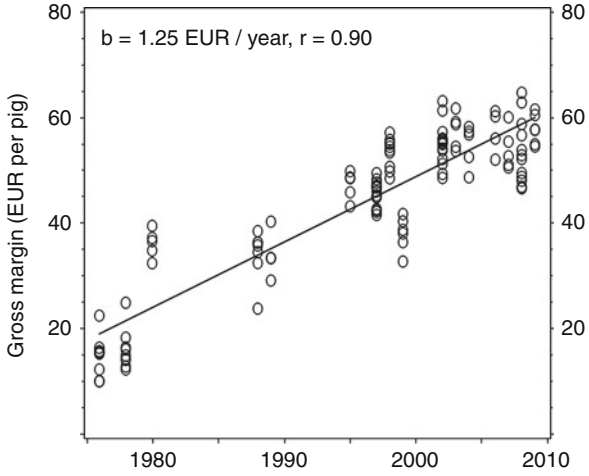
Gross margin (from growth rate, backfat depth, and feed intake) in relation to nitrogen retention rate (N_{ret}) in simulated growing pigs of three genotypes (low, medium, and high lean tissue growth rate), fed three-phase fixed diets or individually tailored rations. The labels "0" and "120" indicate the extremes of a range of weighting [N_{ret}: margin] from [0:1] to [120:1] in the objective function for diet optimization. CHF: Swiss Francs (Data from [106] and Morel PCH, 2010, personal communication)



Pig Breeding for Increased Sustainability. Figure 8
Gross margin (from growth rate, estimated lean content, and feed intake) in slaughter pigs of commercially available genotypes, as recorded 1976–2009 in public Commercial Product Evaluation trials. The trend line is the linear regression. EUR: European Euros (Data from [107])

margin of those genotypes (three-phase fixed-diet, full focus on gross margin) differs by 35.7 CHF (i.e., about 23 EUR).

Time trends of growth and carcass traits in commercially available slaughter pig genotypes [107] can be converted to gross margin trends as in Fig. 8. The average range for a contemporary comparison of seven genotypes (the most common configuration in this data, and also a fair representation of practical local availability of genotypes) is 10 EUR per pig.

This provides an (under)estimate of the range in gross margin among the various slaughter pig genotypes that are commercially available at any point in time (an underestimate, because these CPE trials do not include *all* available genotypes, particularly not the less advanced ones). This number is equivalent to 10/23 = 43% of the difference between Morel's [106] low and high LTGR genotypes. Combined with the above surmise that "Morel's genetic scenarios are more effective [. . .] than his feeding regimes are, both for improving gross margin and for improving N_{ret}," it follows that a well-informed choice of the most appropriate slaughter pig genotype *available at any point in time* will have almost half of the influence on N_{ret} (and on margin) that full implementation of individually tailored diet optimization will have.

Strategies

The above section shows that pig breeding in general makes a considerable contribution to the reduction of nitrogen emission from growing pigs. Up to now, these effects have not been incorporated into formal breeding goals, so they are not under control and cannot be credited, as such. Many governments have an increasingly active policy of pollution reduction, and the global warming potential of the excreta from livestock production is under increasing scrutiny. This has led to a series of economic studies into the effectiveness of taxation of nitrogen (and other chemicals) emission on the farm level, focusing on countries as politically (and productively) different as Italy, Switzerland, and the Netherlands [108–110].

A central element in the associated econometric approaches is the *shadow price* of nitrogen emission. Paul et al. [111] describe the "shadow values for the bad outputs" of an agricultural production system as "the marginal amount that producers [. . .] would be willing to pay for unrestricted use of the environment" to dispose of those bad outputs – e.g., for the right to increase their bad outputs in a situation where legislation attempts to reduce these.

Operationally, shadow prices are estimated as the partial derivative of the producer's profit equation with respect to the bad output factor – equivalent to marginal economic values for production traits in animal breeding. These are demanding statistics. Key et al. [112] studied the productivity of the USA slaughter pig sector, and note that estimating the "shadow price of manure [. . .] with the data available would require making a set of assumptions that would likely introduce substantial error [. . .], an accounting of hog farm output that includes manure is left for future research."

The shadow price of nitrogen emission from growing pigs, sows, and dairy cows in the Netherlands was estimated at 2.7, 10.8, and 6.5 NLG/kg, respectively [110, 113].

The UK government has included the shadow price of GHGs as a structural element of its cost-benefit evaluation of any policy that it funds or supports, using values based on [114] where a shadow price of CO_2 is derived that can be converted to a shadow price of nitrogen (as a component of N_2O) at 9.25 GBP/kg.

Obviously, such shadow prices depend on practically every feature of the production system and its surrounding conditions. Using again Paul et al.'s [111] description above, the amount that producers would be willing to pay for the right to increase their bad outputs in a situation where legislation attempts to reduce these, would depend on (1) how strongly this legislation attempts to enforce the reduction, and (2) the impact of such a reduction on the remaining elements of the producer's profitability. Point (1) is largely a political factor; the UK government was criticized by environmental NGOs for the supposedly artificially low value of its abovementioned shadow price of CO_2. Point (2) may well lead the producer to decide to *not* reduce his bad outputs, because that is still more profitable – as was the case in Paul's study which focused on pesticide usage: her shadow price estimates were negative.

Wall et al. [115] notice the equivalence of the shadow price of a bad output and the marginal economic value of a production trait, in the sense that both can be used to weight their characteristic into a breeding goal. They refer to the EU-ETS Emissions Trading Scheme that was set up to support the EU to meet its commitments to the Kyoto Protocol (ec.europa.eu/environment/climat/emission/index_en.htm), which will effectively determine the shadow price of GHG emission in the EU. They write "suppose [. . .] that agriculture is forced into an [ETS] and that farmers must hold valuable permits either through initial allocation or by purchasing in the ETS. [This] will immediately move GHG mitigation traits from a public to a private breeding objective [. . .]; the prevailing emissions price becomes the relevant economic weight that should be incorporated in any breeding index that includes mitigation potential." The demand for "breeding indexes that include mitigation potential" will become very concrete, once pig producers have to deal with such a scheme – in line with this, the total costs of 2007 environmental government policy in the Netherlands were estimated at "around 0.11 EUR per kg [carcass] weight, of which 0.08 EUR was for manure disposal. In 2013, these costs will be 0.02 EUR higher as a result of the ammonia emission reduction policy" [116].

Figures 6 and 7 show that such a pig breeding policy is technically feasible: Nitrogen retention rate is favorably correlated with the conventional production traits and can easily be included into breeding goals and selection strategies.

Animal Welfare

In 1976, the member states of the European Community ratified the *European convention for the protection of animals kept for farming purposes*, regulating that livestock must be properly housed, fed, and cared for. In 1992, the following text was added (condensed here for clarity): "Breeding procedures which may cause suffering or injury to animals shall not be practiced. No animal shall be kept unless it can be expected, on the basis of its phenotype or genotype, that it can be kept without detrimental effects on its health or

welfare." Five years later again, the EC's Scientific Veterinary Committee recommended that "no selection should occur without reference to the effects of that selection on welfare of [pigs]. The continuation of new genetic lines in which the welfare of the animals is, on average, worse than that of existing lines should not be permitted" [117].

Such statements leave the impression that animal breeding may be bad for the animals involved. This goes back to the late 1970s when animal breeding technology became much more powerful than before, due to improved data recording and processing (BLUP and, above all, computing power), and improved reproductive technology. Simultaneously, animal production in the western world experienced strong intensification connected to a long period of low, volatile, and unpredictable farm profitability [118]. The production sector therefore developed a strong and focused demand for animals with improved production performance.

This led to a strong and effective focus on production traits in livestock breeding in that period, with less attention for animal robustness traits. This lack of balance has caused fitness constraints in pigs, particularly in environmental conditions inadequate to support the improved production potential, and particularly before this problem was being dealt with in modern pig breeding.

Intensification of animal production has also led to housing and management conditions that shelter the pig from climatic, nutritional, parasitic, and predatory challenges – but compromise much of the expression of its instinctive behavioral repertoire. This deprivation leads to frustration, with welfare problems for the affected individual and for its penmates.

Fitness constraints and deprivation are among the "criteria for determining the ethical limit for genetic selection" [119]. A third issue is formed by the routine invasive treatments that have been common, worldwide, since the onset of animal domestication – in pigs mainly tail docking and castration. These aim at a pragmatic (but unrefined and reoccurring) reduction of undesirable features that can also be dealt with through animal breeding – more complicated, but permanent and less physically invasive.

While worldwide demand for pig meat increases, it will become more and more relevant to resolve problems with pig welfare in intensive production systems. It is unlikely that this increasing demand will be met by any other production system than intensive ones, particularly in Latin America, Russia, and Asia. In accordance with FAWC's [120] plea for "a greater emphasis in breeding programs on traits associated with good welfare," animal breeding and genetics technology can then contribute in three areas: (1) robustness, (2) deprivation, and (3) avoidance of invasive treatments. In practice, each of these areas raises (4) ethical arguments, sometimes intense enough to dominate the issue – so although this chapter is about technology, these will be addressed as well. Sections "Robustness" to "Ethical Aspects" deal with these areas in this order.

Robustness

When animals of high-performance genotypes are kept in production systems that are inadequate to provide the resources they need to express their potential, the animals commonly show disturbed resource allocation [121] and functional disorders of the skeletal and cardiovascular systems, muscle physiology, the reproductive system, or immunocompetence [122]. For pigs, obvious indicators of reduced animal welfare in this respect are (1) increased mortality rates and reduced sow longevity, (2) disease (morbidity), and (3) lameness.

The issue here is one of environmental sensitivity. There are two ways to deal with the problem: make the environment more resource providing or make the genotype less sensitive. There are two strategies for the latter: (1) direct selection for robustness traits and (2) selection against environmental sensitivity as measured through reaction norms.

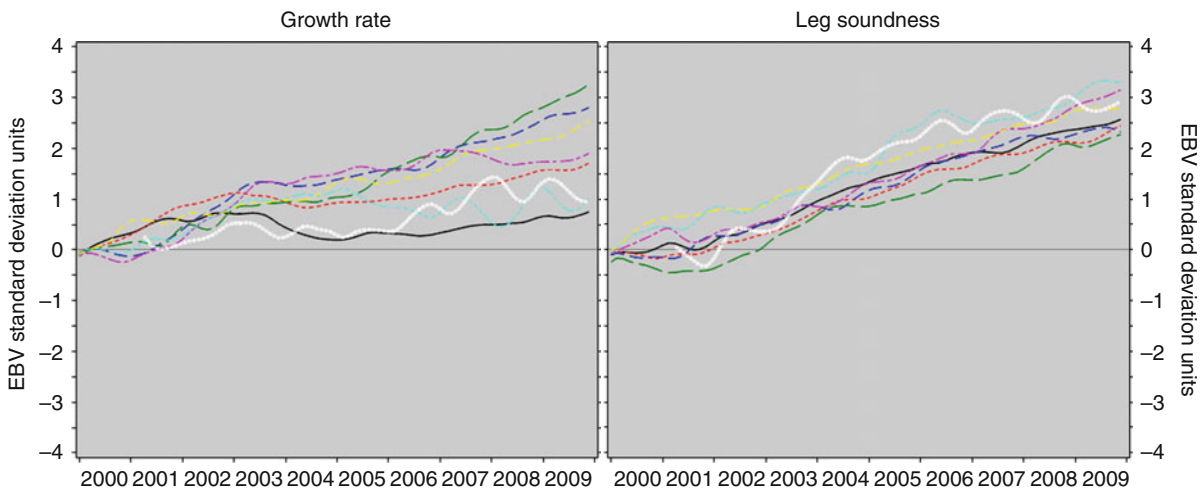
Selection for Robustness Traits Livestock robustness can be defined as "the ability to combine a high production potential with resilience to stressors, allowing for unproblematic expression of a high production potential in a wide variety of environmental conditions" [123]. The classical problem with this ability is in genetic antagonisms between production traits and resilience [121] – natural selection is not powerful enough to maintain (or improve) animal robustness in intensive production systems; it must be supported

by artificial selection. Genetic antagonisms can be neutralized by using adequate selection criteria to select for an adequate breeding goal. Earlier breeding goals were inadequate in this respect, as they did not include robustness traits [124]. Following Gjedrem [125], a breeding goal should include all heritable traits that have an impact on profitability – and mortality, morbidity, and lameness certainly do. Knol et al. [126] discuss this in detail and stress that "simplicity and straightforwardness of the breeding goal has to be weighted against completeness and complexity." Such traits can be included in the profit equation for pig production [127]; this provides marginal economic values, required for inclusion in the breeding goal.

The various strategies for genetic improvement of piglet vitality and survival, leg weakness and longevity, stress sensitivity, and disease resistance are summarized in [128]. These are hard-to-measure traits, mostly categorical with low incidences and relatively low heritabilities, so that large data volumes from adverse environments are required for meaningful breeding value estimation [129]. Their genetic improvement has benefited considerably from BLUP and will benefit just as much from MAS [130, 131]. Figures 9–11 show realized genetic improvement of leg soundness and mortality traits, coinciding with improvement of production performance, in eight pig lines.

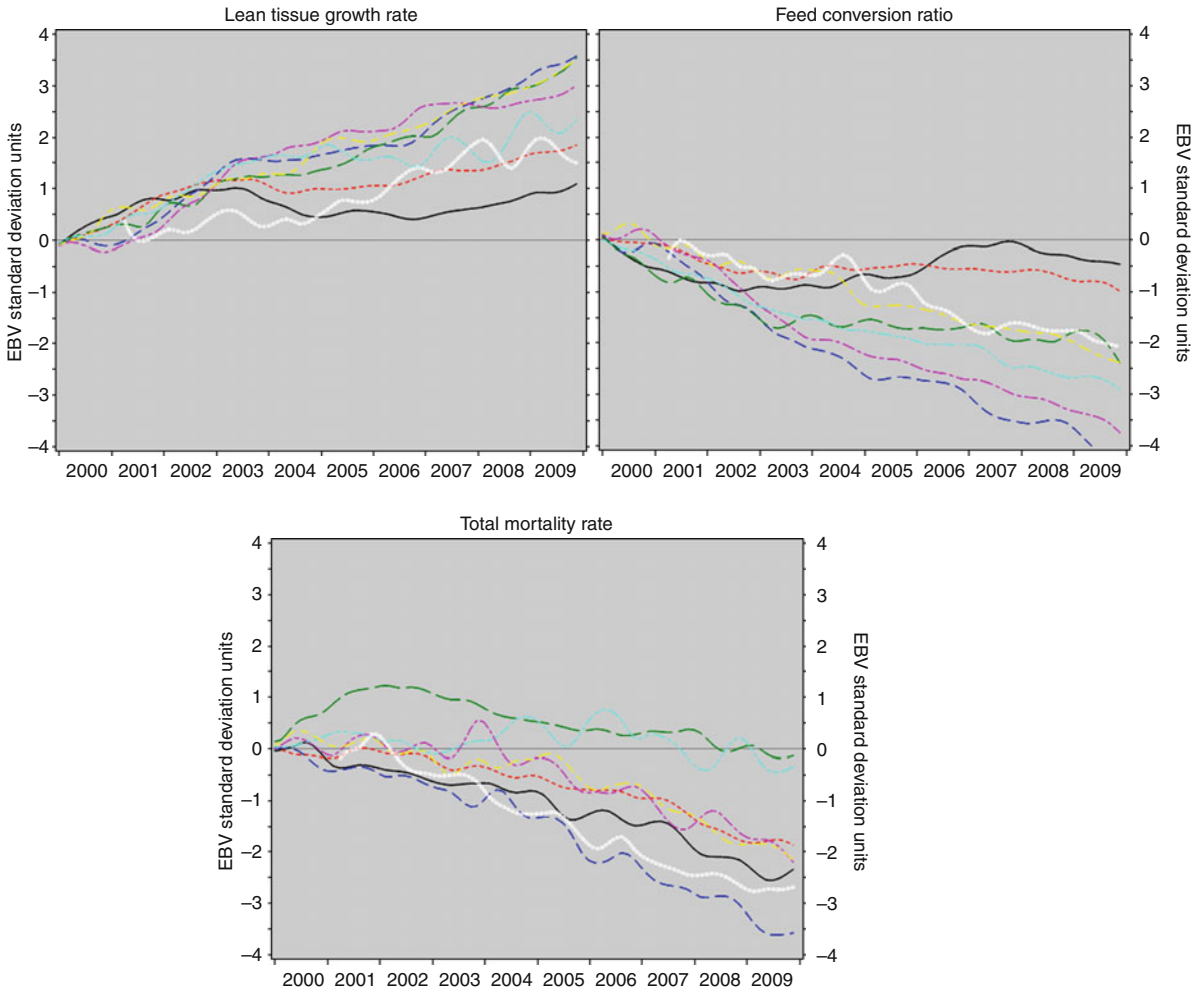
SVC [117] write: "The criterion for selecting animals for use in breeding has been an increase in economic performance and this has often not coincided with improved animal welfare. Hence the term *genetic improvement* is misleading since, in some cases, the changes are not improvements for the animal but may make the life of the animal more difficult." The genetic trends of Figs. 9–11 show that this can be overcome: antagonistic correlations do exist, but genetic improvement can be achieved in production traits and robustness traits simultaneously – neutralizing genetic antagonisms by adequate selection. This effect will depend on the emphasis given to each trait in the breeding goal of each line.

Reaction Norms When progeny of specific sires are (1) identified as such, (2) spread across a wide environmental range (usually through artificial insemination), and (3) recorded for a production trait, their production performance can be regressed on a descriptor of the environment (e.g., a herd-year-season effect). This produces a positive slope overall: better environments lead to better production. When



Pig Breeding for Increased Sustainability. Figure 9

Simultaneous genetic trends of growth rate and leg soundness in eight pig lines. Each trait was scaled by the standard deviation of its estimated breeding values; all trend lines for each trait were forced through the same origin in 2000 to make the trends comparable across lines

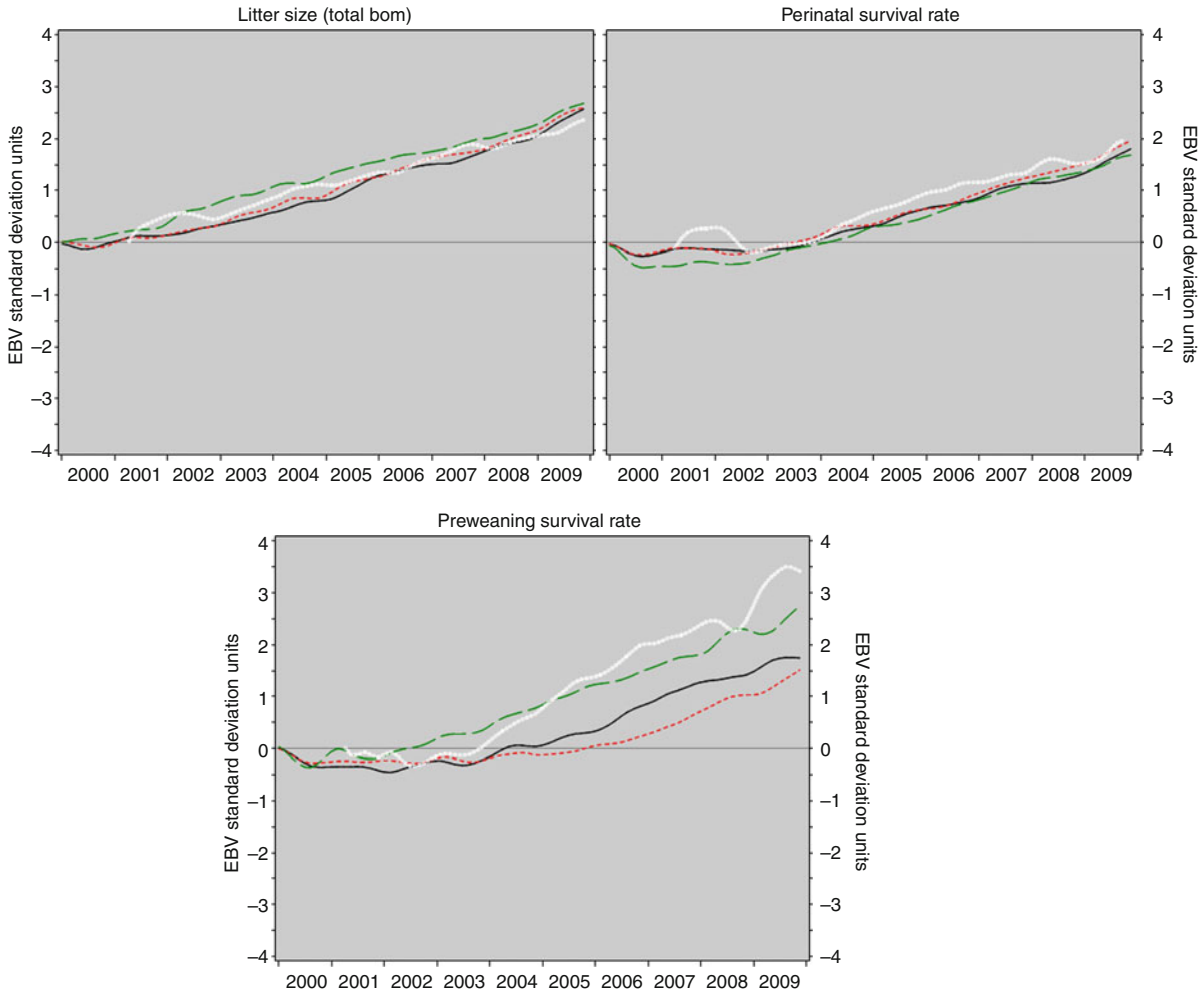


Pig Breeding for Increased Sustainability. Figure 10

Simultaneous genetic trends of lean tissue growth rate, feed conversion ratio, and total mortality from birth to slaughter in eight pig lines (same formatting as in Fig. 9)

the regression is performed separately for sire progeny groups, and if there is genetic variation in environmental sensitivity of the trait's production potential, regression lines are produced ("reaction norms" in population genetics) with different intercepts and slopes for different sires. The intercepts are equivalent to the conventional estimated breeding values for the trait. The slopes quantify an animal's requirements for environmental support of its genetic potential; they detect robustness as defined above.

Environmental sensitivity in pigs was analyzed this way in [132, 133]. Friggens and Van der Waaij [134] discuss how selection for increased production levels (i.e., for high reaction norm intercepts) will cause a gradual increase of environmental sensitivity (i.e., of the slopes). This was confirmed [133] in terms of a strongly positive genetic correlation between intercept and slope of their reaction norms for litter size. The slopes have a very low heritability in that data, so the increase of environmental sensitivity would be very slow. This presents another example of genetic antagonisms, which can be neutralized by including both the intercept and the slope of the reaction norm of each production trait in the breeding goal and in the selection criterion. A way to calculate their marginal economic values is in [123].



Pig Breeding for Increased Sustainability. Figure 11

Simultaneous genetic trends of litter size, perinatal survival rate, and preweaning survival rate in four pig damlines (same formatting as in Fig. 9)

These are demanding statistics. Knap and Su [133] analyzed their data in three consecutively larger subsets. The medium subset held more than 50,000 sows – comparable to the largest litter size datasets in the scientific literature. Still, its parameter estimates for the reaction norm slopes differed considerably from those from the largest dataset with more than 120,000 sows, and the accuracy of its slope estimates was too low to be useful in practical breeding. The smallest subset held more than 30,000 sows, but its parameter estimates were clearly unrealistic and not significantly different from zero. Similar issues hold for the required environmental range in the data.

A single trait's reaction norm is equivalent to "a single-trait definition of robustness" and, as such, not a simple and foolproof recipe that can be applied without proper care for the system as a whole. An animal "that maintains [. . .] production in the face of decreasing [environmental support] is deemed to be robust, but [it] must be diverting nutrients away from other life functions. [. . .] When robustness can be understood as the ability to cope with environmental challenges [. . .] an animal that maintains milk production by suppressing its immune function is clearly less robust than an animal that maintains milk production by reducing growth rate" [134]. Which means that

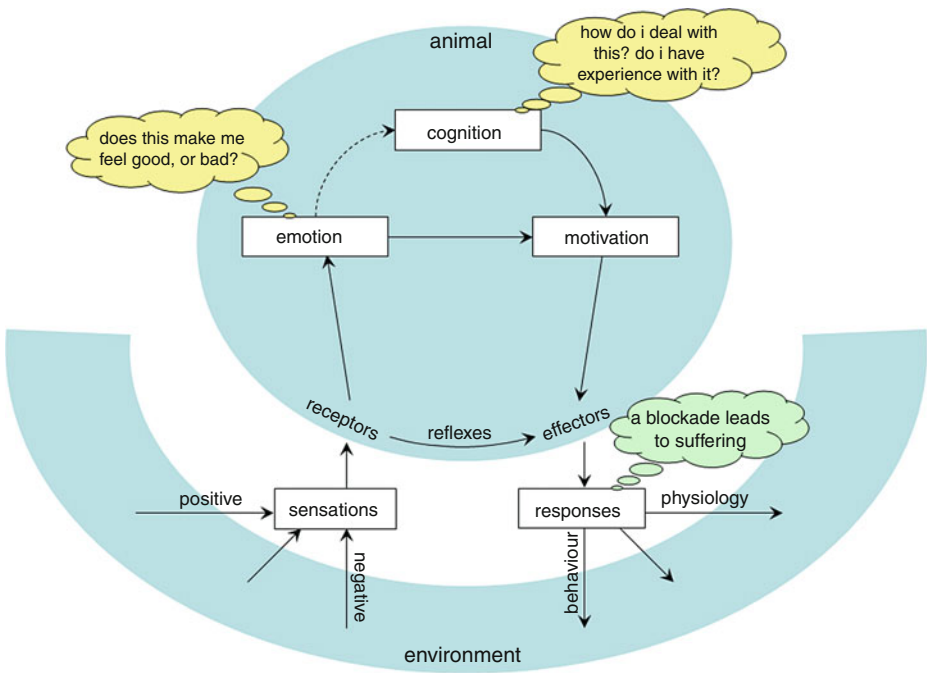
(1) it becomes interesting how the environmental sensitivity rates are correlated among traits, and (2) breeding goals must be designed and monitored with care, as argued above.

Deprivation

Intensive housing and management systems tend to compromise the expression of instinctive behavior patterns ("motivations" [135]) of the pig: foraging, rooting, and exploring in all age classes [117], and nest-building in sows [136] – because intensive housing environments do not provide the required space or substrates. Something similar holds for deprivation of social contact in individually housed sows [137], where the "required substrate" is other pigs. For more detail see [138]. This results in frustration, leading to apparently irrationally redirected behavioral outlet functions: stereotypies or apathy occur when the animal is severely or chronically frustrated [139–141]. Mason and Bateson [142] describe this situation as "internal states of deprivation [...] leading to sustained high motivations that the [animal] cannot reduce: it cannot perform the activity that would result in negative feedback." Another outlet function is wide-sense agonistic behavior such as tail biting [143, 144]; see the section on "Harmful Social Behavior."

In sentient species, such frustration leads to suffering. A sentient animal has been described [145] as an animal that has the capacity to suffer when it learns that it is unable to cope with stress: "it may fail to cope, either because the stress is too [intense], or because [the animal] is constrained in such a way that it is prevented from doing what it feels necessary to relieve the stress." This leads to anxiety or depression. Figure 12 illustrates the interdependence of the various components.

Held et al. [138] write: "pigs used today for pork production seem to have retained many of the faculties of their wild ancestors, and may therefore be behaviourally, cognitively and emotionally at odds with the husbanded environment [...]. Understanding the cognitive abilities, behavioural priorities and emotions of commercial pigs therefore lies at the very heart of improving their welfare." Jensen [146] describes



Pig Breeding for Increased Sustainability. Figure 12
Relationships between emotional, cognitive, and motivational information processing in sentient animals (Modified from [145] and [139])

those "faculties of the wild ancestors" as "subtle [behavioural] differences between domestic and wild animals [...] attributed to modified stimulus thresholds, causing some behaviour patterns to become more common and others to be rarer during domestication." Such changes in pig behavior are described in detail in [147, 148].

One of the options for resolving such cognitive and emotional conflicts in an intensive environment would be to further reduce those faculties of the wild boar, further modifying those stimulus thresholds and simplifying what the animal feels necessary to relieve its stress. Kruska [149] sees changes in behavior and brain size as "adaptations to the special ecological niche of domestication." "Modern housing systems [have a] short history compared to the history of the pig as a domestic animal, and it is likely that adaptation has not kept pace with the intensification of pig husbandry" [150]; also, of course, because most housing systems were not designed to match behavioral needs.

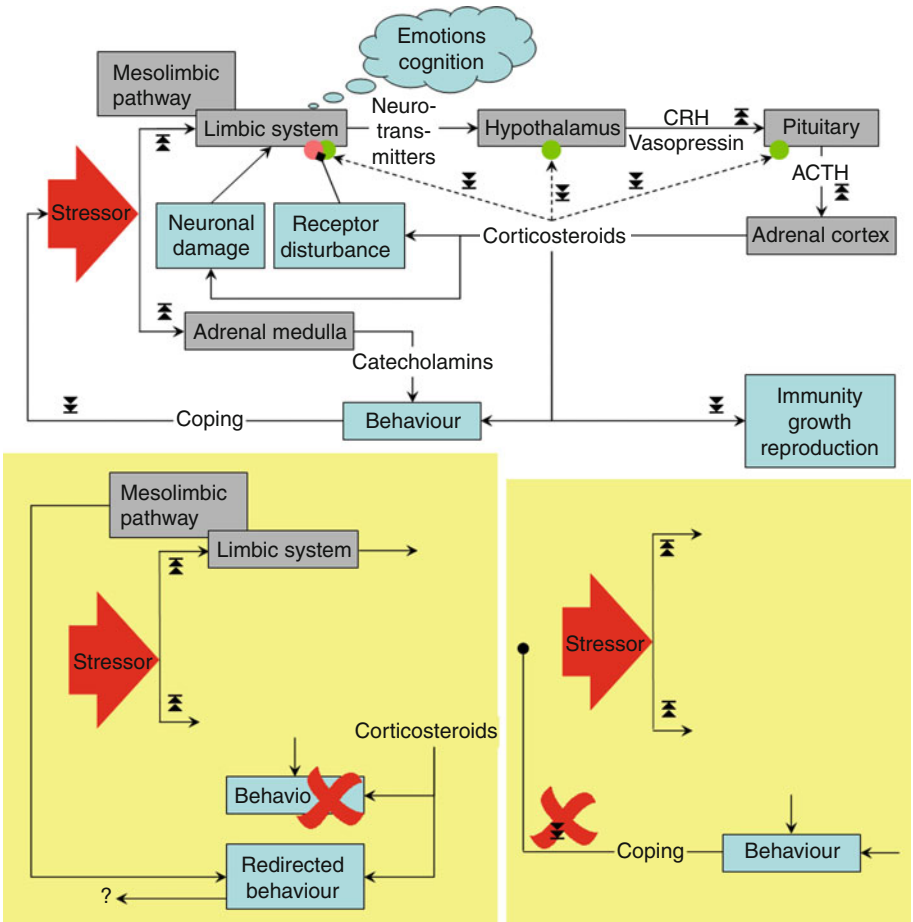
Neuroendocrinology The neuroendocrinological aspects of *coping with stress* (as above) are studied in relation to human conditions such as mental depression [151]. This is a novel area for animal breeding, with legible summaries of the state of the art from [139, 152–154]. Chronic stress affects the hypothalamus-pituitary-adrenal (HPA) axis; it can cause a persistent overproduction of corticosteroids, which can disturb neurotransmitter systems by causing a chronic downregulation and/or an imbalanced activation of the various types of corticosteroid receptors in the brain. Probably independent of the HPA axis (but interacting with its corticosteroids) is the mediation of stress-induced stereotypic behavior by the mesolimbic pathway. Figure 13 presents a simplified model of these systems.

The sympathetic nervous system also influences corticosteroid production, and its interaction with the HPA axis leads to *active* versus *passive* coping strategies. These terms represent the extremes of a continuous distribution of animal-intrinsic behavioral flexibility. This has been described [154–157] as follows: active copers rely on stable conditions, show poor adaptation to changing conditions, and attempt to deal with any challenge through routines and behavior patterns that were successful previously, trying to remove the stressor or move themselves away from it. Passive copers show higher cognitive performance, thrive better in changing conditions, and face challenges by modifying their behavior to deal with a new stressor in its own way, aiming at reduction of the emotional impact of the stress.

This approach has been criticized as an attempt to fit a multidimensional system (reactivity to external factors) into a single (coping) dimension. Ramos and Mormède [158] mention three such dimensions (activity, emotionality, and aggressiveness), and present studies in rodents that quantify these through Principal Components Analysis and similar techniques. Obviously, control of the system through animal breeding would benefit from a detailed focus, so that the various dimensions can be brought under control independently from each other.

These traits are heritable (both coping strategies have natural selective advantages), and rodent populations have been successfully selected into either direction, using various selection criteria [159–161]. Veenema [154] found a higher stress susceptibility in passively coping than in actively coping mice. Her surmise is that this is due to differences in (1) perception of the stressor during acute stress, and (2) coping or habituation during chronic or repeated stress. Under changing conditions, passively coping mice may perform better in terms of dealing with the stressor. But exposure to chronic psychosocial stressors (i.e., living together with a dominant aggressive penmate) induced long-lasting increased activity of the HPA system in Veenema's passively coping animals, which may cause mood disorders like anxiety and depression.

Karman [153] measured the effects of chronic stress (caused by 5 months of individual housing) in gilts that had previously been scored for coping strategy. She characterizes the two strategies in terms of differences in the regulation by the hypothalamus of the pituitary's ACTH production: via CRH in passive copers, and via vasopressin in active copers. In both cases, ACTH levels and corticosteroid production are increased – which comes back to the disturbed neurotransmitter systems of above. Karman concludes that "individual housing is detrimental for the welfare of pigs, independent of coping strategy. Selection of coping strategy [...] will therefore not benefit the welfare of the animals."



Pig Breeding for Increased Sustainability. Figure 13

A simplified model of the neuroendocrine aspects of unsuccessful coping with stress in mammals. *Top*: the full system with its negative-feedback loops that keep the levels of circulating corticosteroids under control. The flow starts with the occurrence of a stressor (*red arrow*). The ⏭ symbol pointing up or down represents upregulation or downregulation, respectively, of the downstream activity. Green and pink circles represent different types of corticosteroid receptors; in the limbic system, these can be disturbed by persistently high corticosteroid levels, obstructing the negative feedback loop. The stressor is neutralized by coping behavior, which terminates its triggering of corticosteroid and catecholamine production. *Bottom*: two options for obstruction of this system. *Left*: an external factor prevents the expression of the required behavior, which leads to redirected behavior (e.g., stereotypies, agonistic behavior) as an outlet function with uncertain consequences. *Right*: an external factor keeps the stressor in place in spite of coping behavior, effectively blocking the stressor's downregulation that would normally follow from coping. In both cases, the stressor is not neutralized and the levels of circulating corticosteroids are out of control; this can result in a reduction of immunity, growth, and reproduction traits, and in damage to the limbic system which brings the system further out of control

If Karman's findings hold, the generic effects of chronic stress in pigs will not be resolved by breeding for an active coping strategy, which would seem to be the obvious approach with Veenema's [154] mice.

This would shift the focus upstream in Fig. 13, aiming at a resolution, through animal breeding, of the effects of chronic stress on the limbic system areas (amygdala, hippocampus) that regulate the hypothalamus. De Kloet [156] makes a distinction between "(1) the core of

the HPA axis with emphasis on dysregulations in the [hypothalamus] and (2) dysregulations in [...] stress inputs to the [hypothalamus] (e.g., from medial prefrontal cortex, hippocampus, amygdala, and brain stem) that are also targets for the stress hormones."

Morris [162] notices that during chronic stress "the hippocampus may become impeded in its role in 'shutting off' HPA axis stress activity. This results in increased secretion of [corticosteroids] and, in a positive feedback cycle with negative consequences, ends up in damaging the hippocampus itself, thereby further reducing [its] ability to regulate the HPA axis. [...] This brain structure is both [i] centrally involved in the neural reaction to aspects of prolonged stress and [ii] itself a target of chronic stress." Loijens [152] reports such findings in tethered sows.

The significant issue here is that the limbic system also regulates emotional and cognitive functions (Fig. 13) – which provides the conceptual connection to Fig. 12. "Sustained activation of [corticosteroid] receptors in the hippocampus [...] may lead to an impairment of declarative (rule-) learning during high levels of chronic stress. [...] The amygdala [...] has been demonstrated to [influence] hippocampal plasticity and hence may be the central link between stress and declarative learning [...]. In farm animals this type of learning occurs during adaptation to [housing] facilities, milking regimes etc." [139].

Selection Objectives "An array of stress-responsive genes has been identified," including genes "related to structural differences in hippocampus of [passively and actively coping] mice. [...] These altered gene patterns can be postulated as markers for *predisposition* for stress-related disorders" [156]. Such gene patterns are being studied in pigs as well, exploring changes of gene expression in the hippocampus, amygdala, and/or frontal cortex due to early weaning and/or social isolation of piglets [163, 164].

"The evidence for a significant genetic contribution to stress responsiveness in vertebrates is overwhelming. [...] Given the complexity of the issues, there is no firm consensus as to whether modification of stress responsiveness can benefit an animal within an intensive rearing environment" [165].

In line with this, the main conclusion from the section on "Deprivation" would be that straightforward selection against specific behavior patterns such as stereotypies and apathy (which would not be difficult to record in intensively housed sows) may be counterproductive. In terms of Fig. 13, such selection might just remove the "redirected behavior" pathway that serves as an outlet for frustrated motivations, and as such forms the animal's final way to deal with the load of the stressor. This would create a system under stress (with its negative consequences for homeostatis and production) without any security valve. D'Eath et al. [166] refer to such animals as *stoics* "because outward signs of suffering appear to be reduced" while the "root cause of the stereotypy" is not changed.

A second conclusion is that the active and passive coping strategies do not seem to offer a useful criterion for pig breeding.

It seems much more useful to look for the abovementioned "adaptations to the special ecological niche of domestication" [149] in terms of changes of the predisposition for stress-related disorders and of perception of the stressor, rather than a change of coping patterns. This would have to target the limbic system, which makes the task much more challenging.

From a very different point of view, Morris [162] quotes Sapolsky: "the body simply has not evolved the capacity or tendency to not secrete [corticosteroids] during a crisis," and adds to this "in effect, evolution has only gotten so far." Clearly, evolution could be moved on (into a more convenient direction) by a much focused targeting of the system that regulates the HPA axis, i.e., the limbic system again.

This amounts to a strategy to modify instinctive patterns so that the motivation for behavior that cannot be supported by the production system is reduced. This would "change the intensity of a behavioral response," which is equivalent to domestication [119]; antipredator responses would be an obvious example. Adaptation of behavior through selection is then effectively an extension of 9,000 years of pig domestication: a process of reducing the animal's drives for exploration, aggression, etc.

Such characteristics form the ultimate example of *hard-to-measure traits* in animal breeding. Genetic improvement will therefore logically focus on marker-assisted selection; phenotypic records will still be required in large volume for marker effect estimation,

but recording can be scheduled on a project basis, and on other animals than selection candidates. As with every trait of livestock species studied up to now, very large numbers of genes are likely to be involved, which makes the candidate gene approach and its search for major genes not very promising – also because of the currently "limited basic knowledge about psychobiological dimensions underlying behavioral trait variability, and the availability of reliable and meaningful measures of these [. . .] free from environmental influences" [167]. The *quantomics* approach that was put forward at www.quantomics.eu seems to offer more power to bring such a system under control: it should "provide the tools to identify rapidly the causative DNA variation underpinning sustainability in livestock, and [. . .] exploit high-density genomic information." Essentially, making use of large numbers of anonymous markers (as in genomic selection) to identify functional elements and their connection to the phenotype (as in QTL studies).

Dominance Aggression Another issue of intensive production systems is avoidance of dominance aggression, particularly when pigs are being mixed into new groups [168, 169] – confinement does not allow for escape from aggressors. Such behavior has significant genetic components [170], possibly but not very clearly connected to coping strategies. The main factor that would complicate selection against such behavior is the difficulty of data recording, which makes marker-assisted selection an interesting option again. QTL associated with such behavior are in the process of being discovered [171, 172].

The ethical aspects of all this are considered in the section on "Ethical Aspects."

Avoidance of Invasive Treatments

There is much societal drive to reduce painful treatments like castration and tail docking of piglets. The relevant issues are then the genetic options to reduce (1) boar taint and (2) tail biting – these form the reasons why those treatments are performed.

Boar Taint Piglet castration needs to be carried out under anesthesia in Norway and Switzerland. The German pig production sector has been recommending castration with analgesia since 2009, and aims at castration-free production on the longer term. The Dutch pig sector aims at castration-free production by 2015; leading Dutch retailers have decided to stop the sales of meat from castrated pigs starting 2011. A logical extrapolation is that by 2020 the European pig production sector will leave most of its male pigs uncastrated. While this provides progress in animal welfare (apart from aggression among entire male penmates), and an advance in gross profitability because entire males grow more efficiently than castrates [173, 174], it causes logistical and technical challenges because of boar taint.

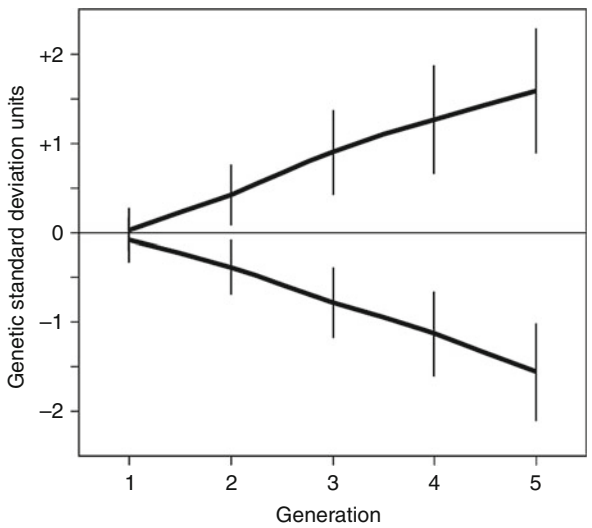
Boar taint is an unpleasant odor of pig meat (occurring in roughly 3–10% of entire males) caused by several chemical components, most importantly androstenone (a sex hormone) and skatole (a metabolite of the gut microflora). The tissue concentrations of both components are variable, line specific, and heritable [175–177], and the genes that influence them are gradually being identified [178, 179] so that it is feasible to select pigs for reduced boar taint levels. Such genetic improvement is a crucial element of the sustainability of sector-wide non-castration: although it is largely uncertain how consumers will react to increased amounts of meat from entire male pigs appearing on the market, boar taint incidence will have to be reduced to manageably low levels to avoid situations where consumer demand for pig meat collapses, or where the processing industry shifts to imported meat from castrates.

Because androstenone is a sex hormone, attempts to reduce its circulating levels may affect similar hormones such as testosterone and the estrogens, with a negative impact on male and female fertility, respectively. This must be counteracted through "balanced breeding" [177], i.e., by simultaneous selection for the relevant fertility traits.

Harmful Social Behavior SVC [117] write about "tail injury caused by biting. Although the motivation of the pig which bites the tail is likely to be investigation, manipulation and perhaps feeding rather than aggression, the consequence for the bitten pig is serious. Bitten tails may attract further biting so that the injury is to the abdomen at the base of the tail after the tail itself has been bitten off." Tail biting is a form of "harmful social behaviour" [180] (HSB; "social"

because it involves other pigs) in intensive animal production [181, 182], possibly a form of redirected outlet behavior (as in the section on "Deprivation") in the absence of rooting substrate such as straw [183]. Other forms are vulva biting in group-housed sows [184], piglet savaging by sows [185], and feather pecking in poultry. Feather pecking and subsequent cannibalistic actions form a major problem in poultry production [186]. In practice, this vice is prevented by beak trimming of the potential actor, whereas tail biting in pigs is prevented by tail docking of the potential recipient; both at a very young age. Both treatments compromise animal welfare, but not performing them may do so too – a circular lose–lose situation to be broken.

Su et al. [187] selected laying hens for increased or reduced feather pecking incidence. Figure 14 shows the genetic trends in their first five generations. The selection trait was the number of pecking bouts delivered by a bird during 3 h, recorded by examining video footage of 250 birds each generation. Behavioral traits are notoriously time intensive to record and therefore a prime candidate for marker-assisted selection (phenotypic records will still be required in large volume for marker effect estimation, but recording can be scheduled on a project basis and on other animals than selection candidates). Motivated by this, "a major dominant allele affecting the [feather pecking] behavior" was identified in the eighth generation of the high-incidence line [188]. More genes with significant associations to feather pecking were found in similar selection lines [189]. Likewise, Quilter et al. [190] report on a search for QTL associated with piglet savaging behavior in sows.



Pig Breeding for Increased Sustainability. Figure 14
Genetic trends of feather pecking incidence in divergent laying-hen selection lines (Data from [187]). The data for each line have been scaled by the within-line genetic standard deviation. Vertical bars represent one standard error each side of the mean value

Social behavior traits involve a recipient and an actor; genetic evaluation should take both into account. Ellen et al. [191] notice that "cannibalism [. . .] differs from conventional breeding traits because it depends on social interactions [. . .]. Selection strategies [. . .] should consider both the direct effect of an individual on its own survival and the social effect of the individual on the survival of its group members (the so-called associative effect)."

In group housing, an individual's phenotype for any trait (growth rate, mortality, etc.) is influenced by its own direct breeding value for the trait and the associative breeding values of its penmates, positive or negative. Hence, if associative effects are significant for the trait, they should be part of the analysis in breeding value estimation – to effectively equip the social environment with a pedigree structure and capture it in more statistical detail. This principle has been worked out in detail for growth rate and feed intake in growing pigs [192, 193]; associative effects contributed the majority of heritable variance in these traits. Intuitively, the same would hold for mortality rates due to cannibalistic HSB.

Muir and Craig [194] discuss *group selection* in laying hens, where "hens of each sire family were housed as a group in a multiple-bird cage and selected as a group" for egg production and survival rate. These hens were housed intensively and were not subjected to beak trimming, allowing for unconstrained expression of HSB. After seven generations of selection, in group housing, the group selection line showed a 20% mortality rate at 58 weeks, compared to 54% in an unselected control line and 89% in a related commercial line (which was selected for egg production and survival rate in individual housing; Muir WM, personal communication, 2010). Plumage scores revealed significantly less HSB in the group selection line. Egg

production in group housing was highest in the group selection line.

These authors conclude that this approach "is effective in improving [welfare] of layers in a relatively short period of time without sacrificing productivity. The way for commercial breeders to develop birds that do not need beak trimming is clear." A study of the endocrine and immune system traits in these lines [195] concluded that "group selection altered the chickens' physiological homeostasis which is reflected in the line's unique coping ability with intensified domestic environments." But the physiological effects of this selection approach are cell-specific [196].

Gunsett [197] describes an application of group selection in pig breeding. He mentions advantages in terms of profitability (improved image of intensive production, increased stocking density, reduced abattoir penalties for damaged carcasses) and animal welfare: (1) reduced incidence of damaged carcasses, i.e., of pigs injured due to HSB, (2) reduced mortality rates, and (3) more docile behavior. He also mentions practical difficulties with the implementation of the method, due to reduced selection intensity and increased rate of inbreeding. Hence the program was changed to a system where the direct and associative breeding values were estimated in an extended BLUP approach [198], which was formally worked out by Bijma [199]. Group selection is then not required anymore. These principles were applied to HSB and its resulting mortality rates in laying hens, leading to the conclusion that "including associative effects in the model will give substantially higher heritable variation than when using the conventional direct effects model [. . .]; prospects for reduction of mortality using the direct-associative effects model are good [. . .]; selection targeting both direct and associative effects is expected to substantially reduce one of the major welfare problems in egg production" [191].

The extension to tail biting in pigs is obvious: Breuer et al. [180] estimated heritabilities of tail biting in two populations (both with an actor incidence of about 3%) at 0.00 and 0.05 on the observed scale, and bravely conclude that "it would be possible to develop a selection index to reduce [. . .] tail-biting behavior through selective breeding" – but any statistical method that delivers substantially higher heritable variation would be very useful here.

Muir and Craig [194] conclude from their selection results that "because group selection is shown to improve well-being in multiple-bird cages, alternatives such as redesigning cage environments, or housing such as floor pens or free ranges, may not be needed." Likewise, Conington et al. [200] write "breeding animals to adapt to their environment, rather than focus on changing environments to match new genotypes (such as altering housing and cubicle design) can minimize the mismatch between them" [200]. Such statements are under debate, following the argument that it would be preferable to adapt the production system to the animal, rather than vice versa, which goes back to Faure [201]. This is in clear conflict with domestication in general, which has always attempted to adapt animals to captivity systems, sometimes by considerable force. The ethical aspects are dealt with in the next section.

Ethical Aspects

Farm animals are there to produce food that people need and want. With an increasing human population and its worldwide purchasing power, there is an equally increasing demand (what people want) for animal products. One of the options of dealing with this increasing demand is to disapprove of it, arguing that the world's carrying capacity does not allow for it [202] and that everyone (particularly in the developed world) should eat less animal products. This raises one of the many arguments in an ethical discussion: to what extent it can be justified to deny people (particularly in the developing world) what they clearly want.

Another (nonexclusive) option is to look for technological solutions. Without doubt, intensive systems will be the norm in worldwide pig and poultry production of the 2020s: in USA, Brazil, the Middle East, Russia, and China – where the enforcement of extraneous norms and regulations is difficult and arguably ethically unjustified. Sections "Robustness" to "Avoidance of Invasive Treatments" show that pig breeding can produce genotypes that are better equipped to fare well in such systems. This would also enhance profitability in such systems (due to lower mortality and morbidity rates), leading to increased worldwide sustainability. The pragmatic approach would then be to

accept this and aim at adapting the pig species to such conditions. There is much debate about this proposition.

Hörning [203] writes: "In general it seems ethically dubious when behavioral problems of intensive production must be reduced by breeding, rather than by changing the management-related causes. On the other hand, selection for certain behavior patterns in extensive production conditions has been recommended by some livestock ethologists: [. . .] maternal behavior of sows in loose housing systems [. . .] or against feather pecking in laying hens in alternative housing systems" (translated).

In line with this, the genetic adaptation of goats, sheep, and beef cattle to marginal (mountainous, wetland, arid) extensive conditions is much explored [204, 205]. Those conditions often lead to severe and persistent violation of the freedom from thirst, hunger, thermal discomfort, parasites, and disease – the breeding of animals that withstand such harsh low-input conditions evokes Kojak's maxim *to survive is a lousy way to live*. The justification of such adaptation strategies is commonly phrased in terms of the economical and/or cultural importance of livestock for such marginal areas (see the section on "Biodiversity," and more specifically pp. 405–419 of [5]), which entirely overlooks animal welfare.

By contrast, animal welfare problems in intensive production systems center around robustness and behavioral deprivation. Strategies to reduce deprivation problems by animal breeding (as outlined in the section on "Deprivation") meet with criticism of an ethical nature, as from Hörning [203], above.

The issue is if *genetic adaptation of livestock species to* the violation of their welfare by thirst, hunger, thermal discomfort, parasites, and disease in extensive conditions (for economic and cultural reasons) would be ethically justified, whereas genetic adaptation to behavioral deprivation in intensive systems (for economic reasons) would be wrong. If it is justified to select poultry against feather pecking in alternative housing systems, the question is valid why such selection in battery cages would be wrong.

There are two elements here: (1) the production system as such and (2) the process of adapting animal species to it through artificial selection. These are difficult to separate, because the argumentation is partly circular.

"Since biology appears to impose few limitations on what is possible, changing the animal to suit the environment raises the question of the ethical acceptability of the environment" [166]. The underlying notion here is that the environment may be intrinsically wrong. Nevertheless, *successful* adaptation of an animal species to any production system would make that system acceptable from the point of view of animal welfare – for that particular species, in that particular system. For anyone who finds such systems unacceptable a priori, such adaptation is therefore undesirable: the circular argument appears here. A housing system that is deemed unacceptable a priori, without taking animal welfare into account, can only make sense from a human perspective.

Artificial Selection Domestication through artificial selection is a human activity, and therefore subject to ethics. By contrast, natural selection just happens.

Natural selection has adapted species to previously hostile conditions: freezing (Antarctic icefish, *Dissostichus mawsoni*), molten sulfur (western Pacific tonguefish, *Symphurus thermophilus)*, cobra venom (mongoose, *Herpestes ichneumon*), high CO_2 and low oxygen levels (naked molerat, *Heterocephalus glaber*), compression (sperm whale, *Physeter macrocephalus*), drought (Arabian camel, *Camelus dromedarius*) and crowding (Mexican free-tailed bat, *Tadarida brasiliensis*), among many others. Natural selection is also adapting *Sus scrofa domesticus* to intensive housing conditions – this is happening now, but so slowly that it is very difficult to notice. Artificial selection can do the same, much faster.

Like natural selection, domestication used to be a slow process – its resulting changes were hardly noticeable with a normal human time horizon. These changes have accelerated considerably since the 1980s, to the extent that they are now measurable within, say, a decade (as in Figs. 9–11) – and many people feel uncomfortable with this. Despite education and popularization of science, the notion of evolution (i.e., genetic change) as a process that is actually taking place today is not widely appreciated. Judeo-Christian culture regards species as fixed entities, which makes

people resist a noticeable change of a species' instinctive repertoire because it is experienced as "unnatural" (which is exactly what it is: domestication, like every other aspect of civilization, is a deliberate move away from nature). This resistance is toward genetic change of the pig *as we know it*. Nine thousand years of domestication have reduced the cephalization ratio (brain size as a proportion of body size) of the domestic pig by 30–40% as compared to the wild boar, the same as the dog-wolf comparison [149, 206]; significantly, the limbic system is most affected, see the section on "Selection Objectives." There is no reason to think that this process has stopped – nor will any dog owner argue that the current situation is wrong. What many people resist is to notice such a process of change actually taking place, if it would be accelerated by more effective artificial selection procedures as in Belyaev's famous fox selection lines [207]. The pig *as we know it* represents one particular stage of an evolutionary continuum, much of which lies in the future. Because this stage is familiar, now, it is experienced as the "natural" one – which it is not: by definition there is no such thing as a natural domestic animal. Accordingly, FAWC [120] stress the distinction between "natural" and "normal" behavior in farm animals.

A common argument is that such further adaptations to the niche of domestication would reduce the animal to a means to an agricultural end, to a commodity – which "embodies an excessively instrumental view on living creatures" [208]; they would violate the animal's *integrity*, "making it in some way less complete than it was previously" [181].

Integrity "Would it be right to produce [. . .] a pig unable to feel pain and unresponsive to other pigs? [. . .] such a pig would not be able to suffer, and its use might lead to significant productivity gains. Someone arguing that [this] would be wrong, would not be able to argue thus on the grounds of animal suffering" [120]. Rather, such argumentation is typically phrased in terms of *integrity*. It is useful to distinguish between two integration levels here: the individual animal, and the species as such.

One view is that violation of an individual animal's integrity is wrong; this is about production systems that keep animals in persistent pain, frustration, or fear – and [209] about breeding that predisposes animals to such conditions.

Quite another view is that it is wrong to breed animals that experience less pain, frustration, or fear in such production systems [210]. This is about species integrity: although the individual pig's integrity is less violated, it would be *less of a pig*, which sounds uncomfortable. Conversely, it can be argued that such a pig would be *less of a wild boar* (*Sus scrofa scrofa*) and therefore *more of a pig* (*Sus scrofa domesticus*) on the evolutionary continuum mentioned above. Importantly, the argument is not about animal welfare but about human values.

Appleby and Sandøe [211] analyze the various schools of philosophical thought on this issue "so that scientists may be more aware of the strengths and weaknesses of their own ideas about animal welfare." Thompson [212] gives an overview of the same; one approach holds that it is important for animals to express their instinctive behavior motivations (see the section on "Deprivation"), as far as "they actually have these [. . .], but whether or not a given animal does or does not have these drives is immaterial. Or put differently, one cannot harm an animal by frustrating a [motivation] that it does not have. Because this view revolves around the [motivations] that individual animals actually have, it does not see anything problematic about producing animals that have different motivations." This goes back to Rollin [213].

An opposing view is that such animals (1) "can be said to have been harmed, even if there is no corresponding adverse affect in terms of animal bodies or animal minds"; this (2) "would regard the use of genetic strategies to address welfare problems as morally problematic" [212]. Gavrell Ortiz [214] disagrees with point (1) but defends point (2) on the grounds of violated animal *dignity*, "even if the modification would improve the animal's welfare."

All this reduces animal welfare to "a subset of human welfare, the animals' preferences and [welfare] having relevance only to the extent that they are important to *us*" [215]. This was extended by Würbel [216]: "it is [. . .] important to distinguish between our intention to protect animals (which may be partly selfish) and true animal protection. Animal protection is

ethically justified by our own human values. What animals need for their protection, however, needs to be justified *biologically* by values that apply to the animals. Only by acknowledging this distinction will we arrive at an ethical and legal framework that satisfies our ethical claims as well as doing justice to the animals" (our emphasis).

The conclusion from this section on "Animal Welfare" is simple and uncomfortable. Intensive pig production systems will expand considerably, particularly in the developing world. Adapting the species to such conditions is technically challenging but feasible; it will improve animal welfare. Argumentation against this serves human moral values, and not animal welfare.

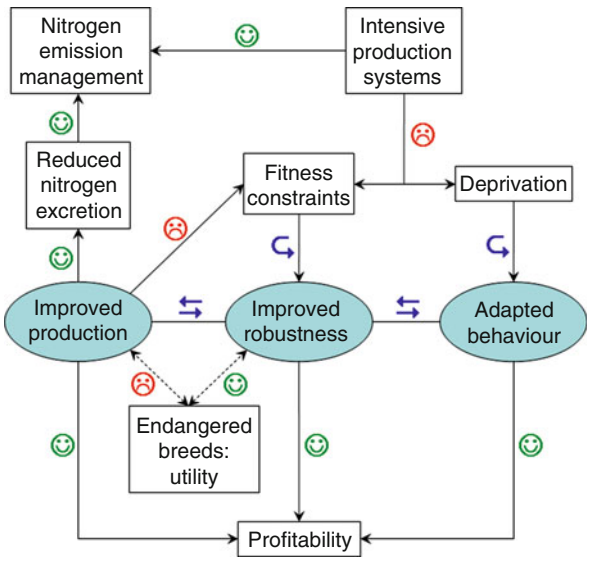
Future Directions

To repeat from the end of the Introduction: *Sustainability will always be a matter of more or less: it can never be an absolute goal.* This can now be made more concrete in terms of conflicting concerns about the various targets of sustainable production (people, pigs, planet, profit), as follows.

De Boer and Cornelissen [217] evaluated three laying-hen housing systems for the sustainability indicators economic performance, ammonia emission, energy use, animal welfare, farmer welfare, and egg quality. These authors notice conflicts such as "improvement of farmer welfare is difficult to achieve in animal-friendly [systems], because unfavorable thoracic dust concentrations [. . .] are a direct result of the presence of litter." With equal weighting to each indicator, the battery cage ranked considerably better for overall sustainability than deep-litter and aviary systems.

Likewise, three scenarios for enhanced sustainability of pig production were studied [218, 219] focusing on (1) animal welfare, (2) pollution, or (3) product quality and safety. Among the reported conflicts are a higher contribution to acidification, a higher greenhouse gas emission, and higher production costs in (1) the animal welfare scenario than in (2) the pollution scenario. "Ranking between the different aspects of sustainability may [. . .] differ between different people and over time. How to evaluate [them] is mainly a political question, and legislation and political decisions can easily change the ranking of the scenarios." This is about production systems, differing in animal management, housing, and feed production strategies. The breeding goals specified in that study were not dramatically different among the scenarios: (1) lean tissue growth rate (LTGR), feed intake, mothering ability, and longevity; (2) LTGR and feed efficiency; and (3) LTGR and meat quality – sets that occur alongside each other in any transnational breeding program, see Figs. 9–11 in the section on "Selection for Robustness Traits," and also Fig. 5 in [107].

However, the inclusion in breeding programs of specific sustainability targets (biodiversity, pollution, animal welfare) will create conflicts that need careful prioritization, as illustrated in Fig. 15. Priorities can be based on economic approaches such as shadow prices (as illustrated for nitrogen excretion in the Pollution section), or benefit functions for animal welfare traits [220]. But the outcome must be a political compromise, and as such will change over time.



Pig Breeding for Increased Sustainability. Figure 15 Elements of pig breeding goals (blue ovals) and their relationships with sustainability issues. The symbols ☹ and ☺ indicate (un-)favorable influences on the downstream element; ↻ indicates that solution of the upstream issue requires the downstream element; ⇆ indicates that a balance must be established. Dotted arrows characterize the sustainability issue in terms of breeding goal elements

A recurring theme of this chapter is: *this technology is statistically demanding*. It follows that sustainable animal breeding equals high-tech animal breeding – just as sustainable animal production must involve precision farming [221] to overcome its inherent conflicts. Earlier breeding programs delivered at lower sustainability levels not only because of incomplete breeding goals (focusing on narrow-sense profitability) but also because the required data recording and processing methodology was not available.

Future directions will have to be set by the production sector and the society that it is part of. The commercial pig breeding sector does not have its own agenda: breeding goals are set based on what the market for breeding stock demands, and those demands are influenced by society – e.g., through legislation, or market regulation, around pollution and animal welfare. This chapter shows that the genetic technology to meet such demands is available, and can be exploited.

Article Outline

Glossary

Phenotyping The activity of measuring the physiological, morphological, developmental, and chemical characteristics of plants.

Trait A measurable phenotypic character or attribute, for example, plant height.

Definition of the Subject

The next generation of crops, capable of being productive in an increasingly variable and changing climate, will rely on genetic interventions based on process understanding, selection of target traits in managed environments, and high-throughput phenotyping and genotyping more than ever before. This entry discusses examples from wheat and rice, recent advances in plant breeding for high yield potential environments, and also those where abiotic stress is a major limitation to productivity. The methodologies and lessons learnt are discussed in the context of breeding in the face of climate change.

Introduction

The effects of climate change on agricultural production and food security are already taking place, creating new challenges for plant breeders to act quickly. The consequences of climate change on agricultural systems across the globe will be heterogeneous [35]. The projections for 2050 indicate that the increase in temperature (1–3°C) and CO_2 together with rainfall changes may benefit crops in the mid- to high latitudes, as temperatures will be closer to optimal for growth and the growing season longer. Over the same period, a decline in agricultural productivity is projected for low-latitude agricultural systems due to detrimental thermal conditions and more frequent extreme weather–related events. In the longer term, if the effects of climate change are not counteracted, productivity could decline both in low and mid- and high latitudes, primarily due to detrimental impacts of high temperatures and water stress [35, 66]. Rising temperatures will lower production by limiting the length of the growing season, exerting direct negative effects on resource capture and processes underpinning growth and yield. Another consequence of rising global temperatures over the next few decades is likely to be the increase in evaporation and acceleration of the global hydrological cycle, which could potentially dry subtropical areas and increase precipitation at higher latitudes. Ongoing challenges to food security will result from these changes, as most developing countries are situated at low latitudes in regions that are already warm and semi-arid [66]. To illustrate this point, two thirds of the undernourished people in the world live in just seven countries (Bangladesh, China, the Democratic Republic of the Congo, Ethiopia, India, Indonesia, and Pakistan) and over 40% live in China and India alone [23].

While general trends are described above, changes can already be observed. In Australia, average temperatures have increased 0.9°C since 1950, with significant regional variation, while the frequency of hot days and nights has increased and that of cold days and nights has declined (www.climatechangeinaustralia.com.au). In parallel, since 1950, most of Eastern and Western Australia has experienced substantial rainfall decline,

while North-West Australia has become wetter. In this context, new crops and crop varieties represent a technical adaptation with the potential to be instrumental in at least reducing climate-related vulnerability at the farm level [33]. For Australia's wheat crops, it has been estimated that, in the absence of adaptive measures, a 1.5–2°C increase in temperature would cancel out the grain yield increase derived from a CO_2 doubling, assuming no change in varietal adaptation ([33] and references therein).

It is important to consider that plant breeding takes time. The objective of a plant breeding program is to create new genetic variation and select gene combinations to create genotypes with superior performance in the target population of environments (TPE) [16]. Combining a range of methods, from traditional plant breeding to molecular tools, it is estimated that it takes 7–12 years to release a wheat cultivar (David Bonnett, pers. comm.) and 5–10 years to release a rice cultivar [9]. Increased climate variability in terms of rainfall patterns and the trends in the evolution of major weather variables such as temperature will lead to longer-term changes in the TPE. Under increased weather variability, a higher genotype x environment interaction (GEI) is expected. An increase in GEI, observed through altered genotypic rankings, makes it harder for breeders to make sustained genetic gains, as already documented for drought [65]. The paradox is that at a time when farmers' needs for new varieties as an adaptation tool intensify, breeding progress may become slower.

In this context, three of the main challenges plant breeding faces in relation to adaptation to climate change are (1) identifying the new target population of environments (TPE), (2) translating this knowledge into practical selection methods to uncover new genetic variation, including large mass phenotyping of potential parental lines, progeny, and wild genetic resources, and (3) integrating complex genotypic information with the large volume of data from high-throughput phenotyping systems. This entry looks at some of the recent advances in plant breeding for high yield potential environments and also those where abiotic stress is a major limitation to productivity. The methodologies and lessons learnt could become useful when breeding in the face of climate change. Examples are given for rice and wheat, because of their important contribution in volume and value to the world economy [24].

Breeding in a Changing Environment

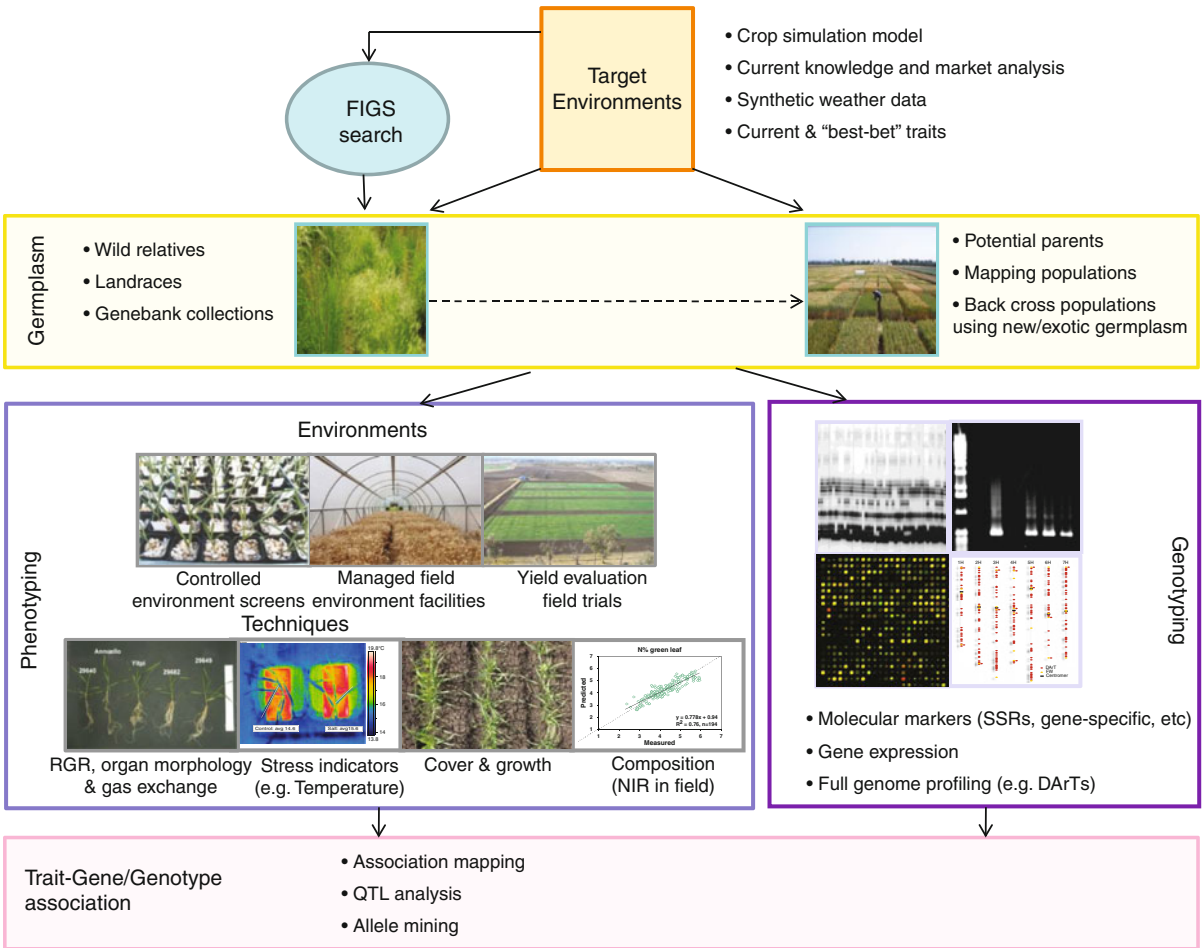
Yield is a complex trait underpinned by many different processes and, as such, highly influenced by environmental conditions. Breeding programs utilize multi-environment trials as a way of sampling the target population of environments (TPE). However, the conditions (weather, soil, agronomy) in those trials are not always a good representation of the TPE that the lines will grow in during their commercial life ([13] and references therein). This gap, between the "selection" TPE and the "commercial life TPE" may increase as a result of increased climate variability. Predicting which type of environments breeders will be targeting and their frequency of occurrence may become a key piece of information in designing the best targeting of selection schemes.

Some lessons can be learnt from experience in breeding for drought-prone environments that could be adopted more widely and potentially extended to selecting for adaptation to high temperatures. In drought-prone areas, an important proportion of the GEI has been attributed to the timing of drought stress with respect to the crop stage. Not surprisingly, different outcomes in yield progress can be expected when selection takes place under different drought patterns [13]. An attempt to describe "types of environment" for a particular region has been conducted for sorghum [13] and wheat [15] in Northern Australia utilizing historic weather data, soil characteristics, and current and virtual crop characteristics (e.g., sorghum: [14]) using the crop simulation model APSIM [38]. This could be expanded to a larger regional scale using synthetic weather data ("future climates") aiming at different outcomes. Although climate projections have their own uncertainty, there is consensus in some of the predicted global trends [32]. At a large scale, describing "types of environments" using synthetic weather data could be a tool to identify shifts in the cultivated area and regions that are likely to experience increased frequency of events that will lead to yield loss [42], for example, high temperature or drought during pollen meiosis in wheat [37] or high temperatures at anthesis in rice [36]. This information can be used to design the layout of multi-environment trials or create managed environment facilities that reliably "reproduce" these conditions, for example, irrigation in the desert (such

as CIMMYT's Obregon facility), rain-out shelters, temperature gradient tunnels, etc., that, depending on their scale, could be used for particular stages of the breeding program. Ultimately, this information could be used to set selection criteria prioritizing particular traits (e.g., [67]) and devise the appropriate tests and technologies to screen for them (Fig. 1).

A Combination of Breeding Approaches Needed to Advance Yield in a Changing Climate

A modern wheat variety carries an elite combination of alleles for productivity, grain quality, and resistance or tolerance to a suite of the most important biotic and abiotic stresses in the environments in which they are grown. In a breeding program targeting development of new varieties for production by farmers, it is usually necessary to make crosses between parents with a high co-ancestry and many attributes in common while differing for a small number of traits important to farmers and end users. Often they will be current varieties or advanced breeding lines. With this approach, the gains made in one breeding cycle are built on in subsequent cycles and progress is incremental. However, in spite of this relative conservatism, most crosses still fail to produce their desired outcome, and breeders



Plant Breeding Under a Changing Climate. Figure 1

Example of how to target traits to introduce in a breeding program for a changing climate. Defining target environments can help direct a FIGS search for exotic germplasm and set up specific populations. Phenotyping will be necessary both in the exotic germplasm and the breeding populations. Genotyping information combined with phenotypic data is the basis for trait–gene association

must make multiple crosses to spread risk. In drier environments subject to greater GEI, progress for yield is usually slower than in more favorable environments. In spite of these constraints, breeding programs have successfully improved water-limited yields over an extended period and new approaches must offer tangible benefits if they are to be adopted [46, 52, 75].

The already commonplace and increasing use of molecular markers in wheat breeding is a good example of the adoption of a technology that successfully supplements conventional approaches. Most markers implemented so far have been for genes of large effect associated with disease resistance, grain quality, or, more recently, the major genes controlling plant phenology. Few if any "yield," "drought tolerance" or "heat tolerance" quantitative trait loci (QTL) have been used in wheat breeding to date. Nonetheless, the major gene markers are useful in allowing more effective selection in earlier generations for a greater range of traits, while still leaving sufficient variation to allow selection of superior individuals for quantitative traits in later generations through conventional phenotypic selection (e.g., [77]). Removal of inferior individuals and alleles earlier in the breeding process means that fewer individuals entering the expensive later stages of yield and quality evaluation will be discarded because they lack some key major genes.

The identification of robust, yield-related QTL markers should allow early generation enrichment of the frequencies of these alleles in much the same way as for major genes. These QTL can be identified through a number of approaches. Initially, biparental mapping populations were used but these have two key problems. First, the population sizes and number of test environments required to accurately identify QTL for yield are large, even in the absence of GEI. Usually, suboptimal population sizes and numbers of test environments were used, leading to some QTL not being identified and the effects of others being overestimated [5]. Other problems with this approach are that only two parents are sampled per population and identified QTL are often population- or environment-specific (e.g., [60]). Further, parents commonly differed for major genes controlling height or phenology and these had by far the largest effects on the quantitative trait being measured making it difficult to identify previously unknown sources of variation in the face of further-reduced effective population sizes [54].

Association mapping and whole genome prediction models (e.g., based on full genome profiling techniques such as DArTs [39]) have been proposed as alternative methods to identify and combine useful variation for a range of traits [10, 30, 31, 43]. The advantages of this approach are that alleles from a greater range of parents can be examined which may have greater relevance to breeding populations if the set is appropriately formulated. In the context of a breeding program aiming to make progress for yield, the most appropriate lines are likely to be breeding lines, and the phenotyping will comprise the routine yield evaluation trials. A key advantage is that the resources allocated to phenotyping are likely to be much greater than is available to any stand-alone QTL mapping project and the associations identified are more likely to be relevant to breeding populations as they were developed in breeding populations. Given the likelihood that the effects of QTLs for complex traits will change over time through fixation of important regions and differing interactions with new alleles at other loci, a continual reassessment of the value of QTLs in breeding populations may be needed in parallel with their use in selection [57]. This requires integration of good multi-environment yield data and efficient whole genome fingerprinting techniques that can be applied to the large numbers of lines making up the yield trials of commercial breeding programs. This approach depends on large amounts of resource for phenotyping, genotyping, and information management that are currently not available within the public sector. Further, association mapping approaches may not give good clues to the underlying mechanisms responsible for the yield effects of QTLs, but given that conventional breeding has achieved yield gains despite ignorance of contributory mechanism(s), this need not be an impediment to their use. Given that there is not a perfect correlation between any one physiological parameter and yield and interrelationships between physiological characters and their effects on yield are often not well understood, widespread mapping and use of QTL for physiological characters are not likely in the public or private sectors in the near future.

A Niche for Indirect Selection for Yield Using Physiological Parameters

Given that all increases in yield must have a physiological basis, it should in theory be possible to identify and select for this variation. "Physiological" or "trait-based" breeding has a niche value as complementary to more conventional crossing and selection methods [63, 73]. For selection of physiological characters to be viable in a breeding program a demonstrated genetic correlation with yield is a prerequisite as is development of a cheap, high-throughput selection tool. The ultimate outcome of selection for yield-related physiological characters must be greater genetic gain per breeding cycle or per unit of investment. The fact that physiological measurements do not depend on knowledge of the number and location of QTLs segregating in any given population means they can be used across a greater number of populations. This also means they can be used to screen exotic germplasm, such as wild relatives, sources for variation that may be based on novel alleles and could be introgressed into breeding populations. High order or composite traits evaluated in the field have been particularly successful as targets of this approach, compared to traits evaluated at the cellular level, which are more prone to be subject to upscaling problems [72]. This is also of value given that agronomically important complex traits have not been particularly amenable to improvement using marker-assisted selection [31].

An analytic physiological approach is also likely to be useful to improve candidate traits for which genetic variation is not readily available, as could be the case in the response to high temperatures, and a targeted search and introduction strategy is needed. To illustrate the possibilities, an example of the use of physiological traits–based breeding to cope with limited water in wheat and improve yield under favorable conditions in rice is presented below.

Packaging Traits to Cope with Limited Water in Wheat and Links with Breeding for High Temperatures

A number of relationships between yield and physiological parameters have been identified in wheat and indirect selection methods for yield subsequently implemented. A good example resulted from the discovery of a positive relationship between irrigated yields and stomatal conductance in a historical series of CIMMYT wheats [25]. Subsequent research showed that selection for higher stomatal conductance could be used in indirect selection for increased yield in irrigated conditions [17]. Selection for high stomatal conductance using canopy temperature as a surrogate is now a routine procedure in the rainfed wheat program at CIMMYT (Manes, personal communication 2010).

Discovery of the relationship between C^{12}/C^{13} carbon isotope discrimination (CID) and yield under drought is another example that grew from postulation of a relationship based on theoretical considerations, subsequent identification of variation in wheat germplasm, demonstrating a relationship with yield, development of a selection tool and germplasm, and ultimately in release of improved varieties Drysdale and Rees [55, 56, 65].

Later genetic dissection identified QTL for CID in several mapping populations that had not been specifically developed for mapping CID and in which the parents were mainly commercial varieties [60]. Although the parents of these populations did not have the most extreme CID levels, the populations showed the genetic complexity of the trait, that diversity for CID alleles was present in current varieties and that it was possible to recover transgressive segregants for CID from these populations as extreme as any identified in previous germplasm surveys. Therefore, with knowledge of the relationship between CID and yield under drought, availability of an appropriate selection screen should allow breeders to indirectly select for higher yield in drought-prone environments. Although use of mass spectrometry to determine carbon isotope composition is a relatively expensive procedure and has not been applied routinely by commercially focused breeding programs, it was successfully applied in germplasm development efforts at CSIRO that led to the release of varieties Drysdale and Rees in collaboration with varietal breeding programs [55, 56]. Development of cheaper techniques to screen for the increased WUE that result in the CID

differences may be applicable on a more routine basis in breeding programs.

QTL mapping of water soluble carbohydrate (WSC) contents in stem [60] and coleoptile length [59] reveal similarly widespread and potentially useful variation for these traits in elite germplasm. In cereals, water soluble carbohydrates (WSC) stored in stems have been acknowledged as contributing to maintenance of grain filling rate when photosynthesis declines due to various stresses, for example, drought ([6, 47 81], heat stress [7], and possibly disease [8]. Increased coleoptiles length can be a useful option for systems utilizing moisture-seeking strategies, such as sowing in deep furrows. This is likely to be a useful combination of traits for climate change in Australia, with the projected temperature increase and the decrease in average annual and winter rainfall (fewer and drier sowing opportunities) in the southern areas of the wheatbelt toward 2030 [32]. Progress for these traits could be made by selecting variation already present in breeders' populations if an efficient selection screen were available.

As mentioned before some of the traits targeted for drought stress are potentially useful under heat stress, which is particularly the case for those related to transpirational cooling [54]. Increased root growth in a soil profile with water available at depth can increase the transpirational cooling of the crop, uncoupling it from air temperature and helping keep tissues in a "safer" temperature window. Epicuticular waxiness is another trait with a dual function, reducing heat load and transpiration. Waxiness can be scored visually in the field, but, despite the theoretical impact there have been no comprehensive studies of its impact in crops [64]. Flowering time has been exploited under terminal drought as a simple way of manipulating the water balance, early flowering leaving more water available to be used during grain filling. Early flowering can also be used to avoid high temperatures during grain filling. In both cases, advancing flowering can carry the penalty of lower biomass at flowering and increased probability of frost damage.

Some processes are directly affected by high temperatures, among them respiration, inflorescence fertility, and starch composition, and hence grain quality ([2, 4, 78, 82]). Night respiration and photorespiration are processes directly affected by temperature; however, the lack of an easy way to phenotype large number of lines and study its effects at the crop level makes it inaccessible as a target for breeders at this point in time. Susceptibility of pollen to high temperatures and traits contributing to heat tolerance (biochemical mechanisms) and avoidance (e.g., anther dehiscence early in the day) is a topic much researched in rice (see [78] and references therein). Pollen sterility induced by drought and genetic variation for it has been confirmed in wheat [37] and could also be potentially triggered by high temperatures. This is likely to be a trait to be screened for in controlled environment facilities or using molecular markers, given how unpredictable high temperatures can be at a particular crop stage in the field. For the purpose of marker development or QTL identification it will be important to "detangle" the phenotype appropriately as, for instance, reduced pollen sterility under high temperature could occur due to lower tissue temperature in a line that has high transpirational cooling due to higher stomatal conductance.

Physiological Traits to Raise Yield Potential in Rice: Different Targets for Temperate Versus Tropical Regions

As highlighted earlier, an increase in the length of the growing season as well as improved growing seasonal conditions are forecasted for high latitudes under climate change. This section illustrates the experience in rice in breeding for increased yield potential. Yield potential is defined as grain yield only limited by incoming radiation and temperature at a given site. Most of rice production is derived from tropical and subtropical areas, where it is grown with irrigation water from the monsoon [79]. The yield potential of rice in the tropics has been stable at 9–10 t ha^{-1} for the last 20 years [51]. However, the arable land for rice is continuously decreasing as a consequence of increasing urbanization, in parallel with the increase in the population of rice consumers. An increase in yield potential of rice of 10–15% is now necessary to cope with this raising demand [69]. Among the main limitations to

rice yield potential in the tropics are (1) the limited amount of incoming radiation (combination of short days and cloudiness), (2) high relative humidity underlying high resistance to transpiration, and (3) a trend toward a short crop cycle to allow the growth of two to three crops per year. Indeed, the highest rice yield potential today is slightly higher or similar to that of IR64, that is, comparable to introgression lines of IR64 background [29], a benchmark inbred line which was developed by IRRI breeders in the middle of the 1980s. Most of the increases in rice yield in the field have been achieved with hybrid rice [50]. In contrast, the main gain in crop productivity in the last 20 years has been observed undernutrient or water limitation [34]. Grain quality has also been a great focus of the last 20 years and has diversified significantly to meet the variable expectations of consumers from different regions [27].

The International Rice Research Institute was a pioneer in using physiological concepts in breeding for an ideotype, as illustrated by the so-called "new plant type" which reached limited success [51]. These guiding principles are still utilized in current efforts to improve yield potential in rice focusing in increasing biomass and harvest index as discussed below. One challenging option is to develop a rice plant with the C_4 photosynthesis pathway: the radiation use efficiency would be increased considerably and so the yield potential up to by 30–50% [44, 68, 80]. It is taking an integrated program involving molecular biologists, geneticists, biotechnologists, and physiologists working together for a considerable number of years. The search for genetic variation in different aspects of the C_4 pathway, such as leaf anatomical and cellular specialization and variation in mechanisms underlying the CO_2 compensation point is already presenting a considerable phenotyping challenge [83, 84]. Another option, still challenging but perhaps more realistic in a shorter timeframe, is to improve the current plant types for high yield. In the tropics, both improved biomass accumulation and partitioning underpin the superiority of hybrid rice versus rice elite inbred lines, with margins between 10% and 20% from wet to dry seasons [11, 40, 49, 50]. It is possible to assume that breeding programs for yield potential could gain much by incorporating traits relevant to hybrid rice superiority into improved inbred lines and lead to a substantial yield gain [41].

Work conducted at the International Rice Research Institute has extensively examined the basis for yield differences between hybrid rice and elite inbred lines of similar crop duration [11, 12, 40]. With an initial focus in the tropics, these authors confirmed, under a range of contrasting conditions, that superior biomass production in the succeeding phenological phases and improved partitioning play a significant role in the higher yields of the hybrids. Hybrids are characterized by (1) higher crop growth rate during each phenological phase leading to overall higher plant biomass at maturity, (2) earlier cessation of tiller production (associated with earlier biomass partitioning to culm and earlier accumulation of reserves) with similar tiller production rate, (3) larger pool of reserves in the culm at anthesis (estimated through a lower value of specific culm length, SCL), (4) larger remobilization of the accumulated reserves from the culm to the panicle during grain filling (associated with quicker grain filling and higher SCL at maturity), and (5) lighter unfilled spikelets indicating that grain filling was more efficient with less partially filled spikelets (associated with larger number of filled grains) [40, 41]. It is clear that it is worth looking for genetic variation in storage of soluble sugars in the stem as well as remobilization capacity, in line with results in wheat [81] and in view of identifying the driving force of the dynamics of soluble sugars. Bueno et al. [12] speculated that improved partitioning, more than source supply, is the key component driving crop performance of high-yielding genotypes in the tropics where variability in biomass accumulation among genotypes is poorly expressed due to low evaporative demand. The sink strength index, as an improved harvest index taking into account the culm vigor [12, 41], can be used as an integrated trait for screening genotypes with high or low partitioning efficiency. It cannot, however, be considered as a "foundation" trait for high yield potential, unlike the traits cited earlier, and seems rather to be the integrated expression at maturity, as sink size at anthesis, of the cumulated higher efficiency of more simple traits. Some other important considerations concern remobilizing assimilates from senescing to productive tillers, avoiding lodging and delaying root senescence during grain filling. Maintaining functional roots throughout grain filling, and maintaining nitrogen uptake, should help delaying leaf senescence; however,

leaf senescence has to be fast toward the end of grain filling to maximize remobilization.

Identification of Variation for Physiological Traits from Exotic Germplasm Sources

While the wheat example cited above indicates considerable variation for several yield-related physiological traits already existing in varieties and advanced breeding lines adapted to drier environments, for some traits, key genetic variation is lacking in existing breeding material. An example of this problem is the difficulty of recovering long coleoptile semidwarfs in wheats carrying the semidwarf alleles *Rht-B1b* and *Rht-D1b* [1, 76]. These alleles are virtually ubiquitous in modern semidwarf genes but have negative pleiotropic effects on coleoptile length. In order to develop semidwarf wheats with substantially longer coleoptiles the introduction of novel dwarfing genes that do not affect coleoptile length is necessary [22, 58]. For other traits such as root depth, likely to be related to yield under drought or heat stress, variation has been found in landraces and wild or synthetic hexaploid material that is greater or absent in existing wheat germplasm available to breeders [61, 62]. The introduction and exploitation of variation from synthetic hexaploid wheats in the CIMMYT wheat program is an example of the potential gains that can be made from exotic germplasm sources. These synthetic wheats were produced by re-synthesizing bread wheat from progenitor species the tetraploid durum wheat and the diploid wild grass *Triticum tauschii* [70, 71]. Derivatives of crosses between synthetic hexaploids and bread wheat now comprise around 30% of the breeding populations in CIMMYTs rainfed wheat program and the best lines have superior yield under drought stressed and more favorable environments than the best conventional wheats [18]. While this demonstrates the possibility of gains from exotic germplasm sources, a more targeted approach in which exotic sources are prescreened for traits related to yield under drought or high temperatures may produce even greater gains. A possible pathway of integration is shown in Fig. 1. In many cases novel yield-related variation in exotic germplasm sources would be difficult or impossible to identify simply by screening directly for yield because it is present in agronomically poor backgrounds. In such instances, screening for physiological traits likely to be related to yield may be a useful precursor to crossing to introduce new variation [62].

A number of other approaches may allow selection of better initial material even prior to screening for physiological traits. Molecular diversity studies have shown, for example, that genetic diversity of emmer wheat is greater than that in durum wheat [19] and studies of synthetic wheats produced by crossing emmers with *A. tauschii* have shown greater yield under drought stress in Mexico, Pakistan, and Eastern India than synthetics produced by durum wheat x *A. tauschii* crosses [71]. Given the distribution of emmer wheats in drought-prone Mediterranean environments the useful variation present in this material may have been predictable. Better predictions based on a greater array of climatic, soil, and location data as exemplified by the focused identification of germplasm strategy or FIGS (e.g., [20, 21]) should further improve the quality of germplasm selected to screen for variation in phenotypic traits (Fig. 1).

Robust and time-efficient phenotyping is also critical for trait-based selection of potential parents for crossing blocks and evaluation of the progeny, such as needed to underpin physiological breeding [63]. Noninvasive technologies, such as those based on spectral reflectance and thermal sensing have a role in the identification and selection of traits in a breeding context, by allowing several crop characteristics to be surveyed in a single measurement at the crop scale [45] (Fig. 1). For example, spectral reflectance has been used to simultaneously survey canopy cover, nitrogen, and water status of the crop [25, 48], while canopy temperature has been used as an indicator of leaf conductance and water use [85]. Potential for continuous developments for high throughput include introducing changes in platforms (wireless systems, unmanned aerial vehicles, etc.) to allow more frequent data capture and greater area coverage. While glasshouse or lab-based screens have been indicated as an option for some traits (e.g., [28, 74]), in most cases, there is a low correlation between this level of evaluation and field-based rankings. The interactions involved not only in upscaling to the crop/canopy level but with the changing environment itself get in the way (examples in [72]). Instead, field canopy scale measurements have more potential since selection can take place at the

crop level, which avoids scaling up issues (e.g., [62]). For instance, reflectance-based indices have proved very useful as indirect selection criteria to increase the efficiency of selection in wheat growing in a reasonably stable environment where the terminal drought is managed [3], while indicators of canopy cover and canopy temperature were a good proxy for performance or QTL detection in a hot environment [54].

Conclusions and Future Directions

Improved crop varieties will be a vital component of adaptation to climate change. Plant breeding will have to operate at a higher level of efficiency to make the necessary genetic progress to address current and projected food needs. In this context, the three main challenges plant breeding faces in relation to climate change are (1) identifying the new target population of environments, (2) translating this knowledge into practical selection methods to uncover new genetic variation, including mass phenotyping of potential parental lines, progeny, and wild genetic resources, and (3) linking genetic and phenotypic information. How to link and interpret the new and comprehensive information on genotypic characteristics and the large volume of data generated by high-throughput phenotyping platforms will be a critical step toward selecting the next generation of traits fit to less predictable environments.

Article Outline

Glossary

Diafiltration Method of cross-flow filtration that separates filtrate from solids.

Industrial enzymes Proteins that are used in commercial applications where very specific catalysts are needed.

Pharmacognosy The study of medicines derived from natural sources.

Plant molecular pharming Production of pharmaceuticals or industrial enzymes from genetically engineered plants.

Sustainability Production to meet present needs without compromising the ability of future generations to meet their own needs.

Transgenic plants Plants genetically engineered by the introduction of foreign genes using recombinant DNA technology.

Definition of the Subject

Plants have been domesticated since around 10,000 years ago in the fertile Babylonian crescent [1] and husbandry and breeding techniques have been applied to increase yield and storage and to retard spoilage [2]. Plants have been used since time immemorial for their medicinal properties, and in ACE 78 Discorides first described 600 medicinal plants in De Materia Medica. Although the first synthetic drug, salicylic acid, entered the market in 1897, plants are still used for pharmacognosy – the preparation of drugs from natural sources [3]. The types of plants used for this purpose, however, are usually distinct from those for food, feed, or fiber. With the advent of molecular techniques, all plants now have the potential to serve as production vehicles for natural or engineered products that were previously limited to other hosts [4, 5]. Plant molecular pharming of industrial proteins refers to recombinant proteins used in industrial processes and produced in plants. Enormous quantities of a variety of enzymes go into the making of products such as paper, leather, detergents, pharmaceuticals, food, beverages, chemicals, and fabric, to name a few, and the economical production of these industrially important enzymes is crucial to commerce. This production must be balanced with the need for sustainability and environmental stewardship.

Sustainable production of industrial enzymes requires that resources are not over-exploited and that the environment is not polluted by wastes. The use of plants as "green" factories can meet both criteria. Plants are a renewable resource and thus generally are not over-exploited and wastes are biodegradable. The problems associated with fertilization runoff, spread of transgenic genes to non-target plants, and crop and land usage must be addressed to allay public concern about the use of transgenic plants. But, combined with modern farming and containment methods, transgenic plants have the potential to produce large quantities of target material safely and sustainably [6, 7].

Introduction

This article provides a review of plant-based production of industrial enzymes as a sustainable solution to increasing demand. The history of interest in sustainable development, industry and industrial enzymes will

set the background for a detailed analysis of how plant-based production systems compare in terms of sustainability to processes that currently exist. A compilation of potentially useful industrial enzymes produced in plants is given and a discussion of the economic, social, and environmental sustainability advantages provided by plant-based production systems is also provided.

Historical Background of Industrial Enzymes

In view of the importance of enzymes to industrial processes, a brief overview of the events leading to this relationship is provided below.

Development of Applications for Industrial Enzymes

Until mechanization and the industrial revolution, most people eked out a subsistence living using human and animal power for agriculture, production, and transport of people and goods. The industrial revolution eventually made possible tremendous increases in commerce, and consequent social upliftment through improved earnings, literacy, and working conditions. There were costs, however, in degradation of the environment through unregulated expansion of industries and consequent pollution. In 1956, the British Parliament enacted the world's first clean air act. Since then, governments have imposed restrictions on locations of industries and the disposal of pollutants and effluents. These measures have helped considerably to alleviate the impact of pollutants on the environment and health [8], but have been costly to the industries themselves. For example, costs imposed on the meat and meat by-products industries, which include industrial enzymes, are passed on to the consumer through increased prices [9] which is often negative for commerce. Thus, the pressure mounts to lower prices across the board.

An assessment of the true cost of product manufacturing is provided by Life Cycle Assessments (LCA) which measures, usually by mass loadings, the cradle-to-grave impact of every stage from resource procurement, inputs for manufacture, and outputs of wastes throughout the process [10]. Although it is often difficult to predict the LCA of a process, especially impacts on biodiversity and environment, key parameters affecting LCA are renewability of the raw material resource and energy inputs. Enzymes lower the activation energy of chemical reactions and are sourced from renewable resources, and thus should lower impact. A theoretical life cycle comparison between the production of biodiesel using inorganic and enzyme catalysis favored the latter as having lower environmental impact, lowered toxicity, and lowered greenhouse gas emissions, all attributed to lower steam heating requirements [11]. Production of large quantities of enzymes therefore comprises a key consideration for future industrial manufacturing processes.

Current Uses of Industrial Enzymes

Today, many industries use enzymes to manufacture a variety of goods (see Table 1) from food to paper to high-value pharmaceuticals. The utilization of industrial enzymes has now extended to almost all industries handling organic compounds. Enzymes are used in the production of detergents, reagents for the analysis of drugs or blood components, food or food additives, for fiber processing or pulp processing in the paper industry, and for environmental purification. The method of enzyme use also varies, for example, as an enzyme preparation, on the surface of an insoluble carrier in a bioreactor, or a biosensor with the enzyme integrated into an electrode. The annual world industrial enzyme market (excluding pharmaceuticals) is in billions of dollars and is composed largely of enzymes used as detergent ingredients and for food processing applications [12, 13]. Thus, enzymes constitute a key lubricant of commercial success in many fields.

Enzymes are formally classified and given an Enzyme Classification (EC) number by the International Union of Biochemistry and Molecular Biology (IUBMB) based on the reaction that they catalyze (http://www.chem.qmul.ac.uk/iubmb/). Each major category is further divided into subclasses and sub-subclasses. Several enzymes with different trivial or common names may share the same EC number based on the type of reaction that they catalyze (see Table 2). For example, lipases and amylases share the same major category, hydrolases, because they catalyze the breakdown of substrate by hydrolysis. However, enzymes of industrial importance are generally referred to by their trivial name, and trivial names will be used in this review. The source of industrial enzymes can be fungal, bacterial, animal, or plant and with the advent

Plant Molecular Pharming, Industrial Enzymes. Table 1 Enzymes used in various industrial segments and their applications (Reprinted from [13]. With permission from Elsevier)

Industry	Industrial enzyme	Industrial effect/application
Detergent laundry and dish wash	Protease	Protein stain removal
	Amylase	Starch stain removal
	Lipase	Lipid stain removal
	Cellulase	Cleaning, color clarification, anti-redeposition (cotton)
	Mannanase	Mannanan stain removal (reappearing stains)
Starch and fuel	Amylase,	Starch liquefication and saccharification
	Amyloglucosidase	Saccharification
	Pullulanase	Saccharification
	Glucose isomerase	Glucose to fructose conversion
	Cyclodextrin-glycosyltransferase	Cyclodextrin production
	Xylanase	Viscosity reduction (fuel and starch)
	Protease	Protease (yeast nutrition-fuel)
Food including dairy	Protease	Milk clotting, infant formulas (low allergenic), flavor
	Lipase	Cheese flavor
	Lactase	Lactose removal (milk)
	Pectin methyl esterase	Firming fruit-based products
	Pectinase	Fruit-based products
	Transglutaminase	Modify visco-elastic properties
Baking	Amylase	Bread softness and volume, flour adjustment
	Xylanase	Dough conditioning
	Lipase	Dough stability and conditioning (in situ emulsifier)
	Phospholipase	Dough stability and conditioning (in situ emulsifier)
	Glucose oxidase	Dough strengthening
	Lipoxygenase	Dough strengthening, bread whitening
	Protease	Biscuits, cookies
	Transglutaminase	Laminated dough strengths
Animal feed	Phytase	Phytate digestability-phosphorus release
	Xylanase	Digestibility
	β-glucanase	Digestibility
Beverage	Pectinase	De-pectinization, mashing
	Amylase	Juice treatment, low calorie beer
	β-glucanase	Mashing
	Acetolactate decarboxylase	Maturation (beer)
	Laccase	Clarification (juice), flavor (beer), cork stopper treatment

Plant Molecular Pharming, Industrial Enzymes. Table 1 (Continued)

Industry	Industrial enzyme	Industrial effect/application
Textile	Cellulase	Denim finishing, cotton softening
	Amylase	De-sizing
	Pectate lyase	Scouring
	Catalase	Bleach termination
	Laccase	Bleaching
	Peroxidase	Excess dye removal
Pulp and paper	Lipase	Pitch control, contaminant control
	Protease	Biofilm removal
	Amylase	Starch coating, de-inking, drainage improvement
	Xylanase	Bleach boosting
	Cellulase	De-inking, drainage improvement, fiber modification
Fats and oil	Lipase,	Transestrefication
	Phospholipase	De-gumming, lyso-lecithin production
Organic synthesis	Lipase	Resolution of chial alcohol and amides
	Acylase	Synthesis of semisynthetic penicillin
	Nitrilase	Synthesis of enantiopure carboxlic acids
Leather	Protease	Unhearing, bating
	Lipase	De-pickling
Personal care	Amyloglucosidase	Antimicrobial (combined with glucose oxidase)
	Glucose oxidase	Bleaching, antimicrobial
	Peroxidase	Antimicrobial

of molecular techniques, many of the genes for these enzymes have been cloned and transformed into organisms that are easy and convenient to grow in an industrial setting. Optimizing gene expression and culture conditions can increase quantities of enzymes produced and consequently lower costs.

In medicine, the prohibitive cost of insulin isolated from human cadavers created a market for porcine insulin despite the negative side effects. Eli Lilly introduced recombinant insulin in 1982, which decreased the cost to a more manageable level through the use of higher-affinity analogs [14], thereby saving innumerable lives. This price decrease is attributed to the use of transgenic bacteria, improved production methods, and also to lower costs of high-purity protease used to cleave the insulin molecule to active form [15].

Another prominent example today is the use of enzymes in the bioconversion of grain to ethanol [16]. In this case the enzymes very efficiently break down starch to fermentable sugars that can then be used to make ethanol. In the near future the hope is that enzymes will also be used to convert cellulosic material into fermentable sugars as well.

The global industrial enzyme market increased from US $1 billion in 1995 to $1.5 billion in the 5-year period to 2000 with growth rates ranging from 2% to 25% annually [13]. The value of the market created by enzyme technology is much higher, at around $80–130 billion. In case studies by the Organization of Economic Cooperation and Development (OECD), the application of biotechnology has generally benefited by improved costs and sustainability, and

Plant Molecular Pharming, Industrial Enzymes. Table 2 Summary of classes of enzymatic reactions and industrial uses

Enzyme class	Reaction catalyzed	Example of industrial enzyme/use
Oxidoreductases	Oxidation or reduction of substrate	Biocatalysis/fine chemical synthesis
Transferases	Transfer of a group from one molecule to another molecule	Transglutaminases/fine chemical synthesis
Hydrolases	Bond cleavage while water is added	Proteases, esterases/food, beverage and paper pulp
Lyases	Non-hydrolytic cleavage of bond and remove group from their substrate	Pectate lyases/food, beverage
Isomerases	Conversion of one isomer to another	Glucose isomerase/food, beverage
Ligases	Joining of two molecules at the expense of chemical energy	Synthetases/fine chemical synthesis

operational costs lowered by between 9% and 90% [12]. It is projected that the enzyme-based biotechnological industries will continue to grow, fuelled by trends including the demand for chiral chemicals, cost savings, emerging technologies, and sustainable industrial development [12, 17]. Novel enzymatic activities can also be generated without prior knowledge of detailed mechanisms [18], providing further impetus for enzyme-based industries.

Enzyme-based industries have certain advantages compared to traditional chemical manufacturing industries. For example, the production of many specialty chemical compounds, especially pharmaceuticals, relies on the use of chirality, or handedness, since many bioactive compounds and receptors show chirality. Chemical processes generally generate a mixture of compounds that are right-handed and left-handed, and separating them is problematic. Enzymes can be rationally designed to produce specific chiral molecules [19–21]. The worldwide market for single enantiomer drugs exceeds $100 billion [22], making this search a worthwhile investment. In addition, enzymes being proteins are biodegradable and not harmful to the environment or difficult to dispose, unlike traditional chemicals which persist in the environment and are sometimes poisonous or bioaccumulate. For example, paper pulp was traditionally whitened using chlorine-based bleaches which are strongly oxidizing. New whiteners incorporate xylanases which are much less harmful than chlorine in the environment [23], and increase chlorine penetration, allowing less chlorine to be used [24, 25]. Many chemicals used in traditional industrial processes are strongly acidic or basic which may skew the pH of the effluents or cause damage to containers. Some enzymes do require extreme pH or temperatures for activity (e.g., some proteases and enzymes from thermophiles) but most industrial enzymes have moderate pH and temperature requirements, overcoming these problems.

Production of Industrial Enzymes

As the source of industrial enzymes varies, so do production procedures. Enzymes sourced from microbes, as well as transgenic enzymes produced in microbes, are usually grown in fermenters and can be extracted from the microbial cells. A preferred method is to secrete the enzyme into the culture media making extraction and purification much easier [26]. Microbial production utilizes microorganisms that have been modified and evaluated for safety and efficient production. Many have been used since historical times in the manufacture of fermented foods such as beer, cheese, soy sauce, and yogurt [13]. The first US patent granted for a transgenic microorganism with an industrial application was US Patent 4,259,444 following a Supreme Court ruling to Ananda Chakrabarty from General Electric Corporation for developing *Pseudomonas* strains harboring plasmids that could degrade aromatic hydrocarbons [27], and subsequently for mixed culture of *Arthrobacter* and *Pseudomonas* suitable "in the biological treatment of a contaminated

material including many persistent compounds of diverse chemical constitution" [28]. The ease of transformation of bacteria with plasmids and protection by patent law catalyzed the development of an industry of selected organisms producing proteins for various purposes.

Methods to optimize gene expression and enhance protein accumulation and purification continue to be developed. The industrial strains used to produce enzymes today are mostly proprietary and are selected for high production and accumulation levels. However, a disadvantage of bacteria is that proteins are not modified post-translationally and are often insoluble and accumulate into inclusion bodies. This can affect activity, especially when the protein is of eukaryotic origin, and methods to recover active proteins from this inactive conglomeration are often tedious [29].

Yeast is often the microbe of choice to express eukaryotic proteins, but hyperglycosylation of transgenic proteins has been observed. Fungal systems are relatively robust, but they have different metabolic pathways, post-translational processing, codon usage, and may form inclusion bodies [30, 31].

Following selection of an efficient microbial producer, the organism is grown in optimized conditions on media which may be solid or liquid. Most industrial enzymes are generally produced in 50–500 m^3 stirred fermenters. A major challenge with fermenters such as these is to maintain sterility, as contamination can cause loss of the entire batch. The integrity of the high producer must also be monitored to ensure that a lower-producing mutant does not outcompete the high-producing strain. But besides operational costs, capital costs can also be high, which makes this system quite expensive [32].

The same considerations apply to cultures of insect and mammalian cell cultures used to overcome the problems of eukaryotic protein expression seen in microorganisms such as glycosylation, folding, subunit association, γ-carboxylation, and cleavage [33]. For cell cultures, each production scale has to be optimized to the product and may vary from high-value, low-demand products being made in small multiple-unit reactors (flasks or roller bottles) and bulk products in large 10,000 L single-unit batch reactors to be cost-effective [34]. In fermenters, cultured mammalian cells are affected by shear forces and are also sensitive to growth conditions such as pH and temperature, metabolites, and dissolved oxygen, which may affect product quantity and quality [5]. Such variation does not permit streamlining or standardization, and makes animal cultures more expensive to operate.

Enzymes such as catalase from liver and rennet from stomach can also be isolated directly from animal tissues, often as byproducts of the meat industry. Transgenic animal sources have the advantages of appropriate modifications of proteins [33], but problems of scale and costs of production, maintenance, and waste disposal. A serious concern with the use of animals is the risk of contamination of end products, especially when they may be used for human therapeutics or consumption, with animal pathogens such as viruses, mycoplasmas, and prions. More recently, Bovine Spongiform Encephalopathy (BSE) or mad cow disease was shown to be transmitted by contamination by small amounts of infective prions in blood and other animal tissues [35]. This had led to fears of contracting this disease by using protein products derived from animals.

Although plants were one of the first sources to be used to produce industrial enzymes such as papain from papaya and β-amylase from barley, only recently have they been developed as recombinant protein production systems [5, 36]. There are several theoretical reasons why plants may be one of the best sources for the long-term supply of exogenous enzymes including: (1) plants represent the least expensive method to produce proteins in general, (2) they do not require the large amount of capital for production compared to microbial fermenters, (3) production can be scaled up or down without major changes in infrastructure, (4) almost any plant in theory can function as a production system, (5) proteins can be targeted to specific compartments allowing for increased accumulation in the desired tissue with little interference in other tissues to reduce potential toxicity to the cell, (6) plants have convenient storage, transport, and processing of component materials; and (7) plants have the potential to combine lines with different enzymes through crossing [37–39].

There are other advantages. Many pharmaceuticals targeted for use in animals are toxic to animal cells. Plants do not share the same receptors and are capable of accumulating such proteins. Since plants do not

form inclusion bodies, the proteins stay soluble and can be purified more easily. Plants can further be engineered to produce protein in specific tissue, allowing the other parts of the plant to be processed to offset the cost of production. Further, the protein is thereby precluded from interfering with metabolism in other parts of the plant. Proteins can also be targeted to subcellular compartments, further reducing the risk of toxicity, as well as increasing production levels. This potential to express different proteins in different locations allows flexibility in storage and purification options [5, 40–42], and will be discussed in more detail below.

One obvious advantage is that plant-produced biologics are free of animal source tissue, thereby eliminating the fear of transmitting animal pathogens. The lower trophic levels plants occupy as producers is advantageous because it indicates that the energy input into plant growth is lower, and therefore the LCA impact is lower compared with microbes and cell lines grown in fermenters and animals on farms. Plants grown in fields require little more than air, rain, soil, and nutrients. Microbes and animals utilize plant material for growth, and unless they can utilize plant resources at 100% efficiency, they can never be as energy proficient as plants themselves. The low cost of production, ability to post-translationally modify proteins and clear growing, handling, and processing knowhow make plants valuable for industrial enzyme production.

In addition to the advantages of plants listed above, plant systems are particularly well suited to inexpensively yield large amounts of a desired product in a relatively small area. For instance, the cost of transgenic seed for extraction of β-glucuronidase in 1998 was estimated to be only $0.20/kg [43], which was considerably less than bacterial cultures [44]. Moreover, because some plant tissues such as seeds can store proteins for years without loss of activity under ambient conditions, a ready supply of material can be manufactured into final form on an as-needed basis [45]. Propagation from stored seed, rapid scale-up, large volumes, and long-term storage are particularly advantageous for industrial enzymes. Low cost combined with the ability to use the raw material directly for industrial processes encourage development in this direction. These advantages have led to a recent increase in use of this technology for the production of new biologics.

While it seems unlikely that one production system could meet all potential needs for the diversity of products, plants do offer some clear theoretical advantages over other systems. A summary of characteristics of different production systems is shown in Table 3.

Production of Recombinant Proteins in Plants

There are a plethora of plants to choose from for heterologous protein production. The choice of the best plant type depends on how the characteristics of the final product complement the characteristics of the plant. Key factors include the ability of certain tissues to accumulate proteins, detrimental compounds such as toxins that may be produced in certain tissues that can co-purify with the protein products, the potential for the industrial crop to inadvertently mix with other food crops or weeds, the ease of purification of the protein from the plant tissue, and the potential to use the plant tissue directly eliminating the need to purify or extract the protein product. Table 4 lists some of the characteristics of different plant systems that can be used for protein production. While most plant systems can be used in theory, the associated cost can make this unsustainable for many industrial proteins. For high volume, the most cost-efficient system is with commodity grains. Grains provide the advantages of high protein content, feasibility for long-term storage, and the ease of downstream processing which give them great potential for future industrial protein production.

While plants are the least expensive source of biomass, they have not been developed to the extent of their microbial counterparts to accumulate proteins. The cost of producing the proteins is inversely related to the amount accumulated in the biomass so this has a direct bearing on the economics. In the past decades, most of the research on plants has focused on improving traditional uses of plants so there has not been much incentive to look at protein accumulation for use as a production vehicle for protein products. Currently high level of expression in plants is usually recognized at levels of 0.1% of the dry weight of the plant tissue. This leaves much room for improvement in the future.

Plant Molecular Pharming, Industrial Enzymes. Table 3 Features of different industrial enzyme production systems

Production system	Bacterial	Fungal	Animal cell lines	Transgenic animals	Plant
Speed of creating transgenic plants	Rapid	Rapid	Rapid	Slow	Moderate
Capital cost to produce raw ingredients (fermenters, chambers)	High	High	Very high	Low to moderate	Low to moderate
Consumables (media and resources)	Moderate	Moderate	High	Moderate	Low
Processing cost	Moderate	Low	Moderate	Moderate	Low
Production issues	Contamination, maintenance of high producers	Contamination	Contamination, animal pathogens	Animal pathogens	

Plant Molecular Pharming, Industrial Enzymes. Table 4 Characteristics of plant systems for the production of transgenic plants (Reprinted from [39]. With permission from Elsevier)

Crop	Advantages	Disadvantages
Wild species	Clearly distinguishable from crops	Low yield
		Outcross to native plants
		Little known about safety
Domesticated species	High yields	Potential to intermix with crops used for other purposes
	Infrastructure and experience exist	
Food	High margin of safety for human health products	Greater potential to intermix with food supply
Non-food	Less potential to intermix with food supply	Greater potential for toxic, antinutritional, or allergenic agents
Fresh tissue	Abundant biomass	Harvest/Transport/Storage
Seed or dry tissue	Harvest/Transport/Storage	
	High protein content	
Hydroponics, cell cultures	Limited exposure to environment	High cost
		Limited knowledge of product safety
Field grown	Low cost	Higher potential to intermix
	Infrastructure in place	
Modified food/feed grain designed for industrial applications	Clearly distinguished by color/shape	Not yet developed
	Non-transferable genetics	
	Low cost	
	Infrastructure and experience transferable from commodity crop	

Commodity plants currently used as a food, feed, or fiber source are being investigated as a production vehicle for industrial proteins. There has been public concern that use of food plants to produce industrial enzymes or pharmaceuticals may lead to inadvertent exposure to these products and cause safety concerns. Production of industrial or pharmaceutical compounds in organisms used in the food chain is far from new. In addition to the many native products isolated from animals, recombinant food organisms such as yeast or eggs play a major role in the production of pharmaceuticals and industrial proteins. There is also precedent in plants for species that produce both food and industrial products. Rapeseed is used primarily for the production of an industrial oil crop while canola seed which was derived from rapeseed, with subtle genetic differences, is used predominantly as a food crop. The key is to keep food and production streams separate [6] and failure to do so can create problems whether the organism is a traditional food or non-food source.

Current government regulations put plants on par with other production systems to prevent inadvertent products entering the food chain or harming the environment. While many of the industrial enzymes in use today are already in the food chain, these added precautions are necessary to limit exposure or can be used to protect against protein products that may not be in the food chain or have not undergone the rigorous or long-term testing needed to give confidence that there are no detrimental effects.

One concern often voiced by the public is that transgenic plants have the potential for dissemination of the transgene through pollen when grown in an open environment. The pollen may be ingested by non-target species, or hybridize with other plants. This situation has been recognized by regulatory agencies and there are strict controls on containment of transgenic plants and pollen. These include physical isolation and temporal delays as well as molecular containment strategies such as pollen and seed sterility and RNA interference have also been adopted to restrict dissemination [46–48]. These measures can lead to increased costs, but are necessary for safety and to allay public unease about transgenic crops.

The types of industrial proteins can include non-enzyme proteins and enzymes that have industrial use for food, feed, or pharmaceutical applications. This also includes proteins used in the making of pharmaceuticals [49], including plantibodies [50–52] and edible vaccines [53, 54]. This may also include pharmaceuticals such as therapeutics and vaccines but these will not be discussed in this contribution.

Like pharmaceutical products, some industrial proteins may require appropriate post-translational modification and folding to be active. Most higher plants can accommodate this in a manner very similar to that which occurs with animal cells with minor modifications. Since plants do not form inclusion bodies, and since many proteins normally harmful to animal cells do not affect plant cells, plants are increasingly and successfully being used for their production.

One of the main limitations in using plants today to produce industrial proteins is the demand that cost must be extremely low compared to pharmaceuticals. This requires that the expression level be high. There are various options in terms of plant type, tissue, and intracellular location, allowing for great potential. However, this versatility also causes uncertainty in the early stages of developing a plant expression system. In addition, the plant's ability to accumulate a particular hydrolytic or oxidative enzyme has the potential for interference with the plant's metabolism and cause damage to the plant long before protein accumulates. While this has been seen in a number of cases, there have also been various ways to overcome this problem by tissue and subcellular targeting. In addition the use of thermophilic [55] and pro-enzymes [56] or the requirement for cofactors lacking in the plant have all been used to increase protein accumulation [57–59]. A list of enzymes from various sources (bacterial, fungal, animal, and synthetic) produced in plants is given in Table 5. This table provides a snapshot of the accumulation levels of specific proteins in selected tissues and the problems that investigators may have encountered by expressing the protein in the tissue.

Options for Plant Transformation

The transformation technology used to express industrial enzymes can have a major impact on the accumulation of the recombinant protein. Therefore, it is important to select the type of transformation protocol that will best fit the application of the enzyme application. As the transformation process is discussed in

Plant Molecular Pharming, Industrial Enzymes. Table 5 List of industrial proteins produced in plants

Enzyme (gene)	Enzyme function; application in industry	Gene source	Host plant	Maximum expression level	Comments	Reference
α-Amylase	Starch degradation; food and beverages, biofuels, textiles, and paper industries	*Bacillus licheniformis*	Tobacco	0.3% total soluble protein (TSP) in leaf	Unaltered plant phenotype Secreted into intercellular space; extra complex sugar chains added; degradation products identical to native protein	[60]
α-Amylase		*Bacillus licheniformis*	*Nicotiana tabacum* SR1	0.4% TSP in seed	Constitutive expression; hydrolysis products identical to purified *B. licheniformis* α-amylase	[61] European Patent 044,9376
Thermostable α-Amylase		*Bacillus licheniformis*	*Vicia norbonnensis* L.	1 mU/mL seed supernatant	Seed specific USP promoter; accumulation in cotyledon protein bodies; post-translationally modified	[62]
α-Amylase OS103		*Oryza sativa* cDNA	*Nicotiana benthamina*	5% TSP in leaf	Viral infection causes mild chlorosisand stunting; moderate glycosylation of protein in plants	[63]
α-Amylase		*Bacillus licheniformis*	*Medicago sativa*	0.01% TSP in leaf	Unaltered phenotype	[64]
Bifunctional thermostable Amylopullula-nase (APU)	Pullulan and amylose degradation; detergent industry	*Thermoanaero-bacter ethanolicus* 39E (ATCC53033)	*Oryza sativa* L. cv Tainung 67	5.7% total soluble protein in seed	Unaltered phenotype; elevation in pullulanase correlates with decrease in amylose; amyloplast location; starch completely hydrolyzed upon heating	[65]
Aprotinin	Inhibitor of trypsin and proteases; medical and research uses	Optimized bovine aprotinin sequence	Maize	0.4% TSP in seed	Multiple copies in genome; ubiquitin promoter; protein accumulation in seed embryo; transgenic protein biochemically identical to native protein	[66]

Plant Molecular Pharming, Industrial Enzymes. Table 5 (Continued)

Enzyme (gene)	Enzyme function; application in industry	Gene source	Host plant	Maximum expression level	Comments	Reference
Aprotinin cDNA fusion with extension signal		Synthetic bovine	*Nicotiana benthamina*	7,100 trypsin inhibitory units/mg extract protein	Transient TMV virion transfection; product biochemically similar to native protein; large-scale production on 1.5 acres open field or 2,500 sq. ft. greenhouse yields 1 kg purified enzyme.	[67]
Arginine decarboxylase (adc) cDNA	Degradation of arginine; medical and research uses	*Datura stramonium*	Rice	2-fold increase in putrescine levels following stress removal	Under drought conditions, wild-type plants are severely affected, whereas transgenic plants have normal phenotype	[68]
Avidin	Irreversibly binds biotin; research uses	Chicken egg white	*Zea mays*	2.3% TSP in seed; 230 mg/kg seed	Partial to complete male sterility in high expressing plants; similar to native glycoprotein; stable during storage for over 3 months	[69]
Endochitinase (ech42) cDNA	Chitin degradation; research and agricultural uses	*Trichoderma atroviride*	Alfalfa	Up to 2,650-fold higher than control plants	Unaltered phenotype; high expression levels do not correlate with higher resistance to pathogen challenge	[70]
Endocellulase E1	Cellulose degradation; biofuels and paper industries	*Acidothermus cellulolyticus*	*Zea mays* L.	Higher levels in ER than mitochondria; max 2.0% total soluble protein	Targeted to ER and mitochondria; ER targeted E1-cellulase called “Spartan Corn 1”	[71]
Endo-1,4-βD-glucanase (E1 cellulase)	Cellulose degradation; biofuels and paper industries	*Acidothermus cellulolyticus*	*Zea mays* L.	6.1% (ER) and 5.6% (vacuole) TSP in seed	No apparent effect on growth; truncated catalytic domain accumulates in ER and vacuole; 16% TSP in single seed indicates high accumulation potential	[41]
Endoglucanase E1		*Acidothermus cellulolyticus*	Lemna minor 8627	0.24% TSP; 0.2 U/mg protein in fresh tissue	Unaltered phenotype	[72]

Endoglucanase E1		*Acidothermus cellulolyticus*	Tobacco	0.25% total soluble protein in leaf (apoplastic targeting)	Unaltered phenotype; stored seeds had 45% more activity after 1 year	[73]
Endoglucanase E1		*Acidothermus cellulolyticus*	Tobacco	Ammonia explosion (AFEX) treatment yielded 35% original activity	AFEX pretreatment is not a suitable method for releasing cellulase enzymes in transgenic plants	[74]
E1 endoglucanase		*Acidothermus cellulolyticus*	*Nicotiana tabacum*	1.35% TSP in leaf	Chloroplast targeting; normal growth and development; activity decreases with leaf age and upon dehydration	[75]
Cellobiohydrolase I (CBHI)	Cellulose degradation; biofuels and paper industries	*Trichoderma reesei*	*Zea mays* L.	3.2% (cell wall) and 4.1% (ER) TSP in seed	Holoenzyme in cell wall; single seed levels of 17.9% indicate high accumulation potential	[41]
Exo-cellobiohydrolase I (CBHI)	Cellulose degradation; biofuels and paper industry	*Trichoderma reesei*	Tobacco	0.11% TSP in leaf and 66.1 μmol/h/g total leaf protein activity; 0.082% TSP in callus and 83.6 μmol h/g total callus protein activity	Unaltered phenotype	[76]
Thermostable (1–3, 1–4) β-glucanase (codon adapted)		*Bacillus* spp.	*Hordeum vulgare* L. (barley)	40 ng enzyme/2 × 105 protoplasts for codon modified constructs compared to none for unmodified constructs	Biolistic transformation; codon usage important for expression; unaltered phenotype; germination induced expression of enzyme in grain	[77]
β (1–3, 1–4)-glucanase		*Bacillus* spp.	*Hordeum vulgare*	1.29 g/mg TS; 5.4% TSP in grain endosperm	Large variations in enzyme levels between transformants; levels stable for 3 years	[78]
Endo-1,4-β -glucanase (EGI, cellulase)		*Trichoderma reesei* egl1	*Hordeum vulgare* L. Kymppi and Golden Promise	0.025% TSP in seed	Plant morphology normal but reduced seed setting in transgenic plants	[79]
Endoglucanase holoenzyme (E1) and catalytic domain (E1cd)		*Acidothermus cellulolyticus*	*N. tabacum*	1.6% TSP in leaf	Unaltered phenotype; apoplast targeting of catalytic domain achieves 500-fold greater expression than cytosolic full length E1	[80]

Plant Molecular Pharming, Industrial Enzymes. Table 5 (Continued)

Enzyme (gene)	Enzyme function; application in industry	Gene source	Host plant	Maximum expression level	Comments	Reference
1,4-β -D-endoglucanase (E1)		*Acidothermus cellulolyticus*	*Solanum tuberosum* L.	2.6% TSP in leaf	Unaltered phenotype; dual crop applications: leaf targeting allows tubers to be used for culinary applications	[81]
Thermostable endo-1,4-$\tilde{\beta}$-D-glucanase		*Acidothermus cellulolyticus*	*Nicotiana tabacum*	Not quantified	Targeting to chloroplast in vitro and in vivo	[82]
Modified endoglucanase cellulase (egl)		*Ruminococcus albus*	BY-2 tobacco suspension cells	0.1% TSP; 30-fold greater truncated form activity than endogenous cellulase	Unaltered phenotype; three forms (pre-form; mature form; truncated form); truncated form has highest expression	[83]
Hybrid (1,4) –β-glucanase (cel-hyb1)		*Neocallimastix patriciarum*	Barley grain	1.5% total grain protein	Endosperm targeted; codon optimization leads to 527-fold increase in expression levels; stable during post-harvest storage	[84]
Catalytic domain endo 1,4-β-D-glucanase (E1cd)		*Acidothermus cellulolyticus*	*Zea mays*	2.1% TSP in leaf and 0.845 nmol/μg/min activity; 2.08% TSP in root and 0.835 nmol/μg/min activity	Set seeds at maturity	[85]
Catalytic domain 1,4-β-endoglucanase E1		*Acidothermus cellulolyticus*	*Zea mays*	1.13% TSP	Unaltered phenotype; apoplast targeted; successful conversion of corn stover into glucose following AFEX pre-treatment	[86]
Thermostable catalytic domain endo-1,4-β-glucanase		*Acidothermus cellulolyticus*	*Oryza sativa* L. Japonica cv. Taipei 309	4.9% TSP	Unaltered phenotype; constitutive promoter; capable of hydrolyzing AFEX-treated stover	[87]
Truncated endoglucanase (t-egl)		*Ruminococcus albus*	Tobacco	0.5% TSP	Unaltered phenotype; cell disruption allows cell wall digestion to occur	[88]

Thermostable 1,4 β -D-endoglucanase catalytic domain		Acidothermus cellulolyticus	*Arabidopsis thaliana*	26% TSP in leaf	No abnormal phenotype; apoplast targeting; activity and immunochemically similar to native enzyme	[89]
Thermostable 1,4-β -D-Endoglucanase E2 and E3		*Thermomonospora fusca*	*M. sativa* L.	E2-0.1% TSP	Unaltered phenotype	[90]
			N. tabacum L.	E3 0.02% TSP		
			S. tuberosum L.			
Thermostable cellulases (Cel6A, Cel6B)		*Thermobifida fusca*	Tobacco	4% TSP	Homoplasmic, transplastomic plants using plastid-directed vector; not optimized	[91]
Recombinant hyperthermostable endoglucanase Cel5A		GenBank accession number At3g4890	Tobacco	5.2% TSP in leaf	Unaltered phenotype; chloroplast targeted; stable active enzymes	[92]
Chimeric chymosin (rennin)	Milk curd formation; dairy industry	Bovine	*Brassica napas*	0.5% (w/w) TSP	Seed targeted	[93] US Patent 7,390,936
Coumarate-3-hydroxylase (C3H)	Lignin modification; biofuels	*Medicago sativa*	*Medicago sativa* cv Regen SY	C3H levels 5% of wild type levels	No serious phenotypic impairment	[94]
Hyperthermo-philic α-glucosidase	Breakdown of maltose; brewing and research uses	*Sulfolobus solfataricus*	*Nicotiana tabacum*	0.04% TSP in leaf	Enzyme levels increase at maturity; unaltered phenotype	[95]
			cv. Xanthi			
Glycosyl hydrolase β-glycosidase	Degradation of glycosidic bonds; biofuels and research uses	*Sulfolobus solfataricus*	Tobacco	0.15% TSP in leaf	Enzyme levels increase at maturity; unaltered phenotype	[95]
ADP-glucose pyrophosphory-lase modified (Sh2r6hs)	Starch synthesis; agricultural and research uses	*Zea mays*	*Triticum aestivum*	5-fold greater protein accumulation	Modified large subunits permit greater stability and yield; endosperm specific promoter	[96]

Plant Molecular Pharming, Industrial Enzymes. Table 5 (Continued)

Enzyme (gene)	Enzyme function; application in industry	Gene source	Host plant	Maximum expression level	Comments	Reference
ADP-glucose pyrophosphorylase modified large subunit (Shrunken 2 gene Sh2r6hs)		*Zea mays* L.	*Triticum aestivum* L.	91% more activity in the presence of 10 mM Pi	Transgenic wheat plants produced 38% more seed weight; 31% higher biomass; transgene stable after five generations	[97]
Human placental β-glucosidase (GCase)	Degradation of glycosidic bonds; biofuels and research uses	Human placenta	Tobacco	750 U/kg seed	Seed viability totally impaired above 500 U/kg; taken up by human fibroblasts; free from immunogenic xylose and fucose	[98]
β-glucuronidase (GUS)	Degradation of glucuronic acid residues; research uses	*E. coli*	*Zea mays*	0.7% TSP in seed	Functionally equivalent to native protein; dispersed in cytoplasm; single integration in transformant with highest expression	[99]
β-glucuronidase (GUS) with αAmy8 regulatory and signal sequence		αAmy8 sequences from rice	Rice, tobacco, and potato suspension cells	40% total secreted proteins	Fusion to β-glucuronidase (GUS); inducible by sugar; tunicamycin causes ER accumulation	[100]
Laccase I	Lignin degradation; biofuels, wood, and paper industry	*Trametes versicolor*	*Zea mays*	0.55% TSP 4 ng/mg dry weight (T2) to 70 ng/mg dry weight (T6)	Variable expression levels; breeding and selection increased levels 20-fold in five generations; embryo-preferred promoter with cell wall targeting supports highest expression; germplasm background affects germination frequency	[110]
Laccase		*Trametes versicolor*	*Zea mays*	0.20% of dried, defatted corn germ	Contains both water soluble and immobilized laccase; some laccase is inactive apoenzyme form	[58]

Laccase riceMaL and ricePcyL cDNA		*Melanocarpus albomyces* *Pycanoporus cinnabarinus*	Rice	13 ppm (riceMaL) 39 ppm (ricePycL)	Endosperm targeted; seed production was normal; recombinant protein is biochemically similar to native proteins, but had lower kinetic parameters	[101]
Lipase	Lipid breakdown; dairy, food, biofuels, and detergent uses	Recombinant dog gastric lipase	Tobacco	5% (vacuolar retention signal) and 7% (secretion signal) of acid extractable protein	Active glycosylated protein with similar properties to native protein; specific activity dependent on subcellular compartment; Normal leaf morphology	[102]
Lipase (rDGL)		Recombinant dog gastric lipase	Maize seed endosperm	Specific activities of 3 U/mg protein(grinding); 3.7 U/mg protein (defatting) and 9 U/mg protein (dry milling)	Comparison of relative efficiency of grinding, defatting, and dry milling of seed prior to selective extraction	[103]
Lipase		Dog gastric lipase	Tobacco	360 U/mg protein	Impact of subcellular targeting on glycosylation; transient expression system	[104]
Manganese-dependent lignin peroxidase (MnP)	Lignin degradation; biofuels, wood, and paper industry	*Phanerochaete chrysosporium*	*Medicago sativa* L.	0.5% TSP in leaf	Reduction in dry matter and height related to expression levels; yellow foliage; MnP expression segregates in sexual progeny	[64]
Manganese peroxidase (MnP)	Lignin degradation; biofuels, wood, and paper industry	*Phanerochaete chrysosporium*	Maize	15% TSP in seed 3% TSP in leaf	Cell wall targeting yields full length MnP; cytoplasmic targeting produces truncated products; seed-targeted promoter has higher expression levels and improved plant health outcomes over constitutive promoter	[59]
Anionic peroxidase cDNA	Lignin structural modification; biofuels, wood, and paper industry	cDNA clone for the primary isoenzyme	*N. tabacum*; *N. sylvestris*	>10× higher peroxidase activity compared to wild type	CMV35S promoter; chronic severe wilting through loss of turgor in leaves initiated at the time of flowering	[105]

Plant Molecular Pharming, Industrial Enzymes. Table 5 (Continued)

Enzyme (gene)	Enzyme function; application in industry	Gene source	Host plant	Maximum expression level	Comments	Reference
Phytase phyA2	Phytic acid breakdown; animal feed uses	*Aspergillus niger*	Maize	2,200 U/kg of seed	Embryo-specific globulin-1 promoter; different glycosylation pattern; stable over four generations; normal transgenic seed germination	[106]
Phytase		*Schwanniomyces occidentalis*	Rice	4.6–10.6 U/g fresh weight in leaves	Stable in silage for 12 weeks	[107]
Rationally designed phytase		*Aspergillus fumigatus*	*Triticum aestivum* L. (wheat)	4,777 FTU/kg seed flour	Vacuole accumulation despite apoplast targeting; unaltered phenotype	[108]
Secretory phytase (PHY)		Synthetic gene	Potato	40% more phosphate in transgenic plants	Trichoblast-specific promoter; healthy plants, but with altered leaf shape	[109]
Chimeric phytase ex::phyA		*Aspergillus niger*	*Nicotiana tabacum*	3.7-fold more phytase secretion and 52% higher P accumulation in transgenic plants	Presence of soil phytate essential	[110]
Phytase phyA		*Aspergillus niger*	*Triticum aestivum* L.	4-fold increase in plants with constructs with a-amylase signal peptide; 56% increase in plants with constructs without signal peptide; Phytase activity 3,000 FTU/kg	Endosperm, but not embryo accumulation; gene stability over three generations	[111]
Phytase gene		*Aspergillus fumigatus*	Rice Japonica var Taipei 309	130-fold increase in grain phytase level	Unchanged phenotype; coexpressed in endosperm with Phaseolus vulgaris ferritin gene and overexpressed endogenous cysteine-rich metallothionein	[112]

Phytase MtPHY1		*Medicago truncatula*	Arabidopsis	12.3- to 16.2-fold higher levels in root apoplast	Dry weight of transgenic plant upto 4.0 times higher than control and P content up to 5.5-fold higher; root-specific and constitutive promoters used	[113]
Phytase		*Aspergillus niger*	Tobacco	1% TSP in seed	Transgenic seed added directly to chicken feed shows improved nutritional quality	[114]
Phytase GmPhy		*Glycine max* L. Merr.	Soybean tissue culture	2–3 fold higher than controls	Novel phytase similar to purple acid phosphatases	[115]
Phytase cDNA		*Aspergillus niger*	*Nicotiana tabacum*	26% dry weight of leaves 14.4% TSP in leaf	Constitutive expression with secretion signal from tobacco pathogen-related protein S; differences in glycosylation compared with native protein	[116]
Phytase phyA		*Aspergillus niger*	*Brassica napus* (Canola)	600 U/g of multi-copy T1seed; 103 U/g in single copy line	Unchanged morphology; seed-specific CruA promoter used; gene-dosage related expression; stable over three generations; no correlation between high expression and seed germination	[117]
Phytase phyA		*Aspergillus niger*	Soybean cell cultures	920 pKat M/g total soluble protein	Secretion and glycosylation may be necessary for activity; transgenic protein smaller than native protein, but has similar biochemical profile	[118]
Phytase SrPf6 (*S. ruminatum*) appA (*E. coli*)		*Selenomonas ruminantium* *Escherichia coli*	*Oryza sativa* L. cv. Tainung 67.	0.6 U/mg (appA); 1.4 U/mg (SrPf6) of TSP in seed; up to 60 times activity of control	No adverse effects; germination-inducible αAmy8 promoter and αAmy8 signal peptide; multiple copy number	[119]
Phytase cDNA		*Aspergillus niger*	*Medicago sativa*	2.0% TSP	Un-glycosylated, but stable	[120]
Transglutaminase (rTGp)	Formation of peptide bonds; food industry	Rat prostate	*Oryza sativa*	0.15 U/mg h leaf	Ca^{2+} dependent enzyme	[121]

Plant Molecular Pharming, Industrial Enzymes. Table 5 (Continued)

Enzyme (gene)	Enzyme function; application in industry	Gene source	Host plant	Maximum expression level	Comments	Reference
Trypsin	Protein hydrolysis; medical and research uses	Bovine pancreas	Zea mays	0.025% seed dry weight	Equivalent to native enzyme. levels suitable for commercial production; produced as zymogen	[56] US Patent 6,087, 558
Xylanase B xynB	Hemicellulose degradation; biofuels, wood, and paper industry	*Streptomyces olivaceoviridis*	Solanum tuberosum L.	5% TSP in leaf	Stable gene expression for several generations	[122]
Xylanase A xynA thermostable catalytic domain xynA1		*Clostridum thermocellum*	Rice	Not quantified	Normal plant phenotype; stable expression in seed and straw; activity in desiccated seed	[123]
Xylanase xynC-oleosin fusion		*Neocallimastix patriciarum*	Canola	2,000 U/kg seed (oil body of seed)	Fusion protein retains optimal temperature, Km, and specificity, but has reduced pH sensitivity	[124]
Xylanase Modified xynC		*Neocallimastix patriciarum*	Barley	0.004% dry weight of seed endosperm	GluB-1 promoter better than Hor2-4 promoter; protein stable during seed maturation, desiccation, and storage; 40% low fertility in one line;	[125]
Xylanase XYLII		*Trichoderma reesei*	*Arabidopsis*	1.2% (cytosol); 3.0% (chloroplast); 1.7% (peroxisome); 4.8% (chloroplast+peroxisome) total soluble protein	Unaltered phenotype; levels highest at flowering; dual targeting to chloroplasts and peroxisomes causes much higher levels than either compartment alone, although RNA levels are similar	[126]

Xylanase xynII		*Trichoderma reesei*	*Arabidopsis*	3.2% TSP in leaf	Chloroplast expression exhibit normal growth, but cytosolic accumulation affected transgenic plant growth	[127]
Xylanase Thermostable, truncated xyn2		*Clostridum thermocellum*	Tobacco	4.1% TSP in leaf	Unaltered phenotype; proteinase II signal peptide used; enzyme enrichment following heat treatment	[128]
Xylanase Thermostable, truncated xyn2		*Clostridum thermocellum*	*Nicotiana tabacum* L. cv Wisconsin	Not quantitated	Clearance zone develops at 3 h	[42]
xylanse (XYLD-A) and β(1-3, 1-4) glucanase (XYLD-C)		*Ruminococcus flavefaciens*	Tobacco	170 μM/min/m^2 xylanase and 2,000 μM/min/m2 glucanase in leaves	Unaltered phenotype; separate constructs; apoplast targeting; glucanase accumulated higher protein levels than xylanase	[129]
1-deoxy-D-xylulose-5-phosphate synthase DXS gene cDNA (CLA1)	Lignin structure modification; biofuels, wood, and paper industry	*Arabidopsis thaliana*	*Arabidopsis thaliana*	Higher or lower levels than wild type	Normal morphology; variable levels of isoprenoid biosynthetic pathway products correlated with increased or decreased enzyme level	[130]

detail elsewhere, only a brief synopsis of how it impacts industrial enzymes is summarized here.

Both stably transformed and transiently expressing plants have been used to express proteins [131]. In stable transformation, the foreign DNA can be targeted to the cytoplasm or a number of different intracellular locations such as the nucleus [132] or into plastid genomes, usually the chloroplast [133]. Mitochondrial targeting is not as well established and has not been pursued in this context. Organelle transformation provides the advantages of high copy number and the transgenes are not passed on by the pollen [6]. This method however is not yet applicable to many types of plants. Stably transformed plants are time consuming to characterize and generate, but once produced, they can be stored as seed. This allows for a ready source upon demand. Transiently expressing foreign DNA can be inserted into somatic tissue with the purpose of short-term expression using viral vectors delivered using Agrobacterium or biolistics [134–136]. Transient expression is useful when a protein needs to be expressed at short notice.

Selection of Plant Species for Transformation

One consideration for industrial protein production is the type of plant used as the production vehicle. The options include: plants grown for their vegetative tissue for large volumes of biomass; plants harvested for grain for their enriched protein and facile storage characteristics; well-established cultivated crops where much is known about growing and processing; wild species that have little use today, making them distinct; food crops that have Generally Regarded as Safe (GRAS) status and pose no safety threat to the crop itself or host protein but have the potential for intermixing with food crops; or a non-food crop with decreased concerns about intermixing with food crops but with greater potential to have compounds that are detrimental or untested with regard to human safety (see Table 3).

Food crops are known to be safe when consumed and they have well-established procedures for growth, harvest, and storage. In cases where the final product may include some or all of the plant tissue as well as the recombinant protein, this has a significant advantage and direct applicability in the case of many industrial enzymes that are used in the food and feed industry.

For example, maize (*Zea mays*; corn) is well accepted as a safe product (GRAS), and is widely used in food, feed, and industrial applications today [137]. The production cost of maize is very low, and the infrastructure can handle large or small acreages for industrial or pharmaceutical products. Storage and transport of seed, and protein purification from flour are compatible and flexible with current practices without special handling. There are no known agents in maize that generally interfere with protein purification. Finally, the grain can be processed with little or no heat inactivation steps without affecting the protein's properties [4, 138, 139].

In addition, maize has an added advantage in that the kernels can be mechanically separated to yield a germ fraction with enriched protein and an endosperm fraction with enriched carbohydrate [137]. This facilitates use of the carbohydrate fraction for industrial applications such as ethanol production [140] or feed. In this way not only is the cost of the raw material reduced but the waste products are conveniently handled as well.

A disadvantage of maize is the fear of inadvertent mixing with the food supply. Intermixing potential can be handled by management practices but will need to gain the public's confidence. While there may be claims that no food source can ever be used to produce pharmaceutical products, it is common knowledge that both eggs and yeast are used to make pharmaceuticals. Not only is there no public outcry of intermixing in these instances, but their perception is that these production systems are distinct from the systems used to make food. This is the perception that food crops must earn as well. Maize as well as other plant systems must build an infrastructure dedicated to industrial protein production, which is as distinct from food production as edible eggs are from vaccine production. Furthermore, this must also be perceived by the public to reduce fears.

One advantage of non-food crops for industrial protein production is that they are less likely to be mistaken for food crops and therefore unlikely to be inadvertently mixed with the food supply. The disadvantage is that non-food crops must be assessed for toxins, allergens, or anti-nutritional agents that may accompany the recombinant protein. For industrial proteins where little purification is performed to keep

the cost down this can be a considerable problem if the protein precuts are to be used in food or feed applications.

Another question that is relevant to selecting a crop for recombinant industrial protein production is whether a cultivated species or wild species is preferred. Cultivated species show "domestication syndrome" and have several advantages for humans than that their wild relatives exhibit through husbandry and selection over thousands of years [141]. Although non-cultivated species have not undergone selection for higher yields or been subject to agronomic practices in past centuries, there may be yield advantages in crossing domesticated plants with wild relatives, with increase in yields of up to 50% in tomato fruit [142]. Finally, the impact of relatively unknown wild species on product safety is unknown. Determination of the degree of this impact would undoubtedly require extensive effort and time, which may be limiting factors for industry.

A further choice is whether to use an open-pollinated or a self-pollinating plant. Self-pollinating plants have the advantage of a lowered risk that pollen will unintentionally transfer onto other plants of the same species. Controlled pollen shed of open-pollinated crops can be used to help alleviate this concern by either physical or genetic means to prevent out-crossing onto weedy species or related food or feed crops [46–48]. The likelihood of gene transfer from engineered to wild plants depends on sexual compatibility, flowering time, and pollen transfer distance between the engineered and wild varieties [143]. This choice is made based on the growing location and the product required.

With a variety of species to select from and the wide variety of products that are possible, it is highly unlikely that any one system will work best for each of these steps and therefore, it is important to select the plant system that best suits the product. Since it is impractical to have thousands of different production systems, it is preferable to adapt a given system to the needs of various products.

Fortunately, some common features exist that will apply to most products enabling a few systems to accommodate most products. The key features include a potential for low cost of goods, maintenance of protein integrity, flexibility with regard to time and temperature for harvest, and maintenance of product safety and environmental safety [144, 145]. Production systems are discussed below as to how they relate to the overall efficiency of the system as well as to the regulatory aspects.

Selection of Plant Growth System

Transgenic plants can be grown in the traditional manner in an open field or in a contained chamber such as a greenhouse [146]. Row-grown transgenic crops are subject to USDA regulations on buffer zones to limit pollen spread and minimize the risk of the intermixing of food crops with "pharma" crops. If the protein source is green tissue, the plants may be harvested before flowering to limit pollen spread. This is also the case when transient transfection is used to express proteins in leaf and other green tissue. When row plants are required to flower and set seed for protein production, such as is the case for grain-targeted proteins, adequate precautions must be taken to avoid pollen transfer. Row plants are capable of higher product accumulation since they are capable of growth to higher biomass [38].

There are strict regulations and permit requirements imposed by APHIS, the branch of USDA with responsibility for animal- and plant-related services (www.aphis.usda.gov). A practical solution proposed for field growth is to dedicate areas to growth of transgenic plants, or to grow transgenic plants in locations within processing areas, such as cellulose-producing plants in a bioethanol production area [140]. This way the material is grown where it is utilized, cutting transportation costs. Alternatively, the transgenic plant can be isolated in greenhouses in soil or in liquid media. This solution is more expensive, but has the advantage of physical isolation of the transgenic plant from the environment.

The potential for inadvertent transfer of the transgene to non-target plants is considerably reduced by containment in a chamber, but production is necessarily limited by cost considerations. Within a chamber, plants can be grown in soil or in liquid growth media where exudates containing the protein of interest may be continuously produced and has similar advantages to plant cell cultures where proteins are secreted into the culture medium [147]. Scalability may also be an

issue. Exudates from roots also facilitate production when secreted into fluid growth medium [40], but chambers for contained growth in liquid medium can be capital intensive and require sterility and media-related expenses. On the other hand, secretion of transgenic proteins into guttation fluid provides a convenient, but labor-intensive method of recovery of secreted proteins. Proof-of-concept was shown with three transgenic proteins in tobacco, [42]. Using this "phyllosecretion" technology, Komaryntsky and colleagues engineered three proteins from different genetic backgrounds (bacterial xylanase, jellyfish green fluorescent protein and human alkaline phosphatase) into *N. tabacum*. The proteins were fused to endoplasmic reticulum signal peptides targeted to leaf apoplast and released into guttation fluid in plants maintained in high humidity conditions. Guttation fluid has lower overall protein content than apoplast fluid, and is also released throughout the plant's life. In addition to continuous production, the process is non-destructive of plants. Levels of up to 1.1 μg/g of leaf dry weight per day, comprising up to 3% TSP, were recovered from the guttation fluid using simplified downstream processing. Although tobacco is not an ideal plant for guttation fluid production, other plants such as tomato and some grasses are highly susceptible to the production of large quantities of guttation fluid and may provide alternative targets for phyllosecretion.

Optimization of Heterologous Protein Production

Because industrial enzymes require a very low cost of production the most critical factor determining the system of choice is the level of accumulation that occurs in the selected tissue. The optimization of expression of heterologous proteins in plants has been studied for various purposes: to improve nutritional value, insect resistance, salt and drought tolerance, and product quality. These other applications however are not nearly as demanding for the level of expression required as for industrial enzymes. Key steps to increase heterologous protein expression are the choice of plant, tissue location, various manipulations of the promoter, codon usage, and compartmentalization of the protein.

After selecting the type of plant, a determination has to be made about which target tissue is best to express the protein. Location of expression is guided by many factors such as the nature of the protein, whether the protein is to be used directly or purified, and accumulation levels desired. Often, strong constitutive promoters such as the CMV 35S promoter are used, and promoter analysis by site-specific mutations has allowed delineation of sequences that modulate expression in tissue-specific locations of this promoter [148]. *Cis*-acting elements in a green-tissue-specific rice promoter P_{D540} acting as activators or suppressors of activity were identified, thereby facilitating control of protein expression in different tissues [149]. Manipulations such as the use of the embryo-specific maize globulin-1 promoter also allow accumulation of proteins in specific locations within tissues [150]. Expression of the heterologous protein can also be controlled by the use of inducible promoters, and a search of patents reveals a plethora of such inducible promoters. A list of promoters in cereals is compared in [151]. Other promoter permutations including the use of inducible promoters, stacking transcriptional units, synthetic bi-directional promoters, global regulatory sequences to recruit transcription factors, and other such approaches have been studied to enhance transcription and are reviewed elsewhere [152].

Further, heterologous gene sequences should be optimized for the plant type and location. For example, chloroplast codon usage is similar to that of prokaryotes, whereas nuclear codon usage varies from plant to plant. Also, RNA silencing is a feature of many plants, and some viruses produce suppressors of silencing, and heterologous protein sequences are often not expressed at high levels because of RNA silencing [49]. This silencing can be turned off by the expression of the heterologous gene together with a suppressor of silencing [153, 154].

In addition to the choice of tissue location, highest expression levels can be obtained when the protein is directed to specific subcellular compartments and especially so if the protein is an enzyme that would interfere with normal cellular activities [38, 41, 152, 155]. Subcellular targeting is critical for accumulation and protein integrity of hydrolytic enzymes. Cell wall targeting allowed expression of full-length manganese peroxidases, but cytoplasmic targeting resulted in truncation of the peptide [41, 59]. In addition, a seed-preferred promoter allowed high accumulation without negative effects on plant health [59]. Interestingly, targeting xylanase to two subcellular locations – the

chloroplast and the peroxisome – accumulated 240% more enzyme than the chloroplast and 160% more than the peroxisome alone. Highest levels also accumulated during flowering time [126]. These are empirical observations, and such permutations may benefit studies of high-level expression of heterologous proteins. Medrano et al. have developed a transient expression system using *Nicotiana* to assess construct efficiency [156], which may be helpful.

Finally, decisions on the expression of a heterologous protein as a fusion or as a free protein depend upon target location and levels of expression desired. For example, fusions to oleosins accumulate in oil bodies in *Brassica napus* seeds [157], and fusions to proteins previously shown to stably accumulate in plant cells may have the effect of stabilizing heterologous proteins as well [158]. Fusions to the C-terminus of ubiquitin also have a stabilizing effect resulting in 10-fold increased levels [159]. Proteins accumulated at high levels may be subjected to cellular protease activity, thus using cell lines with lower protease levels may help stabilize the heterologous protein. The expression of some proteins, such as hydrolytic enzymes, can be detrimental to the cell. The strategy for the protease trypsin was to express it as a zymogen, allowing sufficiently high levels for commercial production, marketed as TrypZean [56].

Product Recovery from Transgenic Plants

The single most important consideration for recovery is whether the protein produced in plants can be used in crude form in the plant extract, or has to be purified prior to use. Obviously, crude extracts are considerably less demanding to make, but the end use of the protein determines the level of purity required. Purification of transgenic proteins is an expensive prospect, regardless of the system, accounting for about 94% of the production cost in the case of maize [44]. Decisions on recovery should form an integral part of assessing production options based on levels of expression, costs, and sustainability. These decisions are based on the nature of protein to be expressed, and include transient or stable expression, type of plant, targeting, and modifications required.

A variety of elegant solutions have been used to overcome the problems of purification, but vary in costs and efficiency. For example, roots have been used to secrete proteins into the growth medium, and guttation liquid produced by plants also provide a useful medium for secretion-based isolation of the transgenic protein, as the growth or secreted liquid can be recovered and filtered for protein recovery [42, 49]. However, they are considerably more labor and energy intensive due to growth in liquid medium as discussed above, and recovery varies based on loss due to dilution factor and protein stability in an extracellular environment [160].

When whole plants are used as production systems, the recovery process depends on the tissue being used for expression. Transient expression in roots or leaves generally requires processing of fresh wet tissue. If stable expression is used, the material may be wet or relatively dry depending on the tissue used. Proteins extracted in fresh tissue are generally unstable and have to be recovered immediately, whereas seed-expressed proteins have shelf-life as long as 3 years [45]. Grain can be subjected to either wet or dry milling followed by separation steps. These include fractionation to obtain enrichment of germ or endosperm in the case of seed, or subcellular compartments targeted for protein accumulation, protein precipitation, adsorption, chromatography, and diafiltration [44]. Methods have been developed to simplify recovery such as post-harvest protein expression using stress-inducible promoters [45, 161] and oleosin-partitioned proteins that can be recovered easily following oil-water separations [124, 162, 163]. A detailed comparison of the economics, processing, and regulatory constraints associated with the most common plant production systems is provided in [145].

In the ideal case, commodity plants that are used for industrial applications would also express the transgenic protein. These transgenic proteins can then be used directly in the industrial process without purification assuming the protein can survive the processing steps. In this best-case scenario, no other inputs are needed to produce, purify, or process the protein leading to lower cost and less detrimental impact on the environment.

Case Study: Economics of Cellulases Produced from Transgenic Plants With the current state of technology for biomass conversion, the overwhelming enzyme

requirement is for cellulases: endo-cellulase, exo-cellulase, and glucosidase [164]. The specific activity of most cellulases is quite low [155, 165] and much effort has focused on increasing their activity levels. However, even with improved enzymes and improved methods of production, the amount of cellulase required to deconstruct the volumes of biomass necessary for 30% replacement of gasoline are in the millions of tons. It has been estimated that 36 billion gallons can require as much as 3.6 million metric tons of cellulase per year [166]. This is an unprecedented challenge in terms of the amount of enzymes and the extreme low cost that is required.

The bioprocessing challenge for ethanol is how to deliver these extremely large volumes to a saccharification facility at an unprecedented low cost. This represents potentially the single greatest application of industrial enzymes.

Currently, cellulases are produced by fungal and bacterial systems, and are a costly component of ethanol production [167]. Plants offer the potential for a production system that can meet the low cost and high volumes required. To do this however, the level of expression needs to be extremely high and the choice of tissue needs careful consideration. There have been many attempts to express cellulase in many types of plants and these have been reviewed elsewhere [37]. Protein and tissue stability, tissue fractionation, protein extraction and formulation, storage, as well as transportation add to this cost and must be considered.

To achieve targeted production cost targets for biomass enzymes the following considerations must be employed: (1) eliminate transportation cost by integrating enzyme processing into biomass conversion facility; (2) minimize fractionation/extraction cost of transgenic material; and (3) reduce the contribution of transgenic plant material to enzyme production cost by capturing plant biomass value through byproduct credits or cellulose. It has been suggested [166] that in order to keep the enzyme cost down, plant production systems that accumulate cellulase in the normally unused or low-value portion of the plants can be competitive when the other parts of the plant are harvested for their traditional use. The obvious example is when the leaves of crops are used to produce the cellulase and the grain is used for food, feed, or other industrial applications. Using the grain for industrial applications is less of a regulatory burden than if the grain is to be used for food or feed. However, according to the US Food and Drug Administration Statement of Policy (http://www.fda.gov/Food/GuidanceComplianceRegulatoryInformation/GuidanceDocuments/Biotechnology/ucm096095.htm) this is still an option, "If plants (or materials derived from plants) used to make nonfood chemicals are also intended to be used for food, producers should consult with FDA to determine whether the non-food chemical would be a food additive requiring an authorizing regulation prior to marketing for food use." These guidelines may change and may vary between countries; therefore, current regulatory practices must be consulted and followed in each case.

A case has been proposed for a fully integrated and synergistic system of ethanol production using maize. Maize grain today is the major source of ethanol production in the USA [168]. Using the stover to make cellulosic ethanol has been proposed as a convenient, economical, and sustainable way to make cellulosic ethanol alongside grain ethanol allowing for lower transportation costs and synergy in the ethanol facilities [170].

Taking this approach one step further, it has been suggested that the leaves themselves can be used to generate the required enzymes [155]. This has great potential if the enzymes can survive in the processing steps and can reach the target levels.

Another option has been proposed using the germ fraction of the grain [140]. In this case the enzymes could be made in the germ which is separated in the dry milling prior to using the endosperm for grain ethanol. The acreage required to grow crops to produce this amount of enzymes has been modeled previously considering the proximity limitations of the lignocellulose biomass to the ethanol facility to avoid large transportation cost. This study demonstrated that if cellulase levels were 0.1% of the dry weight of the seed (1% of germ dry weight), this was more than sufficient to keep the acreage of the cellulase crop less than the acreage needed to supply the lignocellulose biomass. Additional models suggest that when expression levels reach 4% of the dry weight of tissue (0.4% weight of the grain) it may be possible to add the germ tissue without any fractionation [166]. Direct delivery of plant tissue can be the system of choice by eliminating

extraction and purification costs. In addition to the cost of production, this approach allows the entire plant to better utilized without additional acreage or input for growing the plants. There is also no additional stress on the environment due to making or processing the enzymes and this has the potential to meet the current volumes of cellulase projected at a cost below current targets.

The main reason why this is not in use today is that cellulase has not enjoyed the levels of expression required for the models above. However, there is every reason to believe that expression levels will continue to improve in plants as it is a relatively young science compared to microbial production. In maize specifically it has been reported that levels as high as 16% of the total soluble protein were observed [41] and more recently levels of >1% of dry weight in the germ fraction has been achieved [169].

Regulation of Growth and Use of Transgenic Plants

Assuming that one can create plants having industrial enzymes with the characteristics and cost benefits that are desirable, there is still the need to grow these on a commercial scale. The process of growing transgenic plants is highly regulated including those grown for research purposes. However, for research purposes, cost is not a primary concern and the environmental impact is usually minimal due to the small acreage. However, this changes dramatically during scale-up for commercialization. Assuming a yield of 1–10 kg industrial enzyme per acre would require 100–1,000 acres for a relatively low volume of industrial enzymes but this can increase 10- to 1,000-fold for larger volume enzymes. Therefore, the potential for certain individual enzymes to be greater than 100,000 acres creates regulatory scenarios that are much more complex than those addressed in a research environment.

Regulatory systems are a social issue and vary in different countries but they all address human and animal safety as well as environmental implications. They must also address perhaps the most controversial issue, public acceptance. The technical aspects of regulatory concerns are discussed below with the understanding that every country will have its own interpretation and standards for what is acceptable.

Product Safety

The first concern for any product is the inherent safety of the active ingredient. Having a production system different from the native host does not usually change the inherent properties of the enzyme itself. Factors such as exposure to humans, dosage, toxicity, allergenicity, and whether or not the proteins are already a part of the food chain are considered. It is not the intent of this entry to review the regulatory process in detail but rather to point out the difference when using plants as the production vehicle as opposed to other sources. Therefore, the focus is not on the inherent safety of the enzyme but what safety factors arise when produced in plants and what additional challenges are presented with plant production.

For products that have already undergone regulatory approval, it is critical to show, utilizing empirical data, that there is equivalency with the plant-produced process. In many cases plants can produce functionally and chemically equivalent proteins to those made in the native hosts. However, there may be exceptions which in turn can lead to difference in protein structure or function. These differences may be subtle such as a small signal peptide intended to target the protein to the vacuole that is not cleaved and instead retained in the final protein sequence, or carbohydrate structures could be added where none existed before. These types of changes may have no impact on function and may be acceptable in commercial products.

In contrast to that above, some changes may result in proteins that have altered functions or altered safety profiles. As an example, many industrial enzymes are bacterial in origin and therefore are not normally glycosylated proteins. If these bacterial proteins happen to have a glycosylation site that a eukaryote can recognize then that can create a challenge. The possibility exists that the enzyme will be glycosylated when expressed in eukaryotes and potentially lead to a change in function. Fortunately there is little evidence to suggest that glycosylation itself will change enzyme function unless the carbohydrate is added to a key amino acid either in the binding site or catalytic site. An example of this is the bacterial enzyme β-glucuronidase (GUS). GUS protein loses activity due to secretion-specific N-glycosylation of a key amino acid in the protein [171]. Contrary to this

observation, other proteins can be glycosylated such as the bacterial protein organophosphate hydrolase with no significant effect on its biochemical activity [57].

Glycosylation patterns in plants can also be different from those observed in other eukaryotes. Plant glycoproteins contain the same mannose backbone structure found in animal glycoproteins but the additional sugars added to the backbone are usually less complex in plants than animals. Another difference is in β−1-4 linkage versus β−1-6 linkage and the appearance of xylose. In one case the animal protein trypsin was produced in plants and showed evidence of O-glycosylation whereas it is not detected from the native porcine or bovine source [56]. Despite these changes no functional difference in catalytic activity has been observed.

In addition to catalytic activity, there is also the concern that the enzyme may be altered in a way that affects its activity in the desired application. There is little evidence of this for industrial enzymes but there are examples for where carbohydrate structures on proteins can affect their pharmacological properties. In the case of certain pharmaceutical proteins, sialic acid is a terminal sugar on the glycoprotein and leads to a longer half-life in the blood [172]. Since plants do not add sialic acid this leads to an alteration in clearance time in the blood [173]. On the other hand, the plant carbohydrate sequence for antibodies is also critical in vivo but the altered plant sequence appears to work as well as the animal carbohydrate sequence [174]. This demonstrates the need to test the industrial enzymes in the desired application when the composition of matter is different than the native source.

Demonstrating functional equivalency is still not enough from a regulatory standpoint. The addition of carbohydrates has been implicated in a number of studies for allergenicity. This raises the theoretical question of whether plant glycosylation can lead to allergenicity. On the surface this seems highly unlikely since plant proteins are eaten routinely, and plant glycoproteins would seem inherently safe. Therefore, just adding a plant carbohydrate does not make the protein allergenic. On the other hand, there have been reports showing that the carbohydrate sequence of pollen glycoproteins [175] is responsible for an allergenic reaction. Therefore, while generalizing that plant carbohydrates are allergenic is misleading, it is important not only to check whether there is glycosylation but aslo to find out how this may differ from the native source. While there are no current examples where the addition of a plant-specific glycosylation to a transgenic protein has lead to an increase in allergenicity there is still a theoretical concern.

Safety of Host Proteins

While inherent activity is a functionality concern, the addition of extraneous host material is also a regulatory issue. Since most industrial enzymes cannot be purified because of cost restraints, the host material must also be shown to be safe in the final product. For this reason production in plants that already have a proven history of safe use is a great advantage. Certain crops that are known to produce toxins, allergens, antinutritionals, or carcinogens present additional difficulties as hosts. Crops already known to have GRAS (generally regarded as safe) status will be at an advantage because of inherent safety of the crop. In the best case a GRAS enzyme can be produced in a GRAS host greatly reducing the regulatory burden [176].

Environmental Safety

The environmental impact of protein production from a regulatory standpoint can be a concern based on the additional acreage. The consequence of additional inputs, displacement of food crops, and the lack of containment leading to inadvertent exposure to animals and humans must be addressed [177].

Dedicated cropland for the sole purpose of producing industrial enzymes will in most cases be insignificant compared to the acreage already under development for current uses, if produced in tandem with commodity crops. Since expression levels must be high to keep costs low for industrial products, this translates into only a very small percentage (∼1%) of the acreage for even large-volume products. The exception to this scenario is if the by products can be utilized for other, value-added purposes, such as for biomass or feed. In such cases, there is no additional impact either in acreage or inputs.

Of greater concern is the issue of containment and inadvertent exposure. Regulations to evaluate containment of transgenic plants are similar in concept to

those for other hosts, but specifics are very different. One of the areas historically concerning the production process of industrial enzymes is the occurrence of allergenic reactions developed by workers in the production facility. This has led the industry to safer forms of controlling small-particle exposure during microbial production. The concern for plant is that pollen from production fields can act as a carrier of the protein and lead to exposure similar to that observed for microbial production. For this reason, it is suggested that expression of the protein be specific to tissues other than pollen, thereby eliminating this concern.

Field production has the potential to affect wildlife where the crop is grown. Unlike many applied pesticides, transgenic plants are generally non-toxic to wildlife. This may reduce the environmental threat as opposed to many chemicals. The specific protein produced still may have some unwanted effects on wildlife and this aspect needs to be addressed, particularly for endangered species that may be present in the production field. Products that require larger acreage will create more concerns.

The final evaluation and perhaps the most controversial is the potential impact for the industrial enzyme for inadvertent exposure into the food chain. This may occur for several theoretical reasons, including mislabeling of seed, spills during transport, or pollen dissemination into food crops or wild relatives. Pollen dispersion has received the most attention as the other possibilities of inadvertent exposure most likely because the other potential sources are similar to that of other host production systems. To control the flow of pollen several different methods can be employed. These range from male sterility systems and physical isolation of the crops from compatible agricultural crops or weeds. In addition, systems have been proposed for growing transgenic crops within an industrial crop zone thereby further reducing the possibility of inadvertent mixing [140].

The underlying assumption for the production of transgenic proteins produced in plants is that they must be kept at all times isolated from food crops. This is essential for proteins that have the potential for detrimental effects on the population. However, many industrial proteins are used in food processing or derived from material already in the food chain. In these cases the transgenic proteins have the potential to be deregulated. After demonstrating that there is no danger to human safety the strictest of containment conditions may be dropped although some containment may still be desirable, either from a regulatory standpoint or from a commercial necessity.

Plants as Sustainable Sources of Industrial Enzymes

Plants have the potential to provide a sustainable source of industrial enzymes. Most plants can be transformed stably or used to express transiently heterologous proteins at levels that can be used for industrial production. The key sustainable feature of plants is that they are a renewable resource. They do not require intensive efforts for growth and maintenance of sterility, although some may require containment. Even so, the infrastructure and capital investment for growing plants is considerably less than that for fermentation of microbes. In addition, plant waste can be disposed of without intensive treatment, unlike effluents from fermenters. Energy resources for plant growth are also lower than those for maintenance of temperature and sterility of fermenters. In addition, formulations of large volumes of media for culture represent a large input of water, often a limiting resource. Cooling of large fermentation chambers is also energy intensive. These considerations are less severe with plants. Although plants do need regular and sustained watering, they can be grown in traditionally non-irrigated areas or in irrigated land where the input can be spread out using efficient drip hoses and watering procedures over a long period of time, alleviating the need for vast quantities of sterile water at short notice. The water does not need to be sterile, which reduces the energy burden and thereby the LCA.

The projection of 2–25% annual growth of enzyme requirement indicates a massive increase in enzyme production if supply is to keep pace with demand. Large volumes of enzymes imply that a number of fermenters have to be constructed to produce microbial- or cell-culture-based enzymes, or a shift of paradigms to a more efficient supply. Plants can provide the large volumes of enzymes needed with relatively low capital investment, and may represent the only really low-cost option for providing the immense requirements of industrial enzymes anticipated with projected

growth. Depending on the level of purification required, the enzymes can either be used without purification (such as for the production of biofuels) or undergo processing (such as for pharmaceuticals). This decreased processing obviously lowers environmental impact of the procedure. Tissue from plants that are not target for protein accumulation can be processed or disposed of such as to provide a financial buffer to the industrial enzyme production aspect.

The key to using plants for the production of industrial proteins is the increasing expression of transgenic proteins to levels commensurate with economic recovery of protein. A search of the Sigma Aldrich Chemical Company for transgenic-plant-derived products showed that proteins expressed in rice (avidin, lactoferrin, lysozyme), corn (avidin, trypsin), and tobacco (tissue factor proteinase inhibitor II, bovine aprotinin) are commercially marketed. Cell Sciences (www.cellsciences.com) produces over 25 cytokines and growth factors from barley endosperm, especially marketable as they are animal, bacterial, and viral-free. These are fine chemicals produced with high purity, but evidently are also commercially viable, providing a proof of potential. Increasing accumulation levels in plant tissue is an important issue for commercial success.

Storage of enzymes is also energy consuming when produced from microbial fermentation. The protein is usually lyophilized for storage; an energy-intensive process requiring freezing and desiccation simultaneously. Green tissues from plants have to be processed immediately, frozen or dried for protein stability. However, proteins expressed in seeds have been shown to maintain stability, even at room temperature, for at least 3 years without noticeable degradation [45]. This decreases the LCA and increases sustainability, as well as facilitating rapid response to spikes of increased demand.

Plant-based production also results in less waste. The unused portions of the plant body can be funneled into other uses, such as ethanol from biomass, and there is little waste from the recovery process compared to effluents from fermenters, lower waste disposal requirements, and lower net production of greenhouse gases, which is better for environmental sustainability and society.

Future Directions

Plants have historically contributed to industrial processes from dyes and tannins for fabric and leather to drugs for healthcare and pharmaceuticals. The first generation of plant-derived recombinant proteins is now commercially available and the prospects of more products is in the pipeline with many groups working on expressing high levels of laccases, cellulases, plantibodies, and pharmaceutically important proteins. In some cases, enzymes can be directly delivered in the plants, such as cellulolytic enzymes expressed in plants to improve their degradation for production of bioethanol. Alternatively, enzymes can be expressed at high levels and isolated for industrial processes. In order to sustain either process, plants should accumulate proteins in sufficient quantities. Protein targeting to improve expression levels is a topic of major interest and additional studies on inducible expression are being pursued to enhance utility.

Currently, there is a major push to find and utilize renewable energy more efficiently. Plant starch and sugars are major sources of bioethanol, but their production from otherwise discarded lignocellulosic material hold out great promise for fuel production, enabling the real possibility of national fuel self-sufficiency. Plants are a renewable resource, and lower the LCA of processes since energy input into their production is substantially lower than other production systems. In addition, most products of plants can find use elsewhere for feed, silage, or biomass for renewable fuel production. The benefits of large-scale increases with little effort, lower costs, and potential to offset costs with downstream use of waste solely accrue to plants, making this a technology worth investing in.

Article Outline

Glossary

Agrobacterium tumefaciens Gram negative phytopathogenic soil bacterium belonging to the family Rhizobiaceae. *A. tumefaciens* naturally infects a variety of dicotyledonous plant species and induces the formation of tumors (galls) by transferring genes located within the T-DNA.

Biopharmaceuticals Drugs, produced using modern biotechnological methods such as recombinant DNA technology, comprising proteins and/or nucleic acids for therapeutic or in vivo diagnostic purposes.

Epigenetic effects Changes caused in gene expression patterns that are not due to changes in the nucleotide sequence of the DNA but due to nucleotide modifications by methylation or RNA-directed mechanisms.

Glycosylation The co- or posttranslational addition of carbohydrate moieties to polypeptides. The carbohydrates may be either N-linked (at asparagine or arginine side chains) or O-linked (at serine, threonine, tyrosine, hydroxylysine, or hydroxyproline side chains).

Immunoglobulin (Ig) Major component of the adaptive immune system with specific antibody activity. Immunoglobulins are produced by lymphocytes and consist of four polypeptide chains: two identical heavy and two identical light chains. Immunoglobulin G (IgG) is the principal immunoglobulin of the plasma with a molecular weight of 150 kDa. Immunoglobulin A (IgA) is a dimeric 400 kDa molecule secreted by mucosal surfaces. Beside the heavy and the light chains an IgA molecule contains a joining chain and the secretory component. Immunoglobulin M (IgM) is produced early during the immune response. Secreted IgM molecules have a star-shaped pentameric structure.

Molecular farming (also pharming) The production of pharmaceutical or technical proteins in plants or animals.

Monoclonal antibody An immunoglobulin secreted by a single clone of antibody producing cells.

Plastid Plant organelle bound by a double membrane containing its own circular genome. Several types of plastids are known that originate from a common precursor the proplastid. The most prominent form is the chloroplast found in the green tissues.

Posttranslational modification Any modification that occurs once a polypeptide has been synthesized, for example, proteolytic processing, glycosylation, methylation, phosphorylation, and prenylation.

Suspension culture Technique for the cultivation of plant cells or tissues in liquid culture medium under aseptic conditions using shake flasks or fermentation vessels.

T-DNA Transfer DNA. Natural T-DNA is located on large tumor inducing (Ti) or hairy root inducing (Ri) plasmids, although for gene transfer to plants it has been moved onto a smaller, more convenient vector. The T-DNA is transferred to the plant cell with the help of a range of virulence factors, and once in the nucleus it may be stably integrated into the plant genome.

Transformation Transfer of genetic information into a cell by biological (*A. tumefaciens*) or physical means (e.g., gene gun).

Transgene A segment of DNA that is introduced into the genome of a host cell by transformation, and

which integrates into the genome so that it is inherited like any other gene.

Transient expression The temporary expression of a transgene within a host cell without stable integration into the host genome.

Vaccine Preparation of immunogenic material that stimulates active immunity in the recipient without causing disease. Vaccines can be based on killed or attenuated microorganisms or isolated components of the disease causing agent (subunit vaccines).

Viral vector Genetic elements derived from viral genomes for the transient expression of transgenes in a host cell. Viral vectors have the ability to replicate autonomously in the host cell and might be able to infect distant cells (depending on the degree of engineering).

Zinc-finger nucleases Chimeric proteins consisting of a zinc-finger domain conferring sequence specific DNA binding and a nuclease domain for the introduction of a double-strand break at the target site.

Definition of the Subject and Its Importance

The demand for therapeutic proteins has increased in recent years and modern biotechnological methods have, until recently, ensured the production of safe and effective biopharmaceuticals to meet this demand. Various production platforms are currently used in the pharmaceutical industry, most based on the fermentation of engineered pro- and eukaryotic microorganisms, insect cells, or mammalian cells. However, the growth of the market for biopharmaceuticals is predicted to outpace production capacity using these platforms in the next decade, so alternatives are necessary. Intact plants and plant cell cultures are suitable production systems for a wide range of therapeutic proteins and could help to fulfill the need for increased production capacity. The production of pharmaceutical proteins in plants began with a monoclonal antibody expressed in transgenic tobacco plants more than 20 years ago. Since then many different plant species have been genetically engineered to produce valuable pharmaceutical proteins using a variety of transformation methods. Major progress has been achieved in transformation and expression technology, the downstream processing of transgenic plant material and the adaptation of regulatory procedures to encompass the new production platforms, allowing the first plant-made pharmaceuticals to begin clinical trials.

Introduction

Plant cells synthesize a vast array of secondary metabolites, many of which are already used as pharmaceuticals. Recombinant DNA technology combined with techniques for plant transformation and the regeneration of transgenic plants have allowed the pharmaceutical exploitation of plants to be extended to include the production of biopharmaceuticals such as subunit vaccines, antibodies, growth factors, cytokines, enzymes, and blood factors. In many cases, these products need to be purified from plant material and formulated in the same way as conventional biopharmaceuticals. However, many plants are "generally regarded as safe" for both topical and oral administration, so they are particularly suitable for the production of vaccines that can be delivered via the oral route or antibodies applied as topical microbicides, especially where such products are required on a large scale. This reflects the fact that plants can be grown inexpensively on an agricultural scale and that plant-derived pharmaceuticals for topical/oral administration would require only minimal processing. This could potentially bring the costs of production and distribution down to levels suitable for deployment in developing countries with limited financial resources and a poor medical infrastructure. This contribution describes the technologies that facilitate biopharmaceutical production in plants and plant cell cultures either through transient expression or stable transformation. It also discusses issues relating to posttranslational modification, extraction and purification, and regulatory compliance, focusing on those plant-derived pharmaceutical products that have advanced the furthest in the clinic. A compilation of selected technical achievements in plant molecular farming is provided in Table 1.

Plant Transformation

Pharmaceutical proteins can be produced in plants or plant cells either through transient expression or stable transformation. In the first case, the DNA encoding the protein is delivered into plant cells by *Agrobacterium tumefaciens* or a viral vector (or a combination of the two) but there is no integration of this DNA into the

Plant Molecular Pharming, Pharmaceuticals for Human Health. Table 1 Selected research achievements in the field of plant molecular farming between 1989 and 2008

Year	Achievement	Reference
1989	Full-size antibody (mouse IgG) expression in tobacco	[1]
1990	First human protein (HSA) produced in tobacco and potato	[2]
1992	First vaccine candidate (HBsAg) expressed in tobacco	[3]
1995	First secretory antibody (sIgA) produced in tobacco	[4]
1995	Plant seed oilbodies as vehicles for protein production and purification	[5]
1996	Expression of a protein-based polymer in tobacco	[6]
1998	First clinical trial with a vaccine candidate produced in transgenic potato	[7]
1999	Transient expression of an antibody by *Agrobacterium* vacuum infiltration	[8]
1999	N-glycan analysis of a plant-produced antibody	[9]
2000	Human growth hormone produced in tobacco chloroplasts	[10]
2001	N-glycan modification by expression of a human β-1,4 galactosyltransferase	[11]
2004	Knockout mutants of moss lacking plant-specific glycosylation	[12]
2004	Generation of *Arabidopsis* plants lacking plant-specific glycosylation	[13]
2005	*Agrobacterium*-mediated delivery of viral replicons	[14]
2006	Approval of a plant-made vaccine for veterinary medicine	[15]
2007	Production of glucocerebrosidase with terminal mannose residues	[16]
2008	Clinical phase I trial with plant-produced anti-idiotype vaccines	[17]
2008	Engineering of a CMP-sialic acid pathway in plants	[18]
2008	Phase III clinical trial with plant-made glucocerebrosidase	[19]

plant genome and the protein is synthesized for a few hours or days. In the second case, DNA delivered either by *A. tumefaciens* or a physical process such as particle bombardment integrates into the plant genome and becomes a permanent locus, allowing long-term production of the recombinant protein and the transmission of the trait to subsequent generations.

Each method has advantages and disadvantages that need to be evaluated on a case by case basis for each pharmaceutical protein, depending on its intended use and the production scale. The production of an immunoglobulin via stable integration into the nuclear genome was first reported in 1989 when Hiatt and colleagues produced a monoclonal IgG-class antibody in tobacco leaves [1]. They introduced the coding sequences for the gamma heavy chain and kappa light chain of the immunoglobulin into independent tobacco lines and then crossed plants from each line to stack the transgenes in a single plant, which was able to produce the full antibody. The same strategy was used to produce a chimeric secretory (sIgA/G) antibody, although in this case four transgenes were required (encoding the kappa light chain, the chimeric alpha/gamma heavy chain, the joining chain, and the secretory component) and four lines were bred over two generations to generate the final production crop [4]. Later on the assembly of a chimeric secretory sIgA/G antibody could be achieved by simultaneous transformation of all four components in rice plants [20]. These examples clearly show how plant cells can produce even the most complex proteins and modify and assemble them into functional oligomeric structures (two different cell types are required in mammals to produce secretory IgA antibodies). Stable transformation of the nuclear

genome enables the combination of several independent expression cassettes into a single transgenic line and also allows the introduction of a transgene from a laboratory cultivar into other varieties of the same species, to yield a germplasm that is particularly suited for a certain purpose. The latter strategy has been used to breed dent and sweet corn varieties that produce the HIV-specific antibody 2G12. The expression cassettes were initially introduced into a laboratory maize cultivar with little agronomic value and low yield [21]. Using conventional breeding transgenes can be transferred to a germplasm that is either inaccessible for direct transformation or that is particularly suited for the cultivation under certain climate conditions.

A drawback of stable nuclear transformation is the time needed to identify and establish a germplasm with the desired properties. A large number of primary transformants often need to be screened to identify plants showing high-level transgene expression. These lines then need to be analyzed at the molecular level to determine the number and arrangement of the transgenes. For breeding purposes single-copy integration events or multicopy single locus events with a regular transgene arrangement are preferred [22]. In contrast, multiple transgene copies with a complex integration pattern are likely to suffer from both transcriptional gene silencing (TGS) and posttranscriptional gene silencing (PTGS) [23]. The transgenic plants must also be analyzed for unwanted pleiotropic effects that could be caused by the transgene itself or by the changes that are brought about by its integration, since transgene integration following both *Agrobacterium*-mediated transformation and particle bombardment is a random process. Precise transgene integration at a predefined locus can be achieved by homologous recombination (gene targeting) but this has not been possible for most plant species in the past due to its very low efficiency. A notable exception is the moss *Physcomitrella patens*, where transformation by homologous recombination is a straightforward and robust process [24]. In higher plants, efficient homologous recombination has become possible only recently with the use of zinc-finger endonucleases. These are engineered endonucleases containing zinc-finger motifs that bind precise DNA sequences and introduce double-strand breaks at the target site. This in turn stimulates DNA repair in the host, thereby facilitating homologous recombination. This has enabled the precise engineering of transgenic plants, although there have been no reports thus far concerning applications in molecular farming [25–28].

Another disadvantage of nuclear transgenic plants is that the target protein often accumulates at low levels, making them commercially unfeasible. This has been addressed by the use of plastid transformation, where the transgene is integrated in the circular chloroplast or chromoplast genome, typically by particle bombardment. Unlike nuclear transformation, homologous recombination is an efficient method for transgene integration into the plastid genome, allowing precise gene targeting. Every plastid contains several copies of the genome, and each plant cell contains many plastids [29]; therefore, it is possible in principle to generate plant cells containing several thousand transgene copies (and these are not subject to silencing because the TGS and PTGS mechanisms are not present in the plastid). To ensure the transgene is present in every copy of the plastid genome (the homoplasmic state), the primary transformants must undergo multiple rounds of selection and regeneration. This is generally achieved using the marker gene aminoglycoside 3″-adenylyltransferase, which confers resistance to the antibiotic spectinomycin [30]. The high transgene copy number and absence of silencing allows the accumulation of some target proteins to levels exceeding 10% of the total soluble protein (TSP) in the cell. Furthermore, since plastids are evolutionarily derived from bacteria, it is possible to express multiple genes as operons, producing polycistronic mRNA [31].

Many biopharmaceuticals are complex molecules that require several posttranslational processing steps to achieve a functional state. Plastids are equipped to form disulfide bridges, as demonstrated for the production of the human growth hormone somatotropin [10], and they can also assemble oligomers as demonstrated for the production of cholera toxin B-subunit (CTB), which assembled into functional GM1 ganglioside-binding pentamers [32]. Human serum albumin, which requires posttranslational removal of the N-terminal methionine residue, has also been produced successfully in plastids [33]. The enzyme methionine aminopeptidase cleaves off the initiating N-formylmethionine in plastids depending on the

subsequent amino acid sequence context, and this must be considered when dealing with proteins that need to have intact N-termini. Another elegant approach for the production of proteins with a defined N-terminus is the expression of the target protein as an N-terminal ubiquitin fusion protein. Endogenous ubiquitin-specific proteases then remove the ubiquitin moiety precisely, a strategy that has enabled the production of native somatotropin that carries an N-terminal phenylalanine residue [10].

Plastid transformation technique was limited to tobacco for many years but has recently expanded to incorporate certain crop species such as lettuce and tomato [34, 35]. Plastid transformation in crop plants opens new possibilities in the area of oral vaccines, where antigens are produced in the edible parts of plants and delivered via the oral route. A further advantage of plastid transformation is the biosafety aspect, since chloroplasts are inherited maternally in most species and are therefore not present in pollen [36]. However, there are also some limitations. Many biopharmaceuticals need to undergo co- and post-translational glycosylation in order to fold properly or in order to remain functional and stable, but this process does not occur in plastids. Certain target proteins also appear to be unstable or toxic when expressed in plastids, for example, the rotavirus coat protein VP6 and HIV p24 antigen undergo rapid degradation in the chloroplasts of older tobacco leaves, with significant accumulation only possible in the youngest leaves. A codon-optimized HIV p24 construct allowed homogenous expression but all the leaves turned yellow, and rearrangements were observed within the plastid DNA [37].

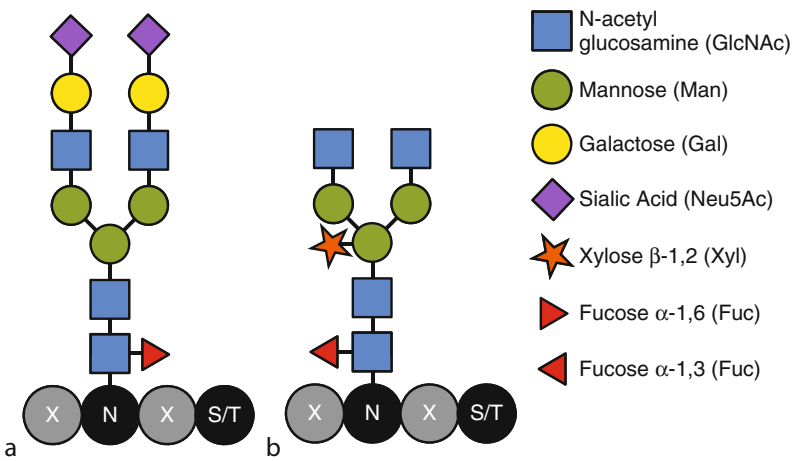
Transient expression allows more rapid production than stable transformation (nuclear or plastid). DNA encoding the pharmaceutical proteins is either included within a T-DNA cassette carried by an *A. tumefaciens* strain delivered into leaf tissue by vacuum infiltration [38, 39], or inserted into a viral vector that is used to infect the plant [40, 41]. Transient expression can be used for the rapid testing of expression constructs for subsequent stable transformation procedures or can be scaled up for use as production system in its own right. Most of the viral vectors are based on RNA viruses such as *Tobacco mosaic virus* (TMV), *Potato virus X* (PVX), and *Cowpea mosaic virus* (CPMV). These vectors have been used both to produce intact proteins and to produce chimeric virus particles that display peptide antigens on their surface. In such peptide display vectors, the target peptide is fused to the coat protein, and because each particle has many copies of the coat protein (and hence the antigen), the particles are strongly immunogenic and can be used without additional adjuvants to provoke an immune response. The versatility of this approach has been demonstrated with an experimental rabies vaccine that induced a protective immune response in mice. Furthermore human volunteers who ingested spinach leaves infected with the recombinant virus mounted a humoral immune response [42]. Conventional viral vectors have a limited capacity, and larger transgenes tend to be truncated or eliminated altogether as the virus spreads. This has been addressed by developing a series of deconstructed viral vectors in which the coat protein gene is deleted to provide space for the transgene. In order to deliver these vectors to a maximum number of plant cells the entire recombinant virus genome is incorporated as a DNA copy into a T-DNA cassette and delivered by *A. tumefaciens* via vacuum infiltration [43]. Two similar systems have been developed, one described as the launch vector system [44] and the other as the magnifection system [14]. They both exploit the ability of *A. tumefaciens* to infect a large range of plants, thereby extending the host range of the natural virus and using the efficient viral replication system to amplify the coding sequence of the target protein. In a proof of concept experiment, the accumulation of green fluorescent protein (GFP) peaked at 4 g kg^{-1} fresh weight in *Nicotiana benthamiana* plants transformed by magnifection [14]. The platform has been refined for the production of oligomeric proteins such as antibodies. Full-size IgG1 immunoglobulins have been produced successfully at levels of up to 0.5 g kg^{-1} fresh weight, by introducing the light and heavy chain coding sequences into two independent noninterfering vectors based on TMV and PVX, respectively [45].

Posttranslational Modification

Approximately 30% of all approved biopharmaceuticals contain N-linked glycans, so N-glycosylation is the most important posttranslational modification that needs to be

taken into account when manufacturing recombinant biopharmaceuticals in plants. The mechanism of N-glycosylation is conserved between plants and mammals, beginning in the endoplasmic reticulum (ER) with the transfer of an oligosaccharide precursor molecule onto asparagine residues within the sequence motif N-X-S/T (where X is any amino acid except proline). The precursor molecule is subsequently trimmed to yield a structure known as a high-mannose type glycan. The protein then passes into the Golgi apparatus where additional glycan modifications take place.

The final complex type glycan structures differ between plants and mammals (Fig. 1), in that plant glycoproteins contain core β1,2-xylose and α1,3-fucose residues whereas mammalian glycoproteins contain β1,4-galactose and terminal N-acetyl-neuraminic acid (sialic acid) residues [46]. Plant-specific glycosylation patterns have been found to induce an immune response upon injection in some mammalian species [47–49]. To prevent these immune responses several strategies have been explored to avoid the addition of plant-specific sugar residues to the glycan structure. One approach is the attachment of a C-terminal H/KDEL amino acid sequence motif to retain the target protein within the ER, thereby preventing exposure to the Golgi apparatus and the attachment of β1,2-xylose and α1,3-fucose residues [50]. This strategy has been applied successfully in the production of a chimeric mouse/human IgG1 antibody against human chorionic gonadotropin [51]. An alternative strategy is the knockout or knockdown of the endogenous plant β1,2-xylosyltransferase and α1,3-fucosyltransferase genes, which has been achieved in the moss *P. patens* by homologous recombination [12]. The double knockout mutant was used to express human erythropoietin devoid of plant-specific glycan structures [52]. In the model plant *Arabidopsis thaliana*, the β1,2-xylosyltransferase and α1,3-fucosyltransferase genes have been knocked out by T-DNA insertional mutagenesis [13]. This plant line has been used to produce the anti-HIV antibody 2G12 with a humanized glycan structure [53]. In the duckweed *Lemna minor*, the human anti-CD30 antibody MDX-060 was produced without plant glycans by co-introducing inverted repeat transgenes matching the sequences of the β1,2-xylosyltransferase and α1,3-fucosyltransferase genes, so that they were silenced by RNA interference (RNAi) [54]. This antibody also demonstrated stronger antibody-dependent cell-mediated cytotoxicity (ADCC) compared to its counterpart produced in Chinese hamster ovary (CHO) cells, reflecting the tenfold higher affinity of the plant-derived antibody for the human Fcγ receptor [54]. The same phenomenon has been demonstrated for other antibodies produced in the duckweed and moss systems [55, 56].



Plant Molecular Pharming, Pharmaceuticals for Human Health. Figure 1
Prototypes of protein N-glycosylation patterns from mammalian (**a**) and plant (**b**) origin. We are grateful to Holger Spiegel (Fraunhofer IME, Aachen, Germany) for the preparation of the graphics

To further humanize the glycan structure of biopharmaceuticals produced in plants, the coding sequence for human β1,4-galactosyltransferase has been introduced into tobacco [57, 58] and alfalfa plants [59]. The recombinant antibodies produced in these modified host plants not only possessed glycans with terminal galactose residues but they also contained fewer core β1,2-xylose and α1,3-fucose residues. Many human glycoproteins possess terminal sialic acid residues that play a pivotal role in serum stability. For example, erythropoietin usually has a half-life of 5 h in rat serum, but enzymatically trimming off the terminal sialic acid residues reduces the half-life to <2 min [60]. There is consequently an ongoing effort to introduce the CMP-sialic acid biosynthesis pathway into plants and thus far four of the enzymes (α2,6-sialyltransferase, UDP-N-acetylglucosamine 2-epimerase/N-acetylmannosamine kinase, N-acetylneuraminic acid phosphate synthase and CMP-N-acetylneuraminic acid synthetase) have been expressed successfully in *A. thaliana* [18, 61]. Recently, the components of the complete pathway have been transiently expressed in *N. benthamiana* and the co-expressed 2G12 mAb has been shown to become sialylated [62].

There is much less information available about the significance of O-glycosylation in pharmaceutical proteins produced in plants. Endogenous plant proteins tend to undergo O-glycosylation at clustered proline residues that are first converted into hydroxyproline, for example, those found in the extension family of hydroxyproline-rich glycoproteins (HRGPs). Such proline clusters are also present in the hinge region of IgA1 antibodies, so a recombinant IgA1 antibody expressed in maize similarly underwent hydroxylation followed by O-glycosylation [63]. An artificial O-glycosylation motif consisting of 20 tandem repeats of the dipeptide serine/proline has been fused to the C-terminus of human interferon α2b (IFNα2-$(SO)_{20}$) expressed in tobacco suspension cells. The fusion protein accumulated in the culture supernatant at levels two orders of magnitude higher than native IFNα2b, reflecting its more efficient secretion and its greater resistance toward proteolysis [64]. The antiviral activity of the fusion protein was comparable to that of native interferon but its higher molecular weight (75 kDa vs. 19.2 kDa) delayed renal clearance therefore increasing its serum half-life in mice by 13-fold [64].

The unwanted processing of recombinant proteins by endogenous plant proteases is a major obstacle in the field of molecular farming because the overall yield of the recombinant protein is reduced and the resulting protein fragments need to be removed during downstream processing. Proteolytic degradation has been observed irrespective of the subcellular localization of the target protein but the extracellular compartments (apoplast and culture medium) appear to be particularly rich in proteolytic enzymes [65–68]. This has been addressed using a number of strategies, including the co-expression of protease inhibitors [69–71] and the co-secretion of unrelated proteins that might act as bait for the proteases [72]. Although the proteases responsible for recombinant protein degradation have yet to be identified, there are indications that certain classes of proteases are involved (e.g., aspartic proteases, metalloproteases, and serine proteases) [66, 68]. Once the proteases responsible for recombinant protein degradation are known, knockout and knockdown strategies can be employed to reduce their abundance. However, proteases play a significant role in many aspects of plant development, stress responses, and pathogen defense, so their elimination may only be suitable for cell and tissue cultures that are grown under sterile and controlled conditions in the absence of pathogens.

Downstream Processing

Most biopharmaceuticals are formulated as a purified product so the majority of biopharmaceuticals produced in plants must be extracted from plant tissue and then purified and formulated in the same way as conventional biopharmaceutical products. Regardless of the upstream production platform, downstream processing can account for up to 80% of the total manufacturing costs for a biopharmaceutical protein [73], but the first downstream processing steps are largely determined by the specific production host [74]. If the target protein is produced in plant suspension cells and secreted into the culture medium, the purification process can begin directly after the cells have been removed by filtration or centrifugation. If the protein is produced in an intact plant and/or if it accumulates inside the plant cell, it must be released by mechanical disruption in the presence of an appropriate extraction buffer and the extract must be clarified by filtration and/or

centrifugation to remove debris, fibers, and other particulates. Aqueous two-phase partition is a useful initial purification step to remove polyphenols and cell debris from crude plant extracts [75, 76]. The removal of polyphenols is critical to prevent fouling of the chromatography media used in subsequent purification steps [74, 77]. After clarification, the product may be captured from the feed if a suitable affinity chromatography resin is available, allowing a high level of purification in a single step. A wide range of natural affinity ligands and an increasing number of synthetic ligands (e.g., mercaptoethylpyridine, MEP HyperCel™) are available, particularly for the capture of antibodies [78]. After capture, polishing is usually achieved by the application of two or more orthogonal separation methods to achieve maximal purity and contaminant removal, for example, ion exchange, hydrophobic interaction, hydroxyapatite, and size exclusion chromatography [79]. If a capture step is not possible, these chromatography methods may be used for intermediate purification prior to polishing. Purification can be facilitated by engineering the physicochemical properties of the target protein through genetic fusions, although the fusion tag must be removed after purification to yield the authentic protein as a final product (a protease cleavage site adjacent to the tag can be used to achieve separation). A fusion with the hydrophobic plant protein oleosin enables enrichment of the target protein by floating centrifugation [80]. Alternatively, fusing the target protein to elastin-like polypeptides (ELPs) allows the target protein to be isolated by thermal phase transition [81].

Potential contaminants include macromolecules such as host cell proteins and nucleic acids, as well as small molecules such as secondary metabolites (e.g., nicotine). The removal of contaminants derived from plant-associated microbes must also be demonstrated, especially endotoxins from *A. tumefaciens* that can cause inflammatory responses in humans. The successful removal of these substances has recently been demonstrated for a monoclonal antibody that has been produced in *N. benthamiana* by magnifection [82].

Biopharmaceuticals produced for human clinical trials must achieve certain quality criteria that are defined by current good manufacturing practice (cGMP). The regulations for biopharmaceutical manufacture are defined by the Food and Drug Administration (FDA) in the USA and by the European Medicines Agency (EMEA) in the European Union. The production of pharmaceuticals using plant suspension cells is very similar in concept to conventional systems based on mammalian cells, but intact plants cultivated in the greenhouse or in the open field are very different in concept and in practice. The FDA and EMEA have published guidance documents covering the production of pharmaceuticals in plants, and these might be refined further in the future [83]. Recently the Fraunhofer Institute for Molecular Biology and Applied Ecology in Aachen, Germany, obtained the first GMP license for the production of a plant-made pharmaceutical protein for clinical phase I trials in Europe. Based on this process the anti-HIV antibody 2G12 was produced in transgenic tobacco plants in the greenhouse.

Plant-Derived Vaccines

Plants have been proposed as an alternative production platform for subunit vaccines, with the added advantage that storage tissues such as cereal grains and potato tubers may be used to keep the vaccine stable without the need for a cold chain and could even be used to administer oral vaccines without processing, thus reducing costs.

Antigens embedded in the plant cell matrix are protected against the acidic conditions in the stomach and are released gradually, allowing the induction of a mucosal immune response. Many antigens that could be used as vaccines in humans or farm animals have been produced in plants including the hepatitis B virus surface antigen [3, 84, 85], the Norwalk virus capsid protein [86–88], the *Escherichia coli* heat labile toxin [89–91], and the rabies glycoprotein [42, 92].

Phase I clinical trials in humans have been conducted for some oral vaccines. The coding sequence for the B-chain of the heat labile toxin from enterotoxigenic *E. coli* (LT-B) has been expressed in transgenic potato and maize. Human volunteers who ingested three 50-g or 100-g doses of peeled raw potato slices containing 0.5–1 mg of LT-B developed anti LT serum IgG antibodies (91%) and half of the vaccinees also produced secretory IgA antibodies in their stools [7]. Similarly human volunteers who ingested 2 g of defatted corn germ meal containing 1 mg of LT-B developed anti LT serum IgG and IgA and sIgA in their stools [93].

Transgenic potato tubers producing the major capsid protein of the Norwalk virus (which causes gastroenteritis) were fed to human volunteers in two or three 150-g doses containing ~500 μg of the protein. Higher levels of IgA antibody-secreting cells were observed in more than 90% of the vaccinees, 20% produced serum IgG or IgM responses, and 30% produced anti-NVCP antibodies in their stools [88].

Two phase I clinical trials with plant-derived hepatitis B surface antigen (HBsAg) have been reported. In the first trial, transgenic lettuce (*Lactuca sativa*) was orally administered to seven seronegative individuals in three 200-g doses containing 0.5–1 μg of HBsAg within 5 weeks. After the third dose, all subjects developed serum anti-HB antibodies of up to 6.3 mIU/ml serum [94]. In the second trial, transgenic potato tubers were fed to individuals who had previously been vaccinated against hepatitis B. The vaccinees received two or three 100-g doses of raw peeled potatoes each containing ~800 μg HBsAg. Higher serum anti-HB titers were observed in 60% of the vaccinee group whereas there was no increase in the control group [95].

Recently, H1N1 and H5N1 influenza virus hemagglutinin (HA) have been transiently expressed in *N. benthamiana* [96]. Both proteins assembled into virus-like particles (VLPs) that budded from the plant plasma membrane, a desirable outcome because VLPs are polyvalent and therefore much more immunogenic than soluble subunit vaccines. Mice parenterally immunized with low doses (0.5 μg) of the VLPs were protected against a lethal challenge with influenza virus [96]. A phase I dose escalation study to assess the safety of a plant-derived H5 VLP in healthy volunteers was initiated in 2010 (www.clinicaltrials.gov; NCT00984945).

Although most vaccines are intended to induce an immune response against pathogens, their use is not limited to the prevention of infectious diseases. More recently, vaccines have been developed for the prevention or the treatment of certain types of cancer. A plant-derived vaccine for the treatment of non-Hodgkin's lymphoma (NHL) based on idiotype antibodies has been evaluated in a phase I trial [97]. NHL is a clonal disease of the B-cell lineage and the malignant cells carry specific immunoglobulins (idiotypes) on their surface. These idiotypes can be used to trigger a specific immune response. Because the idiotypes are different in each patient the vaccine has to be manufactured individually for each treated person. Currently the patient's tumor cells are expanded from a biopsy as human/mouse heteromyelomas. The monoclonal idiotype antibody is purified and coupled to an immunogenic carrier protein like keyhole limpet hemocyanin (KLH) and injected into the patient usually together with granulocyte-macrophage colony stimulating factor (GM-CSF) as an adjuvant [98]. To shorten the time needed to manufacture the patient-specific vaccine a plant-based production system has been developed in which the coding sequences for the variable domains of the idiotype antibody are cloned from the patient's biopsy and inserted into a viral vector for the expression of a single chain antibody (scFv). *N. benthamiana* plants have been infected with such viruses allowing the scFv to be purified from leaves [99, 100]. Sixteen NHL patients who had previously received chemotherapy were treated with two different doses of the tobacco-derived idiotype vaccine either with or without a GM-CSF adjuvant [17]. Most of the treated patients developed a cellular immune response although only three patients developed a humoral immune response. Recently, the Bayer Group announced another phase I clinical trial with idiotype vaccines for NHL using the transient magnifection technology developed by their subsidiary Icon Genetics. The ongoing study will enroll 30 patients with progressive or relapsing NHL. The patients will receive 12 injections over 16 months, each consisting of 1.0 mg of the personalized vaccine. The study is designed as a safety study to evaluate potential toxicity associated with the therapy but will also analyze the relevant immunological parameters of the patients. The final results of the study are expected in 2012 (www.clinicaltrials.gov; NCT01022255).

Plant-Made Pharmaceuticals in Advanced Development

The most advanced plant-derived pharmaceutical in terms of clinical development is glucocerebrosidase manufactured in transgenic carrot suspension cells (prGCD, taliglucerase alpha, Uplyso™). Patients suffering from Gaucher disease, an inherited lysosomal storage disorder, cannot produce active glucocerebrosidase and need enzyme replacement therapy with recombinant glucocerebrosidase, which is currently produced in CHO cells (imiglucerase, Cerezyme™) [101].

This is currently one of the most expensive biopharmaceuticals, with an annual treatment cost of USD 200,000 per patient [102]. The purified recombinant imiglucerase needs to be processed enzymatically to expose terminal mannose residues that are required for the efficient uptake of the enzyme into macrophages. The plant-derived counterpart, taliglucerase alpha, does not require these additional processing steps because it is targeted to the cell vacuole where the complex type N-glycans are trimmed to the paucimannose form exposing terminal mannose residues [16]. A phase III clinical trial with taliglucerase alpha was completed successfully in 2009 (www.clinicaltrials.gov, NCT00376168) and the substance currently awaits market approval from the FDA. Meanwhile patients can get access to taliglucerase alpha under an expanded access protocol [101].

Another plant-derived protein currently in clinical development is alpha-interferon (IFN-α2b) for the treatment of chronic hepatitis C infections. IFN-α2b has a low molecular weight (19 kDa, no glycan chains) and is therefore eliminated rapidly by renal filtration. Special formulations are required to increase its serum half-life, and this is achieved in the current formulation produced in *E. coli* (peginterferone alpha-2b; PEGIntron™), by attachment to polyethylene glycol. The plant-derived protein (Locteron™) is produced in duckweed and formulated in poly(ether-ester) microspheres to achieve controlled release over a defined period [103]. The plant-derived version has been tested successfully in a clinical phase I/II study (www.clinicaltrials.gov, NCT00593151) to establish its safety, tolerability, and efficacy compared to PEGIntron™. Currently two phase IIb clinical trials are underway to determine the optimal dose for the treatment of hepatitis C patients and its efficacy in combination with the antiviral compound ribavirin (www.clinicaltrials.gov, NCT00863239, NCT00953589).

The first recombinant biopharmaceutical on the market was insulin, which received regulatory approval in 1982. A large number of diabetes patients depend on insulin therapy so current demand for the protein exceeds 8 metric tons per year. This demand is currently met by production in *E. coli* and *Saccharomyces cerevisiae* [104, 105]. The successful production of active recombinant human insulin has also been demonstrated in oilseeds, where oleosin fusion can be used to facilitate purification. As stated above, oleosin is a hydrophobic protein component of the seed oilbodies and fusion proteins become concentrated in the oilbodies allowing their purification by floating centrifugation, enzymatic cleavage, and then standard polishing chromatography methods [106]. For large-scale insulin production, the Canadian company SemBioSys Genetics Inc. uses safflower (*Carthamus tinctorius*) plants [107]. The company recently announced the successful completion of a phase I/II clinical trial with healthy volunteers demonstrating that the safflower-derived insulin (SBS-1000) is equivalent to the recombinant insulin currently on the market [108].

Future Directions

Many biopharmaceutical proteins have been produced successfully in plants and plant cell cultures, clearly demonstrating the utility of plant-based production platforms. The demand for biopharmaceuticals is predicted to rise in the future based on the large number of ongoing clinical trials that involve recombinant pharmaceutical proteins, but current fermenter-based production platforms are already struggling to meet the demand. The enormous flexibility offered by different plant production systems and their specific advantages in terms of cost, safety, and scalability, means that plants could provide an alternative source for recombinant biopharmaceuticals when the capacity of current platforms is exhausted.

To become more competitive with the currently established protein production platforms an increase in productivity for the plant cell factories is mandatory. Therefore future research will aim to boost the protein accumulation levels in plant cells. To achieve this goal different strategies are pursued including, among others, gene amplification, high throughput screening for elite events, targeting the protein of interest to suited storage organelles or even to create them artificially, and to shield the target protein against proteolytic degradation. Systems biology approaches will help to identify cellular targets that can be subsequently engineered to further improve the plant cell as a protein production host. The engineering process itself will be more precise in the future by employing the newly developed techniques to facilitate homologous recombination within the nuclear genome.

Beside the quantity also the quality of the final product will be a major focus of future research and development. Especially the engineering of the glycosylation pattern bears a great potential to optimize the stability and efficacy of the biopharmaceutical product. A critical point with respect to the glycosylation pattern will be the detailed understanding of plant-produced glycoproteins with the mammalian immune system. This will be an important prerequisite for tailoring plant-produced subunit vaccines and to avoid unintended side effects. With respect to oral vaccines reliable formulation and administration protocols have to be defined to ensure the anticipated outcome is achieved.

Further optimization of transient plant expression systems will help to address future needs for the delivery of vaccine, personalized medicine, and biopharmaceuticals for the treatment of orphan diseases. The rapid production cycle will also enable a timely reaction to emerging diseases, pandemics, or biohazards. However, unlike stable transgenic plant production systems, there are currently no specific regulatory guidelines for transient technologies, which are becoming a perceived barrier to their widespread use and commercialization. Therefore, the establishment and harmonization of international regulations for transient expression systems are needed to enable the commercial application of this promising technology.

Article Outline

Glossary

Companion animal Animal kept for companionship and enjoyment (household animal).

Edible vaccines Antigenic proteins, which are produced in organs of transgenic plants (e.g., fruits, tubers) and can be directly administered to humans or animals without any purification procedure.

ELP Elastin-like polypeptide containing the hydrophobic amino acids valine, proline, glycine, and guest residues, which shows temperature-dependent, reversible self-aggregation.

ELPylation Genetic C- or N-terminal target protein fusion to elastin-like polypeptides.

Homoplasmy Presence of the transgene in all copies of chloroplast DNA.

Livestock animal Domesticated animal raised in an agricultural setting to produce, e.g., food and fiber.

Molecular pharming The large-scale production and purification of pharmaceutical proteins in plants.

Plant-based expression Process by which information from a transgene is used in the synthesis of a functional protein *in planta*. Different plant-based expression systems are suitable (e.g., transgenic plants, transient expression, and plant cell cultures).

Plantibodies Antibody or antibody derivative produced in genetically engineered plants.

Transgenic plants Genetically engineered plants generated by the biolistic method (particle gun) or by *Agrobacterium tumefaciens* mediated transformation. The introduced transgene, which does not occur naturally in the plant, is transferred to the offspring.

Transient expression Expression of transgenes for a short period of time. In the context of plant-based expression infiltration of recombinant Agrobacteria (Agro-infiltration) or the use of plant viral vectors are the methods of choice to produce a desired protein *in planta*.

Transplastomic plants Introduced transgene is targeted to the chloroplast genome using particle bombardment or other physical DNA delivery techniques.

Zoonotic diseases Infectious disease that can be transmitted from wild and domestic animals to humans.

Definition of the Subject

"Molecular Pharming" refers to the large-scale production and purification of pharmaceutical proteins in plants or plant-based expression systems. Since the successful expression of complete antibodies in transgenic plants in 1989 and the first report of plant-based vaccine production in 1992, a large number of different vaccines, antibodies, as well as antibody fragments have been produced in plants for medical or veterinary purposes. However, only two plant-produced vaccine-related products have gone all the way through the production and regulatory hurdles, and only one, a plant-made single-chain variable fragment (scFv), is used in the production of a recombinant Hepatitis B Virus (HBV) vaccine in Cuba. Edible vaccines and novel methods of downstream processing such as "ELPylation" have been developed over the past years to facilitate the development of recombinant protein-based therapeutics.

Introduction

Plant-based expression systems possess advantages over conventional eukaryotic expression systems (yeast, insect cells, and mammalian cells), e.g., the ability to obtain complex, correctly folded, and posttranslationally modified proteins [50]. They compete favorably with mammalian cells for the production of vaccines and antibodies because of distinct advantages over conventional systems including cost, safety, and scalability [57]. However, the cost of downstream processing (protein extraction, protein recovery, and protein purification) for recombinant expression systems in general are approximately the same and can represent over 80% of the overall processing costs [30] with the majority of such costs attributed to chromatography and associated materials, labor, and capital equipment [57]. Savings in the upstream components (no need for expensive fermenters, special culture media, and skilled workers) are some of the major benefits for the production of pharmaceutical proteins in plants. Costs of goods sold (COGS) from mammalian cell culture are estimated to be $300 per gram therapeutic protein, whereas the raw material costs for 1 g recombinant protein from plants are in the order of $0.10–$1 (depending on the expression level; [33]). The main technical bottleneck limiting the commercial production of pharmaceuticals in plants is the high cost and inefficiency of downstream processing including purification [34].

One-third of the approved biopharmaceuticals are glycoproteins [56] and the activity of antibodies, blood factors, and interferons is dependent on their glycosylation pattern. Accordingly, biopharmaceuticals are often produced in heterologous expression systems with glycosylation capabilities. Plant-specific glycosylation differs from mammalian glycosylation (for review see [26]) and this aspect explains the major limitation for the use of plant-made pharmaceuticals in therapy. Recently, progress toward the humanization of protein N-glycosylation in plant cells has been made, which focused on the targeted expression of therapeutic proteins, the knock-out of plant-specific N-glycan-processing genes, and/or the introduction of the enzymatic machinery catalyzing the synthesis, transport, and addition of mammalian sugar residues (for review see [27]).

With the development of "edible" vaccines, which can be orally administered in the form of a transgenic fruit or vegetable expressing the appropriate antigen without any prior processing, low-cost production systems and effective delivery systems are expected [40]. One of the easiest ways to get vaccinated against a disease might be eating a bite of banana, full of the virus proteins, as it was contemplated by researchers at the Boyce Thompson Institute for Plant Research at Cornell University in 1997 [25]. In reality, this anticipated development did not occur. Major problems of this technology are low yields, weak antigenicity of plant-produced vaccines and the lack of buy-in by governments and pharmaceutical companies [43].

In this chapter, the historical development of plant-produced vaccines and antibodies, so-called plantibodies, and the development of different stable plant production systems including down-stream processing with a specific focus on the progress of animal therapeutics will be discussed.

Plant-Based Expression Systems

Since the first report of plant-based antibody production [32], different formats have been generated ranging from single variable heavy-chain domain (VHH) antibodies [4] and single-chain molecules (scFvs; [3, 23]) to Fab fragments [10], and complete immunoglobulins [35]. Despite substantial progress in the production of antibodies in plants for human health (for review see [9]), their application to the veterinary field is rather limited (for review see [18]). The development of passive immunization commenced in 1890 with the identification of serum therapy by Emil Behring and Shibasaburo Kitasato. They identified substances in the blood they called antibodies which were responsible for the immunity against diphtheria and tetanus toxins. Furthermore, the researchers were able to transfer immunity to immunologically naïve animals by injecting serum of animals treated with nonlethal doses of a crude toxin preparation [2]. At the same time, Paul Ehrlich discovered that antibodies can act as so-called magic bullets for the targeting of cancer cells [12]. A century later, the structures of antibodies and the sequences coding for the immunoglobulin chains were elucidated and mouse hybridomas provided highly specific monoclonal antibodies for therapeutic

applications [36]. The development of innovative recombinant DNA technologies greatly enhanced the clinical efficiency and safety of mouse-derived monoclonal antibodies. The ability to generate large antibody libraries, and the simplified antibody backbone of a single-chain antibody made antibody phage display a powerful tool for the development of new therapeutic agents (for reviews see [3]).

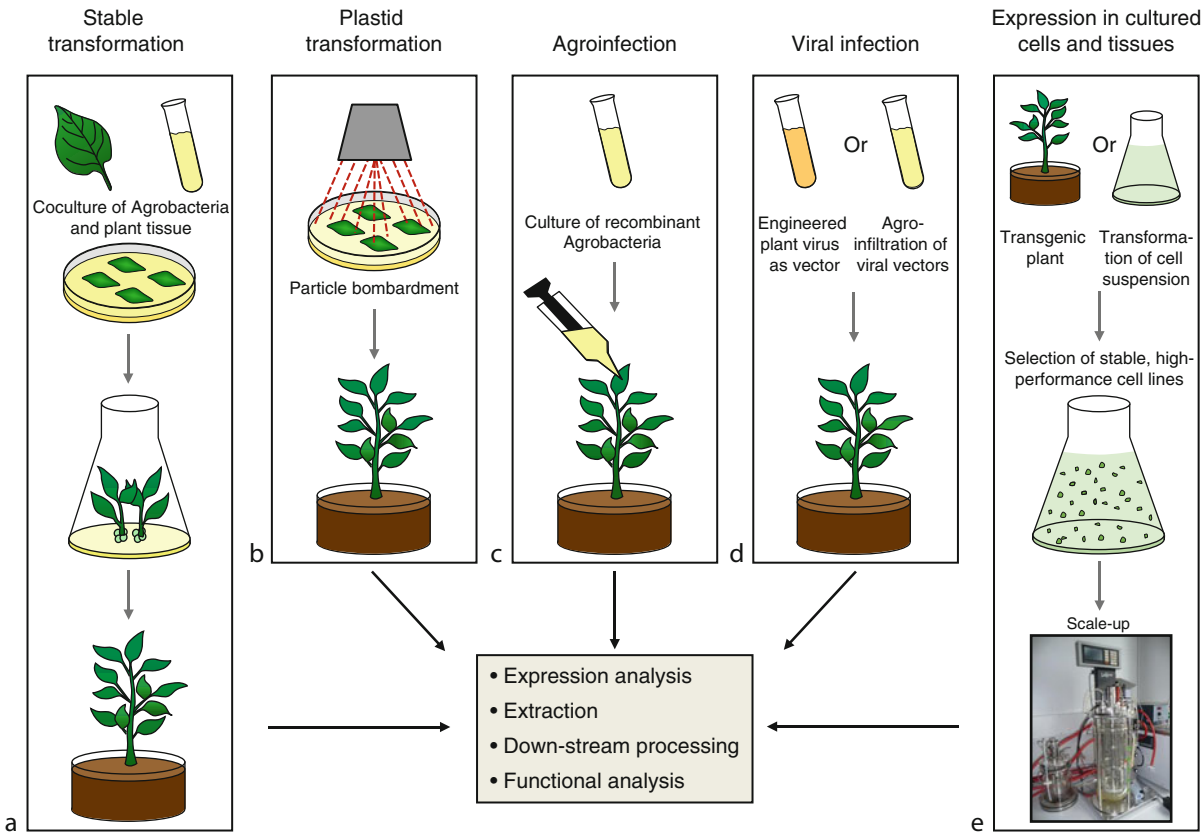
Production shortfalls and high costs are major incentives for further development of alternative antibody production technologies with a focus on active immunization (vaccination). The defining event for the development of "vaccinology" (from the Latin "vacca," meaning cow) dates back more than 200 years. At that time the smallpox vaccine was discovered by Edward Jenner. He inoculated humans with a less virulent, but antigenic related, Cowpox Virus to confer protection against the related human Smallpox Virus. Criteria for the development of veterinary vaccines are different depending on the particular target animals (for review see [38]). Health and welfare of the individual animal are the primary concerns for companion animal vaccines and thus are comparable to those for humans. In contrast, livestock animal vaccines should be inexpensive, prevent, and control infectious diseases of animals used as food to reduce or eliminate health risks to consumers. In some cases, these vaccines are further used to improve the productivity of livestock. To combat zoonotic diseases which are transmittable to humans, e.g., rabies, vaccination of wildlife animals is the method of choice. Furthermore, veterinary vaccines have a significant impact on public health due to the reduction in the administration of veterinary pharmaceuticals such as hormones.

The pioneering work for the expression of vaccines in plants was described in a patent by Curtiss and Cardineau in 1990. They reported the production of the *Streptococcus mutans* surface protein antigen A (SpaA) in transgenic tobacco plants [6]. Subsequently, Mason and co-workers succeeded in expressing the hepatitis B surface antigen in tobacco [37]. In 1993, Usha and co-workers expressed a peptide representing an epitope of the VP1 envelope protein of the Foot-and-Mouth-Disease Virus (FMDV) on the surface of a plant virus particle [55]. This study was the first report of a plant-derived veterinary vaccine. Following this pioneering work, various veterinary candidate vaccines have been produced in a variety of plant species using different expression systems, and they have proven to elicit humoral and mucosal immune responses against toxins, viruses, bacteria, and parasitic pathogens (for reviews see [18, 29, 44, 52, 57]). There are still no plant-derived veterinary vaccines on the market; however, one major step was made at the beginning of 2006 by Dow AgroSciences (DAS, Indianapolis, USA). Their plant cell–expressed vaccine against the Newcastle Disease Virus (NDV), produced in a suspension-cultured tobacco cell line, has gained regulatory approval by the US Department of Agriculture (USDA) Center for Veterinary Biologics – the final authority for veterinary vaccines in the USA [48]. Regrettably, this vaccine has not been introduced to the market. Dow AgroSciences apparently wished to demonstrate that their Concert^{TM} Plant-Cell-Produced system was useful for the production of safe and effective vaccines, fulfilling the approval requirements of the regulatory system [43]. A year prior to the approval of the DAS vaccine, a plant-made scFv, used in the production of a recombinant Hepatitis B Virus (HBV) vaccine in Cuba [41], progressed through the regulatory system and was commercialized. These are the two plant-produced vaccine-related products which have gone through the production and regulatory hurdles, despite nearly 20 years of plant-derived vaccines [43].

Four plant-based expression systems have been developed thus far (Fig. 1):

- Expression in stably transformed transgenic plants including tissue-specific expression (e.g., in seeds or tubers)
- Expression in transplastomic plants
- Transient expression in tobacco leaves (*Nicotiana tabacum, N. benthamiana*) using either plant viruses, *Agrobacterium tumefaciens*, or both to facilitate high accumulation of vaccines and/or antibodies
- Expression in cultured plant cells and tissues, and lower plants including duck weed and mosses

The first plant virus system used was a recombinant Tobacco Mosaic Virus (TMV) where the capsid protein was fused to a malarial epitope [53] followed by others (for review see [43, 57]). "Agro-infection" has been developed as a versatile tool for a rapid production of vaccines and antibodies in transiently



Plant Molecular Pharming, Veterinary Applications. Figure 1

Plant-based expression systems for pharmaceutical proteins. (**a**) Transgenic plants derived by stable transformation, either using *Agrobacterium*-mediated gene transfer [54] or biolistic transformation [1], represent a stable and cheap source for the large-scale production of recombinant proteins. The transgene is genetically fixed and transferred into the next generation. However, the development as well as the selection of a stable transgenic line can take many months. Recombinant proteins may be expressed in the cytoplasm or be localized in other cellular compartments (nucleus, mitochondria, chloroplasts, vacuole, endoplasmic reticulum, or apoplast), or can be produced in different plant tissues (leaves, seeds). (**b**) Transplastomic plants obtained by using particle bombardment often have high yields of the recombinant proteins. However, the system is often not suitable for glycosylated or secreted proteins but this barrier may be overcome soon [27]. (**c**) *Agrobacterium tumefaciens*–mediated transient expression is the standard method for determining if a transgene is expressed *in planta*. Here, a suspension of bacteria is directly injected into the intercellular space of plant leaves either by using a syringe or vacuum. (**d**) Viral vectors can be used for the expression of foreign proteins or of chimeric coat proteins in plants. Two different methods can be used for the delivery of the viral genomes into the plant, either engineered plant viruses (e.g., Tobacco Mosaic Virus) or recombinant Agrobacteria. (**e**) The application of plant cell culture for the production of recombinant proteins is focused on a small number of cell lines, e.g., the tobacco line Bright Yellow-2 (BY-2). Furthermore, transgenic cell lines can be established either from a transgenic plant or by the transformation of cell suspensions either by Agrobacteria or particle bombardment. After selection of stable, high-performance cell lines, the recombinant proteins can be produced in bioreactors under "good manufacturing practice" (GMP)

expressing plant tissues, especially tobacco leaves [15, 16]. Simultaneously, a large number of expression constructs could be tested. This method can easily be scaled up by using vacuum-mediated "Agro-infiltration." Lomonossoff and co-workers positioned a gene of interest (GOI) between the 5' leader sequence and 3' untranslated region (UTR) of RNA-2, thereby emulating a presumably stable mRNA for efficient translation. High-level expression could also be achieved in the absence of RNA-1-derived replication functions using *Agrobacterium*-mediated transient expression. Deletion of an in-frame start codon upstream of the main translation initiation site led to a massive increase in foreign protein accumulation (10–20% of total extractable protein; [47]). The magnICON® system (MagniFection) developed by Icon Genetics (Halle, Germany; now a part of Bayer Innovation GmbH, Düsseldorf, Germany) combined significant mRNA expression enhancement by a TMV-based transient expression vector with systemic delivery based on "Agro-infiltration" [24]. A recent press release announced that Bayer started clinical Phase I study with personalized vaccines from tobacco plants, produced with the magnICON® system, for treatment of non-Hodgkin's lymphoma (http://www.icongenetics.com/html/5954.htm). Stable transformants have been widely used to express antibodies (for review see [9]) and vaccines (for review see [52]) in transgenic plants. The expression of recombinant proteins in storage organs such as seeds [13] resulted in functional and stable products that could be stored at room temperature for extended times without significant loss in amount and activity [51]. Stable expression in dicotyledonous seeds could be significantly boosted by specific regulatory sequences as demonstrated for scFvs [8]. Seed tissues therefore represent a very attractive target for production and extraction of pharmaceutical proteins commercially.

In addition to the expression of recombinant proteins in cultured *Nicotiana* cells (for reviews see [14, 31]), expression in duck weed (*Lemna minor*) and in moss bioreactors are alternative interesting systems providing containment during production. The duck weed system [5] and the moss bioreactors (for review see [11]) provide the possibility of glycan optimization as well. Transgenes could also be targeted to the chloroplast, ensuring that they are embedded in a chloroplast DNA homology region. The number of transgene copies after establishment of homoplasmy was shown to be very high leading to increased expression levels [7]. Epigenetic phenomena (e.g., transgene silencing) are apparently absent in chloroplasts, therefore these plant organelles offer ideal prerequisites for the production of functional vaccine antigens. Moreover, chloroplast DNA is absent in pollen, and thus limits the potential for outcrossing. Unfortunately, chloroplasts lack major post-translational modification machineries such as glycosylation (for review see [57]), and accordingly their utility is limited to molecules which do not require glycosylation.

Edible Vaccines and Purification

The basic idea of edible vaccines was to feed animals with genetically engineered grain directly bypassing purification and complicated and expensive downstream processing.

However, this simple approach has been replaced by plant-derived vaccines because of two main reasons. Firstly, the expression level of the antigen in harvestable parts from the same plant can vary substantially. Secondly, a complete segregation of plants for pharmaceutical or veterinary applications from those meant for human or animal consumption is required [52]. However, another interesting approach making use of high-level expression of recombinant antibodies in legume seeds, e.g., peas [45], was the feeding of neutralizing recombinant antibodies against enterotoxic *Escherichia coli* strains to piglets. These antibodies were sufficiently active in the intestine of the fed animals [28, 46]. A similar approach has been applied for recombinant antibodies against gastrointestinal parasites of chickens, which were expressed in peas [58].

Oral administration is not always the major route for all plant-derived vaccines. In some cases purified antigens are required for injection necessitating the development of specific purification procedures for each product. Two main challenges have to be overcome when purifying proteins from plant material: (1) impurities (proteins, carbohydrates, oils, phenolic compounds, phytic acids, nucleic acids, and other trace products) associated with each plant system must be removed, and (2) low concentrations of the target protein following initial extraction into an aqueous medium have to be avoided. Therefore,

special downstream separation units are required to handle large volumes [39]. Specific methods have to be developed to achieve high amounts of vaccines and/or antibodies in a correctly folded and functional form. The successful development of such methods is also dependent on rather high and stable accumulation of the transgenic proteins *in planta*. Here, fusion to elastin-like polypeptides (ELPs) allows both easy and scalable purification as well as enhancement of the accumulation of the recombinant ELP fusion protein. Elastin-like polypeptides are highly biocompatible proteins. They exhibit the useful property of a thermally responsive reversible phase transition. These characteristics improve the efficiency with which recombinant proteins can be purified. ELP fusion proteins also exhibit reversible phase transition property. This new technology, named "ELPylation," has recently been extended to plant cells and several plant-based expression systems have been evaluated for the production of ELPylated proteins (for review see [22]). The approach has been applied to vaccines [19], complete immunoglobulins [17, 20, 21], and antibody derivatives, scFv [49], as well as VHH [4]. For veterinary purposes, where economical features such as low price and easy-to-handle products are major factors of commercial viability, "ELPylation" is a useful component of enrichment and purification strategies.

Future Directions

Over the past years, plant-based production of recombinant proteins has been developed and 11 plant-derived non-pharmaceutical proteins (avidin, trypsin, β-glucuronidase, aprotinin, lactoferrin, lysozyme, thyroid-stimulating hormone receptor, Hantaan and Puumala viral antigens, peroxidase, laccase, and cellulase) have been brought to the market [52] indicating a huge capability of these expression technologies for the production of diagnostic and therapeutic proteins for both human and veterinary medicine. Six years after the commercialization of the first plant-derived recombinant protein, TrypZean, from corn (ProdiGene, USA), only two plant-derived compounds are in late-stage clinical trials: Interferon α-2b made in aquaculture (*Lemna* expression system, LEX system) for the treatment of hepatitis C infections (Biolex Therapeutics, Pittsboro, USA) and taligurase alfa, a form of the enzyme glucocerebrosidase known as prGCD in development for treatment of Gaucher's disease from Protalix Biotherapeutics (Carmiel, Israel). Recently, Pfizer acquired rights to prGCD produced in carrot cells and became the first big pharma company to commit itself to take to the market a biologic plant-produced drug [42].

In view of the new influenza A H1N1 pandemic, plant-based expression systems represent the fastest production for any influenza vaccine as it was demonstrated by two research groups – at Medicago Inc. (Québec, Canada) and at the Fraunhofer Institute (Plymouth, USA) – via the transient expression of the H1 HA protein in tobacco plants [43]. These results underline the advantages of plant-based expression technologies over traditional expression technologies for the production of antigens. This should be essentially true for veterinary purposes, where costs should be generally lower fitting into economical parameters of animal-based food production. Here, the "old" concept of edible vaccines could be verified much easier, because seeds could be used as a source that is an essential and common component of the feed, which do not need to be treated at harsh conditions as baking or cooking. Farm animals grown in high numbers in confined conditions are a suitable target for future attempts to produce veterinary pharmaceuticals using plant-based expression systems. Nevertheless, further improvement of expression levels and development of easy and cheap downstream processes are still needed before decisions about economic viability of transgenic plant-based pharmaceuticals for animal health could be made.

Acknowledgments

The authors thank Stefan Rose-John and Paul Christou for a critical review of the manuscript.

Polyculture in Aquaculture

Robert R. Stickney
Texas Sea Grant College Program, Texas A&M University, College Station, TX, USA

Article Outline

Glossary

Benthos Organisms that live on or in the sediments in aquatic environments.

Niche A habitat that provides for the needs to support the life or an organism.

Plankton The community of plants and animals suspended in the water column that drift with the currents. They have limited or no swimming ability but may be able to move vertically.

Phytoplankton The plant component of the plankton community.

Zooplankton The animal component of the plankton community.

Definition of Polyculture

Polyculture is the production of two or more cultured species in the same physical space at the same time, often with the objective of producing multiple products that have economic value. They may be a combination of animals, plants and animals, aquatic species only, or aquatic and terrestrial species.

Introduction

Aquaculture has its roots in China, perhaps as long as 4,000 years ago [1]. Interestingly, polyculture was a part of that early history. The Chinese often stocked multiple species of carp together in ponds to take advantage of all the types of food available. The pond would be fertilized, often with terrestrial animal manure, to promote the growth of the food organisms. In addition, terrestrial vegetation might be added. Thus, each of the species stocked occupied its own ecological niche.

Another form of polyculture that has a long history is rice–fish culture. By modifying rice ponds to provide a refuge for fish when a rice paddy is dewatered (usually a trench down one side or in the middle of the paddy), the rice farmer can obtain two types of crops. The most common fishes employed in rice–fish farming are common carp (*Cyprinus carpio*) and tilapia (*Oreochromis* sp.).

Today, polyculture employs a much wider variety of species than those that have been used for millennia in China, and there have been nuances developed in the polyculture approach. In most cases, the species used in polyculture systems need to be compatible, that is, they need to grow well without interfering with one another. One example is culturing freshwater shrimp (*Macrobrachium rosenbergii*) with tilapia [2]. Exceptions do occur. For example, a predatory species may be stocked to prey on unwanted offspring of the primary culture species. A good example is tilapia culture, where stocked fingerlings may become reproductively active well in advance of reaching desirable market size. A fish predator, such as the snakehead (*Channa* sp.), can be stocked at a size too small to consume the tilapia that are in the system for growout, but large enough to prey upon unwanted tilapia fry.

In marine cage culture, fouling by such organisms as bryozoans and barnacles is often a serious problem. Netting may become so fouled that circulation through the cage is reduced to the point that dissolved oxygen depletions can occur. Depending upon the location of the cage culture operation, such fouling can occur within several days to a few weeks, so frequent cleaning is required. If an animal that will consume the fouling organisms can be found and stocked in the cages, it may be possible to extend the time between manual cleanings. There have also been instances where fish have been stocked in marine cages to consume parasites. One example is the stocking of wrasse (family Labridae) to control sea lice in Atlantic salmon cages in Norway [3]. Another is stocking sea cucumbers (class Holothuroidea) in salmon net pens to feed on fish feces, fouling organisms, and unconsumed feed [4].

Polyculture is primarily used to enhance total production within an aquaculture facility while maintaining and, in many cases, enhancing water quality. Mussels grown in the vicinity of salmon net pens, for example, remove phytoplankton that take up nutrients associated with the degradation of fish feces and unconsumed feed. Adding a seaweed, such as kelp (order Laminariales), to the system can further reduce the levels of dissolved nitrogen and phosphorus in the water. Polyculture of fish, shellfish, and algae together is an example of integrated multitrophic aquaculture [5]. While Atlantic salmon (*Salmo salar*) is the most common fish cultured using the technique, it has also been used with rabbitfish (*Siganus* sp.) [6].

Another specialized case of polyculture is hydroponics (sometimes called aquaponics), wherein terrestrial plants are grown in a nutrient solution rather than being planted in soil. Hydroponics is usually conducted in greenhouses. The water for the terrestrial plants, which are often a combination of vegetables and/or herbs, is fertilized to provide all the proper nutrients for rapid growth and, of course, provided with sufficient natural or artificial light for photosynthesis. In many cases, one or more aquatic species (fish or shellfish) are incorporated into the system.

Many nations culture fish in ponds that receive avian, livestock, or even human waste as fertilizer. The practice is particularly common in developing countries where inorganic fertilizer is expensive and often difficult to obtain. Common carp and tilapia are often grown in ponds that receive the waste from the terrestrial animals.

Key Principles

Polyculture is a Technique that Produces Two or More Compatible Species Within the Same Culture System

Not every species in a polyculture system needs to be aquatic in nature. Combinations of terrestrial and aquatic species are common. One or more of the species in a polyculture system may be a terrestrial or an aquatic plant.

Polyculture Systems can Increase the Profitability of a Culture System

By culturing two or more marketable species together in the same culture system or in close proximity to one another, it is often possible to increase the amount of income generated by a producer. While it may not be economically possible to rear one of the species profitably alone, by polyculturing it with a high-value species, total revenue can be increased. An example is culturing seaweed that is a good source of agar or carrageenan and that could add value to a culture facility if grown in the vicinity of a higher value crop like salmon [7].

Polyculture Systems can Reduce the Environmental Impacts from Aquaculture Systems

Nutrients released from cultured fish and shellfish-culture facilities can be effectively removed from the water by culturing plants such as seaweeds in close proximity to the animals [7]. An alternative approach would involve the nutrients from such species as fish or shrimp to support phytoplankton that could, in turn, provide a food source for filter feeding Mollusca, such as oysters, scallops, and mussels [5].

Polyculture Successes

As mentioned, polyculture was developed 1000s of years ago [1] and must be considered successful without question since it is still being employed, not only in China, but also in many other countries. The objective of the Chinese system is to stock species that take advantage of the various available food sources in culture ponds. Silver carp (*Hypophthalmichthys molitrix*) consume phytoplankton, bighead carp (*Hypophthalmichthys nobilis*) graze on zooplankton, mud carp (*Cirrhinus molitorella*) feed primarily on detritus, black carp (*Mylopharyngodon piceus*) are mollusc eaters, while grass carp (*Ctenopharyngodon idella*) consume higher vegetation. Grass carp will eat some species of aquatic macrophytes and will also consume various types of terrestrial plants that may be added to the culture pond. Other species that are used in carp polyculture systems are common carp (*Cyprinus carpio*) and tilapia (*Oreochromis* spp.). There are a wide variety of fish, shellfish, and plants that are used in polyculture around the world. In many cases, they are local species, though introduced species are also commonly found – in many cases those were introduced decades ago, such as is the case with tilapia in Asia and the Americas.

Integrated multi-trophic aquaculture systems have a relatively short history, but appear to be highly effective and are a modern approach to polyculture that is being increasingly adopted. Thus, that approach can also be considered a success. The approach typically involves the co-culture of carnivorous species, such as finfish or shrimp, with a filter feeder and a primary producer, typically some kind of algae [8, 9].

Hydroponics can be considered a success, in that the approach can be used to produce a variety of vegetables and other types of plants. While capital intensive, hydroponic systems can be profitable. Various species of aquatic animals have been grown in such systems to provide nutrients that the plants can use and also to produce an additional marketable product. The aquatic animals cannot be counted upon as the only or even the primary nutrient source for the plants, however. The nutrient levels in the aquatic-animal waste products are insufficient in volume and composition, so a nutrient broth needs to be provided.

Future Directions

Biofloc aquaculture is an approach that has been around since the 1970s, but has as yet to be widely adopted. In biofloc systems, the development of high levels of nonpathogenic bacteria in the water is encouraged. Heavy aeration is required to maintain the dissolved oxygen level for the culture species, which is most commonly shrimp, though such systems have also been used in conjunction with tilapia and other fishes. As more experience and research has occurred over the years, the methods for developing and controlling water quality in such systems have advanced. In 2009, one research group was able to produce shrimp at a final density of 9.75 kg/m^3, which is as much as ten times higher than what is typical [10]. It is likely that the approach will be more widely adopted in the future.

Open-ocean aquaculture is expanding rapidly around much of the globe. In the USA, marine aquaculture is largely confined to production of molluscs in coastal waters and salmon cage and net pen culture in protected waters. Once a regulatory framework for the United States Exclusive Economic Zone has been promulgated, there is a likelihood that offshore aquaculture facilities will be developed. It seems reasonable to assume that a polyculture approach similar to the one that is commonly seen with respect to salmon culture, particularly in Chile, will be employed in conjunction with offshore aquaculture as a means of helping prevent water-quality degradation and increasing profitability. Offshore polyculture may involve rearing molluscs suspended from platforms used as support facilities for sea-cage culture operations. Such support structures may provide housing for the culturists, feed, and equipment storage, and may also be used as hatcheries (oil and gas platforms being appropriate once they are out of production and which have been of interest to some prospective aquaculturists). Seaweeds could also be produced, so an offshore operation might employ the multitrophic approach to culture.

Poultry Breeding

Yoav Eitan, Morris Soller
Department of Genetics, The Silberman Life Sciences Institute, The Hebrew University of Jerusalem, Jerusalem, Israel

Article Outline

Glossary

Breeding value The deviation of trait value of an individual from the overall population mean that is due to genetic factors and hence can be transmitted to the progeny.

Breeding nuclei The closed and pedigreed flocks at the top of the breeding pyramid within which selection is practiced and from which genetic gains are disseminated to the commercial populations.

Feed conversion ratio The weight of food in kg required to produce 1 kg of body weight to market.

Fitness The ability of the animal to reproduce and survive.

Functional traits Traits that contribute to fitness, e.g., reproductive performance, resistance to pathogens and toxins.

Genetic variation Variation in trait expression that is due to variation in structure of the genetic material.

Heritability The proportion of total variation in trait expression that is due to genetic variation.

Index selection Selection based on combination of estimated breeding value of an individual for a number of production and functional traits weighted according to economic importance and genetic correlations to other traits.

Mass selection Selection based on the performance of the individual itself, without consideration of performance of close relatives.

Metabolic heat and water Heat and water produced as a by-product of body metabolism.

Pleiotropic effects Effects of an individual genetic locus on multiple traits.

Primary breeders The commercial organizations that maintain and improve breeding nuclei.

Production traits Traits that contribute directly to production of the animal product that reaches the consumer, e.g., JWfA, FCR, and PBM.

Secondary effect An unintended effect of selection for one trait on some other trait.

Definition of the Subject

Animal breeding today stands on the verge of a methodological revolution that may greatly increase the rate of genetic improvement in production traits. This will modify the physiology of the animals and the genetic architecture of the population at an unprecedented rate. What will be the broader consequences of such extreme modification? What pitfalls and dangers may be encountered as this process unfolds? Beginning about 60 years ago, the broiler chicken has been subject to intense and effective selection for juvenile growth rate (60 generations), feed conversion ratio (40 generations), and body composition (20 generations). This entry describes the ways in which the production and functional traits of the individual bird and

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

Originally published in
Robert A. Meyers (ed.) Encyclopedia of Sustainability Science and Technology, © 2012, DOI 10.1007/978-1-4419-0851-3

accompanying management practices have responded to this unremitting selection, with the objective of suggesting what the future might hold for other agricultural animal species as they enter this new stage of intense and highly effective selection for production traits.

Introduction: Animal Breeding in Transition

Animal breeding today stands in the midst of a methodological revolution based on the availability of microarrays that are capable of genotyping tens and hundreds of thousands of polymorphic markers in a single run, and of low-cost whole genome sequencing that will enable the leading animals in the population to be fully sequenced [1–3]. This has enabled development of deoxyribonucleic acid (DNA)-level diagnostic procedures for highly accurate evaluation of breeding values for production and functional traits. Since DNA can be obtained readily from all animals from birth (and even before) these procedures allow highly effective and intense selection to be implemented at an early age with very high accuracy, and with equal efficiency in males and females; encompassing sex, age, or phenotype-limited characters such as milk and egg production, longevity, and disease resistance. The result will be a quantum leap in the rate of genetic improvement in production traits with consequent far-reaching modification of body development and physiology.

What will be the effects of such intense and effective selection applied to production traits on overall animal performance and capacities? How will management practices and requirements adapt to these changes? The modern broiler chicken, under selection for production traits for over 60 chicken-generations [4] provides an intimation of what to expect [5–9]. The main broiler production traits such as juvenile growth rate, feed conversion ratio, and body composition come to expression in the juvenile bird, are expressed equally in males and females, and have moderate heritabilities, thus enabling highly effective mass selection based on individual phenotype. Introduction of advanced biometrical methods of selection such as Best Linear Unbiased Predictor (BLUP) and Individual Animal Model has made this phenotype-based selection even more effective. Because of the high fecundity of the female chicken, selection for broiler production traits has been intense, and the response to selection has been enormous, converting the broiler chicken from an expensive luxury to a low-cost major meat supplier for the growing human population worldwide [10]. The historical response of the broiler chicken and its management to this selection, models what can be expected from the application of intense and highly effective selection for production traits to other populations of agricultural animals.

Brief History of Broiler Breeding and Broiler Production

The First Commercial Incubator

Keeping a small number of chickens was always a part of the family farm and rural urban household. These were raised primarily for home egg consumption and minor income from sale of surplus eggs and meat. Until the invention of the first commercial incubator in 1875, replacement chicks had to be hatched by the hens, so that each farm reared its own replacements. With the availability of commercial incubators, specialized breeding farms and hatcheries came into being to supply high-quality chicks to the family farms. Prior to the development of vent sexing by the Japanese in the 1930s, and of sex-linked feather sexing in the 1960s, it was not possible to distinguish male and female chicks by gender until they were a few weeks of age. Consequently, when rearing chicks for egg production, all chicks had to be reared to the age of a month or more when cockerels could be recognized. Having invested this much in the cockerels, it was economically rewarding to rear them to market weight. Thus, each year with the renewal of layer flocks by chicks hatched in the early spring, cockerels for sale provided an important secondary income stream. At this time, therefore, chicken meat was a rather rare and costly commodity generally available only in the spring coincident with layer flock renewal. However, recognizing the potential for additional economic return, some farms began raising an extra hatch of chicks in the summer months for sale as meat birds.

Salmonella pullorum Free Flocks, Vitamin D

Large flocks dedicated to poultry meat production as a main source of farm income do not seem to have become widespread until the 1920s, primarily because of high chick mortality due to *Salmonella pullorum*

when large numbers of chicks were reared together. In the early 1920s, a test was developed to identify birds carrying the pathogen, enabling breeders to develop *S. pullorum* free flocks that supplied *S. pullorum*-free chicks. Also about this time (1926), it was found that adding vitamin D to the chick diet in the form of cod liver oil could prevent the development of Rickets in winter broilers. Until then, lack of sunshine had prevented rearing of winter broilers in the Northern states. These two developments made it possible to establish a year round broiler industry [11].

Cornish Breed Males, the "Chicken of Tomorrow Contests," Chick "Sexing"

Growth of the broiler industry was rather slow, and chicken meat remained an expensive specialty item because of the necessity for hand plucking of the feathers. In 1940 the first commercial feather plucker was invented, enabling plucking, evisceration, and packing of broiler carcasses on the same production line. This opened the way to development of a dedicated broiler industry. The use of Cornish breed males to cross with dual-purpose females to produce broiler chicks with higher proportion of breast meat (PBM) was introduced in the 1930s, and by 1942 almost all commercial broiler chicks were crossbreds of "Cornish" males to females of one of the dual-purpose breeds (White Rock, New Hampshire or Barred Rock). In the 1940s, some of the leading White Rock breeders began to develop a bird with high juvenile growth rate specifically for broiler production, while the colored stocks were still bred for the dual-purpose market. From 1946 to 1951, the A&P supermarket chain sponsored a series of "Chicken of Tomorrow" contests [12] in which chicks of leading breeders were reared to 12 weeks of age and compared. By the third of these contests it was clear that the White Rock female, specifically bred for broiler production crossed to Cornish type male was the leading broiler chicken, widely preferred to crosses to dual-purpose colored females. In addition to superior growth rate, the White Rock crosses also gave a clean attractive plucked carcass, in contrast to the unsightly dark-colored pinfeathers remaining on the plucked carcass of the dark-feathered birds.

Thus, by 1952 all the components of the modern broiler chicken were in place. In this year for the first time, specially bred broilers surpassed surplus farm cockerels of the layer flocks as the main source of chicken meat in the USA. With the advent of specialized broiler lines, it was no longer economical to rear layer strain cockerels for meat, as the cockerel of the layer lines, even of dual-purpose breeds, could not achieve the economic returns of the specialized broiler lines. Vent and later feather sexing enabled the male chicks of the layer flocks to be identified at hatch, so that there was no economic incentive to rear these chicks. As a direct consequence, the poultry breeding industry was able to separate into the distinct and completely independent layer and broiler components found today, and intensive broiler breeding focused on the traits of importance for low-cost broiler production commenced in earnest.

Roadmap of the Entry

Broiler breeding experienced three stages with respect to the production traits that were the primary selection objectives. In the first stage, the primary production objective was rapid juvenile growth rate, with some attention to breast conformation. In the second stage, increasing attention was paid to feed conversion ratio in addition to juvenile growth rate [13]. In the third stage, continuing to the present time, increasing the proportion of breast meat in the carcass was added as a third major production goal. At all stages except the very first, good reproductive performance of the female line and fertility of the male line were strong secondary selection objectives. The need to maintain female reproductive performance led in the 1970s to the introduction of crosses between independent White Rock female lines to provide a heterotic lift to performance. Thus, the typical commercial broiler chick today is the product of a three-way cross: A pair of purebred "female lines, of dual-purpose White Rock origin," is crossed to produce the female parent, and this in turn is crossed to males of a purebred "male line of Cornish breed origin" to produce the commercial chick. With the passage of time, selection for health and welfare traits that were negatively affected by the intense selection for production traits has become an increasingly important component of the broiler selection programs.

Each of these three major stages in genetic development of the modern broiler will be considered in turn, describing first the achievements in terms of the

primary production goals, followed by a description of the associated secondary genetic effects on reproductive performance (hatchability and egg numbers) and health (with emphasis on leg and metabolic disorders), and of the management modifications needed to accommodate both the primary genetic effects and their secondary consequences. A common feature of the secondary consequences was inability to predict them in prospect, but ability to explain their appearance in retrospect as a plausible consequence of the changes in primary traits. This will be followed by an overall evaluation of the relative contributions of the breeder and of management to performance of the modern broiler, and a review of possible sources of the genetic variation that has enabled the continuous long-term response to selection for the three major production traits. Welfare issues raised by the genetic and management changes will be addressed, and a framework presented for interpreting the accompanying genetic and management changes in terms of a "resource allocation" model.

Stage 1: Selection for Juvenile Weight for Age (JWfA)

Importance of Juvenile Weight for Age

A day-old chick of one of the dual-purpose breeds that served as the founders for broiler development, typically required up to 90–120 days to reach market weight [4]. This long grow-out period resulted in high feed, labor, veterinary, and capital costs per chick and increased losses by mishap or disease. The number of days to reach market weight is primarily determined by juvenile growth rate – birds growing more rapidly reach market weight earlier. Consequently, increasing juvenile growth rate was the first objective in the development of the modern broiler. The heaviest birds at any given age are obviously the birds that would have reached target weight earliest, so that selection for "age to reach a given target weight" (age for weight) could be achieved by selection for the much more conveniently measured "weight at a given age" (weight for age).

Rapid and Powerful Response to Selection for JWfA

Juvenile weight for age (JWfA) turned out to be an ideal target for selection. The trait had high heritability, meaning that much of the variation in the trait was due to genetic factors. It was easily measured by simply weighing the birds at a given age. It came to expression at an early age equally in males and females. Due to the very high fecundity of hens, only a small proportion of the female chicks and an even smaller proportion of the male chicks produced by a hen had to be retained to renew the breeding population. Consequently, selection was very intense. The response to selection for JWfA was magnificent and continues to the present time yielding a decrease of 1 or 2 days in age for market weight per generation of selection [14] so that the modern broiler reaches market weight at about 35–40 days. This tremendous reduction in market age has reduced broiler-rearing costs in a corresponding manner, bringing chicken from a high-cost luxury food to the lowest-cost meat producer on the market [10]. It should be noted that even during this early period, attention was also paid to breast conformation of the broiler chick [6]. This was needed in order to produce a more attractive whole carcass with a less prominent keel bone on the supermarket shelf. Usually this was done by "touch," i.e., simply handling the birds already selected on JWfA and rejecting those with the sharpest keel bone.

Secondary Effects of Selection for JWfA (I): Excess Adiposity

The first secondary effect of the selection for JWfA, a marked increase in the adiposity of the commercial broiler at slaughter, was noted by the mid-1960s [6, 15]. This was unexpected, since deposition of a gram of fat is more than twice as costly in caloric terms as deposition of a gram of muscle. Thus, the heaviest birds would be expected to be those that had deposited the least fat. Consequently, selection for JWfA should have reduced the proportion of food intake devoted to fat stores, and in this way reduced the proportion of fat content of the carcass. The situation turned out to be more complex. Depositing body mass in a growing bird requires an excess of food intake over body maintenance requirements. Given unlimited access to feed, the magnitude of this excess is a function of appetite. Thus, JWfA is primarily a function of appetite and gross food intake. The birds with the highest intake put on the most weight. However, this high intake introduces a second

factor into the picture. Any excess of intake over maintenance in the juvenile is partitioned between lean body growth (muscle and internal organs) and fat stores. It turns out that the coefficient of partition is itself a function of the excess. When excess is small, almost all goes to build lean body mass (low fat:lean coefficient) but as the excess increases, a greater proportion goes to fat stores (higher fat:lean coefficient). Thus, the animals presenting highest JWfA are primarily those with the highest food intake but these also have the highest fat:lean coefficient, and hence show increased adiposity. The increase in carcass fat content made the carcass unsightly and unattractive to consumers. In addition, the abdominal fat-pad that was discarded in the slaughterhouse represented a waste of feed and was clearly reducing feed conversion ratio on a salable meat basis. This led in the early 1970s to various attempts to select directly against excess fat, e.g., by measuring skin thickness. These approaches were not successful, but control of fat content eventually came from an unexpected direction, as will be seen later.

Secondary Effect of Selection for JWfA (II): EODES in Broiler Breeder Females

A second secondary effect of the intense selection for JWfA was not long in coming and presented as the first of a series of metabolic disorders (see Box 1 for definition and explication) that have afflicted the broiler industry. The disorder manifested as a marked reduction in reproductive performance of the female broiler parent. Egg production dropped precipitously, from over 200 hatching eggs per hen to 120 and below, accompanied by a reduction in fertility and in the hatchability of fertilized eggs. Egg-laying pattern was erratic with many eggs laid outside of the usual time window, and there was a marked increased in double-yolked or otherwise defective eggs. The condition as a whole was termed "Erratic Oviposition Defective Egg Syndrome, EODES" [17]. An outstanding feature was the presence of multiple hierarchies of large yellow follicles in the ovary. The broiler industry was on the verge of collapse, when it was found that restricting (i.e., limiting) feed intake of the broiler pullet during her growth period could completely prevent the problem [18–20]. With this discovery, feed restriction became an essential part of broiler breeder

Box 1 Metabolic Disorders

Metabolism refers to all of the myriad chemical reactions taking place in the cells of a living organism that utilize the chemical and energetic content of ingested food to build and maintain normal body structure and function. These cellular chemical reactions are actively coordinated with one another across the body of the organism and also with the external environment through an intricate network of sensors and regulatory feedback loops so as to maintain life (i.e., stable body function). An outstanding feature of the metabolic system is the ability to actively adapt and modify body structure and function so as to maintain life even under challenging environments.

The metabolic system consists of many thousands of structural, functional, and regulatory components composed of protein or ribonucleic acid (RNA) molecules. All of these are constructed according to instructions coded in the hereditary material of the cell, i.e., its DNA. Mutations in DNA can change the structure or function of the components of the metabolic system. When this happens, the metabolic system may not be able to preserve normal function, and development terminates in the death of the embryo, or in birth of an individual defective in one or more aspects of normal structure and function. Metabolic derangements of this sort are termed "Metabolic Diseases," and there are many hundreds of different hereditary diseases that fall into this category.

Normal metabolism may also be disrupted when the diet does not include essential components that cannot be synthesized by the body but are needed to build the elements of the metabolic system, or conversely, when the diet contains various elements or compounds in toxic excess. Metabolic derangements of this sort are termed "Metabolic deficiency or toxicity disorders". Examples of broiler "Deficiency Disorders" are Rickets, resulting from Vitamin D or mineral deficiencies, and Crazy Chick Disease, resulting from Vitamin E deficiency. Examples of broiler "Toxicity Disorders" are Fluoride and Vanadium toxicity caused by phosphate contamination of feeds, or Selenium toxicity caused by feeding cereals grown on Selenium-rich soil.

The Metabolic Syndrome is a novel form of Metabolic Disorder, which has recently become very

prominent in human populations [16]. This is a constellation of pathologies that increase the risk of artherosclerotic vascular disease and Type II (late onset) diabetes. Risk factors for development of Metabolic Syndrome include obesity, psychosocial stress, sedentary lifestyle, and age. There are no identified genetic lesions, dietary deficiencies, or toxins. Thus, all elements of the metabolic system are present and at an individual level appear to be functioning normally. The central role of obesity in the etiology of the syndrome is of special interest. A moderate degree of adiposity is a normal part of body structure. The very high adiposity defining obesity is thus a normal body structure taken to extreme. Apparently, this excess alone unbalances the metabolic system and imposes a regulatory burden to maintain stable function. When the adiposity load is further exacerbated by the regulatory load imposed by psychosocial stress, sedentary life style, and age, the metabolic regulatory system is unable to cope and the pathologies characteristic of the Metabolic Syndrome emerge. This example indicates that whenever some body structure or function is brought to extreme development, this may impose an overload on the metabolic regulatory system resulting in manifestation of Metabolic Regulatory Disorders, with specific pathology depending on the type of overload.

management, both for males and females. With the passage of generations, it has been necessary to increase the degree of feed restriction from 70% of *ad libitum* initially to about 35% of *ad libitum* today. Since EODES is elicited by *ad libitum* feeding and prevented by restricting feed intake, it is plausible that the proximal cause of this disorder was the increased adiposity of the *ad libitum* fed broiler pullet at entry into lay. Excess adiposity is known to interfere with proper reproductive function in many species. The excess adiposity in turn is due at least in part to disruption of the normal homeostatic control over appetite as a consequence of which *ad libitum* fed female-line broiler pullets continue to eat to excess during the entire pullet rearing stage. The hypothalamic appetite control center may not be fully functional in broilers, since lesions of the hypothalamic appetite control center that lead to hyperphagia in layers, do not increase feed consumption in broilers [21].

The reduced fertility that accompanied the reduction in egg number apparently resulted in part at least, from impairment of male mating performance, perhaps due to sheer physical difficulty of the obese males and females to handle the mechanics of courting and mating or possibly due to hormonal effects on semen quality of the excess adipose tissue in the male. Feed restriction corrected the reduced fertility as well, so that under pullet and male feed restriction, egg production and fertility returned to high levels.

Secondary Effect of Selection for JWfA (III): Increase in Egg Weight and Hatchability Problems

A third secondary consequence of selection for JWfA was an overall increase in egg weight [14] particularly in older hens. The primary reason for this was the increase in mature size of the broiler female, even under feed restriction, as a direct consequence of selection for JWfA. In addition, there may have been indirect selection for large egg size, as a larger egg delivers a larger chick at hatch and higher final weight at market age. The increase in egg size had important effects on incubator management, deriving from the dual function of the incubator in embryo development. The small early stage embryo generates very little internal metabolic heat and must be warmed by the incubator, while the larger and rapidly growing later-stage embryo generates large amounts of metabolic heat and water, both of which must be removed by the incubator (see Box 2). Achieving these multiple goals requires careful control of incubator temperature, humidity, and ventilation (THV). Matters are complicated by the fact that even under the best conditions there is variation in the specific THV conditions at different points within the incubator due to variation in airflow over the eggs, and location of the egg with respect to incubator inlets and outlets. There is also variation in egg size and in shell conductance for water and heat. All of these contribute to variation in internal embryo temperature and water content among the population of eggs within the incubator at any given time. As a result, while most eggs will be comfortably within their optimum temperature and water content, others may lie close to outside limits for one or both of these factors.

Larger egg size impacts negatively on all of the multiple incubator functions. At the early embryo

Box 2 Incubator Management

During the early part of incubation, the embryo generates very little metabolic heat, and must be warmed by the incubator. But during the final week of incubation, the large and rapidly growing embryo generates large amounts of metabolic heat, and must be cooled by the incubator. Both objectives are achieved by setting the incubator air temperature at about 37.5°C. This is sufficient to warm the early embryos, and at the same time, with adequate air movement, will cool the later embryos. Thus, the same incubator (called a "multistage" incubator) was able to accommodate eggs in different stages of development, warming the early embryo eggs and simultaneously cooling the late-embryo eggs. In fact with the multistage incubator, the excess heat produced by the late embryos was used to warm the early embryos.

In addition to producing metabolic heat, the developing embryo also produces water and carbon dioxide. Both carbon dioxide and water escape through the eggshell. However, loss of water must be adjusted carefully. Loss of too much water will dehydrate the chorioallantoic membrane, interfering with importation of oxygen and exportation of metabolic waste, resulting in death of the embryo. It is equally important that the embryo lose more water than it generates (net loss of about 12% of egg weight from beginning to end of incubation). Otherwise, there will be insufficient air space formed for the chick to take its first breath and the chick itself will remain too large to move around inside the shell when trying to pip. In this case, the chick may be unable to break the membrane between itself and the shell, suffocating or drowning to death. Water loss by the embryo is adjusted primarily by adjusting the humidity of the incubation chamber; 50% humidity is close to optimal.

stages, the larger egg makes it more difficult to achieve optimal temperature throughout the egg mass. At the later embryo stages, the larger egg accommodates a larger embryo that generates more metabolic heat and water toward the end of embryonic development. At the same time, the surface/volume ratio of the larger egg is reduced making it more difficult for the embryo to dissipate excess metabolic heat and water [22]. Taken together with variability in TMV conditions within the incubator, and in size and shell conductance of the eggs, an increasing proportion of eggs find themselves outside of the optimal parameter range for development and hatching, yielding grade B chicks, and lower overall hatching proportions. This is exacerbated by the increased difference in egg size between young and old breeder hens that increases variability in egg size and shell conductance within the incubator when eggs of different-aged flocks are incubated together. Thus, as egg weight increased, incubators had to be equipped with more effective ventilation systems, and conditions had to be monitored more closely than in the past to ensure minimum variation and close adherence to optimal temperature and humidity throughout the incubator interior.

Secondary Effect of Selection for JWfA (IV): Skeletal Problems in Commercial Broiler

Initially, broiler chicks were allowed to free access to feed during daylight hours from the first day post-hatch, with the feed provided in the form of coarsely ground grain ("mash" type feed). However, by the 1970s as growth rate increased, the chicks were unable to consume the amounts of feed needed to meet their growth potential. This was solved by compressing and heating the mash to form pellets, enabling the bird to ingest more feed in a shorter time; and by extending hours of light to 23 h per day to provide more time for feeding. It was later found that equivalent results at lower electricity cost could be obtained by alternating 1–2 h of light with 2–4 h of dark ("intermittent light") with the added advantage of reducing energy expenditure for locomotor activity by the growing broiler. Obviously implementing a light-control program of this sort required a shift to light-controlled housing.

However, as chick growth rate increased, the skeleton could not develop rapidly enough to accommodate the large chick body, resulting in many skeletal and leg problems [13, 23, 24]. These include: infected hocks (from staphylococcus, coliform, or viral infections); twisted legs presenting as valgus distortion (knock-kneed: hocks in feet out) or varus distortion (bow-legged: hocks out, feet in); and tibial dyschondroplasia, in which failure of normal chondrolysis and ossification leaves the end-bone epiphyseal plates at the

femoral–tibial junction prone to fracture, infection, and abnormal development resulting in lameness, and swelling of the femoral–tibial joints. These problems did not appear during rearing of broiler parent flocks from day old to maturation with restricted feeding, indicating that the skeletal and leg problems were a result of the very rapid and unbalanced growth rate of the broiler chick, rather than being innate to the animal. This led to more tailored feeding and lighting programs for young broiler chicks, holding growth below the potential in the early part of the growth period, by returning to mash type feed or otherwise decreasing the nutritional content of the diet, and by decreasing hours of light [23, 25]. In the final weeks of the broiler growth period, after the skeleton and body frame were more solidly formed, photoperiod was increased to maximize feed intake, and diet was shifted back to nutritionally dense pelleted form to allow full compensatory growth. Skeletal abnormalities were a leading cause of mortality and carcass condemnations in broiler production in the 1970s. At the present time, however, due to genetic selection to reduce their incidence and formulation of suitable management protocols, skeletal deformities are well controlled.

Stage 2: Combined Selection for JWfA and Feed Conversion Ratio (FCR)

Random sample tests of broiler chickens from different breeding firms were instituted in the 1960s to provide unbiased information as to broiler chick quality. In addition to differences in JWfA, these also showed large differences in feed conversion ratio (FCR) among the various breeders, independent to an appreciable degree of juvenile growth rate. This was surprising, since the metabolic efficiency of feed utilization was thought to be highly correlated with evolutionary fitness and hence it was anticipated that there would be little genetic variation in the trait. Because of the economic importance of FCR, starting in the 1970s breeders included this in their breeding programs as a second major objective along with JWfA, with considerable success.

Further consideration led to the realization that although the metabolic efficiency of catabolism and anabolism may not vary, variation in motor activity, carcass adiposity, and possibly protein turnover rate [14, 26, 27] may all contribute to genetic variation in FCR. Consequently, a positive albeit unexpected secondary effect of selection for reduced FCR was a gradual but steady reduction in carcass adiposity [6, 9], apparently by reducing the fat:lean partition coefficient at high intake. Thus, at the present time, excess broiler fat content of the commercial broiler is no longer considered a problem by the broiler industry.

Secondary Effect of Continued Selection for JWfA and FCR (V): Adverse Effects on Reproductive Performance of Broiler Female and Male Parents

The late 1970s and 1980s, however, brought about a number of additional problems, apparently secondary effects of the continued selection for JWfA and FCR. First of all, female and male reproductive performance again became problematic. As noted, to control EODES, female pullets were reared under feed restriction. Initially, birds of the reproductive flock were shifted to *ad libitum* feeding to induce entry into lay, and remained on *ad libitum* feeding during the entire reproductive period. However, in the 1970s while peak production remained high, post-peak production dropped rapidly. This was apparently due to continued effects of the loss of appetite control that led to overeating and fat accumulation during the laying period, by both females and males. As a consequence, feed restriction was extended into the laying period itself [18, 19]. This continues to the present time and is effective in maintaining egg production.

The extension of feed restriction to the laying period had a further positive effect in that egg weight is closely related to actual body weight and feed consumption, so that egg weight can be closely controlled by monitoring body weight and feed intake during the reproductive period. Control of egg weight in this manner, however, is limited by the ever-increasing optimum mature body weight of the female parent even under feed restriction. This is due in all likelihood to an increase in threshold weight for sexual maturity that has all along accompanied the increase in JWfA.

Secondary Effect of Continued Selection for JWfA and FCR (VI): Increased Water Consumption, Nipple Drinkers

The increased daily feed consumption of the rapidly growing broiler chick required a proportional increase

in water consumption to enable the gizzard and digestive system of the bird to deal effectively with the dry feed. Drinking the additional water from the standard "Bell drinker" resulted in increased water spillage and wet litter causing a host of veterinary and welfare problems, such as foot pad and breast dermatitis, and ammonia production interfering with proper breathing and contributing to pulmonary hypertension syndrome (PHS). This was solved in the early 1980s by the introduction of the "nipple drinker" in which water drops are drawn directly into the chicks' throat in this way greatly reducing spillage and the attendant problems with wet litter.

Secondary Effect of Continued Selection for JWFA and FCR (VII): Delayed Entry into Lay

In the 1980s, a new set of problems arose related to entry of the birds into lay. Under natural conditions, onset of sexual maturity in chickens is controlled by day length (photoperiod). Male and female birds enter sexual maturity in the spring, under the stimulus of gradually increasing photoperiod. Normally, chickens will not enter lay in the fall, due to the negative stimulus of the naturally decreasing photoperiod at this season. In order to have a steady supply of broiler chicks, however, it is necessary to have males and females enter sexual maturity and lay throughout the year. For birds maturing in the fall or winter, this was achieved by extending the photoperiod through the use of supplemental artificial light, added at both ends of the natural day. This produced an artificial spring-type light pattern, and brought the birds into sexual maturity in a reliable manner throughout the year. Beginning in the 1980s, however, onset of sexual maturity was delayed for birds maturing in the fall season of the year, even under the stimulus of supplemental artificial light. Some of the females did not enter lay at all; in others, onset of lay was delayed and peak lay was lower. A management solution was found in the form of "Stimulatory lighting." For this, the chicks are reared in fully enclosed so-called dark-out houses in which photoperiod is under total artificial control, under a regime of 16 h total darkness and 8 h dim light until it is time for them to enter lay. As noted above, during this period they are also under quantitative feed restriction. To bring the birds into lay (generally, at about 6 months of age), they are moved to the laying pens, and exposed to a photoperiod of 14–16 h of daylight, while at the same time feed quantities are increased rapidly (within a few weeks from 100 g/day to over 160 g/day). The combined stimulus of increased photoperiod and feed quantity brings the birds into sexual maturity and lay.

Initially, dark-out rearing and stimulatory lighting were required only for birds entering lay in the fall. However, with the passage of generations, and continued selection for juvenile growth rate and FCR, problems on entering lay appeared even in birds coming to sexual maturity in the spring of the year under optimal natural lighting. At present, therefore, stimulatory lighting to bring the birds into sexual maturity is required at all seasons of the year [28]. Experimental studies showed that the need for stimulatory lighting was due to reduced innate photosensitivity of the broiler chicks [29], as well as to a direct effect of feed restriction per se on photosensitivity. Apparently the control systems of the bird interpret feed restriction as indicating that environmental conditions are not yet suitable for chick rearing, and delay onset of lay accordingly.

Secondary Effect of Continued Selection for JWfA and FCR (VIII): Male Overfeeding

In the mid-1980s, growth and appetite patterns of males and females began to diverge sufficiently, so that even under feed restriction, the males, when fed together with the females, became overweight and lost fertility. This was resolved by the use of special feeders and feed composition for the males, while using barriers preventing the males from having access to the female feeders.

Secondary Effect of Continued Selection for JWfA and FCR (IX): Heat Distress

Heat is produced by all aspects of body metabolism, including digestion and growth. Producing a given total mass of body weight, therefore, generates a more or less fixed total quantity of metabolic heat to digest the food required to grow this body mass and convert the digested food into body mass. This metabolic heat must be dissipated to avoid symptoms of heat distress. When the grow-out period is long, the daily production of metabolic heat for growth and digestion per

unit time is low and readily dissipated by the bird. However, as age to market weight decreases with each generation of selection, this same total metabolic heat is produced in a shorter and shorter grow-out period, so that in each generation the metabolic heat generated per unit time increases [30]. This is particularly true for the final weeks of the grow-out period, when the bulk of body mass is produced.

Generation of metabolic heat interacts strongly with stocking density, a major management determinant of broiler costs through its effect on fixed costs of housing per unit of product. Generally, birds are stocked at a density that gives almost complete ground cover toward the end of the rearing period. Under these conditions, there is maximum radiant heat transmission between birds, and stagnant hot air is trapped between birds and between the birds and the litter. Broilers with slow to moderately rapid growth can be reared in open sheds, with air circulation controlled by opening and closing window flaps or curtains, as the weather dictates. At optimal ambient temperature of 18–22°C, normal air circulation adjusted in this manner is sufficient to dissipate metabolic heat and the birds are comfortable. As ambient temperature increases, the birds cope by generating evaporative heat loss through panting [31]. For broilers with slow to moderately rapid growth, this is ordinarily sufficient to deal with the stress of normal summer peak heat. When peak heat exceeds ability of the bird to cope by panting, metabolic heat can be reduced by reducing food intake during the hottest part of the day, and by artificially "fogging" or "misting" the birds to increase evaporative heat loss when humidity is less than 70%. However, with the increase in growth rate achieved by the early 1980s, metabolic heat production increased to the point where these palliatives were no longer sufficient and the birds exhibited excessive panting and heat distress under conditions that were previously adequate. Heat distress was particularly acute at high stocking densities toward the end of the growing period, when floor cover by the birds was maximal. This led to reduction in growth rate since the birds reduced feed intake during the hottest part of the day, and in some cases to collapse and death of the bird from hyperthermia. To deal with this, fans were introduced into the chicken sheds to create additional circulation of air inside the sheds and to increase exchange of air between the inside and outside of the sheds. This system worked well, and in combination with misting or fogging when outside temperatures were high, enabled rapid growth to continue even under hot summer weather conditions with good FCR and low mortality.

Secondary Effect of Continued Selection for JWfA and FCR (X): Pulmonary Hypertension Syndrome and Sudden Death Syndrome

In 1974, a new pathological condition was reported in broiler birds reared at high altitudes. The condition manifested as sudden death, accompanied by "ascites" (accumulation of protein-rich fluid in the body cavity). Initially, death was attributed to the ascites *per se*, and hence the condition was termed "ascites syndrome." However, further studies showed that the ascites was a secondary consequence of pulmonary hypertension and the disease is now termed "Pulmonary Hypertension Syndrome" (PHS). With time, PHS manifested in broiler flocks growing at lower altitudes causing high mortality particularly in males of rapidly growing broiler lines from 4 weeks of age. The etiology of the disease has been worked out in detail (Box 3), and it appears to be a direct consequence of continued selection for rapid JWfA, exacerbated by selection for reduced FCR.

At about the same time that PHS manifested, a second metabolic disorder, "Sudden Death Syndrome" (SDS), also became prominent [32, 34, 35]. SDS presents as sudden convulsions, with squawking, violent flapping, and loss of balance. Death ensues within less than a minute from the onset of symptoms, with the bird lying on its back with one or both legs extended. Greatest losses are from 3 to 6 weeks of age, primarily in males. The syndrome is associated with the same factors that induce PHS, namely, high carbohydrate intake, dense housing, very rapid growth, and low feed conversion ratios; but most commonly manifests at an earlier age than PHS. Also similar to PHS, under inducing conditions, SDS can be precipitated by any sudden movements or noises that cause a stress response in the birds. It is plausible therefore, that SDS is an early pathological response to the hypoxia that accompanies rapid growth in broilers (see also Box 3).

From the above, it is clear that incidence of mortality due to PHS and SDS will be increased by any

Box 3 Etiology of Pulmonary Hypertension Syndrome and Sudden Death Syndrome

The causal sequence leading from selection for JWfA and FCR to PHS is thought to be as follows: Selection for rapid juvenile growth rate increases metabolic rate for growth resulting in increased need for oxygen in tissues. At the same time, selection for decreased FCR caused the relevant regulatory, circulatory, and hormonal systems to reduce oxygen consumption by the tissues resulting in effective hypothyroidism, and also reduced the proportion of oxygen-supplying organs (lung and heart) relative to oxygen-demanding tissue (muscle). The combination of these two factors results in tissue hypoxia that leads, via the kidney and erythropoietin, to increased production of red blood cells that increases blood viscosity, and also to constriction of pulmonary arterioles to ensure blood flow to all parts of the lungs so as to increase pulmonary oxygen exchange. The result of these two factors was increased lung arteriole pressure leading to increased workload on the heart and hypertrophy of the right (pulmonary) ventricle. This in turn resulted in incomplete closure of the right arterial valve with consequent backup of blood pressure to the hepatic and portal veins generating pulmonary hypertension and impaired uptake of fluid by the lymphatic system. Pulmonary hypertension results in fluid leakage and accumulation of fluid in the lungs (hypertensive lung syndrome) and in the abdominal and pericardial cavities (Ascites), and inability of the heart to supply body oxygen needs through left ventricle heart failure. Any of these final syndromes can result in death of the chick from PHS.

The detailed etiology of SDS differs [34, 35]. Electrocardiograms of broilers in the last stages of SDS show the immediate cause of death in SDS to be acute cardiac arrhythmia terminating in ventricular fibrillation. It is thought that under conditions of hypoxia the myocardium may become hyperirritable, serving as a secondary pacemaker and interfering with normal cardiac rhythms. Indeed, studies of rapidly growing broilers show that they manifest a high rate of cardiac arrhythmia under "normal" high growth-rate conditions, and are highly susceptible to stress-induced cardiac arrhythmia. Thus, under normal high growth-rate conditions, any additional stress may be sufficient to tip the heart from simple arrhythmia to ventricular fibrillation and sudden death [32, 33].

management factor that increases oxygen demands of the animal, such as social stress, low ambient temperature, feeding high-energy food in pellet form that stimulates growth rate; or that limits oxygen supply, such as overcrowding and poor air circulation or avian respiratory disease. Although a major problem in the 1980s, and still a problem today when circumstances combine, by the mid-1990s PHS and SDS were brought under control by a combination of family-based genetic selection against the condition, and careful management minimizing the external factors that contribute to hypoxia.

Stage 3: Combined Selection for JWfA, FCR, and Proportion of Breast Meat (PBM)

From the early 1970s, selection of birds with a less-pronounced keel bone was a part of broiler selection, with primary aim of producing a finished product having a fuller appearance that was more attractive to the consumer. This had a secondary result of selecting birds with more breast meat. With an increasing percentage of birds sold as individual parts, a major price differential between chicken breast "white" meat and chicken leg and thigh "dark" meat became apparent. This meant that the income of the broiler producer was primarily a function of the amount of breast meat produced. In the mid-1980s, realization of this economic fact by the breeders led to the addition of specific selection for a high proportion of breast meat in the broiler carcass as a third major breeding goal in addition to JWfA and FCR. This continues to the present time.

Secondary Effect of Selection for JWfA and PBW (XI): Heat Stress (Again)

The major secondary effect of selection for PBW in the broiler was an additional increase in heat stress effects, due to the increased metabolic load induced by the high metabolic cost of muscle mass synthesis. As a result, the modern broiler could no longer cope with even small deviations from the neutral temperature zone without a significant loss of meat yield. It became clear that the typical broiler-rearing shed of minimal structure with open sides plus fan-ventilation could no longer deal successfully with the enormous metabolic heat produced by the modern broiler flocks.

This led the industry to adopt a closed shed and a shift to "tunnel ventilation" with further option of cooling the air by drip technology. During the 2000s, "tunnel ventilation" with "drip cooling pads" for broilers became an obligatory feature of broiler rearing.

Secondary Effect of Selection for PBM (XII): Quasi-EODES at Entry to Lay

A secondary effect of the selection for PBM was the appearance of a new "quasi-EODES" syndrome at the onset of lay in the broiler breeder female parent, with symptoms very similar to classical EODES but to a less-pronounced degree [36]. This "quasi-EODES" syndrome was characterized by high mortality at entering lay, caused mainly by cloacal prolapse, internal lay, and inflammation of the oviduct. For the surviving birds, the quasi-EODES syndrome has marked negative effects on peak lay and eggshell quality resulting in a lower proportion of hatching eggs out of all eggs and lower hatch of healthy chicks from fertile eggs. The overall result is a marked reduction in chick production. Practical experience of hatchery flock managers, supported by later research revealed that the quasi-EODES syndrome is induced by even minor "overfeeding" during the critical weeks of forced sexual maturation. The modern female breeder became very sensitive to even a slight deviation from optimal feed restriction.

Two factors appear to have combined to generate the quasi-EODES syndrome. The first, is the continued increase in the degree of feed restriction during the pullet growth period, needed for preventing EODES, going, as noted above, from about 70% of *ad libitum* consumption during the 1970s to about 35% of *ad libitum* consumption at present. The second is the continued increase in threshold weight for onset of sexual maturity of the female broiler breeder, as a direct result of the selection for higher JWfA and PBM. For example, recommended 24-week body weight for out-of-season "Cobb 500" female broiler breeders increased from 2700 g in 1987 to 3160 g in 2005 [37] with a higher proportion of body mass as muscle tissue. Thus, the actual gap between the pullet lean mass attained at the point where light and feed stimulation is initiated, and the threshold lean mass required for entering lay has progressively increased, and with it the time required from initiation of light and feed stimulation to actual onset of lay. Attempting to cover this gap more rapidly by increasing feeding levels exceeds the ability of the pullet to rebuild breast mass and results in a surplus of nutrients causing the ovary to behave as if fed *ad libitum* and leading to development of quasi-EODES. Thus, the modern broiler breeder pullet entering lay is delicately balanced at a feeding schedule that will induce lay as rapidly as possible, yet will not induce quasi-EODES. Consequently, the bird is very unforgiving of any deviation from optimum feeding schedule in the direction of overfeeding.

Secondary Effect of Selection for PBW (XIII): Hatchability Problems (Again)

A further secondary effect of the selection for increased proportion of breast meat was a reemergence of hatchability problems. These appeared even though continued selection for rapid JWfA did not result in appreciable further increase in egg weight. Stability of egg weight was achieved due to increasing feed restriction of the broiler mother targeted specifically at controlling egg weight (which responds very rapidly to feed restriction) and to conscious selection against excessive egg size by the breeders. Thus, the situation was unchanged throughout the 1990s. However, the intense selection for increased muscle mass that began in the mid-1980s resulted in an increase in the proportion of muscle mass in the late developing embryo. As noted, the metabolic energy expended in development of muscle is greater than for other body tissues, because of the high metabolic cost of protein synthesis. Hence, this resulted in a further increase in metabolic heat production by the late embryo [38–41]. This additional excess heat was beyond the capacity of multistage incubators, no matter how carefully managed. Consequently, hatchability began to fall again, owing to increased late mortality and decreased yolk uptake leading to an increased proportion of weak chicks, and more grade B chicks [42], and negative effects on broiler bone development and leg health [43, 44].

To meet this challenge, the industry began shifting to "single-stage" incubators [40]. In these incubators, all eggs from flocks of about the same age and same average egg weight are loaded into the incubator on the same day. They are then incubated together until they hatch. Thus, they are all at the same stage of

development at any given time (hence the name "Single-Stage" incubator). This makes it possible to better adjust incubation temperature, according to the stage of the embryos [42] – somewhat warmer at the early embryo stages, when the embryo requires external heat to reach desired internal temperature, and cooler at the later embryo stages, when the embryo needs to rid itself of excess heat. Similarly, humidity can also be adjusted so as to achieve optimal egg water loss across the incubation period [41]. This has proven to be a satisfactory solution, and hatchability and chick quality have improved accordingly.

Secondary Effect of Selection for PBW (XIV): Reduced Locomotor Activity

The very large breast of the modern broiler chick results in an animal that is unbalanced between breast weight and leg and thigh muscles [45]. Consequently, it is difficult for the animal to move, and locomotor activity is much reduced. Toward the end of the growth period, the broiler chick spends over 90% of its time sitting and lying, resting its overdeveloped breast on the litter, and basically moving only to eat and drink. Selection for reduced FCR may also have contributed to the reduction in locomotor activity, since this is one way to reduce metabolic expenditure of the animal. As a result, the animal is very susceptible to contact dermatitis, including footpad lesions and breast blisters. These conditions can be well controlled by meticulous attention to litter quality, specifically litter temperature and humidity, but are exacerbated and can reach high levels when litter quality is poor.

The Role of Breeding and Management in the Improvement in Performance of the Modern Broiler Chicken

Achievements of the Modern Commercial Broiler with Respect to the Three Main Production Traits and the Associated Secondary Traits

The extraordinary improvement in broiler performance for the three main production traits (JWfA, FCR, and PBW) over the past 60 years is best captured by the following table (Table 1), which compares the performance (average of males and females) of representative commercial broiler stocks of 1957, 1991, and 2001.

Poultry Breeding. Table 1 Comparison of performance of broiler stocks of 1957, 1991, and 2001[a]

Trait	1957	1991	2001
Age at sale (d)	84	42	42
Live weight at sale (g)	1646	2132	2672
Feed conversion ratio	3.26	2.04	1.63
Breast meat (%)	12.9	15.0	20.0
Carcass fat (%)	14.7	14.1	13.7
Heart+lungs (%)	1.242	ND	1.023
Mortality to market (%)	2.52	9.70	3.57

[a]Based on [6–9]; data for 1957 average of [6 and 8 and 7 and 9] for birds fed the commercial feed formulations of 1991 [6, 7] and 2001 [8, 9].

It is evident that in the period 1957–2001 enormous improvement has been achieved in the three major production traits. Days to market weight and FCR have been reduced by half, while JWfA has almost doubled, and PBW has increased by almost 30%. Improvement in all traits was continuous, with no indication of reduced rate of gains in the latter decade.

When compared using the feed formulations of 1957, gains in JWfA and FCR were only a bit less. There is no doubt therefore, that genetic selection by the primary breeders was by far the main driving force leading to the gains in these traits. The increase in PBM from 1991 to 2001 is particularly impressive and can be attributed almost completely to the attention devoted to this trait by the primary breeder beginning in late 1980s. However, JWfA and FCR also increased strongly during this period showing the ability of the breeder to deal simultaneously and effectively with the three major production traits.

Along with the phenomenal improvement in production traits, the broiler industry was able to cope successfully with all of the deleterious secondary effects detailed in the preceding sections that accompanied the genetic gains in the three main production traits. Through a combination of genetic selection on the one hand, and continual adjustment and innovation in broiler and breeder flock management and physical facilities on the other, the industry succeeded in maintaining male and female reproductive

performance at very high levels, while keeping losses due to heat sensitivity, skeletal problems, and metabolic disorders at very low levels.

Relative Contribution of Genetics and Management to Modern Broiler Performance

The relative contribution of genetics and management to these achievements depends on the specific trait. In particular, it seems clear that the shift to progressively more active ventilation culminating in the tunnel ventilation with drip cooling in general use at present was the main means for coping with the heat sensitivity of the modern broiler. Similarly, changes in incubator management and the more recent shift from multistage to single-stage incubators together with flock management to reduce egg weight were the main factors maintaining high hatchability rates. However, selection played some role in both cases, since families that display low hatchability and high sensitivity to heat stress are generally culled from the breeding population.

With respect to reproductive performance, feed restriction during pullet growth and the hen laying period, and dark-out housing of the parent stock pullets with stimulatory lighting and feeding at entry into lay, were critical management factors contributing to maintaining reproductive performance in male and female broiler parent stock. However, selection for reproductive performance within this overall management scheme played an important secondary role, as attested by the appreciable differences between genetic stocks in reproductive performance under optimal feeding and lighting schedules. In the same way, while appropriate management is essential to control skeletal problems and metabolic disorders, the effective selection applied to these conditions appears to have been crucial in reducing their incidence in well-managed flocks to present-day low single-digit proportions.

Thus, although the improvement in production traits of the modern broiler compared to its original founder populations can be attributed almost entirely to genetic improvement achieved by selection, the bird that results is able to achieve optimal production and functional performance as broiler and parent stock primarily due to major modifications in broiler housing, and in parent flock and incubator management coupled with a greater or lesser contribution by selection, depending on the trait. Be that as it may, one can only stand in awe at the combined ability and synergistic work of the major players in the industry to overcome the challenges as they arose while maintaining continual progress in overall efficiency of the broiler enterprise.

Breeding Methods for Genetic Improvement

In large part, this is due to the fact that the methods practiced by the primary broiler breeders increased in sophistication in accord with the complexity of the breeding challenges that they faced [46]. In the first stage of broiler genetic improvement, JWfA was the main trait under selection, with a minor goal of improved breast conformation. This was achieved by simple two-step tandem mass selection, the first step being selection for JWfA followed by a second step of selection for breast conformation. Flocks were not pedigreed at this stage. With the addition of reproductive performance, FCR and reduction of adiposity and skeletal problems as breeding objectives in the second stage of broiler genetic improvement, simple mass selection was no longer effective and multiple-stage tandem selection no longer feasible. To meet the new challenges, breeders changed to fully pedigreed flocks to provide information on reproductive performance, FCR, and skeletal problems, and to index selection based on individual and close relatives to combine information on the various traits in an optimal manner. Finally, in the third stage of broiler genetic improvement, with the addition of PBM and reduction of metabolic disorders to the breeding objectives, breeders adopted BLUP and Individual Animal Model statistical methodologies for estimating breeding values for the various traits under selection, based on individual data for the entire current and past population. At the same time, the primary breeders adopted phenotyping procedures that increased the completeness and accuracy with which the traits of importance were evaluated. For example, individual skeletal problems are now assessed by x-ray scanning of bird joints and individual cardiovascular function is assessed by blood oximeter machine. At present, over 50 traits are recorded on the individuals in the breeding nuclei, about half of these relating to various aspects of broiler health.

At all stages, breeding nuclei were kept very large in order to avoid inbreeding and maintain genetic variation. With the advent of genome-wide procedures for estimation of breeding values [1–3], all of the major primary breeders have instituted in-house experimental studies to evaluate the use of these methodologies in their practical breeding programs. Although very promising in initial studies, the results in practice in commercial breeding nuclei remain to be seen.

Accounting for the Long-Term Continuous Response to Selection and for the Punctuated and Coordinated Appearance of Secondary Effects

Commercial breeding nuclei have been under intense and effective directional selection for JWfA for 60 generations, for FCR for 40 generations, and for PBM for 25 generations. Two remarkable features characterize the response to this selection. The first and most striking is that the direct response of the target traits to selection has been positive and continuous for all three traits, with no indications of having reached a selection plateau for any of them. This continued response to selection requires explanation. Since selection acts on all relevant loci at the same time, the intense directional selection for the target traits should have exhausted the existing genetic variation in the original dual-purpose chicken founder populations rather rapidly, leading to selection plateaus for the various traits. The second remarkable feature is the rather sudden manifestation of the secondary effects of the response to selection at about the same time period in the stock of all leading breeders, even though their respective breeding nuclei are effectively isolated from one another. This "punctuated" (i.e., "relatively sudden") and "coordinated" (i.e., relatively universal and synchronous) manifestation of the secondary affects requires explanation. If due to genetic correlations or pleiotropic effects of the initial genetic variation of the founder populations, they would be expected to manifest in a more linear and gradual manner. If due to pleiotropic effects of new mutations, they would be expected to manifest in a more sporadic manner, affecting only stock of one or two of the various breeders.

Sources of Genetic Variation for the Long Continued Response to Selection

Based on classical population genetics, three sources can be envisaged with respect to sources of genetic variation to serve as a substrate for selection. The first is the genetic variation present in the original founder populations of the broiler stocks. Recent research in mapping of the loci responsible for genetic variation in production traits in farm animals (the so-called Quantitative Trait Loci or QTL) indicates that tens of QTL may contribute to genetic variation of such traits. This genetic variation present in the founder populations would have provided the basis for the first decades of response. The second source comprises rare alleles with positive effects on the target traits that were present at low frequency in the founder populations. The primary breeders maintain large breeding nuclei, and these could have included an appreciable number of such loci. In the early generations, because of their low frequency these loci would not have contributed materially to genetic variation in the target traits, or to the response to selection. However, after several decades of intense selection, their frequency would have increased to the point where they could serve as useful targets for the middle stages of selection. Finally, new mutations or rare recombinants would supply a steady stream of new genetic variation that would come into play in the later stages of selection.

Punctuated and Coordinated Appearance of Deleterious Secondary Effects

Similarly, a number of explanations can be offered within classical frameworks, for the punctuated and coordinated appearance of deleterious secondary effects. Some of these effects may be due to non-linear secondary effects of selection interacting with downstream threshold effects. For example, adiposity can be presumed to have increased more or less linearly with selection for JWfA, but the effect on egg production was virtually nil for the first 10–15 generations of selection, and then suddenly became very severe – in the few years just before the introduction of feed restriction in the late 1960s, yearly egg production had fallen by almost 100 eggs per laying hen. Such effects would be expected to manifest in flocks of all

breeders at about the same time, as their breeding populations reached more or less the same degree of expression of the primary traits. Other secondary effects may be due to the introduction of new primary target traits. Thus, an entire group of new secondary effects manifested following the introduction of FCR, and again following the introduction of PBM as targets for selection. Since the primary breeders introduced the same new target traits for selection at more or less the same time, these secondary effects would be expected to manifest in flock of all breeders at about the same time.

Difficulties with the Explanations Within the Classical Framework of Population Genetics

Rare mutations are often those that are held at low frequencies because of deleterious pleiotropic effects on fitness. Similarly, new mutations generally affect numerous traits, with deleterious fitness effects on one or more of them. Intense selection can increase the frequency of genes with strong positive effect on the target trait in spite of negative effects on fitness, but in a long-term selection program this should result in reduced overall functional fitness of the population. Furthermore, because of their low frequency in the founder populations, rare alleles would not distribute uniformly among different breeding populations derived from the same founders. The same would certainly hold for the genes that were affected by mutation. Consequently, fitness traits should be differentially affected in different breeding populations, according to the specific low-frequency genes that were inherited or mutated in each population. This does not appear to have been the case. Similarly, although in almost all cases it was possible to trace in retrospect a causal chain leading from selection for the primary trait to the manifestation of the secondary trait it is somewhat unexpected that the specific form of these manifestations (e.g., PHS, SDS, quasi-EODES, reduced photosensitivity) was the same in stocks of all breeders. If much genetic variation is due to initially rare or mutated loci that are necessarily specific and different in different breeding populations, specific manifestations of secondary traits would be expected to differ as well.

Selection-Induced Genetic Variation (SIGV)

The difficulties with the explanations proposed within the classical framework for long-term response to selection and for punctuated and coordinated appearance of the secondary manifestations have led to a recent proposal for a new previously unrecognized source of genetic variation in ongoing selection programs: selection-induced genetic variation (SIGV) [47]. The SIGV hypothesis is based on the observation that the individual QTL determining genetic variation in production traits often exhibit strong epistatic interactions with one another and with the genetic background. Consequently, a segregating locus with zero effect on the target trait in one genetic background might have a strong effect on the trait in a different genetic background.

The intense continued directional selection, changes the frequency of many alleles in many loci and by means of "hitchhiking effects" of their closely linked neighboring genes as well. This changes the genetic architecture of a population to a marked degree. Thus, some loci that were neutral in their effect on the target trait at the beginning of the selection program, may transform into sources of genetic variation as the selection program progressively modifies the genetic architecture of the population. As the positive alleles at these loci are caught up and brought to high frequency by the ongoing selection, the genetic architecture of the population becomes modified again, and new previously neutral loci come into play as sources of genetic variation. In this way, the population under selection would continually generate new genetic variation to serve as a substrate for the next phase of the directional selection process, with no obvious limit in place.

Since the loci involved in the SIGV process are loci that were present at appreciable frequencies in the original founder populations, they would be present in all breeding stocks, and would be expected to come into play at about the same stage in the selection process in the individual flocks. Thus, genetic progress in the various breeder populations would not depend on rare alleles or new mutations, which would be specific to each population, but on segregating loci already present in the population at useful frequencies, that come into play in a programmed manner, as the genetic architecture of the population changes. On this

hypothesis, the genetic architecture of all breeding populations under the same general selection regime would be similar at all stages of the selection process, and hence the specific form of any secondary effects would also be similar in the different populations. Strong secondary effects on fitness would not be expected, since the loci involved are loci historically present in the populations, and hence have survived the screening effect of natural selection.

Thus, the SIGV hypothesis provides plausible explanations both for the long-term response to selection and for the punctuated and coordinated appearance of secondary effects. Indeed, recent experimental studies analyzing crosses between layers and broilers, and between two-way single-trait selection lines for JWfA, provide significant experimental support for this hypothesis [48, 49]. The SIGV hypothesis emphasizes the importance of epistatic interactions in genetic variation and encourages the development of statistical and genomic methodologies that can exploit these interactions.

Genetic Improvement of Broiler Production Traits and Broiler Welfare

In the previous sections, it was seen that the modern broiler is greatly modified developmentally and physiologically from the original dual-purpose breeds from which it was developed. Furthermore, to achieve optimal economic performance the modern broiler and its parent flocks must be reared, managed, and housed under conditions very different from the husbandry conditions of the founder parent lines. Various aspects of these genetic and management changes impinge on animal welfare, in the sense that they can lead to distress or pain of the individual. These can be considered in two main categories. Those where the distressful situation is unavoidable, and those where the distressful situation is avoidable under good management, but manifests under less than optimal management. There is a third category, which considers aspects where the bird is comfortable and not in distress, but where it is thought that its life might be more joyful if living under different conditions, for example, on free range or scrounging for food in the jungle or farmyard, instead of in a closed shed. This latter raises more profound issues of the morality and ethics of animal agriculture in general and industrial animal agriculture in particular, and will not be considered here.

Unavoidable Distress

The negative effect of excess adiposity on reproductive performance and survival of the modern broiler parent female or male is dramatic and extreme. Consequently, stringent feed restriction of the parent flock pullets and males during the rearing and laying period is essential, if the birds are to achieve optimal reproductive performance. This appears to be the only aspect of the broiler enterprise that causes distress, but is unavoidable. An animal that is fed only 35% of its *ad libitum* consumption, and can be seen to eat ravenously when feed is available, must surely be feeling hunger pangs. The period of stringent feed restriction is rather short, however, from about 4–14 weeks of age, and while it can be presumed to be uncomfortable, does not affect the overall health of the individuals in any way. Indeed, allowing the animal to eat *ad libitum* and become grossly obese would probably entail much more distress over the entire life span of the animal including mortality. The much milder feed restriction that is in effect during lay would not seem to pose a welfare problem, as it is ordinarily sufficiently generous to even allow for some increase in body weight over the course of the laying period.

Avoidable Distress

A review of the preceding sections, however, reveals a considerable list of conditions to which the modern broiler is susceptible due to its changed genetic constitution. These include: quasi-EODES at entry into lay that can result in death from cloacal prolapse or from internal lay; heat stress, skeletal abnormalities, PHS which often manifests as ascites, SDS, and various forms of contact dermatitis. SDS, in which death of the animal occurs within less than a minute from the onset of first symptoms of distress, would seem to occur too rapidly to be a source of significant pain or distress. But the other conditions can be presumed to be moderately to severely painful, according to their respective natures and degree of severity. As emphasized in the previous sections, thanks to the selective work of the breeder on the one hand, and innovative management of the industry on the other, when broiler

commercial or parent flocks are managed with care and attention to detail, all of the above can be kept at very low single-digit levels [46, 50].

Importance of Stocking Density

In this context, stocking density, an aspect of management that was not previously emphasized becomes important [45]. Stocking density interacts with the susceptibilities of the modern broiler in two ways: increasing heat stress and decreasing litter quality with consequent increase in the incidence of contact dermatitis. When stocking density is high, the bodies of the chicks cover the entire floor area, forming a barrier between the litter surface and the ventilated area of the shed. In addition, higher stocking density provides additional nitrogen and moisture to the litter increasing heat production due to microbial growth and metabolism. Taken together, these two factors can generate an appreciable differential between temperature at broiler level and temperature a meter above the floor. High stocking density also limits air movement and increases radiant heat transfer between birds, further increasing heat stress. The increase in litter temperature, humidity, and ammonia concentration resulting from high stocking density also interacts with the limited locomotor activity of the broilers to increase the incidence of contact dermatitis. Accordingly, proper control of stocking density is essential for optimal broiler welfare, and may be less than the economic optimum.

From Farm to Market

The handling of the bird on its final path from shed to slaughterhouse is another case in point. Because of the young age of the broiler at market weight, and its minimal locomotor activity, the long bones of the legs and wings are fragile relative to body weight. Moving the birds from the grow-out shed to the slaughter line is low-wage work with high personnel turnover and great pressure to get the work done with minimal labor costs. Consequently, the birds may be roughly handled at this time resulting in leg and wing bone breakage when they are captured and moved from the pen to the transport crates, and again from the transport crates to the slaughter line [51, 52]. Such breakage results in direct losses to the farmer and hence normally efforts are expended to reduce this to a minimum through mechanization, proper design of facilities, and training of personnel [53].

Welfare and Society

Apparent from the above paragraphs is the critical dependence of broiler welfare on meticulous flock and personnel management. Due to the work of the breeder, with proper management the susceptibilities of the bird remain latent. But there is little room for error. The bird is unforgiving of even slight deviations from optimal management, and will react to such deviations by manifesting one or other of its innate susceptibilities. The modern chicks that manifest any of the conditions above are a net loss to the farmer, and management conditions conducive to such manifestation are often inimical to optimal growth and reproduction. Consequently, for the most part, the welfare of the chick and the economic interests of the farmer correspond. However, achieving optimal management has its costs as well, and economic maximization may result in a management program that is somewhat less than optimal for the bird.

Society as a whole has benefited greatly from the improved production characteristics of the modern broiler, which has added a low-cost highly nutritious staple to the menu at minimal environmental footprint. Along with these benefits comes responsibility for the welfare of the bird in those instances where economic interests of the farmer and the quality of life of the broiler are not perfectly aligned. This is true throughout the broiler enterprise; nowhere more than in the final hours of the chick's life. Happily, society is accepting these responsibilities by designing facilities based on understanding of livestock behavior [53], and by defining acceptable production standards, and embodying these in appropriate regulatory legislation [54, 55].

Future Directions

One stands in awe of the magnificent achievements of the primary broiler breeders who have succeeded in improving the production characteristics of the modern broiler manifold relative to the initial dual-purpose founder populations, while at the same time dealing successfully with the many secondary functional problems that arose along the way, maintaining high reproductive performance together with very low incidence

of health problems. This was not the achievement of the breeder working alone, of course, and at all stages involved combined contributions by all components of the industry in devising novel management programs and physical facilities such as feed restriction and stimulatory photoperiods, dark-out housing, and tunnel ventilation that enabled optimal functional performance of the birds.

The Resource Allocation Model

These results are all the more remarkable, because they differ from what would be expected on the widely accepted resource allocation model for interpreting the effects of selection for production traits on functional traits [56, 57]. The basic assumption of this model is that under the conditions of intensive agriculture, the energy resources available to an animal are fixed. The animal must then allocate these resources to maintenance, to production traits including growth, and to functional traits including reproduction, regulation of physiology and metabolism, and defense against pathogens and toxins. Selection for production traits diverts resources preferentially to these traits, leaving less for the functional traits. Consequently, functional traits are expected to suffer. Indeed, many experimental studies show that production traits suffer when resources are preferentially allocated genetically or experimentally to functional traits, and functional traits suffer when resources are preferentially allocated to production traits. Amazingly, the broiler industry appears to have been able to circumvent this negative correlation, achieving high levels in both production and functional traits.

Management and Biological Costs of the Performance Achievements of the Broiler Industry

More detailed consideration, however, shows these achievements have incurred two costs. The first is the cost of more sophisticated physical facilities and complexity of management. These include sheds with tunnel ventilation and drip cooling for broiler rearing; dark-out houses for pullet rearing; feed restriction, single-stage incubators; and all of the many management and nutritional modifications required for optimum performance. The second cost is the apparent loss of buffering capacity of the animal regulatory systems, resulting in ever-increasing fragility or sensitivity of the animal to environmental challenges. This sensitivity expresses itself as reduced production and functional performance, and increased incidence of health problems as a consequence of even minor deviations from optimum management and environment. The result is not only loss of economic value, but also harmful impact on animal welfare. Because of the high metabolic cost of protein synthesis, a provocative hypothesis suggests that selection for productivity in general, and FCR in particular may reduce protein turnover rate. Since protein synthesis is essential to meet new conditions, this may be the underlying cause for the general loss in buffering capacity [58]. The primary broiler breeders today are attempting to decrease the sensitivity of their populations to environmental insults by testing under multiple environments and selecting for "robustness", as they would select for any other positive health trait. Will they succeed? Or will the future broiler require an increasingly narrow and complex multidimensional management path for optimal performance, with steep losses outside of this path? The coming years will tell, with strong implications for the broiler industry, and for animal breeding in general.

Conclusions and Interpretation

Be that as it may, the broiler experience teaches that deleterious effects on functional traits are almost certain to arise in the course of selection, and can take unexpected forms. The industry, whatever the species, must be alert to this possibility, so as to seek solutions as early as possible. The broiler experience also teaches that the breeder and the industry acting in concert can indeed find these solutions to these problems, enabling a joint genetic-management program that provides very high productive performance together with high functional performance within a framework of innovative physical facilities and increased management complexity. Based on past experience, therefore, as animal breeding enters a new genomic phase with greatly accelerated improvement in production traits, the future can be looked at with appropriate confidence in the ability of the breeder and industry working together to achieve sustained genetic improvement in production traits while maintaining high levels of functional and health performance.

Abbreviations

BLUP	Best linear unbiased predictor
DNA	Deoxyribonucleic acid
EODES	Erratic oviposition defective egg syndrome
FCR	Feed conversion ratio
JWfA	Juvenile weight for age
PBM	Proportion of breast meat
PHS	Pulmonary hypertension syndrome
QTL	Quantitative trait locus
RNA	Ribonucleic acid
SDS	Sudden death syndrome
SIGV	Selection-induced genetic variation

Article Outline

Glossary

Fibrous root system Root system formed by various root axis of similar size, typical of cereals.

Lateral roots Lateral roots are the roots formed from the pericycle cells of other roots. The first-order laterals refer to the roots emerging from the primary and secondary root axes. Second-order laterals emerge from the first-order laterals, and third-order laterals from the second-order lateral, and so on. Usually, lateral branching is limited to the fifth-order laterals.

Primary roots Often called seminal roots, these are the first root axes to develop arising from the coleorhizae of the seed.

Rhizosphere Volume of soil immediately adjacent to plant roots (usually between 10 and 20 mm), which is affected by their growth, secretions, respiration, nutrient and water, and associated soil microorganisms.

Root architecture Describes the spatial configuration of the root system as a whole. Since it describes multiple root axes it subsumes both topology and distribution.

Root cap Root cap is the tissue that covers the apex of the root. It protects the apical meristem, acts as gravisensor tissue, and facilitates the passage of the growing roots by producing root mucilage.

Root distribution Root distribution refers to the distribution of different root traits, often morphologic ones (e.g., weight, length, volume), as a function of several factors, the most common being soil depth.

Root hair Specialized projection formed by a modified epidermal root cell. It augments the total surface area of a root system, dramatically increasing its absorption capacity.

Root morphology Root morphology refers to the surface features of a single root axes as an organ. It includes the characteristics of the epidermis such as root hairs, root cap, pattern of appearance of lateral roots, cortical senescence, and diameter. Weight, volume, and area are also part of the morphology.

Secondary roots Secondary roots are the roots that grow from the hypocotyl, the coleoptile, stem, and tillers; they are also called crown, nodal, or adventitious roots. This term is also used to describe the roots emerging from the primary roots; however, first-order laterals is a better term to describe those roots.

Taproot In many gymnosperms and dicotyledons, the primary root axis to arise from the seed, greatly enlarges to become the most prominent root axis of the plant, and is usually referred to as a taproot.

Taproot system Taproot system refers to the root systems formed from a central and usually relatively large root axis, the taproot.

Topology Describes the branching pattern of the individual root axes.

The main quantitative root traits and resource capture variables discussed in this entry are summarized in Table 1.

Definition of the Subject and Its Importance

The UN forecasts that the world population will reach 9.4 billion by 2050. The world must therefore develop the capacity to feed 10 billion within the next 40–50 years [1, 2]. The increase in production has to come

Roots and Uptake of Water and Nutrients. Table 1 List of physiological variables, their definitions and units

Physiological variable (symbol)	Definition	Units
Nitrogen-use efficiency (NUE)	Grain DM at harvest (kg) per N available (soil + fertilizer) (kg)	Dimensionless
Nitrogen-uptake efficiency (UPE)	Above-ground N (kg) at harvest per N available (soil + fertilizer) (kg).	Dimensionless
Water-use efficiency (WUE)	Above-ground DM per water used (soil evaporation + crop transpiration).	g l^{-1}
Transpiration efficiency (TE)	Above-ground DM (g) per water used (l) through crop transpiration.	g l^{-1}
Radiation-use efficiency (RUE)	Above-ground dry mass (g) per intercepted global radiation (MJ).	g MJ^{-1}
Root to shoot ratio (R:S)	Ratio between the root and above-ground shoot dry mass.	Dimensionless (g g^{-1})
Root mass ratio (RMR)	Ratio between the root dry mass (g) and total plant dry mass (g).	Dimensionless (g g^{-1})
Root mass (RM)	Dry mass (g) of the total root system.	g
Root length (RL)	Total length (cm) of all roots present.	cm
Root length density (RLD)	Root length (cm) per unit of soil volume (cm^3).	cm cm^{-3}
Root volume (RV)	Total volume of the root system (cm^3).	cm^3
Root diameter	Average diameter (mm) of an individual root; commonly assumed to be a cylinder.	mm
Root fineness (RL:RV)	Ratio of the total root length (mm) to total root volume (mm^3).	mm mm^{-3}
Root depth	Maximum depth reached by a plant root system (m)	m
β Parameter	Describes the cumulative root distribution with depth. Estimated from: $p = 1 - \beta^d$, where p is the proportion of roots accumulated from the surface to a depth, d.	Dimensionless
k Parameter	Resource capture coefficient. Estimated from $\Phi = 1 - e^{-k.RLD}$, where Φ is the proportional resource captured (resource captured/ available resource).	m^2
Specific root length (SRL)	Ratio between root length (m) and root weight (g).	m g^{-1}
Root tissue density (RM:RV)	Ratio between root dry mass (mg) and root volume (mm^3).	mg mm^{-3}
Root front velocity(RFV)	Downward extension rate of the root front (mm) per day.	mm day^{-1}
Root longevity	Length of time of which an individual root is present in the soil.	days

from greater yields on existing cropland; but also without proportionate increases in the use of water or fertilizer, and within the context of climate change [3, 4]. A substantial increase in the effectiveness with which available water and nutrients are used is therefore required to ensure food security and environmental protection in future decades. Water is recognized as the most limiting factor in crop production worldwide, though nutrient shortages may often be as important as water scarcity and worldwide recovery of nitrogen (N) fertilizer in cereal systems worldwide is on average low at ca. 30–50% [5], with implications for potential

environmental impacts. Crop improvement under these conditions seems likely to be increasingly dependent on breeding for deeper or denser root systems, which promote soil moisture and nutrient capture and high dry matter production in cultivars subjected to water and/or nutrient stresses. In this entry, information is set out on the current understanding of the structure and functions of crop root systems. The avenues for the optimization of root anatomy and morphology traits that could be applied to the genetic and agronomic improvement of crop root systems for more effective below-ground resource capture are considered. Specifically, the determinants of effectiveness of capture by root systems of two key resources, water and nitrogen, according to their structure and function are considered.

Introduction

All higher plants have roots and the root fraction of the plant's total dry weight varies widely, both between and within species [6]. Although roots encounter many environmental fluctuations that affect their growth, they have a capacity to adjust to these as a whole system that makes them strongly dynamic in their spatial and temporal expansion. Understanding of these modifications in the form and function of the root system and their relationships with resource capture, whether due to environmental response or genetic control, is of importance for sustainable crop production.

Although the influence of canopy characteristics on above-ground productivity of crops is now relatively well understood, due to the difficulty of access and complexity of environment interactions, understanding the role of the root system is less complete. There is no doubt of the importance of the form and function of root systems to water and nutrient capture, and information has increased in the last decades on the role of crop root systems in maintaining yields under abiotic stress [7–9]. Root traits are a relatively new target in crop improvement programs aimed at improving tolerance of abiotic stress (water and nutrients). There are reports that particular root morphology and/or anatomical traits help plants maintain higher grain yields under low resource availability, for example, relatively deeper distribution of roots increasing water uptake under drought in wheat [10] and rice [11], longer root hairs increasing P acquisition under low P availability in barley [12], and narrower root xylem vessels in wheat were associated with increased water uptake during grain filling [13]. Nevertheless, the genetic control of root characteristics is poorly understood in most major staple crops, especially in bread wheat. Future improvement will depend on a better understanding of the morphological and anatomical traits determining below-ground resource capture, as well as the development and application of phenotypic screens to characterize genetic variation in the key traits. In this entry, the prospects for manipulating roots systems for improved resource capture and yield (drought and low nutrient availability) are considered, with a particular emphasis on cereal crops. The root traits that are focused on are principally morphological relating to root proliferation, root biomass and root length density, and their distribution with depth; although some consideration is given to anatomical features, for example, xylem root frequency and diameter. Roots and the uptake of water and nutrients are considered with regard to: (1) root morphology, (2) responses of root systems to water and nutrient stress, (3) the capacity of root systems for resource capture, and (4) prospects for breeding crops with optimized root systems for resilience to abiotic stresses.

Root System Morphology and Anatomy

Due to the difficulty of access and complexity of environmental interactions, roots are still one of the most challenging subjects in plant investigations, but their importance is unquestionable. Anchorage, support, and water and nutrient uptake are the main functions of the plant root system. With regard to crop root systems, the terms morphology and architecture are frequently used. The root system may be characterized according to four main categories of morphology/architecture [14, 15]. "Root morphology" refers to the surface features of a single root axes as an organ. It includes the characteristics of the epidermis such as root hairs, root cap, pattern of appearance of lateral roots, cortical senescence, and diameter. Root weight, volume, and area are also part of the morphology. "Root topology" describes the branching pattern of the individual root axes. "Root distribution" refers to the distribution of root traits, often morphologic ones (e.g., biomass length, biomass, etc.) as a function of several factors, the most common

being soil depth. Finally, "root architecture" relates to the spatial configuration of the root system as a whole.

The root morphology of monocotyledons differs from that of dicotyledons in several important respects. In the monocotyledons, for example, small grain cereals, two types of roots constitute the root system: the primary and the secondary roots [7, 16]. The primary roots (often called seminal roots; usually between three and eight axes) develop first arising from the coleorhizae of the seed [17, 18] and are active throughout all the crop life cycle [18]. Their extension is mainly downward allowing them to occupy the deeper layers of the soil profile [17]. The secondary (often called crown, nodal, or adventitious roots) are the roots that grow from the nodes of the coleoptile, main shoot, and tillers. The onset of tillering is the starting point of the growth of the secondary roots, and their formation is intimately related to tiller formation [19], so that factors favoring tillering will increase secondary root production. In dicotyledons, for example, oilseed rape, for most species the primary root consists of a taproot from which lateral roots and their branches arise. In both monocotyledons and dicotyledons, lateral roots are initiated in the pericycle and grow through the cortex to emerge at the surface of the parent root.

Rooting depth is affected by root-penetration rate and phenology. Generally, the longer a crop is growing, the deeper it roots [20]. Rooting depth (maximum depth reached by the roots) determines the amount of the soil that a plant can explore. Maximum rooting depth is typically 140–200 cm in winter cereals [18, 21] and 80–120 cm in spring cereals [22]. Rooting depth also strongly depends on the soil type and depth as well as below-ground resource availability, but generally the longer a crop grows the deeper the root system. Root growth and rooting depth of crop plants can be restricted because of physical and chemical impediments. Where physical and chemical soil constraints are absent, the maximum depth of rooting on deep soils is genetically determined and differs not only between vegetation types but also between crop species grown under identical conditions [8]. Much of within season variation in maximum rooting depth can be explained by temperature [23].

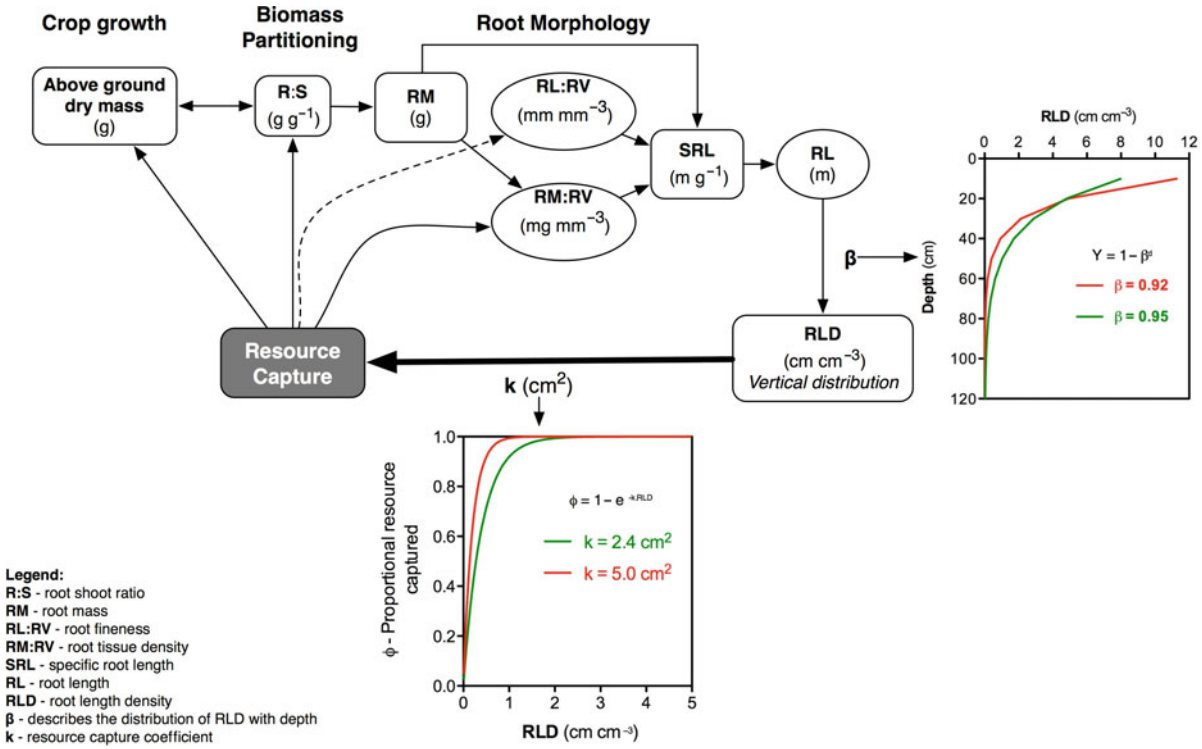
In monocotyledons, immediately after sowing root growth is favored, followed by a gradual decrease in assimilate partitioning to the root in favor of shoot growth after emergence. After flowering, the aboveground growth (fruit and grain formation) is favored, whereas root weight usually remains constant or decreases [24, 25]. Thus, root biomass and total length production generally follow a sigmoidal pattern from sowing to flowering in cereals, at which point further increases are not usually observed [18, 21]. The root dry mass ratio (root DM/total DM; RMR) is ca. 0.3 in wheat and barley during early growth, decreasing to ca. 0.1 at harvest [18, 22]. Another important trait influencing the crop's capacity to capture resources per unit soil volume is the root length density (RLD), which describes the total root length per unit of soil volume. Typical values of RLD in the upper 0.1 m of soil are about 20 cm cm^{-3} in grasses, 5–10 cm cm^{-3} in temperate cereal crops and 1–2 cm cm^{-3} in other crops [8]. The distribution of the RLD through the soil profile typically follows an exponential decrease with depth [26]. The cumulative distribution of RLD with depth (β) can be approximated by the equation described by Gale and Grigal [27] as:

$$Y = 1 - \beta^d \quad (1)$$

where Y is the fraction of the root system accumulated from the soil surface to depth, d, and β is a parameter that describes the shape of the cumulative distribution with depth.

This equation has been widely adopted since (e.g., [28–30]). The distribution of roots of many crops (e.g., cauliflower and winter wheat) is well described by the relationship, but in others (e.g., oilseed rape and sugar beet), this relation is found in the surface layers, but there is a tendency for values of RLD in deeper soil layers to be almost constant [8]. Differences in the distribution of RLD with depth may be associated with the velocity at which roots elongate to depth (root front velocity [RFV]) and the proliferation rate at each soil layer [31]. Root front velocity is closely related with the water and N extracted by the crop [31–33]. Another important trait influencing the potential for water and nutrient acquisition by roots is the mean root diameter (see Root traits and resource capture below).

Specific root length (root length per unit root DM - SRL; km g^{-1}) strongly influences the RLD. Theoretically, a high SRL (thinner roots) would be beneficial especially in resource-deficit situations. Specific root length is also positively correlated with root extension rate [34]. Specific root length varies considerably in the



Roots and Uptake of Water and Nutrients. Figure 1
Interrelationships between these root traits and their relations with resource capture

field and is strongly affected by environment; typical values are 130–250 m g^{-1} for cereals [35–37]. Root tissue density (root weight (RW): root volume (RV)) is highly correlated with root life span but inversely correlated with root expansion [38, 39]. So low RW: RV will may be one strategy to increase SRL of crop root systems [40] and potentially resource acquisition. Specific root length is a complex parameter that is determined by root length, tissue density, and diameter. It influences plant investment in potential resource acquisition (RLD) but also reflects root longevity and root growth rate, and therefore it is of potential interest as a selection criteria in breeding programs for optimized root systems. Maximizing SRL seems to be an advantage particularly in water- and nutrient-limited conditions [39, 41] and is associated with higher RLD. Intuitively, thinner roots would be advantageous for acquiring soil resources, though there may be trade-offs with other root functions such as anchorage, support, and transport [42]. The interrelationships between these root traits and their relations with resource capture are summarized in Fig. 1. Additionally, there are reported effects of root diameter on resource capture, which has been shown to be highly correlated with plant dry mass [43, 44] and the diameter of conducting vessels. The principal root traits described above may be influenced by abiotic stresses during the rapid phase of root growth and expansion in the pre-flowering period with implications for resource capture during later seed filling, and these effects are now considered in the following section of this entry.

Effects of Abiotic Stress and Root Development

Drought and Root Development

Drought overall usually reduces the size of root systems. Water deficits decrease carbon assimilation by the plant due to a reduction of green leaf area, but also due to a decline in net photosynthetic rate. Nevertheless, under drought plants tend to increase the proportion of total carbon allocated to the roots [25, 45]. For example, plants responded to water deficits by

increasing the proportion of assimilate allocated to roots in wheat [46, 47] and barley [48]. Experiments using pulse-labeled 13C in wheat have shown that water deficits increase the allocation of assimilated C to the roots due to a greater reduction of growth in the above-ground than below-ground plant components [49]. Although the relative root dry mass tends to increase with water deficits the absolute weight of both roots and shoots tends to decrease. As the soil dries, there are changes in its physical condition such as increases in soil strength [50]. Shoots are generally more affected by drought than roots, associated with more severe water deficits developing and persisting longer in the transpiring shoots [49, 51, 52]. Thus, roots are typically prioritized during drought to facilitate access to water while decreasing transpiration. The relationship between these two systems is often described as a competition where both roots and shoots compete for carbohydrates, minerals, and water, the most successful being the one nearer the source [24]. Therefore, the growth of the root and shoot systems is an integrative process working in a functional equilibrium [53, 54]. So when light is limited, root growth will be more restricted than shoots and the opposite happens when soil resources are in deficit; this functional balance hypothesis is elegantly explained by Brouwer [24]. In addition, under water-limiting conditions, solutes may accumulate in the root tip attracting the movement of water by diffusion, allowing the cells in the root tip to maintain their turgor and growth [55].

Although water deficits typically increase the percentage of carbon allocated to the roots, there are some reports of contrasting responses of root partitioning to drought amongst cultivars, for example, in glasshouse- [52] and field-grown wheat [56]. Therefore, the root growth response under drought is not simple, since drought not only affects plant and root growth but also the soil structure and N availability [57]. For example, water deficits may have a neutral effect on root weight, but still influence root length and its distribution with depth in wheat [47]; or increase SRL with drought in bread wheat [58] and durum wheat and barley [59]. There is some evidence that thinner roots may themselves be more vulnerable to drought [44, 60]. Therefore, the relatively high diameters reported for irrigated compared to droughted plants [58, 61] might relate to the necessity of the root system to support a larger plant and facilitate faster and greater water uptake and transport in well-watered conditions.

Leaf expansion and senescence are particularly susceptible to water deficiency [62]. The causes for restricted leaf expansion with drought have been discussed extensively, and there are mainly two views on the underlying mechanisms involved. Some authors attribute the cause to water relations (water potential and cell turgor) in the leaf [63, 64], while others attribute it to root chemical signals, such as abscisic acid (ABA), transmitted to the leaves, in response to water depletion in the soil [65–67]. ABA concentration increases in shoots, leaves, and roots in plants grown under water deficits and its exogenous application on well-watered plants mimics many of the drought effects on the plant [68, 69]. The chemical mechanism involves the synthesis of the plant hormone ABA by the roots when sensing the drying of the soil, and the transfer of ABA in the xylem to shoots and leaves inducing stomatal closure hence reducing water uptake and shoot and leaf growth [68, 70–72].

Evidence for water relations as the main cause of the decrease in leaf expansion was described by Boedt & Hensley (1987 in [63]) where leaves of field-grown maize showed visual symptoms of water stress in soil near field capacity. Tazaki et al. (1980 in [63]) in Japan reported similar effects for rice leaves, even though plants were rooted in wet soil. Furthermore, seedling experiments in maize plants using the pressure-pump technique [64] showed that an increase in the water pressure in the roots was quickly and fully transmitted to the base of the leaf increasing the leaf elongation. In contrast with these findings, Passioura [66] growing wheat seedlings in drying soil but maintaining leaf turgidity using the pressure-chamber method, showed a decrease in the relative expansion rate of leaves. Additional evidence for the root chemical signal was given by Gollan et al. [73] where wheat and sunflower plants showed a decrease in stomatal conductance with an increase of water deficits while the pressure in the plant was maintained. Using partial root-zone drying (PRD) techniques where half of the root system is droughted while the other half is irrigated, to maintain the same leaf water status as control plants (full irrigation), results showed a decrease of 65% of leaf area and 70% of water loss in apple plant seedlings subjected to PRD [67].

A more recent hypothesis is that both hydraulic and chemical signals interact and that the importance of one or the other will depend on the timescale considered [74]. Experiments in maize and barley showed that sudden changes in leaf water status by light, humidity, or salinity greatly affect leaf-elongation rate, and that those effects vanished when their roots were placed in a pressure chamber to maintain the xylem and air pressures in equilibrium, showing that hydraulic relations dominated in this response [75]. If the saline or water stress was prolonged, water relations were overridden by chemical signals and pressurization failed to maintain leaf elongation rates [75]. The combination of hydraulic and chemical factors was also demonstrated by differences in the sensitivity of different maize lines under drought to xylem ABA [76].

Nutrients and Root Development

It is well established that plants respond to N and P deficiencies by increasing RMR due to the functional equilibrium between the growth of the root and shoot [24, 77–81]. Crop root systems are plastic and respond by proliferating roots to exploit patches of nutrients where the distribution within the soil is uneven [82]. For example, responses to aqueous fertilizer in wheat have been observed within 24 h of application [83]. Frequently there is a strong association between root length and P uptake. Root proliferation in P-rich patches is, therefore, relatively straightforward to interpret in terms of a "foraging" response. The responses of roots to N- and P-rich patches of soil include proliferation of laterals and stimulation of nutrient inflow (uptake rate per unit root length) within the patch [81]. Nitrate uptake from a N-rich patch may compensate for an uneven supply of nitrate to the whole root system. Localized N application on barley seminal root systems promoted the number and extension rate of both first- and second-order lateral roots [84]. The potential magnitude of the responses to N and P has been demonstrated in barley by Drew and Saker [85, 86]. With regard to genetic effects, Zhang and Forde [87] demonstrated that, in Arabidopsis, the extension of lateral roots in nitrate-rich patches is partly under genetic control. Since irrigation and N fertilizer can cause root proliferation in the surface soil [47, 88], the distribution of the availability of these resources earlier in the crop's growth may alter the relative distribution of roots with depth (β) at anthesis.

For two barley varieties grown in Mediterranean field conditions, RMR increased under low N and P fertilizer supply compared to a control treatment with ample N and P supply [89]. Herrera et al. [90] in wheat showed that high N supply increased the number of roots, and when N was limited root formation ceased earlier. Barraclough et al. [47] observed an increase in RMR with low N supply in N x drought field experiments in winter wheat in the UK. N application effects on SRL are inconsistent, and increases, decreases, or neutral effects are reported for different species [44, 91]. Field experiments on spring barley and durum wheat in Jordan showed no consistent response for SRL for three different levels of N fertilizer [59]. SRL increased with N application under rain-fed conditions for durum wheat, but the opposite was found for spring barley. There appear to be few previous investigations regarding the effects of N fertilization on SRL and its components in cereals in field conditions. N application has been observed to increase mean root diameter in cereals but to decrease RW:RV [44, 91].

Root Traits and Resource Capture

The primary root traits for improved below-ground resource capture would appear to be root morphology (root axis number, rooting depth, rooting length density), root extension rates, root longevity, and root function along the length of the root system [9, 92, 93].

Water Capture

The importance of water for plants is unquestionable; it performs a varied number of physiological and structural functions. Water constitutes on average 80–90% of the fresh weight of herbaceous plants providing a continuous liquid phase in which gases, minerals, and other solutes enter the cells and move from one cell to another and within the different plant organs [94]. Water is a reactant or substrate in most of the plant's biochemical reactions (e.g., photosynthesis) and it maintains the plant turgor essential for cell growth, enlargement, form and movement of various plant structures, like the stomata opening [8, 94].

Crop production is closely related to water transpired; therefore, maintaining an uninterrupted supply

of water to leaves is essential to maximize yields. Water capture is intimately related with root size, usually measured, as surface area, volume, or length. According to the theoretical model of van Noordwijk [95], the rate of water uptake by the plant is mainly limited by the transport in the soil toward the root (soil–root interface). Therefore, the density of roots, measured as length per unit soil volume (root length density – RLD, cm cm^{-3}), is the most suitable parameter to describe water uptake by plant roots. Prolific root systems are more effective at capturing water than sparse systems, but inter-root competition sets a natural ceiling on optimum RLD in cereals, above which further increases require excessive roots which do not have measurable effects on water uptake [95]. Theoretical calculations predict a critical root length density (C_{RLD}) of about 1 cm cm^{-3} for water uptake. This figure broadly concurs with the values reported for water uptake of Gregory and Brown [96] and Barraclough et al. [47] who showed that a RLD of 1 cm cm^{-3} was associated with the abstraction of all of the available water by both spring barley and winter wheat, respectively. However, for upland rice, values of C_{RLD} between 1.5 and 1.6 cm cm^{-3} have been reported [97, 98] and in controlled environment conditions values as low as 0.30 cm cm^{-3} [99].

RLD distribution with depth is principally determined by time for growth (residence times are greater in the topsoil than the subsoil), soil porosity and strength, and water availability [20]. Root length density in wheat is typically below the C_{RLD} of ca. 1 cm cm^{-3} at soil depths below ca. 80 cm [18, 21, 36, 100]. A modeling study concluded that distributing roots relatively deeper in the soil profile and decreasing SRL would confer greater water capture and yield under low water availability in wheat [30]. Experimental evidence also supports the strategy of distributing roots relatively deeper to improve water capture under drought. Synthetic derivative wheat lines showed increased water uptake associated with a root system that was distributed relatively deeper in the soil compared with recurrent parents [10], and the drought tolerance of spring wheat SeriM82 was related to its relatively deep root system compared to the check cultivar Hartog [101]. Further root traits which could be beneficial in boosting water capture include enhanced post-anthesis root longevity and root penetration ability [102], although there is relatively little information on genetic variation in these traits in cereals.

In rice under flooded conditions, attempts to optimize the root system through plant breeding methods must additionally allow for the complicated interplay between adaptations for internal aeration and those for efficient nutrient acquisition. A recent model developed by Kirk [103] provides a coherent representation of the rice root system in submerged soil and predicted that a system of coarse, aerenchymatous primary roots with gas-impermeable walls conducting O_2 down to short, fine, gas-permeable laterals provided the best compromise between the need for internal aeration and the need for the largest possible absorbing surface per unit root mass.

Nutrient Capture

Water and nutrient uptake should really be considered together since nutrients become less available as the soil dries. Nitrate is readily leached down the soil profile and consequently rooting depth is an important attribute for soil N acquisition. For a long time, due to its high mobility in soil, N supply was considered independent of the root system characteristics, assuming that only mass flow and diffusion were the relevant mechanisms for the uptake of N by the plant [90]. The role of crop root systems in capturing N is still a topic of debate. Findings of Robinson et al. [104] indicated only 4–11% of the total root length is involved in N uptake. On the other hand, Palta and Watt [9] demonstrated through 15N labeling experiments on wheat that vigorous root systems captured ca. 60% more N in the top 0.2 m of the soil profile than non-vigorous root systems. Furthermore, a positive correlation was found between nitrate and water uptake and root length density in maize [105–107] and in several catch crop species [108]. These studies indicated that greater root length densities are generally more effective in N acquisition. However, root length is probably more important for the uptake of relatively immobile ions such as phosphates [109, 110]. However, some investigations have found uptake rates of phosphate, calcium, and potassium from solution are poorly related to root length [111, 112], possibly because root length is only significant if the uptake of these nutrients is limiting [7]. In addition, several

investigations have shown that nitrate capture depends on the ability of the root system to respond to spatial and temporal nitrogen supply [81, 113].

The ability to capture N depends mainly on the amount of nitrate present in the soil relative to the morphology of the root system. Nitrate is supplied to the root system by mass flow (ions carried along in the transpiration stream) and diffusion (ions moving down a concentration gradient, either through bulk soil water or along water films surrounding particles). About 50% of the N taken up by wheat crops may be transported by mass flow [16]. As for water uptake, inter-root competition sets a natural ceiling on optimum RLD in cereals of about 1 cm cm^{-3} [95]. RLD distribution with depth is principally determined by time for growth (residence times are greater in the topsoil than the subsoil), soil porosity and strength, and nutrient and water availability [20]. The modeling study of King et al. [30] concluded that distributing roots relatively deeper in the soil profile and increasing SRL would confer greater N capture and yield under low N availability. The particular properties of each nutrient in the soil impose different RLD requirements for effective uptake. For example, due the low mobility of phosphorous (P) in the soil, a higher RLD of ca. 10 cm cm^{-3} is required for effective P uptake compared to water and/or nitrogen [114, 115]. Similar to water uptake, root traits that could be beneficial in boosting N capture include enhanced root longevity post-anthesis and root penetration ability [102], although there is relatively little information on genetic variation in these traits in wheat. Barraclough et al. [47] in N × drought field experiments in winter wheat in the UK found that water uptake increased with N due to a higher RLD and higher ground cover reducing soil evaporation. Positive correlations between nitrogen capture and RLD have also been found in maize [106, 107] and durum wheat and barley [59]. Although higher N supply tends to increases total RLD and N uptake by the crop, this generally results in a decrease in N uptake efficiency (crop N uptake/N available) [116, 117] leading to potentially greater losses of nitrate to the environment. A recent modeling exercise suggested that higher RLD and deeper rooting depths would reduce residual nitrate in high leaching soils [118]. Forde & Clarkson [119] concluded that there was no strong evidence for significant age-dependent changes in capacity of roots to absorb nitrate or ammonium ions.

Nutrient uptake may also be influenced by root membrane transporter systems. With regard to N uptake, recent work in *Arabidopsis* indicates nitrate is actively transported across the plasma membranes of plant cells, but net uptake is a balance between active influx and passive efflux. Two distinct gene families of nitrate transporters, *NRT1* and *NRT2*, have been identified [119–122] in the *Arabidopsis* genome. Some members of both *NRT1* and *NRT2* gene families are nitrate inducible, and are expressed in the root epidermis and in root hairs, and are likely to be responsible for the uptake of nitrate from the soil (e.g., [123–126]). There are prospects for transferring this information to wheat for improving efficiency of N uptake in the long term if the root screens used for *Arabidopsis* could be adapted to the larger and structurally different root system of wheat. An extensive review of this area is beyond the scope of this entry. Fortunately, excellent reviews are recently available in this topic area [127, 128].

With regard to the carbon costs of roots, it seems there is likely only a limited capacity to reduce root partitioning below current values of ca. 10% at anthesis in cereals in high yield potential ideotypes, due to the trade-off with water and N capture required for future biomass gains. However, a deeper relative distribution of roots while maintaining RMR could comprise part of an ideotype to maximize yield in future breeding programs.

Application of Rooting Traits in Breeding for Tolerance of Abiotic Stresses

Genetic variation in root system size has been widely reported in grain crops (e.g., [6, 45, 129]), but root distribution varies strongly with soil characteristics such as water and nutrient availability and mechanical impedance [54]. The RMR of wheat or barley is typically ca. 30% during early vegetative growth decreasing to ca. 10% by anthesis [18, 96, 130]. Effects of increasing plant height on root partitioning have been studied using isolines and are generally either neutral or negative in wheat [22, 130–132].

Breeding cultivars better adapted to particular conditions of drought and/or low nutrient availability will play a major role for the future of crop production for

adaptation to climate change. Breeding for more effective use of water or nutrients while maintaining, or ideally, increasing yield potential is a difficult task. It will be important in the most efficient crop systems to combine optimized agronomy and new cultivars efficient at acquiring below-ground resources. To date there are relatively few examples of root morphological or anatomical traits that have been successfully selected for crop breeding programs to result in improved performance. In a recent review on this topic, Palta and Watt [9] cited five examples of rooting traits directly related to below-ground resource capture in breeding, including long root hairs for increased P uptake in barley [12], reduced xylem vessel diameter in seminal roots of wheat [13], and increased root density at depth through faster root extension rate in wheat [133]. In addition, improved resource capture has been achieved by alleviating other stresses on roots, for example, resistance to cereal cyst nematode in wheat [134]. Another encouraging example of introgression of rooting traits in crop breeding can be found in rice. When near isogenic lines (NILs) obtained through marker-assisted backcrossing for four QTLs for root length were field-tested, they outperformed the recurrent parent for yield and biomass [135]. In order to introgress rooting traits into elite genotypes, it will be necessary to identify genetic diversity for the key traits as well as developing methods for rapid high-throughput screening of lines in breeders trials.

Field phenotyping methods for roots in cereals were reviewed by Manske et al. [136] and Polomski and Kuhn [137], including the use of rhizotrons and assessments of root parameters from soil cores (root washing and root counts/image analysis). Although several screening tests have been designed to generate accurate and robust data from seedling plants grown under artificial conditions, these phenotypes can rarely be extrapolated to field conditions because of the pronounced plasticity of root growth and development processes [138]. Field phenotyping for root traits in breeding programs is currently infeasible, so genetic progress will depend on the development of high-throughput controlled-environment screens or molecular markers for root traits for marker-assisted selection (MAS). The use of root-observation chambers and a nondestructive digital imaging technique offers some promise [139], but may be less suitable for screening of root traits that are expressed at later stages of crop development.

Future Directions

The existence of significant genetic variation for rooting traits has not resulted to date, except for a few exceptions as mentioned above, in the incorporation of rooting traits in conventional breeding. Nevertheless, future genetic progress for resistance to abiotic stresses should be accelerated by the fact that the genetic control of rooting traits can now be revealed through the application of rapidly emerging genetic resources facilitating the fine mapping of root QTL. Indeed, the cloning of the first root QTL is ongoing. However, successful exploitation of genomics tools and strategies in plant breeding requires extensive and precise phenotyping of agronomic traits for breeding materials and mapping populations. The capacity for precise phenotyping under reliable conditions probably represents the most limiting factor for the progress of genomic studies on root traits underlying resilience to abiotic stresses. There is a need for a high precision because the differences may be small, and detailed physiological measurements (e.g., of growth rate) are difficult when a large numbers of genotypes are involved.

Physiological perspectives that require more attention are analyses to measure the full carbon costs of the turnover of root material (and therefore of the root system), which are presently poorly quantified especially in environments where soil stresses are common. The role of organic substances in the rhizosphere secreted by the root that are able to modify the environment to secure improved water uptake requires more attention. Future research should focus on the importance of root plasticity for nutrient capture rather than simply measuring the size of the response. More studies at the plant community level rather than on single plants are required to translate fundamental studies on root growth and function to the improved water and nutrient capture at the crop scale.

Additionally, future work should aim to address the potential use of marker-assisted backcrossing for root QTLs and to exploit findings in *Arabidopsis* where root screens for mutants have identified genes such as AUX1 and LAX3 that regulate important root architectural

traits such as lateral root development [140]. There is a continuing need to integrate "omics" technologies with plant physiology, agronomy, breeding, and disciplines related to the rhizosphere. In the future to meet the challenge of raising biomass and yield potential as well as improving resilience to abiotic stresses it will be crucial that new root research fosters collaborations between breeders, geneticists, physiologists, crop physiologists, and soil scientists (among others) to translate the genetic data generated from the new genomics resources into improved crop performance.

Article Outline

Glossary

Algae A group of autotrophic organisms, containing chlorophyll a and sometimes other accessory pigments, which are able to convert solar energy into chemical energy via photosynthesis.

Aquaculture The farming of autotrophic and heterotrophic organisms in aquatic systems.

Bioextraction An environmental management strategy by which nutrients are removed from an aquatic ecosystem through the harvest of enhanced biological production, including the aquaculture of suspension-feeding shellfish and/or marine macroalgae.

Ecosystem Is the grouping of all living organisms occupying a particular unit of space and interacting with each other and their environment.

EPA Eicosapentaenoic acid is an omega-3 polyunsaturated fatty acid, sometimes presented with the chemical notation 20:5(n-3).

HDL High-density lipoprotein; composed of a high proportion of protein and relatively little cholesterol; high levels of HDL are thought to be associated with a decreased risk of coronary heart disease and atherosclerosis.

Heteromorphic life histories Life histories in which there are clear morphological differences between the different stages of the life cycle, i.e., individuals of the sporophyte and gametophyte stages are morphologically different and distinguishable. In some cases, such as the genus *Porphyra* and members of the kelps, there are macroscopic and microscopic stages alternating life cycle phases.

IMTA Integrated Multi-Trophic Aquaculture is a form of aquaculture in which organisms from different trophic levels, with complementary resource needs, are produced in the same system. Typically, these aquaculture systems integrate the production of a fed organism, such as fish or shrimp, with that of extractive organic aquaculture such as shellfish and the extractive inorganic aquaculture of seaweed.

Isomorphic life histories Life histories in which there are no distinguishing morphological differences between the different stages of the life cycle, i.e., the individuals of the sporophyte (diploid, 2n) and gametophyte (haploid, n) stages are morphologically identical and can be distinguished only when their respective, characteristic reproductive structures are present, e.g., *Chondrus crispus* and *Palmaria palmata*.

LDL Low-density lipoprotein; a lipoprotein that transports cholesterol in the blood, composed of a moderate amount of protein and a large amount of cholesterol; high levels of LDL are thought to be associated with an increased risk of coronary heart disease and atherosclerosis.

Macroalgae A group of macroscopic algae of which at least one part of their life history is multicellular and visible with unaided eye.

Mariculture Farming of autotrophic and heterotrophic organisms in marine systems, i.e., using seawater.

Polysaccharides Complex structural polymers. They have a structural function in the alga but may be

P. Christou et al. (eds.), *Sustainable Food Production*, DOI 10.1007/978-1-4614-5797-8,

Robert A. Meyers (ed.) Encyclopedia of Sustainability Science and Technology, © 2012, DOI 10.1007/978-1-4419-0851-3

extracted industrially to provide a range of polysaccharides used for their rheological properties, e.g., agar, carrageenan, and alginic acid.

Seaweed A group of macroscopic, marine autotrophic algae.

Sea-vegetables A group of macroscopic, marine autotrophic algae, also called seaweeds, seaplants, or macroalgae; they may be used as vegetables for human consumption or raw materials for a range of industrial, commercially important extracts such as bioactives or polysaccharides.

Definition of the Subject and Its Importance

The production of seaweeds for human foods in land-based aquaculture, is an activity poorly presented by the scientific community. Of the thousands of seaweed species identified, a remarkably small subset is actually farmed in the marine environment (i.e., open water) and even fewer are grown in land-based aquaculture systems. Of those that are used in land-based systems, most are monocultures grown for specific high value uses. For instance, *C. crispus, P. palmata*, and *Saccharina latissima* are grown for human consumption; *Chondrocanthus* and the "*Trailiella*" stage of *Bonnemaisonia/Asparagopsis* for the cosmetic industry; and *Gracilaria* spp., *Palmaria* and *Ulva* spp. as feed for abalone). Given the many centuries history of terrestrial production of land plants for human and animal feed crops and the tremendous efforts given over to the selection and crossbreeding of these plants, by contrast, selection and improvement of seaweed crops is very much in its infancy. Even more so, of all the relatively small number of seaweeds which are domesticated for open water cultivation, even fewer species have actually been tested in land-based culture systems. This is in part due to the lack of reliable, domesticated species and their selected strains suitable for the rigors of on-land cultivation, and in part due to the complexities of life histories and the lack of understanding of the environmental regulation of growth. There is, therefore, a need to test other species since open water systems may not be appropriate for niche cultivation applications. The historical development of open water cultivation and multi-species pond cultivation may have originated in Asia (for discussion and references see later section); however, modern land-based aquaculture of seaweeds began with the work of John Ryther at Woods Hole Oceanographic Institute (WHOI) in the late 1960s through the mid-1970s [1]. Land-based Integrated Multi-Trophic Aquaculture systems (IMTA) may contribute to the development of sustainable fed aquaculture systems by minimizing environmental impacts (i.e., removing excess dissolved inorganic nutrients, *d*issolved *o*rganic *m*atter (DOM), and *p*articulate *o*rganic *m*atter (POM). Furthermore, while the systems may yet have to be optimized geographically and in relation to the species utilized, the controlled production of seaweed biomass in these systems may offer a reliable and safe source of food or ingredients for human consumption, fish feeds, as well as a source of valuable compounds for biotechnological applications. As a special focus, this entry will discuss the importance of land-based seaweed aquaculture systems and their global utilization.

Introduction

Seaweed is a popular term used to collectively describe marine macroalgae. Among this large and diverse assemblage of photosynthetic marine organisms are a number of species with a varied array of uses; when used for human consumption, they are more popularly known as "sea-vegetables." This collective of convenience includes the macroscopic, multicellular, red, green, and brown algae [2]. Seaweeds are often abundant and predominantly found in the near-shore marine ecosystems in all the oceans of the world. As a result of their diverse intercellular compounds including alginic acid, carrageenans, and agar, seaweeds have very important industrial applications [3, 4]. Being important primary producers in marine ecosystems, macroalgae are an integral component of near-shore environment and form a fundamental part of the basis of the photosynthetic food chains, playing a role similar to that of terrestrial plants [5]. In these natural environments, seaweeds often perform a large number of ecosystem services [6] (e.g., nurseries, nutrient cycling, and reduction of coastal erosion among others), which are neither fully costed nor often appreciated by the public or users of the marine environment. Humans have wild harvested (sometimes called "wild crafting") and cultivated seaweeds for several centuries for animal and human consumption

as well as other applications including valuable sources of phycocolloids and most recently, researched as feedstock for biofuels and carbon sequestration [7–11].

Some seaweeds may attain lengths exceeding 90 m or more (e.g., the kelp *Macrocystis pyrifera*), while others may grow only a few centimeters per year. Many seaweeds have isomorphic life cycles (e.g., *C. crispus, P. palmata*, where the gametophyte and sporophyte generations are morphologically similar), while others have heteromorphic life histories (e.g., the genus *Porphyra* and many species of brown algae including the kelps, where the generations are morphologically distinct). The morphology of various seaweeds may include multicellular, highly differentiated kelp with their organs such as blades, complex stipes, and their anchoring structure referred to as haptera. Other multicellular seaweeds may be small and bushy with flat or cylindrical axes (*Gracilaria*), while others may form sheet-like specimens of one or two layers of cells thickness (*Porphyra*, *Ulva*, *Monostroma*). Some macroalgae may be encrusting forms, while yet others may have the ability to precipitate calcium carbonate to varying degrees and be lightly calcified yet remain flexible (e.g., *Padina*) or fully calcareous and occur as prostrate crusts (e.g., *Lithothamnion*, *Phymatolithon*) or fully articulated, e.g., many coralline species such as *Corallina* and *Jania*.

This entry will discuss the advantages for land-based aquaculture of seaweeds for human foods and animal consumption. The first section gives a brief introduction to seaweed uses, both past and present, followed by an introduction as to how seaweed aquaculture has been practiced more recently. Section "Introduction of the IMTA Concept" briefly explains the concept of integrated multi-trophic aquaculture (IMTA), since this can also be an integral component of land-based seaweed aquaculture systems. Section "Physiological Considerations for the Production of Seaweeds in Land-Based Cultivation Systems" presents some of the particularities of intensive, land-based seaweed production, which make it different from the more common extensive, open water seaweed mariculture. Section "Examples of Successful On-Land Cultivation Enterprises" presents success stories of land-based seaweed aquaculture. The entry concludes with a discussion of the potential impacts of the development of land-based seaweed aquaculture as well as future directions and perspectives of research in this area.

Past and Present Uses of Seaweeds

Seaweeds have been used in the human diet since ancient times. Although Asian food culture has seen the most prominent use of seaweed for direct human consumption, there is also recent evidence of the use of seaweeds by prehistoric humans, in other parts of the world. Dillehay et al. [12], in an archeological study conducted in Monte Verde, southern Chile, identified remains of nine species of marine algae, including *Durvillaea antarctica* ("cochayuyo"), *Porphyra* sp. ("luche"), *Gracilaria* sp. ("pelillo"), and *Sargassum* sp. These authors also suggest that some algae may have been burned, suggesting that they had been dried to facilitate transportation and/or storage, or were even cooked and could have been used for their medicinal properties as well. Erlandson et al. [13] discussed the cold water, coastal fringing kelp beds on the Pacific Coast of the Americas as being a route, or a "highway," by which early travelers made their way in northerly and southerly migrations. In Asian and Pacific Island countries, the tradition is to consume seaweeds as raw or cooked sea vegetables [14–16]. In Western countries, the principal use of seaweeds has been as a source of phycocolloids (alginate, carrageenan, and agar) which are structural, thickening, and gelling agents for various industrial applications, including uses in textile, paper, food, toothpastes, shampoos, cosmetics, and pharmaceutical industries [3, 4].

There is presently an increasing interest by the general public regarding the impacts of the human diet in general health and the potential health benefits in the consumption of selective seaweeds in a varied human diet. In fact, the physiological or pharmacological functions of food factors were classified as the third function of food in addition to the nutritional and sensory roles as the primary and secondary function, respectively [17, 18]. Among the bioactive compounds known to have an impact in the human health, there are those described as prebiotic functional ingredients. These are defined as nondigestible, selectively fermented compounds that stimulate the growth

Seaweed Aquaculture for Human Foods in Land-Based and IMTA Systems. Table 1 Some examples of seaweeds with their functional ingredients and possible effects on human health (Adapted from Plaza et al. [20]; Kumar et al. [21], Bocanegra et al. [22])

Seaweed	Functional ingredient	Possible health benefits
Sargassum vulgare (B)	Alginic acid, xylofucans	Antiviral activity
Himanthalia elongata (B)	PUFAs	Reduce risk of certain heart diseases
	α-Tocoferol	Antioxidant activity
	Sterols	Reduce total and LDL cholesterol
	Soluble fiber	Reduce total and LDL cholesterol
U. pinnatifida (B)	PUFAs	Reduce risk of certain heart diseases
	Sterols	Reduce total and LDL cholesterol
	Soluble fiber	Reduce total and LDL cholesterol
	Folates	Reduce risk of certain types of cancer
	Sulfated polysaccharides	Antiviral activity
	Fucoxanthin	Preventive effect on cerebrovascular diseases; Increase the metabolism
Porphyra spp. (R)	PUFAs	Reduce risk of certain heart diseases
	Sterols	Reduce total and LDL cholesterol
	Soluble fiber	Reduce total and LDL cholesterol
C. crispus (B)	PUFAs (n-3) fatty acids	Reduce risk of certain heart diseases
	Sterols	Reduce total and LDL cholesterol
	Soluble fiber	Reduce total and LDL cholesterol
Cystoseira spp. (B)	Terpenes	Valuable curative properties
	Sterols	Reduce total and LDL cholesterol
	Sulfated polysaccharides	Regulate the bioactivity of growth factors and cytokines
Ulva spp. (G)	Sterols	Reduce total and LDL cholesterol
Grateloupia filicina (R)	"methanolic extract"	Antioxidant activity
Brown algae (non specified)	Phlorotannins	Detoxification of heavy metals; antibacterial effects
	Fucoidan	Anti-inflammatory, anticoagulant
Colpomenia sinuosa (B)	Fatty acid profile (ω-3)	Increase HDL cholesterol
Hypnea charoides (R)	Fatty acid profile (ω-3)	Decreased LDL cholesterol
A. nodosum (B)	Sodium-binding fiber	Antihypertensive effects

R red, *B* brown, *G* green seaweed

and/or activity of beneficial gut microbiota which, in turn, confer health benefits on the host [19].

Due to their varied nutritional properties, seaweeds are the subject of research seeking new, natural sources of functional ingredients for food. Table 1 presents a summary of that information [20–22]. *Porphyra*, for instance, contains high levels of protein (25–50%), vitamins (higher vitamin C than in oranges), trace minerals, and dietary fibers [23]. This alga contains nearly 17 types of free amino acids, including taurine

which controls blood cholesterol levels and is thought to prevent obesity [24, 25]. Several reviews have been published outlining the nutritional properties of seaweeds (e.g., [21, 22, 26]), the most recent of which include the comprehensive review of Holdt and Kraan [27] and another on antioxidants from macroalgae by Cornish and Garbary [28]. The review of Holdt and Kraan [27] is particularly valuable since it also details the regulatory environment affecting marketing and use of active compounds from seaweeds in human applications. On the other hand, Cornish and Garbary [28] consider the application of seaweed antioxidants in foods, food supplements, nutraceuticals, and medicine from the perspective of benefits to human health. The review provides examples not only from laboratory studies but also from clinical trials where antioxidants derived from seaweeds may provide major health benefits that warrant subsequent investigative studies and possible utilization. Furthermore, those authors advocate that the direct consumption of seaweed products for their antioxidant composition alone provides a useful alternative to nonnatural substances, while simultaneously providing worthwhile nutritional benefits. Finally, the review by Cornish and Garbay [28] includes a comprehensive listing of algal species evaluated for antioxidant activity and potential applications of detected compounds.

Burtin [26] elaborates upon the nutritional value of seaweeds as they are rich in polysaccharides and dietary fibers, minerals, proteins and amino acids, lipids and fatty acids, and micronutrients such as vitamins (vitamin B_{12}, C, and E) and polyphenols (phlorotannins). This author concludes that from a nutritional standpoint, the main beneficial properties of seaweeds are their high mineral (iodine, calcium) and soluble dietary fiber contents, the occurrence of vitamin B_{12} and specific components such as fucoxanthin, fucosterol, and phlorotannins. Burtin also states that seaweeds can be regarded as an underexploited source of health-promoting molecules for food processing and the increasingly important nutraceutical industries [26].

Kumar et al. [21] reviewed the presence and value of various bioactive substances which may be derived from certain seaweeds, namely, polysaccharides and related compounds; proteins and related substances; lipids and related compounds; minerals; vitamins and antioxidant compounds. These authors concluded that seaweeds are a low calorie food source, particularly from the nutritional point of view, since they have high concentrations of certain minerals, vitamins, proteins, and indigestible carbohydrates. Seaweeds also have low lipid content, but the lipids present are of a high quality in terms of their nutritional value. In fact, Blouin et al. [29] suggested that native, Atlantic species of *Porphyra* such as *Porphyra amplissima* and *Porphyra umbilicalis* have potential in foods for North American consumers. They analyzed the fatty acid content of freshly collected *P. umbilicalis* and reported that eicosapentaenoic acid [EPA; 20:5 (n-3)] and palmitic acid were the most common fatty acids. Those authors reported that the concentration of fatty acids found in wild collected *P. umbilicalis* (i.e., 3.2 mg EPA g dry wt^{-1} or 74 mg EPA 100 g fresh wt^{-1}) was not high enough to make this a primary source of daily omega-3 fatty acids, but the favorable n-3/n-6 ratio (2–3:1) in these species constituted an interesting nutritional value. In their review, Kumar et al. [21] concluded that the quality of protein and lipids in seaweeds generally is as acceptable as those present in other dietary vegetables due to high content of essential amino acids and relatively higher levels of unsaturated fatty acids. Furthermore, all of these authors suggested that seaweeds exhibit antioxidant, antimutagenic, anticoagulant, anticancer, and antitumor activity. In many cases, these properties were actually tested and proved in vivo and in vitro, as follows. Zhang et al. [30] showed that a sulfated polysaccharide fraction from *Porphyra haitanensis* could be used to compensate the decline in total antioxidant capacity and activities of antioxidant enzymes. The implications of these findings are that seaweeds and their extracts might play a role in retarding the aging process. In addition, unprocessed powder from the brown seaweed *Fucus vesiculosus* has proven to have strong antioxidant capacities [31]. The authors concluded that the polyphenol (phlorotannin) content of *F. vesiculosus* seemed to provide the main antioxidant properties. Other research using polysaccharides extracted from *Porphyra yezoensis* demonstrated anticoagulant [32] and immune-stimulating activities [33, 34]. Saito et al. [34] showed that *Porphyra* peptides induced a significant reduction in the blood pressure of hypertensive human patients. Various fucoidans, common sulfated polysaccharides of various commercially important brown algae, have been tested

in several studies in rats and in humans, showing beneficial effects as an anticoagulant, antithrombotic, antiviral, and anticancer agent ([35, 36]; see also www.marinova.com). Anticancer properties of seaweeds are also reported in the studies of Teas et al. [37] and Yang et al. [38] among others. In particular, the results of Teas et al. [37] suggested that a diet containing 5% brown seaweed (i.e., *Laminaria*) was effective in delaying the time for chemically induced tumor development in rats. In turn, Yang et al. [38] investigated the association between the intake of *Porphyra* (red seaweed) and *Undaria* (brown seaweed) and the risk of breast cancer, in a case-control study. The authors concluded that the consumption of *Undaria pinnatifida* did not have any significant associations with the disease but the results also suggested that high intake of *Porphyra* may decrease the risk of breast cancer.

Bocanegra et al. [22] reviewed the major physicochemical properties of seaweed fiber, the nutritional properties of the seaweed, and their value as functional foods. In terms of physicochemical properties of the fiber, the authors highlighted the hydration properties and viscosity, the oil retention and fat absorption, the fermentability, and binding capacity (cation-exchange capacity responsible for heavy metal biosorption). As for the nutritional properties of the seaweed, Bocanegra et al. [22] pointed to numerous studies that demonstrated the chemical and nutritional importance of the seaweed, namely in relation to bioavailability, effect on growth and body weight, effects on digestion, excretion and gastrointestinal functions, effects on lowering cholesterol and blood pressure, antioxidant activities and effects on glucose metabolism. Those authors concluded, however, that although some antioxidant compounds are present in algae, other compounds that are also present, such as the arsenic (As), can induce a poor endogenous antioxidant status. Therefore, the use of marine algae in herbal medications or excessive consumption of some of these organisms requires some caution. As with all things, seaweeds should be consumed in moderation as part of a well-balanced diet. Bocanegra et al. [22] also highlighted that, at that point there were no data available on the changes that cooking (e.g., microwave oven, traditional oven, frying, boiling, etc.) might impact on the properties of algal constituents. It is clear that much more work remains to fully realize the full nutritional and health-promoting potential of the consumption of seaweeds. These authors also illustrated that although numerous beneficial health properties can be attributed to seaweed components and extracts, robust studies of potential functional foods containing seaweeds have yet to be carried out, namely, the determination of different matrices affecting their technological and nutritional properties. The points raised by Holdt and Kraan [27], regarding the requirements of various food regulatory agencies, particularly with regard to novel foods and ingredients, should also be carefully considered.

As marine organisms with unique structural and biochemical compositions, seaweeds could be responsibly exploited for their multifunctional properties in the form of food, energy, medicine and cosmetics, and as biotechnological tools. In recent times, the use of seaweeds in a wide variety of biotechnological applications has become more common. Sahoo et al. [39] and Gantt et al. [40] pointed out the advantages of the use of *Porphyra* as a model organism for both applied and basic research. In fact, part of the genome of *P. umbilicalis* and the transcriptome of *Porphyra purpurea* have been recently released by the Joint Genome Institute (U.S. Department of Energy, www.jgi.doe.gov/genome-projects/ Program CSP2008; see also www.porphyra.org) and made available to the public. The aforementioned authors specifically point to the possibility of establishing several pure lines. In particular, the small genome size, which is estimated to be 2.6×10^8 base pairs consisting of three chromosomes and also the short generation time (1–3 months) of the alga are suitable traits for genetic analysis. The "*Porphyra* Genome" project, currently underway, will be one of the first to sequence the full genome of a multicellular red seaweed species and provide valuable information for biotechnological applications [40]. Other macroalgal genome projects include that of *C. crispus*, likely to be published in early 2011 (Jonas Collén, personal communication) and *Ectocarpus* [102]. As has been experienced with microalgal research (see [41, 42] and references therein), such major advances allow for rapid implementation of genetic engineering techniques that may modify seaweeds, thereby increasing their biotechnology applications. Some caution however needs to be applied to

applications of such techniques. Should these "modified" seaweeds be destined for food or food products, then the necessity to label them as GMO (*g*enetically *m*odified *o*rganisms) sources would actually reduce their market acceptance, particularly in Europe and even increasingly in North America.

Seaweed Aquaculture

The largest database reference for seaweed taxonomy (www.algaebase.org) currently has over 10,000 macroalgal species listed, the majority being seaweeds [43]. Despite the variety of life forms and the many thousands of seaweed species, seaweed aquaculture is presently based upon a relatively very small group of less than 100 species worldwide [7]. In fact, only five to seven genera alone (i.e., *Laminaria/Saccharina, Undaria, Porphyra, Eucheuma/Kappaphycus* and *Gracilaria*) account for about 83% of the world seaweed production (Table 2). The basic cultivation techniques of these genera are described in Yarish and Pereira [7] and Pereira and Yarish [44] and the references therein.

The use of seaweeds for food has strong roots in Asian countries such as China, Japan, and the Republic of Korea. For that reason, these are the primary areas where seaweed aquaculture was first developed and, furthermore, the species of seaweed most cultivated are the ones commonly found from those shores. Tseng [46] defined the commercial cultivation of seaweeds as: "the large scale production of macroscopic marine algae for commercial purposes." Doty [47] applied the term "marine agronomy" to define seaweed cultivation as a type of agricultural practice carried out in the sea.

Despite this analogy, marine agronomy is an activity in its infancy, when compared to the traditional terrestrial agronomy, with obvious differences when we compare the developmental status of both activities. While the origin of marine agronomy can be traced back to approximately 200 years ago, the birth of agriculture is still subject of debate among anthropologists but is thought to have happened approximately 10,000–12,000 years ago [48, 49]. In fact, the presently cultivated seaweeds were selected from local flora (i.e., from the wild) and limited "selection and breeding" techniques have been applied to develop domesticated strains, especially when compared to the efforts placed on staple terrestrial crops such as rice, potatoes, wheat, etc. For the latter, agronomic institutions have developed on various continents, which have specialized in their breeding, selection, and improvement, sometimes even using genetic manipulation.

In China, more than 200 years ago, the first methods to manage a seaweed crop, a species of the red marine alga *Porphyra*, consisted of simply cleaning rocky areas in early autumn. This was done just before the mass liberation of algal reproductive spores, so that they had more surface area for attachment and growth [50]. In Japan, a similar approach consisted of inserting bundles of bamboo twigs into sandy/muddy substrata before the spore release season. Net cultivation methods for mass production of "laver" were only introduced in the 1920s, resulting in some increase in productivity but still reliant on the collection of spores released from natural populations [46]. However, the

Seaweed Aquaculture for Human Foods in Land-Based and IMTA Systems. Table 2 Main seaweed aquaculture production and value in 2008, according to FAO 2010 [45]

Genera	Production (metric tons)	Value	
		(*1,000 USD)	USD/ton
Laminaria (=*Saccharina*)	4,765,076	2,835,558	595
Eucheuma/Kappaphycus	3,551,273	563,146	159
Undaria	1,755,913	749,213	427
Porphyra	1,389,360	1,345,414	968
Gracilaria	1,418,986	600,223	423
Others	2,661,054	1,262,018	474

substantive development of the aquaculture of this genus came with the description of the life cycle of *P. umbilicalis* by Katherine Drew (Baker), in 1949 [51]. Drew established that the filamentous red alga, "*Conchocelis rosea*," until then considered as a completely separate entity, was in fact the sporophyte phase of the life cycle *Porphyra*. This finding, together with subsequent research [51–54], allowed for the development of methods which could control the life cycle and also the artificial production and collection of spores. These were monumental findings allowing the aquaculture of *Porphyra* to move into a completely different phase of technological developments. Modern commercial cultivation methods were established in the 1960s which led to the very pronounced expansion of cultivation activities and economic development. China is currently the largest global producer of *Porphyra*, with more than 800,000 t, fresh weight, produced in 2008, followed by Japan – 337,000 t and the Republic of Korea – 224,000 t [45].

The brown, kelp species, *Saccharina japonica* (formerly known as *Laminaria japonica*), is presently the largest single species produced in aquaculture. It is grown as a monoculture and the volumes of production exceed any other marine species, including fish, crustacea, and molluscs. More than three million tons fresh weight (FW) are reported to be cultivated on ropes in open coastal waters. The cultivation of *Saccharina* was developed mainly during the second half of the twentieth century, initially using a stone planting technique. Since 1968, a method called "forced cultivation" led to a reduction of the previous 2-year cycle of production to 1 year; the shift to modern methods allowed for a tremendous increase in productivity and commercialization of the kelp and its products [46, 55].

The commercial cultivation of all other seaweed species is even more recent than that of *Porphyra* and *Saccharina*. For instance, the cultivation of the red alga *Gracilaria* probably began as recently as 1967 in Taiwan [46]. Seaweed aquaculture or marine agronomy is, therefore, an activity still in its relative infancy, especially when compared to traditional, terrestrial agriculture.

Despite being a recently developed activity, when compared with the traditional land agriculture sector, seaweed aquaculture has been developing steadily. According to the latest production data from FAO [45], in 2008, total seaweed aquaculture production was more than 15 million tons FW (fresh weight), valued at more than seven billion USD. This corresponds to 23% of the world's aquaculture production and approximately 7% of its global value. Besides the undeniable economic value of the biomass, seaweed aquaculture is nowadays also increasingly recognized for the significant ecosystems services it provides, namely through its extractive process of nutrient removal [56–58]. Chopin et al. [59] argued that evolving aquaculture practices will require a conceptual shift toward understanding the working of food production networks as opposed to simplistic and narrow focus on technological solutions. One of the innovative solutions promoted for environmental sustainability, as well as for economic stability and societal acceptability, is the system coined "IMTA" (or **I**ntegrated **M**ulti-**T**rophic **A**quaculture), which will be discussed in more detail in the next section.

Introduction of the IMTA Concept

In western countries, an interest in integrated aquaculture began toward the end of the twentieth century. After the initial work of Ryther et al. [1], interest in using algae as nutrient scrubbers in an integrated aquaculture system was renewed by a group of like-minded scientists including: Fujita et al. [60], Kautsky and Folke [61], Neori et al. [62], Krom et al. [63], Buschmann [64], Sphigel and Neori [65], Troell et al. [66], Chopin and Yarish [67], Neori and Shpigel [68], Yarish et al. [69], Chopin et al. [70] and Neori et al. [71], among others. In the last decade particularly, numerous papers continued to establish that the concept and implementation of Integrated Multi-Trophic Aquaculture (*sensu* [56, 71–73]) was and will increasingly be of paramount importance for the sustainable development of aquaculture. The advantages are not just important for a sustainable environment, as evidenced by Matos et al. [74], Msuya and Neori [75] and Abreu et al. [76], but also economic, as shown by Troell et al. [77], Whitmarsh et al. [78], Robertson-Andersson [79], Robertson-Andersson et al. [80], and Nobre et al. [58].

The over-riding principle is that in IMTA systems the "wastes" or by-products of animal (fed) aquaculture are used as nutrient source for growth and development of the other trophic component of the system,

such as macroalgae or other extractive, filter or detrital feeding organisms (e.g., bivalves, sea cucumbers, marine worms). The practical result is an added production of biomass which may have a direct economic value in addition to the ecosystem services which are provided by the extractive organisms. At the same time, the concentric alignment of the trophic levels provides substantial reduction of the load of inorganic nutrients in the effluents from intensive aquaculture systems, which in themselves can constitute a potential ecological problem leading to coastal eutrophication and harmful algal blooms (HABs).

Integrated mariculture has been practiced traditionally, although not necessarily intentionally, in China, Japan, and South Korea, where farms of fish net pens, shellfish, and seaweed have been situated in close proximity to one another [71, 81]. The arrangements and ultimate optimal integration of the trophic elements were largely achieved through trial and error and, as a consequence, traditional information regarding quantification and design has seldom been published (e.g., [82–84]). Nevertheless, in Asian countries, macroalgae are naturally considered as nutrient removers. For instance, the production of *S. japonica* (the Japanese kelp) was estimated as 4.765 million tons in 2008 [45]. Considering a very conservative N content of 2.79% DW (dry weight) and a wet to dry ratio of 5:1 [85], it can be estimated that approximately 5.58 kg of N are removed from the water with every ton FW of *Saccharina* produced. Therefore, the annual production of *S. japonica* removed approximately 26,588 metric tons of N from the surrounding seawater in 2008. In contrast, production of *Porphyra* and *Gracilaria*, while lower biomass volumes were produced, their N tissue content can exceed 7% DW for *Porphyra* [86] and 8% DW for *Gracilaria* [76].

On a global scale, the aquaculture of extractive organisms (e.g., seaweeds and shellfish) already removes a significant fraction of nutrients from the oceans [87]. According to Troell et al. [88], the harvests of those organisms already extract roughly 150,000 metric tons of N. However, as those authors also note, extractive and fed aquaculture are very often separated geographically, rarely balancing each other on a regional or local scale. An environmentally sustainable, balanced integrated aquaculture operation creates a mini-ecosystem in which the plant autotrophy balances the animal and microbial heterotrophy, not only in terms of nutrient removal (particularly C, N, and P) but also with respect to oxygen, pH, and carbon dioxide [87, 89]. It is unfortunate that, to date, there are only a few demonstration IMTA systems, in part due to the seasonality of the extractive seaweeds and the lack of "seed-stock." For instance, kelps for extraction of nutrients are only present for part of the cycle. The efficiency of dissolved nutrient removal will improve as alternation of extractive crop species is more clearly understood and refined.

As mentioned in the previous section, seaweed production is presently also recognized for its "ecosystem services" (see http://www.longislandsoundstudy.net/issues-actions/water-quality/nutrient-bioextraction/). Among these ecosystems services, the bioextraction capacity (through which the removal of biomass removes nutrients from the ecosystem) can be key for urban waterways that are not degraded by industrial pollution or don't have restrictions because they are away from sewage treatment facilities. However, as pointed out by Chopin et al. [59], these ecosystems services [90] have an economic benefit that is often ignored both by the industry and the regulators. A recent book sponsored by the World Conservation Monitoring Centre, in its chapter about Marine Systems, says very little about the role and direct economic value of algae in Marine Ecosystems [91]. Chopin et al. [59] argued that to improve the sustainability of anthropogenically derived nutrient-loading practices such as aquaculture, incentives such as nutrient trading credits (NTCs) are required. This would promote nutrient load reduction or nutrient recovery via a "polluter must pay" principle. The question can be posed that if carbon credits are now part of the internalized costs of some industries, why can the same process not be applied to nitrogen (N) and phosphorus (P), released through fed aquaculture, or point source pollution in the coastal marine environment. Neglecting the release of such nutrients in the marine environment can have quite striking consequences such as recently, when N released was associated with eutrophication of coastal waters resulting in massive algal blooms or "green tides" (see [92]). Also P has been discussed as "the next chemical element in global short supply"; therefore, its recovery makes considerable economic and ecological sense [93]. The land-based

cultivation of seaweeds, particularly as part of an IMTA system, may also play an important role on the future recovery of these nutrient wastes.

A particularly interesting initiative, regarding the promotion of IMTA at a national level, was reported by the Australian government under the auspices of the Rural Industries Research and Development Corporation (RIRDC; [94]). The objective of that report was to clearly identify the potential for seaweeds to be cultured in Australia for domestic and export markets. The report identified an enormous potential for growth and development of this activity and defined that targeted markets should include the food and nutritional sectors. The associated health benefits of human consumption of a variety of seaweeds were also indicated in the report.

Following this initiative, the Australian RIRDC moved to support the formation of "Seaweed Australia" – a new organization for the emerging cultivated seaweed industry in that country. Under that context, a new report was prepared [95] to assist all industry and research groups involved in the production, processing, and marketing of seaweed products in a broad range of industries including health and nutrition, aquaculture, animal feeds, nutraceuticals, and pharmaceuticals. The report is the result not just of desktop research but of a series of meetings, workshops, and other forms of extensive consultation of the different stakeholders (for instance, industry and researchers). The conclusions include a clear identification of the priorities for the development of the cultivated seaweed industry in Australia in terms of: market focus; market research; higher value products; regulatory issues, and industry research.

Physiological Considerations for the Production of Seaweeds in Land-Based Cultivation Systems

The physicochemical parameters that affect seaweed physiology in land-based systems are essentially the same as those that affect these organisms in natural populations and in open water aquaculture systems. Factors such as temperature, light and nutrient availability, pH and salinity are always critical for seaweed growth. The work of Craigie and Shacklock in particular was essential for the development of the cultivation of the red seaweed, Irish Moss (*C. crispus*) and that information is a primer for any land-based seaweed aquaculture facility [96]. These authors described the importance of appropriate site selection as a fundamental requirement for the success of any aquaculture undertaking. Craigie and Shacklock [96] confirmed that seawater in the vicinity of the potential site must be of the highest quality, i.e., low sediment and particulate matter, free of agricultural runoff and pollutants from other activities such as industrial, mining, and urban sources. The authors also briefly presented the requirements of the target cultivated species in terms of temperature, pH, salinity, nutrient requirements (i.e., carbon and nitrogen supply), seawater exchange, plant agitation, and interactions with other species. All of this information was the result of integrated basic research conducted for each one of those factors.

The traditional phycological literature, from the past 3–4 decades, contains considerable fundamental research on the physiology of seaweeds in general. However, this research was mainly conducted under laboratory conditions and much less practical work was undertaken in tank systems at scales relevant for economically viable commercial purposes. As with many other organisms, different algal species have different physiological requirements and optima [97]. As pointed out by Troell et al. [88], after reviewing 28 studies on various IMTA systems, where the majority included tank systems, there is a need to:

1. Understand in detail the important biological/biochemical processes in closed recirculating and open seaweed culture systems
2. Conduct research into these advanced aquaculture technologies at scales relevant to commercial implementation or suitable for extrapolation
3. Broaden the focus to include factors affecting seaweed growth and uptake capacity
4. Improve experimental design for statistical calculations
5. Understand the temporal variability in seaweed-filtered mariculture systems
6. Define numerical design parameters critical for engineers in designing commercial recirculation systems with seaweed filters
7. Study the influences of location-specific parameters, such as latitude, climate, and local seaweed strains/species, on seaweed filter performance

8. Include economic components, considering the added value of seaweeds, their products, and feasibility aspects
9. Analyze the role and function of integrated aquaculture practices for improved environmental, economic, and social acceptability within the broader perspective of integrated coastal management initiatives
10. Develop educational, training, and financial incentive approaches to transfer these novel and somewhat complex technologies of integrated mariculture from the scientists to an industrial scale

Despite the potential benefits for seaweed aquaculture as part of land-based IMTA systems, little progress has been made during the most recent decades, in terms of solving the needs as raised by Troell et al. [88]. The only published and, therefore, known exceptions are the work by Abreu et al. [76] taking into account an appropriate experimental design and scale (Figs. 1 and 2), and the research of Robertson-Anderson [79], Robertson-Anderson et al. [80] and Nobre et al. [58]. The differentiating factor is that Robertsson-Anderson and Nobre et al. performed economic and ecological assessments of a commercial, abalone-seaweed farm in South Africa.

Another less commonly applied method of land-based seaweed production is that of spray cultivation. This method has not been tested extensively on many species, but *Ascophyllum nodosum* [98] and *Gracilaria chilensis* [99] have been grown in such systems with some success. In the spray method, the seaweeds are not fully immersed in seawater but instead are held in adequate containers (often inside a modified greenhouse) and seawater is sprayed continuously or periodically over the target seaweeds. As referred to by Msuya and Neori [75], the documented benefits of seaweed spray culture included: construction and pumping costs, temperature control, gas (CO_2 and O_2) exchange, irradiance, nutrient uptake, and control of pests and epiphytes. Although the reported growth rates for these systems were usually low, Msuya and Neori [75] showed that the performance of *Ulva lactuca* in a spray system was in fact close to that of a standard, air-agitated tank culture system. In that work, *U. lactuca* was spray cultured in a "mattress-like layer," held in air on slanted boards by plastic netting. Fish mariculture effluents were applied by being sprayed onto the algal mattresses. The growth rate, yield, and ammonia-N removal rates were 11.8% day^{-1}, 171 g fresh weight (FW) m^2 day^{-1}, and 5 g N m^2 day^{-1}, respectively, by the spray cultured *U. lactuca*, and 16.9% day^{-1}, 283 g fresh

weight (FW) m^2 day^{-1}, and 7 g N m^2 day^{-1}, respectively, by traditional tank, immersed cultivated materials.

Examples of Successful On-Land Cultivation Enterprises

Acadian Seaplants Limited (www.acadianseaplants.com) is a Canadian company founded in 1981 and is probably the foremost example of an economically successful, land-based seaweed aquaculture enterprise. The company initially began with the collection of wild harvested *C. crispus* (Irish Moss) and progressed to the manual harvesting and processing of Rockweed (*Ascophyllum nodosum*). In particular, harvesting of the rockweed can be regarded as a positive case study for stewardship and successful, sustainable management of a wild resource (see [100, 101]). With respect to *C. crispus*, the company continues to successfully manage wild harvested materials in South West Nova Scotia and Prince Edward Island and also progressed to the land-based production of a specific strain of *Chondrus*.

While the *Chondrus* cultivation enterprise was initially planned to be a source of high-grade carrageenan, the production of *C. crispus* became more sophisticated to produce a value-added, salad product for the Japanese food market. Over the years, this enterprise has grown to become the world's largest, land-based seaweed cultivation system for the production of human food (Fig. 3). The production operation occupies a large site in south-western Nova Scotia, and the seaweeds are grown for the Asian food market and to conduct fundamental and applied research on seaweed extracts.

Spurred on by the needs created by design and construction of the land-based cultivation tanks and the challenges of cultivation of carragenophytes, the company was able to succeed and expand production facilities. The basis for this success was a strong R&D and market development strategies to diversify the company and its products. Presently, the company exports its diversified products to over 70 countries. More than 95% of its products are exported. According to the company managers, the cultivation division of the company has been gaining momentum and future plans include domestication of new species for additional target markets, plus enhancements to the existing edible seaweed product line, new product formats, and additional colors (Fig. 4).

Another example of a land-based seaweed production company is the Sylter Algenfarm GmbH & Co.KG (SAF), founded in 2006 by the marine botanist, Prof. Dr. Klaus Lüning. He spent most of his professional life unraveling the complexities of the environmental and

internal control of seaweed growth and reproduction [2]. SAF cultivates seaweeds in a land-based seaweed farm at the North Sea island of Sylt, using a seawater source flowing from the oyster tanks of Dittmeyer's Austern-Compagnie. The two main seaweed species cultivated by SAF are young sporophytes of the brown alga *S. latissima* (formerly known as *Laminaria saccharina*) harvested in May, at a blade length of approximately 0.8 m, for the human food sector (Fig. 5) and the red alga *P. palmata* for the cosmetics industry. The niche in the *Laminaria* market occupied by SAF is a result of an opportunity due to the fact that the iodine content of imported *Laminaria* (kombu) from the Far East or from France, with concentrations of 3,000–6,000 mg iodine/kg algal dry weight, is considered too high for safe consumption. In contrast to the imported red alga *Porpyhra* (nori) for European Sushi restaurants, which contains very little iodine, imported kombu from Asia cannot pass the German "veterinary barrier" for human food, while the "young *Laminaria*" produced by SAF contains only 600 mg iodine/kg algal dry weight, probably because of the young age of the thin blades: This has enabled SAF to occupy that niche market and gives *Laminaria* the position as an innovative, marine vegetable in German restaurants.

In order to meet the growing demands for "young *Laminaria*" in Germany, in 2008, SAF began a cooperation with two sea farms in the Northern Baltic Sea (Kattegat Sea area), where *S. latissima* is grown on ropes, in the sea, either together with blue mussels (*Mytilus edulis*), or fish (rainbow trout). Harvesting of the young, thin kelp blades in May secures the low iodine content. Moreover, this co-cultivation of kelp with marine animals provides a further example of integrated multi-trophic aquaculture (IMTA). For the fish cultivators in Denmark, this is important since the Danish state urges them to employ countermeasures against the uncontrolled release of ammonium, nitrate, and phosphate from the fish cages into coastal waters. The total N of 6% kelp dry weight assists the fish cultivators to demonstrate that for each ton of fresh harvested kelp (dry weight is $\approx$ 10% of fresh weight), 6 kg of N are removed from the system. This is yet another advantage of the local production of the kelp. Naturally, this ecosystem service (nutrient removal) would not be performed in the direct vicinity of Danish fish farms if the *Laminaria* or *Saccharina* was imported from Asia. On the other

hand, for SAF, the harvested kelp biomass in the Kattegat provides the sufficient biomass for the German food market.

Another example, although not producing seaweeds directly for human food, is the Big Island Abalone Company, in Hawai. This company cultivates a proprietary strain of *Palmaria mollis* on a significant scale as feed for abalone cultivation. More details are available at their Web site (www.bigislandabalone.com).

Future Directions

Land-based cultivation of seaweeds reduces the pressure on wild harvest of seaplants, particularly those which are difficult to access in time or space or their harvest would be unsustainable and perhaps ecologically damaging. Furthermore, land-based seaweed production allows for the evaluation of numerous species that, due to their size, morphology, and/or particular physiological needs might not necessarily be good candidates for traditional, open water systems, such as those routinely used for *Porphyra*, kelp, and the major phycocolloid-producing seaweeds (i.e., *Kappaphycus* and *Eucheuma*). Another important feature of seaweed production in land-based systems is that they allow for much greater environmental and input controls than would ever be possible in open water seaweed aquaculture. Such high levels of control, or intensive production, is critical to provide the necessary traceability, security of supply, high-quality standards and safety, not just for human consumption as food but especially for nutraceutical and pharmacological applications. Furthermore, the control of some environmental parameters (as well as controlling growth and quality) can also be used to promote the expression of desirable characteristics of the seaweeds, such characteristics may be morphological or biochemical. Further advantages of land-based seaweed production are the possibilities to quarantine foreign species, if grown on land with approved effluent water treatment systems. This feature is definitely not possible in open water cultivation systems, and can allow a land-based facility to work with more species than just those locally available. However, the environmental stewardship responsibilities for the introduction of nonnative species cannot be minimized nor lightly undertaken.

One promising avenue of future research associated with on-land cultivation of seaweeds would be to find the most appropriate culture conditions that maximize the production of particular, valuable biochemical constituents. This would be important for the promotion of a variety of seaweeds as functional foods or food-ingredients. More research is required into the genetics and responses of new target species which, in turn, could provide insight to achieve the high level of control. Unlike terrestrial plants and even microalgae, genetic transformation in seaweeds remains at a very low level. The first fully sequenced genome of a seaweed species are that of *P. umbilicalis*, *P. purpurea*, and *Ectocarpus siliculosus* and were concluded only recently ([40, 102]; the genome of *C. crispus* to follow shortly thereafter). Not forgetting the huge potential that remains in specific, selection of seaweed strains, the genomic and molecular tools now available for seaweeds could provide further insights into algal physiology and metabolism. Even taking into account the caveat of lack of public acceptance of GMO food, just as occurred with their terrestrial counterparts, this knowledge might be used in seaweed research to improve productivity, biofiltration efficiency, disease resistance, and to direct metabolic pathways to produce higher concentrations of desirable metabolites and secondary compounds (these might even play a role in biofuel production from seaweed feed stocks). Overall, these activities and discoveries could contribute to an improved market value of the target seaweeds, including new insights into human nutrition.

In addition, future research should focus on the evaluation and selection of more seaweed species suitable for land-based aquaculture that may be used as the extractive inorganic nutrient component in IMTA systems. In fact, we believe that IMTA systems will play an important role in the overall development of land-based seaweed production in the future. Several factors may account for this:

(a) The availability of water and its quality
(b) The size and morphological characteristics of seaweeds making them suitable candidates for tank cultivation
(c) The diversity of products derived from various target species produced in the same system

The water requirements of intensive animal aquaculture ensure a plentiful supply of water available for seaweed cultivation. In terms of synergies and efficiencies, particularly in engineering, the use of the same water stream allows for sharing of the energetic costs associated with water pumping. On the other hand, since water quality is also important for animal production and health, the seaweed component should have access to high-quality water, free of toxins, heavy metals, and other pollutants. Finally, but equally very important, and the essence of the IMTA concept, the extractive, seaweed production system would have access to nutrient-enriched seawater derived from the animal (fed aquaculture) component of the system. As an example, Burri [103] tested the inclusion of the IMTA-produced red seaweed (*G. vermiculophylla*) in a new form of vegetarian sausages for children. This author verified that the chemical composition of the seaweed chemical was below the permitted values for children consumption in terms of mercury (Hg), lead (Pb), and cadmium (Cd). Even when the initial wild collected stocking biomass had metal values close to or above the limits, these values decreased after 4 weeks in the IMTA conditions. In conclusion, pollutant-free seawater, nutrient-rich and at a free or shared cost, would be available for the seaweed production system when associated with an IMTA system.

As mentioned previously, intensive, land-based seaweed production allows for exploitation of seaweeds which are not necessarily suited to open water techniques such as those applied to various kelps or *Porphyra*. For obvious reasons, open water seaweed production is not the most suited, for instance, for free-floating techniques and vegetative propagation for seaweed cultivation. The free-floating method of tank or pond production can, however, be highly suited to land-based systems, allowing for optimization of water volume in the tanks as well as stocking density, thereby ensuring access to light and nutrient supply. Furthermore, on-land production methods are also highly suited to seaweeds where vegetative, or clonal, propagation is possible, in as much as the seaweed production system guaranties the homogeneity of the biomass (provided that the environmental conditions do not overly influence it). This feature can also decrease the operational costs associated with the production of seaweeds with a complex life cycle.

In terms of the production diversity, land-based systems could be planned to include several independent production units. Even considering the increase in the operation costs, these production units, managed independently from one other but sharing common parts of the infrastructure, could have two main advantages:

1. Produce different species/varieties of seaweed
2. Allow for an easier control of the environmental parameters that can influence the quality of the biomass

Depending on the applications of the biomass, the production units could be scaled to produce either a few kilograms or a few tons per year instead of the thousands of tons required for seaweed such as those used as raw materials for polysaccharide extraction. Such relatively small volumes might be more appropriate for the biomass required for some direct human consumption products or for application as ingredients of functional foods and cosmetic products. In turn, this smaller scale would allow a better control of production parameters and the biomass can be tailored more closely to the needs of the final consumer.

In conclusion, land-based seaweed aquaculture can provide for the production of biomass required for human food and other advanced applications. Rather than focusing on biomass production in the order of thousands of tons, this form of seaweed production can specialize in niche markets, which requires highly specific and tailored biomass. By doing this, land-based seaweed production can contribute to the development of more seaweed or seaweed-based products for human food and health. Finally, when used as part of an IMTA system approach, land-based seaweed production can contribute to the sustainable development of intensive fed aquaculture in an economical and ecological perspective.

Article Outline

Glossary

Dormancy Internal inadequacy of a seed that impedes its germination under, otherwise, favorable thermal, hydric, and gaseous conditions.

Abscisic acid Plant growth regulator that, among other processes, inhibits seed germination and is involved in dormancy imposition.

ROS Reactive oxygen species implicated in tissue aging and, more recently, in seed dormancy relief.

Preharvest sprouting Untimely grain germination in the mother plant due to a combination of low dormancy and damp conditions prior to crop harvest.

Stratification thermal time index An index calculated by summing thermal time below a threshold temperature, which is used to estimate dormancy release as a function of stratification temperature and time.

Definition of the Subject

Dormancy is a common attribute of temperate species. Its adaptive significance is quite evident for species living in the wild: dormancy is a mean for restricting germination to the season when environmental conditions are suitable for plant establishment. From an agricultural perspective, dormancy represents a problem, both when it is long lasting and when it is too short. For that reason, selection against dormancy has been always behind any domestication effort. In some cases, the aim of removing dormancy has not been achieved, and in others, it has gone too far resulting in susceptibility to preharvest sprouting. In addition, the fight against weeds is frequently impaired by the existence of long-lasting seed banks as a result of seed dormancy.

Introduction

A seed can be declared to be dormant when it fails to germinate despite it is given all the "proper" conditions (i.e., enough water and appropriate temperature) for germination to happen. Assuming that there is a living seed (a dead seed would not germinate either), then why does it not germinate? Will it ever germinate? These types of questions were probably first asked in despair by farmers about 10,000 years ago, while staring at their useless recently harvested grains that would not give way to a new crop or allow malting for beer (a process that also relies on germination).

Despite historical human concerns with dormancy, this "internal block to germination" has been positively selected throughout millions of years of evolution in most temperate species, and has obvious ecological benefits in the wild. The main apparent role of seed dormancy is to delay germination until a proper environment is encountered, for example, by keeping track with seasonal changes in temperature to avoid unfavorable conditions for plant establishment [1]. Within the life of most plants, the only chance to travel is as a seed. After separating from the mother plant, the seed is moved by different means (wind, gravity, water, animals) until it is randomly located in a new microenvironment that may prove adequate or not for completing its life cycle. Once germination happens, the small plant will most probably remain attached to that spot until its death. As a consequence of plants being sessile organisms, seeds have developed sophisticated mechanisms to collect information from the

environment, and the resulting output is a vital decision: to germinate right away, or not (at least not this time, this place) until new environmental conditions that are good enough are finally met with.

Seed dormancy has been a subject of intensive research during the last decades. Physiological and environmental control of dormancy has been studied deeply and, more recently, its molecular and genetic bases have started to be elucidated. As in other areas of plant science, knowledge on the molecular bases of dormancy has been attained through the use of model organisms. Indeed, work with *Arabidopsis thaliana*, a small winter annual weed preferred by most plant scientists, has revealed the involvement of multiple genes controlling seed dormancy, which is a continuous and complex character. Cultivated species also display different degrees of dormancy, and either the presence or the absence of dormancy can have strong consequences on the utilization of the seeds, and this will be discussed in more detail in this entry. Different strategies exist that are directed to control dormancy through genetic changes (as a result of classical breeding or transgenic events) or to cope with varying degrees of dormancy, such as the development of predictive models. As the level of dormancy a seed will effectively display is the result of its genotype interacting deeply with a changing environment, predictive models have been developed for some species (e.g., malting barley or some weeds). Most of these strategies require a thorough knowledge on the biology of dormancy at different levels.

In this entry, the focus is on what is termed as physiological dormancy, or the lack thereof. The most important challenges facing agriculture, in relation to the presence or the absence of dormancy in both cultivated and weedy species, are also pointed out. Some examples of each type of problem are presented, illustrating on the physiological mechanisms responsible for the expression of the character and commenting how the molecular information coming from studies on *Arabidopsis* and other model species, have started to be used to attain the final aim of solving these dormancy problems.

Dormancy (Classifications and Definitions)

Dormancy is the result of mechanisms operating within the seed that impede germination even when the seed is exposed to an environment known to be friendly for that species (i.e., in which water, oxygen and adequate temperature are available). This impediment or block to seed germination can be determined by both morphological and/or physiological properties of the seed [2]. On the basis of this fact, Baskin and Baskin [3] developed a classification system which includes five classes of seed dormancy: physiological, morphological, morphophysiological, physical, and a combination of physical and physiological. In this entry, mainly physiological dormancy which is the most prevalent dormancy type in temperate seed banks and is also the major form of dormancy in most laboratory model species is referred to [4]. This type of dormancy is caused by a physiological inhibiting mechanism of the embryo that prevents radicle emergence, although other seed structures that cover the embryo can be involved as well [1]. From a physiological point of view, there is enough evidence showing that the mechanism of seed dormancy is mainly regulated by the phytohormones abscisic acid and gibberellins [4, 5].

Dormancy can be also classified in primary and secondary dormancy. Primary dormancy refers to the innate dormancy possessed by seeds upon dispersal from the mother plant. Secondary dormancy refers to a dormant state that is induced in nondormant seeds by unfavorable conditions for germination, or reinduced in once-dormant seeds after a sufficiently low dormancy had been attained.

Primary dormancy is acquired during seed development, and, in most species, is gradually lost after natural seed dispersal (in wild species) or harvest, during post-maturation or after-ripening period. As pointed out before, both the primary dormancy level that seeds present at dispersal or harvest (maturity) and the rate of release from primary dormancy (which determines the time lapse required by a seed population to lose dormancy) are dependent on the genotype, the environment, and the interaction between them. Therefore, although different species or genotypes (i.e., cultivars, inbred lines, etc.) can present more dormant or less dormant seeds at maturity, and faster or slower rates of dormancy release, those traits can be modulated by the environment perceived by the seed during their development-maturation phase (parental environment) and their post-maturation period, respectively. In relation to the parental environment, for example, there is evidence indicating that there are

certain environmental factors tending to have similar effects on different species [6]. For example, low dormancy at seed maturity is generally associated with high temperatures, short days, drought, and nutrient availability during seed development and maturation [7–11]. For the post-maturation period, storage temperature and moisture are the most relevant factors regulating dormancy loss rate in cultivated species, while in natural wild conditions a diverse number of factors can be affecting seed dormancy loss. In wild species (i.e., weeds), the post-maturation process usually takes place in the soil because, after dispersal, seeds usually become part of the soil seed bank [12]. Under these conditions, primary dormancy loss can be affected by many naturally occurring factors, as soil temperature and soil water regime (through changes in seed moisture content), temperature fluctuations, light, etc. [13–15]. Although many factors can be affecting the dormancy level of seeds from cultivated and wild species, there is evidence showing that temperature appears to be primarily responsible for year-to-year variation in dormancy level at maturity [6] and for differences in the dormancy loss rate during post-maturation, though the latter can be modulated by seed moisture content [15, 16].

In many species, nondormant seeds can be reinduced into secondary dormancy after dispersal. There are many factors that can be responsible for induction into secondary dormancy, as specific temperature ranges, changes in light quality and quantity, the gaseous environment, etc. Although induction into secondary dormancy is an uncommon phenomenon in most seeds of cultivated species, it is very common under field conditions for seeds of many wild species, particularly those forming persistence seed banks. Indeed, under natural field conditions, the release from primary dormancy followed by subsequent entrance into secondary dormancy (whenever conditions are given for this entrance) may lead to dormancy cycling. Evidence for dormancy cycling in natural seed soil banks has been obtained for many species.

Dormancy and Its Implications in Agriculture

Seeds in their natural form are still the best way to preserve and propagate most crop species, and their capacity to germinate at the right moment (either in the field or under controlled conditions) is a most important feature. Therefore, any factors (internal or external) affecting the germination capacity of seeds and ultimately their agronomical performance should be understood in order to improve seed quality through breeding and/or crop management strategies. Among the factors that may affect germination, dormancy is probably the most important, as it is a heritable trait that can inhibit germination of a viable seed. Indeed, beyond the fact that dormancy is a highly intriguing biological process and consequently moves the curiosity of scientists, the study of dormancy has strong practical implications. Both farmers and seed companies encounter problems associated either to an anticipated dormancy loss or to a long-lasting dormancy. In the same way, industrial processes like malting, which depends on seed germination, can be largely hampered by the existence of dormancy or, alternatively, face important reductions in the quality of the received lots due to a precocious dormancy termination and pre-germination in the field.

Since dormancy is highly undesirable for agricultural purposes, selection pressure against this trait must have been important throughout the domestication process, particularly in species with temperate origin. In some cases, this pressure must have gone too far, as in the case of cereals, leading to an anticipated dormancy loss which makes some crops susceptible to preharvest sprouting or pre-germination. Nevertheless, intraspecific variability for dormancy exists and "dormancy genes" are still present in some genotypes, although their positive selection through breeding has been difficult due to strong linkage to other undesired traits. In some other cases, selection pressure might have not succeeded in eliminating dormancy, so seeds are not germinable by the time of the next sowing or by the time they need to be "ready" by the malting industry. In any case, dormancy release should take place within a precise "time window." This rarely can be achieved without a solid knowledge of the mechanisms on which dormancy relies in each species.

Dormancy in Cultivated Species

Problems Associated with the *Excess of Dormancy* (Dormancy Persistence)

Sunflower Sunflower is a good example of a crop species with prolonged dormancy. Dormancy

persistence in different sunflower genotypes can vary from several weeks up to almost a year. Also, important variation has been reported on this trait for the same genotype under different environments, indicating a strong interaction with the environment. Sunflower is cultivated in many areas around the globe, and is a summer crop. At harvest time, sunflower seeds are dormant and germinate poorly [17–19]. This dormancy is the result of true embryo dormancy [17, 18] and the inhibitory action of the envelopes [17, 18, 20] including the seed coat and the pericarp, since sunflower "seeds" are achenes. In the case of freshly harvested sunflower seeds, dormancy is expressed at temperatures lower and higher than 25° C [17]. Dormancy expression at low temperatures is attributed to embryo dormancy which is not expressed at high temperatures [17]; conversely, dormancy expressed at high temperatures results from coat-imposed dormancy [17]. The deep dormancy that sunflower grains present at harvest results from the coexistence of coat-imposed dormancy and some remnant embryo dormancy [17]. Embryo dormancy is lost shortly after harvest if the seed is subjected to dry after-ripening, but coat-imposed dormancy persists for longer and may require several weeks of dry after-ripening to be overcome. Consequently, few weeks of dry after-ripening allow seed germination at low temperatures due to termination of embryo dormancy; the acquisition of the capacity to germinate at high temperatures, in contrast, may take several weeks of dry after-ripening [17].

The plant growth regulator ABA appears to be involved in the imposition of embryo dormancy. The inclusion of fluridone (an inhibitor of ABA biosynthesis) in culture media for sunflower embryo development prevents the induction of embryo dormancy [21, 22]. Nevertheless, the pattern of accumulation of ABA in the developing embryo does not coincide with the embryo physiological behavior: during seed development, embryos germinate well at the time when the endogenous ABA level is at its highest (7–12 DAP); thereafter, ABA decreases to a low value when embryo dormancy becomes established [21]. It seems, then, that the ABA peak at early stages is responsible for the imposition of the dormant state that is established immediately after that peak has taken place. Moreover, it appears that ABA needs to be present during a critical time period to induce dormancy. Le Page-Degivry and Garello [22] showed that when young (7 DAP), non-dormant embryos were cultured in the presence of ABA, the hormone produced a temporary inhibition of germination but did not induce dormancy (i.e., embryos were able to germinate when transferred to a basal medium). In contrast, exogenous ABA became effective if applied immediately prior to the natural induction of dormancy. For example, 5 days culture on a medium containing 5×10^{-5} M ABA resulted in partial dormancy in 13 DAP embryos while total induction of dormancy occurred in 17 DAP embryos.

As mentioned before, embryo dormancy can be terminated by dry storage. To identify the process by which dormancy is broken during after-ripening, Oracz et al. [23] focused on the role of reactive oxygen species (ROS) in this phenomenon. After-ripening entailed a progressive accumulation of ROS, namely, superoxide anions and hydrogen peroxide, in cells of embryonic axes. This accumulation, which was investigated at the cellular level by electron microscopy, occurred concomitantly with lipid peroxidation and oxidation (carbonylation) of specific embryo proteins. Incubation of dormant seeds for 3 h in the presence of hydrogen cyanide (a compound that breaks dormancy) or methyl viologen (a ROS-generating compound) also released dormancy and caused the oxidation of a specific set of embryo proteins. In summary, the mechanism proposed by the authors involves ROS production and targeted changes in protein carbonylation patterns [23].

As with other cultivated species such as *Lactuca sativa* [24] and *Arachis hypogea* [25], ethylene (C_2H_4) and etephon strongly stimulate the germination of dormant sunflower seeds [17, 18, 26]. In contrast, gibberellic acid and cold stratification do not overcome dormancy in this species [27] though it was shown that 1 mM GA_3 is effective for overcoming dormancy in some wild sunflowers [28]. Corbineau, Bagniol, and Côme [17] showed that ethylene and its immediate precursor (1-aminocyclopropane-1-carboxylic acid) strongly stimulated germination of primary dormant sunflower seeds; on the contrary, inhibitors of ethylene (i.e., amino-oxyacetic acid and $CoCl_2$) or ethylene action (silver thiosulfate and 2.5 norbomadiene) inhibited germination of nondormant seeds.

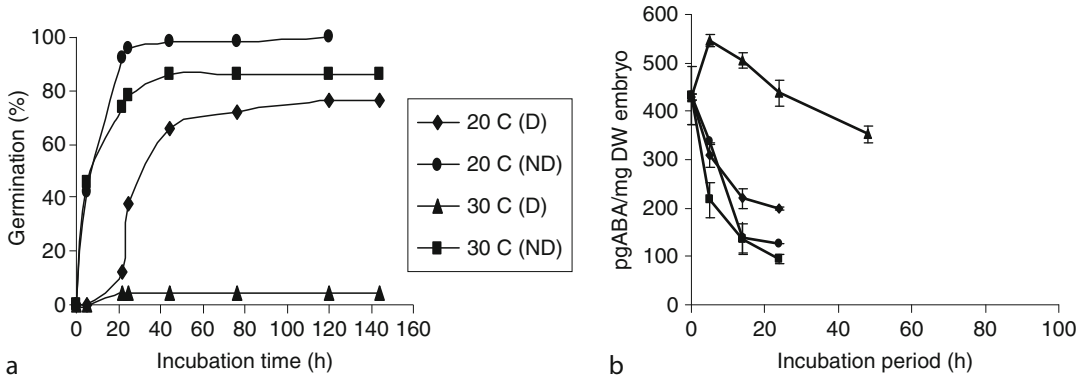
Oracz et al. [29] assessed the possible role of cyanide, which is produced by the conversion of 1-aminocyclopropane 1-carboxylic acid to ethylene, in dormancy release. The beneficial HCN effect on germination of dormant embryos was found to be associated with a marked increase in hydrogen peroxide and superoxide anion generation in the embryonic axes [29].

Malting Barley In addition to impairing a rapid and simultaneous germination after sowing, a persistent dormancy would prevent the utilization of a seed lot for industrial purposes when the process requires germination. This is the case of the malting process which uses barley as the main grain. The malting process itself requires grain germination, so a low dormancy level at harvest is a desirable characteristic because the grain can be malted immediately after crop harvest, thus avoiding costs and deterioration resulting from grain storage until dormancy is terminated. Therefore, breeders have to solve the compromise between obtaining genotypes with low dormancy at harvest, but not with such an anticipated termination of dormancy that leads to sprouting risks (a phenomenon which is referred to in the next section). Dormancy of the barley grain is typically imposed by the seed-covering structures (lemma and palea, pericarp plus seed coat). Indeed, embryos can germinate well from the very early stages of development if they are isolated from the rest of the grain and incubated in water [30]. Limitation of oxygen supply to the embryo by oxygen fixation as a result of oxidation of phenolic compounds in the lemma and palea (hereafter referred to as the glumellae or the hull) has been suggested to be responsible for the dormancy of dressed caryopses of cereals such as barley [31] and oat [32]. In dormant grains of barley, for example, whole intact caryopses germinated with difficulty, even in the air, while de-hulled caryopses were all able to germinate under oxygen tensions of at least 10%, suggesting that oxygen concentration under the covering structures might be less than 10% [31].

Dormancy of the barley grain also appears to be under ABA control: termination of glumellae-imposed dormancy during grain development was shown to be correlated with a sharp decline both in ABA embryonic content and sensitivity [30]. A role for ABA in dormancy maintenance of the barley grain has also been suggested: ABA embryonic content declines during the first hours of incubation of nondormant seeds, whereas it remains at high levels in embryos of dormant grains [33]. In recent years, Benech-Arnold et al. [34] confirmed this role of ABA in dormancy maintenance. The ABA level of the embryo largely decreased during the first hours of incubation and prior to any visible germination in both dormant and nondormant grains at 20° C, the temperature at which dormancy is not expressed, and in nondormant grains incubated at 30° C, suggesting that ABA catabolism and/or conjugation exceeds ABA biosynthesis. By contrast, at 30° C dormancy expression was associated with a maintenance of ABA at high levels: after an initial increase, ABA content decreased very smoothly and was always between two- and fourfold higher than in embryos from grains in which dormancy was not expressed (Fig. 1).

Both the removal of the glumellae and the incubation of de-hulled grains under low oxygen concentrations modified grain germination behavior and ABA content evolution throughout incubation at 30° C [34]. These results indicate that the presence of the glumellae is instrumental for dormancy maintenance because it imposes oxygen deprivation to the embryo which, in turn, promotes ABA synthesis and/or inhibits ABA inactivation. Indeed, removal of the glumellae in dormant grains incubated at 30° C under 21% oxygen suppressed the initial increase in ABA content that was observed in dressed dormant grains incubated at the same temperature. By contrast, incubation under hypoxia (5% oxygen) of de-hulled grains restored it and inhibited germination [34].

Artificially imposed hypoxia also enhanced embryo sensitivity to ABA by several fold [34]. These results suggest that, in addition to interference with ABA metabolism, the presence of the glumellae increases embryo responsiveness to the phytohormone. To explore this possibility, Mendiondo et al. [35] measured the expression of several components of the ABA signaling pathway during incubation of entire and de-hulled grains: the presence of the glumellae enhanced the expression of most of the investigated genes, suggesting that the hull increases the sensitivity to ABA of the enclosed embryos and that this enhancement is effected at the level of gene expression. Again, artificially imposed hypoxia was not able to mimic the effect of the glumellae on the



Seed Dormancy and Agriculture, Physiology. Figure 1
Germination (**a**) and embryo ABA content evolution (**b**) during incubation at 20° C (circles, diamonds) and 30° C (triangles, squares) of dormant (circles, triangles) and nondormant (diamonds, squares) grains. Freshly harvested (dormant, *D*) grains and grains stored dry for at least 3 months at 25° C (nondormant, *ND*). Means of two measurements ± arithmetical spread (germination) and of three measurements ± SD (ABA content) (Redrawn with data originally published in [34])

expression of ABA signaling components, indicating that the apparent enhancement of embryo sensitivity to ABA under low oxygen tensions was in fact due to over-accumulation of ABA as a result of malfunctioning of the enzyme committed to ABA inactivation [34].

Problems Associated with *the Lack of Dormancy* (Preharvest Sprouting in Cereals)

The advantages of having a freshly harvested seed lot with the capacity to germinate rapidly and uniformly under a wide range of environmental conditions are related to the possibility of immediate sowing or malting, thus avoiding financial costs derived from delays and/or storage until germination capacity is good enough. Nevertheless, genotypes that produce nondormant seeds at harvest may already be able to germinate to some degree even before harvest. The main problem related to an early loss of dormancy in crop species is preharvest sprouting (PHS). This phenomenon is characteristic of cereal species like rice, barley, wheat, and sorghum. As these species all exhibit intraspecific variability for the rate of dormancy loss and PHS behavior, genotypes with contrasting sprouting behavior have proved useful for many comparative studies [36–39], in addition to QTL analysis that leads to the identification of several loci related to dormancy [40–43]. When low levels of dormancy during late grain maturation period are combined with rainy or damp conditions in the field, the process of germination is activated while the seeds are still attached to the mother plant, and the resulting emergence of the radicle from the seed coats is called preharvest sprouting (PHS). Depending on the intended purpose for the seeds after harvest, PHS can have serious negative consequences on their quality and this is economically penalized by the industry. Direct economic losses caused by PHS to producers occur in several ways: Desiccation of a sprouted grain leads to its subsequent loss of viability because, together with the activation of metabolism implicated in embryo growth, tolerance to dehydration is lost rendering the sprouted grains useless for sowing or malting. Sprouting also promotes carbohydrate respiration that not only reduces grain yield, but also creates a favorable environment for the attack of saprophytic fungi and bacteria that produce toxins.

Depending on the level of dormancy and environmental cues such as water availability for imbibition and temperature, the germination process can advance to different extents, and not always reaches completion of germination and sprouting (i.e., germination is complete when embryo growth begins, and post-germinative growth leads to visible radicle and/or coleoptile emergence through the seed-covering structures). Even when desiccation occurs before germination is complete, starch degradation may have advanced partially.

This phenomenon is known as pregermination. Pregerminated grains cannot be distinguished visually, but the level of starch degradation is correlated with a decrease in FN values [36] and a reduction in seed lot longevity [44]. Industrial processes based on wheat and barley (flour and malting) are particularly sensitive to sprouting and pregermination. Seed lots are commonly assessed with the falling number (FN) test, with smaller FN values indicating a greater degree of starch degradation. Wheat and barley seed lots can be penalized or even rejected if FN values show moderate incidence of pregermination and sprouting.

The phenomena of PHS and pregermination are closely related with the process of domestication. Cereal crops have a brief period of dormancy as compared to their wild ancestors. Throughout many years, farmers have pressed toward selection of low levels of dormancy along with other traits such as non-shattering, increased grain size, and less pigmentation. The occurrence of PHS depends not only on morphological and physiological traits genetically controlled (such as infructescence structure and permeability of structures surrounding the seeds, and seed dormancy) but also on environmental factors (water availability and temperature). A single genotype may express PHS when grown in some areas but not in others. Seed dormancy is the main heritable factor that contributes to PHS resistance, but the many attempts to control it through breeding programs have shown that dormancy is tightly linked to other interesting traits. Breeding programs that attempted to separate characters associated with seed color, dormancy, and longevity suggest that these characteristics may not always be separable and are referred to as domestication block [45]. For example, in rice, both loci sh-h (for shattering) and Rc (conferring red pericarp) are tightly linked together with a QTL qSDs-7-1 for seed dormancy, implying that this region might represent a domestication block in the evolutionary pathway of rice [46]. A mutation in the *R*-gene in white wheat is required for low tannin content (higher flour quality) but is also responsible for lower levels of dormancy (low PHS resistance). However, grain dormancy is a complex trait that relies on numerous genes, and other QTLs contributing to dormancy that are not linked to seed color have been identified and are being considered in breeding for PHS tolerance in white wheat [47].

In addition to classical breeding techniques, elucidation of the mechanisms involved in the control of dormancy may open other possibilities for manipulation of dormancy through genetic engineering techniques. Cereal species like barley and sorghum have served as model systems to study the mechanisms behind dormancy with the objective to understand the hormonal metabolic and signaling steps involved in the repression of germination (*Barley*: 31, 30, 34, 48; *Sorghum*: 37, 38, 39).

Dormancy in Natural Seed Banks and Its Implications in Weed Control

Dormancy is a common attribute of many weed species, and is probably the most important of a series of processes that determine the seasonal annual pattern of weed emergence from soil seed banks under field conditions [49, 50]. Although there are many environmental factors that can be affecting the dormancy status of seeds composing the soil bank (i.e., alternating temperature, soil water status, light, etc.), seasonal dormancy changes are mainly regulated by soil temperature [4, 51]. For example, in summer annual species, dormancy relief is produced by the low temperatures experienced during winter, while high temperatures enhance their dormancy level during summer. Most winter annual species show the reverse dormancy pattern. Hence, high temperatures during summer produce dormancy relief, while low temperatures during winter induce secondary dormancy. Although much experimental data support the main role of soil temperature as regulator of seed dormancy, there is evidence indicating that the effect of temperature on dormancy may be modulated by soil moisture conditions [16, 52].

Changes in dormancy status of weed seed populations are associated with changes in the range of temperatures and water potentials permissive for seed germination [15]. As dormancy is relieved, the range of temperatures and water potentials permissive for germination widens until it is maximal; on the contrary, as dormancy is induced, the range of temperatures and water potentials over which germination can proceed narrows until germination is no longer possible at any temperature or water potential. Germination in the field is therefore restricted to the period when the field temperature and soil water potential,

and the temperature and water potential range over which germination can proceed, overlap [14, 53].

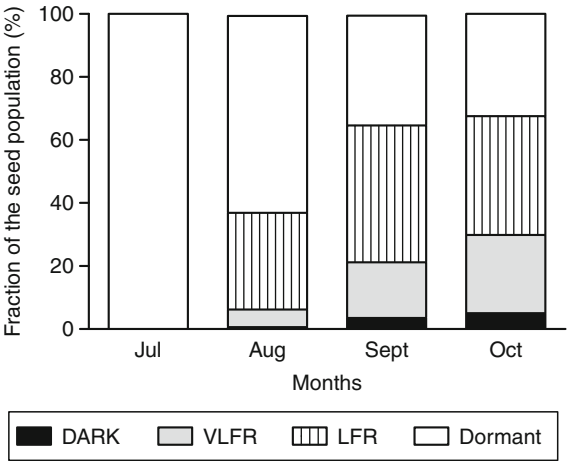
However, in many weed species, once environmental temperature and water potential are within the permissive range, dormancy must be terminated by the effect of additional environmental factors for germination to proceed. In these cases, changes in the degree of dormancy not only comprise changes in temperature and water potential requirements for germination, but also in the sensitivity of the seed population to the effect of those dormancy terminating factors [51]. Fluctuating temperatures and light are two critical environmental factors that can trigger dormancy termination in seeds of many weed species. An ecological interpretation of this requirement to complete exit from dormancy has been related to the possibility of detecting canopy gaps as well as depth of burial under field situations [51, 54, 55].

Agronomic practices can alter the physical environment to which weed seed banks are exposed, and thus, their dormancy status. Knowledge about the ways in which agronomic practices affect the dormancy status of weed seeds could be used to develop and improve weed management strategies [56, 57]. For example, many weed seeds require light to terminate dormancy and give way to the germination process; consequently, the light environment could be managed in order to impede seed germination. Light signals are perceived by seeds through the phytochrome system. Generally, low red/far-red wavelengths ratios inhibit seed germination, while high red/far-red ratios promote seed germination. Light filtered by green leaves are rich in far-red wavelengths and explains the low red/far-red ratios measured under plant canopies [58]. Therefore, plant cover could be managed to reduce some weed problems. For example, changing plant architecture, crop-sowing densities, and crop plant spacing may have a high potential for improving weed management by preventing the exit of weed seeds from dormancy and reducing germination under field situations [59].

The brief light pulse received during soil cultivation can promote seed germination of buried weed seeds. Many weed seeds buried in the soil acquire an extremely high light sensitivity that permits them to detect submilliseconds of sunlight when the soil is disturbed. This is reflected in the high weed emergence rates usually observed following tillage operations, and suggests that germination of light-requiring seeds would be impeded if a non-tillage crop production system is implemented or if cultivation is performed at night [60]. Indeed, Scopel et al. [61] observed a significant reduction in weed emergence (between 70% and 400%) when plots were cultivated at night in comparison to emergence levels obtained under daytime cultivation.

Other environmental factor that usually terminates dormancy in many weed seeds under field conditions is temperature fluctuation. Generally, large temperature fluctuation regimes determine dormancy breakage of a higher proportion of the seed bank population than that observed under small temperature fluctuation regimes. Thus, changing the amplitude of temperature fluctuation regimes in the field environment through management of plant cover or crop residues would lead to a reduction in weed emergence [57, 59]. This is the case of Johnson grass (*Sorghum halepense*), in which seeds do not germinate if they are under a dense plant cover due to the lack of temperature fluctuations stimuli required to terminate seed dormancy [54].

Weed emergence models that predict the proportion and timing of seed bank emergence would be useful tools for determining the most suitable time for seedling control and, consequently, should result in a higher efficacy of controls methods. In the last decade, many models able to predict seed dormancy changes in relation to environmental factors for different weed species have been developed [14, 15]. For example, Batlla et al. [62] and Batlla and Benech-Arnold [63] developed models to account for the effect of fluctuating temperatures and light on *Polygonum aviculare* (a worldwide distributed spring emerging weed) seed dormancy level based on a stratification thermal time index (S_{tt}). This index allow the prediction of changes in seeds sensitivity to increasing doses of cycles of fluctuating temperatures or different light treatments for seeds stratified at different temperatures in relation to the accumulation of degree days units below a ceiling temperature of 17° C. Using these models, for example, the progressive increase in *P. aviculare* seed bank sensitivity to light during winter and early spring can be predicted based on soil temperature records (Fig. 2). Due to the fact that, for example, the acquisition of a very low fluence response (VLFR) phytochrome action mode would permit buried seeds to germinate



Seed Dormancy and Agriculture, Physiology. Figure 2 Simulated proportions of a *Polygonum aviculare* seed bank showing different action modes of phytochrome (low fluence response [*LFR*] and very low fluence response [*VLF*]), seeds not requiring light for germination (darkness) and the non-germinating fraction (dormant) at the beginning of different months. Simulations were done using year 2000 soil temperature and equations published in [63] (Redrawn from [14])

in response to the light flash perceived during soil disturbance [64], this model could be used to predict the proportion of the seed bank that will germinate in response to tillage operations after the accumulation of a certain amount of S_{tt} during winter burial [63].

Another example of how knowledge in relation to regulation of seed bank dormancy by environmental factors could be used to forecast weed emergence is the WeedCast model developed by Forcella [65] at the US Department of Agriculture. This model can be used to predict the "emergence potential" of several summer annual weeds. In the model, the "emergence potential" indicates which fraction of the weed seed bank would be nondormant and available for germination at a given time during the season. The possibility of predicting the "emergence potential" of the different weed species allows farmers to make more rationale decisions regarding the degree and type of weed management required [65].

With increased pressure to reduce pesticide inputs in agricultural systems, optimal timing and rates of chemical products as well as finding sustainable nonchemical options for weed control will be of paramount importance. A better understanding of how environmental factors and agronomic practices affect the dormancy status of weed seed banks could be used to develop and improve weed control strategies in order to meet this challenge.

Future Directions

Seed dormancy has enormous implications in agriculture. Its importance is related both to its persistence and to its lack. Dormancy persistence affects crop establishment as well as grain industrialization whenever this process requires seed germination (i.e., malting), but also the design of weed management practices. The lack of dormancy can lead to untimely germination in the mother plant (i.e., preharvest sprouting) with severe consequences to grain quality. The possibility of assessing the very many aspects of the agricultural activity that could be interfered by the presence or absence of dormancy requires a thorough knowledge of the phenomenon, not only at a fundamental level (i.e., physiological and/or molecular) but also in terms of its control by environmental factors. In this entry, the attempt was to illustrate with examples the way in which these different aspects can be assessed. Only a detailed knowledge of how the dormancy mechanisms are controlled at a physiological, molecular, and environmental level would eventually lead to attain our ultimate aim: to adjust the timing of dormancy release to our convenience from an agricultural point of view.
